Figure 3: Each cell shows the difference between the DDA of our model and that of DMV evaluated on the test data of the column language. Positive numbers are shown in red and negative numbers in blue. Languages are grouped by their families.

setup. Specifically, for each pair of languages, we tested our approach and the baseline of training DMV on the combined training set. Since in this setting DMV is blind to the language identity, we expect that it would perform poorly if the two languages come from different families and hence are very likely to have large difference. On the other hand, our model would not be as sensitive to the difference between the two languages. In Figure 3, we report the difference between the DDA of our model and that of DMV. It shows that the advantage of our model over DMV is more significant for cross-family language pairs than for in-family language pairs, which verifies our expectation.

6 Conclusion

In this paper, we incorporate continuous language identity representations into multilingual grammar induction, which softly tie grammar parameters from different languages, resulting in substantial performance gain over various baseline methods. Analysis of the language embeddings suggests that our approach may capture information about language similarity beyond linguistic phylogenetic knowledge.

While in this work we follow previous work and perform unlexicalized parsing, the proposed model can be extended for lexicalized parsing by replacing POS tag embeddings with cross-lingual word embeddings, which we leave for future work.

Abstract

Many of the world's languages employ grammatical gender on the lexeme. For example, in Spanish, the word for house (*casa*) is feminine, whereas the word for paper (*papel*) is masculine. To a speaker of a genderless language, this assignment seems to exist with neither rhyme nor reason. But is the assignment of inanimate nouns to grammatical genders truly arbitrary? We present the first large-scale investigation of the arbitrariness of noun–gender assignments. To that end, we use canonical correlation analysis to correlate the grammatical gender of inanimate nouns with an externally grounded definition of their lexical semantics. We find that 18 languages exhibit a significant correlation between grammatical gender and lexical semantics.

1 Introduction

In his semi-autobiographic work about his time traveling through Germany, *A Tramp Abroad*, Twain (1880) recounted his difficulty when learning the German gender system: "Every noun has a gender, and there is no sense or system in the distribution; so the gender of each must be learned separately and by heart. In German, a young lady has no sex, while a turnip has. Think what overwrought reverence that shows for the turnip, and what callous disrespect for the girl." Although this humorous take on German grammatical gender is clearly a caricature, the quote highlights the fact that the relationship between the grammatical gender of nouns and their lexical semantics is often quite opaque.

As arbitrary as certain noun–gender assignments may appear overall, a relatively clear relationship often exists between grammatical gender and lexical semantics for some of the lexicon. The portion of the lexicon where this relationship is clear usually consists of animate nouns; nouns referring to people morphologically reflect the sociocultural notion of "natural genders." This portion of the lexicon—the "semantic core"—seems to be present in *all* gendered languages (Aksenov, 1984; Corbett, 1991). But how many *inanimate* nouns can also be included in the semantic core? Answering this question requires investigating whether there is a correlation between grammatical gender and lexical semantics for inanimate nouns.

Our primary technical contribution is demonstrating that grammatical gender and lexical semantics can be correlated using canonical correlation analysis (CCA)—a standard method for computing the correlation between two multivariate random variables. We consider 18 gendered languages, following 3 steps for each: First, we encode each inanimate noun as a one-hot vector representing the noun's grammatical gender in that language; we then create 5 operationalizations of each noun's lexical semantics using word embeddings in 5 genderless "donor" languages (English, Japanese, Korean, Mandarin Chinese, and Turkish); finally, for each genderless language, we use CCA to compute the desired correlation between grammatical gender and lexical semantics. This process yields a single value for each of the 90 gendered–genderless language pairs, revealing a significant correlation between grammatical gender and lexical semantics for 55 of these language pairs.

Secondarily, we investigate semantic similarities between the 18 languages' gender systems—i.e., their assignments of nouns to grammatical genders. We analyze the projections of lexical semantics (operationalized as word embeddings in English) obtained via CCA, finding that phylogenetically

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5734–5739, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

similar languages have more similar projections.

2 Background and Assumptions

2.1 Grammatical Gender

Languages range from employing no grammatical gender on inanimate nouns, like English, Japanese, Korean, Mandarin Chinese, and Turkish, to drawing grammatical distinctions between tens of gender-like classes (Corbett, 1991). Although there are many theories about the assignment of inanimate nouns to grammatical genders, to the best of our knowledge, the linguistics literature lacks any large-scale, quantitative investigation of arbitrariness of noun–gender assignments. However, with the advent of modern NLP methods—particularly with advancements in distributional approaches to semantics (Harris, 1954; Firth, 1957)—and with the copious amounts of text available on the internet, it is now possible to conduct such an investigation. We focus on languages that have either two (masculine–feminine) or three (masculine–feminine–neuter) genders, to which nouns are exhaustively assigned, and investigate whether a correlation exists between grammatical gender and lexical semantics for inanimate nouns—i.e., whether noun–gender assignments are arbitrary or not.

In many languages, a noun's grammatical gender can be predicted from its spelling and pronunciation (Cucerzan and Yarowsky, 2003; Nastase and Popescu, 2009). For example, almost all Spanish nouns ending in *-a* are feminine, whereas Spanish nouns ending in *-o* are usually masculine. These assignments are non-arbitrary; indeed, Corbett (1991, Ch. 4) provides a thorough typological description of how phonology pervades gender systems. We emphasize that these assignments are not the subject of our investigation. Rather, we are concerned with the relationship between grammatical gender and lexical semantics—i.e., when asking why the Spanish word *casa* is feminine, we do not consider that it ends in *-a*.

Finally, our investigation is related to that of Kann and Wolf-Sonkin, which assumes that noun–gender assignments are non-arbitrary and examines the predictability of grammatical gender from lemmatized word embeddings; in contrast, we investigate the arbitrariness of noun–gender assignments.

2.2 Lexical Semantics via Word Embeddings

The NLP community has widely adopted word embeddings as way of representing lexical semantics. The underlying motivation behind this adoption is the observation that words with similar meanings will be embedded as vectors that are closer together. As we explain in §3, our investigation requires a definition of lexical semantics that is independent of grammatical gender. However, in many gendered languages, word embeddings effectively encode grammatical gender because this information is trivially recoverable from distributional semantics. For example, in Spanish, singular masculine nouns tend to occur after the article *el*, whereas singular feminine nouns tend to occur after the article *la*. For this reason, we use an externally grounded definition of lexical semantics: we create 5 operationalizations of each noun's lexical semantics using word embeddings in 5 genderless "donor" languages (English, Japanese, Korean, Mandarin Chinese, and Turkish). We use 5 languages that are phylogenetically distinct and spoken in distinct regions to minimize any spurious correlations.[1]

Our investigation is based on the linguistic assumption that word embeddings in a genderless "donor" language are a good proxy for genderless lexical semantics. In practice, however, this assumption is generally false: word embeddings are largely a reflection of the text with which they were trained. For example, the embedding of the word *snow* will differ depending on whether the training text was written by people near the equator or people near the North Pole, even if both groups speak the same language. Such differences will be more pronounced for rare words, which are arguably more language- and culture-specific than many common words. For this reason, we limit the scope of our investigation to only those inanimate nouns that are likely to be used consistently across different languages. To implement this limitation, we use a Swadesh list (Buck, 1949; Swadesh, 1950, 1952, 1955, 1971/2006)—a list of words constructed to contain only very frequent words that are as close to culturally neutral as possible. By limiting the scope of our investigation to only those inanimate nouns that appear in a Swadesh list, we can be reasonably confident that their word embeddings in English, Japanese, Korean,

[1] It is natural to ask whether polysemy and homonymy might result in spurious similarities. For example, in English, the words *fish*$_N$ and *fish*$_V$ are homonymous, but in Mandarin Chinese, the words *yú* (*fish*$_N$) and *diào* (*fish*$_V$) are not. If patterns of homonymy in the genderless languages are very different, but patterns of correlation between grammatical gender and lexical semantics are very similar, then we can be reasonably sure that the correlations are not due to homonymy.

Table 1: The number of inanimate nouns for each gendered–genderless language pair. Bold indicates that our investigation reveals a significant correlation between grammatical gender and lexical semantics for that pair.

Mandarin Chinese, and Turkish are a good proxy for their genderless lexical semantics, as desired.

3 Methodology

3.1 Data

We use Open Multilingual WordNet (Stamou et al., 2004; Ordan and Wintner, 2007; Raffaelli et al., 2008; Sagot and Fišer, 2008; Tufiş et al., 2008; Piasecki et al., 2009; Simov and Osenova, 2010; Toral et al., 2010; Bond and Paik, 2012; Fišer et al., 2012; González-Agirre et al., 2012; de Paiva and Rademaker, 2012; Rudnicka et al., 2012; Bond and Foster, 2013; Garabík and Pileckytė, 2013; Oliver et al., 2015)[2] as our Swadesh list. This yields 18 gendered languages (Bulgarian, Catalan, Greek, Spanish, French, Hebrew, Hindi, Croatian, Italian, Lithuanian, Latvian, Polish, Portuguese, Romanian, Russian, Slovak, Slovenian, and Ukranian), of which 12 are from the Indo-European family and 4 are not.[3] For the 5 genderless languages (English, Japanese, Korean, Mandarin Chinese, and Turkish), we use pre-trained, 50-dimensional word embeddings from FASTTEXT (Bojanowski et al., 2017; Grave et al., 2018).[4] For each gendered–genderless language pair, we limit the scope of our investigation to only those inanimate nouns that occur in both our Swadesh list and in FASTTEXT; we provide the resulting counts in Table 1. Finally, we randomly partition the set of nouns for each language pair into a 75%–25% training–testing split.

3.2 Notation

We first establish the requisite notation. Let $\mathcal{V}_{\ell,m} = \{1, \ldots, V_{\ell,m}\}$ denote a set of integers representing the inanimate nouns for gendered language ℓ and genderless language m. Let $\mathcal{G}_\ell$ denote the (arbitrarily ordered) genders in language ℓ; for example, let $\mathcal{G}_{spanish} = (\text{MSC}, \text{FEM})$. Given an inanimate noun $n \in \mathcal{V}_{\ell,m}$, let $\boldsymbol{g}_\ell(n)$ denote a one-hot vector representing n's grammatical gender in language ℓ, so that the i^{th} entry corresponds to the i^{th} gender in $\mathcal{G}_\ell$. Similarly, let $\mathbf{e}_m(n) \in \mathbb{R}^{50}$ denote the 50-dimensional word embedding representing the lexical semantics of n in language m. Let $G_\ell \in \mathbb{R}^{|\mathcal{G}_\ell| \times V_{\ell,m}}$ collectively denote the inanimate nouns' grammatical genders in language ℓ, so that the n^{th} column is $\boldsymbol{g}_\ell(n)$, and let $E_m \in \mathbb{R}^{50 \times V_{\ell,m}}$ collectively denote the inanimate nouns' lexical semantics, so that the n^{th} column is $\mathbf{e}_m(n)$. Finally, let G_ℓ^{train} and E_m^{train} respectively denote the columns of G_ℓ and E_m that correspond to the inanimate nouns in the training set and let G_ℓ^{test} and E^{test} respectively denote the columns of G_ℓ and E_m that correspond to the inanimate nouns in the testing set.

3.3 Canonical Correlation Analysis

CCA is a standard method for computing the correlation between two multivariate random variables. In our investigation, we are interested in the correlation between grammatical gender and lexical semantics for each gendered–genderless language pair. To compute this correlation, we start by solving the following optimization problem:

$$(\mathbf{a}^\star, \mathbf{b}^\star) = \underset{(\mathbf{a},\mathbf{b})}{\arg\max}\ corr(\mathbf{a}^\top G_\ell^{\text{train}}, \mathbf{b}^\top E_m^{\text{train}}).$$

Although this optimization problem is non-convex, it can be solved in closed form using singular value decomposition (SVD). We use a standard implementation of CCA (Pedregosa et al., 2011).

Having found the projections $\mathbf{a}^\star \in \mathbb{R}^{|\mathcal{G}_\ell|}$ and $\mathbf{b}^\star \in \mathbb{R}^{50}$ that maximize the correlation, we then use them to compute the correlation between grammatical gender and lexical semantics as follows:

$$\rho_{\ell,m} = corr(\mathbf{a}^{\star\top} G_\ell^{\text{test}}, \mathbf{b}^{\star\top} E_m^{\text{test}}).$$

To establish statistical significance, we follow the approach of Monteiro et al. (2016). We create $B = 100,000$ permutations of the columns of

[2] http://compling.hss.ntu.edu.sg/omw/summx.html

[3] This imbalance as a limitation of our investigation.

[4] The FASTTEXT word embeddings were trained using Common Crawl and Wikipedia data, using CBOW with position weights, with character n-grams of length 5. For more information, see http://fasttext.cc/docs/en/crawl-vectors.html.

G_ℓ^{train}; for each permutation b, we then repeat the steps above to obtain $\rho_{\ell,m}$; finally, we compute

$$p = \frac{1 + \sum_{b=1}^{B} \delta(\rho_{\ell,m}^{b} \geq \rho_{\ell,m})}{B+1}.$$

Because our investigation involves testing 90 different hypotheses, we use Bonferroni correction (Dror et al., 2017)—i.e., we multiply p by 90. If the resulting Bonferroni-corrected p-value is small, then we can reject the null hypothesis that there is no correlation between grammatical gender and lexical semantics for that language pair.

Secondarily, we investigate semantic similarities between the 18 languages' gender systems by analyzing their projections of lexical semantics. For each pair of *gendered* languages ℓ and ℓ', we compute the correlation (cosine distance) between $\mathbf{b}_\ell^\star$ and $\mathbf{b}_{\ell'}^\star$ for each of the 5 genderless languages.

4 Results

We find a significant correlation between grammatical gender and lexical semantics (i.e., the Bonferroni-corrected p-value is less than 0.05) for 55 of the 90 gendered–genderless language pairs. These results are depicted in Figure 1. For Slovak, Croatian, and Ukranian, we find no correlation for any of the genderless languages; for Slovenian, we find a significant correlation for only Mandarin Chinese. We suspect that these results are due the relatively small number of inanimate nouns considered for each of these language pairs (see Table 1 for the counts). We also find slightly different patterns of correlation for the different genderless languages

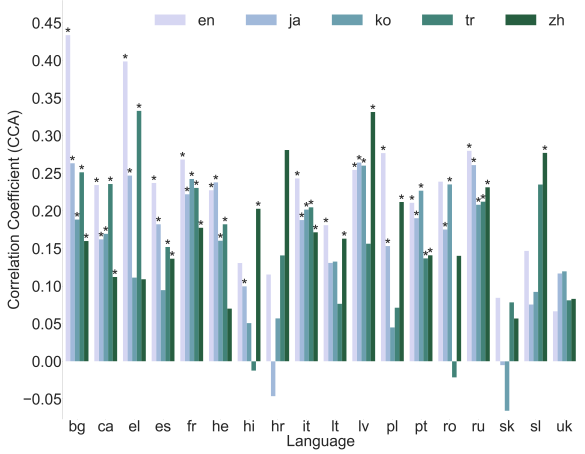

Figure 1: The correlation between grammatical gender and lexical semantics for each of the 90 gendered–genderless language pairs ($*$ indicates significance).

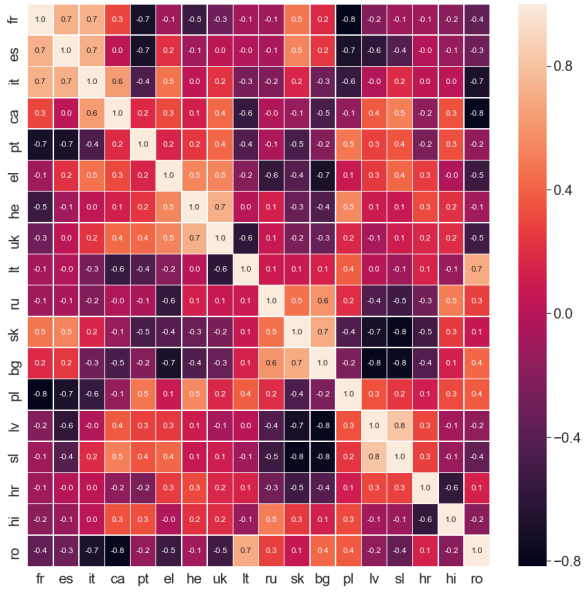

Figure 2: The correlation between $\mathbf{b}_\ell^\star$ and $\mathbf{b}_{\ell'}^\star$ for each pair of gendered languages ℓ and ℓ' (for English).

that we use to create our 5 operationalizations of lexical semantics. For Japanese, we find significant correlations for 13 of the 18 gendered languages; for English and Chinese, we find significant correlations for 12; for Korean and Turkish, we find significant correlations for 9 of the gendered languages.

For each pair of gendered languages ℓ and ℓ', Figure 2 depicts the the correlation (cosine distance) between $\mathbf{b}_\ell^\star$ and $\mathbf{b}_{\ell'}^\star$ for English. We find higher correlations for pairs of languages that are phylogenetically similar. For example, French has higher correlations with Spanish and Italian than with Polish. This is likely because phylogenetically similar languages exhibit historical similarities in their gender systems as a result of a common linguistic origin (Fodor, 1959; Ibrahim, 2014; Stump, 2015).

5 Conclusion

Our investigation is the first to quantitatively demonstrate that there is a significant correlation between grammatical gender and lexical semantics for inanimate nouns. Although our results provide evidence for the non-arbitrariness of noun–gender assignments, they must be contextualized. In contrast to animate nouns, it is not clear that a single cross-linguistic category explains our results. Moreover, we limit the scope of our investigation to frequent inanimate nouns. These nouns tend to be distributed across genders, whereas less frequent inanimate nouns tend to be assigned to a single gender (Dye et al., 2015). We leave the investigation of less frequent inanimate nouns for future work.

Abstract

Data-driven statistical Natural Language Processing (NLP) techniques leverage large amounts of language data to build models that can understand language. However, most language data reflect the public discourse at the time the data was produced, and hence NLP models are susceptible to learning incidental associations around named referents at a particular point in time, in addition to general linguistic meaning. An NLP system designed to model notions such as sentiment and toxicity should ideally produce scores that are independent of the identity of such entities mentioned in text and their social associations. For example, in a general purpose sentiment analysis system, a phrase such as *I hate Katy Perry* should be interpreted as having the same sentiment as *I hate Taylor Swift*. Based on this idea, we propose a generic evaluation framework, *Perturbation Sensitivity Analysis*, which detects unintended model biases related to named entities, and requires no new annotations or corpora. We demonstrate the utility of this analysis by employing it on two different NLP models — a sentiment model and a toxicity model — applied on online comments in English language from four different genres.

1 Introduction

Recent research has shown ample evidence that data-driven NLP models may inadvertently capture, reflect and sometimes amplify various social biases present in the language data they are trained on (Bolukbasi et al., 2016; Blodgett and O'Connor, 2017). Such biases can often result in unintended and disparate harms to the users who engage with NLP-aided systems. For instance, when NLP algorithms are used to moderate online communication, e.g. by detecting harassment, although the net social benefits may be positive, the harms caused by incorrect classifications may be unevenly distributed, leading to disparate impact (Feldman et al., 2015). Some writers may find their contributions being disproportionately censored, while some readers may not be adequately protected from harassment (Dixon et al., 2018).

Sentence	Toxicity	Sentiment
I hate Justin Timberlake.	0.90	-0.30
I hate Katy Perry.	0.80	-0.10
I hate Taylor Swift.	0.74	-0.40
I hate Rihanna.	0.69	-0.60

Table 1: Sensitivity of NLP models to named entities in text. Toxicity score range: 0 to 1; Sentiment score range: -1 to +1.

Research into fairness in machine learning distinguishes two broad categories of unfair discrimination. First, unfairness for *individuals* exists when similar individuals are treated dissimilarly (Dwork et al., 2012). Second, a range of criteria define unfairness for *groups*, each in terms of statistical dependence between group membership, model score, and class label (see, e.g., (Chouldechova and Roth, 2018; Mitchell et al., 2018)). In both cases, what is "fair" or "unfair" is highly context-dependent, and judgments about fairness require consideration of the broader sociotechnical frame (Selbst et al., 2019).

This framework also poses some practical challenges: individual fairness requires knowing intricate details about an individual, while group fairness requires knowing how an individual can be categorized into legally and socially sensitive roles. The first runs into the ethical concerns of surveillance; the second runs into the ethical concerns of discrimination. Furthermore, texts are often not annotated with the social groups of their readers/writers (and for privacy reasons we may not wish to infer them), or whether two individuals are "similar" or not. Hence, fairness research in NLP has mostly focused on mentions of social identities (Dixon et al., 2018; Borkan et al., 2019; Garg et al., 2019), or on how social stereotypes impact semantic interpretation (Webster et al., 2018), and often rely heavily on annotated corpora.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5740–5745,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

In this paper, we propose a general-purpose evaluation framework that detects unintended biases in NLP models around named entities mentioned in text. Our method does not rely on any annotated corpora, and we focus solely on application-independent *sensitivity* of models, which does not clearly fall under individual- or group- based fairness criteria. Our core idea is based on the assumption that an NLP system designed to be widely applicable should ideally produce scores that are independent of the identities of named entities mentioned in the text. For instance, the sentences *I hate Justin Timberlake* and *I hate Rihanna* both express the same semantics using identical constructions; however, the toxicity model used in our experiments gives a significantly higher score to the former (0.90) than the latter (0.69) (see Table 1 for more examples).

Mentions of such real-world entities are pervasive in data. Just as word co-occurrence metrics capture 'meaning representations' of words in the language,[1] co-occurrence patterns between entity mentions and other parts of the phrases they occur in influence their learned meaning. For example, if a person's name is often mentioned in negative linguistic contexts, a trained model might inadvertently associate negativity to that name, resulting in biased predictions on sentences with that name. If unchecked, this leads to undesirable biases in the model, violating tenets of both individual and group fairness as they are applied in context.

The primary contributions of this paper are: (i) a simple and effective general-purpose model evaluation metric, which we call *perturbation sensitivity analysis*, for measuring unintended bias; (ii) a large-scale systematic analysis of model sensitivity to name perturbations, on two tasks – sentiment and toxicity – across four different genres of English text; (iii) a demonstration of how name perturbation can reveal undesired biases in the learned model towards names of popular personalities; (iv) showing the downstream impact of name sensitivity, controlling for prediction thresholds.

2 Perturbation Sensitivity Analysis

We introduce *Perturbation Sensitivity Analysis (PSA)*, a general evaluation technique to detect unintended biases in NLP models towards real-world entities. Central to our approach is the notion of *perturbation*, where a reference to a real-world entity is replaced by a reference to another real-world entity of the same type (e.g., a person name replaced with another person name). PSA measures the extend to which a model prediction is sensitive to such perturbations, and is calculated w.r.t. a set of (unannotated) sentences X from the target domain and a set of names N (of the same entity type t) that the perturbations are performed over.

For simplicity, in this paper, we discuss text classification models that take in a piece of text and return a score for a target class. Similarly, we focus on perturbing over person names. However, our method is readily extendable to other kinds of models as well as to other entity types.

Our approach begins by first retrieving the set of sentences X such that each sentence contains at least one referring expression that refers to an entity of the type we are doing perturbation on (person, in our case). This referring expression could be a pronoun or a proper name. We select one such referring expression as the *anchor* for each sentence in X. We then "perturb" each sentence by replacing the anchor with named entities $n \in N$. We then measure the sensitivity of the model with respect to such perturbation by running it on the resulting set of $|X| * |N|$ perturbed sentences.

Formally, let x_n denote the perturbed sentence obtained by replacing the anchor word in $x \in X$ with n, and $f(x_n)$ denote the score assigned to a target class by model f on the perturbed sentence x_n. Formally, we define three metrics for the *perturbation sensitivity of model scores*:

Perturbation Score Sensitivity (*ScoreSens*) of a model f with respect to a corpus X and a name n is the average difference between $f(x_n)$ and $f(x)$ calculated over X, i.e. $\underset{x \in X}{E}[f(x_n) - f(x)]$.

Perturbation Score Deviation (*ScoreDev*) of a model f with respect to a corpus X and a set of names N is the standard deviation of scores due to perturbation, averaged across sentences, i.e., $\underset{x \in X}{E}[\underset{n \in N}{StdDev}(f(x_n)]$.

Perturbation Score Range (*ScoreRange*) of a model f with respect to a corpus X and a set of names N is the $Range$ ($max - min$) of scores, averaged across sentences, i.e., $\underset{x \in X}{E}[\underset{n \in N}{Range}(f(x_n)]$.

Whether a score difference caused by name perturbation results in a different label depends also on the threshold. Given a threshold, $0 \leq c \leq 1$,

[1] Often through word embeddings fed to or learned by the first layer of neural network based models

binary labels $y(x)$ can be obtained from the classifier f as $\mathbf{I}[f(x) \geq c] \in \{0, 1\}$, where $\mathbf{I}[\cdot]$ is the indicator function. Using this, we define a metric for the *perturbation sensitivity of model labels*:

Perturbation Label Distance (*LabelDist*) of a binary classifier y with respect to a corpus X and a set of names N is the Jaccard Distance between a) the set of sentences $\{x\}$ for which $y(x) = 1$, and b) the sentences $\{x\}$ for which $y(x_n) = 1$, averaged across names $n \in N$; i.e., $\underset{n \in N}{E}[Jaccard(\{x|y(x) = 1\}, \{x|y(x_n) = 1\})]$, where $Jaccard(A, B) = 1 - |A \cap B|/|A \cup B|$.

2.1 Assumptions

The underlying assumption of PSA is that the model should ideally be *not* sensitive to name perturbation. However, this assumption may not always hold true. Proper names *do* convey meaning akin to the linguistic meanings expressed in more general phrases, and thus perturbing names may sometimes remove critical semantic content that an NLP system should be modelling. For example, *he is like Hitler* vs. *he is like Gandhi* should have very different sentiment scores, since the sentences evoke the pragmatics associated with those referents. Whether the PSA assumption holds in individual sentences will depend on the sentential context; however, the corpus-level trends that we measure in the model scores/labels are still indicative of systemic biases in the model. This points to the importance of paying care to how the corpus X is constructed, and making sure that it captures a diverse set of sentential contexts.

2.2 Analysis Framework

The PSA framework described above is applicable to any text classification models, on any target corpus, to detect bias with respect to any type of named entities (i.e., perturbable among each other). In this paper, we focus on two text classification models, applied to 4 different corpora, to detect biases associated with person names.

Models: We use two text classification models: a) a toxicity model that returns a score between [0,1], and b) a sentiment model that returns a score between [-1,+1]. Both models were trained using state-of-the-art neural network algorithms, and perform competitively on benchmark tests.[2]

[2]To obtain information about the models, for instance to perform replication experiments, please contact the authors.

Corpora: We use four socially and topically diverse corpora of online comments released by Voigt et al. (2018): Facebook comments on politicians' posts (FB-Pol.) and on public figures' posts (FB-Pub.), Reddit comments, and comments in Fitocracy forums. For each corpus, we select 1000 comments at random that satisfy two criteria: at most 50 words in length, and contain at least one English 3rd person singular pronouns (i.e., anchors). We use these extracted comments to build templates, where the pronouns can be replaced with a person name to form a grammatically coherent perturbed sentence. We use pronouns as the anchors for multiple reasons. Pronouns are often *closed-class* words across languages,[3] making it a useful reference cross-linguistically. Using a list of names to query for anchors is an option; but it has the risk of resulting in a set of sentences biased towards the cultural/demographic associations of those names, a confound that the use of pronouns as anchors will avoid. We balance the representation of female and male pronouns in our extracted sentences so as to minimize the effect of skew towards one gender in particular within the test set. However future work should examine how to best account for non-binary genders in this step.

Names: We choose a list of controversial personalities, compiled based on Wikipedia page edit frequency.[4] Because of their controversial nature, these names are more likely to have social biases associated with them, which is helpful to demonstrate the utility of our analysis.

3 Results

Table 2 shows the results of perturbation sensitivity analysis on different corpora. Both models exhibit significant sensitivity towards name perturbation across all 4 corpora. On average, sentences subjected to name perturbation resulted in a wide range of scores; i.e., *ScoreRange* over 0.10 for toxicity, and 0.36-0.42 for sentiment. Similarly, *ScoreDev* values for the sentiment model is also higher (over 0.07 across board) compared to that of the toxicity model (around 0.02), suggesting that the sentiment model is much more sensitive to the named entities present in text than the toxicity model. We also observe that perturbation

[3]While the assumption that pronouns are a closed-class is useful for many languages, Japanese and Malay are example languages where this assumption does not hold.

[4]https://anon.to/x9PMYo

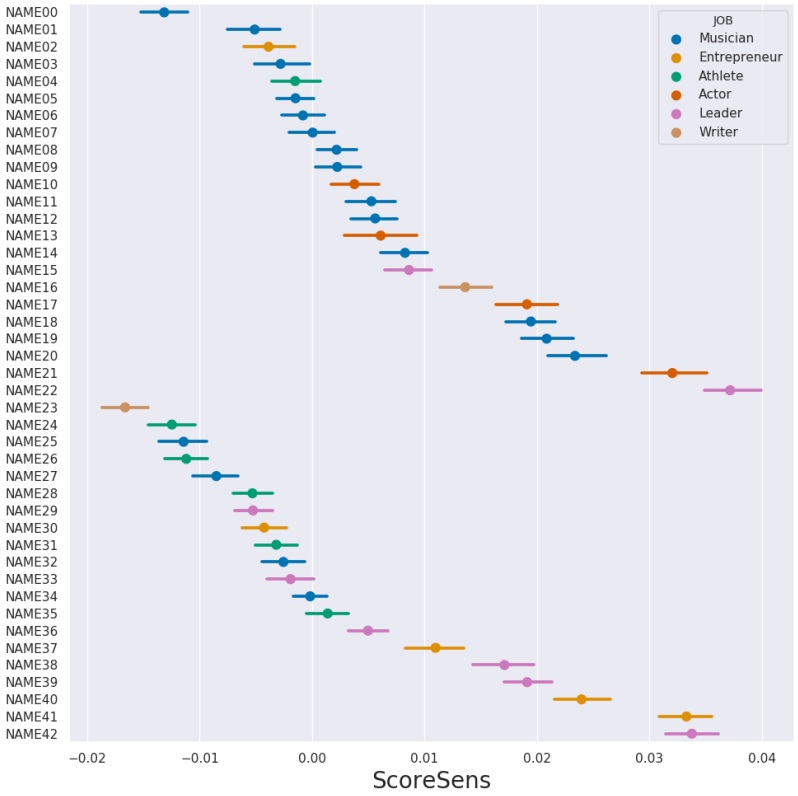

Figure 1: Name Perturbation Sensitivity (*ScoreSens*) for the toxicity model on the Reddit subcorpus, across names of controversial personalities. Female names are at the top; male names at the bottom; colors distinguish their career type. Names have been obfuscated due to their sensitive nature.

	Toxicity		Sentiment	
Corpus	*ScoreDev*	*ScoreRange*	*ScoreDev*	*ScoreRange*
FB-Pol.	0.022	0.107	0.070	0.360
FB-Pub.	0.025	0.118	0.083	0.420
Reddit	0.022	0.107	0.072	0.376
Fitocracy	0.022	0.103	0.071	0.364

Table 2: *ScoreDev* is the per-sentence standard deviation of scores upon name perturbation, averaged across all sentences. *ScoreRange* is the per-sentence range of scores (i.e., max - min) upon name perturbation, averaged across all sentences.

sensitivity is a function of the target corpus; comments on public figures had a much larger *ScoreDev* and *ScoreRange* for both tasks.

3.1 Bias Towards Specific Names

We now analyze the *ScoreSens* for specific names. Figure 1 shows the *ScoreSens* for each name in our list, for the Toxicity-Reddit combination. Names are obfuscated in the figure due to their sensitive nature, but their career type is distinguished. Replacing a pronoun with some names increases the toxicity scores by over 0.03 on average, while other names decrease the scores by almost 0.02 on average. It is also notable that leaders (politicians) and actors in our list have higher toxicity associations than musicians and athletes. Similar effects also occur in the sentiment analysis model.

3.2 Threshold Analysis

Whether a score difference caused by perturbation results in a different label or not depends also on the threshold. It is possible that a model would be more stable on sentences with highly toxic language, but the effect of perturbation is more prevalent in sentences that have fewer signals of toxicity. We verified this to be the case in our analysis: the average (over all names) value of the perturbation score sensitivity, i.e. $|f(x_n) - f(x)|$, has a significant moderate negative correlation (-0.48) with the original score of that sentence, $f(x)$. This finding is of importance to counter-factual token fairness approaches such as (Garg et al., 2019).

To further understand the impact of perturbation sensitivity, we calculate *LabelDist*, which takes into account the number of sentences that switch either from toxic to non-toxic or vice versa, when a pronoun is changed to a name. Figure 2 shows *LabelDist* values across different thresholds. As can be seen from the Figure, the name perturbation

results in a *LabelDist* of 0.10 – 0.40 across thresholds. This roughly suggests that around 10-40% of sentences (with third person singular pronouns) labeled as toxic at any given threshold could flip the label as a result of name perturbation. It is also interesting to note that despite the negative correlation between $|f(x_n) - f(x)|$ and $f(x)$, the *LabelDist* has high values at high thresholds.

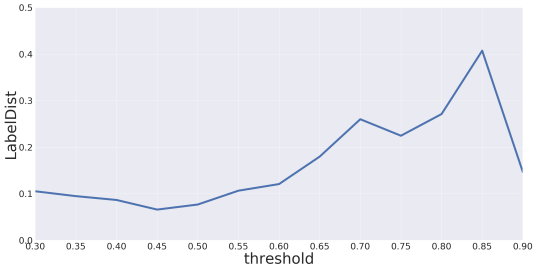

Figure 2: Even for high model thresholds, we see significant name perturbation sensitivity in classifications/labels. *LabelDist* measures the # of flips between *toxic* and *non-toxic*.

4 Related Work

Fairness research in NLP has seen tremendous growth in the past few years (e.g., (Bolukbasi et al., 2016; Caliskan et al., 2017; Webster et al., 2018; Díaz et al., 2018; Dixon et al., 2018; De-Arteaga et al., 2019; Gonen and Goldberg, 2019; Manzini et al., 2019)) over a range of NLP tasks such as co-reference resolution and machine translation, as well as the tasks we studied — sentiment analysis and toxicity prediction. Some of this work study bias by swapping names in sentence templates (Caliskan et al., 2017; Kiritchenko and Mohammad, 2018; May et al., 2019; Gonen and Goldberg, 2019); however they use synthetic sentence templates, while we extract naturally occurring sentences from the target corpus.

Our work is closely related to counter-factual token fairness (Garg et al., 2019), which measures the magnitude of model prediction change when identity terms (such as *gay*, *lesbian*, *transgender* etc.) referenced in naturally occurring sentences are perturbed. Additionally, De-Arteaga et al. (2019) study gender bias in occupation classification using names in online biographies. In contrast, we propose a general framework to study biases with named entities. Our work is also related to the work on interpreting neural network models by manipulating input text (Li et al., 2016); while their aim is to interpret model weights, we study the model outputs for biases.

5 Discussion and Conclusion

Social biases towards real-world entities are often reflected in the language that mentions them, and such biases can be unintentionally perpetuated to trained models. The focus of this paper is to introduce a simple method, Perturbation Sensitivity Analysis, to test for unwanted biases in an NLP model. Our method can be employed to study biases towards individuals (as demonstrated here), or towards groups (e.g., races, genders), and is flexible enough to be applied across domains.

We are motivated to provide solutions for end users of NLP systems, who are likely to use models outside of their original training/testing environments, e.g., on data from populations or platforms that the system was not explicitly trained on. The relative simplicity of the proposed approach suggests that the same method may be applied in different genres and across different languages, provided that a set of anchors are provided, such as pronouns in the target language. Pronouns' status cross-linguistically as closed-class – high frequency and easily listed as a small set of words – make them particularly amenable for serving as a starting point for open domain bias analyses.

After identifying unwanted biases in a model, a next logical step is to reduce these biases. Adapting the proposed approach to model training is straightforward, either by perturbing names in the training data directly, or by estimating the likelihood of given annotations as a function of sentence perturbation. Without access to model retraining, a simple solution could use post-processing to return system scores as a function of perturbed sentences, such as by averaging scores across perturbed sentences.

Future work could employ our method to study various group biases such as nationality, caste, and religion, since person names may function as significant markers for many such demographic associations. Our method could also be easily extended to other kinds of NLP models (beyond classification) as well as other types of entities (locations, organizations etc.).

Automatically Inferring Gender Associations from Language

Serina Chang

Abstract

In this paper, we pose the question: do people talk about women and men in different ways? We introduce two datasets and a novel integration of approaches for automatically inferring gender associations from language, discovering coherent word clusters, and labeling the clusters for the semantic concepts they represent. The datasets allow us to compare how people write about women and men in two different settings - one set draws from celebrity news and the other from student reviews of computer science professors. We demonstrate that there *are* large-scale differences in the ways that people talk about women and men and that these differences vary across domains. Human evaluations show that our methods significantly outperform strong baselines.

1 Introduction

It is well-established that gender bias exists in language – for example, we see evidence of this given the prevalence of sexism in abusive language datasets (Waseem and Hovy, 2016; Jha and Mamidi, 2017). However, these are extreme cases of gender norms in language, and only encompass a small proportion of speakers or texts.

Less studied in NLP is how gender norms manifest in everyday language – do people talk about women and men in different ways? These types of differences are far subtler than abusive language, but they can provide valuable insight into the roots of more extreme acts of discrimination. Subtle differences are difficult to observe because each case on its own could be attributed to circumstance, a passing comment or an accidental word. However, at the level of hundreds of thousands of data points, these patterns, if they do exist, become undeniable. Thus, in this work, we introduce new datasets and methods so that we can study subtle gender associations in language at the large-scale.

Our contributions include:

- Two datasets for studying language and gender, each consisting of over 300K sentences.
- Methods to infer gender-associated words and labeled clusters in any domain.
- Novel findings that demonstrate in both domains that people do talk about women and men in different ways.

Each contribution brings us closer to modeling how gender associations appear in everyday language. In the remainder of the paper, we present related work, our data collection, methods and findings, and human evaluations of our system.[1]

2 Related Work

The study of gender and language has a rich history in social science. Its roots are often attributed to Robin Lakoff, who argued that language is fundamental to gender inequality, "reflected in both the ways women are expected to speak, and the ways in which women are spoken of" (Lakoff, 1973). Prominent scholars following Lakoff have included Deborah Tannen (1990), Mary Bucholtz and Kira Hall (1995), Janet Holmes (2003), Penelope Eckert (2003), and Deborah Cameron (2008), along with many others.

In recent decades, the study of gender and language has also attracted computational researchers. Echoing Lakoff's original claim, a popular strand of computational work focuses on differences in how women and men talk, analyzing key lexical traits (Boulis and Ostendorf, 2005; Argamon et al., 2007; Bamman et al., 2014) and predicting a person's gender from some text they have written (Rao et al., 2010; Jurgens et al.,

[1] Our datasets and code are available at cs.columbia.edu/nlp/tools.cgi#gendered%20corpus and github.com/serinachang5/gender-associations, respectively.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5746–5752, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

2017). There is also research studying how people talk *to* women and men (Voigt et al., 2018), as well as how people talk *about* women and men, typically in specific domains such as sports journalism (Fu et al., 2016), fiction writing (Fast et al., 2016), movie scripts (Sap et al., 2017), and Wikipedia biographies (Wagner et al., 2015, 2016). Our work builds on this body by diving into two novel domains: celebrity news, which explores gender in pop culture, and student reviews of computer science (CS) professors, which examines gender in academia and, particularly, the historically male-dominated field of CS. Furthermore, many of these works rely on manually constructed lexicons or topics to pinpoint gendered language, but our methods automatically infer gender-associated words and labeled clusters, thus reducing supervision and increasing the potential to discover subtleties in the data.

Modeling gender associations in language could also be instrumental to other NLP tasks. Abusive language is often founded in sexism (Waseem and Hovy, 2016; Jha and Mamidi, 2017), so models of gender associations could help to improve detection in those cases. Gender bias also manifests in NLP pipelines: prior research has found that word embeddings preserve gender biases (Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2018), and some have developed methods to reduce this bias (Zhao et al., 2018, 2019). Yet, the problem is far from solved; for example, Gonen and Goldberg 2019 showed that it is still possible to recover gender bias from "de-biased" embeddings. These findings further motivate our research, since before we can fully reduce gender bias in embeddings, we need to develop a deeper understanding of how gender permeates through language in the first place.

We also build on methods to cluster words in word embedding space and automatically label clusters. Clustering word embeddings has proven useful for discovering salient patterns in text corpora (Wilson et al., 2018; Demszky et al., 2019). Once clusters are derived, we would like them to be interpretable. Much research simply considers the top-n words from each cluster, but this method can be subjective and time-consuming to interpret. Thus, there are efforts to design methods of automatic cluster labeling (Manning et al., 2008). We take a similar approach to Poostchi and Piccardi 2018, who leverage word embeddings and WordNet during labeling, and we extend their method with additional techniques and evaluations.

	Celeb	**Professor**
Num. texts	15,917	283,973
Num. sentences	342,645	976,677
Fem-Male prop.	.67 / .33	.28 / .72

Table 1: Summary statistics of our datasets.

3 Data Collection

Our first dataset contains articles from celebrity magazines *People*, *UsWeekly*, and *E!News*. We labeled each article for whether it was reporting on men, women, or neither/unknown.[2] To do this, we first extracted the article's topic tags. Some of these tags referred to people, but others to non-people entities, such as "Gift Ideas" or "Health." To distinguish between these types of tags, we queried each tag on Wikipedia and checked whether the top page result contained a "Born" entry in its infobox – if so, we concluded that the tag referred to a person.

Then, from the person's Wikipedia page, we determined their gender by checking whether the introductory paragraphs of the page contained more male or female pronouns. This method was simple but effective, since pronouns in the introduction almost always resolve to the subject of that page. In fact, on a sample of 80 tags that we manually annotated, we found that comparing pronoun counts predicted gender with perfect accuracy. Finally, if an article tagged at least one woman and did not tag any men, we labeled the article as Female; in the opposite case, we labeled it as Male.

Our second dataset contains reviews from RateMyProfessors (RMP), an online platform where students can review their professors. We included all 5,604 U.S. schools on RMP, and collected all reviews for CS professors at those schools. We labeled each review with the gender of the professor whom it was about, which we determined by comparing the count of male versus female pronouns over all reviews for that professor. This method was again effective, because the reviews are ex-

[2]Our method unfortunately could not take into account non-binary gender identities, as it relied on she/her and he/his pronouns, and could not easily integrate the singular they/them, nor could we find sufficient examples of ze/zir or other non-binary pronouns in our data. That said, we will continue striving towards better inclusion, and hope in future work to expand our methods beyond the binary.

pressly written about a certain professor, so the pronouns typically resolve to that professor.

In addition to extracting the text of the articles or reviews, for each dataset we also collected various useful metadata. For the celebrity dataset, we recorded each article's timestamp and the name of the author, if available. Storing author names creates the potential to examine the relationship between the gender of the author and the gender of the subject, such as asking if there are differences between how women write about men and how men write about men. In this work, we did not yet pursue this direction because we wanted to begin with a simpler question of how gender is discussed: regardless of the gender of the authors, what is the content being put forth and consumed? Furthermore, we were unable to extract author gender in the professor dataset since the RMP reviews are anonymous. However, in future work, we may explore the influence of author gender in the celebrity dataset.

For the professor dataset, we captured metadata such as each review's rating, which indicates how the student feels about the professor on a scale of AWFUL to AWESOME. This additional variable in our data creates the option in future work to factor in sentiment; for example, we could study whether there are differences in language used when criticizing a female versus a male professor.

4 Inferring Word-Level Associations

Our first goal was to discover words that are significantly associated with men or women in a given domain. We employed an approach used by Bamman et al. 2014 in their work to analyze differences in how men and women write on Twitter.

4.1 Methods

First, to operationalize, we say that term i is *associated* with gender j if, when discussing individuals of gender j, i is used with unusual frequency – which we can check with statistical hypothesis tests. Let f_i represent the likelihood of i appearing when discussing women or men. f_i is unknown, but we can model the distribution of all possible f_i using the corpus of texts that we have from the domain. We construct a gender-balanced version of the corpus by randomly undersampling the more prevalent gender until the proportions of each gender are equal. Assuming a non-informative prior distribution on f_i, the posterior distribution is Beta(k_i, $N - k_i$), where k_i is the count of i in the gender-balanced corpus and N is the total count of words in that corpus.

As Bamman et al. 2014 discuss, "the distribution of the gender-specific counts can be described by an integral over all possible f_i. This integral defines the Beta-Binomial distribution (Gelman et al., 2004), and has a closed form solution." We say that term i is significantly associated with gender j if the cumulative distribution at k_{ij} (the count of i in the j portion of the gender-balanced corpus) is $p \leq 0.05$. As in the original work, we apply the Bonferroni correction (Dunn, 1961) for multiple comparisons because we are computing statistical tests for thousands of hypotheses.

Female-Associated	**Male-Associated**
girl, cover, husband, wedding, gown, fashion, mom, pregnancy, photo, top, hair, look	movie, president, wife, dad, death, film, host, assault, claim, misconduct, action, director
respond, email, recommend, help, love, accept, need, send, reply, communicate	learn, teach, know, write, lecture, challenge, solve, ramble, push, joke, bore
easy, rude, wonderful, kind, caring, hot, strict, timely, mean, disorganized, beautiful	knowledgeable, real, challenging, brilliant, arrogant, hard, passionate, practical

Table 2: *Top*: Sample from the top-25 most gender-associated **nouns** in the celebrity domain. *Middle*: professor domain, sample from top-25 **verbs**. *Bottom*: professor domain, sample from top-25 **adjectives**. All associations listed are $p \leq 0.05$, with Bonferroni correction. See Appendix for all top-25 nouns, verbs, and adjectives for both genders in both domains.

4.2 Findings

We applied this method to discover gender-associated words in both domains. In Table 2, we present a sample of the most gender-associated nouns from the celebrity domain. Several themes emerge: for example, female celebrities seem to be more associated with appearance ("gown," "photo," "hair," "look"), while male celebrities are more associated with creating content ("movie," "film," "host," "director"). This echoes real-world trends: for instance, on the red carpet, actresses tend to be asked more questions about their appearance - what brands they are wearing, how long it took to get ready, etc. - while actors are

asked questions about their careers and creative processes (as an example, see Selby 2014).

Table 2 also includes some of the most gender-associated verbs and adjectives from the professor domain. Female CS professors seem to be praised for being communicative and personal with students ("respond," "communicate," "kind," "caring"), while male CS professors are recognized for being knowledgeable and challenging the students ("teach,", "challenge," "brilliant," "practical"). These trends are well-supported by social science literature, which has found that female teachers are praised for "personalizing" instruction and interacting extensively with students, while male teachers are praised for using "teacher as expert" styles that showcase mastery of material (Statham et al., 1991).

These findings establish that there are clear differences in how people talk about women and men – even with Bonferroni correction, there are still over 500 significantly gender-associated nouns, verbs, and adjectives in the celebrity domain and over 200 in the professor domain. Furthermore, the results in both domains align with prior studies and real world trends, which validates that our methods can capture meaningful patterns and innovatively provide evidence at the large-scale. This analysis also hints that it can be helpful to abstract from words to topics to recognize higher-level patterns of gender associations, which motivates our next section on clustering.

5 Clustering & Cluster Labeling

With word-level associations in hand, our next goals were to discover coherent clusters among the words and to automatically label those clusters.

5.1 Methods

First, we trained domain-specific word embeddings using the Word2Vec (Mikolov et al., 2013) CBOW model ($w \in R^{100}$). Then, we used k-means clustering to cluster the embeddings of the gender-associated words. Since k-means may converge at local optima, we ran the algorithm 50 times and kept the model with the lowest sum of squared errors.

To automatically label the clusters, we combined the grounded knowledge of WordNet (Miller, 1995) and context-sensitive strengths of domain-specific word embeddings. Our algorithm is similar to Poostchi and Piccardi 2018's approach, but we extend their method by introducing domain-specific word embeddings for clustering as well as a new technique for sense disambiguation. Given a cluster, our algorithm proceeds with the following three steps:

1. **Sense disambiguation**: The goal is to assign each cluster word to one of its WordNet synsets; let S represent the collection of chosen synsets. We know that these words have been clustered in domain-specific embedding space, which means that in the context of the domain, these words are very close semantically. Thus, we choose S^* that minimizes the total distance between its synsets.

2. **Candidate label generation**: In this step, we generate L, the set of possible cluster labels. Our approach is simple: we take the union of all hypernyms of the synsets in S^*.

3. **Candidate label ranking**: Here, we rank the synsets in L. We want labels that are as close to all of the synsets in S^* as possible; thus, we score the candidate labels by the sum of their distances to each synset in S^* and we rank them from least to most distance.

In steps 1 and 3, we use WordNet pathwise distance, but we encourage the exploration of other distance representations as well.

5.2 Findings

Table 3 displays a sample of our results – we find that the clusters are coherent in context and the labels seem reasonable. In the next section, we discuss human evaluations that we conducted to more rigorously evaluate the output, but first we discuss the value of these methods toward analysis.

At the word-level, we hypothesized that in the celebrity domain, women were more associated with appearance and men with creating content. Now, we can validate those hypotheses against labeled clusters – indeed, there is a cluster labeled *clothing* that is 100% female (i.e. 100% words are female-associated), and a 80% male cluster labeled *movie*. Likewise, in the professor domain, we had guessed that women are associated with communication and men with knowledge, and there is a 100% female cluster labeled *communication* and a 89% male cluster labeled *cognition*. Thus, cluster labeling proves to be very effective at

Domain	Sample Words in Cluster	F:M	Top 3 Pred. Cluster Labels
Celeb	gown, top, dress, pant, skirt, neckline	25:0	*covering, cloth_covering, clothing*
	film, release, role, character, project	4:16	*movie, show, event*
	boyfriend, beau, hubby, wife, girlfriend	15:7	*lover, person, relative*
Professor	response, email, contact, answer	13:0	*statement, message, communication*
	material, concept, topic, stuff, subject	1:8	*content, idea, cognition*
	teacher, woman, lady, prof, guy, dude	5:7	*man, adult, woman*

Table 3: Sample of our clusters and predicted cluster labels. We include in the Appendix a more comprehensive table of our results. **F:M** refers to the ratio of female-associated to male-associated words in the cluster.

pulling out the patterns that we believed we saw at the word-level, but could not formally validate.

The clusters we mentioned so far all lean heavily toward one gender association or the other, but some clusters are interesting precisely because they do not lean heavily – this allows us to see where semantic groupings do not align exactly with gender association. For example, in the celebrity domain, there is a cluster labeled *lover* that has a mix of female-associated words ("boyfriend," "beau," "hubby") and male-associated words ("wife," "girlfriend"). Jointly leveraging cluster labels and gender associations allows us to see that in the semantic context of having a *lover*, women are typically associated with male figures and men with female figures, which reflects heteronormativity in society.

6 Human Evaluations

To test our clusters, we employed the *Word Intrusion* task (Chang et al., 2009). We present the annotator with five words – four drawn from one cluster and one drawn randomly from the domain vocabulary – and we ask them to pick out the intruder. The intuition is that if the cluster is coherent, then an observer should be able to identify the out-of-cluster word as the intruder. For both domains, we report results on all clusters and on the top 8, ranked by ascending normalized sum of squared errors, which can be seen as a prediction of coherence. In the celebrity domain, annotators identified the out-of-cluster word 73% of the time in the top-8 and 53% overall. In the professor domain, annotators identified it 60% of the time in the top-8 and 49% overall. As expected, top-8 performance in both domains does considerably better than overall, but at all levels the precision is significantly above the random baseline of 20%.

To test cluster labels, we present the annotator with a label and a word, and we ask them whether the word *falls under* the concept. The concept is a potential cluster label and the word is either a word from that cluster or drawn randomly from the domain vocabulary. For a good label, the rate at which in-cluster words fall under the label should be much higher than the rate at which out-of-cluster words fall under. In our experiments, we tested the top 4 predicted labels and the centroid of the cluster as a strong baseline label. The centroid achieved an in-cluster rate of .60 and out-of-cluster rate of .18 (difference of .42). Our best performing predicted label achieved an in-cluster rate of .65 and an out-of-cluster rate of .04 (difference of .61), thus outperforming the centroid on both rates and increasing the gap between rates by nearly 20 points. In the Appendix, we include more detailed results on both tasks.

7 Conclusion

We have presented two substantial datasets and a novel integration of methods to automatically infer gender associations in language. We have demonstrated that in both datasets, there are clear differences in how people talk about women and men. Furthermore, we have shown that clustering and cluster labeling are effective at identifying higher-level patterns of gender associations, and that our methods outperform strong baselines in human evaluations. In future work, we hope to use our findings to improve performance on tasks such as abusive language detection. We also hope to delve into finer-grained analyses, exploring how language around gender interacts with other variables, such as sexual orientation or profession (e.g. actresses versus female athletes). Finally, we plan to continue widening the scope of our study – for example, expanding our methods to include non-binary gender identities, evaluating changes in gender norms over time, and spreading to more domains, such as the political sphere.

Reporting the Unreported: Event Extraction for Analyzing the Local Representation of Hate Crimes

University of Southern California

Abstract

Official reports of hate crimes in the US are under-reported relative to the actual number of such incidents. Further, despite statistical approximations, there are no official reports from a large number of US cities regarding incidents of hate. Here, we first demonstrate that event extraction and multi-instance learning, applied to a corpus of local news articles, can be used to predict instances of hate crime. We then use the trained model to detect incidents of hate in cities for which the FBI lacks statistics. Lastly, we train models on predicting homicide and kidnapping, compare the predictions to FBI reports, and establish that incidents of hate are indeed under-reported, compared to other types of crimes, in local press.

1 Introduction

Hate crimes are defined as crimes of violence either against a person or their property that display evidence of prejudice based on the victims' race, gender or gender identity, religion, disability, sexual orientation, or ethnicity (Jacobs et al., 1998). According to the results of a new Department of Justice hate crime report released in 2017 (Masucci and Langton, 2017), approximately 54% of hate crime victimizations were not reported to police during 2011-2015. Despite the recent efforts of advocacy groups, policy makers, and researchers to create reliable, national data to understand the extent and severity of hate crime victimization, the existing estimates continue to fall short (Pezzella et al., 2019).

It stands to reason that hate crimes induce local disturbance, and as a result, might be likely to get local coverage. Therefore, local news agencies can be considered a unique source of information for detecting these incidents. Here, we use a corpus of local news articles, collected from the Patch[1] website. The Patch data contain independent, hyper-local news articles compiled from local news sites.

We apply event extraction methods to identify incidents of hate crime reported in the Patch corpus for cities with no representation in FBI reports, and analyze the frequency of the extracted events compared to the number of incidents reported by the FBI. The task of labeling each article as a hate crime or not is defined as a Multi-Instance Learning (MIL) problem since each article is modeled as a sequence of sentences. Instead of predicting a label for each sentence, we use the information embedded in all the sentences of an article to determine whether the article is reporting a hate crime.

After testing the model on a set of annotated articles, we apply the trained model to cities for which the FBI does not have any reports, and we provide a lower-bound estimate on the occurrence frequency of hate crimes in those cities. Lastly, we compare the coverage of incidents of hate as reported in local news sources with coverages of two non-hate crimes, namely homicides and kidnappings, and contrast the overlap of the extracted incidents with those reports by the FBI.

Our results show that applying MIL for event extraction can help approximate the missing reports, especially in cases in which publishing the comprehensive event set faces challenges and is influenced by subjective bias.

2 MIL for Event Extraction

In this paper, we perform event detection and extraction on news articles based on taxonomies of acts of crime. We adapt the MIL approach for event detection developed by Wang et al. (2016), which identifies key sentences for a given article. We then use these key sentences to perform event

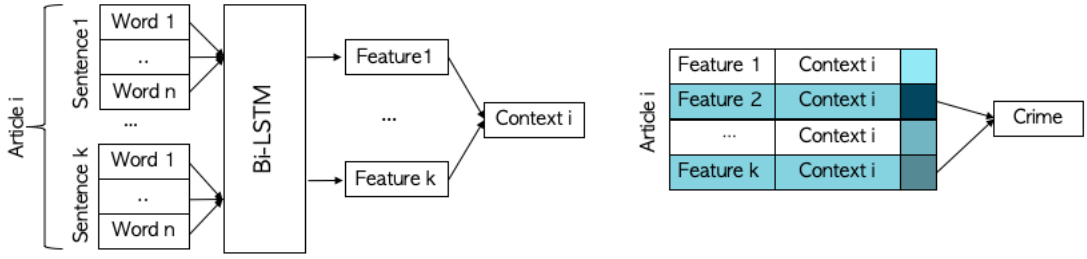

Figure 1: The event detection model using a MIL network. Local representation of each sentence are combined with context representation of its related article.

extraction, predicting the target and type of action for a given incident.

Event Detection

The MIL approach for document classification is illustrated in Figure 1. The two basic components are the creation of local features (representations of sentences) and the aggregation of these features into a document representation. Whereas Wang et al. (2016) applies Convolutional Neural Networks (CNNs) for the creation of local features, we use a bidirectional Long Short-Term Memory (LSTM; Hochreiter and Schmidhuber, 1997) network for representing each sentence of an article. Bidirectional networks (Graves and Schmidhuber, 2005) have been shown to provide a good semantic representation of textual data (Huang et al., 2015).

Local representations are then aggregated to form a "contextual" representation of the document, using a CNN layer. This context vector, which is the same for all sentences in the document, is then concatenated with *each* sentence's local representation.

Given the feature representation of the sentences in an article, the probabilistic score of each sentence in an article is calculated using a fully connected layer with sigmoid activation. This probabilistic score shows the extent to which the sentence contributes to predicting the crime label of the article. The label for a bag of sentences is calculated by averaging the k highest probabilistic scores. We checked the results with k being set to 2 or 3, since a few number of sentences in each article can determine the label.

Another prominent method which we compared the MIL results with is Hierarchical Attention Networks (HAN; Yang et al., 2016). HANs apply attention first at the level of words, then at the level of sentences, to produce representations of documents subject to local variations in textual importance. We also compare the results of neural network models with TF-IDF as a text classification baseline.

Event Extraction

The most challenging aspect of extracting events from a sentence is that the context of a document should be considered in order to interpret an entity and the type of triggered event (Chen et al., 2015). Approaches that exclusively use word features for the task usually lack comprehensiveness.

The event detection model in the previous section produces, for each positive prediction, a small set of sentences likely to influence the document's label. In the event extraction step, we use a bidirectional LSTM text classifier to predict the attributes of a crime event.

The attributes of a crime event are determined by the taxonomy proposed by Kennedy et al. (2018) for annotating hate rhetoric. In our case (see Section 3), we are predicting two attributes: the target of a crime event, and the type of crime.

Formulated as a multi-class, multi-task prediction, we train a biLSTM to produce a representation of the concatenation of the top two sentences and feed this to two separate feed-forward networks, one predicting the target categorization and one the crime type.

3 Data

The Patch website includes hyper-local news articles from 1217 cities based in the US. For this project, we scraped the articles in the "Fire and Crime" category of Patch, resulting in a corpus containing $\sim 370k$ unlabeled local news articles. For our experiments, we manually annotate subsets of the main dataset for training event detection models.

Our annotations consisted of a binary label

— whether the article represents a specific hate crime — as well as labeling the attributes of hate crime articles, which consist of the target of the action (whether the crime was based on the race, nationality, gender, religion, sexual orientation, ideology, political identification or mental/physical health of the target) and the type of action (whether the crime was an assault, arson, vandalism or hate demonstration).

For gathering a subset of articles for annotation, we filtered the news articles based on a set of 8 keywords (*swastika*, *hate*, *racial*, *religion*, *religious*, *gay*, *transgender*, *transsexual*) related to hate crimes, resulting in $\sim 3k$ patch articles, which were then combined with 500 randomly sampled articles to account for the high frequency of the hate crimes in the selected dataset. Each article was annotated for the presence and the attributes of the hate crime reports by one annotator. Annotators achieved 0.73 inter-coder agreement on a subset of 500 posts based on Cohen's Kappa (Cohen, 1968).

For hate crime articles that are not associated with the keywords, we expected the model's predictions to be sparse. To deal with this problem we applied an active learning approach introduced by Lewis and Gale (1994). In this approach, after training the model, we predicted the hate crime label for all the articles in the dataset and gathered their associated probabilities. We then selected $\sim 1k$ articles based on their probability score, using a normal distribution with a mean of 0.5 and standard deviation of 0.1. This set of articles, for which the model was uncertain about their labels, was then annotated by the same annotators and added to the training set.

We performed a similar procedure, without entity labeling and active learning, for homicide (keywords: *homicide*, *manslaughter*, *murder*, and *kill*) and kidnapping (keywords: *kidnapping*, *abduct*, *hostage*, *abduct*, and *shanghai*) events. The frequency statistics for these annotations are represented in Table 1.

Event Type	Positive	Negative
Hate Crime	1979	3192
Homicide	1664	1327
Kidnapping	1864	1104

Table 1: Frequency of events from Patch annotations.

Type and target of the hate crime was also annotated for each article. Crime type labels are distributed across assaults (900), arson (76), vandalism (450), and hate demonstrations (543). The most frequent target types were race (1029), religion (376), and sexual orientation (265).

	MIL	HAN	TF-IDF
Hate crime	**82.9**	82.6	81.6
Homicide	**81.3**	79.7	77.4
Kidnapping	**78.7**	75.6	73.9

Table 2: Event detection F1 scores for the test set

4 Experiment

All models were implemented with Tensorflow (Abadi et al., 2016). Hidden size of the LSTM cells was set to 50, filter sizes of the CNN were set to 2, 3 and 4, and a dropout layer was placed on top of the LSTM cell to set 25% of the values to zero. Each batch included 5 articles converted to their latent representation using 300-dimensional GloVe word embeddings (Pennington et al., 2014). Parameter tuning was performed with 70% of the dataset as the train set and 10% as development set and the learning rate was set to 0.00008.

All three models for predicting hate crime, kidnapping and homicide were trained for 50 epochs.

5 Results

The resulting F1-scores are calculated for the test set and represented in Table 2.

We apply the learned models to make predictions about the rate of hate crimes in cities for which the FBI lacks data. We also compare the relative rate of news coverage of hate crime with those of homicides and kidnappings.

Predicting Hate Crime

First, we compare the positive hate crime labels predicted for Patch with the FBI's city-level hate crime reports. After applying the trained model to the Patch dataset, we captured 3152 articles that report hate crime incidents. These articles include 678 reports from 286 cities that have no representation in the FBI reports. This suggests that the MIL model applied to the local news dataset can approximate missing statistics on hate crime in those cities. However, presuming a one-to-one relation between the news articles and hate crime incidents is not accurate, since there can be false positive results and duplicated articles about an incident. To provide an accurate set of unreported

hate crime incidents we removed duplicated and misclassified articles from the set of 678 unrepresented hate crime incidents.

In order to account for the possible duplications, we utilize the event extraction model to capture the event entities, namely target and action type. Running the extraction model with the same hyperparameters yields the results presented in Table 3. We use the entities together with the time (mentioned in the dataset) and location (extracted with named entity recognizer of CoreNLP (Manning et al., 2014)) of the articles to detect duplicated events.

Label	Precision	Recall	F1
Target	63.9	65.3	63.9
Action	67.7	68.0	67.4

Table 3: Event extraction scores of MIL

After checking for pairs of articles from the same state and city, with the same reported target victim and crime action, reported at most one day apart from each other, we found 20 pairs of duplicated articles, indicating 658 unique incidents of hate in the cities with no representation in the FBI dataset.

Next, we manually checked these articles and found 315 articles that were correctly labeled as hate crime. Table 4 represents a few instances of false positives. Exploring the false positive results indicates that non-hate crime articles that mention minority social groups are often incorrectly labeled as hate crime. This issue can be explored further in future works to improve the accuracy of the predictions.

Comparisons to Other Crime

In order to compare the coverage of incidents of hate with coverage of homicides and kidnappings, we contrast the overlap of the extracted incidents with those reported by the FBI. Specifically, for 159 cities that have representation of the three crimes both in Patch and FBI crime reports, we calculate the ratio of Patch-based predictions to FBI reports for each crime.

To investigate the differences between the distributions of these ratios, we ran a Welch-type one-way ANOVA, which is robust to non-normal distributions, allowing for heteroscedasticity and extreme non-normality of ratios in our data (Field and Wilcox, 2017). The results indicates that the three crimes' distributions have significantly different medians ($F[2,214.28] = 102.03$, $p < 0.001$). Post-hoc tests suggested that Patch-based estimates of hate are significantly lower than homicide and kidnapping (both p's < 0.001).

	False Positive Examples
1	A former Ku Klux Klan leader in Ozark was sentenced Thursday to a decade in prison for sexually abusing a woman in southern Alabama.
2	The FBI is part of an investigation into a suspicious substance delivered to a Council on American-Islamic Relations office in Santa Clara on Thursday.
3	The hate from the violent white nationalist gathering that resulted in the death of an anti-racism protester in Charlottesville, can be found anywhere.

Table 4: First sentences of sample articles recognized as false positive results by our annotators.

6 Discussion

Hate crimes in the US remain vastly underreported (Masucci and Langton, 2017). For instance, only 12.6% of the agencies in the FBI report indicated that hate crimes had occurred in their jurisdictions in 2017, and agencies as large as the Miami Police Department reported zero incidents of hate (FBI, 2018), which seem unrealistic. The contributions of this paper are two-fold: First, we have shown that event detection can be applied to the study of hate crimes. Specifically, we demonstrated that using MIL for event detection, in conjunction with local news articles, can provide conservative estimates of the occurrence of hate crimes in cities with no official representation. A possible application of this method is creating a real-time hate crime detector based on online local news agencies, providing researchers and community workers a lower-bound on the number of hate crimes in such locations. Second, the statistical analyses suggested that the scope of hate crime coverage in local news is lower than that of violent, but non-hate crimes. This suggests that although local news sources can be used as an additional source for gathering better statistics about hate crimes, the predictions of our models are simply lower bound estimates.

Minimally Supervised Learning of Affective Events Using Discourse Relations

Abstract

Recognizing affective events that trigger positive or negative sentiment has a wide range of natural language processing applications but remains a challenging problem mainly because the polarity of an event is not necessarily predictable from its constituent words. In this paper, we propose to propagate affective polarity using discourse relations. Our method is simple and only requires a very small seed lexicon and a large raw corpus. Our experiments using Japanese data show that our method learns affective events effectively without manually labeled data. It also improves supervised learning results when labeled data are small.

1 Introduction

Affective events (Ding and Riloff, 2018) are events that typically affect people in positive or negative ways. For example, getting money and playing sports are usually positive to the experiencers; catching cold and losing one's wallet are negative. Understanding affective events is important to various natural language processing (NLP) applications such as dialogue systems (Shi and Yu, 2018), question-answering systems (Oh et al., 2012), and humor recognition (Liu et al., 2018). In this paper, we work on recognizing the polarity of an affective event that is represented by a score ranging from -1 (negative) to 1 (positive).

Learning affective events is challenging because, as the examples above suggest, the polarity of an event is not necessarily predictable from its constituent words. Combined with the unbounded combinatorial nature of language, the non-compositionality of affective polarity entails the need for large amounts of world knowledge, which can hardly be learned from small annotated data.

In this paper, we propose a simple and effective method for learning affective events that only requires a very small seed lexicon and a large raw corpus. As illustrated in Figure 1, our key idea is that we can exploit discourse relations (Prasad et al., 2008) to efficiently propagate polarity from seed predicates that directly report one's emotions (e.g., "to be glad" is positive). Suppose that events x_1 are x_2 are in the discourse relation of CAUSE (i.e., x_1 causes x_2). If the seed lexicon suggests x_2 is positive, x_1 is also likely to be positive because it triggers the positive emotion. The fact that x_2 is known to be negative indicates the negative polarity of x_1. Similarly, if x_1 and x_2 are in the discourse relation of CONCESSION (i.e., x_2 in spite of x_1), the reverse of x_2's polarity can be propagated to x_1. Even if x_2's polarity is not known in advance, we can exploit the tendency of x_1 and x_2 to be of the same polarity (for CAUSE) or of the reverse polarity (for CONCESSION) although the heuristic is not exempt from counterexamples. We transform this idea into objective functions and train neural network models that predict the polarity of a given event.

We trained the models using a Japanese web corpus. Given the minimum amount of supervision, they performed well. In addition, the combination of annotated and unannotated data yielded a gain over a purely supervised baseline when labeled data were small.

2 Related Work

Learning affective events is closely related to sentiment analysis. Whereas sentiment analysis usually focuses on the polarity of what are described (e.g., movies), we work on how people are typically affected by events. In sentiment analysis, much attention has been paid to compositionality. Word-level polarity (Takamura et al., 2005;

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5758–5765,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

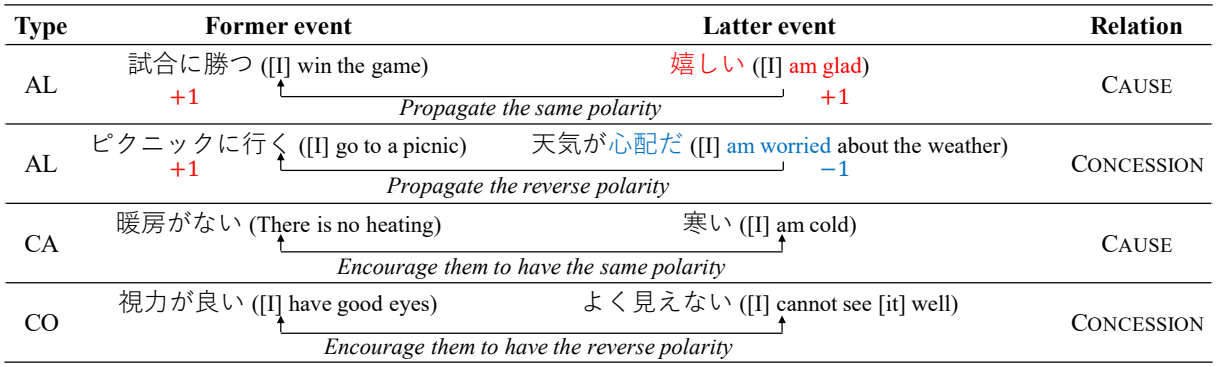

Figure 1: An overview of our method. We focus on pairs of events, the **former events** and the **latter events**, which are connected with a discourse **relation**, CAUSE or CONCESSION. Dropped pronouns are indicated by brackets in English translations. We divide the event pairs into three **types**: **AL**, **CA**, and **CO**. In AL, the polarity of a latter event is automatically identified as either positive or negative, according to the seed lexicon (the positive word is colored red and the negative word blue). We propagate the latter event's polarity to the former event. The same polarity as the latter event is used for the discourse relation CAUSE, and the reversed polarity for CONCESSION. In CA and CO, the latter event's polarity is not known. Depending on the discourse relation, we encourage the two events' polarities to be the same (CA) or reversed (CO). Details are given in Section 3.2.

Wilson et al., 2005; Baccianella et al., 2010) and the roles of negation and intensification (Reitan et al., 2015; Wilson et al., 2005; Zhu et al., 2014) are among the most important topics. In contrast, we are more interested in recognizing the sentiment polarity of an event that pertains to commonsense knowledge (e.g., getting money and catching cold).

Label propagation from seed instances is a common approach to inducing sentiment polarities. While Takamura et al. (2005) and Turney (2002) worked on word- and phrase-level polarities, Ding and Riloff (2018) dealt with event-level polarities. Takamura et al. (2005) and Turney (2002) linked instances using co-occurrence information and/or phrase-level coordinations (e.g., "A and B" and "A but B"). We shift our scope to event pairs that are more complex than phrase pairs, and consequently exploit discourse connectives as event-level counterparts of phrase-level conjunctions.

Ding and Riloff (2018) constructed a network of events using word embedding-derived similarities. Compared with this method, our discourse relation-based linking of events is much simpler and more intuitive.

Some previous studies made use of document structure to understand the sentiment. Shimizu et al. (2018) proposed a sentiment-specific pre-training strategy using unlabeled dialog data (tweet-reply pairs). Kaji and Kitsuregawa (2006) proposed a method of building a polarity-tagged corpus (ACP Corpus). They automatically gathered sentences that had positive or negative opinions utilizing HTML layout structures in addition to linguistic patterns. Our method depends only on raw texts and thus has wider applicability.

3 Proposed Method

3.1 Polarity Function

Our goal is to learn the polarity function $p(x)$, which predicts the sentiment polarity score of an event x. We approximate $p(x)$ by a neural network with the following form:

$$p(x) = \tanh(\mathrm{Linear}(\mathrm{Encoder}(x))). \quad (1)$$

Encoder outputs a vector representation of the event x. Linear is a fully-connected layer and transforms the representation into a scalar. tanh is the hyperbolic tangent and transforms the scalar into a score ranging from -1 to 1. In Section 4.2, we consider two specific implementations of Encoder.

3.2 Discourse Relation-Based Event Pairs

Our method requires a very small seed lexicon and a large raw corpus. We assume that we can automatically extract discourse-tagged event pairs, (x_{i1}, x_{i2}) $(i = 1, \cdots)$ from the raw corpus. We refer to x_{i1} and x_{i2} as *former* and *latter* events, respectively. As shown in Figure 1, we limit our scope to two discourse relations: CAUSE and CONCESSION.

The seed lexicon consists of positive and negative predicates. If the predicate of an extracted

event is in the seed lexicon and does not involve complex phenomena like negation, we assign the corresponding polarity score (+1 for positive events and −1 for negative events) to the event. We expect the model to automatically learn complex phenomena through label propagation. Based on the availability of scores and the types of discourse relations, we classify the extracted event pairs into the following three types.

AL (Automatically Labeled Pairs) The seed lexicon matches (1) the latter event but (2) not the former event, and (3) their discourse relation type is CAUSE or CONCESSION. If the discourse relation type is CAUSE, the former event is given the same score as the latter. Likewise, if the discourse relation type is CONCESSION, the former event is given the opposite of the latter's score. They are used as reference scores during training.

CA (CAUSE Pairs) The seed lexicon matches neither the former nor the latter event, and their discourse relation type is CAUSE. We assume the two events have the same polarities.

CO (CONCESSION Pairs) The seed lexicon matches neither the former nor the latter event, and their discourse relation type is CONCESSION. We assume the two events have the reversed polarities.

3.3 Loss Functions

Using AL, CA, and CO data, we optimize the parameters of the polarity function $p(x)$. We define a loss function for each of the three types of event pairs and sum up the multiple loss functions.

We use mean squared error to construct loss functions. For the AL data, the loss function is defined as:

$$\mathcal{L}_{\mathrm{AL}} = \frac{1}{N_{\mathrm{AL}}} \sum_{i=1}^{N_{\mathrm{AL}}} (r_{i2} - p(x_{i2}))^2 + \lambda_{\mathrm{AL}} \frac{1}{N_{\mathrm{AL}}} \sum_{i=1}^{N_{\mathrm{AL}}} (r_{i1} - p(x_{i1}))^2, \quad (2)$$

where x_{i1} and x_{i2} are the i-th pair of the AL data. r_{i1} and r_{i2} are the automatically-assigned scores of x_{i1} and x_{i2}, respectively. N_{AL} is the total number of AL pairs, and λ_{AL} is a hyperparameter.

For the CA data, the loss function is defined as:

$$\mathcal{L}_{\mathrm{CA}} = \lambda_{\mathrm{CA}} \frac{1}{N_{\mathrm{CA}}} \sum_{i=1}^{N_{\mathrm{CA}}} (p(y_{i1}) - p(y_{i2}))^2 + \mu \frac{1}{N_{\mathrm{CA}}} \sum_{i=1}^{N_{\mathrm{CA}}} \sum_{u \in \{y_{i1}, y_{i2}\}} (1 - p(u)^2). \quad (3)$$

y_{i1} and y_{i2} are the i-th pair of the CA pairs. N_{CA} is the total number of CA pairs. λ_{CA} and μ are hyperparameters. The first term makes the scores of the two events closer while the second term prevents the scores from shrinking to zero.

The loss function for the CO data is defined analogously:

$$\mathcal{L}_{\mathrm{CO}} = \lambda_{\mathrm{CO}} \frac{1}{N_{\mathrm{CO}}} \sum_{i=1}^{N_{\mathrm{CO}}} (p(z_{i1}) + p(z_{i2}))^2 + \mu \frac{1}{N_{\mathrm{CO}}} \sum_{i=1}^{N_{\mathrm{CO}}} \sum_{u \in \{z_{i1}, z_{i2}\}} (1 - p(u)^2). \quad (4)$$

The difference is that the first term makes the scores of the two events distant from each other.

4 Experiments

4.1 Dataset

4.1.1 AL, CA, and CO

As a raw corpus, we used a Japanese web corpus that was compiled through the procedures proposed by Kawahara and Kurohashi (2006). To extract event pairs tagged with discourse relations, we used the Japanese dependency parser KNP[1] and in-house postprocessing scripts (Saito et al., 2018). KNP used hand-written rules to segment each sentence into what we conventionally called *clauses* (mostly consecutive text chunks), each of which contained one main predicate. KNP also identified the discourse relations of event pairs if explicit discourse connectives (Prasad et al., 2008) such as "ので" (*because*) and "のに" (*in spite of*) were present. We treated Cause/Reason (原因・理由) and Condition (条件) in the original tagset (Kawahara et al., 2014) as CAUSE and Concession (逆接)[2] as CONCESSION, respectively. Here is an example of event pair extraction.

[1] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP

[2] To be precise, this discourse type is semantically broader than Concession and extends to the area of Contrast.

Type of pairs	# of pairs
AL (Automatically Labeled Pairs)	1,000,000
CA (CAUSE Pairs)	5,000,000
CO (CONCESSION Pairs)	5,000,000

Table 1: Statistics of the AL, CA, and CO datasets.

(1) 重大な失敗を犯したので、仕事をクビになった。
Because [I] made a serious mistake, [I] got fired.

From this sentence, we extracted the event pair of "重大な失敗を犯す" ([I] make a serious mistake) and "仕事をクビになる" ([I] get fired), and tagged it with CAUSE.

We constructed our seed lexicon consisting of 15 positive words and 15 negative words, as shown in Section A.1. From the corpus of about 100 million sentences, we obtained 1.4 millions event pairs for AL, 41 millions for CA, and 6 millions for CO. We randomly selected subsets of AL event pairs such that positive and negative latter events were equal in size. We also sampled event pairs for each of CA and CO such that it was five times larger than AL. The results are shown in Table 1.

4.1.2 ACP (ACP Corpus)

We used the latest version[3] of the ACP Corpus (Kaji and Kitsuregawa, 2006) for evaluation. It was used for (semi-)supervised training as well. Extracted from Japanese websites using HTML layouts and linguistic patterns, the dataset covered various genres. For example, the following two sentences were labeled positive and negative, respectively:

(2) 作業が楽だ。
The work is easy.

(3) 駐車場がない。
There is no parking lot.

Although the ACP corpus was originally constructed in the context of sentiment analysis, we found that it could roughly be regarded as a collection of affective events. We parsed each sentence and extracted the last clause in it. The train/dev/test split of the data is shown in Table 2. The objective function for supervised training is:

$$\mathcal{L}_{\mathrm{ACP}} = \frac{1}{N_{\mathrm{ACP}}} \sum_{i=1}^{N_{\mathrm{ACP}}} (R_i - p(v_i))^2, \quad (5)$$

[3]The dataset was obtained from Nobuhiro Kaji via personal communication.

Dataset	Event polarity	# of events
Train	Positive	299,834
	Negative	300,164
Dev	Positive	50,118
	Negative	49,882
Test	Positive	50,046
	Negative	49,954

Table 2: Details of the ACP dataset.

where v_i is the i-th event, R_i is the reference score of v_i, and N_{ACP} is the number of the events of the ACP Corpus.

To optimize the hyperparameters, we used the dev set of the ACP Corpus. For the evaluation, we used the test set of the ACP Corpus. The model output was classified as positive if $p(x) > 0$ and negative if $p(x) \leq 0$.

4.2 Model Configurations

As for Encoder, we compared two types of neural networks: BiGRU and BERT. GRU (Cho et al., 2014) is a recurrent neural network sequence encoder. BiGRU reads an input sequence forward and backward and the output is the concatenation of the final forward and backward hidden states.

BERT (Devlin et al., 2019) is a pre-trained multi-layer bidirectional Transformer (Vaswani et al., 2017) encoder. Its output is the final hidden state corresponding to the special classification tag (`[CLS]`). For the details of Encoder, see Sections A.2.

We trained the model with the following four combinations of the datasets: AL, AL+CA+CO (two proposed models), ACP (supervised), and ACP+AL+CA+CO (semi-supervised). The corresponding objective functions were: $\mathcal{L}_{\mathrm{AL}}$, $\mathcal{L}_{\mathrm{AL}} + \mathcal{L}_{\mathrm{CA}} + \mathcal{L}_{\mathrm{CO}}$, $\mathcal{L}_{\mathrm{ACP}}$, and $\mathcal{L}_{\mathrm{ACP}} + \mathcal{L}_{\mathrm{AL}} + \mathcal{L}_{\mathrm{CA}} + \mathcal{L}_{\mathrm{CO}}$.

4.3 Results and Discussion

Table 3 shows accuracy. As the Random baseline suggests, positive and negative labels were distributed evenly. The Random+Seed baseline made use of the seed lexicon and output the corresponding label (or the reverse of it for negation) if the event's predicate is in the seed lexicon. We can see that the seed lexicon itself had practically no impact on prediction.

The models in the top block performed considerably better than the random baselines. The performance gaps with their (semi-)supervised counterparts, shown in the middle block, were less than

Training dataset	Encoder	Acc
AL	BiGRU	0.843
	BERT	0.863
AL+CA+CO	BiGRU	**0.866**
	BERT	0.835
ACP	BiGRU	0.919
	BERT	**0.933**
ACP+AL+CA+CO	BiGRU	0.917
	BERT	0.913
Random		0.500
Random+Seed		0.503

Table 3: Performance of various models on the ACP test set.

Training dataset	Encoder	Acc
ACP (6K)	BERT	0.876
+AL		**0.886**
ACP (6K)	BiGRU	0.830
+AL+CA+CO		**0.879**

Table 4: Results for small labeled training data. Given the performance with the full dataset, we show BERT trained only with the AL data.

7%. This demonstrates the effectiveness of discourse relation-based label propagation.

Comparing the model variants, we obtained the highest score with the BiGRU encoder trained with the AL+CA+CO dataset. BERT was competitive but its performance went down if CA and CO were used in addition to AL. We conjecture that BERT was more sensitive to noises found more frequently in CA and CO.

Contrary to our expectations, supervised models (ACP) outperformed semi-supervised models (ACP+AL+CA+CO). This suggests that the training set of 0.6 million events is sufficiently large for training the models. For comparison, we trained the models with a subset (6,000 events) of the ACP dataset. As the results shown in Table 4 demonstrate, our method is effective when labeled data are small.

The result of hyperparameter optimization for the BiGRU encoder was as follows:

$$\lambda_{\mathrm{AL}} = 1,\ \lambda_{\mathrm{CA}} = 0.35,\ \lambda_{\mathrm{CO}} = 1,\ \mu = 0.5.$$

As the CA and CO pairs were equal in size (Table 1), λ_{CA} and λ_{CO} were comparable values. λ_{CA} was about one-third of λ_{CO}, and this indicated that the CA pairs were noisier than the CO pairs. A major type of CA pairs that violates our assumption was in the form of "$problem_{\mathrm{negative}}$ causes $solution_{\mathrm{positive}}$":

(4) (悪いところがある, よくなるように努力する)
(there is a bad point, [I] try to improve [it])

The polarities of the two events were reversed in spite of the CAUSE relation, and this lowered the value of λ_{CA}.

Input event	Polarity
道に迷う ([I] get lost)	-0.771
道に迷わない ([I] don't get lost)	0.835
笑う ([I] laugh)	0.624
笑われる ([I] am laughed at)	-0.687
脂肪を落とす ([I] lose body fat)	0.452
肩を落とす ([I] feel disappointed)	-0.653

Table 5: Examples of polarity scores predicted by the BiGRU model trained with AL+CA+CO.

Some examples of model outputs are shown in Table 5. The first two examples suggest that our model successfully learned negation without explicit supervision. Similarly, the next two examples differ only in voice but the model correctly recognized that they had opposite polarities. The last two examples share the predicate "落とす" (drop) and only the objects are different. The second event "肩を落とす" (lit. drop one's shoulders) is an idiom that expresses a disappointed feeling. The examples demonstrate that our model correctly learned non-compositional expressions.

5 Conclusion

In this paper, we proposed to use discourse relations to effectively propagate polarities of affective events from seeds. Experiments show that, even with a minimal amount of supervision, the proposed method performed well.

Although event pairs linked by discourse analysis are shown to be useful, they nevertheless contain noises. Adding linguistically-motivated filtering rules would help improve the performance.

Acknowledgments

We thank Nobuhiro Kaji for providing the ACP Corpus and Hirokazu Kiyomaru and Yudai Kishimoto for their help in extracting event pairs. This work was partially supported by Yahoo! Japan Corporation.

A Appendices

A.1 Seed Lexicon

Positive Words 喜ぶ (rejoice), 嬉しい (be glad), 楽しい (be pleasant), 幸せ (be happy), 感動 (be impressed), 興奮 (be excited), 懐かしい (feel nostalgic), 好き (like), 尊敬 (respect), 安心 (be relieved), 感心 (admire), 落ち着く (be calm), 満足 (be satisfied), 癒される (be healed), and スッキリ (be refreshed).

Negative Words 怒る (get angry), 悲しい (be sad), 寂しい (be lonely), 怖い (be scared), 不安 (feel anxious), 恥ずかしい (be embarrassed), 嫌 (hate), 落ち込む (feel down), 退屈 (be bored), 絶望 (feel hopeless), 辛い (have a hard time), 困る (have trouble), 憂鬱 (be depressed), 心配 (be worried), and 情けない (be sorry).

A.2 Settings of Encoder

BiGRU The dimension of the embedding layer was 256. The embedding layer was initialized with the word embeddings pretrained using the Web corpus. The input sentences were segmented into words by the morphological analyzer Juman++.[4] The vocabulary size was 100,000. The number of hidden layers was 2. The dimension of hidden units was 256. The optimizer was Momentum SGD (Sutskever et al., 2013). The mini-batch size was 1024. We ran 100 epochs and selected the snapshot that achieved the highest score for the dev set.

BERT We used a Japanese BERT model[5] pretrained with Japanese Wikipedia. The input sentences were segmented into words by Juman++, and words were broken into subwords by applying BPE (Sennrich et al., 2016). The vocabulary size was 32,000. The maximum length of an input sequence was 128. The number of hidden layers was 12. The dimension of hidden units was 768. The number of self-attention heads was 12. The optimizer was Adam (Kingma and Ba, 2014). The mini-batch size was 32. We ran 1 epoch.

Abstract

Syntactic relations are broadly used in many NLP tasks. For event detection, syntactic relation representations based on dependency tree can better capture the interrelations between candidate trigger words and related entities than sentence representations. But, existing studies only use first-order syntactic relations (i.e., the arcs) in dependency trees to identify trigger words. For this reason, this paper proposes a new method for event detection, which uses a dependency tree based graph convolution network with aggregative attention to explicitly model and aggregate multi-order syntactic representations in sentences. Experimental comparison with state-of-the-art baselines shows the superiority of the proposed method.

1 Introduction

As an important information extraction task, event detection aims to find event mentions with specific event types from given texts. Each event mention is identified by a word or phrase called event trigger, which serve as the main word(s) to the corresponding event. For example, in the sentence presented in Figure 1, an event detection system should be able to recognize the trigger word "fired" corresponding to the event type "Attack".

Among existing methods for event detection, sequence based ones (e.g., Chen et al. (2015); Nguyen et al. (2016)) only use the given sentences, which suffer from the low efficiency problem in capturing long-range dependency; On the contrary, dependency tree based methods utilize the syntactic relations (i.e., arcs) in the dependency tree of a given sentence to more effectively capture the interrelation between each candidate trigger word and its related entities or other triggers. For example, Nguyen and Grishman (2018) and Liu et al. (2018) treat each dependency tree as a graph and adopt Graph Convolution Network (GCN) (Kipf and Welling, 2016) to extract event triggers.

The syntactic relations between trigger words and related entities may be of first order, embodied as the direct arcs in the dependency tree. They may also be of high-order (i.e., the paths more than one hop in the dependency tree). Particularly, according to our statistics on the benchmark ACE-2005 dataset, about 51% (4977/9793) of event related entities need more than one hop to get to the corresponding trigger words and related entities in their dependency trees. For example, in Figure 1, it needs at least 4 hops (i.e., "fired"–"evidence"–"blood"–"soldiers") to figure out that the word "fired" means "shot" instead of "dismissed".

However, the above dependency tree based methods explicitly use only first-order syntactic relations, although they may also implicitly capture high-order syntactic relations by stacking more GCN layers. However, as the number of GCN layers increases, the representations of neighboring words in the dependency tree will get more and more similar, since they all are calculated via those of their neighbors in the dependency tree. This is the so-called over-smoothing problem (Zhou et al., 2018), which damages the diversity of the representations of neighboring words.

To overcome this problem, this paper proposes a Multi-Order Graph Attention Network based method for Event Detection, called MOGANED. It utilizes both first-order syntactic graph and high-order syntactic graphs to explicitly model multi-order representations of candidate trigger words. In order to calculate multi-order representations for each word, we apply Graph Attention Network (GAT) proposed in (Veličković et al., 2017) to weight the importance of its neighboring words in the syntactic graphs of different orders. We then employ an attention aggregation mechanism to merge its multi-order representations. Finally,

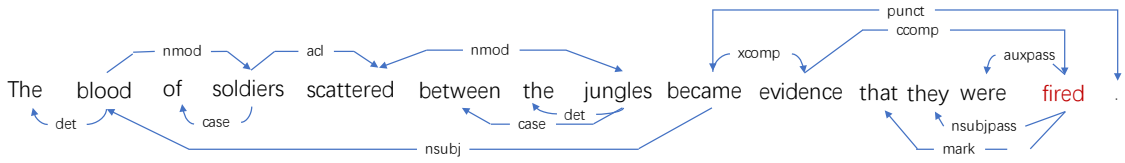

Figure 1: An example sentence with the dependency parsing result.

through experimental comparison with state-of-the-art baselines we show the superiority of the proposed method in terms of both precision and F1-measure. It should be mentioned that, to the best of our knowledge, this is the first study applying GAT to event detection.

2 The Proposed Model

Following the existing studies, we regard event detection as a multi-class classification problem. Let $W = w_1, w_2, ..., w_n$ be a sentence of length n, where w_i is its i-th token. Since event triggers may contain multiple words, we adopt the "BIO" schema to make annotation. The number of labels is thus be $2L + 1$, where L is the number of predefined event types.

The proposed model contains three modules: (i) word encoding, which encodes input sentence to a sequence of vectors; (ii) multi-order graph attention network that performs graph attention convolution over multi-order syntactic graphs; (iii) attention aggregation, which aggregates multi-order representations of each word with different attention weights to predict its label.

2.1 Word Encoding

The word encoding module first transforms each input token w_i into a comprehensive embedding vector x_i by concatenating its word embedding $word_i$, entity type embedding et_i, POS-tagging embedding pos_i and position embedding ps_i (Nguyen et al., 2016; Nguyen and Grishman, 2018), where $word_i$ is obtained by looking up a pre-trained word embedding table on a large corpus and others are randomly initialized.

The input sentence W will then be transformed to a sequence of vectors $X = x_1, x_2, ..., x_n$. Since each word can only be updated by its neighbors in the dependency tree through dependency arcs, following the previous methods (Liu et al., 2018), we employ a Bidirectional Long-Short Term Memory network (BiLSTM) (Hochreiter and Schmidhuber, 1997) to encode X with its context as $P = p_1, p_2, ..., p_n$, which will be used as the input of the multi-order GAT. Here,

$$p_i = [\overrightarrow{LSTM}(x_i)||\overleftarrow{LSTM}(x_i)], \quad (1)$$

where $||$ is the concatenation operation.

2.2 Multi-Order Graph Attention Network

Each dependency tree can be represented as a first-order syntactic graph in terms of an adjacency matrix. Let A be the adjacency matrix of the first-order syntactic graph, which is generated from the dependency tree of the sentence, W. A contains three sub matrixes A_{along}, A_{rev} and A_{loop} (Marcheggiani and Titov, 2017) of the same dimensions $n \times n$. $A_{along}(i, j) = 1$, if there is a dependency arc from w_i to w_j in the dependency tree, otherwise 0. As the reverse graph of A_{along}, $A_{rev} = A^T_{along}$. A_{loop} is an identity matrix.

The adjacency matrix of the k-th-order syntactic graph is $A^k_{subg} = (A_{subg})^k$, where $subg \in \{along, rev, loop\}$. A^k_{subg} records all k-hop paths of A_{subg}. Note that $A^k_{loop} = A_{loop}$, since it is an identity matrix. For simplicity, in what follows we use a^k, b^k, c^k to denote A^k_{along}, A^k_{rev} and A^k_{loop}, respectively.

The multi-order GAT module simply learns a list of representations over multi-order syntactic graphs by a few parallel GAT layers (Veličković et al., 2017), which weights the importance of neighbors of each word in each syntactic graph during convolution.

The representations h^k_i of the k-th-order syntactic graph A^k are calculated from the representations of the subgraphs of A^k:

$$h^k_i = f(p_i, a^k) \oplus f(p_i, b^k) \oplus f(p_i, c^k), \quad (2)$$

where $f(\cdot)$ is the graph attention convolution function and $\oplus$ is element-wise addition, and

$$f(p_i, a^k) = \sigma\left(\sum_{j=1}^{n}(u_{ij}a^k_{ij}(W_{a,k}p_j + \epsilon_{a,k})\right), \quad (3)$$

where σ is exponential linear unit (ELU) (Clevert et al., 2015); $W_{a,k}$ and $\epsilon_{a,k}$ are the weight matrix and bias item for a^k; u_{ij} is the normalized weight of the neighbor w_j when updating w_i,

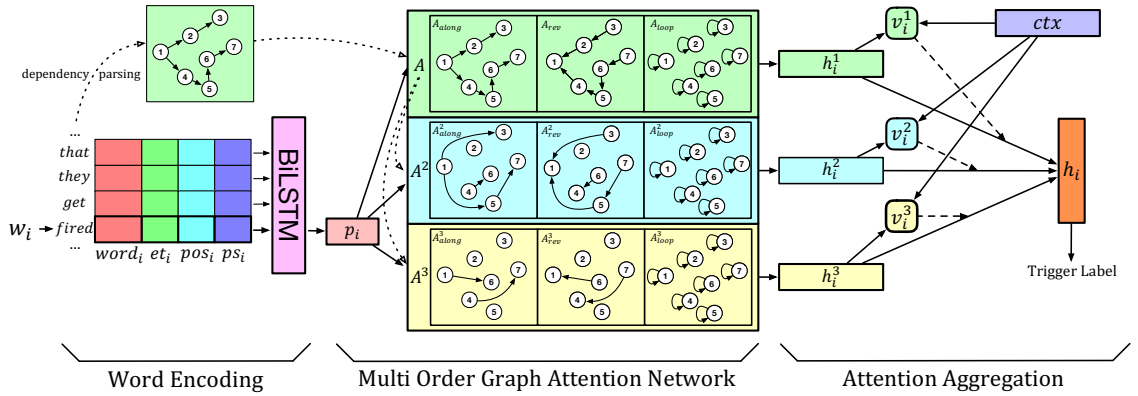

Figure 2: The illustrative architecture of the proposed MOGANED method, where K=3.

$$u_{ij} = softmax(e_{ij}) = \frac{exp(e_{ij})}{\sum_{j \in \mathcal{N}_i} exp(e_{ij})}, \quad (4)$$

where $e_{ij} = \gamma(W_{comb}[W_{att}p_i||W_{att}p_j])$. Here, $\mathcal{N}_i$ is the neighbor set of w_i in the subgraph, γ is LeakyReLU (with negative input slope α = 0.2) (Maas et al., 2013); W_{comb} and W_{att} are weight matrices.

After graph attention convolution, each candidate trigger word w_i gets a list of multi-order representations $h_i^k, k \in [1, K]$, where K is the highest order used in this module.

2.3 Attention Aggregation

To aggregate the list of multi-order representations h_i^k of each word w_i, we employ a weighted attention aggregation mechanism from Hierarchical Attention Networks (Yang et al., 2016):

$$h_i = \sum_{k=1}^{K} v_i^k h_i^k, \quad (5)$$

where v_i^k is the normalized weight of the k-th order graph representation of the word w_i, which is calculated by

$$v_i^k = softmax(s_i^k) = \frac{exp((s_i^k)^T ctx)}{\sum_{j=1}^{K} exp((s_i^j)^T ctx)}, \quad (6)$$

where $s_i^j = tanh(W_{awa}h_i^j + \epsilon_{awa})$. Here, W_{awa} and ϵ_{awa} are the weight matrix and the bias term, respectively; ctx is a randomly initialized context vector, which captures the importance of graph representations of each order.

Finally, we use the aggregated representation h_i to predict the trigger label of word w_i as follows:

$$y_i^t = softmax(O_i^t) = \frac{exp(O_i^t)}{\sum_{q=1}^{2L+1} exp(O_i^q)}, \quad (7)$$

where y_i^q denotes the probability assigning label q to word w_i and $O_i = w_o h_i + \epsilon_o$. Here, w_o and ϵ_o are the weight matrix and the bias item, respectively.

2.4 Bias Loss Function

Since the number of "O" labels in the data is much larger than that of event labels, we use a bias loss function (Chen et al., 2018) to enhance the influence of event labels during training:

$$J(\theta) = -\sum_{i=1}^{N_s}\sum_{j=1}^{N_{i,w}} (\log p(y_j^t|s_i,\theta) \cdot I(O) + \lambda \log p(y_j^t|s_i,\theta) \cdot (1 - I(O))), \quad (8)$$

where N_s is the number of sentences; $N_{i,w}$ is the number of words in s_i; $I(O)$ equals 1, if the label of the word is "O"; otherwise 0; λ is the weight parameter larger than 1.

3 Experiments

3.1 Experiment Settings

Dataset and Resources We compare our MOGANED model with baseline methods on ACE-2005 with the same data split, where 40 newswire documents are used as the test set, 30 newswire documents as the validation set and 529 remained documents as the training set.

For data preprocessing, we use the Stanford CoreNLP toolkit for sentence splitting, tokenizing, POS-tagging and dependency parsing. We adopt word embeddings trained over the New York Times corpus with the Skip-gram algorithm (Mikolov et al., 2013; Chen et al., 2018).

Hyper Parameter Setting The hyper parameters are tuned on the validation set. For all experiments

Method	P	R	F_1
Cross Event	68.7	68.9	68.8
DMCNN	75.6	63.6	69.1
JRNN	66.0	73.9	69.3
DEEB-RNN	72.3	**75.8**	74.0
dbRNN†	74.1	69.8	71.9
GCN-ED†	77.9	68.8	73.1
JMEE†	76.3	71.3	73.7
MOGANED†	**79.5**	72.3	**75.7**

Table 1: Overall performance of different methods on the test set with gold-standard entities. † indicates that the method uses dependency arcs.

below, we use 100 as the dimension of word embeddings and 50 as that of the rest embeddings. We set the hidden units of the BiLSTM network to 100. We set the highest order K to 3 and the dimension of graph representation to 150. We set batch size to 30 and utilize a fixed maximum sentence length $n = 50$ by padding short sentences and cutting longer ones. During training, we use the AdaDelta update rule (Zeiler, 2012) with a learning rate of 0.001. We set the dropout rate to 0.3 and the L2-norm to $1e-5$. We set the bias loss parameter λ to 5.

3.2 Overall Performance

We compare our model with the following state-of-the-art baselines: 1) Cross Event (Liao and Grishman, 2010), which uses document level information for event extraction; 2) DMCNN (Chen et al., 2015), which builds a dynamic multi-pooling CNN model; 3) JRNN (Nguyen et al., 2016), which uses a bidirectional RNN and human designed features; 4) DEEB-RNN (Zhao et al., 2018), which uses hierarchical supervised attention with document level information for event detection; 5) dbRNN (Sha et al., 2018), which adds dependency arcs over a Bi-LSTM network to improve event extraction; 6) GCN-ED (Nguyen and Grishman, 2018), which uses an argument pooling mechanism for event detection based on GCN; 7) JMEE (Liu et al., 2018), which uses GCN with highway network and self-attention.

Table 1 presents the performance comparison between different methods. We can see that MOGANED achieves 1.6% and 1.7% improvement on precision and F_1-measure, respectively, compared with the best baselines. MOGANED reaches a lower recall than two sequence based methods, JRNN and DEEB-RNN. This may be caused by the propagated error from the dependency parsing tool. There are long sentences where trigger words and their corresponding entities are parsed into two independent dependency trees without connection. Therefore, the trigger words and their related entities are unable to interact in multi-order graph attention network, which leads to a lower recall. However, MOGANED still achieves the best performance in terms of precision, recall, F_1-measure among all dependency based methods, which suggests the effective of multi-order representations.

Method	P	R	F_1
MOGANED-First	71.0	69.9	70.4
MOGANED-GCN	75.7	71.1	73.3
MOGANED-Mean	77.3	70.9	74.0
MOGANED	**79.5**	**72.3**	**75.7**

Table 2: Performance of modified architectures based on MOGANED.

3.3 Ablation Study

This study aims to validate the impacts of multi-order representation, graph attention network and attention aggregation. For this purpose, we design three architectures based on MOGANED: 1) MOGANED-First: it only uses first-order syntactic graph (i.e., K=1); 2) MOGANED-GCN: it uses traditional GCN instead of GAT; 3) MOGANED-Mean: it adopts mean pooling as the attention aggregation mechanism of multi-order representations for each word.

The experimental result is shown in Table 2. All of these three modified models get lower performance than MOGANED. MOGANED-First achieves the worst performance, which suggests that high-order syntactic relations play an important role in event detection. MOGANED-GCN drops more on precision than recall, which illustrates that the attention learned from GAT helps MOGANED predict trigger words more precisely. The performance drop of MOGANED-Mean is the smallest among the three modified models. Although the average of multi-order representations achieves competitive performance for event detection, the proposed attention aggregation module still distinguishes the importance of syntactic representations of different order, which achieves 1.7% improvement on F_1-measure.

4 Conclusion

In this paper, we proposed the MOGANED model for modeling multi-order representations via GAT and employed an attention aggregation mechanism to better capture dependency contextual information for event detection. The experimental results well demonstrate its effectiveness and superiority.

Abstract

Scalar implicatures are language features that imply the negation of stronger statements, e.g., *"She was married twice"* typically implicates that she was not married thrice. In this paper we discuss the importance of scalar implicatures in the context of textual information extraction. We investigate how textual features can be used to predict whether a given text segment mentions all objects standing in a certain relationship with a certain subject. Preliminary results on Wikipedia indicate that this prediction is feasible, and yields informative assessments.

1 Introduction

Following the cooperative principle, natural language utterances can implicate a range of assertions that are not explicitly stated (Grice, 1975). One specific class of implicatures are scalar implicatures, which concern the negation of stronger statements (Carston, 1998). Scalar implicatures are derived from Grice's maxim of quantity - that speakers would make stronger statements if possible, therefore, negation can be deduced if these are not made.

Yet the maxim of quantity interacts with the maxim of relevance, i.e., what is implicated depends on what is relevant in a given context. Consider the examples in Figure 1. From the first sentence, typical for biographical descriptions, most humans would draw the implicature that Obama has no other children. For the second sentence about Jolie, this implicature would typically not be drawn - she might well have other children that are too young or too old to be brought to school, but are not relevant in the school context.

The interaction between the maxims of quantity and relevance has implications for textual information extraction (IE). Textual IE usually produces (ideally canonicalized) subject-predicate-object triples, and annotates them with estimates of *correctness* (also called accuracy, precision or confidence), e.g., a 93% belief that Malia is really Obama's child. In contrast, IE usually lacks such an ability for *coverage* (also called recall or completeness). It is not able to estimate whether its extractions represent all facts pertaining to a certain topic, e.g., all children of Jolie.

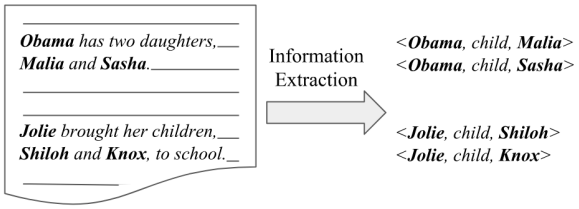

Figure 1: Two sentences with different coverage.

Importance of coverage-awareness. Coverage-awareness of IE is a crucial and highly desirable property for several downstream use cases. (i) Today's *question answering* systems are well geared for questions where exactly one answer should be returned (e.g., quiz questions or reading-comprehension tasks) (Fader et al., 2014; Yang et al., 2015). In contrast, for questions with sets of answers, QA systems often merely yield subsets, and do not inform the user about that. Similarly, they struggle with questions that have no answer, too often still returning a best-effort answer even if it is incorrect. Coverage awareness would enable a better treatment of both cases. (ii) Guiding editors in how to *prioritize curation* efforts is a key issue for collaboratively built and maintained knowledge bases such as Wikidata (Balaraman et al., 2018). Yet, methods to automatically identify incomplete parts are largely based on aggregate-level statistics, and do not consider entity-specific textual context (Razniewski et al., 2017; Galárraga et al., 2017). (iii) Coverage awareness would also be useful for *automated knowledge base construc-*

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5771–5776, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tion techniques, either to dynamically adjust confidence thresholds, i.e., lowering thresholds in case of low coverage, and increasing thresholds in case of too many extractions, or to reallocate search budgets to low-coverage regions, while stopping the exploration of complete areas (Ipeirotis et al., 2007; Jain et al., 2008).

Contribution and Approach. In this paper we analyze the viability of text coverage prediction. We use textual features to estimate whether a text segment contains all objects for a given subject-predicate pair, e.g., whether a given text mentions all children of Jolie. For an experimental study, we use fact counts for 5 Wikidata relations as ground truth. Using these counts, we train and evaluate on Wikipedia-extracted sentences and paragraphs, finding that coverage prediction is generally feasible and yields informative assessments.

Our conceptual contributions are:

- We introduce and define the novel problem of textual coverage prediction, and we discuss its key features.
- We present a method, along with experimental results that demonstrate its practical value.

Our experiments confirm that coverage estimation is possible, and yield the following technical insights:

- Features: Unigrams and bigrams provide informative cues towards coverage estimation.
- Scope: Coverage estimation is feasible for diverse domains ranging from family relations to organizational membership, and both on the level of sentences and paragraphs.

2 Background

Information extraction from text sources has been greatly advanced over the past two decades; see e.g., (Agichtein and Gravano, 2000; Etzioni et al., 2004; Suchanek et al., 2009; Mintz et al., 2009; Riedel et al., 2013; Dong et al., 2014; Shin et al., 2015; Mausam, 2016; Chiticariu et al., 2018; Stanovsky et al., 2018). The underlying methodologies span regular-expression matching, rule-based extraction, conditional random fields, constraint reasoning, all the way to deep learning. Depending on the task at hand, IE often achieves high correctness (sometimes above 90%). However, evaluating its coverage is inherently hard, as this would require exhaustively annotated corpora as gold standard. As a consequence, assessing and optimizing coverage has typically been an afterthought at best, and is usually completely disregarded.

In contrast, coverage (recall) is one of the key metrics in information retrieval (IR), i.e., in search applications. Here, recall is measured in terms of retrieving a large fraction of the relevant documents or passages, where relevance is stated by gold-standard annotations. In the context of entire IE workflows (e.g., for text analytics over business news), the prior works of Ipeirotis et al. (2007) and Jain et al. (2008) have considered optimizations for recall. However, this solely refers to the search-centric parts of such workflows, that is, the document or passage sets that are then fed into IE steps.

Grice's maxims of cooperative communication (Grice, 1975) introduce the concept of implicatures, which are conclusions that humans draw even though texts do not literally support them. The implicatures of interest here are scalar implicatures, i.e., the conclusion that no more facts are true than those explicitly stated (Carston, 1998). Scalar implicatures are closely connected to the closed-world assumption in logics, where statements are assumed to be false, unless explicitly stated. Yet, as exemplified in in Figure 1, due to the maxim of relevance, the scope of scalar implicatures may vary significantly.

Closest to coverage-awareness is recent work on counting quantifier extraction (Mirza et al., 2018). There, relation counts are extracted from phrases such as *"Jolie has six children"*, which, in a second step, are compared against fact counts in an existing KB. In contrast, the present work aims to directly predict the coverage of text segments.

3 Problem and Approach

While information extraction is a noisy process with both false positives and false negatives, our focus here is on whether, in principle, a text segment allows the extraction of all facts that hold in reality. For this purpose, we assume we have perfect knowledge of *all real-world facts* for the objects that are connected to a specific subject s and property p; we denote this object set as $RW\{o \mid sp\}$. Now assume an educated and linguistically versed human is presented with a text segment t and the task of telling which objects o she would assign to a fixed subject s and property p given solely the text t. We denote this ground-

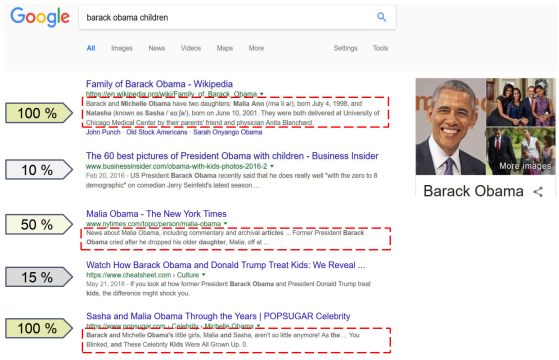

Figure 2: Possible application of a coverage classifier on web search snippets.

truth extraction as $GTE\{o \mid sp, t\}$.

Text Coverage Prediction Problem. Given a text segment t for a fixed subject s and property p, predict whether the human ground-truth from reading t matches the real-world facts:

$$GTE\{o \mid sp, t\} = RW\{o \mid sp\}.$$

This problem is different from assessing the quality of specific IE methods and tools. Since there are no perfect IE tools, considering the extractions from an IE tool would confound two distinct issues: 1) whether a text segment contains all information of interest (our present problem), and 2) what the recall of the specific IE tool is (a standard evaluation criterion for IE methods). Although our automated evaluation below necessarily builds on concrete choices for IE methods, our emphasis is on the fundamental problem of recall assessment given solely a text segment, as described above.

By casting the problem into a binary classification task, we look only at two cases: a) $GTE\{o \mid sp, t\}$ contains all real-world facts (*complete*), and b) it does not (*incomplete*). This formulation disregards complex graded cases, such as $GTE\{o \mid sp, t\}$ containing at least 70% of the real-world facts. Nevertheless, the problem naturally invites the use of scores that are confidences/probabilities. For example, for the first sentence in Figure 1, the probability to contain all $\langle Obama, child, *\rangle$-facts might be 0.9, while for the second sentence, the probability to contain all $\langle Jolie, child, *\rangle$ facts might be 0.4. An illustration of how such confidence scores could be applied to Web search snippets is shown in Figure 2.

Methods and baselines. We approach the problem as classification task for t. As state-of-the-art text classification methods, we use interpretable feature-based Support Vector Machines (SVMs) with unigrams and bigrams from t as input, and Long Short-Term Memory networks (LSTMs) (Tai et al., 2015). LSTMs are used to encode sentences/paragraphs, using word representations (d=100) that are learned from scratch (initialized uniformly). One hidden layer of size 256 with ReLU activation and an output layer with sigmoid activation are used for binary classification. We employ the Adam optimizer with default parameter values. The models were trained for 20 epochs. We also experimented with using pretrained (word2vec) embeddings, but found no improvement, possibly due to the unorthodox nature of the problem, where typical word semantics as relevant for classic NLP tasks like QA, translation etc. do not help.

In web extraction scenarios one could additionally also consider features such as subject popularity, the relative position of a text segment, or web-source reliability scores.

We employ three baselines. Two natural baselines are *length* and *#pnames*, which classify the longest text segments (by character length) or the text segments containing most proper names as complete, i.e., assume that the more information, the better. A lower bound is given by a third baseline, *random*, which simply tosses a coin to decide whether a text segment is classified as complete, or not. For all baselines, the classification thresholds/coin bias is chosen so that input class distributions are maintained, therefore their precision and recall coincide.

4 Experimental Setup

Predicates. We perform experiments for 5 Wikidata predicates that span three different domains: (i) family relations: *child* (P40), *spouse* (P26), (ii) education and work: *educatedAt* (P69), *employer* (P108), (iii) band compositions: via *hasPart* (P527) for instances of the *musical ensemble* (Q2088357) class.

Approximating ground-truth extractions. Due to the intellectual complexity of fact extraction, crowdsourcing annotations faces scalability challenges, particularly at the paragraph level. We therefore opt for approximating the ideal human extractions $GTE\{o \mid sp, t\}$ via the combination of open information extraction, predicate paraphrase matching and object label matching. Note that this specific choice is not decisive for our approach

and merely serves as a concrete scalable instantiation of our framework, human labels or other automated IE methods could be plugged in as well.

To evaluate whether a text segment contains an $\langle s, p, o \rangle$-fact, we rely on the open information extraction system OpenIE 4 (Pal and Mausam, 2016), the PATTY predicate paraphrase dictionary (Nakashole et al., 2012), and Wikidata entity alias names.

For example, suppose we are interested in extracting facts for the *child* property for the subject *Angelina Jolie*. OpenIE extracts the triple $\langle \underline{Maddy}, is\ first\ adopted\ \underline{son}\ [of], Jolie \rangle$ from the text segment *"Jolie's first adopted son is Maddy."* As *(i) Maddy* is one of the aliases of *Angelina Jolie's* child *Maddox Chivan* in IMDb, and *(ii) son* appears in the list of paraphrases for the *child* predicate, we consider that the text segment contains the fact $\langle Angelina\ Jolie, child, Maddox\ Chivan \rangle$.

Labelled data. We use distant supervision to automatically label data. Assuming that Wikidata's coverage is near-perfect for popular entities, for each of the predicates we collect the 1000-8000 most popular subjects in Wikidata, along with their facts for the respective property (see Table 1).[1] As many properties have a skew towards low frequencies, which may make completeness prediction trivial, we only considered subjects having at least two objects in Wikidata (#subj w/ $\geq$2 obj). We collected two granularities of text units, *sentences* and *paragraphs* that contain at least one object, as found on the Wikipedia pages of the respective subjects. To ensure that general features are learned, we mask proper names and specific numbers with generic placeholders. A text segment is labelled *complete*, if it contains, for each object listed on Wikidata, at least one first names or alias. It is labelled as *incomplete* otherwise. In total, we obtain about 300 complete and 2000 incomplete sentences and paragraphs per relation, which we split into 80% for training and 20% for testing.

5 Results and Discussion

Table 2 shows the precision, recall and F1-score in terms of identifying complete text segments. Both

[1]While using Wikidata as source for labels for distant supervision of Wikipedia texts may seem circuitous, we note that unlike Wikipedia, Wikidata is language-independent, thus, has potential for much higher coverage especially for entities more famous outside English-speaking countries.

Table 2: Performance of coverage prediction.

SVMs and LSTMs outperform the baselines by a considerable margin, performing slightly better at paragraph than at sentence level. They perform best there on the *spouse* property (.73/.70 F1), followed by *educated at* (.63-.58 F1). They comparably fail at sentence level on *employer* (.14/0 F1), presumably because it is rather rare that all employments are listed in the same sentence. For instance, it is more common to find *"He served as a professor at* [*University A*]*, and also held an appointment at* [*University B*]*. In July 2007, he left* [*University A*] *and joined the faculty of* [*University C*]*. He was also a visiting professor at the* [*University D*]*."* as a complete paragraph.

In Table 3 we show the most informative bigrams for the n-gram-based SVMs on the paragraph level, for predicates having reasonably good F1 scores. Most of the highly weighted bigrams signal the beginning of name listing, such as *daughters* $\langle pname \rangle$, *married twice*, *featuring lineup* and *attended* $\langle pname \rangle$. Some bigrams convey temporal information, such as *later married*, *briefly attended* and *left graduating*, which indicate that the paragraph contains a narrative that lists object names for different time periods. This was particularly true for the *spouse*, *employer* and *educatedAt* predicates, for which usually only one object is valid at each timepoint.

We also find various terms indicating incompleteness, for instance *surviving* ("Had 5 children, but only Mary and Bob were surviving to adulthood"), *succeeded* ("She was later succeeded by her son James in her role as ..."), *addition* ("In addition, a daughter, Susan, was born in ...") among

child	*spouse*	*hasPart*	*educatedAt*
⟨*pname*⟩ *sons*	*married twice*	*featuring lineup*	*educated* ⟨*pname*⟩
grandsons ⟨*pname*⟩	*children* ⟨*pname*⟩	*lineup* ⟨*pname*⟩	*briefly attended*
⟨*num*⟩ *grandsons*	*second marriage*	*consists* ⟨*pname*⟩	*attended* ⟨*pname*⟩
daughters ⟨*pname*⟩	⟨*num*⟩ *son*	⟨*num*⟩ *tour*	*left graduating*
sons ⟨*pname*⟩	*later married*	*vocals* ⟨*propname*⟩	⟨*pname*⟩ *left*

Table 3: Selected important paragraph-level bigrams indicating completeness for SVMs.

Sentence	LSTM score
He was the father of actor Pierre Renoir (1885-1952), filmmaker Jean Renoir (1894-1979) and ceramic artist Claude Renoir (1901-1969).	0.54
His daughter Julie Gavras and his son Romain Gavras are also filmmakers.	0.46
Genghis Khan was aware of the friction between his sons (particularly between Chagatai and Jochi) and worried of possible conflict between them if he died.	0.42
"From this moment I am no longer the king; the king is Victor my son."	0.17

Table 4: Example LSTM predictions at sentence-level.

unigrams indicating incompleteness of *child* at sentence level, or *leaving* and *previously* for *employer*.

While at paragraph level, there is no clear winner, at sentence level LSTMs outperform SVMs. Possibly, this is due to latent representations being more important when features are sparse (i.e., text segments are short). Anecdotal LSTM sentence-level predictions are shown in Table 4. The full input and resulting predictions will be made available on Github.

6 Discussion

Task Difficulty. The prediction results, ranging in F1-score from 0 to .64 for the sentence level and .09 to .73 for the paragraph level, are significantly lower than typical scores in information extraction (e.g., up to .83 F1 in the KBP TAC 2017 challenge (Getman et al., 2017)). Several aspects contribute to the problem's hardness.

- *Training data quality*. We find that distantly supervised training data for recall is much noisier than for classical IE tasks, because knowledge bases such as Wikidata, despite having low error rates, have many gaps where they are incomplete (rather than incorrect). This mirrors a similar problem as found in (Mirza et al., 2018).
- *Low NED recall*. The task requires to match text mentions against KB entities. Yet even famous subjects frequently have obscure objects, e.g., none of Bill Gates' children has a Wikipedia page. NED tools consequently often failed to correctly resolve related mentions. In the present work we thus opted for lexical matching, trading a higher recall against a lower precision.
- *Time-variance*. While some KB relations are quite stable (e.g., children), others are more volatile, and may both grow or shrink over time (e.g., band membership) (Wijaya et al., 2015). Such dynamicity adds complexity to the recall assessment, as recall may then be specific to certain time points.

Relative recall. Our work has focused on estimating the recall w.r.t. reality, as judged by gold-standard annotators. An equally important question, close to previous work on species-count estimation (Salloum et al., 2013), is to estimate the recall relative to what can be maximally achieved by using the union of all possible sources. For instance, for many long-tail subjects, no source would hold complete information, but specific sources could still hold maximal information.

Modelling and reasoning. While we have shown that textual information can be useful in inferring the recall of extractions, recall estimation might benefit from more explicit modelling and reasoning. One relevant aspect could be temporal reasoning, for instance, a professional career without temporal gaps (e.g., high school till 1993, BSc. 1994-1997, then launch of a startup in 1998) is a helpful indicator towards complete education extraction. Such reasoning could be applied on top of temporal information extraction (Ling and Weld, 2010). Another aspect are statistical priors and typicality information. Information that rock bands often consist of one bassist, 1-2 guitarists, one vocalist and one drummer could be helpful in assessing extraction recall at extraction time, similar as done post-hoc in (Galárraga et al., 2017).

7 Conclusion

This paper presented a first investigation on IE coverage estimation. Our results support linguistic theories about scalar implicatures, and show that coverage estimation is generally feasible. The next challenge is to incorporate this into actual noisy IE extraction pipelines.

Abstract

Existing event extraction methods classify each argument role independently, ignoring the conceptual correlations between different argument roles. In this paper, we propose a Hierarchical Modular Event Argument Extraction (HMEAE) model, to provide effective inductive bias from the concept hierarchy of event argument roles. Specifically, we design a neural module network for each basic unit of the concept hierarchy, and then hierarchically compose relevant unit modules with logical operations into a role-oriented modular network to classify a specific argument role. As many argument roles share the same high-level unit module, their correlation can be utilized to extract specific event arguments better. Experiments on real-world datasets show that HMEAE can effectively leverage useful knowledge from the concept hierarchy and significantly outperform the state-of-the-art baselines. The source code can be obtained from https://github.com/thunlp/HMEAE.

1 Introduction

Event argument extraction (EAE) aims to identify the entities serving as event arguments and classify the roles they play in an event. For instance, given that the word "sold" triggers a `Transfer-Ownership` event in the sentence "*Steve Jobs* sold *Pixar* to *Disney*", EAE aims to identify that "*Steve Jobs*" is an event argument and its argument role is "`Seller`". Most event extraction (EE) methods treat EE as a two-stage problem, including event detection (ED, to identify the trigger word and determine the event type) and EAE. As ED is well-studied (Nguyen and Grishman, 2018; Zhao et al., 2018) in recent years, EAE becomes the bottleneck of EE.

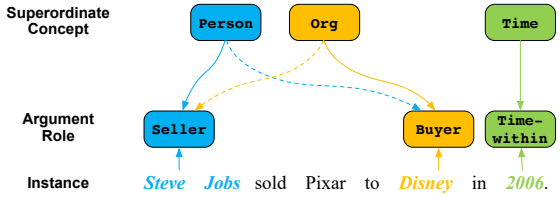

Figure 1: An example of the concept hierarchy.

Since EE benefits many NLP applications (Yang et al., 2003; Basile et al., 2014; Cheng and Erk, 2018), intensive efforts have been devoted to detecting events and extracting their event arguments. Traditional feature-based methods (Patwardhan and Riloff, 2009; Liao and Grishman, 2010b,a; Huang and Riloff, 2012; Li et al., 2013) rely on hand-crafted features and patterns. With the ongoing development of neural networks, various neural networks have been used to automatically represent textual semantics with low-dimensional vectors, and further extract event arguments based on those semantic vectors, including convolutional neural networks (Chen et al., 2015) and recurrent neural networks (Nguyen et al., 2016; Sha et al., 2018). Advanced techniques also have been adopted to further improve EE, such as zero-shot learning (Huang et al., 2018), multi-modal integration (Zhang et al., 2017), and weakly supervised methods (Chen et al., 2017; Wang et al., 2019).

However, the existing methods all treat argument roles as independent of each other, regardless of the fact that some argument roles are conceptually closer than others. Taking Figure 1 as an example, "`Seller`" is conceptually closer to "`Buyer`" than "`Time-within`", because they share the same superordinate concepts "`Person`" and "`Org`" in the concept hierarchy. Intuitively, the concept hierarchy will provide extra informa-

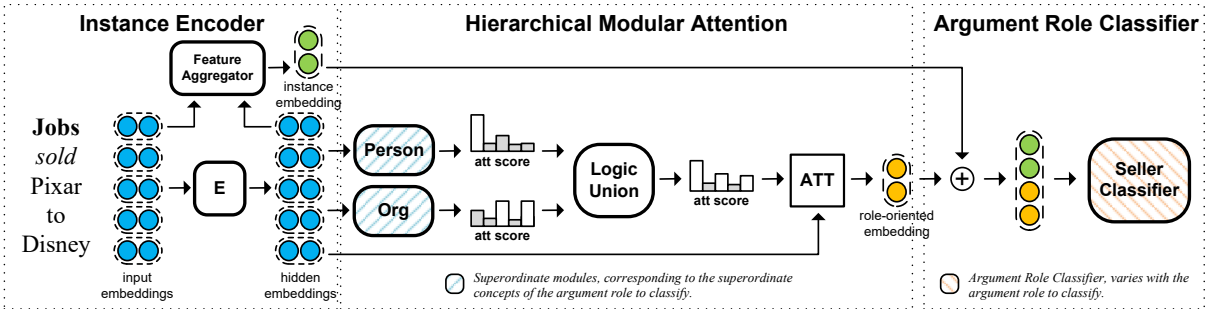

Figure 2: The overall architecture of HMEAE. Take the argument role "Seller" as an example.

tion about the correlation between argument roles and help the argument role classification.

To leverage the concept hierarchy information to improve EAE, we propose the Hierarchical Modular Event Argument Extraction (HMEAE) model. Inspired by the previous hierarchical classification works (Qiu et al., 2011; Shimura et al., 2018; Han et al., 2018) and the neural module networks (NMNs) (Andreas et al., 2016), HMEAE adopts the NMNs to enable a flexible network architecture imitating the concept hierarchical structure, which can provide effective inductive bias for better classification performance.

As Figure 1 shows, we divide the concepts into two types: the superordinate concepts representing more abstractive concepts, and the fine-grained argument roles. An argument role can belong to more than one superordinate concept, e.g., "Seller" belongs to both "Person" and "Org". As shown in Figure 2, we set a neural module network for each concept, and hierarchically compose them as the structure of the concept hierarchy into a role-oriented modular network to predict the argument role for each entity: (1) First, for each superordinate concept, a superordinate concept module (SCM) is instantiated to highlight the textual information related to the concept; (2) Then for each argument role, the SCMs corresponding to its superordinate concepts are composed by role-specific logic union modules to obtain a unified high-level module; (3) Finally, an argument role classifier is set to predict whether the entity is of the given argument role relying on the output of high-level modules.

Intuitively, considering the concept hierarchy in our model brings the following benefits: (1) The high-level modules can significantly enhance the classifiers, e.g., it is easier to determine whether an entity is "Time-within" when paying more attention to the words about "Time". (2) A superordinate concept module is shared among different argument roles in the concept hierarchy. Hence, it can capture the concept features from the shared information in the data of its subordinate argument roles, and further provide the correlation information as an effective inductive bias to the argument role classifiers. We conduct experiments on two real-world datasets. The experimental results show that our methods can achieve state-of-the-art results.

2 Methodology

In this section, we will introduce the overall framework of HMEAE. As shown in Figure 2, HMEAE consists of three components: (1) The instance encoder represents a sentence into hidden embeddings and utilizes a feature aggregator to aggregate sentence information into a unified instance embedding. (2) The hierarchical modular attention component builds a role-oriented embedding to highlight the information about the superordinate concepts of the argument role in the predefined concept hierarchy. (3) The argument role classifier relies on the instance embedding and the role-oriented embedding to estimate the probability of a certain argument role for the instance.

2.1 Instance Encoder

We denote an instance as an n-word sequence $x = \{w_1, \ldots, t, \ldots, a, \ldots, w_n\}$, where t, a denote the trigger word and the candidate argument respectively. The trigger word is detected by the previous event detection models (independent of our work) and each named entity in the sentence is a candidate argument.

Sentence Encoder is adopted to encode the word sequence into hidden embeddings,

$$\{\boldsymbol{h}_1, \boldsymbol{h}_2 \ldots, \boldsymbol{h}_n\} = \mathrm{E}\big(w_1, \ldots, t, \ldots, a, \ldots, w_n\big), \quad (1)$$

where $\mathrm{E}(\cdot)$ is the neural network to encode the sentence. In this paper, we select CNN (Chen et al., 2015) and BERT (Devlin et al., 2019) as encoders.

Feature Aggregator aggregates the hidden embeddings into an instance embedding. Our method is independent of the feature aggregator mechanism. Here, we follow Chen et al. (2015) and use dynamic multi-pooling as the feature aggregator:

$$\begin{aligned}
[\boldsymbol{x}_{1,p_t}]_i &= \max\{[\boldsymbol{h}_1]_i, \ldots, [\boldsymbol{h}_{p_t}]_i\}, \\
[\boldsymbol{x}_{p_t+1,p_a}]_i &= \max\{[\boldsymbol{h}_{p_t+1}]_i, \ldots, [\boldsymbol{h}_{p_a}]_i\}, \\
[\boldsymbol{x}_{p_a+1,n}]_i &= \max\{[\boldsymbol{h}_{p_a+1}]_i, \ldots, [\boldsymbol{h}_n]_i\}, \\
\boldsymbol{x} &= [\boldsymbol{x}_{1,p_t}; \boldsymbol{x}_{p_t+1,p_a}; \boldsymbol{x}_{p_a+1,n}]
\end{aligned} \tag{2}$$

where $[\cdot]_i$ is the i-th value of a vector, p_t, p_a are the positions of the trigger t and the candidate argument a respectively. We concatenate the piecewise max-pooling results as the instance embedding $\boldsymbol{x}$.

2.2 Hierarchical Modular Attention

As shown in Figure 2, given the hidden embeddings $\{\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_n\}$, a superordinate concept module gives an attention score for each hidden embedding to model its correlation with the specific superordinate concept. As an argument role can belong to more than one superordinate concept, we set a logic union module to combine the scores from different superordinate modules together. For each argument role, we hierarchically compose its superordinate concept modules into the integrated hierarchical modular attention component to build its role-oriented embedding.

Superordinate Concept Module For a specific superordinate concept c, we represent its semantic features with a trainable vector $\boldsymbol{u}_c$. Following Luong et al. (2015), we adopt a multi-layer perceptron to calculate the attention scores. We first calculate the hidden state,

$$\boldsymbol{h}_i^c = \tanh(\boldsymbol{W_a}[\boldsymbol{h}_i; \boldsymbol{u}_c]). \tag{3}$$

Then, we apply a softmax operation to get the attention score for the hidden embedding $\boldsymbol{h}_i$,

$$s_i^c = \frac{\exp(\boldsymbol{W_b}\boldsymbol{h}_i^c)}{\sum_{j=1}^{n}\exp(\boldsymbol{W_b}\boldsymbol{h}_j^c)}, \tag{4}$$

where $\boldsymbol{W_a}$ and $\boldsymbol{W_b}$ are trainable matrices shared among different superordinate concept modules.

Logic Union Module Given an argument role $r \in \mathcal{R}$, we denote its k superordinate concepts as $c_1, c_2, \ldots, c_k$, and the corresponding attention scores for $\boldsymbol{h}_i$ are $s_i^{c_1}, s_i^{c_2}, \ldots, s_i^{c_k}$ computed by Eq. (4). As information about all the superordinate concepts should be retained in the role-oriented embedding, we calculate the mean of the attention scores as the role-oriented attention score,

$$s_i^r = \frac{1}{k}\sum_{j=1}^{k} s_i^{c_j}, \tag{5}$$

and then calculate the weighted sum of hidden embeddings as the role-oriented embedding,

$$\boldsymbol{e}^r = \sum_{i=1}^{n} s_i^r \boldsymbol{h}_i. \tag{6}$$

2.3 Argument Role Classifier

We concatenate the instance embedding $\boldsymbol{x}$ and the role-oriented embedding $\boldsymbol{e}^r$ as the input feature for the argument role classifier, and estimate the probability of $r \in \mathcal{R}$ of instance x as follows:

$$p(r|x) = \frac{\exp(\boldsymbol{r}^\top[\boldsymbol{x}; \boldsymbol{e}^r])}{\sum_{\tilde{r}\in\mathcal{R}}\exp(\tilde{\boldsymbol{r}}^\top[\boldsymbol{x}; \boldsymbol{e}^{\tilde{r}}])}, \tag{7}$$

where $\boldsymbol{r}$ is the embedding of the argument role r.

The objective function is defined as follows:

$$\mathcal{L}(\theta) = -\sum_{l}\log p(r_l|x_l), \tag{8}$$

where θ is all parameters of our model. We adopt Adam (Kingma and Ba, 2015) to minimize $\mathcal{L}(\theta)$.

3 Experiments

3.1 Experimental Settings

In the experiments, our model with CNN as the encoder is named **HMEAE (CNN)**, whose most hyperparameters are the same as Chen et al. (2015) for a fair comparison. Our model with BERT as the encoder is named **HMEAE (BERT)**. For a fair comparison, we set a vanilla BERT baseline named **DMBERT**, which is without the hierarchical modular attention module but with a dynamic multi-pooling layer (Chen et al., 2015) as the feature aggregator. As our work does not involve the event detection stage, we conduct the argument role classification based on the event detection models in Chen et al. (2015) and Wang et al. (2019) for **HMEAE (CNN)** and **HMEAE (BERT)** respectively.

Datasets and Evaluation

We evaluate our models on two real-world datasets: the widely-used ACE 2005 (Walker et al., 2006) and the newly-developed TAC KBP 2016 (Ellis et al., 2015).

ACE 2005 (LDC2006T06) is the most widely-used dataset in event extraction. It contains 599 documents, which are annotated with 8 event types, 33 event subtypes, and 35 argument roles. We evaluate our models by the performance of argument classification. An argument is correctly classified if its event subtype, offsets and argument role match the annotation results. Following the previous works (Liao and Grishman, 2010b; Chen et al., 2015), we use the same test set containing 40 newswire documents, a development set with 30 randomly selected documents and training set with the remaining 529 documents.

TAC KBP 2016 The Text Analysis Conference (TAC) is a series of evaluation workshops organized to encourage research in NLP and related applications. In this paper, we use the data of the TAC KBP 2016 Event Argument Extraction track (LDC2017E05). This competition annotates difficult test data but no training data. They encourage participants to use training data from any other sources. Hence we use the ACE 2005 dataset as our training data, which is less than the data used by the baselines on TAC KBP 2016.

Concept Hierarchy Design

Considering there is not an existing ontology in the datasets, we manually design a concept hierarchy with 8 different superordinate concepts for our models. The principle of designing the concept hierarchy is to induce superordinate concepts from the specific labels using human experience. For instance, people can easily summarize "`Origin`" and "`Destination`" into "`Place`", which is the desired superordinate concept. Although the hierarchy used in this paper may not be generalized to other datasets with different label definitions, it is tractable to design an appropriate concept hierarchy with minimal human efforts and provide effective inductive bias via our method. For the details about the specific concept hierarchy used in this paper, please refer to the appendix.

Hyperparameter Settings

CNN slides a convolution kernel over the input embedding sequence to get hidden embeddings. Following previous work, the input embedding of each word consists of its word embedding, position embedding, and event type embedding. The hyperparameter settings for HMEAE (CNN) are shown in Table 1.

Learning Rate	1e-03
Batch Size	20
Word Embedding Dimension	100
Dropout Probability	0.5
Hidden Layer Dimension	300
Kernel Size	3
Position Embedding Dimension	5
Event Type Embedding Dimension	5
u_c dimension	900
W_b dimension	900

Table 1: Hyperparameter settings for CNN models.

BERT adopts multi-layer bidirectional transformers to encode the input embedding sequence into hidden embeddings. The hyperparameters of DMBERT and HMEAE (BERT) are the same as the $\text{BERT}_{\text{BASE}}$ model. To utilize the event type information in our model, we append a special token into each input sequence for BERT to indicate the event type. Additional hyperparameters used in our experiments are shown in Table 2.

Learning Rate	6e-05
Batch Size	50
Kernel Size	3
Warmup Rate	0.1
u_c dimension	900
W_b dimension	900

Table 2: Hyperparameter settings for BERT models.

3.2 Overall Evaluation Results

We compare our models with various state-of-the-art baselines on ACE 2005: (1) Feature-based methods, including **Li's joint** (Li et al., 2013) and **RBPB** (Sha et al., 2016). (2) Vanilla neural network methods, including **DMCNN** (Chen et al., 2015) and **JRNN** (Nguyen et al., 2016). (3) Neural network with syntax information, like **dbRNN** (Sha et al., 2018) enhancing the recurrent neural network with dependency bridges to consider syntactically related information.

On TAC KBP 2016, we compare our models with the top systems (Dubbin et al., 2016; Hsi et al., 2016; Ferguson et al., 2016) of the competition as well as DMCNN and DMBERT.

Method	Argument Role Classification		
	P	R	F1
Li's Joint (Li et al., 2013)	64.7	44.4	52.7
DMCNN (Chen et al., 2015)	62.2	46.9	53.5
RBPB (Sha et al., 2016)	54.1	53.5	53.8
JRNN (Nguyen et al., 2016)	54.2	**56.7**	55.4
dbRNN (Sha et al., 2018)	**66.2**	52.8	58.7
HMEAE (CNN)	57.3	54.2	55.7
DMBERT	58.8	55.8	57.2
HMEAE (BERT)	62.2	56.6	**59.3**

Table 3: The overall results (%) on ACE 2005.

Method	Argument Role Classification		
	P	R	F1
DISCERN-R (Dubbin et al., 2016)	7.9	7.4	7.7
Washington4 (Ferguson et al., 2016)	32.1	5.0	8.7
CMU CS Event1 (Hsi et al., 2016)	**31.2**	4.9	8.4
Washington1 (Ferguson et al., 2016)	26.5	6.8	10.8
DMCNN (Chen et al., 2015)	17.9	16.0	16.9
HMEAE (CNN)	15.3	22.5	18.2
DMBERT	22.6	24.7	23.6
HMEAE (BERT)	24.8	**25.4**	**25.1**

Table 4: The overall results (%) on TAC KBP 2016.

The results are shown in Table 3 and Table 4. We have the following observations from the results: (1) HMEAE (CNN) and HMEAE (BERT) achieve improvements (about 2% in F1) as compared with DMCNN and DMBERT respectively, which have almost the same network framework with our models except the hierarchical modular attention. It indicates that our hierarchical modular method works well to enhance the EAE models with the inductive bias from the concept hierarchy. (2) HMEAE (BERT) is comparable to dbRNN and achieves the state-of-the-art performance among existing methods. Our methods adopt modular networks to consider the hierarchical concept knowledge in EAE, which is compatible with the sophisticated linguistic knowledge adopted in dbRNN. We will explore to integrate this two kinds of external knowledge together to further improve EAE in the future.

3.3 Case Study

To verify whether the superordinate concept modules work as we designed, we conduct a case study. We visualize the attention score s_i^c of HMEAE (BERT) on a sentence randomly sampled from the ACE 2005 dataset in Figure 3. We

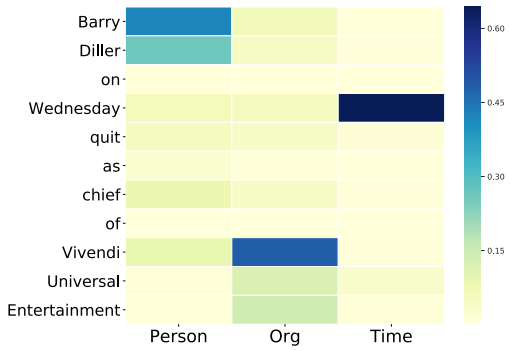

Figure 3: Heatmap for attention scores of three superordinate concept modules of the left sentence.

observe that the attention scores for the hidden embeddings of words related to the superordinate concept are much higher than the others. It indicates that as the superordinate concept modules are shared among their subordinate argument roles, the superordinate concept modules can capture the concept features well without being specially trained with exclusive data.

4 Conclusion and Future work

In this paper, we propose a hierarchical modular event argument extraction model (HMEAE), which adopts flexible modular networks to utilize the hierarchical concept correlation among argument roles as effective inductive bias. Experimental results show that HMEAE achieves the state-of-the-art performance. In the future, we will further explore to leverage other kinds of inductive bias from human experience to improve extensive tasks with our modular networks .

Abstract

We examine the capabilities of a unified, multi-task framework for three information extraction tasks: named entity recognition, relation extraction, and event extraction. Our framework (called DyGIE++) accomplishes all tasks by enumerating, refining, and scoring text spans designed to capture local (within-sentence) and global (cross-sentence) context. Our framework achieves state-of-the-art results across all tasks, on four datasets from a variety of domains. We perform experiments comparing different techniques to construct span representations. Contextualized embeddings like BERT perform well at capturing relationships among entities in the same or adjacent sentences, while dynamic span graph updates model long-range cross-sentence relationships. For instance, propagating span representations via predicted coreference links can enable the model to disambiguate challenging entity mentions. Our code is publicly available at https://github.com/dwadden/dygiepp and can be easily adapted for new tasks or datasets.

1 Introduction

Many information extraction tasks – including named entity recognition, relation extraction, event extraction, and coreference resolution – can benefit from incorporating global context across sentences or from non-local dependencies among phrases. For example, knowledge of a coreference relationship can provide information to help infer the type of a difficult-to-classify entity mention. In event extraction, knowledge of the entities present in a sentence can provide information that is useful for predicting event triggers.

To model global context, previous works have used pipelines to extract syntactic, discourse, and other hand-engineered features as inputs to structured prediction models (Li et al., 2013; Yang and Mitchell, 2016; Li and Ji, 2014) and neural scoring functions (Nguyen and Nguyen, 2019), or as a guide for the construction of neural architectures (Peng et al., 2017; Zhang et al., 2018; Sha et al., 2018; Christopoulou et al., 2018). Recent end-to-end systems have achieved strong performance by dynmically constructing graphs of spans whose edges correspond to task-specific relations (Luan et al., 2019; Lee et al., 2018; Qian et al., 2018).

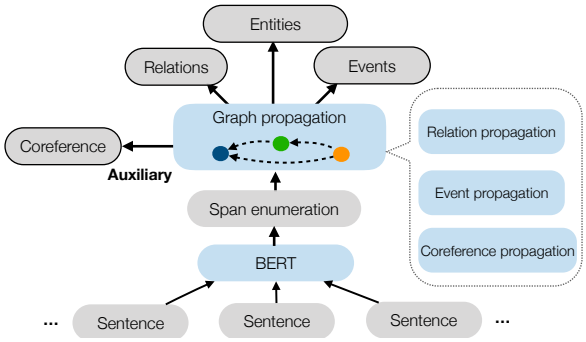

Figure 1: **Overview of our framework**: **DyGIE++**. Shared span representations are constructed by refining contextualized word embeddings via span graph updates, then passed to scoring functions for three IE tasks.

Meanwhile, contextual language models (Dai and Le, 2015; Peters et al., 2017, 2018; Devlin et al., 2018) have proven successful on a range of natural language processing tasks (Bowman et al., 2015; Sang and De Meulder, 2003; Rajpurkar et al., 2016). Some of these models are also capable of modeling context beyond the sentence boundary. For instance, the attention mechanism in BERT's transformer architecture can capture relationships between tokens in nearby sentences.

In this paper, we study different methods to incorporate global context in a general multi-task IE framework, building upon a previous span-based IE method (Luan et al., 2019). Our DyGIE++ framework, shown in Figure 1, enumerates candidate text

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5784–5789, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

spans and encodes them using contextual language models and task-specific message updates passed over a text span graph. Our framework achieves state-of-the results across three IE tasks, leveraging the benefits of both contextualization methods.

We conduct experiments and a thorough analysis of the model on named entity, relation, and event extraction. Our findings are as follows: (1) Our general span-based framework produces state-of-the-art results on all tasks and all but one subtasks across four text domains, with relative error reductions ranging from 0.2 - 27.9%. (2) BERT encodings are able to capture important within and adjacent-sentence context, achieving improved performance by increasing the input window size. (3) Contextual encoding through message passing updates enables the model to incorporate cross-sentence dependencies, improving performance beyond that of BERT alone, especially on IE tasks in specialized domains.

2 Task and Model

Our DyGIE++framework extends a recent span-based model for entity and relation extraction (Luan et al., 2019) as follows: (1) We perform event extraction as an additional task and propagate span updates across a graph connecting event triggers to their arguments. (2) We build span representations on top of multi-sentence BERT encodings.

2.1 Task definitions

The input is a document represented as a sequence of tokens D, from which our model constructs spans $S = \{s_1, \ldots, s_T\}$, the set of all possible within-sentence phrases (up to a threshold length) in the document.

Named Entity Recognition involves predicting the best entity type label e_i for each span s_i. For all tasks, the best label may be a "null" label. Relation Extraction involves predicting the best relation type r_{ij} for all span pairs (s_i, s_j). For the data sets studied in this work, all relations are between spans within the same sentence. The coreference resolution task is to predict the best coreference antecedent c_i for each span s_i. We perform coreference resolution as auxiliary task, to improve the representations available for the "main" three tasks.

Event Extraction involves predicting named entities, event triggers, event arguments, and argument roles. Specifically, each token d_i is predicted as an event trigger by assigning it a label t_i. Then, for each trigger d_i, event arguments are assigned to this event trigger by predicting an argument role a_{ij} for all spans s_j in the same sentence as d_i. Unlike most work on event extraction, we consider the realistic setting where gold entity labels are not available. Instead, we use predicted entity mentions as argument candidates.

2.2 DyGIE++ Architecture

Figure 1 depicts the four-stage architecture. For more details, see (Luan et al., 2019).

Token encoding: DyGIE++ uses BERT for token representations using a "sliding window" approach, feeding each sentence to BERT together with a size-L neighborhood of surrounding sentences.

Span enumeration: Spans of text are enumerated and constructed by concatenating the tokens representing their left and right endpoints, together with a learned span width embedding.

Span graph propagation: A graph structure is generated dynamically based on the model's current best guess at the relations present among the spans in the document. Each span representation $\mathbf{g}_j^t$ is updated by integrating span representations from its neighbors in the graph according to three variants of graph propagation. In coreference propagation, a span's neighbors in the graph are its likely coreference antecedents. In relation propagation, neighbors are related entities within a sentence. In event propagation, there are event trigger nodes and event argument nodes; trigger nodes pass messages to their likely arguments, and arguments pass messages back to their probable triggers. The whole procedure is trained end-to-end, with the model learning simultaneously how to identify important links between spans and how to share information between those spans.

More formally, at each iteration t the model generates an update $\mathbf{u}_x^t(i)$ for span $s^t \in \mathbb{R}^d$:

$$\mathbf{u}_x^t(i) = \sum_{j \in B_x(i)} V_x^t(i,j) \odot \mathbf{g}_j^t, \qquad (1)$$

where $\odot$ denotes elementwise multiplication and $V_x^t(i,j)$ is a measure of similarity between spans i and j under task x – for instance, a score indicating the model's confidence that span j is the coreference antecedent of span i. For relation extraction, we use a ReLU activation to enforce sparsity. The final updated span representation $\mathbf{g}_j^{t+1}$ is computed as a convex combination of the previous representation and the current update, with weights determined by a gating function.

Multi-task classification: The re-contextualized representations are input to scoring functions which make predictions for each of the end tasks. We use a two-layer feedforward neural net (FFNN) as the scoring function. For trigger and named entity prediction for span $\mathbf{g}_i$, we compute $\text{FFNN}_{\text{task}}(\mathbf{g}_i)$. For relation and argument role prediction, we concatenate the relevant pair of embeddings and compute $\text{FFNN}_{\text{task}}([\mathbf{g}_i, \mathbf{g}_j])$.

3 Experimental Setup

Data We experiment on four different datasets: ACE05, SciERC, GENIA and WLPC (Statistics and details on all data sets and splits can be found in Appendix A.). The **ACE05** corpus provides entity, relation, and event annotations for a collection of documents from a variety of domains such as newswire and online forums. For named entity and relation extraction we follow the train / dev / test split from Miwa and Bansal (2016). Since the ACE data set lacks coreference annotations, we train on the coreference annotations from the OntoNotes dataset (Pradhan et al., 2012). For event extraction we use the split described in Yang and Mitchell (2016); Zhang et al. (2019). We refer to this split as ACE05-E in what follows. The **SciERC** corpus (Luan et al., 2018) provides entity, coreference and relation annotations from 500 AI paper abstracts. The **GENIA** corpus (Kim et al., 2003) provides entity tags and coreferences for 1999 abstracts from the biomedical research literature with a substantial portion of entities (24%) overlapping some other entity. The **WLPC** dataset provides entity, relation, and event annotations for 622 wet lab protocols (Kulkarni et al., 2018). Rather than treating event extraction as a separate task, the authors annotate event triggers as an entity type, and event arguments as relations between an event trigger and an argument.

Evaluation We follow the experimental setups of the respective state-of-the-art methods for each dataset: Luan et al. (2019) for entities and relations, and Zhang et al. (2019) for event extraction. An entity prediction is correct if its label and span matches with a gold entity; a relation is correct if both the span pairs and relation labels match with a gold relation triple. An event trigger is correctly identified if its offsets match a gold trigger. An argument is correctly identified if its offsets and event type match a gold argument. Triggers and arguments are correctly classified if their event types and event roles are also correct, respectively.

Dataset	Task	SOTA	Ours	Δ%
ACE05	Entity	88.4	**88.6**	1.7

	Relation	64.1	**65.9**	5.0

Table 1: **DyGIE++ achieves state-of-the-art results**. Test set F1 scores of best model, on all tasks and datasets. We define the following notations for events: *Trig*: Trigger, *Arg*: argument, *ID*: Identification, *C*: Classification. * indicates the use of a 4-model ensemble for trigger detection. See Appendix E for details. The results of the single model are reported in Table 2 (c). We ran significance tests on a subset of results in Appendix D. All were statistically significant except Arg-C and Arg-ID on ACE05-Event.

Model Variations We perform experiments with the following variants of our model architecture. **BERT + LSTM** feeds pretrained BERT embeddings to a bi-directional LSTM layer, and the LSTM parameters are trained together with task specific layers. **BERT Finetune** uses supervised fine-tuning of BERT on the end-task. For each variation, we study the effect of integrating different task-specific message propagation approaches.

Comparisons For entity and relation extraction, we compare DyGIE++ against the DyGIE system it extends. DyGIE is a system based on ELMo (Peters et al., 2018) that uses dynamic span graphs to propagate global context. For event extraction, we compare against the method of Zhang et al. (2019), which is also an ELMo-based approach that relies on inverse reinforcement learning to focus the model on more difficult-to-detect events.

Implementation Details Our model is implemented using AllenNLP (Gardner et al., 2017). We use $\text{BERT}_{\text{BASE}}$ for entity and relation extraction tasks and use $\text{BERT}_{\text{LARGE}}$ for event extraction. For BERT finetuning, we use BertAdam with the learning rates of 1×10^{-3} for the task specific layers, and 5.0×10^{-5} for BERT. We use a longer warmup period for BERT than the warmup period for task specific-layers and perform linear decay of the learning rate following the warmup

period. Each of the feed-forward neural networks has two hidden layers and ReLU activations and 0.4 dropout. We use 600 hidden units for event extraction and 150 for entity and relation extraction (more details in Appendix E).

4 Results and Analyses

State-of-the-art Results Table 1 shows test set F1 on the entity, relation and event extraction tasks. Our framework establishes a new state-of-the-art on all three high-level tasks, and on all subtasks except event argument identification. Relative error reductions range from 0.2 - 27.9% over previous state of the art models.

Benefits of Graph Propagation Table 2 shows that Coreference propagation (CorefProp) improves named entity recognition performance across all three domains. The largest gains are on the computer science research abstracts of SciERC, which make frequent use of long-range coreferences, acronyms and abbreviations. CorefProp also improves relation extraction on SciERC.

Relation propagation (RelProp) improves relation extraction performance over pretrained BERT, but does not improve fine-tuned BERT. We believe

Task	Variation	1	3
Relation	BERT+LSTM	59.3	**60.6**
	BERT Finetune	62.0	**62.1**
Entity	BERT+LSTM	90.0	**90.5**
	BERT Finetune	88.8	**89.7**
Trigger	BERT+LSTM	**69.4**	68.9
	BERT Finetune	68.3	**69.7**
Arg Class	BERT+LSTM	48.6	**51.4**
	BERT Finetune	**50.0**	48.8

Table 6: **Effect of BERT cross-sentence context**. F1 score of relation F1 on ACE05 dev set and entity, arg, trigger extraction F1 on ACE05-E test set, as a function of the BERT context window size.

this occurs because all relations are within a single sentence, and thus BERT can be trained to model these relationships well.

Our best event extraction results did not use any propagation techniques (Table 4). We hypothesize that event propagation is not helpful due to the asymmetry of the relationship between triggers and arguments. Methods to model higher-order interactions among event arguments and triggers represent an interesting direction for future work.

Benefits of Cross-Sentence Context with BERT Table 6 shows that both variations of our BERT model benefit from wider context windows. Our model achieves the best performance with a 3-sentence window across all relation and event extraction tasks.

Pre-training or Fine Tuning BERT Under Limited Resources Table 5 shows that fine-tuning BERT generally performs slightly better than using the pre-trained BERT embeddings combined with a final LSTM layer.[1] Named entity recognition improves by an average of 0.32 F1 across the four datasets tested, and relation extraction improves by an average of 1.0 F1, driven mainly by the performance gains on SciERC. On event extraction, fine-tuning decreases performance by 1.6 F1 on average across tasks. We believe that this is due to the high sensitivity of both BERT finetuning and event extraction to the choice of optimization hyperparameters – in particular, the trigger detector begins overfitting before the argument detector is finished training.

Pretrained BERT combined with an LSTM layer and graph propagation stores gradients on 15 million parameters, as compared to the 100 million pa-

[1]Pre-trained BERT without a final LSTM layer performed substantially worse than either fine-tuning BERT, or using pre-trained BERT with a final LSTM layer.

	SciERC		GENIA
	Entity	Relation	Entity

Best SciBERT	**72.0**	**45.3**	**79.5**

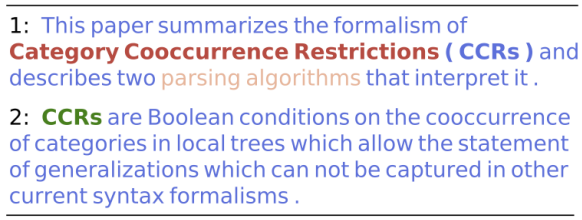

Table 7: In-domain pre-training: SciBERT vs. BERT

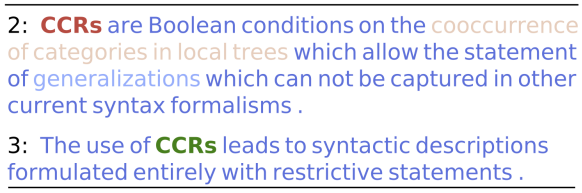
rameters in $\text{BERT}_{\text{BASE}}$. Since the BERT + LSTM + Propagation approach requires less memory and is less sensitive to the choice of optimization hyperparameters, it may be appealing for non-experts or for researchers working to quickly establish a reasonable baseline under limited resources. It may also be desirable in situations where fine-tuning BERT would be prohibitively slow or memory-intensive, for instance when encoding long documents like scientific articles.



Importance of In-Domain Pretraining We replaced BERT (Devlin et al., 2018) with SciBERT (Beltagy et al., 2019) which is pretrained on a large multi-domain corpus of scientific publications. Table 7 compares the results of BERT and SciBERT with the best-performing model configurations. SciBERT significantly boosts performance for scientific datasets including SciERC and GENIA. These results indicate that introducing unlabeled text of similar domains for pre-training can significantly improve performance.

Qualitative Analysis To better understand the mechanism by which graph propagation improved performance, we examined all named entities in the SciERC dev set where the prediction made by the BERT + LSTM + `CorefProp` model from Table 2 was different from the BERT + LSTM model. We found 44 cases where the `CorefProp` model corrected an error made by the base model, and 21 cases where it introduced an error. The model without `CorefProp` was often overly specific in the label it assigned, labeling entities as *Material* or *Method* when it should have given the more general label *Other Scientific Term*. Visualizations of the disagreements between the two model variants can be found in Appendix C. Figure 2 shows an example where span updates passed along a coreference chain corrected an overly-specific entity identification for the acronym "CCRs". We observed similar context sharing via `CorefProp` in the GENIA data set, and include an example in Appendix C.

Coreference propagation updated the span representations of all but one of 44 entities, and in 68% of these cases the update with the largest coreference "attention weight" came from a text span in a different sentence that was itself a named entity.

(a) The green span *CCRs* in sentence 2 is updated based on its predicted coreference antecedent.

(b) The mention of *CCRs* in sentence 2 serves as a bridge to propagate information from sentence 1 to the mention of *CCRs* in sentence 3

(c) Coreference link strength. Red is strong.

Figure 2: **`CorefProp` enables a correct entity prediction**. In each subplot, the green token is being updated by coreference propagation. The preceeding tokens are colored according to the strength of their predicted coreference links with the green token. Tokens in **bold** are part of a gold coreference cluster discussing *CCRs*. During the `CorefProp` updates, the span *CCRs* in sentence 2 is updated based on its antecedent *Category Cooccurrence Restrictions*. Then, it passes this information along to the span *CCRs* in sentence 3. As a result, the model changes its prediction for *CCRs* in sentence 3 from *Method* – which is overly specific according to the SciERC annotation guideline – to the correct answer *Other Scientific Term*.

5 Conclusion

In this paper, we provide an effective plug-and-play IE framework that can be applied to many information extraction tasks. We explore the abilities of BERT embeddings and graph propagation to capture context relevant for these tasks. We find that combining these two approaches improves performance compared to using either one alone, with BERT building robust multi-sentence representations and graph propagations imposing additional structure relevant to the problem and domain under consideration. Future work could extend the framework to other NLP tasks and explore other approaches to model higher-order interactions like those present in event extraction.

Next Sentence Prediction helps Implicit Discourse Relation Classification within and across Domains

Abstract

Implicit discourse relation classification is one of the most difficult tasks in discourse parsing. Previous studies have generally focused on extracting better representations of the relational arguments. In order to solve the task, it is however additionally necessary to capture what events are expected to cause or follow each other. Current discourse relation classifiers fall short in this respect. We here show that this shortcoming can be effectively addressed by using the bidirectional encoder representation from transformers (BERT) proposed by Devlin et al. (2019), which were trained on a next-sentence prediction task, and thus encode a representation of likely next sentences. The BERT-based model outperforms the current state of the art in 11-way classification by 8% points on the standard PDTB dataset. Our experiments also demonstrate that the model can be successfully ported to other domains: on the BioDRB dataset, the model outperforms the state of the art system around 15% points.

1 Introduction

Discourse relation classification has been shown to be beneficial to multiple down-stream NLP tasks such as machine translation (Li et al., 2014), question answering (Jansen et al., 2014) and summarization (Yoshida et al., 2014). Following the release of the Penn Discourse Tree Bank (Prasad et al., 2008, PDTB), discourse relation classification has received a lot of attention from the NLP community, including two CoNLL shared tasks (Xue et al., 2015, 2016).

Discourse relations in texts are sometimes marked with an explicit connective (e.g., *but*, *because*, *however*), but these explicit signals are often absent. With explicit connectives acting as informative cues, it is relatively easy to classify the discourse relation with high accuracy (93.09% on four-way classification in (Pitler et al., 2008)). When there is no connective, classification has to rely on semantic information from the relational arguments. This task is very challenging, with state-of-the-art systems achieving accuracy of only 45% to 48% on 11-way classification. Consider example 1:

(1) [*The joint venture with Mr. Lang wasn't a good one.*]$_{Arg1}$ [**The venture, formed in 1986, was supposed to be Time's low-cost, safe entry into women's magazines.**]$_{Arg2}$
implicit `Comp.Concess.expectation` relation from PDTB: wsj_1903

In order to correctly classify the relation, it is necessary to understand that Arg1 raises the expectation that the next discourse segment may provide an explanation for why the venture wasn't good (e.g., that it was risky), and Arg2 contrasts with this discourse expectation. More generally, this means that a successful discourse relation classification model would have to be able to learn typical temporal event sequences, reasons, consequences etc. for all kinds of events. Statistical models attempted to address this intuition by giving models word pairs from the two arguments as features (Lin et al., 2009; Park and Cardie, 2012; Biran and McKeown, 2013; Rutherford and Xue, 2014), so that models could for instance learn to recognize antonym relations between words in the two arguments.

Recent models exploit such similarity relations between the two arguments, as well as simpler surface features that occur in one relational argument and correlate with specific coherence relations (e.g., the presence of negation, temporal expressions etc. may give hints as to what coherence relation may be present, see Park and Cardie (2012); Asr and Demberg (2015)). However, relations between arguments are often a lot more diverse than simple contrasts that can be captured

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5790–5796, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

through antonyms, and may rely on world knowledge (Kishimoto et al., 2018). It is hence clear that one cannot learn all these diverse relations from the very small amounts of available training data. Instead, we would have to learn a more general representation of discourse expectations.

Many recent discourse relation classification approaches have focused on cross-lingual data augmentation (Shi et al., 2017, 2019), training models to better represent the relational arguments by using various neural network models, including feed-forward network (Rutherford et al., 2017), convolutional neural networks (Zhang et al., 2015), recurrent neural network (Ji et al., 2016; Bai and Zhao, 2018), character-based (Qin et al., 2016) or formulating relation classification as an adversarial task (Qin et al., 2017). These models typically use pre-trained semantic embeddings generated from language modeling tasks, like Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018).

However, previously proposed neural models still crucially lack a representation of the *typical relations between sentences*: to solve the task properly, a model should ideally be able to form discourse expectations, i.e., to represent the typical causes, consequences, next events or contrasts to a given event described in one relational argument, and then assess the content of the second relational argument with respect to these expectations (see Example 1). Previous models would have to learn these relations only from the annotated training data, which is much too sparse for learning all possible relations between all events, states or claims.

The recently proposed BERT model (Devlin et al., 2019) takes a promising step towards addressing this problem: the BERT representations are trained using a language modelling and, crucially, a "next sentence prediction" task, where the model is presented with the actual next sentence vs. a different sentence and needs to select the original next sentence. We believe it is a good fit for discourse relation recognition, since the task allows the model to represent what a typical next sentence would look like.

In this paper, we show that a BERT-based model outperforms the current state of the art by 8% points in 11-way implicit discourse relation classification on PDTB. We also show that after pre-trained with small size cross-domain data, the model can be easily transferred to a new domain: it achieves around 16% accuracy gain on BioDRB compared to state of the art model. We also show that the Next Sentence Prediction task played an important role in these improvements.

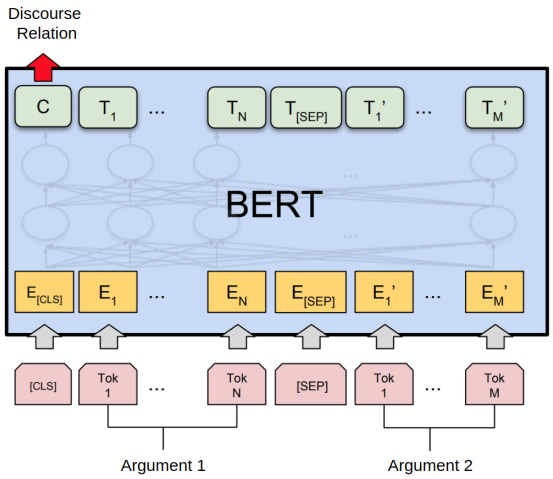

Figure 1: The architecture from BERT (Devlin et al., 2019) for fine-tuning of implicit discourse relation classification.

2 Next Sentence Prediction

Devlin et al. (2019) proposed the Bidirectional Encoder Representation from Transformers (BERT), which is designed to pre-train a deep bidirectional representation by jointly conditioning on both left and right contexts. BERT is trained using two novel unsupervised prediction tasks: Masked Language Modeling and Next Sentence Prediction (NSP). The NSP task has been formulated as a binary classification task: the model is trained to distinguish the original following sentence from a randomly chosen sentence from the corpus, and it showed great helps in multiple NLP tasks especially inference ones. The resulting BERT representations thus encode a representation of upcoming discourse content, and hence contain discourse expectation representations which, as we argued above, are required for classifying coherence relations.

3 Experiments and Results

As shown in Figure 1, E denotes the input tokens' embedding and T are the target words. In our case they are identical. We fit the implicit discourse relation task into sentence-pair classification proposed in BERT. Argument 1 and Argu-

Methods	PDTB-Lin	PDTB-Ji	Cross Validation

Table 1: Accuracy (%) with standard deviation in brackets of implicit discourse relation classification on different settings of PDTB level 2 relations. NSP refers to the subtask "next sentence prediction" in the pre-training of BERT. Numbers in bold signal significant improvements over the previous state of the art ($p<0.01$). Numbers with $*$ denote significant improvements over BERT + WSJ w/o NSP with $p<0.01$.

ment 2 are separated with token "[SEP]"; "[CLS]" is the special classification embedding while "C" is the same as "[CLS]" in pre-training but the ground-truth label in the fine-tuning. In the experiments, we used the uncased base model[1] provided by Devlin et al. (2019), which is trained on *BooksCorpus* and *English Wikipedia* with 3300M tokens in total.

3.1 Evaluation on PDTB

We used the Penn Discourse Tree Bank (Prasad et al., 2008), the largest available manually annotated discourse corpus. It provides a three level hierarchy of relation tags. Following the experimental settings and evaluation metrics in Bai and Zhao (2018), we use two most-used splitting methods of PDTB data, denoted as PDTB-Lin (Lin et al., 2009), which uses sections 2-21, 22, 23 as training, validation and test sets, and PDTB-Ji (Ji and Eisenstein, 2015), which uses 2-20, 0-1, 21-22 as training, validation and test sets and report the overall accuracy score. In addition, we also performed 10-fold cross validation among sections 0-22, as promoted in Shi and Demberg (2017). We also follow the standard in the literature to formulate the task as an 11-way classification task.

Results are presented in Table 1. We evaluated three versions of the BERT-based model. All of our BERT models use the pre-trained representations and are fine-tuned on the PDTB training data. The version marked as "BERT" does not do any additional pre-training. BERT+WSJ in addition performs further pre-training on the parts of the *Wall Street Journal* corpus that do not have discourse relation annotation. The model version "BERT+WJS w/o NSP" also performs pre-training on the WSJ corpus, but only uses the Masked Language Modelling task, not the Next Sentence Prediction task in the pre-training. We added this variant to measure the benefit of in-domain NSP on discourse relation classification (note though that the downloaded pre-trained BERT model contains the NSP task in the original pre-training).

We compared the results with four state-of-the-art systems: Cai and Zhao (2017) proposed a model that takes a step towards calculating discourse expectations by using attention over an encoding of the first argument, to generate the representation of the second argument, and then learning a classifier based on the concatenation of the encodings of the two discourse relation arguments. Kishimoto et al. (2018) fed external world knowledge (ConceptNet relations and coreferences) explicitly into MAGE-GRU (Dhingra et al., 2017) and achieved improvements compared to only using the relational arguments. However, we here show that it works even better when we learn this knowledge implicit through next sentence prediction task. Shi and Demberg (2019) used a seq2seq model that learns better argument representations due to being trained to explicitate the implicit connective. In addition, their classifier also uses a memory network that is intended to help remember similar argument pairs encountered during training. The current best performance was achieved by Bai and Zhao (2018), who combined representations from different grained em-

[1] https://github.com/google-research/bert#pre-trained-models

beddings including contextualized word vectors from ELMo (Peters et al., 2018), which has been proved very helpful. In addition, we compared our results with a simple bidirectional LSTM network and pre-trained word embeddings from Word2Vec.

We can see that on all settings, the model using BERT representations outperformed all existing systems with a substantial margin. It obtained improvements of 7.3% points on PDTB-Lin, 5.5% points on PDTB-Ji, compared with the ELMo-based method proposed in (Bai and Zhao, 2018). What's more, the BERT model outperformed (Shi and Demberg, 2019) on cross validation by around 8%, with significance of $p<0.01$. Significance test was performed by estimating variance of the model from the performance on different folds in cross-validation (paired t-test). For the Lin and Ji evaluations, we estimated variance due to random initialization by running them 5 times and calculating the likelihood that the state-of-the-art model result would come from that distribution.

3.2 Evaluation On BioDRB

The Biomedical Discourse Relation Bank (Prasad et al., 2011) also follows PDTB-style annotation. It is a corpus annotated over 24 open access full-text articles from the GENIA corpus (Kim et al., 2003) in the biomedical domain. Compared with PDTB, some new discourse relations and changes have been introduced in the annotation of BioDRB. In order to make the results comparable, we preprocessed the BioDRB annotations to map the relations to the PDTB ones, following the instructions in Prasad et al. (2011).

The biomedical domain is very different from the WSJ or the data on which the BERT model was trained. The BioDRB contains a lot of professional words / phrases that are extremely hard to model. In order to test the ability of the BERT model on cross-domain data, we performed fine-tuning on PDTB while testing on BioDRB. We also tested the state of the art model of implicit discourse relation classification proposed by Bai and Zhao (2018) on BioDRB. From Table 2, we can see that the BERT base model achieved almost 12% points improvement over the Bi-LSTM baseline and 15% points over Bai and Zhao (2018). When fine-tuned on in-domain data in the cross-validation setting, the improvement increases to around 17% points.

Method	Cross-Domain	In-Domain
Bi-LSTM + w2v_300	32.97	46.49
Bai and Zhao (2018)	29.52	55.90
BioBERT (Lee et al., 2019)	**44.33**	**67.58**
BERT	**44.79**	**63.02**
BERT + GENIA w/o NSP	**43.99**	**65.02**
BERT + GENIA	**45.19**$*$	**66.04**$*$

Table 2: Accuracy (%) on BioDRB level 2 relations with different settings. Cross-Domain means trained on PDTB and tested on BioDRB. For the In-Domain setting, we used 5-fold cross-validation and report average accuracy. Numbers in bold are significantly better than the state of the art system with $p<0.01$ and numbers with $*$ denote denote significant improvements over BERT + GENIA w/o NSP with $p<0.01$.

It is also interesting to know whether the performance of the BERT model can be improved if we add additional pre-training on in-domain data. BioBert (Lee et al., 2019) continues pre-training BERT with bio-medical texts including PubMed and PMC corpora (around 18B tokens), which achieved the best results on in-domain setting. Similarly, BERT+GENIA refers to a model in which the downloaded BERT representations are further pre-trained on the parts of the GENIA corpus which consists of 18k sentences and is not annotated with coherence relations. Evaluation shows that this in-domain pre-training yields another 3% point improvement; our tests also show that the NSP task again plays a substantial role in the improvement. We believe that gains for further pre-training on GENIA for the biomedical domain are higher than for pre-training on WSJ for PDTB because the domain difference between the *BooksCorpus* and the biomedical domain is larger.

Currently there are not so many published results that we can compare with on BioDRB for implicit discourse relation classification. We compared BERT model with naïve Bayes and MaxEnt methods proposed in Xu et al. (2012) on one-versus-all binary classification. We followed the settings in Xu et al. (2012) and used two articles ("GENIA_1421503", "GENIA_1513057") for testing and one article ("GENIA_111020") for validation. During training, we employed down-sampling or up-sampling to keep the numbers of positive and negative samples in each relation consistent. The BERT base model achieved 43.03% average F_1 score and 77.34% average accuracy in one-versus-all level-1 classification. Compared with the current state-of-the-art perfor-

Method		Comp.	Cont.	Exp.	Temp.	Average
Naïve Bayes	(Xu et al., 2012)	7.69(61.45)	3.88(60.24)	68.54(55.02)	17.19(57.43)	24.33(58.54)

Table 4: Precision, Recall and F_1 score for each level-2 relation on PDTB-Lin setting and BioDRB with "BERT + WSJ/GENIA" systems w/ and w/o NSP. "-" indicates 0.00 and "C." means the number of each relation in the test set.

mances (26.64% F_1 and 58.54% accuracy) in Xu et al. (2012), it achieves around 16% and 19% points improvement when trained in-domain, as illustrated in Table 3.

3.3 Discussion

The usage of the BERT model in this paper was motivated primarily by the use of the next-sentence prediction task during training. The results in Table 1 and Table 2 confirm that removing the "Next Sentence Prediction" hurts the performance on both PDTB and BioDRB.

In order to have better insights about which relation has benefited from the NSP task, we also reported the detailed performance for each relation with and without it in BERT. As illustrated in Table 4, we can see that performances on relations like *Temporal.Synchrony, Comparison.Contrast, Expansion.Conjunction and Expansion.Alternative* have been improved by a large margin. This shows that representing the likely upcoming sentence helps the model form discourse expectations, which the classifier can then use to predict the coherence relation between the actually observed arguments.

However, compared with BERT+GENIA, the results of BioBert (Lee et al., 2019) in Table 2 show that having large in-domain data for pre-training also has limited ability in learning domain specific representations. We therefore believe that the model could be further improved by including external domain-specific knowledge from an ontology (as in Kishimoto et al. (2018)) or a causal graph for biomedical concepts and events.

4 Conclusion and Future work

In this paper, we show that BERT has very good ability in encoding the semantic relationship between sentences with its "next sentence prediction" task in pre-training. It outperformed the current state-of-the-art systems significantly with a substantial margin on both in-domain and cross domain data. Our results also indicate that the next-sentence prediction task during training indeed plays a role in this improvement. Future work should explore the joint representation of discourse expectations through implicit representations that are learned during training and the inclusion of external knowledge. In addition, Yang et al. (2019) showed that NSP only helps tasks with longer texts. It would be interesting to see whether it has the same effect on implicit discourse relation classification task, we'd like to leave that in the future work.

Abstract

Rhetorical Structure Theory (RST) parsing is crucial for many downstream NLP tasks that require a discourse structure for a text. Most of the previous RST parsers have been based on supervised learning approaches. That is, they require an annotated corpus of sufficient size and quality, and heavily rely on the language and domain dependent corpus. In this paper, we present two language-independent unsupervised RST parsing methods based on dynamic programming. The first one builds the optimal tree in terms of a dissimilarity score function that is defined for splitting a text span into smaller ones. The second builds the optimal tree in terms of a similarity score function that is defined for merging two adjacent spans into a large one. Experimental results on English and German RST treebanks showed that our parser based on span merging achieved the best score, around 0.8 F_1 score, which is close to the scores of the previous supervised parsers.

1 Introduction

Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is one of the theories that are most widely utilized for representing a discourse structure of a text in downstream NLP applications, such as automatic summarization (Marcu, 1998; Hirao et al., 2013), sentiment analysis (Bhatia et al., 2015), and text categorization (Ji and Smith, 2017). RST represents a text as a kind of constituent tree, whose leaves are Elementary Discourse Units (EDUs), clause-like units, and whose non-terminal nodes cover text spans consisting of a sequence of EDUs or a singleton EDU. The label of a non-terminal node represents the attribution of a text span, *nucleus* or *satellite*. A discourse relation is also assigned between two adjacent non-terminal nodes.

Since the RST tree can be regarded as a standard constituent (phrase structure) tree, syntactic parsing models for constituency parsing can also be successfully applied to RST parsing. In most cases, RST parsers have been developed on the basis of supervised learning algorithms, which require a high quality annotated corpus of sufficient size. As a result, research on RST parsing has focused on English, with the largest annotated corpus being the RST Discourse Treebank (RST-DT) (Carlson et al., 2001). These supervised RST parsing methods might not be applied to languages with only a small-size corpus.

This paper presents two types of language independent unsupervised RST parsing methods based on the CKY-like dynamic programming-based approach. One method builds the most likely parse tree in terms of a dissimilarity score defined for splitting a text span into two smaller ones. The other builds the optimal tree in terms of a similarity score defined for merging two adjacent text spans into a larger one. The similarity and dissimilarity scores between text spans are calculated on the basis of their distributional representations. Note that since our method is fully unsupervised, the parser predicts only the skeleton of an RST tree.

Moreover, we exploit multiple granularity levels of a document: (1) we first independently build three types of trees, a tree whose leaves correspond to a paragraph, a tree whose leaves correspond to a sentence, and a tree whose leaves correspond to an EDU, and then (2) merge them to obtain the whole RST tree.

We conducted experimental evaluation on English and German datasets, RST-DT and the Potsdam Commentary Corpus (PCC) (Stede and Neumann, 2014), respectively. The results demonstrated that our method with span merging outperformed our method with span splitting and ob-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5797–5802,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tained .811 and .784 span scores for RST-DT and PCC, respectively. The scores are close to the scores of early supervised RST parsers.

2 Unsupervised RST Parsing

2.1 Motivation

Generally, RST trees with multinulcear relations are transformed into binary trees by applying right-heavy binarization as in syntactic parsing. As the result, we can easily imagine the following two simple parsing methods. First, when a split score for splitting a text span into two smaller spans is given for each candidate splitting point in the text span, we can build an RST tree by recursively splitting a text span with the best candidate points. Second, when a merge score for merging two adjacent spans into a larger one is given for each candidate pair of the spans, we can build an RST tree by recursively merging the best candidate pairs. Here, we can regard dissimilarity between two text spans as the split score and similarity between them as the merge score. Note that the dissimilarity score can be defined as $1 -$ similarity score. We propose the similarity score that is based on distributional representations of text spans in Section 2.2.

In general, while a parse tree can be obtained either by splitting or merging with a greedy parsing method, as mentioned above, it cannot be always optimal in terms of the total split or merge score. Thus, we propose our dynamic programming-based approach to obtain the optimal tree in Section 2.3.

Of course, it would be possible to utilize both similarity and dissimilarity scores. However, in this paper, we investigate which one is suitable for unsupervised RST parsing as the first step.

2.2 Similarity and Dissimilarity Scores between Text Spans

When two adjacent text spans, the left span ℓ from i-th to k-th atomic text unit[1] and the right span r from $k+1$ to j-th atomic text unit are given, we define the similarity score between them as follows:

$$\mathrm{sim}(\overrightarrow{\ell_{i:k}}, \overrightarrow{r_{k+1:j}}) = \frac{1}{2}\left\{\frac{\overrightarrow{\ell_{i:k}} \cdot \overrightarrow{r_{k+1:j}}}{\|\overrightarrow{\ell_{i:k}}\|\|\overrightarrow{r_{k+1:j}}\|} + 1\right\}. \quad (1)$$

[1] A paragraph, a sentence or an Elementary Discourse Unit (EDU).

Here, $\overrightarrow{\ell_{i:k}}$ and $\overrightarrow{r_{k+1:j}}$ indicate the vector representations of the left and right spans, which are defined as a concatenation of two vectors for the left most atomic unit and the right most atomic unit as follows:

$$\begin{aligned}\overrightarrow{\ell_{i:k}} &= [\overrightarrow{u_i}; \overrightarrow{u_k}],\\ \overrightarrow{r_{k+1:j}} &= [\overrightarrow{u_{k+1}}; \overrightarrow{u_j}].\end{aligned} \quad (2)$$

The definition is inspired by that of (Ji and Eisenstein, 2014), which employs words at the beginning and end of a text span as important features to build an RST tree.

$\overrightarrow{u_t}$ is the vector representation of a t-th atomic unit u_t, which is defined on the basis of SIF (Arora et al., 2017)[2] as follows:

$$\overrightarrow{u_t} = \sum_{w \in W_t} \frac{a}{p(w) + a}\overrightarrow{w}. \quad (3)$$

$p(w)$ is the occurrence probability for word w, $\overrightarrow{w}$ is the vector representation of the word and W_t is a set of words in u_t. We use a concatenation of two word vectors obtained from ELMo (Peters et al., 2018) and Glove (Pennington et al., 2014) as a vector representation of a word. a is a parameter to decay the score of frequent words and is defined as $a = (1 - \alpha)/(\alpha Z)$, where α is a hyper parameter and Z is the total number of words.

2.3 Dynamic Programming-Based Approach for Building Optimal Trees

We propose a dynamic programming-based approach to obtain the optimal tree in terms of either the total split or merge score from all the possible trees.

We first illustrate the algorithm with a merge (similarity) score. We define $V[b][e]$, which stores the maximum merge score for a span $u_{b:e}$ consisting from b-th unit to e-th unit, as follows:

$$V[b][e] = \begin{cases} 1, & b = e \\ \max\limits_{b \le k < e} V[b][k] \times \\ \quad \mathrm{sim}(\overrightarrow{\ell_{b:k}}, \overrightarrow{r_{k+1,e}}) \times \\ \quad\quad V[k+1][e], & \text{otherwise} \end{cases} \quad (4)$$

where $V[b][k]$ stores the maximum merge score for a sub-span $u_{b:k}$, and $V[k+1][e]$ stores the maximum merge score for a sub-span $u_{k+1:e}$.

[2] As for the representation for sentences and paragraphs, (Arora et al., 2017) compared SIF with the following three: avg-GloVe, tfidf-GloVe, skip-thought vectors (Kiros et al., 2015).

Algorithm 1 Dynamic Programming-Based RST Parsing

1: $V^p[1][d] \leftarrow$DP$(u^p_{1:d})$
2: BACKTRACE$(V^p[1][d])$
3: **for** $i = 1$ to m **do**
4: $b_i \leftarrow \text{start}(u^p_i)$, $e_i \leftarrow \text{end}(u^p_i)$
5: $V^s_i[b_i][e_i] \leftarrow$DP$(u^s_{b_i:e_i})$
6: BACKTRACE$(V^s_i[b_i][e_i])$
7: **for** $j = b_s$ to e_s **do**
8: $b_j \leftarrow \text{start}(u^s_j)$, $e_j \leftarrow \text{end}(u^s_j)$
9: $V^e_j[b_j][e_j] \leftarrow$DP$(u^e_{b_j:e_j})$
10: BACKTRACE$(V^e_j[b_j][e_j])$
11: **function** DP(SPAN)
12: $V \leftarrow \phi$
13: $B \leftarrow \text{start}(\text{SPAN})$,$E \leftarrow \text{end}(\text{SPAN})$
14: **for** $i = 0$ to $E - B$ **do**
15: **for** $j = 0$ to $E - B - i$ **do**
16: $b \leftarrow B + j$, $e \leftarrow B + j + i$
17: **if** $b = e$ **then**
18: $V[b][e] = 1$
19: **else**
20: $V[b][e] = \max_{b \le k < e} V[b][k] \times$
21: $\text{sim}(\overrightarrow{\ell_{b:k}}, \overrightarrow{r_{k+1,e}}) \times V[k+1][e]$
return $V[B][E]$
22: **procedure** BACKTRACE$(V[b][e])$
23: $\hat{k} = \underset{k \in \{b,\ldots,e-1\}}{\arg\max} V[b][k] \times \text{sim}(\overrightarrow{\ell_{b:k}}, \overrightarrow{r_{k+1,e}}) \times$
24: $V[k+1][e]$
25: $C_\ell(u_{b:e}) \leftarrow u_{b:\hat{k}}$
26: $C_r(u_{b:e}) \leftarrow u_{\hat{k}+1:e}$
27: BACKTRACE$(V[b][\hat{k}])$
28: BACKTRACE$(V[\hat{k}+1][e])$

Algorithm 1 shows a dynamic programming-based RST parsing algorithm to build the optimal RST tree in terms of the total merge score. In the algorithm, DP is a function that fills out the triangular matrix V as in the CKY algorithm, and BACKTRACE is a procedure to build a tree by recursively determining the left and right children for a span. Figure 1 shows an example of table V. The parse tree is obtained by recursively tracing back the path with the maximum score from $V[1][6]$. For example, the left child of span $u_{1:6}$ is span $u_{1:4}$ and the right child is span $u_{5:6}$.

Furthermore, we regard a document as a text span consisting of three different granularity levels: (1) a span from 1st to d-th paragraphs, assuming that the document consists of d paragraphs, denoted as $u^p_{1:d}$, (2) a span from b_i-th to e_i-th sentences for the i-th paragraph u^p_i, which we denote as $u^s_{b_i:e_i}$, and (3) a span from b_j-th to e_j-th EDUs for the j-th sentence u^s_j, which we denote as $u^e_{b_j:e_j}$.

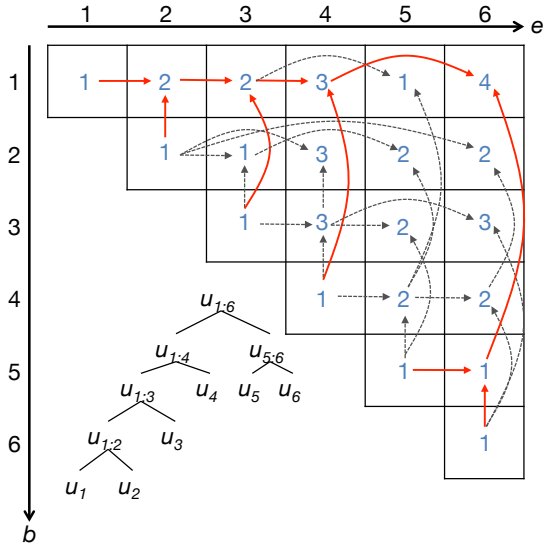

Figure 1: DP table and the RST tree-building.

	RST-DT	PCC

# of EDUs/Doc.	56.6	16.1
# of Sents./Doc.	22.5	11.4
# of Para./Doc.	9.99	2.10
# of EDUs/Sent.	2.51	1.41
# of EDUs/Para.	5.67	7.66

Table 1: Statistics of the datasets.

First, the algorithm builds a document tree (lines 1-2). Then, it builds paragraph trees for each paragraph (lines 3-6) and builds sentence trees for each sentence (lines 7-10). Finally, we obtain an RST tree for the whole document by connecting the trees.

By replacing the similarity score, sim(,) with the dissimilarity score, $1-\text{sim}(,)$, we can obtain the optimal tree in terms of the split score. When we use the split score, the span consisting of only two atomic units can be divided into two uniquely, without calculating the split score for the span. Therefore, we compute $V[b][e] = 1$ when $e - b < 2$, instead of when $b = e$, in Equation (4). In addition, Algorithm 1, from lines 17 to 18, must be modified.

3 Experiments

3.1 Experimental Setting

We evaluated our methods on two datasets, the English RST treebank, RST-DT and the German RST treebank, PCC. RST-DT has 347 training docu-

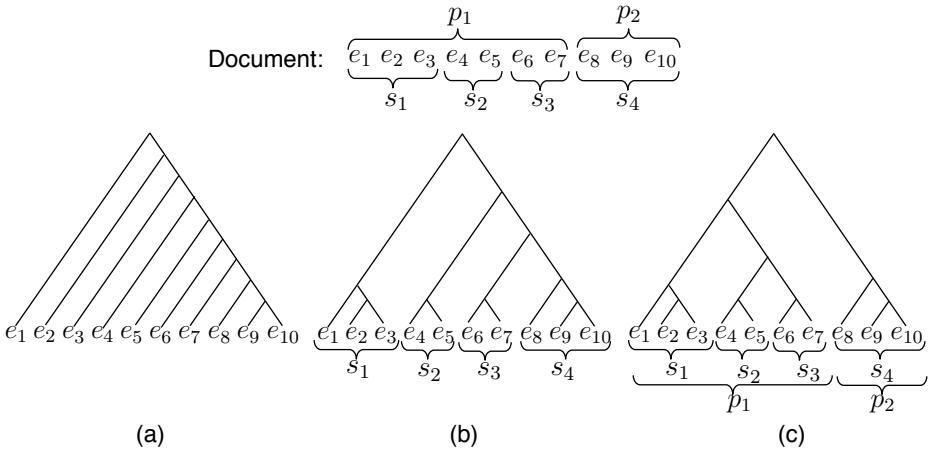

Figure 2: Right branching-trees of a document consists of ten EDUs, four sentences and two paragraphs. A right branching-tree with D2E setting (a), that with D2S2E setting (b) and that with D2P2S2E setting.

ments and 38 test documents. PCC[3] is smaller than RST-DT, and the number of documents is 174. We used the whole dataset as the test set on both datasets. Table 1 shows the statistics of the datasets. The numbers of paragraphs, sentences and EDUs per document for PCC are quite smaller than those for RST-DT.

We evaluated three variants of our methods, D2P2S2E, which is described in Algorithm 1, D2S2E, which employs two different granularity levels, *i.e.*, it regards a document as a span consisting of sentences and a sentence as a span consisting of EDUs, and D2E, which employs a single granularity level, *i.e.*, it regards a document as a span consisting of EDUs. To the best of our knowledge, there are no recent researches on unsupervised RST parsing, while we could find many on supervised RST parsing. As the result, we employed right-branching trees by merging the right most two spans, at each granularity level as baselines and compare those with ours. Figure 2 shows right branching trees at each granularity level. From the figure, we can see that the right-branching tree with two or three granularity, (b) and (c), have more complex structure than that with single granularity (a).

Since our unsupervised RST parsers can only construct unlabeled RST parse trees, we used only micro F_1 span score (Marcu, 2000) as an evaluation metric. Following previous studies, we conducted all the experiments on manually segmented EDUs.

[3]Since PCC contains two invalid RST trees, maz-12666 and maz-8838, we excluded them.

Dataset	Gran.	Split	Merge	RB
RST-DT	D2E	.602	**.656**	.545
	D2S2E	.755	**.788**	.751
	D2P2S2E	.793	**.811**	.803
PCC	D2E	.656	**.669**	.626
	D2S2E	.757	**.760**	.749
	D2P2S2E	.787	.784	**.789**

Table 2: Micro Span F_1 scores for RST-DT and PCC.

3.2 Results

Table 2 shows the evaluation results. Merge outperformed Split in most cases, and D2P2S2E achieved the best scores among our variants on both RST-DT and PCC. To clearly show the differences between our proposed method and RB, we performed significance tests, using paired bootstrap resampling (Koehn, 2004) at significance level=0.05. The results showed that there were significant differences between our method and RB at all the settings (D2E, D2S2E, D2P2S2E) for English, and at D2E and D2S2E for German, while there were no significant differences at D2P2S2E for German. The results imply that merging two adjacent spans and dividing with three granularity levels is suitable for unsupervised RST parsing. Comparing our methods with the baseline, right-branching (RB), we could find larger differences without considering the granularity levels of a document, whereas the differences became smaller by considering three granularity levels. In particular, right-branching

Method	Span F_1 score
Merge	.808
HHN16	.826
WLW17	.856

Table 3: Micro Span F_1 scores on the test set of RST-DT.

was slightly better than our method on PCC. We think the result was related to the right-heavy binary conversion of RST trees: RST trees with multi-nuclear relations were transformed into binary trees beforehand by applying the right-heavy branching procedure. As a result, RB obtains better scores when the number of documents whose RST trees contain the multi-nuclear relations is larger. In fact, the ratio of the documents whose RST trees contain multi-nuclear relations in PCC is 0.712, while that in RST-DT is 0.464. We can obtain the information of sentences boundaries in most cases, however, sometimes we cannot obtain the information of paragraph boundaries. Thus, it is significant that our method outperformed baselines on D2S2E settings.

Moreover, we compared our method with some supervised RST parsers on the test set of RST-DT. Table 3 shows the results. In the table, HHN16 denotes a simple transition-based RST parser (Hayashi et al., 2016), and WLW17 denotes a current state-of-the-art transition-based RST parser (Wang et al., 2017). Although the score of our method is lower than the scores of the supervised parsers, the score is close to that of HHN16. The results demonstrated the effectiveness of our unsupervised RST parsing method. For reference, (Braud et al., 2017) reported that their supervised RST parser obtained .802 span F_1 score on PCC. However, we cannot compare the score with our score because the test set differs from ours.

4 Conclusion

This paper proposed two kinds of unsupervised RST parsing methods based on dynamic programming that can build the optimal RST tree in terms of either a span splitting score or a span merging score. We regarded a document as a text span consisting of three different granularity levels and built trees at each level, a document tree, paragraph trees for each paragraph, and sentence trees for each sentence. Then, we obtained an RST tree by connecting all trees together. To the best of our knowledge, this is the first study on unsupervised RST parsing. The evaluation results on RST-DT and PCC showed the effectiveness of our proposal; the dynamic programming-based approach with the span merging score, exploiting three granularity levels in a document, achieved .811 and .784 span F_1 scores on RST-DT and PCC, respectively. The results are close to the traditional transition-based supervised parser.

Abstract

We apply BERT to coreference resolution, achieving strong improvements on the OntoNotes (+3.9 F1) and GAP (+11.5 F1) benchmarks. A qualitative analysis of model predictions indicates that, compared to ELMo and BERT-base, BERT-large is particularly better at distinguishing between related but distinct entities (e.g., President and CEO). However, there is still room for improvement in modeling document-level context, conversations, and mention paraphrasing. Our code and models are publicly available[1].

1 Introduction

Recent BERT-based models have reported dramatic gains on multiple semantic benchmarks including question-answering, natural language inference, and named entity recognition (Devlin et al., 2019). Apart from better bidirectional reasoning, one of BERT's major improvements over previous methods (Peters et al., 2018; McCann et al., 2017) is passage-level training,[2] which allows it to better model longer sequences.

We fine-tune BERT to coreference resolution, achieving strong improvements on the GAP (Webster et al., 2018) and OntoNotes (Pradhan et al., 2012) benchmarks. We present two ways of extending the c2f-coref model in Lee et al. (2018). The *independent* variant uses non-overlapping segments each of which acts as an independent instance for BERT. The *overlap* variant splits the document into overlapping segments so as to provide the model with context beyond 512 tokens. BERT-large improves over ELMo-based c2f-coref 3.9% on OntoNotes and 11.5% on GAP (both absolute).

A qualitative analysis of BERT and ELMo-based models (Table 3) suggests that BERT-large (unlike BERT-base) is remarkably better at distinguishing between related yet distinct entities or concepts (e.g., Repulse Bay and Victoria Harbor). However, both models often struggle to resolve coreferences for cases that require world knowledge (e.g., *the developing story* and *the scandal*). Likewise, modeling pronouns remains difficult, especially in conversations.

We also find that BERT-large benefits from using longer context windows (384 word pieces) while BERT-base performs better with shorter contexts (128 word pieces). Yet, both variants perform much worse with longer context windows (512 tokens) in spite of being trained on 512-size contexts. Moreover, the *overlap* variant, which artificially extends the context window beyond 512 tokens provides no improvement. This indicates that using larger context windows for pretraining might not translate into effective long-range features for a downstream task. Larger models also exacerbate the memory-intensive nature of span representations (Lee et al., 2017), which have driven recent improvements in coreference resolution. Together, these observations suggest that there is still room for improvement in modeling document-level context, conversations, and mention paraphrasing.

2 Method

For our experiments, we use the higher-order coreference model in Lee et al. (2018) which is the current state of the art for the English OntoNotes dataset (Pradhan et al., 2012). We refer to this as *c2f-coref* in the paper.

2.1 Overview of c2f-coref

For each mention span x, the model learns a distribution $P(\cdot)$ over possible antecedent spans Y:

[1] https://github.com/mandarjoshi90/coref

[2] Each BERT training example consists of around 512 word pieces, while ELMo is trained on single sentences.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5803–5808, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

$$P(y) = \frac{e^{s(x,y)}}{\sum_{y' \in Y} e^{s(x,y')}} \quad (1)$$

The scoring function $s(x, y)$ between spans x and y uses fixed-length span representations, $\mathbf{g_x}$ and $\mathbf{g_y}$ to represent its inputs. These consist of a concatenation of three vectors: the two LSTM states of the span endpoints and an attention vector computed over the span tokens. It computes the score $s(x, y)$ by the mention score of x (i.e. how likely is the span x to be a mention), the mention score of y, and the joint compatibility score of x and y (i.e. assuming they are both mentions, how likely are x and y to refer to the same entity). The components are computed as follows:

$$s(x, y) = s_m(x) + s_m(y) + s_c(x, y) \quad (2)$$
$$s_m(x) = \text{FFNN}_m(\mathbf{g_x}) \quad (3)$$
$$s_c(x, y) = \text{FFNN}_c(\mathbf{g_x}, \mathbf{g_y}, \phi(x, y)) \quad (4)$$

where $\text{FFNN}(\cdot)$ represents a feedforward neural network and $\phi(x, y)$ represents speaker and metadata features. These span representations are later refined using antecedent distribution from a span-ranking architecture as an attention mechanism.

2.2 Applying BERT

We replace the entire LSTM-based encoder (with ELMo and GloVe embeddings as input) in c2f-coref with the BERT transformer. We treat the first and last word-pieces (concatenated with the attended version of all word pieces in the span) as span representations. Documents are split into segments of `max_segment_len`, which we treat as a hyperparameter. We experiment with two variants of splitting:

Independent The *independent* variant uses non-overlapping segments each of which acts as an independent instance for BERT. The representation for each token is limited to the set of words that lie in its segment. As BERT is trained on sequences of at most 512 word pieces, this variant has limited encoding capacity especially for tokens that lie at the start or end of their segments.

Overlap The *overlap* variant splits the document into overlapping segments by creating a T-sized segment after every $T/2$ tokens. These segments are then passed on to the BERT encoder independently, and the final token representation is derived by element-wise interpolation of representations from both overlapping segments.

Let $\mathbf{r_1} \in \mathbb{R}^d$ and $\mathbf{r_2} \in \mathbb{R}^d$ be the token representations from the overlapping BERT segments. The final representation $\mathbf{r} \in R^d$ is given by:

$$\mathbf{f} = \sigma(\mathbf{w}^T[\mathbf{r_1}; \mathbf{r_2}]) \quad (5)$$
$$\mathbf{r} = \mathbf{f} \cdot \mathbf{r_1} + (\mathbf{1} - \mathbf{f}) \cdot \mathbf{r_2} \quad (6)$$

where $\mathbf{w} \in \mathbb{R}^{2d \times d}$ is a trained parameter and $[;]$ represents concatenation. This variant allows the model to artificially increase the context window beyond the `max_segment_len` hyperparameter.

All layers in both model variants are then fine-tuned following Devlin et al. (2019).

3 Experiments

We evaluate our BERT-based models on two benchmarks: the paragraph-level GAP dataset (Webster et al., 2018), and the document-level English OntoNotes 5.0 dataset (Pradhan et al., 2012). OntoNotes examples are considerably longer and typically require multiple segments to read the entire document.

Implementation and Hyperparameters We extend the original Tensorflow implementations of c2f-coref[3] and BERT.[4] We fine tune all models on the OntoNotes English data for 20 epochs using a dropout of 0.3, and learning rates of 1×10^{-5} and 2×10^{-4} with linear decay for the BERT parameters and the task parameters respectively. We found that this made a sizable impact of 2-3% over using the same learning rate for all parameters.

We trained separate models with `max_segment_len` of 128, 256, 384, and 512; the models trained on 128 and 384 word pieces performed the best for BERT-base and BERT-large respectively. As span representations are memory intensive, we truncate documents randomly to eleven segments for BERT-base and 3 for BERT-large during training. Likewise, we use a batch size of 1 document following (Lee et al., 2018). While training the large model requires 32GB GPUs, all models can be tested on 16GB GPUs. We use the cased English variants in all our experiments.

Baselines We compare the c2f-coref + BERT system with two main baselines: (1) the original ELMo-based c2f-coref system (Lee et al., 2018), and (2) its predecessor, e2e-coref (Lee et al.,

2017), which does not use contextualized representations. In addition to being more computationally efficient than e2e-coref, c2f-coref iteratively refines span representations using attention for higher-order reasoning.

3.1 Paragraph Level: GAP

GAP (Webster et al., 2018) is a human-labeled corpus of ambiguous pronoun-name pairs derived from Wikipedia snippets. Examples in the GAP dataset fit within a single BERT segment, thus eliminating the need for cross-segment inference. Following Webster et al. (2018), we trained our BERT-based c2f-coref model on OntoNotes.[5] The predicted clusters were scored against GAP examples according to the official evaluation script. Table 2 shows that BERT improves c2f-coref by 9% and 11.5% for the base and large models respectively. These results are in line with large gains reported for a variety of semantic tasks by BERT-based models (Devlin et al., 2019).

[5]This is motivated by the fact that GAP, with only 4,000 name-pronoun pairs in its dev set, is not intended for full-scale training.

3.2 Document Level: OntoNotes

OntoNotes (English) is a document-level dataset from the CoNLL-2012 shared task on coreference resolution. It consists of about one million words of newswire, magazine articles, broadcast news, broadcast conversations, web data and conversational speech data, and the New Testament. The main evaluation is the average F1 of three metrics – MUC, B^3, and $CEAF_{\phi_4}$ on the test set according to the official CoNLL-2012 evaluation scripts.

Table 1 shows that BERT-base offers an improvement of 0.9% over the ELMo-based c2f-coref model. Given how gains on coreference resolution have been hard to come by as evidenced by the table, this is still a considerable improvement. However, the magnitude of gains is relatively modest considering BERT's arguably better architecture and many more trainable parameters. This is in sharp contrast to how even the base variant of BERT has very substantially improved the state of the art in other tasks. BERT-large, however, improves c2f-coref by the much larger margin of 3.9%. We also observe that the *overlap* variant offers no improvement over *independent*.

Concurrent with our work, Kantor and Globerson (2019), who use higher-order entity-level representations over "frozen" BERT features, also report large gains over c2f-coref. While their feature-based approach is more memory efficient, the fine-tuned model seems to yield better results. Also concurrent, SpanBERT (Joshi et al., 2019), another self-supervised method, pretrains span representations achieving state of the art results (Avg. F1 79.6) with the *independent* variant.

256	73.9	76.9
384	73.4	77.3
450	72.2	75.3
512	70.7	73.6

Table 5: Performance on the English OntoNotes dev set with varying values for `max_segment_len`. Neither model is able to effectively exploit larger segments; they perform especially badly when `maximum_segment_len` of 512 is used.

4 Analysis

We performed a qualitative comparison of ELMo and BERT models (Table 3) on the OntoNotes English development set by manually assigning error categories (e.g., pronouns, mention paraphrasing) to incorrect predicted clusters.[6] Overall, we found 93 errors for BERT-base and 74 for BERT-large from the same 15 documents.

[6]Each incorrect cluster can belong to multiple categories.

Strengths We did not find salient qualitative differences between ELMo and BERT-base models, which is consistent with the quantitative results (Table 1). BERT-large improves over BERT-base in a variety of ways including pronoun resolution and lexical matching (e.g., *race track* and *track*). In particular, the BERT-large variant is better at distinguishing related, but distinct, entities. Table 3 shows several examples where the BERT-base variant merges distinct entities (like *Ocean Theater* and *Marine Life Center*) into a single cluster. BERT-large seems to be able to avoid such merging on a more regular basis.

Weaknesses An analysis of errors on the OntoNotes English development set suggests that better modeling of document-level context, conversations, and entity paraphrasing might further improve the state of the art.

Longer documents in OntoNotes generally contain larger and more spread-out clusters. We focus on three observations – (a) Table 4 shows how models perform distinctly worse on longer documents, (b) both models are unable to use larger segments more effectively (Table 5) and perform worse when the `max_segment_len` of 450 and 512 are used, and, (c) using overlapping segments to provide additional context does not improve results (Table 1). Recent work (Joshi et al., 2019) suggests that BERT's inability to use longer sequences effectively is likely a by-product pretraining on short sequences for a vast majority of updates.

Comparing preferred segment lengths for base and large variants of BERT indicates that larger

models might better encode longer contexts. However, larger models also exacerbate the memory-intensive nature of span representations,[7] which have driven recent improvements in coreference resolution. These observations suggest that future research in pretraining methods should look at more *effectively* encoding document-level context using sparse representations (Child et al., 2019).

Modeling *pronouns* especially in the context of conversations (Table 3), continues to be difficult for all models, perhaps partly because c2f-coref does very little to model dialog structure of the document. Lastly, a considerable number of errors suggest that models are still unable to resolve cases requiring *mention paraphrasing*. For example, bridging *the Royals* with *Prince Charles and his wife Camilla* likely requires pretraining models to encode relations between entities, especially considering that such learning signal is rather sparse in the training set.

5 Related Work

Scoring span or mention pairs has perhaps been one of the most dominant paradigms in coreference resolution. The base coreference model used in this paper from Lee et al. (2018) belongs to this family of models (Ng and Cardie, 2002; Bengtson and Roth, 2008; Denis and Baldridge, 2008; Fernandes et al., 2012; Durrett and Klein, 2013; Wiseman et al., 2015; Clark and Manning, 2016; Lee et al., 2017).

More recently, advances in coreference resolution and other NLP tasks have been driven by unsupervised contextualized representations (Peters et al., 2018; Devlin et al., 2019; McCann et al., 2017; Joshi et al., 2019). Of these, BERT (Devlin et al., 2019) notably uses pretraining on passage-level sequences (in conjunction with a bidirectional masked language modeling objective) to more effectively model long-range dependencies. SpanBERT (Joshi et al., 2019) focuses on pretraining span representations achieving current state of the art results on OntoNotes with the *independent* variant.

Linguistic Versus Latent Relations for Modeling Coherent Flow in Paragraphs

Dongyeop Kang Hiroaki Hayashi Alan W Black Eduard Hovy
Carnegie Mellon University, Pittsburgh, PA, USA
{dongyeok,hiroakih,awb,hovy}@cs.cmu.edu

Abstract

Generating a long, coherent text such as a paragraph requires a high-level control of different levels of relations between sentences (e.g., tense, coreference). We call such a logical connection between sentences as a (paragraph) *flow*. In order to produce a coherent flow of text, we explore two forms of inter-sentential relations in a paragraph: one is a human-created linguistical relation that forms a structure (e.g., discourse tree) and the other is a relation from latent representation learned from the sentences themselves. Our two proposed models incorporate each form of relations into document-level language models: the former is a supervised model that jointly learns a language model as well as discourse relation prediction, and the latter is an unsupervised model that is hierarchically conditioned by a recurrent neural network (RNN) over the latent information. Our proposed models with both forms of relations outperform the baselines in partially conditioned paragraph generation task. Our codes and data are publicly available[1].

1 Introduction

When composing multiple sentences into a paragraph, as in novels or academic papers, we often make design decisions in advance (Byrne, 1979) such as topic introduction and content ordering to ensure better coherence of the text. For instance, McKeown (1985); Swan (2002) proposed effective patterns for scientific writing: a hypothesis at first, followed by supporting sentences to validate the hypothesis, and lastly a concluding sentence. We call such a logical connection between sentences in a written paragraph as a *flow*. A coherent flow between sentences requires an understanding of various factors including tense, coreference, plans (Appelt, 1982; Hovy, 1991), scripts (Tomkins, 1978) and several others. We focus on the paragraph-level plan between sentences.

In text planning, underlying relations in text are broadly categorized into two forms: an explicit human-defined relation (e.g., a discourse tree) (Reiter and Dale, 2000) or an implicitly learned latent relation (Yang et al., 2016). While the former is defined and manuallly annotated based on linguistic theories, the latter is simply determinable from how people in fact put sentences together. In this work, we provide an empirical comparison between a linguistically-informed and a latent form of relations in context of a paragraph generation.

We compare the effectiveness of the two forms of relations using language modeling for paragraph generation. Due to the different characteristics of the two forms, we employ comparable but different components in addition to the base language model. For linguistic relations (e.g., discourse), we cast the problem into multi-task learning of supervised language modeling and discourse relation prediction. On the other hand, for latent relations, we learn an unsupervised hierarchical language model that is hierarchically conditioned by RNNs over linear operations between sentences.

We evaluate our models on partial paragraph generation task; producing the rest of text in a paragraph given some context of text. We observe that linguistically annotated discourse relations help produce more coherent text than the latent relations, followed by other baselines.

2 Related Work

There has been a variety of NLG systems that incorporate additional information between sentences (Appelt, 1982; Reiter and Dale, 2000; Gatt and Krahmer, 2018) which can be broadly categorized into two forms: linguistic and latent.

Linguistic relations are explicitly represented as external labels in the form of predefined rules or plans, formats, knowledge base, discourse parses, and more. Hovy (1985, 1990); Dalianis and Hovy (1996) integrated text planning in generation, where the plans are considered in knowledge, formatted rules and so forth. However, they are limited to small scale (i.e. few examples) and hand-written rules. Kang et al. (2017); Gardent et al. (2017); Kang et al. (2018b); Wang et al. (2018) used an external knowledge base to micro-planning for generating a corresponding text, while our work focuses on comparing two forms of relations from the text itself.

Moore and Paris (1993); Young and Moore (1994) utilized discourse structures such as rhetorical structure theory (RST) (Mann and Thompson, 1988) for parsing a document. A script (Tomkins, 1978) is another structured representation that describes a typical sequence of events in a particular context. Zhang et al. (2016); Ji and Eisenstein (2014) proposed better discourse parsers using neural networks. The prior works, however, used the discourse representations to describe the structure of the paragraph, while we focus on applicability of the discourse relations to language generation.

Latent relations use implicit information in a document such as hierarchical structure of the document: Lin et al. (2015); Chung et al. (2016) used hierarchical RNN for modeling a document. Similarly, the hierarchical model can be extended to other variants such as attention (Yang et al., 2016), encoder-decoder framework (Serban et al., 2017; Sordoni et al., 2015), auto-encoding (Li et al., 2015), and multiscale (Chung et al., 2016). However, the hierarchical recurrence of sentences, which is dependent on topics, are less likely modeling a flow of a document.

We further summarize the fundamental differences between the two forms of relations in Appendix.

3 FlowNet: Language Modeling with Inter-sentential Relations

We propose language models that incorporate each relation to capture a high-level flow of text.

3.1 Discourse-driven FlowNet

As a linguistic relation, we employ RST (Mann and Thompson, 1988) trees to represent discourse connections in the text. For simplicity, we limit usage of the discourse trees by only considering relations between adjacent phrases[2]: relations are inserted between adjacent phrases and represented as a flattened sequence of phrases and relations. If two consecutive RST relations are given, the deeper level of relation is chosen. If the central elementary discourse unit (EDU) or phrase is after its dependent, the relation is excluded. We consider each sequence of the flattened discourse relations as a writing flow. For example, people often write a text by elaborating basic information (`Elaboration`) and then describing a following statement attributed to the information (`Attribution`).

We view discourse relations as additional labels to predict at the same time we predict next words in language modeling. Specifically, we propose to jointly train a model that predicts a sequence of words and a sequence of RST labels by taking advantage of shared representations, following previous sequence labeling problems such as named entity recognition (Collobert et al., 2011) and part-of-speech tagging (Huang et al., 2015). Note that the RST relations are only used during training to obtain better representation for the two tasks, but not at test time.

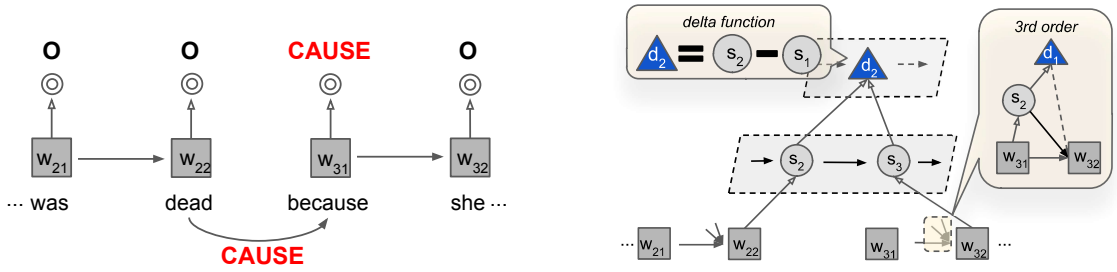

Figure 1(a) shows our FlowNet using discourse relations. Let a paragraph be a sequence of sentences D=$\{s_1, s_2, \ldots, s_M\}$. This model treats adjacent sentences as pairs for learning the standard seq2seq model. The first objective is to maximize the likelihood of the current sentence given the previous sentence. Hence, we maximize the following:

$$\mathbb{L}_{s2s} = \sum_j \log P(w_{ij} | w_{i,<j}, s_{i-1}) \qquad (1)$$

where s_i=$\{w_{i1}, w_{i2}, \ldots, w_{iT_i}\}$, and T_i is the number of tokens of s_i.

To better guide the model with discourse context, we use the shared representations to predict RST relations at the same time. For each paragraph, we run the pre-trained RST parser (Ji and Eisenstein, 2014) and flatten the parse tree to obtain RST relations for each sentence Y_i=$(y_1, \ldots, y_{K_i})$, where K_i is the number of discourse relations in s_i. We then make a label sequence over tokens in the sentence with

[2]The full discourse tree can be incorporated using other types of language model such as Tai et al. (2015).

(a) Discourse-driven (b) Delta-driven

Figure 1: FlowNet with linguistic (i.e., discourse) versus latent (i.e., delta) relation. (a) For each word, a form of discourse relation and next word are jointly predicted using CRF (◎) and language model, respectively. (b) Decoding w_i is conditioned on previous word (w_{i-1}), previous sentence (s_{i-1}), and delta between two previous sentences (d_{i-2}). Best viewed in color.

by placing y at the first word of EDUs and filling up the rest with a *null* relation o: $Y_i' = (o, \ldots, o, \mathbf{y_1}, o, \ldots, \mathbf{y_{K_i}}, o, \ldots, o)$. We incorporate a sequence labeling objective by employing conditional random field (Lafferty et al., 2001) to find the label sequence that maximizes the score function for each sentence s_i: $\mathbf{S}(s_i, Y_i') = \sum_{j=1}^{T_i-1} W^T_{y_j', y_{j+1}'} h_j + b_{y_j', y_{j+1}'}$ where h_j, W and b are the hidden representation of w_{ij}, weight matrix, and the bias vector corresponding to the pair of labels (y_i', y_{i+1}'), respectively. For training, we maximize the conditional likelihood:

$$\mathbb{L}_{CRF} = \mathbf{S}(s_i, y_i') - \sum_{\mathbf{y} \in \mathbb{Y}_x} \log \mathbf{S}(s_i, \mathbf{y}) \quad (2)$$

where $\mathbb{Y}_x$ represents all possible discourse label sequences. Decoding is done by greedily predicting the output sequence with maximum score. Both training and decoding can be computed using dynamic programming. The final objective is represented as the sum of two objective functions:

$$\mathbb{L}_{\texttt{disc}} = \mathbb{L}_{s2s} + \alpha * \mathbb{L}_{CRF} \quad (3)$$

where α is a scaling parameter to control the impact of CRF objective. The value is chosen empirically by searching based on validation set.

3.2 Delta-driven FlowNet

In this model, we aim to utilize latent representations to characterize the flow between sentences. Specifically we define *delta*, subtractions of hidden represenations of adjacent sentences as such latent information. Figure 1(b) shows how we hierarchically model different levels of information: words, sentences, and *deltas*.

Each word is encoded using a RNN encoder g_{word}. We take the last hidden representation of word as sentence embeddings $s_1, ..., s_M$. Similar to hierarchical RNN (Lin et al., 2015), each sentence representation is encoded using another RNN encoder g_{sent}. While discourse flow provides an explicit relation symbols, delta flow calculates a latent relation by subtracting previous representation s_{i-1} from current representation s_i[3]:

$$d(s_{i-1}, s_i) = d_{i-1} = s_i - s_{i-1} \quad (4)$$

Given a sequence of M-1 delta relations $d_1, ..., d_{M-1}$ for a paragraph of M sentences, we again encode them using another RNN encoder g_{delta}. The model takes the word, sentence and delta information altogether to predict the next (t-th) word in the m-th sentence:

$$h_t = f(h_{t-1}, x_t, s_{m-1}, d_{m-2}) \quad (5)$$

where x_t is a word representation, s_{m-1} is a sentence representation and d_{m-2} is a delta information. Note that sentence representation is from the previous sentence, and delta information is calculated by two previous sentences. If there is no previous information given, the parameters are randomly initialized.

4 Experiment

Due to the absence of goal-oriented language generation task, we collect paragraph data and define a new task of generating partial text of a paragraph given some context.

4.1 Data

We collect paragraphs from three different domains: `Papers` are paragraphs extracted from

[3]Our experiment includes a comparison among other types of linear operations between sentences such as addition or a learnable function.

	Train	Valid	Test
Papers	16,173	899	899
SciFi	157,031	8,724	8,724
Fantasy	317,654	17,649	17,649

Table 1: Number of paragraphs in our dataset.

academic manuscripts in computer science domain from the PeerRead (Kang et al., 2018a), and Fantasy and SciFi are paragraphs of two frequent categories extracted from the BookCorpus (Zhu et al., 2015), where paragraphs are extracted using the line breaker in the dataset.

We only use paragraphs whose lengths are from 4 to 7, in order to measure the performance change according to paragraph length. The dataset is randomly split by 0.9/0.05/0.05 for train, valid, and test set, respectively. Table 1 shows the numbers of paragraphs for each domain. All paragraphs are parsed into RST trees using the state-of-the-art discourse parser by Ji and Eisenstein (2014).

4.2 *Bridging*: Partial Paragraph Generation

We evaluate our models on partial text generation task; given a partial information (e.g., some sentences), producing the rest of text.

[1] Inside the club we moved straight for the bar. [2] Devlin ordered a beer for himself and a glass of my favorite wine for me. [3] I love that I didn't have to tell him what I wanted. [4] He knew me well and always thought about what I wanted or needed, in and out of bed.

Figure 2: Bridging task: given [1] and [4] sentences, guessing [2,3] sentences (red, underlined).

Figure 2 shows our bridging task. It requires a generation of masked sentences in the middle of a paragraph given the first and the last sentences. If only the first sentence is given, the generation can be too divergent. The existence of the last sentence makes the generation more coherent and converged to some point.

We evaluate it with one hard and one soft automatic metrics: METEOR (M) (Banerjee and Lavie, 2005) and VectorExtrema (VE) (Liu et al., 2016) by calculating cosine similarity of averaged word embeddings (Pennington et al., 2014), and human performance.

4.3 Models and Setup

We compare various baseline seq2seq models which encode the context; a concatenated first and last sentences, and decode the intermediate words: **S2S** is attentional seq2seq model (Bahdanau et al., 2014), and **HS2S**: is a hierarchical version of the S2S by combining two baselines: HRNN (Lin et al., 2015) hierarchically models sequence of words and sentences, and HRED (Serban et al., 2017; Sordoni et al., 2015) encodes the given context and decodes the words. **FlowNet (delta/disc.)** is our proposed language model with delta and discourse relations, respectively.

We find the best hyper-parameters on validation set using grid search. Here are the final parameters used: 32 for batch size, 25 for maximum sentence length, 300 for word embedding size initialized by GloVe (Pennington et al., 2014), 1 LSTM layer (Hochreiter and Schmidhuber, 1997) with 512 size, clipping by 0.25, 0.2 learning rate and 0.5 decay rate with Adagrad (Duchi et al., 2011) optimizer, and 50,000 for the vocabulary size. The total number of distinct discourse relations is 44.

4.4 Results

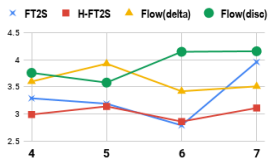
	Papers		SciFi		Fantasy	
	M	**VE**	**M**	**VE**	**M**	**VE**
S2S	3.7	56.3	3.5	71.0	3.3	66.3
HS2S	3.7	54.7	3.4	**73.0**	3.0	69.7
FlowNet (delta)	3.1	**58.5**	3.6	69.7	3.6	**73.9**
FlowNet (disc.)	**4.0**	57.2	**4.2**	70.3	**3.9**	71.8

Table 2: Performance on bridging task. **M**ETEOR and **V**ector**E**xtrema are used. The higher the better.

In Table 2, both discourse and delta driven FlowNet outperform the baseline models across most of the metrics except for VecterExtrema on SciFi. Especially, as the number of training size increases (Papers<<SciFi<Fantasy), the improvements gained from the FlowNet become bigger. This is probably because the model learns more information of the (discourse or latent) relations from the larger data.

	M	VE
SUBTRACT	3.35	**67.20**
ADD	**3.45**	65.35
MLP	3.32	62.97

Table 3: Comparison of different delta functions.



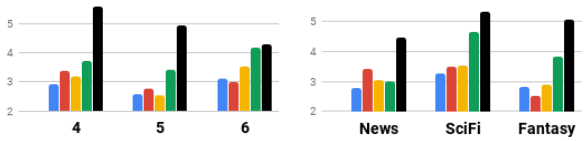


Figure 3: Comparison of paragraph lengths. Best viewed in color.

Table 3 shows performance comparison among different delta operations: SUBTRACT, ADD, and

FIRST: Satyrs never wear armor, including helmets, Newel began, using his hands expressively. **LAST**: Anyhow, as we actors were laying siege, a big chunk of the battlement dislodged from atop the tower.
REF: [M1] "But years ago I was in a play, and the helm was part of my costume. [M2] During the big battle scene, a few of us were assailing a castle. [M3] We had quite a set. [M4] The main tower must have been fifteen feet tall, fashioned from real stone. **HUMAN**: [M1] Actually he needed to wear any protectors to prevent him from a big accident. [M2] We planned to make a prank cam to make him wear those always. [M3] "I have a good idea," Newel kept talking continuously. [M4] "Let's play a role like we are under the attack.
S2S: [M1] he's a good man [M2] the UNK, the one who's a man who's a man and the other [M3] and the other, the one who 's a good friend [M4] he's a good man **HS2S**: [M1] i'm not sure that," he said [M2] i'm not sure that i'm not sure [M3] i'm not sure that i'm not a fool [M4] "i'm not sure that," he said **FLOWNET (DELTA)**: [M1] he's a good man [M2] i'm not sure what to do [M3] i'm not sure that i'm not going to be a vampire [M4] he's a good man **FLOWNET (DISC.)**: [M1] perhaps they were not quite good, but he was not a master, and they were the most powerful [M2] the only way to do not like a little, but i' d been in the world [M3] "you're right," he said "i am not a fool you're here [M4] you're going to be a bit more than the other

Table 4: An example paragraph and predicted texts in `Fantasy` dataset. Given **FIRST** and **LAST** sentences, the models generate middle sentences (e.g., [M1] → [M2]..). **REF** and **HUMAN** are reference middle sentences and sentences written by human annotator, respectively. Please find more examples in the appendix.

MLP which is a multi-layer perceptron network. All scores are macro-averaged across datasets. While ADD shows good performance on METEOR, SUBTRACT does on the soft metric (i.e., VecExt), indicating that subtraction can help the model capture the better semantics than the other functions. Figure 3 shows how performance changes on `Fantasy` as the paragraph lengths increase. Both of FlowNet achieve more improvements when generating longer paragraphs. Especially, discourse relations achieve the best performance at length 6 and 7.

(a) By paragraph lengths (b) By domains

Figure 4: Comparison (METEOR) with human performance (black bars): S2S (blue), HS2S (red), Flow:delta (yellow), and Flow:disc. (green). Best viewed in color.

We conduct a comparison with human performance (See Figure 4). We randomly choose 100 samples per dataset and per paragraph length and ask an annotator to perform the bridging task on the final 1,000 samples. Human outperforms the models by large margins. FlowNet with discourse relations outperforms the FlowNet with latent relations and other baselines by a large margin. As the paragraph length increases or more data is trained, discourse relations become more useful.

Table 4 shows an example paragraph with text produced by the models as well as reference and human annotation. Given only the partial context (i.e., first and last sentences), bridging task is very challenging even for human. The reference sentences and human annotations are semantically very different indeed. Among the latent models, FlowNet (delta) produces more coherent flow of text compared to S2S and HS2S. Surprisingly, FlowNet (discourse) enables generating more diverse sentences with a bit of coherence, because each sentence is generated based on the representation conditioned on the predicted RST discourse relation.

5 Conclusion and Discussion

We explore two forms of inter-sentential relations: linguistic relation such as discourse relations and a latent representation learned from the text. The proposed models for both relations achieve significant improvements over the baselines on partial paragraph generation task.

Despite the empirical effectiveness and difference between the linguistic and latent relations, they are not directly aligned for comparison. A potential direction for future study is to directly couple them together and see whether one form contains the other, or vice versa. Another direction is to check their effectiveness on top of the recent pre-trained language models.

Abstract

We propose new BERT-based methods for recognizing event causality such as "smoke cigarettes" → "die of lung cancer" written in web texts. In our methods, we grasp each annotator's policy by training multiple classifiers, each of which predicts the labels given by a single annotator, and combine the resulting classifiers' outputs to predict the final labels determined by majority vote. Furthermore, we investigate the effect of supplying background knowledge to our classifiers. Since BERT models are pre-trained with a large corpus, some sort of background knowledge for event causality may be learned during pre-training. Our experiments with a Japanese dataset suggest that this is actually the case: Performance improved when we pre-trained the BERT models with web texts containing a large number of event causalities instead of Wikipedia articles or randomly sampled web texts. However, this effect was limited. Therefore, we further improved performance by simply adding texts related to an input causality candidate as background knowledge to the input of the BERT models. We believe these findings indicate a promising future research direction.

1 Introduction

Event causality, such as "smoke cigarettes" → "die of lung cancer," is critical knowledge for NLP applications such as machine reading (Rajpurkar et al., 2016). For the task of recognizing event causality written in web texts, we propose new BERT-based methods that exploit independent labels in a gold dataset provided by multiple annotators. In the creation of the dataset we used (Hashimoto et al., 2014), three annotators independently labeled the data and the final labels were determined by majority vote. In the previous work, each annotator's independent judgments were ignored, but in our proposed method, we exploit each annotator's judgments in predicting the majority vote labels.

The dataset we used had a reasonable degree of inter-annotator agreement (Fleiss' Kappa value was 0.67), but a discrepancy remained among the annotators. Despite this discrepancy, we assume that their judgments are more or less consistent and that we can improve performance by training multiple classifiers, each from the labels provided by an individual annotator to grasp her/his policy, and by combining the resulting outputs of these classifiers.

Researchers have studied how to exploit the differences between the behaviors of annotators and crowd workers to improve the quality of gold datasets (Snow et al., 2008; Zaidan and Callison-Burch, 2011; Zhou et al., 2012; Jurgens, 2013; Plank et al., 2014; Jamison and Gurevych, 2015; Felt et al., 2016; Li et al., 2017). In an attempt that resembles ours, one study (Jamison and Gurevych, 2015) successfully improved the performance of several NLP tasks by computing the agreement ratio of each training instance and using only those instances with high agreement. Another work (Plank et al., 2014) improved part-of-speech tagging by measuring the inter-annotator agreement on a small number of sampled data and incorporating this value during training via a modified loss function. However, neither of them directly used each annotator's judgments, as we did in this work.

As another research direction, we also investigate how to appropriately exploit *background knowledge*. In previous work, text fragments such as binary patterns (e.g., "A causes B") and texts expressing causalities (e.g., "He died due to lung cancer") retrieved from large corpora were given to causality recognizers as background knowledge (Hashimoto et al., 2014; Kruengkrai et al., 2017), as well as association among words (Torisawa,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5816–5822,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

2006; Riaz and Girju, 2010; Do et al., 2011), semantic polarities (Hashimoto et al., 2012), answers obtained from a web-based open-domain why-QA system and other causality related texts (Kruengkrai et al., 2017), and causality-related word embeddings (Xie and Mu, 2019).

In this work, we investigate whether BERT (Devlin et al., 2019) (especially its pre-training) enables novel ways to exploit background knowledge. Our assumption is that if a BERT model is pre-trained using a large amount of causality-rich texts, it can learn some sort of background knowledge from the text. If the pre-training is adequately performed, background knowledge in the form of text fragments and a special mechanism for dealing with them might become obsolete. Our experimental results show that a BERT model pre-trained with causality-rich texts achieved significantly better performance than models using Wikipedia articles or randomly sampled web texts, both of which can be viewed as texts that do not specifically focus on causality. But the BERT model does not seem to sufficiently capture background knowledge, at least in our task setting. Further improvement is possible by simply concatenating, to an input causality candidate, text fragments related to it as background knowledge.

In our experiments, we show that our best method significantly outperformed a state-of-the-art method (Kruengkrai et al., 2017) by about 5% in average precision.

2 Proposed Method

We propose three BERT-based methods for event-causality recognition, and show an overview of them in Figure 1. All of the methods take input matrix $\mathbf{x}$, which represents an input causality candidate such as "smoke cigarettes" $\rightarrow$ "die of lung cancer," and obtain each annotator's labels (either *ProperCausality* or *NonProperCausality*), which are denoted by y^A, y^B, and y^C for three annotators A, B, and C, respectively. These are used for predicting final labels y^{MV}, which are determined by majority vote. Here, we assume that the dataset was labeled by three annotators, A, B and C, but extending the methods to deal with an arbitrary number of annotators is straightforward.

The proposed methods compute the probability $P(y^{\mathrm{MV}}|\mathbf{x})$ that a causality candidate represented by $\mathbf{x}$ expresses a proper event causality. We regard the candidate as proper if and only if $P(y^{\mathrm{MV}}|\mathbf{x}) > \theta$ ($\theta = 0.5$).

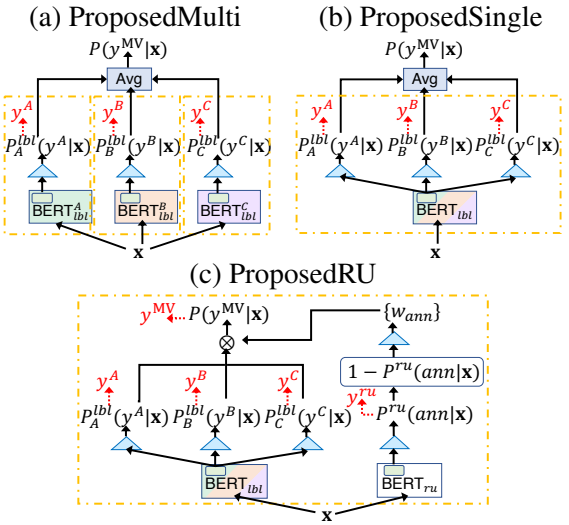

Figure 1: Proposed architectures, where red symbols (e.g., y^A) stand for gold labels used in training.

$$P(y^{\mathrm{MV}}|\mathbf{x}) = \sum_{ann} w_{ann} P^{lbl}_{ann}(y^{ann}|\mathbf{x}) \quad (1)$$

$$P^{lbl}_{ann}(y^{ann}|\mathbf{x}) = \mathrm{softmax}(\mathbf{W}_{ann}\mathrm{BERT}_{lbl}(\mathbf{x})) \quad (2)$$

$$P^{ru}(ann|\mathbf{x}) = \mathrm{softmax}(\mathbf{W}_D\mathrm{BERT}_{ru}(\mathbf{x})) \quad (3)$$

$$w_{ann} = \mathrm{softmax}_{ann}(1 - P^{ru}(ann|\mathbf{x})) \quad (4)$$

$\mathbf{W}_D \in \mathbb{R}^{3\times d}$ and $\mathbf{W}_{ann} \in \mathbb{R}^{2\times d}$ are trainable matrices, where d is size of hidden state in BERT models.

Table 1: Equations used in ProposedRU

ProposedMulti: The outputs of this method are achieved by an ensemble of three classifiers, each of which is independently trained (or, more precisely, fine-tuned) with the judgments of one of three annotators to mimic her/his judgments. The architecture of this method is shown in Figure 1(a) and consists of three pairs of a BERT model and a subsequent softmax layer, where each pair computes the probability $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$ of labels y^{ann} of each annotator $ann \in \{A, B, C\}$, in the same manner as Equation (2) in Table 1. Probability $P(y^{\mathrm{MV}}|\mathbf{x})$ of final label y^{MV} is the average of $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$.

ProposedSingle: This method uses multi-task learning in which each task corresponds to predicting labels given by one of the three annotators. The architecture of this method is shown in Figure 1(b) and consists of a single BERT model with three softmax layers, where the output of each softmax layer corresponds to an annotator's label. $P(y^{\mathrm{MV}}|\mathbf{x})$

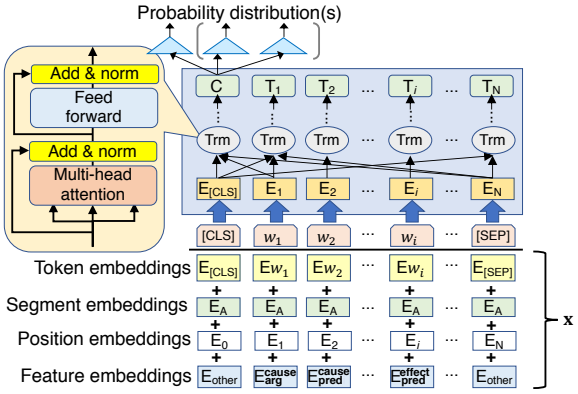

Figure 2: Proposed BERT architecture and its input $\mathbf{x}$

is computed in the same way as in **Proposed-Multi**.

ProposedRU: This method uses the **Proposed-Single** architecture, which consists of a BERT model (BERT_{lbl} in Figure 1(c)) and three softmax layers, to compute probability $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$ for annotator ann. We also add another BERT model (BERT_{ru}) and its subsequent softmax layer to the architecture to assign a lower weight to the predictions of an annotator who is likely to disagree with the majority vote. The entire computation is done using the equations in Table 1. Since each causality candidate is independently labeled by three annotators, at most one annotator disagrees with the majority vote label. To identify that annotator, BERT_{ru}, along with the softmax layer, estimates the probability $P^{ru}(ann|\mathbf{x})$ that annotator ann disagrees with the majority vote. We call this probability the *relative unreliability* of ann (Equation (3)). Instead of averaging $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$ as in **ProposedSingle**, **ProposedRU** uses the weighted sum of $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$ to predict the final label (Equation (1)). Weight w_{ann} is computed from $P^{ru}(ann|\mathbf{x})$ to consider the relative unreliability of ann (Equation (4))[1].

Representation $\mathbf{x}$ of the input causality candidate is computed from the entire sentence (e.g., "He smoked cigarettes and died of lung cancer caused by them") that contains a pair of cause phrase ("smoke cigarettes") and effect phrase ("died of lung cancer"). $\mathbf{x}$ consists of the token, position, and segment embeddings of each word (Devlin et al., 2019). We distinguish the words in the cause and effect candidates from the other words by giving them *feature embeddings*; the cause argument, the cause predicate, the effect argument, the effect predicate, and the other words are all given a different feature embedding vector that is randomly initialized (see Figure 2).

$$L = \alpha L^{\text{MV}} + \beta \sum_{ann} L^{lbl}_{ann} + \gamma L^{ru} \quad (5)$$

$$L^{\text{MV}} = -\log P(y^{\text{MV}}|\mathbf{x}) \quad (6)$$

$$L^{lbl}_{ann} = -\log P^{lbl}_{ann}(y^{ann}|\mathbf{x}) \quad (7)$$

$$L^{ru} = \begin{cases} 0 & \text{if } y^A = y^B = y^C \\ -\log P^{ru}(ann|\mathbf{x}) & \text{otherwise} \end{cases} \quad (8)$$

Table 2: Loss functions used in ProposedRU

Note that we followed the fine-tuning scheme presented in Devlin et al. (2019) in the training of **ProposedMulti** and **ProposedSingle**. For training **ProposedRU**, we designed a special loss function L in Equation (5) in Table 2 as the weighted sum of L^{MV}, L^{lbl}_{ann}, and L^{ru}, each of which is a loss function for $P(y^{\text{MV}}|\mathbf{x})$, $P^{lbl}_{ann}(y^{ann}|\mathbf{x})$, and $P^{ru}(ann|\mathbf{x})$, respectively. Here, α, β, and γ are hyper-parameters ($\alpha + \beta + \gamma = 1.0$).

The BERT model in our methods is pre-trained from scratch using causality-rich texts to investigate whether such BERT models can learn background knowledge during their pre-training. We used 19,567,386 sentences from 2,799,079 passages extracted from four billion web pages, where each passage consists of seven sentences and includes at least one event causality detected by a CRF-based causality recognizer[2] (Oh et al., 2013) (3,046,619 event causalities were detected in the passages).

We also introduce **ProposedRU+BK**, which integrates the background knowledge used in the previous work into **ProposedRU**. As input, **ProposedRU+BK** is given a *pseudo sentence*, which is the concatenation of the original input sentence and Kruengkrai et al. (2017)'s text fragments embodying background knowledge[3] along with a

[1] Note that this method is applicable only for the problem setting in which the final binary-class label is determined by using three annotators' labels. Some extension is needed for computing relative unreliability $P^{ru}(ann|\mathbf{x})$ for an arbitrary number of annotators by considering the probability that each annotator agrees with the majority.

[2] The recognizer was applied only to passages that were extracted by specifically focusing on clue terms such as "because." Event causalities recognized this way are a different type than those under focus in this work.

[3] We used all three types of text fragments from Krueng-

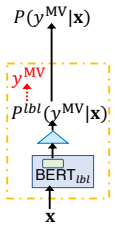
separator to compute input representation $\mathbf{x}$.

Here, we hypothesized that BERT models could learn some sort of background knowledge by using causality-rich texts in pre-training. To investigate whether this is true, we pre-trained several BERT models, each using either causality-rich texts or general texts, and then fine-tuned each of the models using the same architecture as used in **ProposedRU**. We introduce **ProposedRU$_{\text{wiki}}$** and **ProposedRU$_{\text{web}}$**, in which the pre-training is performed from scratch using a single corpus, that is, either Wikipedia articles (19,567,381 sentences retrieved in August 2018) or randomly sampled web texts (19,567,396 sentences in 1,990,472 web pages randomly sampled from the four billion web pages), respectively. The fine-tuning is then done as in **ProposedRU**.

In contrast to the above single-step pre-training, we also attempted to start from the pre-trained model for **ProposedRU$_{\text{web}}$**, which was pre-trained using general web text, and then additionally pre-train it with causality-rich texts to make the model suitable for causality-event recognition[4]. More precisely, to focus on the event causality part described in each passage, we extracted the pairs of cause and effect parts detected by Oh et al. (2013)'s CRF-based causality recognizer and used them as a causality-rich corpus while assuming that the cause and effect are sentence pairs for the next-sentence prediction task (9,783,691 pairs or 19,567,382 sentences). This model is called **ProposedRU$_{\text{web+pair}}$** hereafter.

For comparison, we also introduce **ProposedRU$_{\text{web+web}}$**, which uses another set of web sentences randomly sampled from four billion web pages, as a corpus of the general but not causality-rich texts. The size is the same as that of the cause-effect pairs used for **ProposedRU$_{\text{web+pair}}$**.

3 Experiments



3.1 Settings

We used the datasets for event-causality recognition in Japanese of Hashimoto et al. (2014). They regard causality candidate $A \rightarrow B$ proper if and only if "if A happens, the probability of B increases." To annotate this dataset, three annotators used their own judgment independently, and each annotator's individual labels are included in the datasets. Table 3 shows their statistics[5].

Data	#Instances	#True causalities
Training	107,068	8,986
Development	23,602	3,759
Test	23,650	3,647

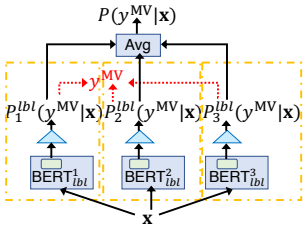


Table 3: Statistics of datasets

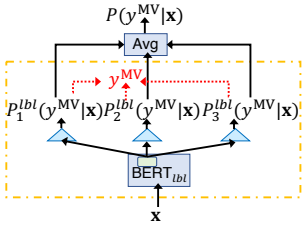
(d) VanillaBERT



We trained a single BERT model and its softmax layer with majority vote labels.

(e) MajorityMulti

The architecture is identical to **ProposedMulti**, but the training was performed with majority vote labels.

(f) MajoritySingle

The architecture is identical to **ProposedSingle**, but the training was performed with majority vote labels.

Figure 3: Baseline architectures

As baselines, we used the state-of-the-art method of Kruengkrai et al. (2017), **MCNN**, which uses a CNN and exploits text fragments retrieved from four billion web pages as background knowledge, and three BERT-based methods, **VanillaBERT**, **MajorityMulti**, and **MajoritySingle**, which use only majority vote labels (Figure 3). These BERT-based baselines used the same pre-trained BERT model (pre-trained with causality-rich texts) as in our proposed methods.

As the parameter settings of the pre-training for all of the BERT models, we followed the BERT$_{\text{BASE}}$ settings[6] (Devlin et al., 2019) except for a batch size of 50. For **ProposedRU$_{\text{web+pair}}$** and **ProposedRU$_{\text{web+web}}$**, we additionally pre-

krai et al. (2017) (i.e., short binary patterns, why-QA system's answers, and sentences with clue terms). Every text fragment was extracted from four billion Japanese web pages.

[4] This approach is recommended by Google's BERT implementation (https://github.com/google-research/bert) for computational efficiency.

[5] The number of training instances in Hashimoto et al. (2014)'s dataset was 112,098, but we excluded the duplicates in it and used the resulting 107,068 instances for training each method.

[6] 12-layers, 768 hidden states, 12 heads, and training for one million steps with a warmup rate of 1% using an Adam optimizer with a learning rate of 1e-4.

Model	R	P	F	Avg.P
MCNN	40.2	**61.1**	48.5	55.1
VanillaBERT	63.6	49.7	55.8*	54.2
MajorityMulti	61.5	51.8	56.2*	55.7
MajoritySingle	48.3	56.8	52.2*	54.4
ProposedMulti	63.9	51.3	56.9*	56.7
ProposeSingle	62.8	52.7	57.3*†	57.1
ProposedRU	**64.0**	52.0	**57.4***	**57.4**

'*' stands for significant improvement over MCNN and '†' means that over MajorityMulti (McNemar test, $p = 0.05$).

Table 4: Results of event-causality recognition

Model	R	P	F	Avg.P
ProposedRU$_{\text{wiki}}$	57.4	49.6	53.2$\star$	53.3
ProposedRU$_{\text{web}}$	59.0	50.9	54.6$\star$	54.5
ProposedRU	64.0	52.0	57.4	57.4
ProposedRU$_{\text{web+web}}$	62.5	49.0	54.9$\star$	54.8
ProposedRU$_{\text{web+pair}}$	64.3	48.2	55.1$\star$	55.3
ProposedRU+BK	**67.4**	**52.3**	**58.9**	**59.9**

'$\star$' stands for significant difference from ProposedRU.

Table 5: Results of ProposedRU and its variants

trained the models for 0.3 million steps with a learning rate of 2e-5. As for the fine-tuning, we chose the combination of epochs {1, 2, 3} and learning rates {5e-6, 1e-5, 2e-5, 3e-5, 4e-5, 5e-5} that achieved the best average precision on 50% of the development dataset, as done in Kruengkrai et al. (2017). For **ProposedRU** and its variants, we additionally optimized the α, β, and γ hyper-parameters in the same way.

3.2 Results

The recall, precision, F1-score, and average precision of each method on the majority vote labels of the test dataset are presented in Table 4. **ProposedRU** achieved the best F1-score and average precision. All of the proposed methods (**ProposedMulti**, **ProposedSingle**, and **ProposedRU**) outperformed all of the baseline methods (**MCNN**, **VanillaBERT**, **MajorityMulti**, and **MajoritySingle**) in average precision. This suggests that using each annotator's labels produced a positive effect. The F1-scores of **ProposedRU** and **ProposedSingle** were not significantly different (McNemar test, $p = 0.05$).

Table 5 shows the results of our investigation into the pre-training of some sort of *background knowledge*. Among the methods to be compared in Table 5, the first three methods (i.e., **ProposedRU$_{\text{wiki}}$**, **ProposedRU$_{\text{web}}$**, and **ProposedRU**) utilized a single-step pre-training from scratch, whereas the next two methods (**ProposedRU$_{\text{web+web}}$** and **ProposedRU$_{\text{web+pair}}$**) performed additional pre-training before the fine-tuning. The results show that pre-training using causality-rich texts contributes to further performance improvement than that using general texts, such as Wikipedia articles and random web texts (see **ProposedRU** vs. **ProposedRU$_{\text{wiki}}$**, **ProposedRU** vs. **ProposedRU$_{\text{web}}$**, and **ProposedRU$_{\text{web+pair}}$** vs. **ProposedRU$_{\text{web+web}}$**). In short, we can say that BERT might learn some sort of background knowledge from causality-rich texts. An interesting point is that, although the amount of texts used for **ProposedRU** is almost the same as that of the second-step causality-rich pre-training for **ProposedRU$_{\text{web+pair}}$**, the performance differs considerably (about 2% difference). This suggests that the design of the pre-training steps is not straightforward and thus merits further research.

We further evaluated **ProposedRU+BK**, in which text fragments embodying background knowledge are concatenated to the input sentence as explained in Section 2. Table 5 shows that **ProposedRU+BK** improved the average precision over **ProposedRU** by about 2.5% (i.e., **ProposedRU+BK** significantly outperformed the state-of-the-art method, **MCNN**, by about 5%), suggesting that background knowledge in the form of text fragments is still useful, at least in our current experimental setting. However, the usefulness might be lost when a model is appropriately pre-trained with a larger amount of texts that covers even more background knowledge.

4 Conclusion

This paper proposed BERT-based methods for recognizing event causality that exploit each annotator's independent judgments. By using each annotator's judgments, we showed that even a simple multi-task learning approach or an ensemble method improved performance in our experiments. Our best-performing method significantly outperformed the state-of-the-art method by about 5% in average precision. We also confirmed that the pre-trained BERT model learns some sort of background knowledge for event causality from causality-rich texts, although text fragments embodying background knowledge remain useful, at least in our current setting. As future work, we are examining the possibility of using an adversarial learning framework (Goodfellow et al., 2014), which was recently used in the why-QA task (Oh et al., 2019) for causality recognition.

Abstract

Memory neurons of long short-term memory (LSTM) networks encode and process information in powerful yet mysterious ways. While there has been work to analyze their behavior in carrying low-level information such as linguistic properties, how they directly contribute to label prediction remains unclear. We find inspiration from biologists and study the affinity between individual neurons and labels, propose a novel metric to quantify the sensitivity of neurons to each label, and conduct experiments to show the validity of our proposed metric. We discover that some neurons are trained to specialize on a subset of labels, and while dropping an arbitrary neuron has little effect on the overall accuracy of the model, dropping label-specialized neurons predictably and significantly degrades prediction accuracy on the associated label. We further examine the consistency of neuron-label affinity across different models. These observations provide insight into the inner mechanisms of LSTMs.

1 Introduction

In recent years, the application of deep learning to natural language processing (NLP) has been a success. Many consider the employment of distributed representations to be one of the reasons for deep learning's success (LeCun et al., 2015; Young et al., 2018). However, how these distributed representations encode information in deep neural networks, especially long short-term memory (LSTM) networks that are prevalent in NLP, still remains unclear (Feng et al., 2018). One of the potential ways to understand how neural networks function is to analyze the behavior of individual neurons that carry the distributed representation. While there have been a number of works that analyze low-level information stored in individual LSTM neurons, such as linguistic properties (Bau et al., 2019; Qian et al., 2016), syntax of source code (Karpathy et al., 2015), and sentiment (Radford et al., 2017), how each neuron contributes directly to the final classification layer remains unclear.

We find inspiration to analyze individual neurons of LSTMs from how biologists analyze neurons of roundworms (White et al., 1986). Biological neural systems consist of a huge number of neurons, and can react to the environment in complicated ways. Biologists start with analyzing basic components of reactions, what stimuli trigger them, and which neurons are excited during the process. To verify the relationship between stimuli, neurons, and reactions, biologists further dissect neurons which are correlated with specific basic reactions, and see if the reaction still occurs for the same stimuli.

We adopt the same methodology to study LSTMs, using a representative task in NLP: named-entity recognition (NER) (Ratinov and Roth, 2009; Lample et al., 2016). Even though the output of a neural network may be complicated, we focus on basic components of the output: whether a label is predicted or not. We feed into the neural model various input instances, and analyze the relationship between the value of each LSTM neuron and the predicted label. We quantify the sensitivity of neurons to each label, and study how label-specific information is distributed among all neurons. We discover that each individual neuron is specialized to carry information for a subset of labels, and the information of each label is only carried by a subset of all neurons. We further conduct experiments to gradually drop out individual neurons. This significantly lowers the accuracy of labels that the neuron is specialized on, while having little effect on the overall performance of the model. We also study the corre-

lation between labels, and discover some patterns that are shared among different models.

Our contributions are as follows: (1) To the best of our knowledge, we are the first to have taken this neuron-label affinity focused approach to understanding the inner workings of LSTMs. (2) We propose a novel metric to quantify such affinity, and conduct experiments to verify the validity and consistency of this metric.

2 Related Work

Recently, work has been done to analyze continuous representations in NLP. Shi et al. (2016) and Qian et al. (2016) analyze linguistic properties carried by representation vectors using external supervision. Bau et al. (2019) and Dalvi et al. (2019) further analyze linguistic information in individual neurons from neural machine translation representations in an unsupervised manner. For LSTMs of language models, Karpathy et al. (2015) identify individual neurons that trigger for specific information, such as bracket and sequence length, and Radford et al. (2017) discover neurons that encode sentiment information.

In computer vision, Zhou et al. (2018) analyze the relationship between individual units of a CNN and label prediction. To the best of our knowledge, however, in the field of NLP, there has been little work on analyzing the affinity between labels and neurons of recurrent networks. This paper aims to address this problem.

3 Model and Experiments

3.1 Model Selection

Named-entity recognition is a sequence labeling task. The input of the model is a sequence of words $x^{(t)}, t = 1, 2, \cdots$. Each input word has a corresponding label $z^{(t)} \in \mathcal{L}$, where $\mathcal{L}$ is the set of all labels $\{l_j\}, j = 1, 2, \cdots, m$. The label indicates whether the word is an entity or not, and if yes, which kind of entity it is.

A typical modern NER model consists of a bi-directional LSTM and a conditional random field (CRF) on top of the LSTM (Collobert et al., 2011; Huang et al., 2015). Sometimes there is also a convolutional neural network (CNN) (Ma and Hovy, 2016; Chiu and Nichols, 2016). However, the goal of this paper is not to achieve state-of-the-art performance on this task, but rather we are trying to understand the mechanisms of LSTMs. Therefore, we choose a relatively simple model (see Figure 1) for the experiments: a single layer uni-directional LSTM with a fully-connected layer on top of it.

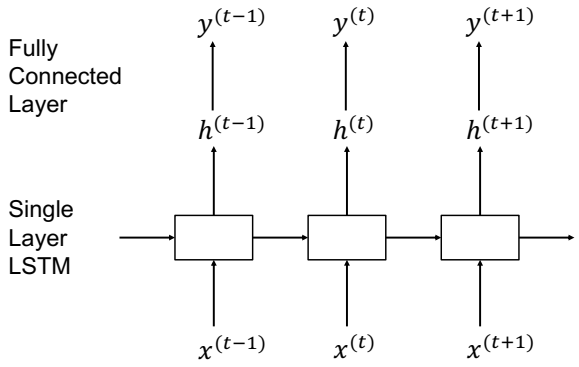

Figure 1: The model we use for this task: a single layer uni-directional LSTM with a fully-connect layer on top of the LSTM.

We denote $\mathbf{h}^{(t)} \in \mathbb{R}^n$ as the LSTM's hidden state at timestep t, and $\mathbf{h}_i^{(t)}$ its i-th entry. $\mathbf{W} \in \mathbb{R}^{n \times m}$ is the weight matrix of the fully-connected layer. The output of the entire model at timestep t is therefore the vector

$$\mathbf{y}^{(t)} = \text{Softmax}(\mathbf{W}^\top \mathbf{h}^{(t)}), \quad (1)$$

where $\mathbf{y}^{(t)} \in \mathbb{R}^m$ and each entry is the predicted probability of a label in $\mathcal{L}$:

$$\Pr(z^{(t)} = l_j) = \mathbf{y}_j^{(t)} \quad (2)$$

$$= \frac{\exp\left(\mathbf{W}_{:,j}^\top \mathbf{h}^{(t)}\right)}{\sum_{j'} \exp\left(\mathbf{W}_{:,j'}^\top \mathbf{h}^{(t)}\right)}, \quad (3)$$

where $\mathbf{W}_{:,j}^\top$ is the transpose of the j-th column vector of the matrix $\mathbf{W}$. The final prediction $\tilde{z}^{(t)}$ is chosen as the label with greatest probability.

3.2 Experiment Setup

The model is trained on the CoNLL2003 (Sang and De Meulder, 2003) training dataset. Development and test sets of CoNLL2003 will be used in experiments in Section 4. In this dataset there are nine labels in total, under the BIO tagging schema. See the first row of Figure 3 for the complete set of labels.

Code for this paper is adopted from the toolkit by Yang and Zhang (2018). We set the hidden size of the LSTM to 50, since a larger hidden size does not significantly improve the results. Other hyper-parameters, such as learning rate, batch size, and drop out rate, are kept unchanged. The model is trained for 10 epochs, and we pick the checkpoint

based on the best F1 score on the development set. The chosen checkpoint has an F1 score of 86.4. For comparison, the F1 score obtained by the same toolkit using a bi-directional LSTM and a CRF is 89.5 (Yang et al., 2018).

4 Analyzing Neuron-Label Affinity

In this section, we first identify important neurons by quantifying the sensitivity of a neuron to a label, and then verify the quantification by neuron ablation experiments.

4.1 Identifying Important Neurons

A neuron of an LSTM corresponds to an entry (dimension) of $\mathbf{h}^{(t)}$. For a certain label l_j, we try to identify neurons that are important for its prediction in the following way.

We define the *contribution* of the i-th neuron to the j-th label at timestep t as

$$u_{i,j}^{(t)} = \mathbf{W}_{i,j}\mathbf{h}_i^{(t)}. \quad (4)$$

Note that contribution is defined with the number after multiplied by $\mathbf{W}$ in the fully-connected layer. Therefore the contribution value itself is what matters, not its absolute value.

The *sensitivity* of the i-th neuron to the j-th label is further defined as

$$s_{i,j} = \mathbb{E}(u_{i,j}^{(t)}|\tilde{z}^{(t)} = l_j) - \mathbb{E}(u_{i,j}^{(t)}|\tilde{z}^{(t)} \neq l_j), \quad (5)$$

where $\mathbb{E}$ stands for taking average over t. This is the difference of the mean contribution over l_j entity words versus other words. The higher $s_{i,j}$ is, the more sensitive the i-th neuron is for predicting the label l_j.

We compute $s_{i,j}$ for all i and j pairs, and the average is done over the entire development set. A part of the results is shown in Figure 2, and the full results are shown in the appendix.

From the figure we can see that information is distributed across different neurons in a highly non-uniform way:

- Each neuron has a different sensitivity to different labels. Some neurons are only sensitive to one label, e.g., neuron #10 for B-MISC; some are sensitive to multiple labels, e.g., neuron #17 for B-LOC and I-MISC; some are even not sensitive to any, e.g., neuron #7.

- For each label, there are multiple neurons that are sensitive to it, as well as multiple neurons that are not.

From these, we can come to the conclusion that the prediction of each label is based on information that is distributed among multiple, but not all, neurons. Furthermore, different types of information are distributed differently.

For each label, we further rank all neurons based on their sensitivity, and obtain an *importance ranking* for the label. The top ten neurons for each label are shown in Figure 3, and the full results are shown in the appendix.

4.2 Verifying the Importance of Neurons

We try to verify whether the *sensitivity* we define in the previous subsection is a valid and consistent indicator of a neuron's importance for a label.

The way to do this is to perform model evaluation on the test set,[1] while incrementally ablating neurons[2] from the model, in a certain order. If the sensitivity of neurons we obtain is valid and consistent, when we ablate neurons in the order of *importance ranking* of the label l_j, the performance on the test set should drop fastest for predicting l_j, and slower for other labels.

We choose two pairs of labels: (B-PER, B-MISC) and (B-LOC, I-ORG). In each pair, we conduct neuron ablation according to each label's

[1] Recall that we obtain the value of sensitivity only from the development set.

[2] Ablating a neuron here means setting $\mathbf{h}_i^{(t)}$ to 0.

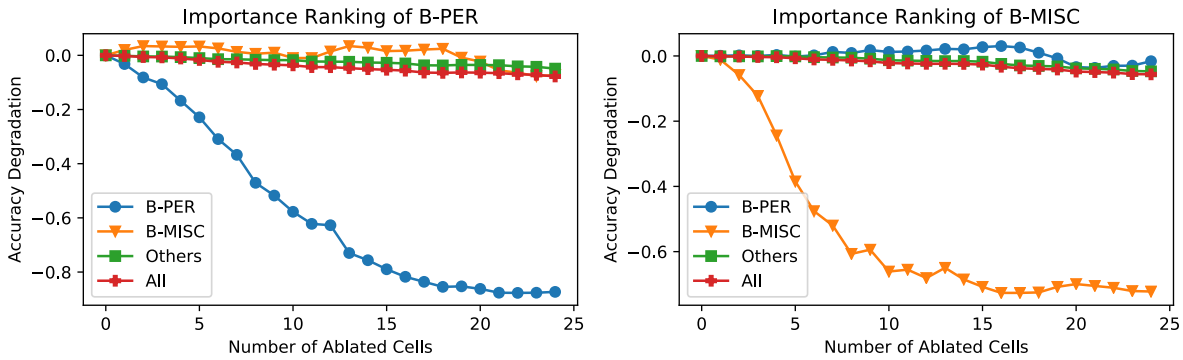

Figure 4: Ablation according to importance ranking of B-PER and B-MISC (yellow columns in Figure 3).

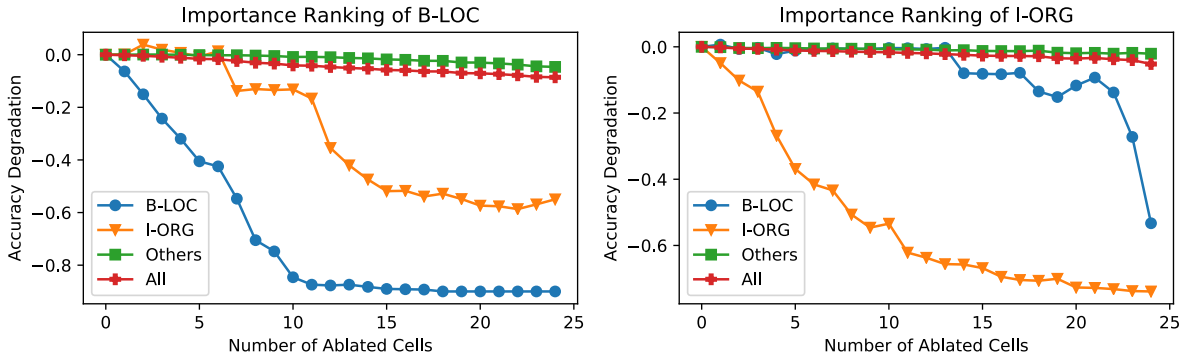

Figure 5: Ablation according to importance ranking of B-LOC and I-ORG (green columns in Figure 3).

importance ranking, and compare the model's performance for predicting each label. The results are shown in Figures 4 and 5. We only show the first half of the importance ranking, since the latter half not only is less important, but also has more overlap between different labels.

From the figures we can see that when ablating neurons according to a certain label's importance ranking, the accuracy of the label drops much faster than the other labels. The overall performance, however, remains more or less unaffected. This shows that while a single neuron can be important for a subset of labels, the overall performance is more robust to neuron ablation. This further verifies our observations from the previous subsection: information is distributed among multiple neurons in various ways. A neuron may have encoded important information for a certain label, but it is unlikely that all important information is concentrated in one neuron.

It is worth noting that a neuron can be important for multiple labels. Therefore, when ablating neurons according to one label's importance ranking, the performance for other labels may also degrade. This can be seen in the left plot of Figure 5. Neuron #38 appears in both the top ten lists of B-LOC and I-ORG (shaded boxes in Figure 3), and when it is ablated (the seventh ablated neuron), not only the performance of B-LOC, but also that of I-ORG, is compromised. The fourth ablated neuron in the right plot of Figure 5 has a similar behavior, but it is less significant, probably because this neuron is ranked seventh for B-LOC and is therefore less important than it is for I-ORG. This phenomenon is less significant in Figure 4, since the top neurons from importance rankings of B-PER and B-MISC have fewer overlaps.

4.3 Correlation Between Labels

Even though the distribution of information in neurons may seem arbitrary, we want to see if multiple, independently-trained models share any common traits.

In addition to the model we have used in previous sections, we train three more models with the same model architecture and hyperparameters but different random seeds. We compute neuron-label sensitivity for all four models using both develop-

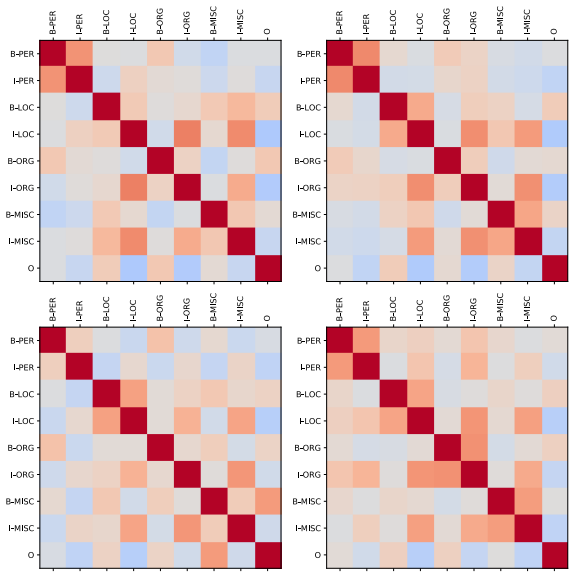

Figure 6: Correlation between all labels for four different models.

ment set and test set. For each of the models, we compute the correlation between all labels among different neurons. The sensitivity matrix for each model has 50 rows (neurons) and 9 columns (labels); see Figure 7 in the appendix for example. Correlation is computed among all rows in the matrix. The results are shown in Figure 6.

While there are differences among the four correlation plots, they share the following patterns:

- Label pairs of the form B-x and I-x (where x is PER/LOC/ORG/MISC) are generally positively correlated. We can observe some dark-red 2×2 blocks on the diagonal. Although for each trained model, it might be different neurons (i.e., neuron #) that encode information about B-x, these neurons typically also carry information about I-x.
- The label triples I-LOC, I-ORG, and I-MISC are also positively correlated.
- Label pairs of the form B-x and I-y (where x and y are different entities) are generally negatively correlated, e.g., I-PER with any of B-LOC, B-ORG, and B-MISC.
- The label O is negatively correlated with all I-x labels.

Although it remains unclear what information the neurons exactly encode, we speculate that there are at least two kinds of information, based on the observed patterns:

- Coarse-grain types of the current word. For example, whether the word is related to PER, or LOC/ORG/MISC, or O.
- Entity boundary location. If the previous prediction is O, it means the current word should be either another O or the left boundary of an entity, and thus the model should only predict O or B-x, but never I-x. Hence, I-x is negatively correlated with B-y and O.

5 Conclusion

In this paper, we try to understand the mechanisms of LSTMs by measuring and dissecting LSTM neurons. We discover that the prediction of each label is based on label-specific information, which is distributed among different groups of neurons. We propose a method to quantify and rank the importance of each neuron for each label, and further conduct ablation experiments to verify the validity and consistency of such importance rankings. Results show that the importance of a neuron is very different for different labels.

Future work. We consider the following three directions as future work. (1) While we now know how label-specific information is distributed among neurons and how important each neuron is to different labels, we can only make speculations about what the information is. It would be meaningful to study how the neurons are trained to encode label-specific information and what exactly the information is. (2) From the sensitivity figures, some neurons do not seem important to any label. It would be interesting to see what will happen if they are removed, and furthermore, how this can help model compression and hidden size selection. (3) Transformers (Vaswani et al., 2017; Devlin et al., 2019) have been increasingly popular in NLP, and it would be important to extend our work to understanding these architecture.

Abstract

Recurrent neural networks can learn to predict upcoming words remarkably well on average; in syntactically complex contexts, however, they often assign unexpectedly high probabilities to ungrammatical words. We investigate to what extent these shortcomings can be mitigated by increasing the size of the network and the corpus on which it is trained. We find that gains from increasing network size are minimal beyond a certain point. Likewise, expanding the training corpus yields diminishing returns; we estimate that the training corpus would need to be unrealistically large for the models to match human performance. A comparison to GPT and BERT, Transformer-based models trained on billions of words, reveals that these models perform even more poorly than our LSTMs in some constructions. Our results make the case for more data efficient architectures.

1 Introduction

Recurrent neural network language models (LMs) can learn to predict upcoming words with remarkably low perplexity (Mikolov et al., 2010; Jozefowicz et al., 2016; Radford et al., 2019). This overall success has motivated targeted paradigms that measure whether the LM's predictions reflect a correct analysis of sentence structure. One such evaluation strategy compares the probability assigned by the LM to a minimal pair of sentences differing only in grammaticality (Linzen et al., 2016). In the following example, the LM is expected to assign a higher probability to the sentence when the verb agrees in number with the subject (1a) than when it does not (1b):

(1) a. The author laughs.
b. *The author laugh.

RNN LMs have been shown to favor the grammatical variant in the vast majority of cases sampled at random from a corpus (Linzen et al., 2016), but their accuracy decreases in the presence of distracting nouns intervening between the head of the subject and the verb, especially when those nouns are in relative clauses (Marvin and Linzen, 2018). Can we hope to address these deficits by training larger and larger networks on larger and larger corpora, relying on the "unreasonable effectiveness" of massive datasets (Halevy et al., 2009) and computational power?[1] Or would architectural advances be necessary to improve our LMs' syntactic representations (Kuncoro et al., 2018)?

This paper takes a first step towards addressing this question. We train 125 RNN LMs with long short-term memory (LSTM, Hochreiter and Schmidhuber, 1997) units, systematically varying the size of the training corpus and the dimensionality of the models' hidden layer, and track the relationship between these parameters and the performance of the models on agreement dependencies in a range of syntactic constructions (Marvin and Linzen, 2018). We also compare our RNNs' accuracy to that of GPT (Radford et al., 2018) and BERT (Devlin et al., 2019), Transformer-based LMs trained on very large corpora.

We find that model capacity does not consistently improve performance beyond a minimum threshold. Increased corpus size likewise has a moderate and inconsistent effect on accuracy. We estimate that even if training data yielded consistent improvements, an unreasonable amount of data would be required to match human accuracy. We conclude that reliable and data-efficient learning of syntax is likely to require external supervision signals or a stronger inductive bias than that provided by RNNs and Transformers.

2 Language models

Architecture: All of the models we trained consisted of two LSTM layers. We trained models with 100, 200, 400, 800 or 1600 units in each hidden layer. Input and output weights were tied during training (Press and Wolf, 2017; Inan et al., 2017); consequently, the input embedding had the same dimensionality as the hidden layers.

Training data: We trained networks of each size on 2M, 10M, 20M, 40M and 80M words (2M = 2 million). We extracted five disjoint sections of the WikiText-103 corpus (Merity et al., 2016) for each corpus size;[2] in total, we trained 125 models (5 layer sizes $\times$ 5 corpus sizes $\times$ 5 corpus subsets).[3] We used the WikiText-103 validation set for validation.

Vocabulary: To ensure comparability across different models trained on different data, we used the same vocabulary for all the models we trained. The vocabulary consisted of an intersection of the 400k word GloVe vocabulary (Pennington et al., 2014) with the 50k words used by GRNN (see below); the resulting vocabulary had 28,438 words.

GRNN: We also report the syntactic performance of a publicly available LSTM LM (Gulordava et al., 2018, henceforth GRNN). This trained model has been the focus of a considerable amount of analysis work in the past year. The model has two layers of 650 units each, and was trained on 80M words.

Comparison with Transformers: Finally, we report results from two publicly available LMs based on non-recurrent self-attention (Transformers; Vaswani et al., 2017): GPT (Radford et al., 2018) and BERT (Devlin et al., 2019). Both of these models have been argued to learn powerful syntactic representations (Goldberg, 2019; Wolf, 2019). We compare our results to those reported by Wolf (2019) on a similar challenge set for these two Transformer models.[4]

GPT is a 12-layer Transformer with 110 million parameters (compared to GRNN's 39 million parameters); it was trained on 1 billion words. BERT has a similar architecture to GPT,[5] with three differences: it is bidirectional, it was trained on 3.3 billion words, and it has a different training objective than the typical LM: it attempts to predict a single masked word in a sentence given the words both before and after the target word. For comparability to the LSTMs and GPT, we examine the agreement performance of BERT when only the words before the target are given (in contrast to the bidirectional tests reported by Goldberg 2019).

3 Evaluation

We tested each trained model on the constructions from the Marvin and Linzen (2018) challenge set, which is based on the agreement paradigm described in the introduction.[6] We replaced the verbs used by Marvin and Linzen with the high-frequency verbs *is/are*, *was/were* and *has/have*. This was done to ensure that even the models trained on smaller corpora will have had exposure to both forms of the verb in question.

We performed statistical tests of our hypotheses using Bayes factors, which quantify the support the data provide for a more complex model compared to a simpler one (Rouder et al., 2009). We computed two-sample Bayes factors using `ttestBF` from the `BayesFactor` R package (Morey and Rouder, 2018) using default settings. Our null hypothesis was that there is no difference in accuracy between the two sets of models in question (e.g., all models with 400 units per layer compared to all models with 800 units per layer). The magnitude of the resulting Bayes factor K can be interpreted as follows (Jeffreys, 1961): $K < 1$ indicates that there is no difference in accuracy between the two model groups, and $K > 10$ provides strong evidence that the model groups obtain different accuracies.

4 Results

Increasing model size improved syntactic prediction accuracy up to 400 units per layer; further in-

[2] We made each of the 40M- and 80M-token training sets as disjoint as possible, but since Wikitext-103 only contains 103M tokens, it was not possible to make them wholly disjoint using Wikitext-103 as the mother corpus.

[3] Each model was initialized randomly and was trained to convergence with a dropout of 0.2 using a batch size of 20, backpropagating error for 35 observations. An initial learning rate of 20 was gradually annealed.

[4] The comparison is not exact because the Transformers were evaluated based on the rank of the two target verbs given the prefix, and the LSTMs based on the total log-probability of the sentence (including the final period); in addition, Wolf (2019) did not modify the dataset to use only high frequency verbs, as we describe in Section 3.

[5] BERT Base showed more accurate syntactic predictions than BERT Large (Goldberg, 2019), which has more parameters, so we only consider BERT Base.

Corpus size		Layer size	
2M → 10M	**5508.8**	100 → 200	**768.5**
10M → 20M	0.1	200 → 400	**63.5**
20M → 40M	**12.9**	400 → 800	0.2
40M → 80M	0.2	800 → 1600	0.1

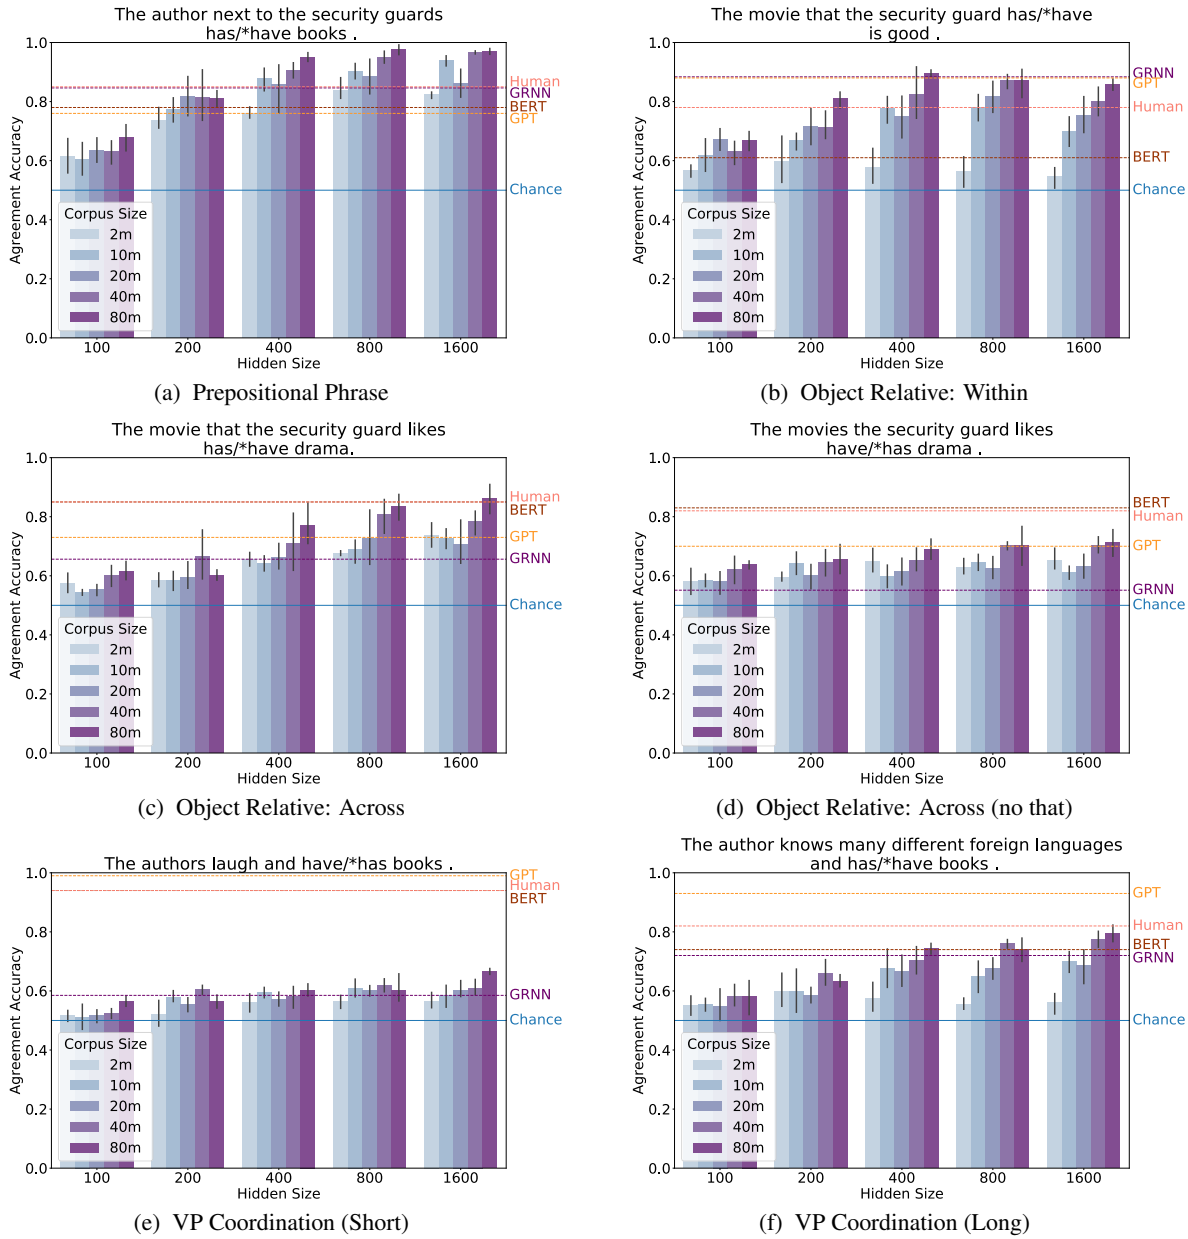
Table 1: Strength of evidence for improvements in agreement prediction accuracy as a result of increasing corpus size averaging across layer size (left) or layer size averaging across corpus size (right), as quantified by Bayes factors. Boldfaced Bayes factors indicate strong evidence of improvement.

creases in model size had no effect (see Table 1 for the statistical tests). Increasing the amount of training data impacted accuracy in an inconsistent way. Training on 10M tokens produced general improvements across all constructions compared to 2M tokens. Doubling the corpus to 20M did not affect accuracy, but doubling it again to 40M did. There was no evidence of further improvement between 40M and 80M words.

In the remainder of this section we analyze the effect of increasing model size and training corpus size on the models' predictions for each construction in the data set.[7] A subset of the results is shown in Fig. 1; for the full results, see Figs. 3, 4 and 5 in the Appendix.

Local number agreement: All models trained on 10M words or more obtained perfect or near-perfect accuracy (mean $> 99\%$) in the cases where the verb was adjacent to its subject: simple agreement (*the author has/*have books*) and agreement within a sentential complement (*the mechanics said the author has/*have books*). When trained on 2M words, the models performed slightly worse, but their accuracy was still very high (mean 95.6%), regardless of model size. Overall, we conclude that the plurality of specific nouns and the generalization that a verb has to agree with a noun can be learned very quickly.

Attractors: Agreement across subject relative clauses (*the author that likes the guards has/*have books*) and across prepositional phrases (*the author next to the guards has/*have books*; Fig. 1a) benefited from increasing the hidden layer size to 400, but showed little improvement when hidden layer size was increased further. Accuracy in these constructions consistently improved as the amount of training data increased.



Object relative clauses: Expanding the training corpus improved local agreement **within** object relative clauses (*the movies that the guard has/*have are good*; Fig. 1b) for all model sizes, but only improved agreement **across** those clauses (*the movie that the guards like has/*have drama*; Fig. 1c) in models with larger hidden layers. Larger hidden layers improved accuracy in object relatives only when a relativizer was present, and only up to about 80% accuracy. When a sentence lacked an overt relativizer (*the movies the security guard has/*have are good*; Fig. 1d), all models performed poorly, with accuracy levelling off around 70%.

Coordination: Perhaps surprisingly, all LSTM LMs struggled with agreement in a coordinated verb phrase (*the authors laugh and have/*has books*; Fig. 1e), even though this construction does not include distracting nouns between the subject and the second verb. In larger models trained on more data, accuracy was higher when the second verb was **further** from the subject (*the authors know many different languages and have/*has books*; Fig. 1f).

Training on more than 10M tokens did not improve accuracy in short VP coordination, even when the amount of data was multiplied by eight (10M → 80M: $K < 1$), unlike coordination across long VPs, which benefited from additional data (10M → 80M: $K > 90$). These results further challenge the assumption that increased amounts of training data will lead to adequately abstract syntactic representations: RNNs show a limited ability to generalize from instances of a construction that have longer constituents to instances with shorter constituents.

Reflexive anaphora: A reflexive pronoun such as *themselves* must have an antecedent with the appropriate plurality in the same clause as the pronoun (*The manager that the architects like doubted himself/*themselves*). Accuracy was not strongly affected by the parameters we varied: reflexive agreement accuracy across a relative clause was consistently mediocre (61%–76%) regardless of model size or the amount of training data.

[7] See Table 2 in the Appendix for a Bayes factor analysis of the improvement in each construction for each amount of training data.

(a) Prepositional Phrase

(b) Object Relative: Within

(c) Object Relative: Across

(d) Object Relative: Across (no that)

(e) VP Coordination (Short)

(f) VP Coordination (Long)

Figure 1: LSTM agreement performance in several syntactic constructions. The solid horizontal line indicates chance performance. The dashed lines show the performance of GPT and BERT as reported by Wolf (2019), the performance of humans as reported by Marvin and Linzen (2018), and the performance of GRNN. Error bars reflect standard deviation across the five models in each category.

Transformers: Despite having more parameters and having been trained on significantly larger corpora, the two Transformer models performed either as well as or more poorly than our LSTMs in seven of the ten subject-verb agreement conditions. BERT underperformed GPT in several conditions despite having been trained on three times as many tokens as GPT.[8]

5 How much data would be enough?

How much training data would be required for an LSTM LM to perform at a human level (as reported by Marvin and Linzen 2018) in the condi-

[8] Goldberg (2019) reports much better results using a setup in which BERT has access to both left and right context. We hypothesize that the task is made significantly simpler when the model knows where the target word is relative to the end of the sentence. For example, if the point of prediction is at the last word of the sentence, it is also the last point at which the verb agreeing with the main clause subject could possibly occur; the model does not need to detect the end of the relative clause to perform the task in this case.

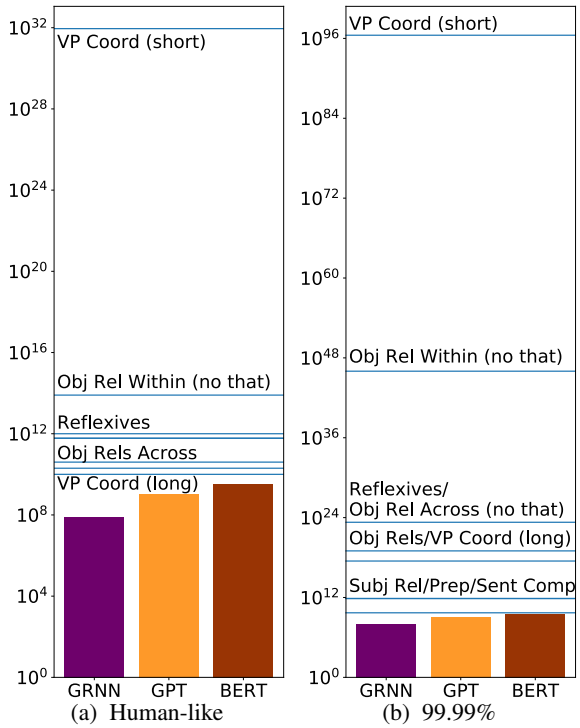


Figure 2: Lines depict number of training tokens needed for LSTMs to achieve human-like (left) or 99.99% accuracy (right) in each syntactic agreement condition, according to our estimates. Bars depict the amount of data on which each model was trained.

tions in which our models do not already perform at a human level? As a conservative estimate, we measured the error reduction achieved by doubling the data from 20M to 40M tokens (the largest error reduction we observed beyond 2M $\rightarrow$ 10M).[9] Under the assumption that each subsequent doubling of training data would produce the same percent error reduction, we predicted the amount of data required to obtain human-like and 99.99% accuracy (see Fig. 2).[10] We found that every remaining construction would require over 10 billion tokens to achieve human-like performance, and most would require trillions of tokens to achieve perfect accuracy – an impractically large amount of training data, especially for these relatively simple syntactic phenomena.

[9]See Tables 3 and 4 in the Appendix for data requirements estimated from other error reduction rates.

[10]Human performance on this task is well known to be far from perfect, with error rates approaching 25% in some contexts (Bock and Miller, 1991). While modeling human errors is of considerable interest to cognitive scientists (Linzen and Leonard, 2018), we believe that in most applied contexts it is desirable for the model to make no errors at all.

6 Discussion

We have investigated the effect of network size and training corpus size on the quality of the syntactic representations of LSTM LMs, as measured by agreement prediction accuracy. Increased model size had limited benefits; models with 400 hidden units performed significantly better than smaller models, but further increases in network size had no effect. The limited effect of network size is consistent with previous findings on sequence labeling tasks (Reimers and Gurevych, 2017; Greff et al., 2017). We have also shown that increasing the amount of training data is unlikely to result in human-like accuracy in all cases.

We found a striking difference in agreement accuracy between short and long coordinated verb phrases: performance on short phrases was poorer. While RNNs are known to struggle with generalizing short patterns to longer sequences, this pattern constitutes a failure to generalize to *shorter* sequences (cf. Trask et al., 2018); techniques for improving longer distance dependency learning in LMs (e.g., Trinh et al., 2018; Dai et al., 2019) are unlikely to mitigate this deficit. This suggests that challenge sets should include materials that can be used to ascertain whether the model's syntactic representations are robust to syntactically irrelevant factors such as constituent length.

GPT and BERT, Transformer models trained on very large corpora, did not consistently outperform the LSTMs trained on several orders of magnitude less data. Other studies suggest that Transformer models suffer from similar problems as the LSTMs we have analyzed. BERT's agreement accuracy decreases as the subject becomes more distant from its verb (Bacon and Regier, 2019). Dramatically increasing the pre-training corpus for a BERT-like model from 562M words to 18G words only leads to a modest improvement in its natural language inference accuracy, from 81.7% to 82.3% (Baevski et al., 2019). Overall, this body of results points to the limited data efficiency of standard RNNs and Transformers, and indicates that learning syntax from realistic amounts of data—in particular the amount of data available to humans when they learn language—may require syntactically structured architectures or explicit syntactic supervision (Enguehard et al., 2017; Kuncoro et al., 2018, 2019; Wilcox et al., 2019).

Abstract

Representational Similarity Analysis (RSA) is a technique developed by neuroscientists for comparing activity patterns of different measurement modalities (e.g., fMRI, electrophysiology, behavior). As a framework, RSA has several advantages over existing approaches to interpretation of language encoders based on probing or diagnostic classification: namely, it does not require large training samples, is not prone to overfitting, and it enables a more transparent comparison between the representational geometries of different models and modalities. We demonstrate the utility of RSA by establishing a previously unknown correspondence between widely-employed pretrained language encoders and human processing difficulty via eye-tracking data, showcasing its potential in the interpretability toolbox for neural models.

1 Introduction

Examining the parallels between human and machine learning is a natural way for us to better understand the former and track our progress in the latter. The "black box" aspect of neural networks has recently inspired a large body of work related to interpretability, i.e. understanding of representations that such models learn. In NLP, this push has been largely motivated by linguistic questions, such as: *what linguistic properties are captured by neural networks?* and *to what extent do decisions made by neural models reflect established linguistic theories?* Given the relative recency of such questions, much work in the domain so far has been focused on the context of models in isolation (e.g. *what does model* **X** *learn about linguistic phenomenon* **Y**?) In order to more broadly understand models' representational tendencies, however, it is vital that such questions be formed not only with other models in mind, but also other representational methods and modalities (e.g. behavioral data, fMRI measurements, etc.). In context of the latter concern, the present-day interpretability toolkit has not yet been able to afford a practical way of reconciling this.

In this work, we employ Representational Similarity Analysis (RSA) as a simple method of interpreting neural models' representational spaces as they relate to other models and modalities. In particular, we conduct an experiment wherein we investigate the correspondence between human processing difficulty (as reflected by gaze fixation measurements) and the representations induced by popular pretrained language models. In our experiments, we hypothesize that there exists an overlap between the sentences which are difficult for humans to process and those for which per-layer encoder representations are least correlated.

Our intuition is that such sentences may exhibit factors such as low-frequency vocabulary, lexical ambiguity, and syntactic complexity (e.g. multiple embedded clauses), etc. that are uncommon in both standard language and, relatedly, the corpora employed in training large-scale language models. In the case of a human reader, encountering such a sentence may result in a number of processing delays, e.g. longer aggregate gaze duration. In the case of a sentence encoder, an uncommon sentence may lead to a degradation of representations in the encoder's layers, wherein a lower layer might learn to encode vastly different information than a higher one. Similarly, different models' representations may emphasize different aspects of these more complex sentences and therefore diverge from each other. With this in mind, our hypothesis is that sentences which are difficult for humans to process are likely to have divergent representations within models' internal layers and between different models' layers.

Understanding and analysing language encoders In recent years, some prominent efforts towards interpreting neural networks for NLP have included: developing suites that evaluate network representations through performance on downstream tasks (Conneau et al., 2017a; Wang et al., 2018; McCann et al., 2018); analyzing network predictions on carefully curated datasets (Linzen et al., 2016; Marvin and Linzen, 2018; Gulordava et al., 2018; Loula et al., 2018; Dasgupta et al., 2018; Tenney et al., 2018); and employing diagnostic classifiers to assess whether certain classes of information are encoded in a model's (intermediate) representations (Adi et al., 2016; Chrupała et al., 2017; Hupkes et al., 2017; Belinkov et al., 2017).

While these approaches provide valuable insights into how neural networks process a large variety of phenomena, they rely on decoding accuracy as a probe for encoded linguistic information. If properly biased, this means that they can detect whether information is encoded in a representation or not. However, they do not allow for a direct comparison of representational structure between models. Consider a toy dataset of five sentences of interest and three encodings derived from quite different processing models; a hidden state of a trained neural language model, a *tf-idf* weighted bag-of-words representation, and measurements of fixation duration from an eye-tracking device. Probing methods do not allow us to quantify or visualise, for each of these encoding strategies, how the encoder's responses to the five sentences relate to each other. Moreover, probing methods would not directly reveal whether the fixations from the eye-tracking device aligned more closely with the tf-idf representation or the states of the neural language model. In short, while probing classifier methods can establish if phenomena are separable based on the provided representations, they do not tell us about the overall geometry of the representational spaces. RSA, on the other hand, provides a basis for higher-order comparisons between spaces of representations, and a way to visualise and quantify the extent to which they are isomorphic.

Indeed, RSA has seen a modest introduction within interpretable NLP in recent years. For example, Chrupała et al. (2017) employed RSA as a means of correlating encoder representations of speech, text, and images in a post-hoc analysis of a multi-task neural pipeline. Similarly, Bouchacourt and Baroni (2018) used the framework to measure the similarity between input image embeddings and the representations of the same image by an agent in an language game setting. More recently, Chrupała and Alishahi (2019) correlated activation patterns of sentence encoders with symbolic representations, such as syntax trees. Lastly, similar to our work here, Abnar et al. (2019) proposed an extension to RSA that enables the comparison of a single model in the face of isolated, changing parameters, and employed this metric along with RSA to correlate NLP models' and human brains' respective representations of language. We hope to position our work among this brief survey and further demonstrate the flexibility of RSA across several levels of abstraction.

2 Representational Similarity Analysis

RSA was proposed by Kriegeskorte et al. (2008) as a method of relating the different representational modalities employed in neuroscientific studies. Due to the lack of correspondence between the activity patterns of disparate measurement modalities (e.g. brain activity via fMRI, behavioural responses), RSA aims to abstract away from the activity patterns themselves and instead compute representational dissimilarity matrices (RDMs), which characterize the information carried by a given representation method through dissimilarity structure.

Given a set of representational methods (e.g., pretrained encoders) M and a set of experimental conditions (sentences) N, we can construct RDMs for each method in M. Each cell in an RDM corresponds to the dissimilarity between the activity patterns associated with pairs of experimental conditions $n_i, n_j \in N$, say, a pair of sentences. When $n_i = n_j$, the dissimilarity between an experimental condition and itself is intuitively 0, thus making the $N \times N$ RDM symmetric along a diagonal of zeros (Kriegeskorte et al., 2008).

The RDMs of the different representational methods in M can then be directly compared in a Representational *Similarity* Matrix (RSM). This comparison of RDMs is known as second-order analysis, which is broadly based on the idea of a *second-order isomorphism* (Shepard and Chipman, 1970). In such an analysis, the principal point of comparison is the match between the dissimilarity structure of the different representa-

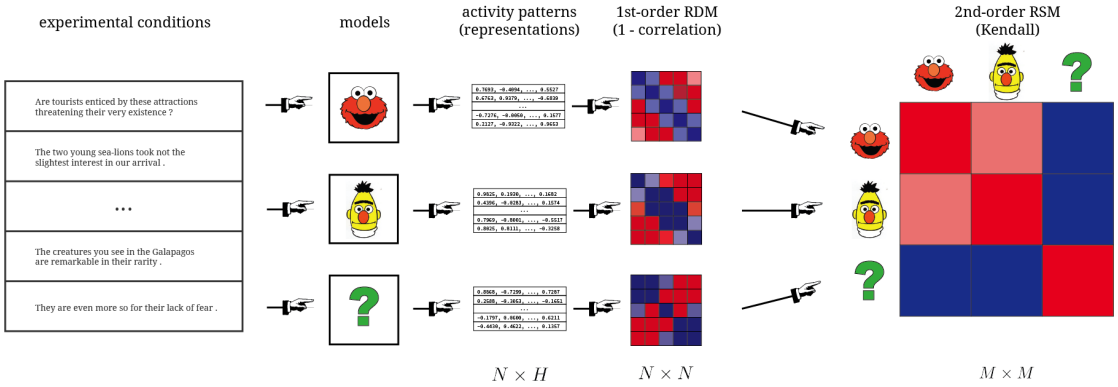

Figure 1: An example of first- and second-order analyses, where $N = \#$ of experimental conditions, $M = \#$ of models, and $H = \#$ of activity patterns observed for a given model (i.e. dimensionality). The right-most side of the figure depicts a representational similairty matrix (RSM) of correlations between RDMs.

tional methods. Intuitively, this can be expressed through the notion of *distance between distances*, and is thus related to Earth Mover's Distance (Rubner et al., 2000).[1] Figure 1 shows an illustration of the first and second order analyses for pretrained language encoders.

Note that RSA is meaningfully different from, and complementary to, methods that employ saturating functions of representation distances (e.g. decoding accuracy, mutual information), which suffer from **(a)** a ceiling effect: being able to distinguish experimental phenomenon A from B with with an accuracy of 100% and experimental phenomenon C from D with an accuracy of 100% does not mean that the distance between A and B is the same as that between C and D; and **(b)** discretization (Nili et al., 2014).

We follow Kriegeskorte et al. (2008) in using the correlation distance of experimental condition pairs $n_i, n_j \in N$ as a dissimilarity measure, where $\bar{n_i}$ is the mean of n_i's elements, $\cdot$ is the dot product, and $\|$ is the l_2 norm: $corr(x) = 1 - \frac{(n_i - \bar{n_i}) \cdot (n_j - \bar{n_j})}{\|(n_i - \bar{n_i}\|_2 \|(n_j - \bar{n_j}\|_2}$. Compared to other measures, correlation distance is preferable as it normalizes both the mean and variance of activity patterns over experimental conditions. Other popular measures include the Euclidean distance and the Malahanobis distance (Kriegeskorte et al., 2006).

3 Fixation Duration and Encoder Disagreement

Gaze fixation patterns have been shown to strongly reflect the online cognitive processing demands of human readers (Raney et al., 2014; Ashby et al., 2005) and to be dependent upon a number of linguistic factors (Van Gompel, 2007). Specifically, it has been demonstrated that word frequency, syntactic complexity, and lexical ambiguity play a strong part in determining which sentences are difficult for humans to process (Rayner and Duffy, 1986; Duffy et al., 1988; Levy, 2008).

Using the RSA framework, we aim to explore how gaze fixation patterns and the linguistic factors associated with sentence processing difficulty relate to the representational spaces of popular language encoders. Namely, we hypothesize that, for a given sentence, disagreement between hidden layers corresponds to processing difficulty. Because layer disagreement for a sentence measures the extent to which two layers (e.g. within BERT) disagree with each other about the pairwise similarity of the sentence (with other sentences in the corpus), a sentence with high layer disagreement will have unstable similarity relationships to other sentences in the corpus. This indicates that it has a degraded encoder representation. Going further, we also hypothesize that models' representations of said sentences may be confounded, in part, by factors that are known to influence humans.

Eye-tracking data For our experiments, we make use of the Dundee eye-tracking corpus (Kennedy et al., 2003), the English part of which consists of eye-movement data recorded as 10 native participants read 2,368 sentences from 20 newspaper articles. We consider the following fixation features: TOTAL FIXATION DURATION and FIRST PASS DURATION. For each of the features, we first take the average of the measurements recorded for all 10 participants per word, then ob-

[1] More precisely, our measure of dissimilarity between experimental conditions is analogous to *ground distance* and dissimilarity between RDMs to *earth mover's distance.*

tain sentence-level annotations by summing the measurements of all words in a sentence and dividing by its length. The result of this is two vectors V_{totfix} and $V_{firstpass}$ of length $2,368$, where each cell in the vector corresponds to a sentence's average total fixation and average first pass duration, respectively.

Syntactic complexity, word frequency, and lexical ambiguity We also consider the three following linguistic features which affect processing difficulty. For each of the following the result is also a vector of length $2,368$ where each cell corresponds to a sentence:

a. the average word log frequency per sentence extracted from the British National Corpus (Leech, 1992), $V_{logFreq.}$.

b. the average number of senses per word per sentence extracted from WordNet (Miller, 1995), $V_{wordSense}$.

c. Yngve scores, a standard measure of syntactic complexity based on cognitive load (Yngve, 1960) , V_{Yngve}.

Pretrained encoders We conduct our analysis on pretrained BERT-large (Devlin et al., 2018) and ELMo (Peters et al., 2018), two widely employed contextual sentence encoders. To obtain a representation of a sentence from a given layer L, we perform mean-pooling over the time-steps which correspond to the words of a sentence, obtaining a vector representation of the sentence. Mean-pooling is a common approach for obtaining vector representations of sentences for downstream tasks (Peters et al., 2018; Conneau et al., 2017b). We refer to ELMo's lowest layer as E1, BERT's 11th layer as B11, etc.

RDMs We construct an RDM (see §2) for each contextual encoder's layers. Each RDM is a $2,368 \times 2,368$ matrix which represents the dissimilarity structure of the layer, (i.e., each row vector in the matrix contains the dissimilarity of a given sentence to every other sentence). We then compute the correlations between the two different RDMs. For our evaluation of how well the representational geometry of a layer correlates to another, we employ Kendall's τ_A as suggested in Nili et al. (2014), computing the pairwise correlation for each two corresponding rows in two RDMs. This second-order analysis gives us a pairwise relational similarity vector $V_{Corr_{L_i-L_j}}$ of length $2,368$, which has the correlations between two layers L_i and L_j's RDMs for each of the sentences.

Third-order analysis The final part of our analysis involves computing correlations (Spearman's ρ) of $\{V_{Corr_{L_i-L_j}}, V_{logFreq}, V_{Yngve}, V_{wordSense}\}$ with each of V_{totfix} and $V_{firstpass}$. The results from this are shown in Table 1. The top section of the table shows correlations when L_i and L_j are the three final adjacent layers in BERT and ELMo. The middle section shows the results for top three BERT layer pairs L_i and L_j which maximize the correlation scores. The final section shows correlation with the linguistic features. Finally, Figure 2 shows Spearman's ρ correlations between $V_{Corr_{L_i-L_j}}$ and each of V_{totfix}, and V_{Yngve} for all combinations of the 24 BERT layers.

4 Discussion

Our results show highly significant negative correlations between $V_{Corr_{L_i-L_j}}$ and sentence gaze fixation times. These findings confirm the hypothesis that the sentences that are most challenging for humans to process, are the sentences **(a)** the layers of BERT disagree most on among themselves; and **(b)** that ELMo and BERT disagree most on, indicating that there may be common factors which affect human processing difficulty and result in disagreement between layers. By Layer disagreement we refer to the expression $1 - V_{Corr_{L_i-L_j}}$. It is important to note that these encoders are trained with a language modelling objective, unlike models where reading behaviour is explicitly modelled (Hahn and Keller, 2016) or predicted (Matthies and Søgaard, 2013). Indeed, the similarities here emerge naturally as a function of the task being performed. This can be seen as analogous to the case of similarities observed between neural networks trained to perform object recognition and spatio-temporal cortical dynamics (Cichy et al., 2016).

Syntactic complexity Figure 2 shows that, for all combinations of BERT layers, total fixation time and Yngve scores have strong negative and positive correlations (respectively) with layer disagreement. Furthermore, we observe that disagreement between middle layers seems to show the strongest correlation with Yngve scores. To confirm this, we split the correlations into four groups: "low" ($i, j \in [1, 8]$), "middle" ($i, j \in$

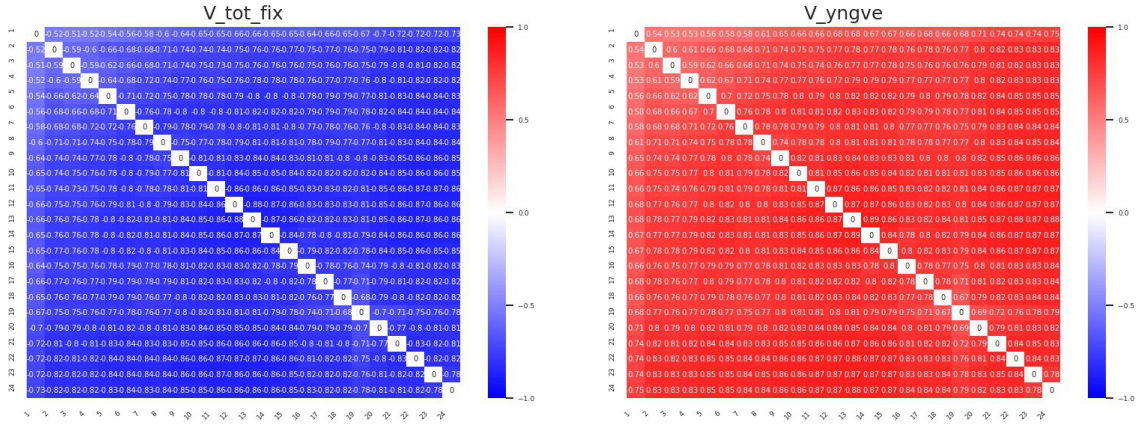

Figure 2: RSMs showing (Spearman's ρ) correlation between disagreement among layers i and j ($V_{Corr_{L_i-L_j}}$) and V_{totfix} (left) and V_{Yngve} (Right). BERT layers are denoted with numbers from 1 (topmost) to 24 (lowest).

Layer Disagreement	Total Fixation	First Pass Duration
E1-B22	-0.46	-0.46
E2-B23	-0.66	-0.67
E3-B24	-0.22	-0.23
B11-B12	-0.88	-0.87
B12-B13	-0.87	-0.85
B10-B21	-0.87	-0.86
Linguistic Features		
Log Freq.	-0.20	-0.19
Avg. Senses per Word	-0.007*	-0.004*
Yngve Score	0.66	0.66

Table 1: Spearman's ρ between $V_{Corr_{L_i-L_j}}$, $V_{logFreq.}$, $V_{wordSense}$, V_{Yngve} and each of V_{totfix} and $V_{firstpass}$. All correlations significant with $p < 0.0001$ after Bonferroni correction unless marked with *.

$[9, 16]$), "high" ($i, j \in [17, 24]$), and "out" ($|i - j| > 7$), with the latter representing out-of-group correlations (e.g. $Corr_{L_1-L_{24}}$). To account for correlations between disagreeing adjacent layers (e.g. $|i - j| = 1$) and Yngve scores being higher (as a possible confounding factor), we also distinguish layers as either "adjacent" or "non-adjacent". Considering these two factors as three- and two-leveled independent variables respectively, we conduct a two-way analysis of variance. The analysis reveals that the effect of group is significant at $F(3, 275) = 78.47, p < 0.0001$, with "low" ($\mu$ = 0.65, σ = 0.08), "middle" (μ = 0.84, σ = 0.03), "high" (μ = 0.80, σ = 0.05), and "out" (μ = 0.80, σ = 0.05). Neither the effect of adjacency nor its interaction with group proved to be significant.

This can be seen as (modest) support for the findings of previous work (Blevins et al., 2018; Tenney et al., 2019): namely, that the intermediate layers of neural language models encode the most syntax, and are therefore possibly more sensitive towards syntactic complexity. A very similar pattern is observed for total fixation time. When considered together with the correlation between V_{Yngve} and fixation times, this indicates a tripartite affinity between layer disagreement, syntactic complexity, and fixation.

Lexical Ambiguity and Word Frequency Finally, we observe that $V_{logFreq.}$ has a moderate correlation with both fixation time and layer disagreement and that $V_{wordSense}$ is nearly uncorrelated to both. Detailed plots of the latter can be found in Appendix A.

5 Conclusion

We presented a framework for analyzing neural network representations (RSA) that allowed us to relate human sentence processing data with language encoder representations. In experiments conducted on two widely used encoders, our findings show that sentences which are difficult for humans to process have more divergent representations both intra-encoder and between different encoders. Furthermore, we lend modest support to the intuition that a model's middle layers encode comparatively more syntax. Our framework offers insight that is complimentary to decoding or probing approaches, and is particularly useful to compare representations from across modalities.

Abstract

Domain-specific training typically makes NLP systems work better. We show that this extends to cognitive modeling as well by relating the states of a neural phrase-structure parser to electrophysiological measures from human participants. These measures were recorded as participants listened to a spoken recitation of the same literary text that was supplied as input to the neural parser. Given more training data, the system derives a better cognitive model — but only when the training examples come from the same textual genre. This finding is consistent with the idea that humans adapt syntactic expectations to particular genres during language comprehension (Kaan and Chun, 2018; Branigan and Pickering, 2017).

1 Introduction

Natural language processing (NLP) systems based on deep neural networks are sensitive to the amount and type of training data that they receive. A "data hungry" method may not work well until it is supplied with sufficient examples (e.g. Yogatama et al., 2019). Likewise, transfer to a different textual genre may be poor (Petrov and McDonald, 2012). This is the classic problem of domain adaptation[1] which arises in many areas of NLP.

This paper revisits domain adaptation in the context of human-like parsing. With this human-like aspect in mind, we consider models that use linguistically-plausible trees (see Frank, 2011 for a review) and operate incrementally from left to right (e.g. Steedman, 2000). We quantify the fit to human language performance using freely-available electrophysiological data (henceforth: EEG) that was elicited by a pre-existing literary text (Brennan and Hale, 2019).

These EEG data come from a naturalistic stimulus, and in virtue of their higher temporal resolution, are more detailed than reading times or plausibility judgments. Hale et al. (2018) were the first to model them using a neural parser. In that study, textual training data came from the same book as did the human participants' stimuli. While this yielded a model that was quite well-matched to the EEG modeling task, its training data was confined to just 1543 sentences (24K words). In contrast, recent studies suggest that neural language models require substantially more data to achieve human-like linguistic competence (Gulordava et al., 2018; Futrell et al., 2019; Frank and Hoeks, 2019).

We investigate this question of data size together with a contrast between textual domains or "genres". Modeling human neural signals, we find that in-domain training leads to a better and better fit as more examples are added to the training set whereas with out-of-domain data, more examples do not help. This is interesting given the consistent reductions in language modeling perplexity with more data, which we observe across both domains. We further find that, across all amounts of training data, models that incorporate linguistically-plausible phrase structure achieve a better fit to human EEG data than models that do not. This suggests that phrase structure should play an important role in human-like models of language comprehension, even in models that benefit from large training data.

2 Methodology

We proceed by comparing parsing systems that are based on Recurrent Neural Network Grammars (Dyer et al., 2016; Wilcox et al., 2019, henceforth; RNNG) and trained according to fourteen

[1] It remains quite difficult to reconcile human-like incremental parsing with high performance out-of-domain; many researchers take a nonincremental whole-sentence approach (Gildea, 2001; Baucom et al., 2013; Joshi et al., 2018).

complexity metric:	surprisal of hypotheses in beam (Hale, 2001; Roark et al., 2009)
amount of training data:	39832,$\{100, 250, 500, 750\}$K, 1M and 1437575 sentences
genre:	newspaper text (Graff et al., 2005) and lexically-similar literature (Gutenberg)

Table 1: Training regimes

different regimes. These training regimes cross seven different amounts of training data with two different genres of writing. The question across all regimes is: how well does a complexity metric derived from these parsers improve the modeling of EEG data from human participants engaged in language comprehension of the same text? Note that the dependent variable here is not parsing performance or language modeling perplexity of the RNNG, but rather the helpfulness, as regards cognitive modeling, of a derived measure based on the intermediate states that the RNNG visits during decoding of the stimulus text that the human participants heard. Table 1 summarizes these training regimes.

3 Materials

3.1 Lexically-similar literature

In the first genre, we ranked e-books from the freely-available Project Gutenberg collection according to the CosineTop50 metric from McClosky et al. (2010). This (dis)similarity metric compares vectors whose components are attestation counts from the 50 most frequent words in a reference text. Here, the reference text is the one that human EEG study participants listened to – the first chapter of Alice in Wonderland. Table 2 shows some highly-ranked books on this scheme. It yielded largely juvenile literature from the 19^{th} century aimed at girls. The average sentence length in this selection was 17 words.

dissimilarity	title	author
0.0584	The Admiral's Caravan	Charles E. Carryl
0.0620	The Secret Garden	Frances Hodgson Burnett
0.0628	The Lodger	Marie Belloc Lowndes
0.0687	The Girls and I: A Veracious History	Mary Louisa Stewart Molesworth
0.0689	What Timmy Did	Marie Adelaide Belloc
0.0724	Little Miss Peggy	Mrs. Molesworth
0.0725	The Girls of St. Olave's	Mabel Mackintosh
0.0741	The Celebrity at Home	Violet Hunt
0.0750	I've Married Marjorie	Margaret Widdemer
0.0752	The Forged Note	Oscar Micheaux
0.0755	Mary Erskine	Jacob Abbott
0.0758	The Bountiful Lady	Thomas Cobb
0.0758	Legacy	James H Schmitz
0.0763	Some Little People	George Kringle
0.0774	In the Wilderness	Robert Hichens

Table 2: Alice-like books from Project Gutenberg

3.2 Newspaper text

In the second genre, we randomly sampled news articles from the English Gigaword corpus (Graff et al., 2005). This sampling was made regardless of the particular national source, i.e. Agence France-Press, New York Times or Xinhua News Agency. Sentences in this sample were, on average, 20 words long. This out-of-domain text had a CosineTop50 dissimilarity level of 0.56.

3.3 Presumptive Trees

Both genres were parsed using a re-implementation of the Berkeley parser (Petrov et al., 2006) to yield presumptively-correct, "silver-grade" trees. This Berkeley parser was trained on a diverse set of annotated data. These include the Penn Treebank's Wall Street Journal materials (Marcus et al., 1993), the Question Treebank (Judge et al., 2006), Ontonotes (e.g. Pradhan and Ramshaw, 2017) and Parsing-the-Web Corpora (Petrov and McDonald, 2012). In a manual inspection of randomly sampled silver trees, the only obvious mistakes were tagging errors (1 newspaper, 2 literature), which are not harmful since RNNGs do not use part of speech tags. Indeed, the bracketing and phrase labels on these silver trees appeared to be fully consistent with the Penn Treebank Bracketing Guidelines (Bies et al., 1995). Before being passed to the RNNG as training data, these trees were post-processed to remove empty elements, punctuation, and function tags.

4 Training

4.1 Hyperparameters

We tuned RNNG hyperparameters to optimize development set perplexity. The development set comprises the entire Alice in Wonderland book as obtained from Project Gutenberg.[2] To control for

[2]While the first chapter of Alice in Wonderland that we use as stimuli is thus a subset of the development set, recall from section 2 that our evaluation metric is fit to the human EEG, rather than validation perplexity.

model capacity, across all training regimes we used the same hyper-parameter that consistently achieved good validation perplexities across all configurations.[3]

4.2 Vocabulary

Within each of the two genres, we facilitate comparison across different training set sizes by running the RNNGs with a shared vocabulary derived from the largest training configuration. An attestation frequency cut-off was applied to each of them to ensure broadly comparable rates of out-of-vocabulary words on the development set, Alice in Wonderland. For the lexically-similar literature, this threshold was 5 attestations, whereas for the newspaper text this threshold was 20 attestations. On the validation set, these cut-offs yielded out-of-vocabulary rates of 2.3 to 2.4 percent for newspaper text and 0.5 to 1.28 percent for lexically-similar literature.

4.3 Achieved perplexity

Per-action perplexity levels[4] achieved by the trained RNNG parsing models on the development set are shown in Figure 1. Validation perplexity consistently improves with more and more silver-grade training data, even when that data comes from a different domain.[5]

5 EEG Regression model

Surprisal values from a beam search parser based on RNNG are entered as predictors into a regression model of scalp voltages. Models are fit with the `brm` function in R and model fits were compared using Bayesian model comparison (Vehtari et al., 2017). These regression models include random intercepts for participant along-side predictors to account for factors of non-interest that nevertheless are known to influence sentence processing difficulty (see e.g. Goodkind and Bicknell, 2018). These are: sentence position in the stimulus text, word position within each sentence, acoustic sound power, unigram word frequency in the HAL corpus (Balota et al., 2007). Unigram predictors are included for the previous word, the current word and the next word.

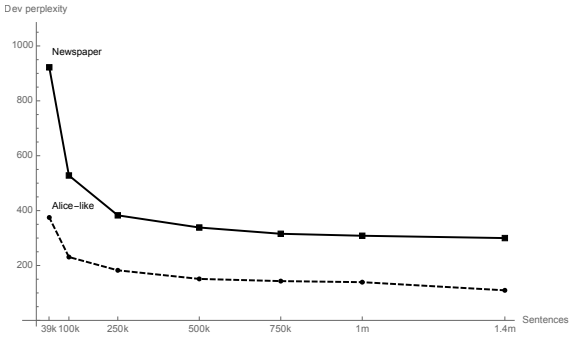

Figure 1: Language modeling perplexity (lower is better) on Alice in Wonderland across the two genres of training data.

The EEG data themselves come from 33 datasets that were collected by Brennan and Hale (2019) while participants listened to the first chapter of Alice in Wonderland.[6] Ocular artifacts and other noise sources are removed from the raw signal using ICA and visual inspection. The EEG data are reduced to a single spatio-temporal region of interest (ROI) comprising the data from anterior channels across both hemispheres between 200 and 400 ms after the onset of content-words. This anterior ROI has, uniquely, shown sensitivity to surprisal values from incremental parsers under a data-driven whole-scalp analysis in Brennan and Hale (2019). Note that this ROI is earlier and more anterior than the usual locus of the N400 component, which typically manifests on central electrodes at or around 400 ms post-stimulus (for a review see Kaan, 2007).

6 Results

Figure 2 plots the goodness-of-fit of a regression model that includes RNNG-derived complexity metrics. As the neural phrase structure parser is trained on increasingly larger corpora, the regression model of EEG amplitudes fits better and better. However, this pattern only obtains with in-domain training data that is lexically-similar to the first chapter of Alice in Wonderland. When trained on newspaper text from the Gigaword cor-

[3] The RNNG hyperparameters are: 2-layer stack LSTM (Dyer et al., 2015), 450 hidden units, and an initial SGD learning rate of 0.3, decayed exponentially with a factor of 0.1 applied after the tenth epoch.

[4] The per-action perplexity is computed based on the joint probability of strings ($\mathbf{x}$) and trees ($\mathbf{y}$), denoted as $p(\mathbf{x}, \mathbf{y})$, which therefore aggregate the perplexity of the next-word prediction with the perplexity of tree-building actions. Approximate inference methods such as important sampling can be used to derive an estimate of $p(\mathbf{x})$ (Dyer et al., 2016).

[5] While relative perplexity levels internal to a genre are comparable in virtue of a shared vocabulary, absolute perplexity values are not directly comparable across the genres since these vocabularies are different.

[6] These data are available at: https://doi.org/10.7302/Z29C6VNH.

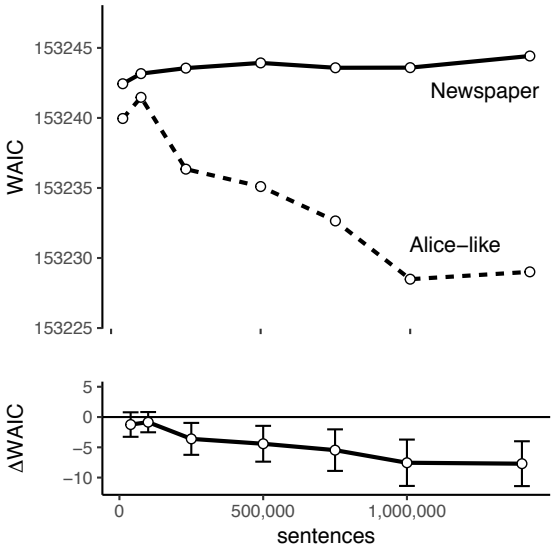

Figure 2: Goodness of fit of surprisal predictions from RNNG at beam size $k = 200$ syntactic analyses on anterior electrodes during the time window 200-400ms after the onset of a spoken word in the first chapter of Alice in Wonderland. The widely-applicable information criterion WAIC is described further in Vehtari et al. (2017). Lower WAIC indicates a better fit.

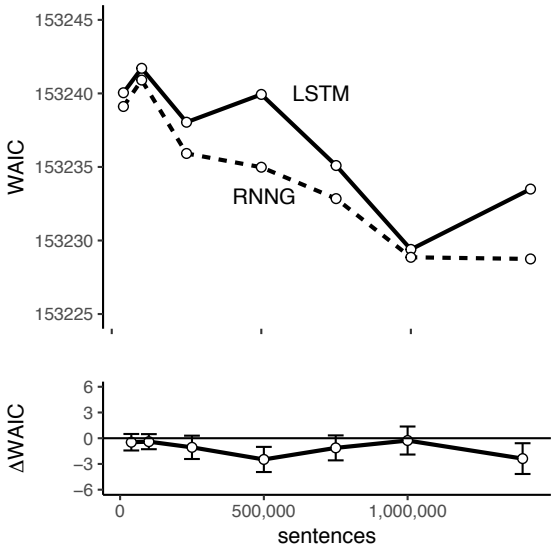

Figure 3: Comparison between RNNG with explicit hierarchical representations and LSTM without such representations. Lower WAIC indicates a better fit to human electrophysiological data.

pus, the goodness of fit to human EEG data remains about the same no matter how much training data is supplied. Tukey's test of additivity indicates an interaction between genre and training set size, $F(1, 5) = 171.3, p < 0.000001$. No effect of surprisal values obtained in electrodes and timepoints corresponding to the N400 component.

Figure 3 compares the RNNG, which explicitly uses phrase structure representations, to an LSTM sequence model which does not (Hochreiter and Schmidhuber, 1997). Here, both models receive the benefit of in-domain training on the lexically-similar literature. But regardless of how much in-domain training data is made available, the explicitly phrase-structural RNNG always offers a better account of the EEG signal.

7 Related Work

The importance of domain adaptation in NLP has been well-established in earlier work (see Daumé III, 2007 and footnote 1), including applications to parsing (Sarkar, 2001; McClosky et al., 2006; Søgaard and Rishøj, 2010; Weiss et al., 2015). Our approach to in-domain data selection is closely related to earlier work in language modeling and machine translation (Keller and Lapata, 2003; Moore and Lewis, 2010; Axelrod et al., 2011). Our focus on large training sets responds to recent work in language modeling (Devlin et al., 2019; Radford et al., 2019). The research reported here differs in two ways from these earlier studies. First, we consider the interaction between domain and amount of training data, rather than examining each variable in isolation. Second, we investigate the impact of these variables on cognitive modeling, which reveals a pattern that is different from what we observe in the standard perplexity evaluation. We focus on text genre, rather than online adaptation as van Schijndel and Linzen (2018) do. Despite coming at the problem from a different direction (and using EEG rather than self-paced reading) our results agree with van Schijndel and Linzen in suggesting that some kind of adaptation must be going on in human language comprehension.

8 Conclusion

These comparisons confirm that genre matters. If surprisal describes human linguistic expectations, then we can say that those expectations are better-modeled by a parsing system that benefits from in-domain training. This would follow if, as Kaan and Chun (2018) have suggested, people are able to very rapidly adjust their syntactic expectations to match a particular genre.

Indeed, these expectations seems to be phrase-

structural in nature. Certainly the presence of unigram nuisance predictors in the EEG regression (section 5) and the comparatively worse performance of the LSTM sequence model (Figure 3) render it unlikely that this finding is due to word frequency or superficial co-occurrence. Rather, the neural parser has learned something about 19^{th} century children's literature that can be captured at the syntactic level. Whatever these syntactic properties are, it could have been the case that they were equally learnable from newswire text or Alice-like books. But in fact Alice-like books generalize better to human EEG data.

This use of moment-by-moment processing difficulty to adjudicate between trained NLP systems offers a reminder that the quest for human-level performance in language technology should always be understood in relation to a particular kind of linguistic performance in a particular genre.

Feature2Vec: Distributional semantic modelling of human property knowledge

Steven Derby **Paul Miller** **Barry Devereux**

Queen's University Belfast, Belfast, United Kingdom
{sderby02, p.miller, b.devereux}@qub.ac.uk

Abstract

Feature norm datasets of human conceptual knowledge, collected in surveys of human volunteers, yield highly interpretable models of word meaning and play an important role in neurolinguistic research on semantic cognition. However, these datasets are limited in size due to practical obstacles associated with exhaustively listing properties for a large number of words. In contrast, the development of distributional modelling techniques and the availability of vast text corpora have allowed researchers to construct effective vector space models of word meaning over large lexicons. However, this comes at the cost of interpretable, human-like information about word meaning. We propose a method for mapping human property knowledge onto a distributional semantic space, which adapts the *word2vec* architecture to the task of modelling concept features. Our approach gives a measure of concept and feature affinity in a single semantic space, which makes for easy and efficient ranking of candidate human-derived semantic properties for arbitrary words. We compare our model with a previous approach, and show that it performs better on several evaluation tasks. Finally, we discuss how our method could be used to develop efficient sampling techniques to extend existing feature norm datasets in a reliable way.

1 Introduction

Distributional semantic modelling of word meaning has become a popular method for building pretrained lexical representations for downstream Natural Language Processing (NLP) tasks (Baroni and Lenci, 2010; Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014; Bojanowski et al., 2017). In this approach, meaning is encoded in a dense vector space model, such that words (or concepts) that have vector representations that are spatially close together are similar in meaning. A criticism of these real-valued embedding vectors is the opaqueness of their representational dimensions and their lack of cognitive plausibility and interpretability (Murphy et al., 2012; Şenel et al., 2018). In contrast, human conceptual property knowledge is often modelled in terms of relatively sparse and interpretable vectors, based on verbalizable, human-elicited features collected in property knowledge surveys (McRae et al., 2005; Devereux et al., 2014). However, gathering and collating human-elicited property knowledge for concepts is very labour intensive, limiting both the number of words for which a rich feature set can be gathered, as well as the completeness of the feature listings for each word. Neural embedding models, on the other hand, learn from large corpora of text in an unsupervised fashion, allowing very detailed, high-dimensional semantic models to be constructed for a very large number of words. In this paper, we propose *Feature2Vec*, a computational framework that combines information from human-elicited property knowledge and information from distributional word embeddings, allowing us to exploit the strengths and advantages of both approaches. Feature2Vec maps human property norms onto a pretrained vector space model of word meaning. The embedding of feature-based information in the pretrained embedding space makes it possible to rank the relevance of features using cosine similarity, and we demonstrate how simple composition of features can be used to approximate concept vectors.

2 Related Work

Several property-listing studies have been conducted with human participants in order to build *property norms* – datasets of normalized human-verbalizable feature listings for lexical concepts (McRae et al., 2005; Devereux et al., 2014).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5853–5859, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

One use of feature norms is to critically examine distributional semantic models on their ability to encode grounded, human-elicited semantic knowledge. For example, Rubinstein et al. (2015) demonstrated that state-of-the-art distributional semantic models fail to predict attributive properties of concept words (e.g. the properties *is-red* and *is-round* for the word *apple*) as accurately as taxonomic properties (e.g. *is-a-fruit*). Similarly, Sommerauer and Fokkens (2018) investigated the types of semantic knowledge encoded within pretrained word embeddings, concluding that some properties cannot be learned by supervised classifiers. Collell and Moens (2016) compared linguistic and visual representations of object concepts on their ability to represent different types of property knowledge. Research has shown that state-of-the-art distributional semantic models built from text corpora fail to capture important aspects of meaning related to grounded perceptual information, as this kind of information is not adequately represented in the statistical regularities of text data (Li and Gauthier, 2017; Kelly et al., 2014). Motivated by these issues, Silberer (2017) constructed multimodal semantic models from text and image data, with the goal of grounding word meaning using visual attributes. More recently, Derby et al. (2018) built similar models with the added constraint of sparsity, demonstrating that sparse multimodal vectors provide a more faithful representation of human semantic representations. Finally, the work that most resembles ours is that of Fagarasan et al. (2015), who use Partial Least Squares Regression (PLSR) to learn a mapping from a word embedding model onto specific conceptual properties. Concurrent work recently undertaken by Li and Summers-Stay (2019) replaces the PLSR model with a feedforward neural network. In our work, we instead map property knowledge directly into vector space models of word meaning, rather than learning a supervised predictive function from concept embedding dimensions to feature terms.

3 Method

We make primary comparison with the work of Fagarasan et al. (2015), although their approach differs from ours in that they map from an embedding space onto the feature space, while we learn a mapping from the feature domain onto the embedding space. We outline both methods below.

3.1 Distributional Semantic Models

For our experiments, we make use of the pretrained GloVe embeddings (Pennington et al., 2014) provided in the *Spacy*[1] package trained on the Common Crawl[2]. The GloVe model includes $685,000$ tokens with embedding vectors of dimension 300, providing excellent lexical coverage with a rich set of semantic representations.

In our analyses we use both the McRae property norms (McRae et al., 2005), which contain 541 concepts and 2526 features, and the CSLB norms (Devereux et al., 2014) which have 638 concepts with 2725 features. For both sets of norms, a feature is listed for a concept if it has been elicited by five or more participants in the property norming study. The number of participants listing a given feature for a given concept name is termed the *production frequency* for that concept×feature pair. This gives sparse production frequency vectors for each concept over all the features in the norms.

3.2 Partial Least Square Regression (PLSR)

Fagarasan et al. (2015) used partial least squares regression (PLSR) to map between the GloVe embedding space and property norm vectors. Suppose we have two real-valued matrices $G \in \mathbb{R}^{n \times m}$ and $F \in \mathbb{R}^{n \times k}$. In this context, G and F represent GloVe embedding vectors and property norm feature vectors, respectively. For n available concept words, G is a matrix which consists of stacked pretrained embeddings from GloVe and F is the (sparse) matrix of production frequencies for each concept×feature pair. G and F share the same row indexing for concept words. For a new dimension size $p \in \mathbb{N}$, a partial least squared regression learns two new subspaces with dimensions $n \times p$, which have maximal covariance between them. The algorithm solves this problem by learning a mapping from the matrix G onto F, similar to a regression model. The fitted regression model thus provides a framework for predicting vectors in the feature space from vectors in the embedding space.

In this work, we use the PLSR approach as a baseline for our model. In implementing PLSR, we set the intermediate dimension size to 50, following Fagarasan et al. (2015). We also build a PLSR model using 120 dimensions, which in preliminary experimentation we found gave the best

The network learns semantic feature embeddings for feature labels in property norm datasets instead of context embeddings.

performance from a range of values tested.

3.3 Skip-Gram Word2Vec

Mikolov et al. (2013) proposed learning word embeddings using a predictive neural-network approach. In particular, the skip-gram implementation with negative sampling mines word co-occurrences within a text window, and the network must learn to predict the surrounding context from the target word. More specifically, for a vocabulary V, two sets of embeddings are learned through gradient decent, one for target embeddings and one for context embeddings. Given a target word $w \in V$ and a context word $c \in V$ in its window, the network calculates the dot product for the embeddings for w and v and a sigmoid activation is applied to the output (Fig. 1(a)). Negative samples are also generated for training, where the context is not in the target word's window. Let $(w, c) \in D$ be the positive word and context pairs and $(w, c) \in D'$ be the negative word and context pairs. Then, using binary cross entropy loss, we learn a parameterization θ of the neural network that maximizes the function

$$\mathcal{J}(\theta) = \sum_{(w,c)\in D} log(\sigma(v_c \cdot v_w)) + \sum_{(w,c)\in D'} log(\sigma(-v_c \cdot v_w))$$

where σ is the sigmoid function and v_w and v_c are the corresponding real-valued embeddings for the target words and context words (Goldberg and Levy, 2014).

In this work, we adapt this skip-gram approach to the task of constructing semantic representations of human property norms by mapping properties into an embedding space (Figure 1). We achieve this by using a neural network to predict the properties from the input word, using the skip-gram architecture with negative sampling on the properties. We replace context embeddings and windowed co-occurrence counts from the conventional skip-gram architecture with property embeddings and concept-feature production frequencies. The loss function for training remains the same; however, there are two modifications to the learning process. The first is that the target embeddings for the concept words are pre-trained (i.e. the GloVe embeddings), and gradients are not applied to this embedding matrix. The layer for the property norms is randomly initialized, and gradients are applied to these vectors to learn a semantic representation for properties aligned to the pre-trained distributional semantic space for the words. Secondly, the negative samples are generated from randomly sampled properties. We downweight negative samples by multiplying their associated loss by one over the negative sampling rate, so that the system pays more attention to real cases and less to the incorrect negative examples. Due to the sparsity of word-feature production frequencies, we generate all positive instances and randomly sample negative examples after each epoch to create a new set of training samples. We name this approach *Feature2Vec*[3]. We use a learn-

For PLSR, predicted feature vectors for test concepts are compared to actual feature vectors. For Feature2Vec, predicted concept word embeddings are compared to the actual GloVe embedding vectors.

ing rate of 0.001 and Adam optimization to train for 120 epochs. We use a negative sampling rate of 20 for both the McRae and CLSB datasets. In contrast to the PSLR approach, *Feature2Vec* learns a mapping from the feature norms onto the GloVe embedding space.

4 Experiments

We train with the McRae and CSLB property norms separately and report evaluations for each dataset. For the McRae dataset we use 400 randomly selected concepts for training and the remaining 141 for testing, and for the CSLB dataset we use 500 randomly selected concepts for training and the remaining 138 for testing[4].

4.1 Predicting Feature Vectors

We first evaluate how well the baseline PLSR model performs on the feature vector reconstruction task used by Fagarasan et al. (2015). In this evaluation, the feature vector for a test concept is predicted and we test whether the real concept vector is within the top N most similar neighbours of the predicted vector. We report results over both 50 (as in Fagarasan et al. (2015)) and 120 dimensions for a range of values of N (Table 1).

4.2 Constructing Concept Representations from Feature Vectors

For *Feature2Vec*, we embed property norm features into the GloVe semantic space, giving a representation of properties in terms of GloVe dimensions. To predict a held-out concept embedding, we build a representation of the concept word by averaging the learned feature embedding vectors for that word using the ground truth information from the property norm dataset. This gives a method to construct embeddings for new words using property knowledge and associated production frequencies (for example, for a held-out word *unicorn*, its GloVe embedding vector might be predicted from all features of *horse*, along with the features *is-white*, *has-a-horn*, and *is-fantastical*). We compare these predicted embeddings to the held-out Glove embeddings (Table 1). However, we note that this approach is different to the PLSR models, so we do not make a direct comparison between PLSR and Feature2vec nearest neighbour results. Nevertheless, the results show that the word embeddings composed from the learned *Feature2Vec* feature embeddings appear relatively frequently amongst the most similar neighbour words in the pretrained GloVe space, indicating that feature embedding composition approximates the original word embedddings reasonably well.

Feature2Vec	90.70	35.33	90.31	44.30

Table 2: The average percentage of features that each method can predict for a given concept vector.

4.3 Predicting Property Knowledge

The evaluation task that we are most interested in is how well the models can predict feature knowledge for concepts, given the distributional semantic vectors. More specifically, for a given concept with K features, we wish to take the top K predicted features according to each method, and record the overlap with the true property norm listing. In this evaluation, we make direct comparisons between all three models (PLSR 50, PLSR 120, & Feature2Vec). For the PLSR models, we predict the feature vector for a given target word using the embedding vector as input and take the top K weighted features. For Feature2Vec, we

Table 3: Top 10 predictions from CSLB-trained Feature2Vec model. The properties in bold and underlined are those that agree with the available ground truth features from the CSLB dataset. The first two concepts are from the CSLB test set, whilst the final two words were randomly sampled from the word embedding lexicon.

rank all feature embeddings by their distance to the embedding for the target word, using cosine similarity, and take the top K most similar features (Table 2). The results demonstrate that Feature2Vec outperforms the PLSR models on property knowledge prediction, for both training and testing datasets.

4.4 Analysis

Following previous work, we provide the top 10 feature predictions for a few sample concepts, displayed in Table 3. Properties underlined and in bold represent features that match the available ground truth data (i.e., the concept×feature pair occurs in the norms). The first two words in Table 3 were sampled from the CSLB norms test set, whilst the last two words were randomly sampled from the word embedding lexicon and are not concept words appearing in the CSLB norms. We find that the predicted features that are not contained within the ground truth property set still tend to be quite reasonable, even for the two concepts not in the test dataset. As property norms do not represent an exhaustive listing of property knowledge, this is not surprising, and predicted properties not in the norms are not necessarily errors (Devereux et al., 2009; Fagarasan et al., 2015). Moreover, the set of features used within the norms are dependent on the concepts that were presented to the human participants. It is therefore notable that the conceptual representations predicted by our model for the two out-of-norms concept words are particularly plausible, even though the attributes were never intended to conceptually represent these words. Our analysis supports the view that such supervised models could be utilised as an assistive tool for surveying much larger vocabularies of words.

5 Conclusion

We proposed a method for constructing distributional semantic vectors for human property norms from a pretrained vector space model of word meaning, which outperforms previous methods for predicting concept features on two property norm datasets. As discussed by Fagarasan et al. (2015) and others, it is clear that property norm datasets provide only a semi-complete picture of human conceptual knowledge, and more extensive surveys may provide additional useful property knowledge information. By predicting plausible semantic features for concepts through the leveraging of corpus-derived word embedding data, our method offers a useful tool for guiding the expensive and laborious process of collecting property norm listings. For example, existing property norm datasets can be extended through human verification of features predicted with high confidence by Feature2Vec, with these features being added to the norms and subsequently incorporated into Feature2Vec in an iterative, semi-supervised manner (Kelly et al., 2012). Thus, Feature2Vec provides a useful heuristic to add interpretable feature-based information to these datasets for new words in a practical and efficient way.

Sunny and Dark Outside?! Improving Answer Consistency in VQA through Entailed Question Generation

[1]Arijit Ray, [1]Karan Sikka, [1]Ajay Divakaran, [*]Stefan Lee, [1]Giedrius Burachas
[1]first.last@sri.com, [*]steflee@gatech.edu
[1]SRI International, [*]Georgia Institute of Technology

Abstract

While models for Visual Question Answering (VQA) have steadily improved over the years, interacting with one quickly reveals that these models lack consistency. For instance, if a model answers "red" to "What color is the balloon?", it might answer "no" if asked, "Is the balloon red?". These responses violate simple notions of entailment and raise questions about how effectively VQA models ground language. In this work, we introduce a dataset, ConVQA, and metrics that enable quantitative evaluation of consistency in VQA. For a given observable fact in an image (e.g. the balloon's color), we generate a set of logically consistent question-answer (QA) pairs (e.g. Is the balloon red?) and also collect a human-annotated set of common-sense based consistent QA pairs (e.g. Is the balloon the same color as tomato sauce?). Further, we propose a consistency-improving data augmentation module, a Consistency Teacher Module (CTM). CTM automatically generates entailed (or similar-intent) questions for a source QA pair and fine-tunes the VQA model if the VQA's answer to the entailed question is consistent with the source QA pair. We demonstrate that our CTM-based training improves the consistency of VQA models on the ConVQA datasets and is a strong baseline for further research.

1 Introduction

"A skeptic, I would ask for consistency first of all."

Sylvia Plath (Plath, 2007)

Visual Question Answering (VQA) (Antol et al., 2015) involves answering natural language questions about images. Despite the recent progress on VQA, we observe that existing methods are prone to making blatant mistakes while answering questions regarding the same visual fact but from slightly different perspectives (Figure 1). This reveals a critical limitation of the state-of-the-art models in maintaining consistency.

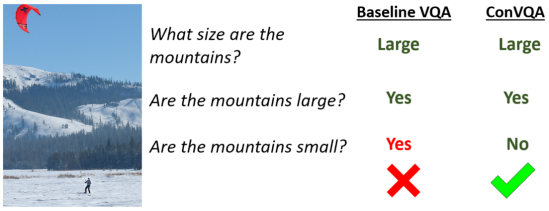

Figure 1: Current VQA models often fail at consistently answering semantically rephrased questions. To address this limitation, we construct a consistent VQA (ConVQA) dataset with diverse QA pairs that query the same visual fact. We also propose a Consistency Teacher Module (CTM) that improves VQA consistency by rewarding consistent behavior.

In particular, we motivate our definition of consistency based on classical deductive logic (Tarski and Tarski, 1994) that defines a consistent theory as one that does not entail a contradiction. Correspondingly, we define consistency, in the context of VQA, as being able to answer questions posed from different semantic perspectives about a certain fact without any contradiction. In addition, consistent Question-Answer (QA) pairs can be derived based on simple notions of logic or by commonsense reasoning. For instance, say an image contains a "large building". Logic-based QA pairs can be "is the building small? no" and "what size is the building? large". On the other hand, if an image contains "vegetarian pizza", commonsense-based QA pairs can be "is it a vegetarian pizza? yes" and "is there pepperoni on the pizza? no", which requires commonsense knowledge that "pepperoni" is not vegetarian.

While attempts have been made to construct logic-based consistent VQA datasets (Hudson and Manning, 2019), they still fall short on commonsense-based consistency. To this end, our ConVQA Dataset consists of two subsets: 1) a challenging human-annotated set comprised of commonsense-based consistent QA's (shown in

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5860–5865, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

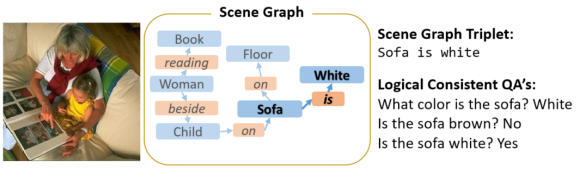

Figure 2: Qualitative examples from our ConVQA dataset derived based on logic.

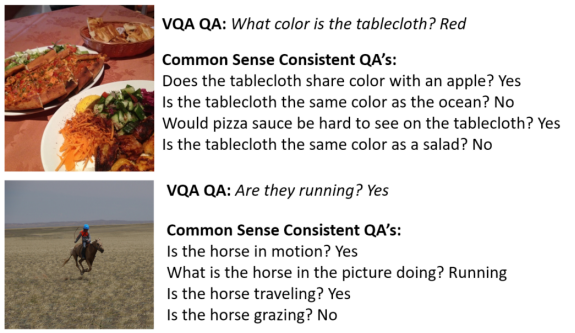

Figure 3: Qualitative examples from our human-annotated commonsense-based ConVQA Dataset.

Figure 3), and 2) an automatically generated logic-based consistent QA dataset (shown in Figure 2).

To improve the consistency of VQA models, we propose a Consistency Teacher Module (CTM), which consists of a Question Generator that synthesizes entailed (or similar-intent) questions given a seed QA pair and a Consistency Checker that examines whether answers to those similar-intent questions are consistent. For training a consistent VQA model, our CTM acts as a consistency-based data augmentation scheme that trains a VQA model with consistent answers to entailed questions. We demonstrate that our approach improves the performance of a baseline VQA model on our ConVQA testing sets in terms of both accuracy and consistency. Our datasets and models will be available at https://bit.ly/32exlM7.

2 Related Work

Checking for consistency can be considered as an interrogative Turing Test (Radziwill and Benton, 2017) for linguistic robustness (Stede, 1992), (Li et al., 2017). Works such as Xu et al. (2018) explore the robustness of VQA with respect to image variations, whereas works such as Ray et al. (2016) and Mahendru et al. (2017) focus on the understanding of the premise of a question instead of relying on dataset biases (Agrawal et al., 2017) (Goyal et al., 2017) or linguistic biases (Ramakrishnan et al., 2018).

Recently, the research community has shown great interest in evaluating VQA for consistency and plausibility. GQA (Hudson and Manning, 2019) is established as a scene-graph based QA dataset. Their questions, similar to Johnson et al. (2017), require multiple hops of reasoning, and are not validated or annotated by humans. Our ConVQA differs from GQA in the following two aspects. First, we provide a human-validated test set of the automatically generated logic-based consistent QA's for a more accurate performance evaluation. Second, we collect human-annotated QA pairs based on common-sense in addition to the logic-based QA's. The most relevant work to ours is Shah et al. (2019). However, they focus strictly on question paraphrases that maintains the same answers as the source question. We, however, focus on generating questions which can have different answers, but are about the same visual fact, which greatly increases the diversity of the resulting QA pairs. To the best of our knowledge, the proposed ConVQA dataset is the first consistent QA dataset that contains human-annotated consistent QA's based on common-sense.

Other works have also looked into question generation (Zhang et al., 2016), (Mostafazadeh et al., 2016) for training better VQA models. In Misra et al. (2017), QA pairs are obtained from an oracle in a simulated environment. In contrast, our CTM-based training operates on real images and uses a learned consistency measure to train the VQA module with consistent QA's.

3 ConVQA Datasets

The consistent QA pairs in our ConVQA are generated automatically based on simple notions of logical consistency or are human-annotated using commonsense reasoning.

Logic-based Consistent QA. (L-ConVQA) Consider the Visual Genome (Krishna et al., 2017) scene graph in Figure 2 consisting of objects, attributes, and their relationships. We consider each triplet to encode a single 'visual fact', for instance, that the sofa is white. We employ slot-filler NLP techniques to generate a set of QA pairs for each triplet (object-relation-subject) in the scene graph. Currently, we focus on attribute (e.g., color, size), existential (e.g., is there) and relational (e.g., sofa on floor) consistency. We leverage Wordnet (Miller, 1995) and a manually generated list of antonyms (e.g., white vs. black) and hypernyms (e.g., white $\rightarrow$ color) to generate these QA pairs.

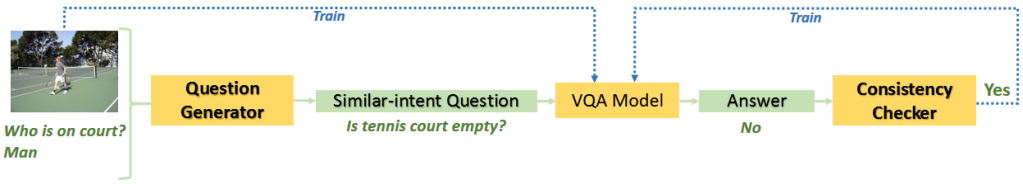

Figure 4: Block diagram of the proposed CTM including a Question Generator that synthesizes questions with similar intent and a Consistency Checker that classifies QA pairs as consistent, unrelated, or contradictory. CTM finetunes VQA models via reinforcement learning with the answer consistency as the reward to encourage VQA models to answer rephrased questions more consistently. The examples shown are from a real run.

For example, for the attribute "white" of an object "cup", we generate QA pairs such as "is the cup white? yes", "is the cup black? no" and "what color is cup? white". We also filter objects and relationships by frequency and saliency (e.g., based on bounding boxes) to avoid non-salient and infrequent objects or noisy relationships. We have a total of 880,141 QA pairs in 255,910 sets on 70,292 images. We split the data into a training set with 47,999 images, a validation set with 9,993 images, and a test set with 12,300 images. Notably, we create a smaller clean test set (12,325 QA pairs on 725 images) using Amazon Mechanical Turk (AMT) where three independent workers were asked to remove incorrect or unnatural QA's.

Commonsense-based Consistent QA. While the logic-based consistent QA set provides a first step into large-scale examination of VQA consistency, the generated questions require limited reasoning and commonsense and are, therefore, frequently simpler than human-annotated ones. Hence, we collect more challenging QA pairs based on commonsense (**CS-ConVQA**) by asking AMT workers to write intelligent rephrases of QA pairs sampled from the VQA2.0 (Goyal et al., 2017) validation dataset. AMT workers were instructed to avoid simple word paraphrases and instead to write rephrases that require commonsense reasoning in order to answer the question consistently. We collect approximately 3.5 consistent QA pairs per image for 6439 images. After filtering images that overlap with the training set of the L-ConVQA subset, we split this data into a training set (1568 images), a validation set (450 images), and a test set (1590 images).

4 Approach

To improve VQA consistency, we propose training a VQA model using a Consistency Teacher Module (CTM) that generates entailed questions and performs a consistency-based data augmentation. More specifically, CTM consists of two trainable components – an entailed question generator and a consistency checker.

Entailed Question Generator. For a given a source question-answer pair, we define entailed questions as those for which the answer should be obvious given the source QA pair. For example, given the source QA pair "Who is on court? Man", an appropriate entailed question might be "Is the tennis court empty?". We train a question generation model that given representations of the image and the source QA pair, generates a new question. Specifically, our question generator concatenates the deep features of an image (extracted using a ResNet152 (He et al., 2016) network) and a QA pair (extracted using a 1-layer LSTM (Hochreiter and Schmidhuber, 1997)) to represent a visual fact. These features are fed into another LSTM model to generate a similar-intent question. We train this module on the automatically generated Logical L-ConVQA train set. We also include some closely related (according to averaged Word2Vec (Mikolov et al., 2013) distance) Visual Genome (Krishna et al., 2017) QA pairs in the training of the question generator to add some diversity to the generated questions.

Consistency Checker. Once the VQA model produces an answer for the generated entailed question, it may or may not be consistent with the source question. To evaluate this and provide feedback to the VQA model, we train a consistency checker that processes the image and both the source and entailed QA pairs. Similar to the question generator architecture, the consistency checker takes in deep features of the image and two QA pairs and classifies the QA pairs as consistent, inconsistent or unrelated. This model is trained using the automatically generated L-ConVQA train set alone. Inconsistent examples in the L-ConVQA set are made using simple techniques such as flipping yes/no answers and replac-

Figure 5: Qualitative examples of entailed question generation and consistency checking for training the VQA.

ing entities in the scene graph triplets.

Consistency Teacher Module (CTM). Putting these two components together, we can train a VQA model based on its consistency on generated entailed questions. Figure 4 shows our pipeline. During training, for each source VQA QA pair ("Who is on court? Man"), we generate an entailed question ("Is tennis court empty?") and produce the VQA model's answer ("No"). We then run the consistency checker to determine if the generated answer is consistent with the source QA (in this case, "Who is on court? Man"). If the answer is consistent (and VQA confidence > 0.7), we treat it as the ground truth for the entailed question and update the VQA model as if this example were part of the original dataset. Likewise if it is deemed inconsistent, or if the question is deemed unrelated, it is unclear what the correct answer should be, so we do not update the model.

5 Experiments

To evaluate our approach, we apply the Consistency Teacher Module (CTM) module to a state-of-the-art VQA model trained on VQAv2 and evaluate performance on the ConVQA datasets. We describe training procedures, metrics, and baselines in this section.

Consistency Teacher Module Training. We train the components of CTM – Entailed Question Generation and Consistency Checker – using only the synthetic L-ConVQA train set (referred as the standard **CTM**) or a mix of Visual Genome and L-ConVQA train (referred as **CTMvg**) and keep them frozen when fine-tuning the VQA model. When we train the VQA, the sets used to finetune the VQA or seed the CTM come from splits not

Figure 6: Qualitative examples of our improved VQA consistency by CTM training compared to baseline bottom-up VQA. Green is correct, Red is wrong. GT is Ground Truth.

seen during training of the CTM - val split of L-ConVQA and train split of CS-ConVQA.

Qualitative examples of our Entailed Question Generator trained only on L-ConVQA are shown in Figure 5. Despite only being trained on the automatically-generated L-ConVQA data, it generates reasonably well-entailed questions on human-annotated questions.

Our Consistency Checker has a high accuracy of classification on the L-ConVQA test set (90%). However, when tested with a mix of commonsense-based CS-ConVQA, the accuracy drops to 64% (chance is 33% for 3 classes). We find that precision is important when training the VQA using the pre-trained Consistency Checker. Hence, we use the classifier at above 90% confidence threshold, where the precision is 70.38%.

Evaluation Metrics for ConVQA. We report three metrics for ConVQA – capturing notions of consistency and performance.

– **Perfect-Consistency (Perf-Con).** A model is perfectly consistent for a question set if it answers all questions in the set correctly. We report the percentage of such sets as Perf-Con.
– **Average Consistency (Avg-Con).** We also report the average accuracy within a consistent question set over the entire dataset as Avg-Con.
– **Accuracy (top-1).** Finally, we report the top-1 accuracy over all questions in the dataset.

Baselines. We compare to a number of baseline models to put our CTM results into context:

Table 1: Performance comparison of baseline VQA trained on VQA2.0, baseline VQA finetuned on ConVQA, and VQA trained using our CTM. **L-ConVQA** is the human-cleaned Logical Consistent QA dataset, **CS-ConVQA** is the human annotated Common-sense Consistency Dataset and **VG** is Visual Genome. CTM-based training produces the best results in terms of overall accuracy and consistency. **DATA** denotes the data used to fine-tune VQA or seed the CTM question generator.

	DATA	L-ConVQA			CS-ConVQA				
		Perf Con	**Avg Con**	**Top1**	**Perf Con**	**Avg Con**	**Top1**	**Yes/No**	**Num**
a) VQA	VQA2.0	36.25	71.36	70.34	26.13	59.61	60.03	65.49	31.39

c) FineTune	L/CS-ConVQA	**54.68**	**83.42**	**83.16**	24.70	59.30	59.60	65.14	33.33
d) **+CTM**	L/CS-ConVQA	54.6	83.23	82.79	25.94	**60.39**	**60.78**	**66.63**	**36.89**
e) FineTune	L/CS-ConVQA,VG	36.40	71.60	70.94	25.22	59.19	59.56	65.30	31.39
f) **+CTMvg**	L/CS-ConVQA,VG	51.41	81.66	81.37	**27.49**	59.75	60.15	66.41	34.95

– **VQA.** We take the bottom-up top-down VQA model (Anderson et al., 2018) as our base model for these experiments. To evaluate consistency in existing models, we present results on ConVQA of this model pretrained on VQA2.0.
– **Finetuned models:** We present results for models finetuned on ConVQA and Visual Genome – **Finetune CS-ConVQA** finetuned on the commonsense ConVQA dataset, **Finetune L/CS-ConVQA** on both logical and commonsense ConVQA, and **Finetune L/CS-ConVQA,VG** extending to Visual Genome questions.

When we apply our CTM model to the finetuned baselines above, we seed the question generator with the associated dataset.

6 Results and Analysis

Table 1 shows quantitative results on our L-ConVQA and CS-ConVQA datasets. We make a number of observations below.

The state-of-the-art VQA has low consistency. The baseline VQA system **(row a)** retains similarly high top-1 accuracy on the ConVQA splits (63.58% on VQAv2 vs 70.34% / 60.03% on L-ConVQA / CS-ConVQA); however, it achieves only 26.13% perfect consistency on the human generated CS-ConVQA questions.

Finetuning is an effective strategy for the synthetic L-ConVQA split. Finetuning on L-ConVQA train results in 18.43% gains in perfect consistency on L-ConVQA test (**row c vs a**). This is unsurprising given the templated questions and simple concepts in L-ConVQA; however, perfect consistency is low in absolute terms at 54.68%.

Finetuning does not lead to significant gains in consistency for human-generated questions. Finetuning the VQA model on CS-ConVQA **(row b)** leads to an improvement in consistency of only 0.26%. Likewise, adding L-ConVQA **(row c)** and extra Visual Genome questions **(row e)** actually reduces consistency.

CTM-based training preserves or improves consistency when leveraging additional data. When we apply CTM to the Finetuned L/CS-ConVQA model, we improve CS-ConVQA perfect consistency by 1.24% **(row d vs c)** while modestly improving other metrics. Extending to Visual Genome questions, the CTM augmented model improves perfect consistency in CS-ConVQA by 2.27% over the finetuned model **(row f vs e)**. Interestingly, the CTM modules were never trained with the human-annotated CS-ConVQA questions and yet lead to this improvement on CS-ConVQA by acting as an intelligent data augmenter/regularizer.

7 Conclusion and Discussion

In this paper, we introduced a ConVQA dataset consisting of logic-based and commonsense-based consistent QA pairs about visual facts in an image. We also proposed a Consistency Teacher Module that acts as a consistency-based data augmenter to teach VQA models to answer consistently. As future work, we plan to look into improving our automatically generated consistent QA pairs using external knowledge-bases.

{gcheng,daixinyu,yzqu}@nju.edu.cn,zhoul@nlp.nju.edu.cn

Abstract

Scenario-based question answering (SQA) has attracted increasing research attention. It typically requires retrieving and integrating knowledge from multiple sources, and applying general knowledge to a specific case described by a scenario. SQA widely exists in the medical, geography, and legal domains—both in practice and in the exams. In this paper, we introduce the GeoSQA dataset. It consists of 1,981 scenarios and 4,110 multiple-choice questions in the geography domain at high school level, where diagrams (e.g., maps, charts) have been manually annotated with natural language descriptions to benefit NLP research. Benchmark results on a variety of state-of-the-art methods for question answering, textual entailment, and reading comprehension demonstrate the unique challenges presented by SQA for future research.

1 Introduction

Scenario-based question answering (SQA) is an emerging application of NLP (Lally et al., 2017). Different from traditional QA, a question in SQA is accompanied by a *scenario*, e.g., a patient summary in the medical domain asking for diagnosis or treatment. A scenario differs from a document given in the reading comprehension task where the answer can be extracted or abstracted from the document (Rajpurkar et al., 2016; Nguyen et al., 2016; Lai et al., 2017). SQA requires retrieving and integrating knowledge from multiple sources, and applying general knowledge to a specific case described by the scenario.

SQA has found application in many fields, especially in the legal domain (Ye et al., 2018; Luo et al., 2017; Zhong et al., 2018) and in high-school geography exams (Ding et al., 2018; Zhang et al., 2018). The latter is particularly challenging because a geographical scenario consists of both text and diagrams (e.g., maps, charts). Questions include city planning, climates, agriculture planning, transportation, etc. An example of a scenario and a question is presented in Figure 1.

Geographical SQA has posed great challenges to NLP and related research, ranging from scenario understanding to cross-modal knowledge integration and reasoning. However, there is a lack of large datasets and benchmarking efforts for this task. In this paper, we introduce GeoSQA—an SQA dataset in the geography domain consisting of 1,981 scenarios and 4,110 multiple-choice questions at high school level. In particular, each diagram has been manually annotated with a high-quality natural language description of its content, as illustrated in Figure 1. This labor-intensive effort significantly extends the use of GeoSQA, which can support visual SQA (using the diagrams), natural language based SQA (using the annotations of diagrams), and even the diagram-to-text research. We test the effectiveness of a variety of methods for question answering, textual entailment, and reading comprehension on GeoSQA. The results demonstrate its unique challenges, waiting for more effective solutions.

The remainder of the paper is organized as follows. Section 2 discusses related work. Section 3 describes the GeoSQA dataset. Section 4 reports benchmark results. Section 5 concludes the paper.

2 Related Work

2.1 Scenario-based Question Answering

Scenario-based question answering (SQA) is introduced by Lally et al. (2017), where the Watson-Paths system is presented to answer questions that describe a medical scenario about a patient and ask for diagnosis or treatment. SQA also finds application in the legal domain, where a legal case de-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5866–5871,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Scenario: The diagram shows the urban planning of a satellite city in 2010. The city commonly receives NW winds. Read the diagram and answer the question.

Question: Location M in the diagram is suitable for
A. Waterworks
B. Incineration plant
C. Sewage treatment plant **(the correct answer)**
D. Thermal power plant

Diagram annotations --- templated text:
M is to the north of the river.
M is in the northwest of the satellite city.

Diagram annotations --- free-form text:
The river flows north.

Figure 1: An example of a scenario, a question, and diagram annotations.

scribes a scenario to be decided (Ye et al., 2018; Luo et al., 2017; Zhong et al., 2018).

For some domains, reasoning with domain knowledge is essential to SQA. Therefore, such questions often appear in exams like China's version of the SAT called Gaokao. For example, for the geography domain, Ding et al. (2018) and Zhang et al. (2018) construct a knowledge graph to support answering scenario-based geography questions at high school level.

2.2 Related Datasets

There are many datasets for traditional QA, such as WebQuestions (Berant et al., 2013) and WikiQA (Yang et al., 2015). A closely related task is reading comprehension, where the answer to a question is extracted or abstracted from a given document (Rajpurkar et al., 2016; Nguyen et al., 2016; Lai et al., 2017). By comparison, SQA is arguably more difficult because a scenario is present and contextualizes a question, but no direct answer can be identified from the scenario.

The GeoSQA dataset introduced in this paper is not the first resource for geographical SQA. Ding et al. (2018) and Zhang et al. (2018) have made their datasets public. However, compared with GeoSQA, their datasets are small and, more importantly, they ignore diagrams which represent a unique challenge to geographical SQA. By contrast, diagrams are included in GeoSQA for completeness, and have been manually annotated with natural language descriptions for extended use—including but not limited to NLP research.

Existing SQA datasets for other domains include the TREC Precision Medicine track (Roberts et al., 2018) for the medical domain, and CAIL (Xiao et al., 2018) for the legal domain. However, SQA in the geography domain requires different forms of knowledge and different reasoning capabilities, and has posed different research challenges.

3 The GeoSQA Dataset

GeoSQA is an SQA dataset in the geography domain, containing 1,981 scenarios and 4,110 multiple-choice questions at high school level. A scenario consists of a piece of text and a diagram, supporting 1–5 questions. A diagram is annotated with a natural language description of its content. A question has four options that are possible answers. Exactly one of them is the correct answer. The dataset is available online[1].

3.1 Data Collection and Deduplication

We crawled over 6,000 scenarios and 13,000 questions from Gaokao and mock tests that are available on the Web. However, some scenarios are just copies or trivial variants of others. There is a need to clean and deduplicate the collected data.

Method. The problem is to decide whether a pair of scenarios are (near) duplicates or not.

We firstly establish a matching between their structures. The matching consists of 6 pairs of their text elements: 1 pair of their scenario text, 1 pair of their most similar questions, and 4 pairs of the most similar options of the above two questions. Text similarity is computed by the cosine similarity between two bags of words.

Then we extend a popular text matching method called MatchPyramid (Pang et al., 2016) to classify a pair of scenarios as duplicates or not. The original implementation of MatchPyramid can

[1] ws.nju.edu.cn/gaokao/geosqa/1.0

only process a pair of text. We extend it to process all the 6 pairs of text by concatenating their feature vectors inside MatchPyramid.

Experiments. To evaluate our method, we manually label 1,000 pairs of scenarios where positive and negative examples are balanced. The set is divided into training, validation, and test sets with a 60-20-20 split. Our method achieves an accuracy of 95.3% on the test set, showing its satisfying performance.

Then we apply our method to the entire dataset. We index all the scenarios using Apache Lucene. For each scenario, we retrieve 10 top-ranked scenarios as suspect duplicates. Each pair of scenarios is classified by our method, which is trained using all the 1,000 labeled examples.

To verify the quality of the final results, we randomly sample and manually check 100 pairs of scenarios that are predicted to be duplicates. Indeed, all of them are decided correctly. We also randomly sample 50 scenarios and, for each of them, we retrieve and manually check 10 top-ranked scenarios that are predicted to be non-duplicates. Only 6% are decided incorrectly, suggesting a low degree of redundancy of our data.

3.2 Diagram Annotation

Crawled diagrams are images. To extend the use of GeoSQA and to better support NLP research, we manually annotate each diagram with a high-quality natural language description of its content so that NLP researchers can use these text annotations instead of the original diagrams.

Annotation. We recruited 30 undergraduate students from one of the top-ranked universities in China as annotators. All of them had an excellent record in geography during high school.

Each diagram is assigned to one annotator, who also has access to the scenario text and related questions. The annotator firstly categorizes the diagram according to a hierarchy of categories. Each category is associated with a set of text templates that are recommended to be used in annotations as far as possible. However, the annotator is free to use any form of text to annotate information that is not covered by the provided templates.

Annotations are required to precisely reflect the content of the diagram. All the information related to every supported question and every option should be annotated. On the other hand, inferring new knowledge via human reasoning is prohibited.

Note that the entire annotation process is designed to be iterative. The 22 diagram categories and 81 text templates are not predefined but incrementally induced during the experiment. However, there are still 11% of the diagrams that are believed to not belong to any category. No templates are provided for their annotations.

An example of annotations is shown in Figure 1.

Audit. To ensure the quality of the annotations, we recruited 3 senior annotators to audit the results. Each diagram is audited by one senior annotator, who rates the annotations from three dimensions in the range of 1–5.

- Sufficiency: The annotations cover all the necessary information in the diagram that is useful for answering related questions.
- Fairness: The annotations are not biased towards any particular option of a question.
- Objectiveness: The annotations are plain descriptions of the diagram—not influenced by human reasoning.

The scenarios where the annotations of the diagram are rated below 3 in any dimension are excluded from the dataset.

4 Benchmark Results

We tested several state-of-the-art methods for question answering, textual entailment, and reading comprehension on our GeoSQA dataset.

4.1 Corpora

We use two corpora as background knowledge. **Textbooks** contains 15K sentences extracted from two high-school geography textbooks. **Wikipedia** contains 1M articles in the latest Chinese edition of Wikipedia. We index their sentences using Apache Lucene.

4.2 Methods

We tested two text matching methods. In **IR** (Clark et al., 2016), for each option, we use a combination of the scenario text, the question, and the option as a query, to retrieve the top-ranked sentence from a corpus. We use the ranking score of this sentence as the score of the option. Finally, we choose the option with the highest score as the answer. In **PMI** (Clark et al., 2016), for each option, we calculate the Pointwise Mutual Information (PMI) between the question and the option as

the score of the option. Finally, we choose the option with the highest score as the answer. Probabilities in PMI are estimated based on a corpus.

We tested four textual entailment methods: **ESIM** (Chen et al., 2017), **DIIN** (Gong et al., 2018), **BERT**$_{NLI}$ (Devlin et al., 2018), and **BiMPM** (Wang et al., 2017). The first three methods were trained on the XNLI dataset (Conneau et al., 2018). The last method was trained on the LCQMC dataset (Liu et al., 2018). For each option, a textual entailment method retrieves six top-ranked sentences from a corpus to form the entailing text. Retrieval follows the procedure described in the above-mentioned **IR** method. The scenario text and diagram annotations may or may not be included in the entailing text, depending on the configuration. A combination of the question and the option form the entailed text. Finally, we choose the option with the highest entailment score as the answer.

We tested one reading comprehension method: **BERT**$_{RC}$ (Devlin et al., 2018). It was trained on the DuReader dataset (He et al., 2018). For each option, a reading comprehension method retrieves six top-ranked sentences from a corpus as part of the passage for reading comprehension. Retrieval follows the procedure described in the above-mentioned **IR** method. The scenario text and diagram annotations may or may not be included in the passage, depending on the configuration. Finally, the reading comprehension method extracts a text span from the passage. We choose the option that is the most similar to the extracted text span as the answer. Similarity is computed by the cosine similarity between two bags of words.

4.3 Results

The results are summarized in Table 1. Note that a question has four options. Even guessing randomly, the expected proportion of correctly answered questions would be 25%.

Almost all the methods performed similar to random guess, showing that SQA on our dataset has its unique challenges.

4.4 Discussion

To explain the poor performance of existing methods, we have identified the following challenges. First, SQA relies on domain knowledge that is not provided in the scenario. However, relevant knowledge may fail to be retrieved from the corpus. Second, for some questions, commonsense knowledge is needed but is not included in textbooks and may fail to be retrieved from Wikipedia. Third, the retrieved general knowledge needs to be applied to the specific case described by a scenario. Existing QA and reading comprehension methods hardly have this capability.

	Textbooks	Wikipedia
IR	25.24	25.14
PMI	26.22	25.19
ESIM w/o scenario	25.85	25.41
ESIM w/ scenario	24.34	24.41
DIIN w/o scenario	24.15	25.20
DIIN w/ scenario	25.11	24.89
BERT$_{NLI}$ w/o scenario	24.29	24.17
BERT$_{NLI}$ w/ scenario	24.97	24.68
BiMPM w/o scenario	24.13	24.51
BiMPM w/ scenario	24.76	23.81
BERT$_{RC}$ w/o scenario	24.81	24.78
BERT$_{RC}$ w/ scenario	23.66	23.01

Table 1: Proportions of correctly answered questions.

5 Conclusion

We have contributed GeoSQA—a large SQA dataset where diagrams are present and have been manually annotated with natural language descriptions. We have tested a variety of existing methods on our dataset. The results are not satisfactory, thus demonstrating the unique challenges presented by the SQA task on our dataset. In future work, we will work towards more effective solutions to meet the challenges.

Researchers are invited to use GeoSQA to support their own tasks, including but not limited to natural language based SQA, visual SQA, and the diagram-to-text task.

Revisiting the Evaluation of Theory of Mind through Question Answering

Matthew Le **Y-Lan Boureau** **Maximilian Nickel**

Abstract

Theory of mind, i.e., the ability to reason about intents and beliefs of agents is an important task in artificial intelligence and central to resolving ambiguous references in natural language dialogue. In this work, we revisit the evaluation of theory of mind through question answering. We show that current evaluation methods are flawed and that existing benchmark tasks can be solved without theory of mind due to dataset biases. Based on prior work, we propose an improved evaluation protocol and dataset in which we explicitly control for data regularities via a careful examination of the answer space. We show that state-of-the-art methods which are successful on existing benchmarks fail to solve theory-of-mind tasks in our proposed approach.

1 Introduction

Humans interact and communicate with other people in a highly efficient way, as described for instance as Grice's cooperative principle (Grice et al., 1975). Inferring other people's mental state is a crucial component of cognitive development, playing a role in how humans learn the meaning of words (Bloom, 2002), distinguish beliefs from reality (Gopnik and Astington, 1988), predict people's behavior (Wimmer and Perner, 1983), understand what others refer to, and reduce ambiguity in conversation (Clark, 1981; Keysar et al., 2000). This ability to reason about the mental state of other agents, called *theory of mind*, is thus an important component of an intelligent system aiming to emulate and interact with humans.

In developmental psychology, classic tests such as the *Sally-Anne test* (Baron-Cohen et al., 1985) have been used to assess the ability to infer false beliefs in others. Recently, Grant et al. (2017) and Nematzadeh et al. (2018) proposed to adapt these tests to evaluate the capability of machine learning models to form a theory of mind. The key insight of Grant et al. (2017) was to cast them as question answering tasks, where a system is given a story and has to answer questions about the beliefs of agents in that story. This allows to adapt the bAbi benchmarking protocol (Weston et al., 2016) to evaluate theory of mind capabilities of modern neural network architectures: stories are automatically generated so that a suitably large number of examples can be provided for training.

We believe this is a promising approach for advancing research on theory of mind, as it decouples its evaluation from problems such as multi-agent systems, game theory, and meta-learning, which are all components of other evaluation methods (Rabinowitz et al., 2018; Bard et al., 2019). However, artificial data runs the risk of displaying hidden artifacts and biases that correlate with the prediction task and can be exploited by models (Jabri et al., 2016; Gururangan et al., 2018; Poliak et al., 2018). The highly systematic nature of data generation puts synthetic benchmarks at an even higher risk of overestimating the target competence of interest.

This paper shows that current theory-of-mind QA benchmarks do indeed suffer from data biases, and are perfectly solvable without theory of mind. To overcome this, we propose an improved evaluation method and dataset[1]. We then show that state-of-the-art memory-augmented models – which are successful on existing benchmarks – fail to solve theory-of-mind tasks in our improved approach.

2 Theory of Mind Benchmarks

This section briefly reviews the Sally-Anne test and related paradigms for evaluating theory of mind.

First-Order Beliefs The so-called *Sally-Anne test* (Baron-Cohen et al., 1985) examines children's

[1]Our code and dataset will be made available at https://github.com/facebookresearch/ToMi

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5872–5877, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ability to reason about other agents' false beliefs. The child observes the actions of two agents (Sally, Anne). First, Sally puts an object into a container. Second, Anne moves the object without Sally observing this action. Third, the child is asked multiple questions about reality and the agents' beliefs:

First-Order Belief: Where will Sally look for the marble?

Reality: Where is the marble really?

Memory: Where was the marble in the beginning?

The first question tests the ability of the child to infer the correct mental state of Sally, i.e., that she has the false belief of the marble being in the basket. The reality and memory questions ensure that the child has a correct understanding of the state of the world and is not responding at chance.

Second-Order Beliefs "Sally-Anne"-type questions are well-suited to evaluate *first-order* beliefs. Nematzadeh et al. (2018) proposed to also evaluate *second-order* theory of mind, i.e., the ability to infer beliefs about beliefs. Perner and Wimmer (1985) proposed a set of experiments to test such second-order beliefs in children. The experiments can be summarized as follows: Two agents (Mary, John) see an icecream van in the park. The vendor tells them that he will be in the park all afternoon. After Mary leaves the park, the vendor decides to leave the park and tells John he is going to the church. On the way to the church, the vendor meets Mary and tells her also that he will be at the church. The child is then asked the following question:

Second-Order Belief: Where does John think Mary will go to get ice-cream?

As control, children are also asked memory, reality, and first-order belief questions.

Psychology Tests as AI Benchmarks Grant et al. (2017) cast the aforementioned experiments as question answering tasks and proposed to create a bAbi-style dataset (Weston et al., 2016) to evaluate theory of mind in artificial intelligence models. For instance, this is the bAbi question-answering task version of the Sally-Anne test:

Sally puts a marble in her basket
Sally leaves the room
Anne moves the marble in her box

Q: *Where would Sally look for the marble?*
A: Basket

Nematzadeh et al. (2018) evaluate several modern neural network architectures over the resulting dataset and report that all fail on theory-of-mind tasks, especially when irrelevant sentences are introduced into stories at test time. In the following, we refer to these benchmarks as *ToM-bAbi*.

3 Evaluating Theory of Mind Evaluation

This section examines shortcomings of ToM-bAbi for evaluating a model's theory of mind abilities and proposes an improved approach.

Related Work on Dataset Artifacts It is challenging to determine what specific competence is revealed by the successful completion of a task, as illustrated by the case of *Clever Hans*, the famous horse whose skill at reading human reactions passed for arithmetic ability (Pfungst, 1911). Recent analyses of several AI benchmarks have uncovered similar difficulties when probing learning models. In the domain of visual question answering, baselines solely relying on candidate answers have shown surprisingly good performance (Jabri et al., 2016), leading to the creation of a carefully designed diagnostic dataset (Johnson et al., 2017). Similarly, natural language inference benchmarks have been shown to be vulnerable to bias exploitation (Gururangan et al., 2018; Poliak et al., 2018), and multimodal machine translation benchmarks have been demonstrated to be too simple to require multi-modality (Caglayan et al., 2019). We follow the same approach here of examining the performance of a baseline that does not make use of a type of information crucial to the target competence. Taking "reasoning about another agent" as a working definition of theory of mind, a reasonable prerequisite of benchmarks probing theory of mind competence is that they be impossible to solve without some input about the other agent.

Leveraging Dataset Biases in ToM-bAbi Reviewing the generation process of ToM-bAbi uncovers predictable regularities that allow a model to use corner-cutting heuristics instead of keeping track of agents: the stories follow a strict event sequence template for each task type, shown in Fig. 1. The ToM-bAbi dataset takes precautions to guard against the most simplistic heuristic (e.g., 'always output the location of line 4') by adding irrelevant sentences at random places as noise, but many regularities and correlations remain. These regularities make it possible to construct a parsimonious set

Algorithm 1: Rules to solve ToM-bAbi

```
Data: question q, story s
Result: location l
if "beginning" ∈ q then        // Memory
    l ← location of first object occurrence;
else if "really" ∈ q then      // Reality
    l ← location of last object occurrence;
else if "look" ∈ q then    // 1st Order
    if "exited" ∈ s after last "object is in"
     then
        l ← location of last object
          occurrence before last "exited";
    else
        l ← location of last object
          occurrence;
    end
else if "think" ∈ q then   // 2nd Order
    if "exited" ∈ s after last "object is in"
     then
        l ← location of last object
          occurrence before first "exited";
    else
        l ← location of last object
          occurrence;
    end
end
```

of rules that perfectly solve all tasks without ever extracting any information about the agents. As shown in the pseudo-code implementation of Algorithm 1, these rules only involve simple lexical and ordinal patterns (code provided in the supplemental material).

Towards Robust ToM Evaluation in QA To increase robustness against such regularities and correlations, we build upon the ideas of ToM-bAbi but improve data generation and evaluation in multiple ways. We refer to the supplementary material for the full pseudo-code of our dataset generator.

First, to generate a balanced dataset over story types, ToM-bAbi uses different generators for true-belief, false-belief, and second-order false-belief stories. However, the different generators add clear biases to the data which can be exploited to identify the story type (for example, lack of the word "exited" signals a true belief story – see Fig. 1). To overcome this issue, we use the same randomized generation method for all stories and keep track of which type is produced. We then sample from this randomized story generator with rejection to create a balanced dataset over all three types of stories.

Second, to decrease the amount of information that can be predicted from any given event, we add the following random distractors during data generation: actions of unrelated agents to decorrelate actions from answers, distractor statements about locations and objects to make the number of mentions less informative, randomization of the order of exit/move/re-entry actions, and randomization of the agent whose beliefs are being queried. This leads to stories that are a lot less predictable (see examples in Fig. 1).

Third, theory of mind manifests in "Sally-Anne" type tests through the understanding that an agent's belief is different from the actual state of the world, and that both coexist at the same moment. It is therefore crucial to evaluate both, the ability to infer the state of the world *and* the mental state of an agent. Although current benchmarks include reality and memory control questions, only one type of question is asked for each different, separately generated story. This can obscure revealing correlations in the models' responses e.g., that accuracy in first-order belief questions is associated with lower performance on reality questions. Since a correct answer to a false-belief question is only meaningful if the reality question is also answered correctly, it is especially important to check that the models can distinguish between states *for each story*. For this reason, we propose to systematically ask all question types for each generated story. In particular, for a single story involving agents `A`, `B`, and object `O`, we ask *all* following questions:

Reality: Where is `O`?

Memory: Where was `O` in the beginning?

First-Order Belief `A`: Where will `A` look for `O`?

First-Order Belief `B`: Where will `B` look for `O`?

Second-Order Belief `A`: Where does `A` believe `B` will look for `O`?

Second-Order Belief `B`: Where does `B` believe `A` will look for `O`?

Furthermore, we propose to count a story s as answered correctly if all questions about s are jointly correct, and to measure overall accuracy as the fraction of correctly answered stories. This ensures that a model is not acquiring theory of mind at the expense of its ability to perform other tasks and that it correctly answers reality and false-beliefs

ToM-bAbi dataset

Three types of stories

1 $\langle A \rangle$ entered $\langle L \rangle$
2 $\langle B \rangle$ entered $\langle L \rangle$
3 Phone rang. *// Distractor can appear anywhere*
4 The $\langle O \rangle$ is in $\langle C1 \rangle$.
5 $\langle B \rangle$ exited $\langle L \rangle$ *// if story type 1 or 2*
6 $\langle A \rangle$ moved the $\langle O \rangle$ to $\langle C2 \rangle$.
7 $\langle A \rangle$ exited the $\langle L \rangle$ *// if story type 2*
8 $\langle B \rangle$ entered the $\langle L \rangle$ *// if story type 2*

Example story

1 Isla entered the bathroom.
2 Benjamin entered the bathroom.
3 The cabbage is in the green_pantry.
4 Phone rang.
5 Isla moved the cabbage to the red_drawer.

Answers for each story-question pair

	Story 1	Story 2	Story 3
First Order	C1	C2	C2
Second Order	C1	C1	C2
Memory	C1	C1	C1
Reality	C2	C2	C2

ToMi dataset

Examples of stories from the ToMi dataset

1 Oliver dislikes the kitchen
2 Carter entered the porch.
3 Abigail entered the porch.
4 The potato is in the green_suitcase.
5 Abigail exited the porch.
6 Abigail entered the hall.
7 Carter moved the potato to the green_envelope.
8 Oliver entered the hall.

1 Mila entered the closet.
2 Isla entered the closet.
3 Ava entered the closet.
4 The orange is in the blue_container.
5 Isla exited the closet.
6 Isla entered the garage.
7 Ava moved the orange to the green_bathtub.

1 William entered the staircase.
2 Aiden entered the staircase.
3 Aiden exited the staircase.
4 Aria entered the staircase.
5 The potato is in the red_drawer.
6 Aiden dislikes the grapefruit
7 William moved the potato to the blue_container.
8 Aria exited the staircase.

Figure 1: *Left:*Stories from the ToM-bAbi dataset follow three strict templates, with the possible random insertion of the distractor phrase "Phone rang." This makes it easier to devise rules to locate the answers for all pairs of question and story types, as shown in Alg. 1. For example, C1 always appears in the same sentence as the first object occurrence. *Right:* the ToMi dataset we propose is generated with considerably more randomness, with distractor phrases, distractor locations, distractor characters, and shuffling of the order of actions.

questions jointly. Formally, we define this *joint accuracy* as

$$Acc_J(\mathcal{S}) = \frac{1}{|\mathcal{S}|} \sum_{s \in \mathcal{S}} \prod_{q \in \mathcal{Q}_s} \mathbb{1}(\widehat{a}_q = a_q) \quad (1)$$

where $\mathbb{1} : \{\bot, \top\} \rightarrow \{0, 1\}$ is the indicator function, $\mathcal{S}$ the set of all stories, $\mathcal{Q}_s$ the set of all questions about story s, and $a_q, \widehat{a}_q$ are the correct and the model's answer for question q respectively.

4 Experimental Evaluation

This section evaluates state-of-the-art question answering methods on the original ToM-bAbI and on our improved dataset. We follow Nematzadeh et al. (2018) and consider Memory Networks (MemNN; Sukhbaatar et al. 2015), Relation Networks (RelNet; Santoro et al. 2017, and Recurrent Entity Networks (EntNet; Henaff et al. 2017), which solve the original bAbI question answering tasks.

Table 1 shows the average accuracy over all questions for the original ToM-bAbI benchmarks (ToM-easy, ToM) and our improved dataset (ToMi).

Table 1: Accuracy on benchmark datasets. "Average" indicates the average accuracy over all questions. "Joint" indicates the joint accuracy as defined in Eq. (1).

	Average			**Joint**
	ToM-easy	ToM	ToMi	ToMi
Rules	100.0	100.0	77.5	36.5
MemNN	100.0	90.7	77.2	44.3
EntNet	100.0	94.9	90.6	66.8
RelNet	100.0	94.4	86.0	57.4

Moreover, for ToMi we also show the joint accuracy as defined in Equation (1). Algorithm 1 achieves perfect accuracy on ToM-easy and ToM. Since all QA models have the capacity to capture these simple heuristics, it is not surprising that they also perform very well on the original benchmarks, i.e., perfect accuracy on ToM-easy and over 90% percent accuracy on ToM.[2] Moreover, we found that the drop in accuracy in ToM is mostly caused

[2]These results are better than in the ToM-bAbI paper. Communication with the authors has not provided clear reasons why, so this may be due to more extensive optimization.

Table 2: Average accuracy by question type (MemNN)

	ToM-easy	ToM	ToMi
Memory	100.0	71.9	98.90
Reality	100.0	100.0	93.39
First-Order	100.0	98.6	70.72
Second-Order	100.0	95.3	64.66

Table 3: Average accuracy per question type in ToMi. "FB" and "'w/o FB" indicate question-story pairs that do and do not involve false beliefs, respectively.

		MemNN	RelNet	EntNet
w/o FB	First Order	85.45	96.42	94.29
	Second Order	82.67	95.37	85.08
	Reality	93.39	100.0	100.0
	Memory	98.90	99.90	100.0
FB	First Order	12.62	10.40	54.95
	Second Order	17.27	17.81	36.55

by *memory* questions. This is because ToM stories are significantly longer and the location of the first occurrence of the queried object can exceed the memory capacity of the models. Table 2 shows an ablation for MemNNs that illustrates this effect.

By contrast, Algorithm 1[3] and QA models fail to solve the ToMi tasks. This is especially clear when looking at the joint accuracy of Table 1, which is not inflated by easy-to-answer memory and reality questions. Our ablation in Table 3 provides further insights into these results. It lists the average accuracy per question type and further splits the results into false-belief and non-false-belief question-story pairs. All models do reasonably well on question-story pairs that do not involve false beliefs, i.e., where the mental state of an agent should coincide with the state of the world. However, for question-story pairs with false beliefs, all models fail to provide correct answers consistently. Recurrent Entity Networks, which explicitly aim to keep track of the state of the world, are performing best on false beliefs tasks, indicating that this is a useful inductive bias for QA models on theory-of-mind tasks.

5 Discussion

Theory of mind is an important component of intelligent systems which interact with humans. In the context of natural language, theory of mind is not only of interest because of its evaluation through question answering but also because it is a crucial component to understand references and reduce ambiguities. This work re-examined the evaluation of theory of mind through bAbi-style question answering tasks. We revealed exploitable regularities in the generated data of existing benchmarks, and proposed to remedy this with a new dataset and evaluation method. We also showed that existing question answering methods that were capable of solving the previously proposed benchmarks are not able to solve the new tasks anymore. In future work, we aim at developing models to solve the newly proposed tasks.

Achieving this would demonstrate some level of ability to reason about first- and second-order false beliefs. But an important point to keep in mind when using our benchmark is that it still relies on synthetic data and tasks. We chose this approach since synthetic data generation can be especially useful in novel and early-stage research efforts, as it provides a controlled environment and allows for detailed analyses of a model's ability to solve a task. However, while methods such as Recurrent Entity Networks have shown promise for keeping track of the state-of-the-world in our experiments, this is still in scenarios where the complexity of natural language is relatively simple. On real-world data, this ability would be much weaker as it would require additional competencies such as co-reference resolution, handling polysemy and ambiguities, and common-sense reasoning. Therefore, solving the tasks we propose can only be considered a prerequisite for a fully functional theory of mind which will ultimately have to be evaluated in real-world scenarios.

[3] A more elaborate set of rules could solve the tasks, but would require to take the agents into account.

Abstract

BERT model has been successfully applied to open-domain QA tasks. However, previous work trains BERT by viewing passages corresponding to the same question as independent training instances, which may cause incomparable scores for answers from different passages. To tackle this issue, we propose a multi-passage BERT model to globally normalize answer scores across all passages of the same question, and this change enables our QA model find better answers by utilizing more passages. In addition, we find that splitting articles into passages with the length of 100 words by sliding window improves performance by 4%. By leveraging a passage ranker to select high-quality passages, multi-passage BERT gains additional 2%. Experiments on four standard benchmarks showed that our multi-passage BERT outperforms all state-of-the-art models on all benchmarks. In particular, on the OpenSQuAD dataset, our model gains 21.4% EM and 21.5% F_1 over all non-BERT models, and 5.8% EM and 6.5% F_1 over BERT-based models.

1 Introduction

BERT model (Devlin et al., 2018) has achieved significant improvements on a variety of NLP tasks. For question answering (QA), it has dominated the leaderboards of several machine reading comprehension (RC) datasets. However, the RC task is only a simplified version of the QA task, where a model only needs to find an answer from a given passage/paragraph. Whereas, in reality, an open-domain QA system is required to pinpoint answers from a massive article collection, such as Wikipedia or the entire web.

Recent studies directly applied the BERT-RC model to open-domain QA (Yang et al., 2019; Nogueira et al., 2018; Alberti et al., 2019). They firstly leverage a passage retriever to retrieve multiple passages for each question. During training, passages corresponding to the same question are taken as independent training instances. During inference, the BERT-RC model is applied to each passage individually to predict an answer span, and then the highest scoring span is selected as the final answer. Although this method achieves significant improvements on several datasets, there are still several unaddressed issues. **First**, viewing passages of the same question as independent training instances may result in incomparable answer scores across passages. Thus, globally normalizing scores over all passages of the same question (Clark and Gardner, 2018) may be helpful. **Second**, previous work defines passages as articles, paragraphs, or sentences. However, *the question of proper granularity of passages* is still underexplored. **Third**, passage ranker for selecting high-quality passages has been shown to be very useful in previous open-domain QA systems (Wang et al., 2018a; Lin et al., 2018; Pang et al., 2019). However, we do not know whether it is still required for BERT. **Fourth**, most effective QA and RC models highly rely on explicit inter-sentence matching between questions and passages (Wang and Jiang, 2017; Wang et al., 2016; Seo et al., 2017; Wang et al., 2017), whereas BERT only applies self-attention layers over the concatenation of a question-passage pair. It is unclear whether the inter-sentence matching still matters for BERT.

To answer these questions, we conduct a series of empirical studies on the OpenSQuAD dataset (Rajpurkar et al., 2016; Wang et al., 2018a). Experimental results show that: (1) global normalization makes QA model more stable while pinpointing answers from large number of passages; (2) splitting articles into passages with the length of 100 words by sliding window brings 4% improvements; (3) leveraging a BERT-based passage

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5878–5882,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ranker gives us extra 2% improvements; and (4) explicit inter-sentence matching is not helpful for BERT. We also compared our model with state-of-the-art models on four standard benchmarks, and our model outperforms all state-of-the-art models on all benchmarks.

2 Model

Open-domain QA systems aim to find an answer for a given question from a massive article collection. Usually, a retriever is leveraged to retrieve m passages $P = [P_1, ..., P_i, ..., P_m]$ for a given question $Q = (q^1, ..., q^{|Q|})$, where $P_i = (p_i^1, ..., p_i^{|p_i|})$ is the i-th passage, and $q^k \in Q$ and $p_i^j \in P_i$ are corresponding words. A QA model will compute a score $Pr(a|Q, P)$ for each possible answer span a. We further decompose the answer span prediction into predicting the start and end positions of the answer span $Pr(a|Q, P) = P_s(a_s|Q, P)P_e(a_e|Q, P)$, where $P_s(a_s|Q, P)$ and $P_e(a_e|Q, P)$ are the probabilities of a_s and a_e to be the start and end positions.

BERT-RC model assumes passages in P are independent of each other. The model concatenates the question Q and each passage P_i into a new sequence "[CLS] $p_i^1, ..., p_i^{|p_i|}$ [SEP] $q^1, ..., q^{|Q|}$ [SEP]", and applies BERT to encode this sequence. Then the vector representation of each word position from BERT encoder is fed into two separate dense layers to predict the probabilities P_s and P_e (Devlin et al., 2018). During training, the log-likelihood of the correct start and end positions for each passage is optimized independently. For passages without any correct answers, we set the start and end positions to be 0, which is the position for the first token [CLS]. During inference, BERT-RC model is applied to each passage individually to predict an answer, and then the highest scoring span is selected as the final answer. If answers from different passages have the same string, they are merged by summing up their scores.

Multi-passage BERT: BERT-RC model normalizes probability distributions P_s and P_e for each passage independently, which may cause incomparable answer scores across passages. To tackle this issue, we leverage the global normalization method (Clark and Gardner, 2018) to normalize answer scores among multiple passages, and dub this model as multi-passage BERT. Concretely, all passages of the same question are processed independently as we do in BERT-RC until the normalization step. Then, $softmax$ is applied to normalize all word positions from all passages.

Passage ranker reranks all retrieved passages, and selects a list of high-quality passages for the multi-passage BERT model. We implement the passage ranker as another BERT model, which is similar to multi-passage BERT except that at the output layer it only predicts a single score for each passage based on the vector representation of the first token [CLS]. We also apply $softmax$ over all passage scores corresponding to the same question, and train to maximize the log-likelihood of passages containing the correct answers. Denote the passage score as $Pr(P_i|Q, P)$, then the score of an answer span from passage P_i will be $Pr(P_i|Q, P)P_s(a_s|Q, P)P_e(a_e|Q, P)$.

3 Experiments

Datasets: We experiment on four open-domain QA datasets. (1) *OpenSQuAD*: question-answer pairs are from SQuAD 1.1 (Rajpurkar et al., 2016), but a QA model will find answers from the entire Wikipedia rather than the given context. Following Chen et al. (2017), we use the 2016-12-21 English Wikipedia dump. 5,000 QA pairs are randomly selected from the original training set as our validation set, and the remaining QA pairs are taken as our new training set. The original development set is used as our test set. (2) *TriviaQA*: TriviaQA unfiltered version (Joshi et al., 2017) are used. Following Pang et al. (2019), we randomly hold out 5,000 QA pairs from the original training set as our validation set, and take the remaining pairs as our new training set. The original development set is used as our test set. (3) *Quasar-T* (Dhingra et al., 2017) and (4) *SearchQA* (Dunn et al., 2017) are leveraged with the official split.

Basic Settings: If not specified, the pre-trained BERT-base model with default hyper-parameters is leveraged. ElasticSearch with BM25 algorithm is employed as our retriever for OpenSQuAD. Passages for other datasets are from the corresponding releases. During training, we use top-10 passages for each question plus all passages (within the top-100 list) containing correct answers. During inference, we use top-30 passages for each question. Exact Match (EM) and F_1 scores (Rajpurkar et al., 2016) are utilized as the evaluation metrics.

No.	Model	EM	F_1
1	Single-sentence	34.8	44.4
2	Length-50	35.5	45.2
3	Length-100	35.7	45.7
4	Length-200	34.8	44.7
5	w/o sliding-window (same as (3))	35.7	45.7
6	w/ sliding-window	40.4	49.8
7	w/o passage ranker (same as (6))	40.4	49.8
8	w/ passage ranker	41.3	51.7
9	w/ passage scores	**42.8**	**53.4**
10	BERT+QANet	18.3	27.8
11	BERT+QANet (fix BERT)	35.5	45.9
12	BERT+QANet (init. from (11))	36.2	46.4

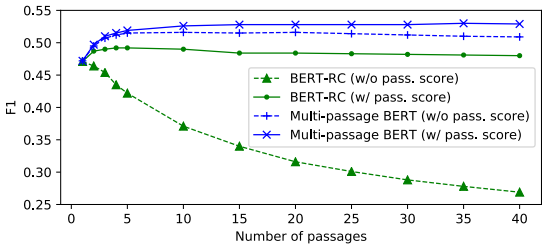

Figure 1: Effect of global normalization.

3.1 Model Analysis

To answer questions from section 1, we conduct a series of experiments on OpenSQuAD dataset, and report the validation set results in Table 1. Multi-passage BERT model is used for experiments.

Effect of passage granularity: Previous work usually defines passages as articles (Chen et al., 2017), paragraphs (Yang et al., 2019), or sentences (Wang et al., 2018a; Lin et al., 2018). We explore the effect of passage granularity regarding to the passage length, i.e., the number of words in each passage. Each article is split into non-overlapping passages based on a fixed length. We vary passage length among {50, 100, 200}, and list the results as models (2) (3) (4) in Table 1, respectively. Comparing to single-sentence passages (model (1)), leveraging fixed-length passages works better, and passages with 100 words works the best. Hereafter, we set passage length as 100 words.

Effect of sliding window: Splitting articles into non-overlapping passages may force some near-boundary answer spans to lose useful contexts. To deal with this issue, we split articles into overlapping passages by sliding window. We set the window size as 100 words, and the stride as 50 words (half the window size). Result from the sliding window model is shown as model (6) in Table 1. We can see that this method brings us 4.7% EM and 4.1% F_1 improvements. Hereafter, we use sliding window method.

Effect of passage ranker: We plug the passage ranker into the QA pipeline. First, the retriever returns top-100 passages for each question. Then, the passage ranker is employed to rerank these 100 passages. Finally, multi-passage BERT takes top-30 reranked passages as input to pinpoint the final answer. We design two models to check the effect of the passage ranker. The first model utilizes the reranked passages but without using passage scores, whereas the second model makes use of both the reranked passages and their scores. Results are given in Table 1 as models (8) and (9) respectively. We can find that only using reranked passages gives us 0.9% EM and 1.0% F_1 improvements, and leveraging passage scores gives us 1.5% EM and 1.7% F_1 improvements. Therefore, passage ranker is useful for multi-passage BERT model.

Effect of global normalization: We train BERT-RC and multi-passage BERT models using the reranked passages, then evaluate them by taking as input various number of passages. These models are evaluated on two setups: with and without using passage scores. F_1 scores for BERT-RC based on different number of passages are shown as the dotted and solid green curves in Figure 1. F_1 scores for our multi-passage BERT model with similar settings are shown as the dotted and solid blue curves. We can see that all models start from the same F_1, because multi-passage BERT is equivalent to BERT-RC when using only one passage. While increasing the number of passages, BERT-RC without using passage scores decreases the performance significantly, which verifies that the answer scores from BERT-RC are incomparable across passages. This issue is alleviated to some extent by leveraging passage scores. On the other hand, performance from multi-passage BERT without using passage scores increases at the beginning, and then flattens out after passage number is over 10. By utilizing passage scores, multi-passage BERT gets better performance while using more passages. This phenomenon shows the effectiveness of global normalization, which enables the model find better answers by utilizing more passages.

Does explicit inter-sentence matching matter? Almost all previous state-of-the-art QA and RC models find answers by matching pas-

Multi-Passage BERT (Base)	**51.3**	59.0	**65.2**	70.6	62.0	67.5	51.2	59.0
Multi-Passage BERT (Large)	51.1	**59.1**	65.1	**70.7**	**63.7**	**69.2**	**53.0**	**60.9**

Table 2: Comparison with state-of-the-art models, where the first group are models without using BERT, the second group are BERT-based models, and the last group are our multi-passage BERT models.

sages with questions, aka inter-sentence matching (Wang and Jiang, 2017; Wang et al., 2016; Seo et al., 2017; Wang et al., 2017; Song et al., 2017). However, BERT model simply concatenates a passage with a question, and differentiates them by separating them with a delimiter token [SEP], and assigning different segment ids for them. Here, we aim to check whether explicit inter-sentence matching still matters for BERT. We employ a shared BERT model to encode a passage and a question individually, and a weighted sum of all BERT layers is used as the final token-level representation for the question or passage, where weights for all BERT layers are trainable parameters. Then the passage and question representations are input into QANet (Yu et al., 2018) to perform inter-sentence matching, and predict the final answer. Model (10) in Table 1 shows the result of jointly training the BERT encoder and the QANet model. The result is very poor, likely because the parameters in BERT are catastrophically forgotten while training the QANet model. To tackle this issue, we fix parameters in BERT, and only update parameters for QANet. The result is listed as model (11). It works better than model (10), but still worse than multi-passage BERT in model (6). We design another model by starting from model (11), and then jointly fine-tuning the BERT encoder and QANet. Model (12) in Table 1 shows the result. It works better than model (11), but still has a big gap with multi-passage BERT in model (6) . Therefore, we conclude that the explicit inter-sentence matching is not helpful for multi-passage BERT. One possible reason is that the multi-head self-attention layers in BERT has already embedded the inter-sentence matching.

3.2 Comparison with State-of-the-art Models

We evaluate BERT-RC and Multi-passage BERT on four standard benchmarks, where passage scores are leveraged for both models. We build another multi-passage BERT for each dataset by initializing it with the pre-trained BERT-Large model. Experimental results from our models as well as other state-of-the-art models are shown in Table 2, where the first group are open-domain QA models without using the BERT model, the second group are BERT-based models, and the last group are our multi-passage BERT models.

From Table 2, we can see that our multi-passage BERT model outperforms all state-of-the-art models across all benchmarks, and it works consistently better than our BERT-RC model which has the same settings except the global normalization. In particular, on the OpenSQuAD dataset, our model improves by 21.4% EM and 21.5% F_1 over all non-BERT models, and 5.8% EM and 6.5% F_1 over BERT-based models. Leveraging BERT-Large model makes multi-passage BERT even better on TriviaQA and OpenSQuAD datasets.

4 Conclusion

We propose a multi-passage BERT model for open-domain QA to globally normalize answer scores across mutiple passages corresponding to the same question. We find two effective techniques to improve the performance of multi-passage BERT: (1) splitting articles into passages with the length of 100 words by sliding window; and (2) leveraging a passage ranker to select high-quality passages. With all these techniques, our multi-passage BERT model outperforms all state-of-the-art models on four standard benchmarks.

In future, we plan to consider inter-correlation

among passages for open-domain question answering (Wang et al., 2018b; Song et al., 2018).

Abstract

Machine Reading Comprehension (MRC) has become enormously popular recently and has attracted a lot of attention. However, the existing reading comprehension datasets are mostly in English. In this paper, we introduce a Span-Extraction dataset for Chinese machine reading comprehension to add language diversities in this area. The dataset is composed by near 20,000 real questions annotated on Wikipedia paragraphs by human experts. We also annotated a challenge set which contains the questions that need comprehensive understanding and multi-sentence inference throughout the context. We present several baseline systems as well as anonymous submissions for demonstrating the difficulties in this dataset. With the release of the dataset, we hosted the Second Evaluation Workshop on Chinese Machine Reading Comprehension (CMRC 2018). We hope the release of the dataset could further accelerate the Chinese machine reading comprehension research.[1]

1 Introduction

To read and comprehend natural languages is the key to achieve advanced artificial intelligence. Machine Reading Comprehension (MRC) aims to comprehend the context of given articles and answer the questions based on them. Various types of machine reading comprehension datasets have been proposed, such as cloze-style reading comprehension (Hermann et al., 2015; Hill et al., 2015; Cui et al., 2016), span-extraction reading comprehension (Rajpurkar et al., 2016; Trischler et al., 2016), open-domain reading comprehension (Nguyen et al., 2016; He et al., 2017), reading comprehension with multiple-choice (Richardson et al., 2013; Lai et al., 2017), etc. Along with the development of the reading comprehension dataset, various neural network approaches have been proposed and made a big advancement in this area (Kadlec et al., 2016; Cui et al., 2017; Dhingra et al., 2017; Wang and Jiang, 2016; Xiong et al., 2016; Liu et al., 2017; Wang et al., 2017; Hu et al., 2018; Wang et al., 2018; Yu et al., 2018).

We also have seen various efforts on the construction of Chinese machine reading comprehension datasets. In cloze-style reading comprehension, Cui et al. (2016) proposed a Chinese cloze-style reading comprehension dataset: People's Daily & Children's Fairy Tale. To add difficulties to the dataset, along with the automatically generated evaluation sets (development and test), they also release a human-annotated evaluation set. Later, Cui et al. (2018) propose another dataset, which is gathered from children's reading material. To add more diversity and for further investigation on transfer learning, they also provide another evaluation dataset, which is also annotated by human experts, but the query is more natural than the cloze type. The dataset was used in the first evaluation workshop on Chinese machine reading comprehension (CMRC 2017). In open-domain reading comprehension, He et al. (2017) propose a large-scale open-domain Chinese machine reading comprehension dataset (DuReader), which contains 200k queries annotated from the user query logs on the search engine. Shao et al. (2018) proposed a reading comprehension dataset in Traditional Chinese.

Though we have seen that the current machine learning approaches have surpassed the human performance on the SQuAD dataset (Rajpurkar et al., 2016), we wonder if these state-of-the-art models could also give a similar performance on the dataset of different languages. To further accelerate the development of the machine reading comprehension research, we propose a span-

[Passage] 《黄色脸孔》是柯南·道尔所著的福尔摩斯探案的56个短篇故事之一，收录于《福尔摩斯回忆录》。孟罗先生素来与妻子恩爱，但自从最近邻居新入伙后，孟罗太太则变得很奇怪，曾经凌晨时份外出，又藉丈夫不在家时偷偷走到邻居家中。于是孟罗先生向福尔摩斯求助，福尔摩斯听毕孟罗先生的故事后，认为孟罗太太被来自美国的前夫勒索，所以不敢向孟罗先生说出真相，所以吩咐孟罗先生，如果太太再次走到邻居家时，即时联络他，他会第一时间赶到。孟罗太太又走到邻居家，福尔摩斯陪同孟罗先生冲入，却发现**邻居家中的人是孟罗太太与前夫生的女儿，因为孟罗太太的前夫是黑人，她怕孟罗先生嫌弃混血儿，所以不敢说出真相。**	**[Passage]** "The Adventure of the Yellow Face", one of the 56 short Sherlock Holmes stories written by Sir Arthur Conan Doyle, is the third tale from The Memoirs of Sherlock Holmes. Mr. Munro has always been loved by his wife, but since the new neighbors recently joined, Mrs. Munro has become very strange. She used to go out in the early hours of the morning and secretly went to her neighbors when her husband was not at home. ... Mrs. Munro went to the neighbor's house again, and Holmes accompanied Mr. Munro to rush in, only to find that the neighbor's family was the daughter of Mrs. Munro and her ex-husband, **because Mrs. Munro's ex-husband was black, and she was afraid of Mr. Munro hate the mixed-race, so she did not dare to tell the truth.**
[Question] 孟罗太太为什么在邻居新入伙后变得很奇怪? **[Answer 1]** 邻居家中的人是孟罗太太与前夫生的女儿，因为孟罗太太的前夫是黑人，她怕孟罗先生嫌弃混血儿 **[Answer 2]** 邻居家中的人是孟罗太太与前夫生的女儿，因为孟罗太太的前夫是黑人，她怕孟罗先生嫌弃混血儿，所以不敢说出真相。 **[Answer 3]** 邻居家中的人是孟罗太太与前夫生的女儿，因为孟罗太太的前夫是黑人，她怕孟罗先生嫌弃混血儿，所以不敢说出真相。	**[Question]** Why Mrs. Munro became strange after the new neighbors moved in? **[Answer 1]** because Mrs. Munro's ex-husband was black, and she was afraid of Mr. Munro hate the mixed-race **[Answer 2]** because Mrs. Munro's ex-husband was black, and she was afraid of Mr. Munro hate the mixed-race **[Answer 3]** because Mrs. Munro's ex-husband was black, and she was afraid of Mr. Munro hate the mixed-race, so she did not dare to tell the truth.

Figure 1: An example of the proposed CMRC 2018 dataset (challenge set). English translation is also given for comparison.

extraction dataset for Chinese machine reading comprehension. Figure 1 shows an example of the proposed dataset. The main contributions of our work can be concluded as follows.

- We propose a Chinese span-extraction reading comprehension dataset which contains near 20,000 human-annotated questions, to add linguistic diversity in reading comprehension field.
- To thoroughly test the ability of the MRC systems, besides the development and test set, we also make a challenge set which contains carefully annotated questions that require various clues in the passage. The BERT-based approaches could only give under 50% F1-score on this set, indicating its difficulty.
- The proposed Chinese RC data could also be a resource for cross-lingual research purpose when studied along with SQuAD and other similar datasets.

2 The Proposed Dataset

2.1 Task Definition

Generally, the reading comprehension task can be described as a triple $\langle \mathcal{P}, \mathcal{Q}, \mathcal{A} \rangle$, where $\mathcal{P}$ represents **P**assage, $\mathcal{Q}$ represents **Q**uestion and the $\mathcal{A}$ represents **A**nswer. Specifically, for span-extraction reading comprehension task, the question is annotated by the human, which is much more natural than the cloze-style MRC datasets (Hill et al., 2015; Cui et al., 2016). The answer $\mathcal{A}$ should be a span which is directly extracted from the passage $\mathcal{P}$. According to most of the works on SQuAD, the task can be simplified by predicting the start and end pointer in the passage (Wang and Jiang, 2016).

2.2 Data Pre-Processing

We downloaded Chinese portion of Wikipedia webpage dump[2] on Jan 22, 2018 and used open-source toolkit *Wikipedia Extractor*[3] for pre-processing the raw files into plain text. We also convert the Traditional Chinese characters into Simplified Chinese for normalization purpose using *opencc*[4] toolkit.

2.3 Human Annotation

The questions in the proposed dataset are completely annotated by human experts, which is different from previous works that rely on the automatic data generation (Hermann et al., 2015; Hill et al., 2015; Cui et al., 2016). Before annotating, the document is divided into several passages, and each passage is limited to have no more than 500 Chinese words, where the word is counted by using LTP (Che et al., 2010). Then, the annotator was instructed to first evaluate the appropriateness of the passages, because some of the passages are extremely difficult for the public to understand. Following rules are applied when discarding the passages.

[2] https://dumps.wikimedia.org/zhwiki/latest/

[3] http://medialab.di.unipi.it/wiki/Wikipedia_Extractor

[4] https://github.com/BYVoid/OpenCC

- Contain over 30% non-Chinese characters.
- Contain many professional words that hard to understand.
- Contains many special characters and symbols.
- The paragraph is written in classical Chinese, which is substantially different from the Chinese language nowadays.

After identifying the passage is appropriate for annotation, the annotator will read the passage and ask the questions based on it and annotated a primary answer. During the question annotation, the following rules are applied.

- No more than five questions for each passage.
- The answer MUST be a span in the passage to meet the task definition.
- Encourage the question diversity, such as who/when/where/why/how, etc.
- Avoid directly using the description in the passage. Use paraphrase or syntax transformation to add difficulties for answering.
- Long answers (say over 30 characters) will be discarded.

For the evaluation sets, i.e., development, test, challenge, there are three answers available for better evaluation. Besides the primary answer that was annotated by the question proposer, we also invite two additional annotators to write the second and third answers for the question. During this phase, the annotators could not see the primary answer to ensure the answer was not copied from others and encourage the diversities in the answer.

2.4 Challenge Set

In order to examine how well can reading comprehension models deal with the questions that need comprehensive reasoning over various clues in the context, we additionally annotated a small challenge set for this purpose while keeping the span-extraction style. The annotation was also done by three annotators in a similar way that for development and test set. Figure 1 shows an example in the challenge set. The question should meet the following standards to be qualified into this set.

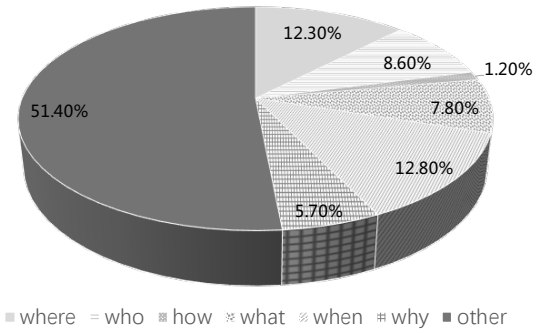

Figure 2: Question types of the development set.

- The answer cannot be only inferred by a single sentence in the passage if the answer is a single word or short phrase. We encourage the annotator to ask the questions that need comprehensive reasoning in the passage to increase the difficulties.
- If the answer belongs to a type of named entity, or specific genre (such as date, color, etc.), it can not be the only one in the context, or the machine could easily pick it out according to its type. For example, if there is only one person name appears in the context, then it cannot be used for annotating questions. There should be at least two person names that could mislead the machine for answering.

2.5 Statistics

The general statistics of the pre-processed data are given in Table 1. The question type distribution of the development set is given in Figure 2.

	Train	Dev	Test	Challenge
Question #	10,321	3,351	4,895	504
Answer per Q	1	**3**	**3**	**3**
Max P tokens	962	961	980	916
Max Q tokens	89	56	50	47
Max A tokens	100	85	92	77
Avg P tokens	452	469	472	464
Avg Q tokens	15	15	15	18
Avg A tokens	17	9	9	19

Table 1: Statistics of the CMRC 2018 dataset. (P: Passage, Q: Question, A: Answer)

3 Evaluation Metrics

In this paper, we adopt two evaluation metrics following Rajpurkar et al. (2016). However, as

	Development		Test		Challenge	
	EM	F1	EM	F1	EM	F1
Estimated Human Performance	*91.083*	*97.348*	*92.400*	*97.914*	*90.382*	*95.248*
Z-Reader (single model)	**79.776**	**92.696**	**74.178**	**88.145**	13.889	**37.422**
MCA-Reader (ensemble)	66.698	85.538	71.175	88.090	15.476	37.104
RCEN (ensemble)	76.328	91.370	68.662	85.753	15.278	34.479
MCA-Reader (single model)	63.902	82.618	68.335	85.707	13.690	33.964
OmegaOne (ensemble)	66.977	84.955	66.272	82.788	12.103	30.859
RCEN (single model)	73.253	89.750	64.576	83.136	10.516	30.994
GM-Reader (ensemble)	58.931	80.069	64.045	83.046	**15.675**	37.315
OmegaOne (single model)	64.430	82.699	64.188	81.539	10.119	29.716
GM-Reader (single model)	56.322	77.412	60.470	80.035	13.690	33.990
R-NET (single model)	45.418	69.825	50.112	73.353	9.921	29.324
SXU-Reader (ensemble)	40.292	66.451	46.210	70.482	N/A	N/A
SXU-Reader (single model)	37.310	66.121	44.270	70.673	6.548	28.116
T-Reader (single model)	39.422	62.414	44.883	66.859	7.341	22.317
BERT-base (Chinese)	63.6	83.9	67.8	86.0	18.4	42.1
BERT-base (Multi-lingual)	64.1	84.4	68.6	86.8	18.6	43.8

Table 2: Baseline results and CMRC 2018 participants' results. Note that, some of the submissions are using development set for training as well.

the Chinese language is quite different from English, we adapt the original metrics in the following ways. Note that, the common punctuations, white spaces are ignored for normalization.

3.1 Exact Match

Measure the exact match between the prediction and ground truths that is 1 for the exact match. Otherwise, the score is 0. This is the same as the one proposed by Rajpurkar et al. (2016).

3.2 F1-Score

Measure the character-level fuzzy match between the prediction and ground truths. Instead of treating the predictions and ground truths as bag-of-words, we calculate the length of the longest common sequence (LCS) between them and compute the F1-score accordingly. We take the maximum F1 over all of the ground truth answers for a given question. Note that, non-Chinese words will not be segmented into characters.

3.3 Estimated Human Performance

We also report the estimated human performance in order to measure the difficulty of the proposed dataset. As we have illustrated in the previous section, there are three answers for each question in development, test, and challenge set. Unlike Rajpurkar et al. (2016), we use a cross-validation method to calculate the performance. We regard the first answer as human prediction and treat the rest of the answers as ground truths. In this way, we can get three human prediction performance by iteratively regarding the first, second, and third answer as the human prediction. Finally, we calculate the average of three results as the final estimated human performance on this dataset.

4 Experimental Results

4.1 Baseline System

Following Devlin et al. (2019), we adopt BERT for our baseline system. Specifically, we slightly modify the `run_squad.py` script[5] for adjusting our dataset, while keeping the most of the original implementation. For the baseline system, we used an initial learning rate of 3e-5 with a batch size of 32 and trained for two epochs. The maximum lengths of document and query are set to 512 and 64.

4.2 Results

The results are shown in Table 2. Besides the baseline systems, we also include the participants' results of CMRC 2018 evaluation. We release the training and development set to the public and accepted submissions from participants to evaluate their models on the hidden test and challenge set to preserve the integrity of the evaluation process following Rajpurkar et al. (2016). As we can see that most of the participants could obtain over 80 in the test F1. While compared to F1 metric, the EM metric is substantially lower compared

[5] https://github.com/google-research/bert/blob/master/run_squad.py

to the SQuAD dataset (usually within 10 points). This suggests that how to determine the exact span boundary in Chinese machine reading comprehension plays a key role to improve the system performance.

Not surprisingly, as shown in the last column of Table 2, though the top-ranked systems obtain decent scores on the development and test set, they are failed to give satisfactory results on the challenge set. However, as we can see that the estimated human performance on the development, test, and challenge set are relatively similar, where the challenge set gives slightly lower scores. We also observed that though Z-Reader obtains best scores on the test set, it failed to give consistent performances on the EM metric of the challenge set. This suggests that the current reading comprehension models are relatively not capable of handling difficult questions that need comprehensive reasoning among several clues in the passage.

BERT-based approaches show competitive performance against participants submissions.[6] Though traditional models have higher scores in the test set, when it comes to the challenge set, BERT-based baselines are consistently higher, demonstrating that rich representation provided by BERT is beneficial for solving harder questions and generalize well among both easy and hard questions.

5 Conclusion

In this work, we propose a span-extraction dataset for Chinese machine reading comprehension. The dataset is annotated by human experts with near 20,000 questions as well as a challenging set which is composed of the questions that need reasoning over multiple clues. The evaluation results show that the machine could give excellent scores on the development and test set with only near 10 points below the estimated human performance in F1-score. However, when it comes to the challenge set, the scores are declining drastically while the human performance remains almost the same with the non-challenge set, indicating that there are still potential challenges in designing more sophisticated models to improve the performance. We hope the release of this dataset could bring language diversity in machine reading comprehension task, and accelerate further investigation on solving the questions that need comprehensive reasoning over multiple clues.

[6] As CMRC 2018 workshop was held before the publication of BERT, systems of the participants are not based on BERT.

Open Challenge

We would like to invite more researchers doing experiments on our CMRC 2018 dataset and evaluate on the hidden test and challenge set to further test the generalization of the models. You can follow the instructions on our CodaLab Worksheet to submit your model via https://bit.ly/2ZdS8Ct

Acknowledgments

We would like to thank the anonymous reviewers for their thorough reviewing and providing thoughtful comments to improve our paper. We would like to thank our resource team for annotating and verifying evaluation data. Also, we thank the Seventeenth China National Conference on Computational Linguistics (CCL 2018)[7] and Changsha University of Science and Technology for providing venue for evaluation workshop. MICRON: Multigranular Interaction for Contextualizing RepresentatiON in Non-factoid Question Answering

Hojae Han*, **Seungtaek Choi***, **Haeju Park, Seung-won Hwang**
Department of Computer Science, Yonsei University, Seoul, Korea
{stovecat, hist0613, phj0225, seungwonh}@yonsei.ac.kr

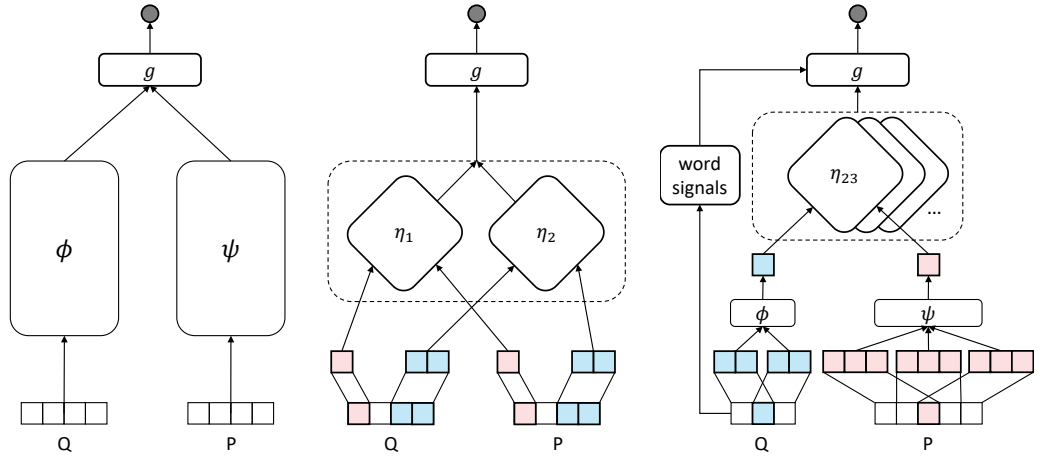
Abstract

This paper studies the problem of non-factoid question answering, where the answer may span over multiple sentences. Existing solutions can be categorized into representation- and interaction-focused approaches. We combine their complementary strength, by a hybrid approach allowing multi-granular interactions, but represented at word level, enabling an easy integration with strong word-level signals. Specifically, we propose **MICRON: Multigranular Interaction for Contextualizing RepresentatiON**, a novel approach which derives contextualized *uni*-gram representation from *n*-grams. Our contributions are as follows: First, we enable multi-granular matches between question and answer *n*-grams. Second, by contextualizing word representation with surrounding n-grams, MICRON can naturally utilize word-based signals for query term weighting, known to be effective in information retrieval. We validate MICRON in two public non-factoid question answering datasets: WikiPassageQA and InsuranceQA, showing our model achieves the state of the art among baselines with reported performances on both datasets.

1 Introduction

Non-factoid questions, unlike factoid questions answered by short facts like a word or a phrase, may get answered by a long answer spanning across multiple sentences. Following the definition in (Guo et al., 2019), neural approaches for this task can be roughly categorized into **representation-** and **interaction-focused** approaches.

First, **representation-focused** approaches (Rücklé and Gurevych, 2017; Shao et al., 2019) encode query and answer into vectors of the same size, and match the two by computing vector similarity. Models in this category have advantages of efficiency, as representations can be pre-computed and indexed for efficient retrieval. However, structural information, such as some question word matching another in answer, is missing in this representation. In addition, structural information can be diluted when squeezing a long text into a single vector. This weakness is often complemented by auxiliary information such as attention (Tan et al., 2016; Santos et al., 2016; Wang and Jiang, 2016). Figure 1a illustrates a representative architecture in this category (Shao et al., 2019).



Second, **interaction-focused** approaches aim to preserve structural information above. A naive structural information is a matrix storing pairwise word interaction, or 1:1. However, due to a typical length difference between a question and a long answer in our problem setting, most answer words are left unmatched, except a few *uni*-gram in the answer. Later work relaxes 1:1 constraint, to 1:N and M:N, by allowing a match to *n-gram* (1:N) or a match between query and answer *bi*-grams (2:2). A state-of-the-art in this category (Rücklé et al., 2019), shown in Figure 1b, uses *bi*-gram Convolutional Neural Network (CNN) to represent query/answer *bi*-grams and their interactions. Similar architecture was generalized for N:N or N:M matches (Song et al., 2019; Chen et al., 2018), which may introduce a new challenge of multi-granular interaction we discuss later.

Our work is of combining the strength of the two, as shown in Figure 1c. We illustrate our technical contributions using the following running example:

Example 1 *Consider a running example of matching a question, "Who is in charge of this education process", with a matching passage on "the institution of higher learning". Interaction between a query bi-gram "education process" and the 5-gram "the institution of higher learning" is a key*

*The authors contribute equally to this paper.

(a) Representation-focused (b) Interaction-focused (c) Ours: MICRON

Figure 1: Comparative illustration of three approaches.

indicator explaining this match. In addition, external word-level importance signals, such as Inverse Document Frequency (IDF), are observed to be simple yet most powerful (Guo et al., 2016), in matching a short query (or, question) with a long document, as in information retrieval or non-factoid question answering scenarios. For our example question with eight words, the IDF weight is highest for education, appearing rarely in other questions, while that is lower for common words.

Below are our two key contributions, inspired by the above running example.

1) Multigranular interaction: Figure 1c shows a dotted area, where interaction between *m*- and *n*-grams are represented. This enables matching between different sized n-grams: η_{25} enables the interaction between the *bi*-gram *"education process"* and the 5-gram *"the institution of higher learning"* in our running example. However, existing multigranular interaction (Chen et al., 2018) cannot combine word-level signal, such as a high IDF score of word "*education*".

2) N-gram contextualized word representation: Our next step is to combine this matching signal into a contextualized word representation For example, we represent word *higher* as an aggregation of its participating consecutive 5-grams, where *"... the institution of higher"* and *"the institution of higher ..."* disambiguate that the term should not be matched a question on *"high school"*. Similarly, question word *education* is represented by surrounding 2-grams: *"education process"* and *"of education"*. Contextualizing into word-level representation makes it natural to combine with word-level IDF scores in the model, and also enables indexing (Hwang and Chang, 2005). This shares the spirit of contextualized embedding, such as BERT (Devlin et al., 2018) and ELMo (Peters et al., 2018), but specialized for **short-distance** phrase context **localized** within question and passage.

We summarize the main contributions of this paper as follows. First, we utilize multigranular interaction to extract important information from the question/passage matching by proposing **MICRON: Multigranular Interaction for Contextualizing RepresentatiON**. Second, we leverage strong word-level signals, which we will discuss later.

We evaluate our method in two public non-factoid QA datasets: WikiPassageQA (Cohen et al., 2018) and InsuranceQA (Feng et al., 2015). The results show that our model achieves the state of the art among baselines with reported performances on both datasets. Our source code is freely-available at `https://github.com/stovecat/MICRON` for further study.

2 Our approach

In this section, we introduce our method in detail. MICRON mainly consists of three modules: encoding module, matching module, and scoring module. We use a Siamese architecture for encoding module, which is a common setting in our target problem (Rücklé and Gurevych, 2017; Shao et al., 2019; Rücklé et al., 2019).

Encoding Module For a word vector sequence $W \in \mathbb{R}^{|W| \times d}$ with dimensionality d, we encode

it by n-gram CNN as the following:

$$\Gamma_n(W) = \texttt{n-gramCNN}(W) \quad (1)$$

where n is the window size of n-gram CNN. Each $\Gamma_n(W) \in \mathbb{R}^{|W| \times d}$ represents n-gram semantics.

As a distinction from other interaction-focused approaches, we introduce an additional **Contextualization Layer** Φ, which returns a word representation, contextualized by surrounding n-gram phrases of the word belongs to. In our work, we define Φ as the arithmetic mean of n-gram representations, formalized as follows[1]:

$$[\Phi_n(W)]_k = \frac{\sum_{i=1}^{n} [\Gamma_n(W)]_{k-i+1}}{n} \quad (2)$$

where $[\Gamma_n(W)]_k$ is k-th row vector of $\Gamma_n(W)$, and each row of $\Phi_n(W) \in \mathbb{R}^{|W| \times d}$ is the contextualized n-gram representation, corresponding to each word.

Matching Module Query and candidate answer $Q \in \mathbb{R}^{|Q| \times d}$ and $P \in \mathbb{R}^{|P| \times d}$ can be encoded into $\Phi_n(Q)$ and $\Psi_m(P)$. We build an interaction matrix η_{nm} by computing dot product between $\Phi_n(Q)$ and $\Psi_m(P)$:

$$\eta_{nm} = \Phi_n(Q)\Psi_m(P)^T \quad (3)$$

Output matrix $\eta_{nm} \in \mathbb{R}^{|Q| \times |P|}$ contains the relevance scores of all pairs between n-grams in query and m-grams in answer.

From η_{nm}, we conduct a row-wise max-pooling to obtain A_{nm}, relaxing the length constraint in interactions (Rücklé et al., 2019).

$$[A_{nm}]_i = \max_j([\eta_{nm}]_{ij}) \quad (4)$$

Scoring Module We then aggregate the best matching scores A_{nm} across all combinations of question n-grams and answer m-grams from $F = \{1, 2, 3, 5\}$ following the convention of (Shao et al., 2019), yielding the cumulative score for each question word $\gamma \in \mathbb{R}^{|Q|}$:

$$\gamma = \sum_{n \in F} \sum_{m \in F} A_{nm} \quad (5)$$

Finally, we obtain the relevance score Ω from γ vector. Note that we could adopt any effective word-based signals $\tau \in \mathbb{R}^{|Q|}$, known a priori. By applying dot product between γ and τ, we can contrast matching scores by word importance. Specifically,

$$\Omega = \begin{cases} \gamma \cdot \tau, & \text{if } \tau \text{ exists} \\ \sum_{i=1}^{|\gamma|} \gamma_i, & \text{otherwise} \end{cases} \quad (6)$$

A widely adopted example of τ is IDF, computed either globally (treating all passages in the dataset as a corpus) or locally (treating only candidate passages of given question as a corpus) (Blair-Goldensohn et al., 2003). Note that effective word-level signals may depend on the characteristic of dataset. We will further show empirically which measure is more effective for each dataset and explain why in later section.

Loss function Our model is trained by the loss function studied in (Cohen and Croft, 2016):

$$L = \sum_{q \in Q} (1 - (\mu_{q_r} - \max q_{nr}))BCE_q \quad (7)$$

where BCE_q is the standard binary cross entropy for the question, μ_{q_r} is the mean score of all relevant answers and $\max q_{nr}$ is the max score of all irrelevant answers for q.

3 Experiments

3.1 Dataset

We evaluate MICRON on two non-factoid question answering datasets: 1) **WikiPassageQA** (Cohen et al., 2018) is a recent Wikipedia based collection. There are high contextual similarity between answers and non-answers since all candidate answers are from the same document. 2) **InsuranceQA** (Feng et al., 2015) is another well-known large-scale non-factoid QA dataset from insurance domain constructed by putting the ground truth answers into the pool and randomly sampling negative answers[2]. Table 2 shows the statistics of two datasets.

3.2 Baselines

We divide the models into following four categories: 1) IR scores, 2) Representation-focused, 3) Interaction-focused, and 4) MICRON in Table 1. As state of the art in one dataset is not likely to be that in another, we focused on baselines either open source or reported results on both datasets.

We implement two interaction-focused and one representation-focused baselines: **N-gram CNN**

[1]We omit Ψ for simplicity. Φ and Ψ are the same in our architecture.

[2]Among two test sets available, V1 and V2, we used the latter.

Model	InsuranceQA	WikiPassageQA

Table 1: Results of the different models on the InsuranceQA and WikiPassageQA. [1] are reported in (Rücklé et al., 2019) . COALA syntax-aware (Rücklé and Gurevych, 2017) is a variant of COALA using dependency parse trees (Schuster and Manning, 2016).

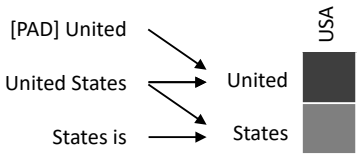
Dataset	# of Questions			Answer
	Train	Valid	Test	Length
WikipassageQA	3332	417	416	153
InsuranceQA	10391	1592	1625	112

Table 2: Statistics of datasets

builds N:N matching matrices respectively. The size of N is the same with our method for fair comparison. **Unigram CNN** uses 1:1 word matching, and is able to utilize word-based signals as query term weighting value.

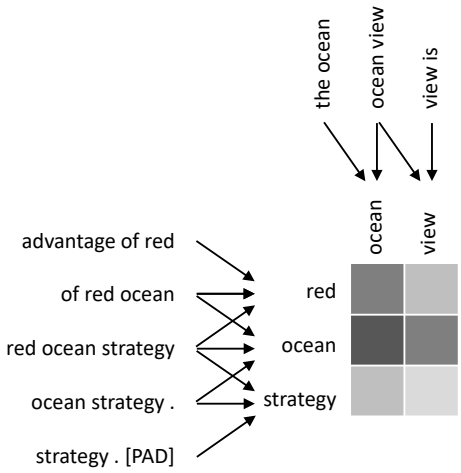
3.3 Implementation Details

For word embeddings, we use 300d pre-trained Glove (Pennington et al., 2014). The sequence length of the passage are all different for each dataset: 400 tokens for WikiPassageQA, 200 tokens for InsuranceQA. The dropout is applied after every layers with a keep rate of 0.7. All weights except embedding matrices are constrained by L2 regularization with constant values of 10^{-7} and 10^{-5} respectively for WikiPassageQA and InsuranceQA. We use Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 10^{-6} and 10^{-4} for each dataset. The learning parameters were chosen by the best performance on the dev set.



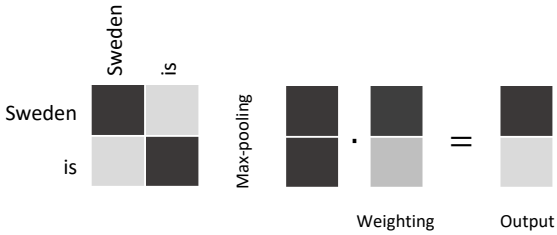
3.4 Results

Table 1 shows the results on WikiPassageQA and InsuranceQA datasets. We observe that our proposed approach, named MICRON, significantly outperforms both representation-focused and interaction-focused baselines in various evaluation metrics, achieving the best performance in both datasets.



Our finding could be summarized as below: First, we manifest the effectiveness of multigranular interaction. Compared to N-gram CNN, MICRON allows matching between different n-grams (e.g., 2:3, 3:5) and achieves the improvement on both datasets by 4.0% point accuracy, 2.57% point MAP respectively.

Second, we relax length constraint in n-gram from COALA and achieve relative gain in InsuranceQA dataset. However, this gain is marginal when the phrase is short as in WikiPassageQA dataset, considering the better performance of COALA over N-gram CNN.



Third, word-based signals may help considerably in WikiPassageQA, where both global and local IDF scores of words are vary significantly (high variance). This variance is especially high for local IDF, which serves as a strong signal as consistently observed in (Blair-Goldensohn et al., 2003). In contrast, in InsuranceQA, the variance

(a) An example of multigranular interaction over different n-grams (2:1).

(b) An example of contextualized representation for the word *ocean*, lowering the matching score for negative candidate.

(c) Effect of word-based signals of enhancing query term weighting.

Figure 2: Qualitative examples of MICRON in the WikiPassageQA dataset.

of word signals are low. Consequently, the use of IDF cannot contribute to performance, or even contributes negatively.

3.5 Qualitative Examples

We illustrate several qualitative examples of MICRON in Figure 2. In Figure 2a, multigranular interaction (2:1) between the *bi*-gram *"United States"* and the *uni*-gram *"USA"* allows the matching. Figure 2b shows the case of where the contextualized representation enables to lower the matching score between *"red ocean"* and *"ocean view"*. From Figure 2c, we can see the word based signals can control the impact of each contextualized word scores: amplifying the matching of *"Sweden"*-*"Sweden"* and reducing the *"is"*-*"is"* matching.

4 Conclusion

In this paper, we study non-factoid question answering. Specifically, our approach is inspired by the complementary strength of representation- and interaction-focused approaches. We combine the strength of the two, by allowing multigranular interactions, but represented per-word basis, contextualized by participating n-grams. For this purpose, we propose MICRON, allowing to match flexible n-grams and to combine with word-based query term weighting, achieving the state of the art among baselines with reported performances on both datasets[3].

Abstract

Leveraging external knowledge is an emerging trend in machine comprehension task. Previous work usually utilizes knowledge graphs such as ConceptNet as external knowledge, and extracts triples from them to enhance the initial representation of the machine comprehension context. However, such method cannot capture the structural information in the knowledge graph. To this end, we propose a Structural Knowledge Graph-aware Network (SKG) model, constructing sub-graphs for entities in the machine comprehension context. Our method dynamically updates the representation of the knowledge according to the structural information of the constructed sub-graph. Experiments show that SKG achieves state-of-the-art performance on the ReCoRD dataset.

1 Introduction

Machine reading comprehension (MRC) is an important subtask in natural language processing, which requires a system to read a given passage and answer questions about it. The ability of utilizing external knowledge is of great significance in an MRC system (Rajpurkar et al., 2016; Trischler et al., 2017). Latest large-scale datasets, e.g. ReCoRD (Zhang et al., 2018) specify that external knowledge is required to answer questions.

Many previous studies have introduced external knowledge in machine comprehension (Weissenborn, 2017; Mihaylov and Frank, 2018; Bauer et al., 2018). They often acquire external knowledge from structural knowledge graphs, such as ConceptNet (Speer et al., 2017) and Freebase (Tanon et al., 2016), in which knowledge is organized by triples like *"(shortage, related_to, lack)"* and *"(need, related_to, lack)"*. However, most of them fail to make full use of the structural information in the knowledge graph, and use sequence modeling methods like recurrent neural networks (RNNs) to generate the representation of knowledge, rather than based on graph structure.

In this paper, we present a Structural Knowledge Graph-aware Network (SKG) model to leverage the structural information of external knowledge. The advantages of our proposed method are two folds: a) the constructed sub-graphs contain both MRC context and external knowledge nodes, reserving the knowledge structure; b) the graph neural network is capable of updating the nodes dynamically according to the structure of sub-graphs, instead of using external knowledge as pre-trained representations. Concretely, we first construct sub-graphs from external knowledge such as ConceptNet based on the context, and initialize the representation of nodes via knowledge graph embedding method (Yang et al., 2015). Then we employ graph attention networks to dynamically update the representation of nodes on sub-graphs. Finally, we utilize the final representation of nodes to augment the representation of context via gate mechanisms.

Our contributions can be summarized as:

- We present a simple but effective method to construct sub-graphs from a knowledge graph, which can reserve the structure of knowledge;
- Graph attention networks are employed to dynamically update the representation of knowledge based on sub-graph structure, which can make full advantage of structural information of external knowledge;
- Experiments demonstrate that SKG model is able to effectively leverage external knowledge in MRC task, and achieves state-of-the-art performance on the ReCoRD dataset.

2 Related work

External Knowledge Enhanced MRC Models
There are several models that use knowledge for machine comprehension (Yang and Mitchell, 2017; Mihaylov and Frank, 2018; Weissenborn, 2017; Bauer et al., 2018; Pan et al., 2019). Mihaylov and Frank (2018) relies on the ability of the attention mechanism to retrieve relevant pieces of knowledge, and Bauer et al. (2018) employs multi-hop commonsense paths to help multi-hop reasoning. They treat retrieved knowledge triples as sequences and use sequence modeling methods to compress the representation of knowledge, which are not based on graph structure. On the contrary, we organize knowledge as sub-graphs, then update the representation of nodes on sub-graphs with graph neural network.

Graph Neural Netwoks
Graph neural netwoks (Kipf and Welling, 2016; Schlichtkrull et al., 2018; Veličković et al., 2017) have been shown successful on many Natural Language Processing (NLP) tasks (Cao et al., 2018; Zhou et al., 2018; Song et al., 2018; Cao et al., 2019). They are good at dealing with graph-structured data. In (Cao et al., 2018; Song et al., 2018; Cao et al., 2019), Graph Convolutional Networks (GCNs) have been applied in multi-documnent machine comprehension for multi-hop reasoning question answering, but they consider only the internal structure information in the MRC context without incorporating external knowledge. To the best of our knowledge, our work is the first to study graph attention networks in machine comprehension with external knowledge.

3 SKG Model

The architecture of SKG is shown in Figure 1. It contains four modules: (1) Question and paragraph modeling module, which acquires the contextual representation of question and paragraph with BERT; (2) Knowledge sub-graph construction module, which retrieves sub-graphs from knowledge graph based on the context; (3) Graph attention module, which updates the representation of nodes on graph; (4) Output layer module, which is employed to generate the final answer.

3.1 Question and Paragraph Modeling

We first encode the tokens with BERT (Devlin et al., 2018). BERT has become one of the most successful natural language representation models

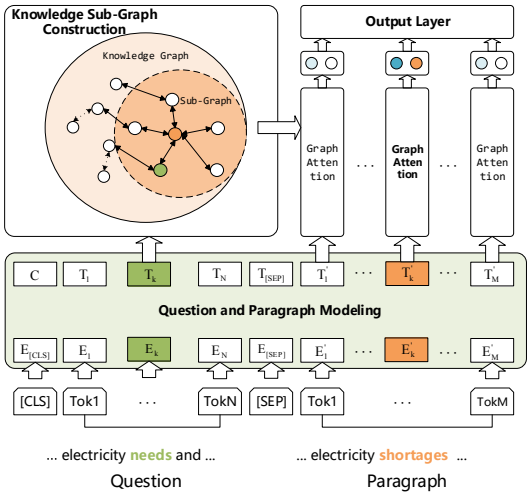

Figure 1: Framework of our SKG model.

on various NLP datasets, including SQuAD (Rajpurkar et al., 2016). BERT's model architecture is a multi-layer bidirectional Transformer (Vaswani et al., 2017) encoder, which is pre-trained on large-scale corpus. We represent the input question and paragraph as a single packed sequence as follows:

$$[CLS]Question[SEP]Paragraph[SEP]$$

where $[CLS]$ is a specific classifier token and $[SEP]$ is a sentence separator which are defined in BERT. And we use BERT to generate the contextual representation of question and paragraph. The final hidden output from BERT for the i^{th} input token is denoted as $\boldsymbol{t}_{b_i} \in \mathbb{R}^H$, and H is the output hidden size of BERT model.

3.2 Knowledge Sub-Graph Construction

We first use knowledge graph embedding approach to generate the initial representation of nodes and edges in terms of the whole knowledge graph.

We consider a knowledge triple in a knowledge graph as *(head, relation, tail)*. For the i^{th} token t_i in paragraph, we retrieve all triples whose head or tail contains lemmas of the token. Take token "shortage" as an example, we retrieve triples like *"(shortage, related_to, lack)"*. Then, we retrieve the neighbor triple of them, and reserve ones that contain lemmas of any token of the question. Thus we can acquire triples like *"(need, related_to, lack)"*. We reorganize these triples into a sub-graph via connecting identical entities and reserving the relations as edges in these triples. So

we can construct a simple sub-graph like *"(shortage, related_to,* ***lack****, related_to, need)"*, where "lack" is the identical entity. The sub-graph can be denoted as g_i and the nodes and edges of it are initiated by the embeddings above.

3.3 Graph Attention

Our graph attention network is designed to update the representation of the nodes in a constructed sub-graph, which is inspired by (Veličković et al., 2017; Zhou et al., 2018). For the i^{th} token t_i in paragraph, its sub-graph is $g_i = \{n_1, n_2, .., n_k\}$, where k is the number of nodes. And N_j is the set of the j^{th} node neighbors.

The representation of nodes is updated L times. At the l^{th} update, the updating rules are as follows, which are designed to model the interaction between the j^{th} node and its neighbor nodes. In this way, the nodes are dynamically updated according to the structure of sub-graphs.

$$\boldsymbol{h}_j^{l+1} = \sum_{n=1}^{N_j} \alpha_n \boldsymbol{t}_n^l \tag{1}$$

$$\alpha_n = \frac{\exp(\beta_n)}{\sum_{j=1}^{N_j} \exp(\beta_j)} \tag{2}$$

$$\beta_n = \left(\mathbf{W}_r^l \boldsymbol{r}_n^l\right)^\top \tanh\left(\mathbf{W}_h^l \boldsymbol{h}_n^l + \mathbf{W}_t^l \boldsymbol{t}_n^l\right) \tag{3}$$

where $\boldsymbol{h}_j^l \in \mathbb{R}^d$ is hidden state of the j^{th} node, and its neighbor's hidden state is $\boldsymbol{t}_n^l$, and the hidden state of relation is $\boldsymbol{r}_n^l$, and d is the hidden state dimension. $\mathbf{W}_h^l$, $\mathbf{W}_t^l$ and $\mathbf{W}_r^l$ are trainable weight matrices for the node, its neighbors and relations respectively. After L updates, we can get the final hidden state of the central node as the final representation, which can be denoted as $\boldsymbol{t}_{k_i}$.

3.4 Output Layer

In the output layer, we combine this knowledge representation $\boldsymbol{t}_{k_i}$ with the textual representation $\boldsymbol{t}_{b_i}$ via a sigmoid gate, since external knowledge is not always necessary for reasoning.

$$w_i = \sigma((W\left[\boldsymbol{t}_{b_i}; \boldsymbol{t}_{k_i}\right])) \tag{4}$$

$$\boldsymbol{t'}_i = w_i \odot \boldsymbol{t}_{b_i} + (1 - w_i) \odot \boldsymbol{t}_{k_i} \tag{5}$$

We denote $T = \{\boldsymbol{t'}_1, \boldsymbol{t'}_2, ..., \boldsymbol{t'}_n\}$ as the final representation, where $\boldsymbol{t'}_i \in \mathbb{R}^H$. And we study a start vector $S \in \mathbb{R}^H$ and an end vector $E \in \mathbb{R}^H$ like (Devlin et al., 2018), which take T as input. Then, the probability of the i^{th} token being the start of the answer span is computed as a dot product between T_i and S followed by a softmax over all of the words in the paragraph:

$$P_i^s = \frac{e^{S \cdot T_i}}{\sum_j e^{S \cdot T_j}} \tag{6}$$

Let P_i^e be the probability of the i^{th} token to be the end of an answer span, which can be calculated by the same above formula, and the maximum scoring span is used as the answer. The training objective is the loglikelihood of the correct start and end positions.

4 Experiments

4.1 Dataset

ReCoRD We report results on ReCoRD dataset (Zhang et al., 2018), a large-scale dataset for machine comprehension requiring external knowledge. There are 100,730, 10,000 and 10,000 examples in the training set, the development set and the test set respectively. The test set is not public, which needs to submit the model to the organization[1] to get the results.

External Knowledge We consider two knowledge sources as our external knowledge: WordNet and ConceptNet. For WordNet, we use the preprocessed data provided by Bordes et at. (2013), which contains 151,442 triples with 40,943 synsets and 18 relations. For ConceptNet, we use the preprocessed data provided by Bauer et al. (2018), which contains 2,808,998 triples with 978,672 entities and 46 relations.

4.2 Implementation Details

Our model is implemented with pytorch[2], and uses the framework[3] for BERT model. We employ the open-source framework OpenKE (Han et al., 2018) to obtain the embedding of entities and relations with the BILINEAR model (Yang et al., 2015). The size of embedding of entities and relations is 100. The update times L of graph attention network is set to 5. We use Adam optimizer. The learning rate uses the linear schedule to decrease from 0.00003 to 0.

4.3 Results and Analysis

Results on ReCoRD

We choose several baselines: (1) QANet (Yu et al., 2018) is one of the top MRC models, which is different from many other MRC models due to the use of transformer (Vaswani et al., 2017). (2) SAN (Liu et al., 2018) is a top-rank MRC model, which employs a stochastic answer module. (3) DocQA (Clark and Gardner, 2018) is a strong baseline model, which consists of bidirectional attention flow and self-attention.

The results of different models are shown in Table 1. Our SKG+BERT-Large[4] model achieves better performance than all previous published models, which is 26.13% higher in value than the state-of-art model DocQA with ELMo.

The Effectiveness of External Knowledge

Moreover, ablation experimental results on the dev set[5] are given in Table 2. Once we remove the module incorporating external knowledge, the model degenerates into the fine-tuing BERT model, and the results show significant performance drop with 4.80% and 4.95% on different pre-trained model sizes respectively. The results demonstrate that our model can effectively utilize external knowledge.

Different Ways to Use External Knowledge

In the original paper of ReCoRD (Zhang et al., 2018), there is no research on existing models that use external knowledge to improve MRC task. So we study the recent model MHPGM+NOIC (Bauer et al., 2018) , which utilizes multi-hop relational knowledge paths from ConceptNet. As shown in Table 3, our SKG model is more proper for introducing external knowledgse. In addition, to investigate the impact of the structural information on performance, we replace our sub-graph construction module with KG+LSTM, which retrieves knowledge triples without reconstructing the structure of them, and considers paths among them as sequences. We employ Long Short-Term Memory (LSTM) model to generate the representation of knowledge. As shown in Table 3, the performance drops 2.3% in F1, which means that the incorporation of structural information in the knowledge graph is able to make better use of external knowledge.

5 Conclusion

We propose SKG model for improving machine comprehension. Rather than treating triples from knowledge graph independently and separately, we construct sub-graphs from external knowledge. Then we generate the representation of knowledge with graph attention networks to improve the representation of context. Experimental results indicate that our model achieves the best performance in the challenging ReCoRD dataset.

[4]Our first module is based on different BERT model sizes. BERT-Base contains 110M parameters and BERT-Large contains 340M parameters.

[5]Due to several weeks evaluation wait-time on the non-public test set, we just report results of our supplementary experiments on the dev set. In previous submissions, the results in dev set are consistent with test set.

Answering Conversational Questions on Structured Data without Logical Forms

Abstract

We present a novel approach to answering sequential questions based on structured objects such as knowledge bases or tables without using a logical form as an intermediate representation. We encode tables as graphs using a graph neural network model based on the Transformer architecture. The answers are then selected from the encoded graph using a pointer network. This model is appropriate for processing conversations around structured data, where the attention mechanism that selects the answers to a question can also be used to resolve conversational references. We demonstrate the validity of this approach with competitive results on the Sequential Question Answering (SQA) task (Iyyer et al., 2017).

1 Introduction

In recent years, there has been significant progress on conversational question answering (QA), where questions can be meaningfully answered only within the context of a conversation (Iyyer et al., 2017; Choi et al., 2018; Saha et al., 2018). This line of work, as in single QA setup, falls into two main categories, (i) the answers are extracted from some text in a reading comprehension setting, (ii) the answers are extracted from structured objects, such as knowledge bases or tables. The latter is commonly posed as a semantic parsing task, where the goal is to map questions to some logical form which is then executed over the knowledge base to extract the answers.

In semantic parsing, there is extensive work on using deep neural networks for training models over manually created logical forms in a supervised learning setup (Jia and Liang, 2016; Ling et al., 2016; Dong and Lapata, 2018). However, creating labeled data for this task can be expensive and time-consuming. This problem resulted in research that investigates semantic parsing with weak supervision where training data consists of questions and answers along with the structured resources to recover the logical form representations that would yield the correct answer (Liang et al., 2016; Iyyer et al., 2017).

In this paper, we follow this line of research and investigate answering sequential questions with respect to structured objects. In contrast to previous approaches, instead of learning the intermediate logical forms, we propose a novel approach that encodes the structured resources, i.e. tables, along with the questions and answers from the context of the conversation. This approach allows us to handle conversational context without the definition of detailed operations or a vocabulary dependent on the logical form formalism that are required in the weakly supervised semantic parsing approaches.

We present empirical performance of the proposed approach on the Sequential Question Answering task (SQA) (Iyyer et al., 2017) which improves the state-of-the-art performance on all questions, particularly on the follow-up questions that require effective encoding of the context.

2 Approach

We build a QA model for a sequence of questions that are asked about a table and can be answered by selecting one or more table cells.

2.1 Graph Formulation

We encode tables as graphs by representing columns, rows and cells as nodes. Figure 1 shows an example graph representing how we encode the table in relation to q_2, which is the follow up question to q_1. Within a column, cells with identical texts are collapsed into a single node. In the example graph, we only create a single node for *"Toronto"* and a single node for *"Montreal"*. We then add 4 directed edges that connect columns

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5902–5910, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

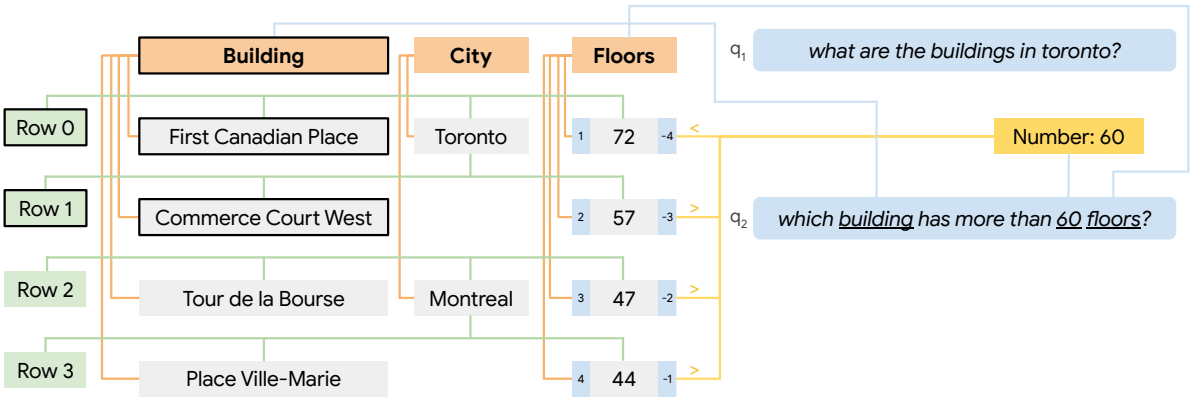

Figure 1: Example of a table encoded as a graph in relation to q_2, the follow up question to q_1. Columns (orange boxes), rows (green boxes) and cells (gray boxes) are represented by interconnected nodes. Questions words are linked to the table by edit distance (blue lines). Numerical values in question and table are connected by comparison relations (yellow lines). Additionally numerical cells are annotated with their numerical rank and inverse rank with respect to the column (small blue boxes). The answer column, rows and cells of q_1 are also marked (nodes with borders).

and rows to cells, one in either direction (orange and green edges in the figure).

The question is represented by a node covering the entire question text and a node for each token. The main question node is connected to each token, column and cell node. [1]

Nodes have associated nominal feature sets. All nodes have a feature indicating their type: column, row, cell, question and question token. The text in column (i.e., the column name), cell, question and token nodes are added to the corresponding node feature set adopting a bag-of-words representation. Column, row and cell nodes have additional features that indicate their column (for cell and column nodes) and row (for cell and row nodes) indexes.

We align question tokens with column names and cell text using the Levenshtein edit distance between n-grams in the question and the table text, similar to previous work (Shaw et al., 2019). In particular, we score every question n-gram with the normalized edit distance [2] and connect the cell to the token span if the score is > 0.5. Through the alignment, the cell is connected to all the tokens of the matching span and the binned score is added as an additional feature to the cell. In Figure 1, the *"building"* and *"floors"* tokens in the questions are connected to the matching *"Building"* and *"Floors"* column nodes from the table.

[1] We do not show some of these connections in the figure to avoid clutter.

[2] $\text{ned}(v, w) = \frac{\text{ed}(v,w)}{\max(|v|,|w|)}$

Numeric Operations In order to allow operations over numbers and date expressions, we extend our graph with a set of relations involving numerical values in the question and table cells. We infer the type of the numerical values in a column, such as the ones in the *"Floors"* column, by picking their most frequent type (number or date). Then, we add special features to each cell in the column: the rank and inverse rank of the value in the cell, considering the other cell values from the same column. These features allow the model to answer questions such as *"what is the building with most floors?"*. In addition, we add a new node to the graph for each numeric expression from the question (such as the number *60* from the second question in Figure 1), and we connect it to the tokens it spans. The numerical nodes originated from the question are connected to the table cells containing numerical values. The connection type encodes the result of the comparison between the question and cell values, lesser, greater or equal, as shown in the figure (yellow edges). This relations allow the model to answer questions such as *"which buildings have more than 50 floors?"*.

Context We extend the model to capture conversational context by using the feature-based encoding in the graph formulation. In order to handle follow-up questions, we add the previous answers to the graph by marking all the answer rows, columns and cells with nominal features. The nodes with borders in Figure 1 contain the answers to the first question q_1: *"what are the buildings*

in toronto?". In the example, the first two rows receive a feature ANSWER_ROW, the *"building"* column a feature ANSWER_COLUMN and *"First Canadian Place"* and *"Commerce Court West"* a feature ANSWER_CELL. Notice that the content of q_1 is not encoded in the graph, only its answers.

2.2 Node Representations

Before the initial encoder layer, all nodes are mapped to vector representations using learned embeddings. For nodes with multiple features, such as column and cell nodes, we reduce the set of feature embeddings to a single vector using the mean. We also concatenate an embedding encoding whether the node represents a question token, or not.

2.3 Encoder

We use a Graph Neural Network (GNN) encoder based on the Transformer (Vaswani et al., 2017). The only modification is that the self-attention mechanism is extended to consider the edge label between each pair of nodes.

We follow the formulation of Shaw et al. (2019) that uses additive edge vector representations. The self-attention weights are therefore calculated as:

$$s_{ij} = (\mathbf{W}^q x_i)^\intercal (\mathbf{W}^k x_j + r_{ij}), \qquad (1)$$

where s_{ij} is the unnormalized attention weight for the node vector representations x_i and x_j, and $\mathbf{W}^q$ and $\mathbf{W}^k$ are parameter matrices. This extension introduces r_{ij} to the calculation, which is a vector representation of the edge label between the two nodes. Edge vectors are similarly added when summing over node representations to produce the new output representations.

We use edge labels corresponding to relative positions between tokens, alignments between tokens and table elements, and relations between table elements, as described in Section 2.1. These amount to 9 fixed edge labels in the graph (4 between rows/cells/columns, 2 between question and cells/columns, and 3 numeric relations) and a tunable number of relative token positions).

2.4 Answer Selection

We extend the Transformer decoder to include a copy mechanism based on a pointer network (Vinyals et al., 2015). The copy mechanism allows the model to predict sequences of answer

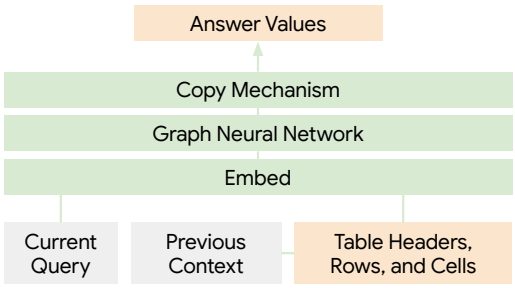

Figure 2: The model input is a graph, with nodes corresponding to query words and table elements, and edge labels capturing their relations. A graph neural network encoder generates contextualized node representations. Answers values are selected from nodes corresponding to table elements.

columns and rows from the input, rather than select symbols from an output vocabulary. Figure 2 visualizes the entire model architecture.

3 Related Work

Semantic parsing models can be trained to produce gold logical forms using an encoder-decoder approach (Suhr et al., 2018) or by filling templates (Xu et al., 2017; Peng et al., 2017; Yu et al., 2018). When gold logical forms are not available, they are typically treated as latent variables or hidden states and the answers or denotations are used to search for correct logical forms (Yih et al., 2015; Long et al., 2016; Iyyer et al., 2017). In some cases, feedback from query execution is used as a reward signal for updating the model through reinforcement learning (Zhong et al., 2017; Liang et al., 2016, 2018; Agarwal et al., 2019) or for refining parts of the query (Wang et al., 2018). In our work, we do not use logical forms or RL, which can be hard to train, but simplify the training process by directly matching questions to table cells.

Most of the QA and semantic parsing research focuses on single turn questions. We are interested in handling multiple turns and therefore in modeling context. In semantic parsing tasks, logical forms (Iyyer et al., 2017; Sun et al., 2018b; Guo et al., 2018) or SQL statements (Suhr et al., 2018) from previous questions are refined to handle follow up questions. In our model, we encode answers to previous questions by marking answer rows, columns and cells in the table, in a non-autoregressive fashion.

In regards to how structured data is represented, methods range from encoding table information,

metadata and/or content, (Gur et al., 2018; Sun et al., 2018b; Petrovski et al., 2018) to encoding relations between the question and table items (Krishnamurthy et al., 2017) or KB entities (Sun et al., 2018a). We also encode the table structure and the question in an annotation graph, but use a different modelling approach.

4 Experimental Setup

We evaluate our method on the SequentialQA (SQA) dataset (Iyyer et al., 2017), which consists of sequences of questions that can be answered from a given table. The dataset is designed so that every question can be answered by one or more table cells. It consists of 6,066 answer sequences containing 17553 questions (2.9 question per sequence on average). Table 2 shows an example.

We lowercase and remove punctuation from questions, cell texts and column names. We then split each input utterance on spaces to generate a sequence of tokens.[3] We only keep the most frequent 5,000 word types and map everything else to one of 2,000 OOV buckets. Numbers and dates are parsed in a similar way as in the DynSp and the Neural Programmer (Neelakantan et al., 2016a).

We use the Adam optimizer (Kingma and Ba, 2014) for optimization and tune hyperparameters with Google Vizier (Golovin et al., 2017). More details and the hyperparameter ranges can be found in the appendix (A).

All numbers given for our model are averaged over 5 independent runs with different random initializations.

5 Results

We compare our model to Float Parser (FP) (Pasupat and Liang, 2015), Neural Programmer (NP) (Neelakantan et al., 2016b), DynSp (Iyyer et al., 2017) and Camp (Sun et al., 2018b) in Table 1.

We observe that our model improves the SOTA from 45.6% by Camp to 55.1% in question accuracy (ALL), reducing the relative error rate by 18%. For the initial question (POS1), however, it is behind DynSp by 3.7%. More interestingly, our model handles follow up questions especially well outperforming the previously best model FP by 20% on POS3, a 28% relative error reduction.

[3] Whitespace tokenization simplifies the preprocessing but we can expect an off-the-shelf tokenizer to work as good or even better.

Model	ALL	SEQ	POS1	POS2	POS3
FP *	34.1	7.2	52.6	25.6	25.9
NP *	39.4	10.8	58.9	35.9	24.6
DynSp	42.0	10.2	**70.9**	35.8	20.1
FP † *	33.2	7.7	51.4	22.2	22.3
NP † *	40.2	11.8	60.0	35.9	25.5
DynSp †	44.7	12.8	70.4	41.1	23.6
Camp † *	45.6	13.2	70.3	42.6	24.8
Ours *	45.1	13.3	67.2	42.4	26.4
Ours † *	**55.1**	**28.1**	67.2	**52.7**	**46.8**
Ours † * (RA)	61.7	28.1	67.2	60.1	57.7

Table 1: SQA test results. † marks contextual models using the previous question or the answer to the previous question. * marks the models that use the table content. RA denotes an oracle model that has access to the previous reference answer at test time. ALL is the average question accuracy, SEQ the sequence accuracy, and POS X, the accuracy of the X'th question in a sequence.

As in previous work, we also report performance for a non-contextual setup where follow up questions are answered in isolation. We observe that our model effectively leverages the context information by improving the average question accuracy from 45.1% to 55.1% in comparison to the use of context in DynSp yielding 2.7% improvement. If we provide the previous reference answers, the average question accuracy jumps to 61.7%, showing that 6.6% of the errors are due to error propagation.

Numeric operations For understanding how effective our model is in handling numeric operations, we trained models without the specific handling explained in Section 2. We find that that the overall accuracy decreases from 55.1% to 51.5%, demonstrating the competence of our approach to model such operations. This effectiveness is further emphasized when focusing on questions that contain a superlative (e.g., *"tallest"*, *"most expensive"*) with a performance difference of 47.3% with numeric relations and 40.3% without. It is worthwhile to call out that the model without special number handling still out-performs the previous SOTA Camp by more than 5 points (45.6% vs 55.1%).

Table size. We observe that our model is not sensitive to table size changes, with an average accuracy of 52.4% for the 10% largest tables (vs.

What are all the nations?
Australia, Italy, Germany, Soviet Union, Switzerland, United States, Great Britain, France

Which won gold medals?
Australia, Italy, Germany, Soviet Union

Which won more than one?

6	United States	0	1	0	1
7	Great Britain	0	0	1	1
7	France	0	0	1	1

Table 2: A sequence of questions (left) and the corresponding table (right) selected from the SQA dataset that is answered correctly by our approach. This example requires handling conversational context and numerical comparisons.

55.1% overall).[4]

Error analysis. Table 2 shows an example that is consistently handled correctly by the model. It requires a simple string match (*"nations"* → *"nation"*), and implicit and explicit comparisons.

We performed error analysis on test data over 100 initial (POS1) and 100 follow up questions (POS$>$ 1) to identify the limitations of our approach.

For the initial questions, we find that 26% are match errors, e.g., the model does not match *"episode"* to *"Eps #"*, or cases where the model has to exclude rows with empty values from the results. 29% of the errors require a more sophisticated table understanding, e.g., rows that represent the total of all other rows should often not be included in the answers. For 15% of the errors, we think that the reference answer is incorrect and for another 15% the model prediction is correct but contains duplicates because multiple rows contain the same value. 12% of the errors are around complex matches such as selecting certain ranks (*"the first two"*), exclusion or negation.

For the follow up questions, 38% are caused by complex matches; 17% are match errors; 13% of the errors are due to incorrect reference answers and 11% would require advanced table understanding. Only 8% of the errors are due to incorrect management of the conversational context. Section B of the appendix contains a more detailed analysis and error examples.

6 Discussion

We present a model for table-centered conversational QA that predicts the answers directly from the table. We show that this model improves SOTA on SQA dataset and particularly handles conversational context effectively.

As future work, we plan to expand our model with pre-trained language representations (e.g., BERT (Devlin et al., 2018)) in order to improve performance on initial queries and matching of queries to table entries. To handle larger tables, we will investigate sharding the table row-wise, running the model on all the shards first, and then on the final table which combines all the answer rows.

[4]Fig. 3 of the appendix shows a scatter plot of table size vs. accuracy.

A Hyperparameters

We tune hyperparameters with Google Vizier (Golovin et al., 2017). For the encoder and decoder, we select the number of layers from $[3, 6]$ and embedding and hidden dimensions from $\{128, 256, 512\}$, setting the feed forward layer hidden dimensions $4\times$ higher. We employ dropout at training time with $P_{dropout}$ selected from $\{0.2, 0.4, 0.5\}$. We select the attention heads from $\{4, 8, 16\}$ and use a clipping distance of 6 for relative position representations.

We use the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-9}$. We tune the learning rate and use the same warm-up and decay strategy for learning rate as Vaswani et al. (2017), selecting a number of warm-up steps up to a maximum of 2000. We run the training until convergence for a fixed number of steps $(100,000)$ and use the final checkpoint for evaluation. We choose batch sizes from $\{32, 64\}$.

B Results

Table Size Given that our model makes use of the whole table, it is conceivable that the performance of our approach can be more sensitive to the table size than methods that predict intermediate representations. Plotting the model performance with respect to number of cells in the table (Figure 3), we observe that the performance does not vary significantly by the table size.

Error Analysis For a detailed analysis, we annotated 100 initial and follow-up questions with the following match types:

MATCH A lexical or semantic match error such as not matching *"episode"* with *"EPS #"*.

TABLE_UNDERSTANDING A question that would require a higher level table understanding to be answered correctly. For example, we often have to decide that a row is just the total of all other rows and should not be selected.

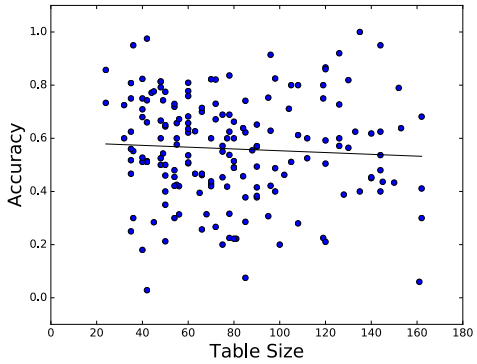

Figure 3: Scatter-plot of accuracy and table size. Each point represents the accuracy on all the questions asked about a test set table of the corresponding size.

Error type	Counts
TABLE_UNDERSTANDING	29
COMPLEX_MATCH	12
MATCH	26

Table 3: Errors on 100 random initial (a) and follow-up (b) questions

COMPLEX_MATCH A question that would require a numerical value match, some sort of sorting or a negation to be answered. *"what is the area of all of the non-remainders?"*

GOLD A question with a wrong reference answers. *"what gene functions are listed?"* – Gold points to Category column rather than Gene Functions.

ANSWER_SET The returned answer should be duplicate free. *"what are all of the rider's names?"*, but the table contains *"Carl Fogarty"* multiple times.

CONTEXT Only used in follow-up questions. This error indicates that a more sophisticated context management is needed.

OTHER Any other kind of error.

Table 3 contains the error counts for initial questions and follow-ups, respectively. Table 4 contains interesting examples.

Question	Notes
COMPLEX_MATCH	
who scored more than earnie stewart?	2-hop reasoning. Requires comparison on top of the result of the inner question.
and which has been active for the longest?	Reasoning with text and date (1986-present)
who else is in that field?	Exclusion.
of these, which did not publish on february 9?	Negation. The model is doing the right thing but missing one of the values.
what is the highest passengers for a route?	The model selects the 2nd highest and not the 1st.
TABLE_UNDERSTANDING	
now, during which year did they have the worst placement?	Requires understanding that *"Withdrawal .."* is worse than any position.
which of these seasons have four judges?	Requires counting the number of named entities within a single cell.
GOLD	
what gene functions are listed?	Gold points to *"Category"* column rather than *"Gene Functions"*
which aircraft have 1 year of service	Gold points to the 4th column (*"in service"*) instead of the 1st column (*"aircraft"*)
CONTEXT	
when was thaddeus bell born?, when was klaus jurgen schneider born?, which is older?	The correct birthday is selected, but not the person.

Table 4: Some interesting error cases with comments.

Improving Answer Selection and Answer Triggering using Hard Negatives

Abstract

In this paper, we establish the effectiveness of using hard negatives, coupled with a siamese network and a suitable loss function, for the tasks of answer selection and answer triggering. We show that the choice of sampling strategy is key for achieving improved performance on these tasks. Evaluating on recent answer selection datasets - InsuranceQA, SelQA, and an internal QA dataset, we show that using hard negatives with relatively simple model architectures (bag of words and LSTM-CNN) drives significant performance gains. On InsuranceQA, this strategy alone improves over previously reported results by a minimum of 1.6 points in P@1. Using hard negatives with a Transformer encoder provides a further improvement of 2.3 points. Further, we propose to use quadruplet loss for answer triggering, with the aim of producing globally meaningful similarity scores. We show that quadruplet loss function coupled with the selection of hard negatives enables bag-of-words models to improve F1 score by 2.3 points over previous baselines, on SelQA answer triggering dataset. Our results provide key insights into answer selection and answer triggering tasks.

1 Introduction

Question answering (QA) is an active field of research, drawing attention from the natural language processing (NLP) and information retrieval (IR) community. Selection-based QA is the task of selecting an answer for a given question, from a set of candidate answers. Two tasks have been proposed for selection-based QA. Given a question and an answer candidate pool, **answer selection** is the task of ranking valid answers higher than irrelevant answers, where it is assumed that there is at least one valid answer in the candidate pool. **Answer triggering**, defined for cases where the candidate pool may or may not have a valid answer, is the task of finding a valid answer, while being allowed to abstain.

Recently released datasets (Feng et al., 2015; Yang et al., 2015; Jurczyk et al., 2016) have led to significant development in end-to-end neural network Selection-based QA. These networks are learned by posing answer selection as either a ranking problem or a classification problem. When posed as a ranking problem, a common choice is to use a triplet loss defined over a question, a correct answer and a (usually sampled) negative answer. Triplet loss penalises relative distances between positive and negative pairs, making the choice of negatives critical. Recent progress in image understanding tasks suggests that learning in ranking tasks can be enhanced by focusing on sampling strategies in conjunction with the loss function employed (Hermans et al., 2017; Chen et al., 2017). In this work, we investigate the expressive power of siamese architectures (Bromley et al., 1994) coupled with hard negatives (i.e., difficult negative samples for the model being learnt), against more sophisticated models. Specifically, all our models ignore any interaction between question and answer representations, and use a shared encoder to independently encode questions and answers. Siamese architectures provide low-latency solutions in the presence of large candidate answer pools (by caching candidate representations).

In this paper, we first show that using hard negatives with vanilla neural architectures improves over previously reported results on InsuranceQA answer selection task (Feng et al., 2015). The proposed strategy achieves P@1 of 73.3%, as compared to the previously reported 71.1% (dos Santos et al., 2016). Further, using a Transformer encoder coupled with the proposed strategy achieves

P@1 of 75.6%. Next, we propose the use of quadruplet loss (Chen et al., 2017) for answer triggering. We show that by employing online selection of hard negatives with quadruplet loss, bag-of-words models improve upon previous baselines on SelQA answer triggering task (Jurczyk et al., 2016). The proposed strategy achieves an F1 score of 53.21, as compared to the previously reported 50.89 (Jurczyk et al., 2016).

We note that the performance gains demonstrated in this paper are obtained with a restricted class of models. Specifically, we restrict to siamese networks, and don't model any interaction between question and answer representations. The previously reported results which we compare against use architectures that are not restricted to be siamese, and model the interaction between question and answer representations.

2 Related Work

For answer selection, CNN, LSTM and LSTM-CNN architectures (Tan et al., 2015; dos Santos et al., 2016), trained with a triplet loss, have been explored. Recent focus has been on designing the interaction layer, between a question and a candidate answer, through various models of attention (Yu et al., 2014; Rao et al., 2016; Zhou et al., 2015; Zhang et al., 2017; Bian et al., 2017). Compare-aggregate architectures have also been studied as sentence matching models and applied to answer selection (Wang and Jiang, 2016; Wang et al., 2017). Similarly, for answer triggering, different architectural changes have been proposed (Zhao et al., 2017; Acheampong et al., 2016; Gupta et al., 2018; Li and Wu, 2017). Often, the architectural advances are coupled with subtle changes in the training process. For example, dos Santos et al. (2016) incorporate a form of negative mining. This makes it difficult to separate the benefits gained from the mining strategy from the architectural advances.

Triplet loss and mining of hard negatives have been studied for computer vision tasks with triplet networks being popular for estimating feature embeddings for images. The key issue with triplet networks is that, for a training set with N samples, the number of triplets is cubic in N. Training becomes intractable for modest sizes of the training set. A solution in the form of importance sampling has been studied. Schroff et al. (2015) learn image embeddings using triplet loss, trained using moderately hard negatives. While other approaches have been studied for the task of person re-identification, which combine classification with a verification loss, Hermans et al. (2017) show that a vanilla CNN with triplet loss and the right sampling strategy could outperform the best models at the time. Wu et al. (2017) present a distance-weighed sampling approach.

Triplet loss, while useful for ranking tasks, doesn't produce globally meaningful scores for tasks such as person re-identification. This can be attributed to the fact that triplet loss doesn't try to learn a global threshold to separate all inter-class pairs from all intra-class pairs, and learns only relative distances with respect to an anchor (a question, in the context of this paper). This has been addressed by accounting for the global structure of the embedding space (Kumar et al., 2016; Ustinova and Lempitsky, 2016), and directly optimizing for inter-class distances to be larger than intra-class distances. Quadruplet loss (Chen et al., 2017) prvoides another way to produce globally meaningful scores, and is suitable for our setting. Quadruplet loss extends triplet loss to ensure smaller intra-class distances and larger inter-class distances. This is achieved by additionally penalizing positive and negative pairs with different probes (questions, in the context of this paper).

While selection of hard negatives has been used for problems in computer vision, its usefulness has not been evaluated for QA tasks. In this work, we first present the selection of hard negatives with triplet loss for answer selection. Next, we show that quadruplet loss is suitable for the task of answer triggering, and when coupled with online selection of hard negatives, improves over previous baselines. As far as we know, we are the first to use quadruplet loss for question answering.

3 Data

Dataset	#Q	#QA	$\mathbf{L_q}$	$\mathbf{L_a}$
InsuranceQA	12887	18540	7.15	95.54
SelQA	5524	6390	11.02	25.39
LargeQA	341869	502763	14.06	30.34

Table 1: Comparison of answer selection datasets. **#Q**: Number of questions; **#QA**: Number of correct question-answer pairs; $\mathbf{L_q}/\mathbf{L_a}$: Average number of tokens in a question/answer.

Insurance QA (Feng et al., 2015), a domain-specific non-factoid QA dataset, is suitable for

evaluating answer selection. SelQA (Jurczyk et al., 2016), a recent open-domain factoid QA dataset provides data for evaluating both answer selection and answer triggering.

While these datasets provide standardised comparison, we also evaluate our methods on a large internal answer selection dataset, LargeQA, created using Community Question-Answers (CQnA) asked on a website. The dataset was created similar to InsuranceQA, with the size of candidate pool fixed to 100 answers in test sets.

Table 1 presents some statistics on the training data used in these datasets.

We don't include WikiQA (Yang et al., 2015) and TrecQA (Wang et al., 2007) datasets which have been previously used to report improvements in answer selection. This is due to the large variance in our experiments as well as in the reproduction of existing methods, also noted by Crane (2018), perhaps due to their smaller sizes.

4 Method

For selection-based QA , the training data X, can be characterized as a list of questions $Q = \{q_1, q_2, \ldots, q_s\}$, and sets of correct answer(s) $A_q = \{a_1, a_2, \ldots, a_p\}$ for each question $q \in Q$.

In the following, we discuss online selection of hard negatives with triplet loss for answer selection, and with quadruplet loss for answer triggering. In each case, a siamese architecture is used where questions and answers are encoded independently by identical copies of a neural network denoted by f. Cosine similarity is used to compute the similarity between a question and an answer: $S(x, y) = \text{cosine}(f(x), f(y))$.

4.1 Answer Selection

Siamese networks can be trained for answer selection using triplets (q, a^+, a^-), where $a^+ \in A_q$ is a correct answer and $a^- \notin A_q$ an incorrect answer chosen randomly from the entire answer pool. A triplet loss with margin m is formulated as:

$$L_{\text{triplet}} = \max(0, m - S(q, a^+) + S(q, a^-)). \quad (1)$$

In this work, we employ online selection of hard negatives within a batch of sampled question-answer pairs. The model is trained using batch gradient descent, with batches $B = \{(q_i, a_i, a_i^H) : 1 \leq i \leq b\}$, where b is the batch size, $a_i \in A_{q_i}$ and a_i^H is the hardest negative answer chosen as:

$$a_i^H = \underset{j: a_j \notin A_{q_i},\ 1 \leq j \leq b}{\text{argmax}} (S(q_i, a_j)). \quad (2)$$

Selection of negatives from within a batch of sampled question-answer pairs has several advantages. First, it does not require any extra computation from the embedding model. Second, there is no need to employ additional heuristics to avoid the hardest negatives. Selection from within a stochastic batch ensures that the selected hardest negatives in a batch are not dominated by false negatives or noisy hard negatives during training (See Appendix C for experimental results).

4.2 Answer Triggering

Answer triggering differs from answer selection in that we need to identify if a valid answer is present in the candidate pool. Triplet loss is not suitable as it promotes scores to be discriminative only relative to a given question. While classification based methods have been studied, we hypothesize that globally meaningful scores can be obtained in a ranking setup. Essentially, we need the similarity scores for all wrongly paired question-answers to be smaller than the scores for correct question-answer pairs. We propose to use quadruplet loss for answer triggering. Quadruplet loss, introduced by Chen et al. (2017) for Person re-identification, aims at keeping all inter-class distances larger than all intra-class distances. This, we believe, is what we need to obtain globally meaningful scores for answer triggering.

The network can be trained using quadruplets of the form (q, a^+, a^-, q'), where $a^+ \in A_q$, $a^- \notin A_q$, and q' is a negative question for both a^+ and a^- chosen randomly from the entire question pool, with $a^+ \notin A_{q'}$, $a^- \notin A_{q'}$. Quadruplet loss for answer triggering can be formulated as:

$$L_{\text{quad}} = \max(0, m_1 - S(q, a^+) + S(q, a^-)) + \max(0, m_2 - S(q, a^+) + S(q', a^-)) \quad (3)$$

where m_1 and m_2 are fixed margins.

As with triplet loss, we believe the selection of negatives is critical for learning with quadruplet loss. We propose to select both the negative answer and the negative question using online selection of hard negatives. The model is trained using batch gradient descent with batches $B = \{(q_i, a_i, a_i^H, q_i^H) : 1 \leq i \leq b\}$, where b is the batch size, $a_i \in A_{q_i}$, a_i^H is chosen as in Equation 2, and q_i^H is selected to be the hardest negative question for a_i^H:

$$q_i^H = \underset{k: a_i^H \notin A_{q_k},\ 1 \leq k \leq b}{\text{argmax}} (S(q_k, a_i^H)). \quad (4)$$

Method	P@1		
	Dev	Test1	Test2
Attentive Pooling + CNN (dos Santos et al., 2016)	**68.8**	69.8	66.3

LSTM-CNN + Hard Negatives	**72.5**	**73.3**	**69.1**
Transformer encoder + Random Negatives	65.8	67.1	63.8
Transformer encoder + Hard Negatives	**75.7**	**75.6**	**73.4**

Table 2: *Answer selection on InsuranceQA*. **Top**: Baselines. **Middle** & **Bottom**: Our Max-Pooling, LSTM-CNN and Transformer encoder results. When coupled with hard negatives, simpler architectures such as Max-Pooling become competitive, while LSTM-CNN improves over previously reported results. The effectiveness of using hard negatives, compared to random negatives, is also evident when training the Transformer encoder model.

During inference, for a given question, we predict the highest scoring answer, provided the score exceeds the threshold. The optimal threshold is obtained using performance on the development set.

5 Results and Analysis

We present quantitative results using MRR and P@1 for answer selection on InsuranceQA, LargeQA and SelQA, and F1 score (Yang et al., 2015) for answer triggering on SelQA, followed by an ablation study of the proposed method for answer triggering.

5.1 Experimental Setup

Following Tan et al. (2015), we experiment with an LSTM-CNN model, where a CNN layer is employed on top of LSTM encoding of the input sentence, followed by Max Pooling to obtain a fixed length representation for the sentence.

Motivated by the performance of bag-of-words like sentence representations (Arora et al., 2016), we also experiment with distributional bag-of-words models where sentence embeddings are obtained by pooling across the dimensions of corresponding word embeddings. In particular, we used Max-Pooling and Max-Min-Pooling, the latter being obtained by concatenating the outputs of Max and Min Pooling.

Finally, we experiment with the Transformer encoder (Vaswani et al., 2017; Devlin et al., 2019) for answer selection.

Training details are available in Appendix A.

5.2 Answer Selection

InsuranceQA: LSTM-CNN model coupled with hard negatives outperforms the best reported numbers on both test sets by a significant margin (1.6 and 2.7 points gain in P@1 with p-values of 0.066 and 0.008 on Test1 and Test2 respectively) on InsuranceQA (Table 2). Finally, the Transformer encoder model with hard negatives provides significant performance gains for the task (3.9 and 7.0 points gain in P@1), while still learning with siamese networks without any interaction between question and answer representations.

Method	P@1	MRR
LSTM-CNN + Random Negatives	+0	+0
LSTM-CNN + Hard Negatives	**+2.5**	**+0.015**

Table 3: *Answer selection on LargeQA*; reported numbers are relative to the baseline.

LargeQA: The gains due to hard negatives are also observed on LargeQA (Table 3), with an improvement of 2.5 in P@1 and 0.015 in MRR.

Model	MRR
RNN + Attention Pooling (Jurczyk et al., 2016)	0.876
CNN-Hinge (dos Santos et al., 2017)	0.881
ACNN (Shen et al., 2018)	0.880
AdaQA (Shen et al., 2018)	0.910
DRCN (Kim et al., 2019)	**0.930**
Max-Pooling + Random Negatives	0.843
Max-Pooling + Hard Negatives	0.896

Table 4: *Answer selection on SelQA*. **Top**: Baselines. **Bottom**: Max-Pooling results from this work.

SelQA: For answer selection on SelQA (See Table 4), Max-Pooling models performed best among the models we investigated, perhaps due to the smaller size of the dataset (other results omitted).

Key Observations: First, siamese bag-of-words models, coupled with hard negatives, are competitive with models which rely on various ways of question-answer interaction. Second, siamese networks coupled with hard negatives are particularly suited for domain specific QA (In-

suranceQA). We believe open-domain QA has a greater need for interaction between question and answer representations. Third, we believe employing hard negatives is especially useful for the Transformer encoder model, which has a much larger set of parameters. With the Transformer encoder model, there is an improvement of 8.5 points on InsuranceQA Test1 dataset when using hard negatives as opposed to using random negatives. With the LSTM-CNN model, the corresponding gain is 3.0 points.

5.3 Answer Triggering

Method	F1	
	Dev	Test
CNN (Jurczyk et al., 2016)	49.16	50.89
RNN + AP (Jurczyk et al., 2016)	44.02	45.67
Max-Min-Pooling + Quadruplet loss + Hard negatives	**54.95**	**53.21**

Table 5: *Answer triggering on SelQA.* **Top**: Baselines. **Bottom**: Our approach using quadruplet loss with Max-Min-Pooling model. The choice of the loss function and the sampling strategy proposed in this paper is justified by the improved results obtained using a relatively simpler Max-Min-Pooling model.

The proposed approach with the Max-Min-Pooling model for answer triggering improves upon the previously reported baselines significantly (2.32 points) on SelQA (See Table 5).

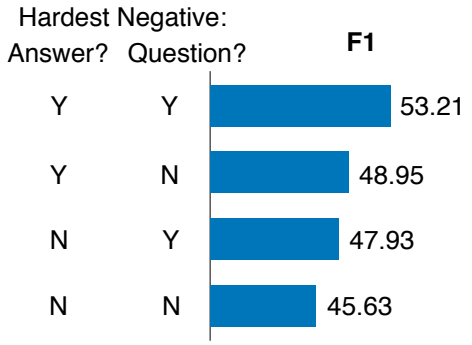

Figure 1: *Ablation study for answer triggering.* The columns on the left indicate whether online selection of hardest negative answer/question was done. To obtain best results with quadruplet loss, it is critical to sample both hard negative answers and hard negative questions.

An ablation study (Figure 1) reveals that the selection of both hardest negative answers and questions is needed to get the majority improvement. Quadruplet loss with the Max-Min-Pooling model without hard negatives is competitive with baselines (Table 5), justifying its usage for answer triggering.

Further, we also compared against using triplet loss with the Max-Min-Pooling model for answer triggering. We found that quadruplet loss outperforms triplet loss (F1 of 51.89 on development set, and 50.08 on Test set) by 3.13 points in F1.

6 Conclusion & Future Work

We have shown that selection of hard negatives is a powerful tool for answer selection. We improve over previously reported results on recent benchmarks using siamese architectures and hard negatives, outperforming interaction-based models. We show the generality of the approach using shallow as well as deep neural network models.

For answer triggering, we presented results supporting the hypothesis that quadruplet loss with hard negatives is suitable for the task, and improves upon previous baselines. Our ablation study confirms the importance of using hard negatives.

As future work, we plan to further investigate the generality of the approach with other tasks and base models.

Acknowledgments

We would like to thank the reviewers for their valuable feedback.

Abstract

Question answering is an AI-complete problem, but existing datasets lack key elements of language understanding such as coreference and ellipsis resolution. We consider sequential question answering: multiple questions are asked one-by-one in a conversation between a questioner and an answerer. Answering these questions is only possible through understanding the conversation history. We introduce the task of question-in-context rewriting: given the context of a conversation's history, rewrite a context-dependent into a self-contained question with the same answer. We construct, CANARD, a dataset of 40,527 questions based on QuAC (Choi et al., 2018) and train Seq2Seq models for incorporating context into standalone questions.

1 Introduction

Question Answering (QA) is an AI complete problem (Webber, 1992), but existing QA datasets do not rise to the challenge: they lack key NLP problems like anaphora resolution, coreference disambiguation, and ellipsis resolution. The logic needed to answer these types of questions requires deeper NLP understanding that simulates the context in which humans naturally answer questions.

Neural techniques question answering have improved (Devlin et al., 2018) machine reading comprehension (Rajpurkar et al., 2016, MRC): computers can take a single question and extract answers from datasets like Wikipedia. However, QA models struggle to generalize when questions do not look like the standalone questions systems in training data: e.g., new genres, languages, or closely-related tasks (Yogatama et al., 2019).

Conversational question answering (Reddy et al., 2019, CQA) is a generalization that ask *multiple* questions in an information-seeking dialogs. Unlike MRC, CQA requires models to link questions together to resolve the conversational dependencies between them: each question needs to be understood in the conversation context. For example, the question *"What was he like in that episode?"* cannot be understood without knowing what *"he"* and *"that episode"* refer to, which can be resolved using the conversation context.

We reduce challenging, interconnected CQA examples to independent, stand-alone MRC to create CANARD—**C**ontext **A**bstraction: **N**ecessary **A**dditional **R**ewritten **D**iscourse—a new dataset[1] that rewrites QuAC (Choi et al., 2018) questions. We crowdsource context-independent paraphrases of QuAC questions and use the paraphrases to train and evaluate question-in-context rewriting.

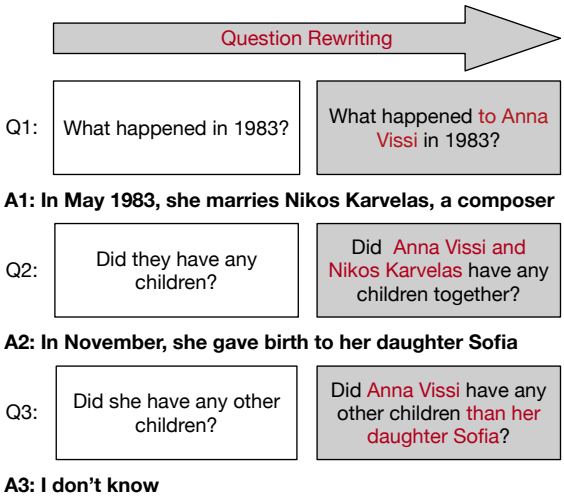

Figure 1: Question-in-context rewriting task. The input to each step is a question to rewrite given the dialog history which consists of the dialog utterances (questions and answers) produced before the given question is asked. The output is an equivalent, context-independent paraphrase of the input question.

Characteristic	Ratio
Answer Not Referenced	0.98
Question Meaning Unchanged	0.95
Correct Coreferences	1.0
Grammatical English	1.0
Understandable w/o Context	0.90

Table 1: Manual inspection of 50 rewritten context-independent questions from CANARD suggests that the new questions have enough context to be independently understandable.

Section 2 formally defines the task of question de-contextualization. Section 3 constructs CANARD, a new dataset of question-in-context with corresponding context-independent paraphrases. Section 5 analyzes our rewrites (and the underlying methodology) to understand the linguistic phenomena that make CQA difficult. We build several baseline rewriting models and compare their BLEU scores to our human rewrites in Section 4.

2 Defining Question-In-Context Rewrites

We formally define the task of question-in-context rewriting (de-contextualization). Given a conversation topic t and a history H of $m-1$ turns, each turn k is a question q_i and an answer a_i; the task is to generate a rewrite q'_m for the next question q_m based on H. Since q_m is part of the conversation, its meaning often involves references to parts of its preceding history. A valid rewrite q'_m should be self-contained: a correct answer to q'_m by itself is a correct answer to q_m combined with the question's preceding history H.

Figure 1 shows the assumptions of CQA and how they are made explicit in rewrites. The first question omits the title of the page (Anna Vissi), the second question omits the answer to the first question (replacing both Anna Vissi and her husband with the pronoun "they"), and the last question adds a scalar implicature that must be resolved.

3 Dataset Construction

We elicit paraphrases from human crowdworkers to make previously context-dependent questions *unambiguously* answerable. Through this process, we resolve difficult coreference linkages and create a pair-wise mapping between ambiguous and context-enriched questions. We derive CANARD from QuAC (Choi et al., 2018), a sequential question answering dataset about specific Wikipedia sections. QuAC uses a pair of workers—a "student" and a "teacher"—to ask and respond to questions. The "student" asks questions about a topic based on only the title of the Wikpedia article and the title of the target section. The "teacher" has access to the full Wikipedia section and provides answers by selecting text that answers the question. With this methodology, QuAC gathers 98k questions across 13,594 conversations. We take their entire dev set and a sample of their train set and create a custom JavaScript task in Mechanical Turk that allows workers to rewrite these questions. JavaScript hints help train the users and provides automated, real-time feedback.

We provide workers with a comprehensive set of instructions and task examples. We ask them to rewrite the questions in natural sounding English while preserving the sentence structure of the original question. We discourage workers from introducing new words that are unmentioned in the previous utterances and ask them to copy phrases when appropriate from the original question. These instructions ensure that the rewrites only resolve conversation-dependent ambiguities. Thus, we encourage workers to create minimal edits; in Section 5.2, we take advantage of this to use BLEU for evaluating model-generated rewrites.

We display the questions in the conversation one at a time, since the rewrites should include only the previous utterance. After a rewrite to the question is submitted, the answer to the question is displayed. The next question is then displayed. This repeats until the end of the conversation. The full set of instructions and the data collection interface are provided in the appendix.

We apply quality control throughout our collection process. During the task, JavaScript checks automatically monitor and warn about common errors: submissions that are abnormally short (e.g., 'why'), rewrites that still have pronouns (e.g., 'he wrote this album'), or ambiguous words (e.g., 'this article', 'that'). Many QuAC questions ask about 'what/who else' or ask for 'other' or 'another' entity. For that class of questions, we ask workers to use a phrase such as 'other than', 'in addition to', 'aside from', 'besides', 'together with' or 'along with' with the appropriate context in their rewrite.

We gather and review our data in batches to screen potentially compromised data or low quality workers. A post-processing script flags suspicious

ORIGINAL: Was this an honest mistake by the media?
REWRITE: Was the claim of media regarding Leblanc's room come to true?
ORIGINAL: What was a single from their album?
REWRITE: What was a single from horslips' *album*?
ORIGINAL: Did they marry?
REWRITE: Did Hannah Arendt and Heidegger marry?

Table 2: Not all rewrites correctly encode the context required to answer a question. We take two failures to provide examples of the two common issues: Changed Meaning (top) and Needs Context (middle). We provide an example with no issues (bottom) for comparison.

rewrites and workers who take and abnormally long or short time. We flag about 15% of our data. *Every* flagged question is manually reviewed by one of the authors and an entire HIT is discarded if one is deemed inadequate. We reject 19.9% of submissions and the rest comprise CANARD. Additionally, we filter out under-performing workers based on these rejections from subsequent batches. To minimize risk, we limit the initial pool of workers to those that have completed 500 HITs with over 90% accuracy and offer competitive payment of $0.50 per HIT.

We verify the efficacy of our quality control through manual review. A random sample of fifty questions sampled from the final dataset is reviewed for desirable characteristics by a native English speaker in Table 1. Each of the positive traits occurs in 90% or more of the questions. Based on our sample, our edits retain grammaticality, leave the question meaning unchanged, and use pronouns unambiguously. There are rare occasions where workers use a part of the answer to the question being rewritten or where some of the context is left ambiguous. These infrequent mistakes should not affect our models. We provide examples of failures in Table 2.

We use the rewrites of QuAC's development set as our test set (5,571 question-in-context and corresponding rewrite pairs) and use a 10% sample of QuAC's training set rewrites as our development set (3,418); the rest are training data (31,538).

	Dev	Test
Copy	33.84	36.25
Pronoun Sub	47.72	47.44
Seq2Seq	51.37	49.67
Human Rewrites*	59.92	

Table 3: BLEU scores of the baseline models on development and test data. Seq2Seq improves up to four points over naive baselines but still well below human accuracy. Human accuracy (*) is computed from a small subset of the validation set.

4 Baselines

We compare three baseline models for the question-in-context rewriting task. In the **Copy** baseline, the rewrite q'_m is set to be the same as the input question q_m without making any changes.

We also try a **Pronoun Substitution** baseline in which the first pronoun in q_m is replaced with the topic entity of the conversation. We use the title of the corresponding Wikipedia article to the original QuAC conversation as the topic entity. Similar to the Copy baseline, the training data is not used in that baseline.

Unlike the previous baselines which do not use our rewrites as training data, the third baseline is a neural sequence-to-sequence (**Seq2Seq**) model with attention and a copy mechanism (Bahdanau et al., 2015; See et al., 2017). We construct the input sequence by concatenating all utterances in the history H, prepending them to q_m, and adding a special separator token between utterances. We use a bidirectional LSTM encoder-decoder model with shared the word embeddings between the encoder and the decoder.[2]

Since questions are written by humans, a human rewrites are the upper-bound for this task. However, annotators (especially crowdworkers) can be inconsistent or disagree. To estimate the human accuracy, we collect 100 pairs of rewritten questions; each pair has two rewrites of the same question (in its given context) by two different workers. We manually verify that all rewrites are valid and then use the pair of rewrites as a hypothesis and a reference.

Table 3 shows the BLEU scores produced by the baselines and humans over both the validation and the test sets.[3] Although a well-trained standard

[2]We initialize the embeddings with GloVE (Pennington et al., 2014) and train with a batch-size of 16 for 200000 steps. We use OpenNMT (Klein et al., 2018) implementation.

[3]We use multi-bleu-detok.perl (Sennrich et al., 2017)

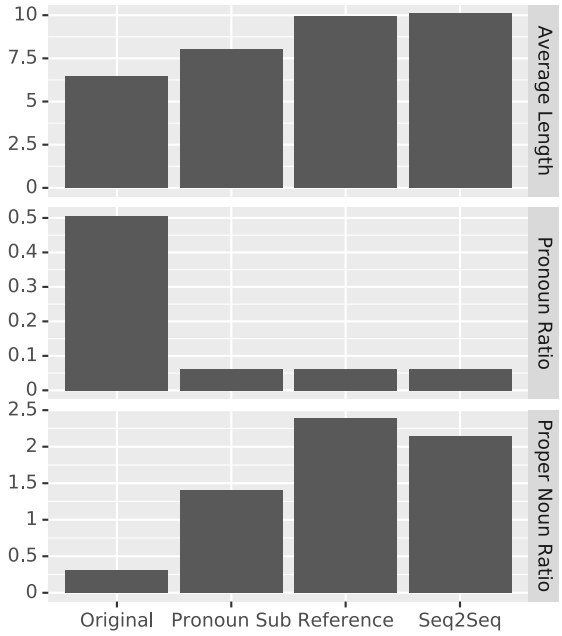

Figure 2: Human rewrites are longer, have fewer pronouns, and have more proper nouns than the original QuAC questions. Rewrites are longer and contain more proper nouns than our Pronoun Sub baseline and trained Seq2Seq model.

neural sequence-to-sequence improves 2–4 BLEU points over naive baselines, it is still 9 BLEU points below human-accuracy. We analyze sources of errors in the following section.

5 Dataset and Model Analysis

We analyze our dataset with automatic metrics after validating the reliability of our data (Section 3). We compare our dataset to the original QuAC questions and to automatically generated questions by our models. Then, we manually inspect the sources of rewriting errors in the seq2seq baseline.

5.1 Anaphora Resolution and Coreference

Our rewrites are longer, contain more nouns and less pronouns, and have more word types than the original data. Machine output lies in between the two human-generated corpora, but quality is difficult to assess. Figure 2 shows these statistics. We motivate our rewrites by exploring linguistic properties of our data. Anaphora resolution and coreference are two core NLP tasks applicable to this dataset, in addition to the downstream tasks evaluated in Section 4.

Pronouns occur in 53.9% of QuAC questions. Questions with pronouns are more likely to be ambiguous than those without any. Only 0.9% of these have pronouns that span more than one category (e.g., 'she' and 'his'). Hence, pronouns within a single sentence are likely unambiguous. However, 75.0% of the aggregate history has pronouns and the percentage of mixed category pronouns increase to 27.8% of our data. Therefore, pronoun disambiguation potentially becomes a problem for a quarter of the original data. An example is provided in Table 4.

Label	Text
QUESTION	How long did he stay there?
REWRITE	How long did Cito Gaston stay at the Jays?
HISTORY	*Cito Gaston* **Q:** What did Gaston do after the world series? ... **Q:** Where did he go in 2001? **A:** In 2002, he was hired by the Jays as special assistant to president and chief executive officer Paul Godfrey.

Table 4: An example that had over ten flagged proper nouns in the history. Rewriting requires resolving challenging coreferences.

Approximately one-third of the questions generated by our pronoun-replacement baseline are within 85% string similarity to our rewritten questions. That leaves two-thirds of our data that cannot be solved with pronoun resolution alone.

5.2 Model Analysis

By manually examining the predictions of the seq2seq model, we notice that the main source of errors is that the model tends to find a short path to completing the rewrites. That often results in *under-specified questions* as in Example 1 in Table 5, *question meaning change* as in Example 2 or *meaningless questions* as in Example 3.

Another source of errors is having related entities mentioned in the context as Example 4 in Table 5, where the model confused "Copa America" with "Argentina". The model also struggles with listing multiple entities mentioned in different parts of the context. Example 5 in Table 5 show the output and the reference rewrites of the question *"Did she have any more works than those 3?"*, where two of the three entities—"United States of Banana", "La Comedia" and "Asalto al tiempo"—are lost in the rewrite.

	Seq2Seq output	Reference
1	What did Chamberlain's men do?	What did Chamberlain's men do during the Battle of Gettysburg?
2	How many games did Ozzie Smith win?	How many games did the Cardinals win while Ozzie Smith played?
3	Did 108th get to the finals?	Did the US Women's Soccer Team get to the finals in the 1999 World Cup?
4	Did Gabriel Batistuta reside in any other countries, besides touring in the Copa America?	Besides Argentina, did Gabriel Batistuta reside in any other countries?
5	Did La Comedia have any more works than La Comedia 3?	Did Giannina Braschi have any more works than United States of Banana, La Comedia and Asalto al tiempo?

Table 5: Example erroneous rewrites generated by the Seq2Seq models and their corresponding reference rewrites. The dominant source of error is the model tendency to produce short rewrites (Examples 1–3). Related entities (Copa America and Argentina in Example 4) distract the model. The model struggles with listing multiple entities mentioned in different parts of the context (Example 5).

6 Related Work and Discussion

Recent work in CQA has used simple concatenation (Elgohary et al., 2018), sequential neural models (Huang et al., 2019), and transformers (Qu et al., 2019a) for modeling the interaction between the conversation history, the question and reference documents. Some of the components in those models, such as relevant history turn selection (Qu et al., 2019b), can be adopted in question rewriting models for our task. An interesting avenue for future work is to incorporate deeper context, either from other modalities (Das et al., 2017) or from other dialog comprehension tasks (Sun et al., 2019).

Parallel to our work, Rastogi et al. (2019) and Su et al. (2019) introduce utterance rewriting datasets for dialog state tracking. Rastogi et al. (2019) covers a narrow set of domains and the rewrites of Su et al. (2019) are based on Chinese dialog with two-turn fixed histories. In contrast, CANARD has histories of variable turn lengths, covers wider topics, and is based on CQA.

Training question rewriting using reinforcement learning with the task accuracy as reward signal is explored in retrieval-based QA (Liu et al., 2019) and in MRC (Buck et al., 2018). A natural question is whether reinforcement learning could learn to retain the necessary context to rewrite questions in CQA. However, our dataset could be used to pretrain a question rewriter that can further be refined using reinforcement learning.

More broadly, we hope CANARD can drive human-computer collaboration in QA (Feng and Boyd-Graber, 2019). While questions typically vary in difficulty (Sugawara et al., 2018), existing research either introduces new benchmarks of difficult (adversarial) stand-alone questions (Dua et al., 2019; Wallace et al., 2019, inter alia), or models that simplify hard questions through paraphrasing (Dong et al., 2017) or decomposition (Talmor and Berant, 2018). We aim at studying QA models that can ask for human assistance (feedback) when they struggle to answer a question.

The reading comprehension setup of CQA provides a controlled environment where the main source of difficulty is interpreting a question in its context. The interactive component of CQA also provides a natural mechanism for improving rewriting. When the computer cannot understand (rewrite) a question because of complicated context, missing world knowledge, or upstream errors (Peskov et al., 2019) in the course of a conversation, it should be able to ask its interlocutor, "can you unpack that?" This dataset helps start that conversation; the next steps are developing and evaluating models that efficiently decide when to ask for human assistance, and how to best use this assistance.

Abstract

Machine comprehension of texts longer than a single sentence often requires coreference resolution. However, most current reading comprehension benchmarks do not contain complex coreferential phenomena and hence fail to evaluate the ability of models to resolve coreference. We present a new crowdsourced dataset containing more than 24K span-selection questions that require resolving coreference among entities in over 4.7K English paragraphs from Wikipedia. Obtaining questions focused on such phenomena is challenging, because it is hard to avoid lexical cues that shortcut complex reasoning. We deal with this issue by using a strong baseline model as an adversary in the crowdsourcing loop, which helps crowdworkers avoid writing questions with exploitable surface cues. We show that state-of-the-art reading comprehension models perform significantly worse than humans on this benchmark—the best model performance is 70.5 F_1, while the estimated human performance is 93.4 F_1.

1 Introduction

Paragraphs and other longer texts typically make multiple references to the same entities. Tracking these references and resolving coreference is essential for full machine comprehension of these texts. Significant progress has recently been made in reading comprehension research, due to large crowdsourced datasets (Rajpurkar et al., 2016; Bajaj et al., 2016; Joshi et al., 2017; Kwiatkowski et al., 2019, *inter alia*). However, these datasets focus largely on understanding local predicate-argument structure, with very few questions requiring long-distance entity tracking. Obtaining such questions is hard for two reasons: (1) teaching crowdworkers about coreference is challenging, with even experts disagreeing on its nuances (Pradhan et al., 2007; Versley, 2008; Recasens et al., 2011; Poesio et al., 2018), and (2) even if we can get crowdworkers to target coreference phenomena in their questions, these questions may contain giveaways that let models arrive at the correct answer without performing the desired reasoning (see §3 for examples).

Byzantines were avid players of tavli (Byzantine Greek: τάβλη), a game known in English as backgammon, which is still popular in former Byzantine realms, and still known by the name tavli in Greece. Byzantine nobles were devoted to horsemanship, particularly ***tzykanion***, now known as *polo*. The game came from Sassanid Persia in the early period and a Tzykanisterion (stadium for playing *the game*) was built by Theodosius II (r. 408–450) inside the Great Palace of Constantinople. Emperor Basil I (r. 867–886) excelled at **it**; Emperor Alexander (r. 912–913) died from exhaustion while playing, Emperor Alexios I Komnenos (r. 1081–1118) was injured while playing with Tatikios, and John I of Trebizond (r. 1235–1238) died from a fatal injury during a game. Aside from Constantinople and Trebizond, other Byzantine cities also featured tzykanisteria, most notably Sparta, Ephesus, and Athens, an indication of a thriving urban aristocracy.

Q1. What is the Byzantine name of the game that Emperor Basil I excelled at? **it → tzykanion**
Q2. What are the names of the sport that is played in a Tzykanisterion? *the game → tzykanion*; *polo*
Q3. What cities had tzykanisteria? cities → Constantinople; Trebizond; Sparta; Ephesus; Athens

Figure 1: Example paragraph and questions from the dataset. Highlighted text in paragraphs is where the questions with matching highlights are anchored. Next to the questions are the relevant coreferent mentions from the paragraph. They are bolded for the first question, italicized for the second, and underlined for the third in the paragraph.

We introduce a new dataset, QUOREF,[1] that contains questions requiring coreferential reasoning (see examples in Figure 1). The questions are derived from paragraphs taken from a diverse set of English Wikipedia articles and are collected using an annotation process (§2) that deals with the aforementioned issues in the following ways:

[1]Links to dataset, code, models, and leaderboard available at https://allennlp.org/quoref.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5925–5932, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

First, we devise a set of instructions that gets workers to find anaphoric expressions and their referents, asking questions that connect two mentions in a paragraph. These questions mostly revolve around traditional notions of coreference (Figure 1 Q1), but they can also involve referential phenomena that are more nebulous (Figure 1 Q3). Second, inspired by Dua et al. (2019), we disallow questions that can be answered by an adversary model (uncased base BERT, Devlin et al., 2019, trained on SQuAD 1.1, Rajpurkar et al., 2016) running in the background as the workers write questions. This adversary is not particularly skilled at answering questions requiring coreference, but can follow obvious lexical cues—it thus helps workers avoid writing questions that shortcut coreferential reasoning.

QUOREF contains more than 24K questions whose answers are spans or sets of spans in 4.7K paragraphs from English Wikipedia that can be arrived at by resolving coreference in those paragraphs. We manually analyze a sample of the dataset (§3) and find that 78% of the questions cannot be answered without resolving coreference. We also show (§4) that the best system performance is 70.5% F_1, while the estimated human performance is 93.4%. These findings indicate that this dataset is an appropriate benchmark for coreference-aware reading comprehension.

2 Dataset Construction

Collecting paragraphs We scraped paragraphs from Wikipedia pages about English movies, art and architecture, geography, history, and music. For movies, we followed the list of English language films,[2] and extracted plot summaries that are at least 40 tokens, and for the remaining categories, we followed the lists of featured articles.[3] Since movie plot summaries usually mention many characters, it was easier to find hard QUOREF questions for them, and we sampled about 40% of the paragraphs from this category.

Crowdsourcing setup We crowdsourced questions about these paragraphs on Mechanical Turk. We asked workers to find two or more co-referring spans in the paragraph, and to write questions such that answering them would require the knowledge that those spans are coreferential. We did not ask them to explicitly mark the co-referring spans. Workers were asked to write questions for a random sample of paragraphs from our pool, and we showed them examples of good and bad questions in the instructions (see Appendix A). For each question, the workers were also required to select one or more spans in the corresponding paragraph as the answer, and these spans are not required to be same as the coreferential spans that triggered the questions.[4] We used an uncased base BERT QA model (Devlin et al., 2019) trained on SQuAD 1.1 (Rajpurkar et al., 2016) as an adversary running in the background that attempted to answer the questions written by workers in real time, and the workers were able to submit their questions only if their answer did not match the adversary's prediction.[5] Appendix A further details the logistics of the crowdsourcing tasks. Some basic statistics of the resulting dataset can be seen in Table 1.

	Train	Dev.	Test
Number of questions	19399	2418	2537
Number of paragraphs	3771	454	477
Avg. paragraph len (tokens)	384±105	381±101	385±103
Avg. question len (tokens)	17±6	17±6	17±6
Paragraph vocabulary size	57648	18226	18885
Question vocabulary size	19803	5579	5624
% of multi-span answers	10.2	9.1	9.7

Table 1: Key statistics of QUOREF splits.

3 Semantic Phenomena in QUOREF

To better understand the phenomena present in QUOREF, we manually analyzed a random sample of 100 paragraph-question pairs. The following are some empirical observations.

Requirement of coreference resolution We found that 78% of the manually analyzed questions cannot be answered without coreference resolution. The remaining 22% involve some form of coreference, but do not require it to be resolved for answering them. Examples include a paragraph that mentions only one city, "*Bristol*", and a sentence that says "*the city was bombed*". The associated question, *Which city was bombed?*, does not really require coreference resolution from a model

[2] https://en.wikipedia.org/wiki/Category:English-language_films

[3] https://en.wikipedia.org/wiki/Wikipedia:Featured_articles

[4] For example, the last question in Table 2 is about the coreference of {*she*, *Fania*, *his mother*}, but none of these mentions is the answer.

[5] Among models with acceptably low latency, we qualitatively found uncased base BERT to be the most effective.

Reasoning	Paragraph Snippet	Question	Answer
Pronominal resolution (69%)	Anna and Declan eventually make their way on foot to a roadside pub, where they discover **the three van thieves** going through Anna's luggage. **Declan fights *them***, displaying unexpected strength for a man of his size, and retrieves Anna's bag.	Who does **Declan get into a fight** with?	the three van thieves
Nominal resolution (54%)	Later, **Hippolyta** was granted a daughter, Princess Diana, . . . **Diana defies *her mother*** and . . .	What is the name of the person who is **defied by her daughter**?	Hippolyta
Multiple resolutions (32%)	The now upbeat collective keep **the toucan**, nicknaming it "**Amigo**" . . . When authorities show up to catch **the bird**, Pete and Liz spirit **him** away by **Liz hiding *him* in her dress** . . .	What is the name of the character who **hides in Liz's dress**?	Amigo
Commonsense reasoning (10%)	Amos reflects back on his early childhood . . . with **his mother *Fania* and father Arieh**. . . . One of **his mother**'s friends is killed while hanging up laundry during the war. . . . **Fania** falls into a depression. . . **she** . . . goes to . . . Tel Aviv, where **she** kills **herself** by overdose . . .	How does **Arieh's wife** die?	kills herself by overdose

Table 2: Phenomena in QUOREF. Note that the first two classes are not disjoint. In the final example, the paragraph does not explicitly say that *Fania* is *Arieh*'s wife.

that can identify city names, making the content in the question after *Which city* unnecessary.

Types of coreferential reasoning Questions in QUOREF require resolving pronominal and nominal mentions of entities. Table 2 shows percentages and examples of analyzed questions that fall into these two categories. These are not disjoint sets, since we found that 32% of the questions require both (row 3). We also found that 10% require some form of commonsense reasoning (row 4).

4 Baseline Model Performance on QUOREF

We evaluated two classes of baseline models on QUOREF: state-of-the art reading comprehension models that predict single spans (§4.1) and heuristic baselines to look for annotation artifacts (§4.2).

We use two evaluation metrics to compare model performance: exact match (EM), and a (macro-averaged) F_1 score that measures overlap between a bag-of-words representation of the gold and predicted answers. We use the same implementation of EM as SQuAD, and we employ the F_1 metric used for DROP (Dua et al., 2019). See Appendix B for model training hyperparameters and other details.

Method	Dev		Test	
	EM	F_1	EM	F_1
Heuristic Baselines				
passage-only BERT QA	19.77	25.56	21.25	29.27
passage-only XLNet QA	18.44	27.59	18.57	28.24
Reading Comprehension				
QANet	34.41	38.26	34.17	38.90
QANet+BERT	43.09	47.38	42.41	47.20
BERT QA	58.44	64.95	59.28	66.39
XLNet QA	**64.52**	**71.49**	**61.88**	**70.51**
Human Performance	-	-	86.75	93.41

Table 3: Performance of various baselines on QUOREF, measured by exact match (EM) and F_1. Boldface marks the best systems for each metric and split.

4.1 Reading Comprehension Models

We test four single-span (SQuAD-style) reading comprehension models: (1) **QANet** (Yu et al., 2018), currently the best-performing published model on SQuAD 1.1 without data augmentation or pretraining; (2) **QANet + BERT**, which enhances the QANet model by concatenating frozen BERT representations to the original input embeddings; (3) **BERT QA** (Devlin et al., 2019), the adversarial baseline used in data construction, and (4) **XLNet QA** (Yang et al., 2019), another large pretrained language model based on the Transformer architecture (Vaswani et al., 2017) that outperforms BERT QA on reading comprehension

benchmarks SQuAD and RACE (Lai et al., 2017).

We use the AllenNLP (Gardner et al., 2018) implementation of QANet modified to use the marginal objective proposed by Clark and Gardner (2018) and `pytorch-transformers`[6] implementation of base BERT QA[7] and base XLNet QA. BERT is pretrained on English Wikipedia and BookCorpus (Zhu et al., 2015) (3.87B wordpieces, 13GB of plain text) and XLNet additionally on Giga5 (Napoles et al., 2012), ClueWeb 2012-B (extended from Smucker et al., 2009), and Common Crawl[8] (32.89B wordpieces, 78GB of plain text).

4.2 Heuristic Baselines

In light of recent work exposing predictive artifacts in crowdsourced NLP datasets (Gururangan et al., 2018; Kaushik and Lipton, 2018, *inter alia*), we estimate the effect of predictive artifacts by training BERT QA and XLNet QA to predict a single start and end index given only the passage as input (**passage-only**).

4.3 Results

Table 3 presents the performance of all baseline models on QUOREF.

The best performing model is XLNet QA, which reaches an F_1 score of 70.5 in the test set. However, it is still more than 20 F_1 points below human performance.[9]

BERT QA trained on QUOREF under-performs XLNet QA, but still gets a decent F_1 score of 66.4. Note that BERT QA trained on SQuAD would have achieved an F_1 score of 0, since our dataset was constructed with that model as the adversary. The extent to which BERT QA does well on QUOREF might indicate its capacity for coreferential reasoning that was not exploited when it was trained on SQuAD (for a detailed discussion of this phenomenon, see Liu et al., 2019). Our analysis of model errors in §4.4 shows that some of the improved performance may also be due to artifacts in QUOREF.

We notice smaller improvements from XLNet QA over BERT QA (4.12 in F_1 test score, 2.6 in EM test score) on QUOREF compared to other reading comprehension benchmarks: SQuAD and RACE (see Yang et al., 2019). This might indicate the insufficiency of pretraining on more data (XL Net was pretrained on 6 times more plain text, nearly 10 times more wordpieces than BERT), for coreferential reasoning.

The passage-only baseline under-performs all other systems; examining its predictions reveals that it almost always predicts the most frequent entity in the passage. Its relatively low performance, despite the tendency for Wikipedia articles and passages to be written about a single entity, indicates that a large majority of questions likely require coreferential reasoning.

4.4 Error Analysis

We analyzed the predictions from the baseline systems to estimate the extent to which they really understand coreference.

Since the contexts in QUOREF come from Wikipedia articles, they are often either about a specific entity, or are narratives with a single protagonist. We found that the baseline models exploit this property to some extent. We observe that 51% of the QUOREF questions in the development set that were correctly answered by BERT QA were either the first or the most frequent entity in the paragraphs, while in the case of those that were incorrectly answered, this value is 12%. XLNet QA also exhibits a similar trend, with the numbers being 48% and 11%, respectively.

QA systems trained on QUOREF often need to find entities that occur far from the locations in the paragraph at which that the questions are anchored. To assess whether the baseline systems exploited answers being close, we manually analyzed predictions of BERT QA and XLNet QA on 100 questions in the development set, and found that the answers to 17% of the questions correctly answered by XLNet QA are the nearest entities, whereas the number is 4% for those incorrectly answered. For BERT QA, the numbers are 17% and 6% respectively.

5 Related Work

Traditional coreference datasets Unlike traditional coreference annotations in datasets like those of Pradhan et al. (2007), Ghaddar and Langlais (2016), Chen et al. (2018) and Poesio et al. (2018), which aim to obtain complete coref-

[6] https://github.com/huggingface/pytorch-transformers

[7] The large BERT model does not fit in the available GPU memory.

[8] https://commoncrawl.org/

[9] Human performance was estimated from the authors' answers of 400 questions from the test set, scored with the same metric used for systems.

erence clusters, our questions require understanding coreference between only a few spans. While this means that the notion of coreference captured by our dataset is less comprehensive, it is also less conservative and allows questions about coreference relations that are not marked in OntoNotes annotations. Since the notion is not as strict, it does not require linguistic expertise from annotators, making it more amenable to crowdsourcing. Guha et al. (2015) present the limitations of annotating coreference in newswire texts alone, and like us, built a non-newswire coreference resolution dataset focusing on Quiz Bowl questions. There is some other recent work (Poesio et al., 2019; Aralikatte and Søgaard, 2019) in crowdsourcing coreference judgments that relies on a relaxed notion of coreference as well.

Reading comprehension datasets There are many reading comprehension datasets (Richardson et al., 2013; Rajpurkar et al., 2016; Kwiatkowski et al., 2019; Dua et al., 2019, *inter alia*). Most of these datasets principally require understanding local predicate-argument structure in a paragraph of text. QUOREF also requires understanding local predicate-argument structure, but makes the reading task harder by explicitly querying anaphoric references, requiring a system to track entities throughout the discourse.

6 Conclusion

We present QUOREF, a focused reading comprehension benchmark that evaluates the ability of models to resolve coreference. We crowdsourced questions over paragraphs from Wikipedia, and manual analysis confirmed that most cannot be answered without coreference resolution. We show that current state-of-the-art reading comprehension models perform significantly worse than humans. Both these findings provide evidence that QUOREF is an appropriate benchmark for coreference-aware reading comprehension.

Acknowledgments

We thank the anonymous reviewers for the useful discussion. Thanks to HuggingFace for releasing `pytorch-transformers`, and to Dheeru Dua for sharing with us the crowdsourcing setup used for DROP.

Appendices

A Crowdsourcing Logistics

A.1 Instructions

The crowdworkers were giving the following instructions:

"In this task, you will look at paragraphs that contain several phrases that are references to names of people, places, or things. For example, in the first sentence from sample paragraph below, the references Unas and the ninth and final king of Fifth Dynasty refer to the same person, and Pyramid of Unas, Unas's pyramid and the pyramid refer to the same construction. You will notice that multiple phrases often refer to the same person, place, or thing. Your job is to write questions that you would ask a person to see if they understood that the phrases refer to the same entity. To help you write such questions, we provided some examples of good questions you can ask about such phrases. We also want you to avoid questions that can be answered correctly by someone without actually understanding the paragraph. To help you do so, we provided an AI system running in the background that will try to answer the questions you write. You can consider any question it can answer to be too easy. However, please note that the AI system incorrectly answering a question does not necessarily mean that it is good. Please read the examples below carefully to understand what kinds of questions we are interested in."

A.2 Examples of Good Questions

We illustrate examples of good questions for the following paragraph.

"The Pyramid of Unas is a smooth-sided pyramid built in the 24th century BC for the Egyptian pharaoh Unas, the ninth and final king of the Fifth Dynasty. It is the smallest Old Kingdom pyramid, but significant due to the discovery of Pyramid Texts, spells for the king's afterlife incised into the walls of its subterranean chambers. Inscribed for the first time in Unas's pyramid, the tradition of funerary texts carried on in the pyramids of subsequent rulers, through to the end of the Old Kingdom, and into the Middle Kingdom through the Coffin Texts which form the basis of the Book of the Dead. Unas built his pyramid between the complexes of Sekhemket and Djoser, in North Saqqara. Anchored to the valley temple via a nearby lake, a long causeway was constructed to provide access to the pyramid site. The causeway had elaborately decorated walls covered with a roof which had a slit in one section allowing light to enter illuminating the images. A long wadi was used as a pathway. The terrain was difficult to negotiate and contained old buildings and tomb superstructures. These were torn down and repurposed as underlay for the causeway. A significant stretch of Djoser's causeway was reused for embankments. Tombs that were on the path had their superstructures demolished and were paved over, preserving their decorations."

The following questions link pronouns:

Q1: What is the name of the person whose pyramid was built in North Saqqara? **A:** Unas

Q2: What is significant due to the discovery of Pyramid Texts? **A:** The Pyramid of Unas

Q3: What were repurposed as underlay for the causeway? **A:** old buildings; tomb superstructures

The following questions link other references:

Q1: What is the name of the king for whose afterlife spells were incised into the walls of the pyramid? **A:** Unas

Q2: Where did the final king of the Fifth dynasty build his pyramid? **A:** between the complexes of Sekhemket and Djoser, in North Saqqara

A.3 Examples of Bad Questions

We illustrate examples of bad questions for the following paragraph.

"Decisions by Republican incumbent Peter Fitzgerald and his Democratic predecessor Carol Moseley Braun to not participate in the election resulted in wide-open Democratic and Republican primary contests involving fifteen candidates. In the March 2004 primary election, Barack Obama won in an unexpected landslidewhich overnight made him a rising star within the national Democratic Party, started speculation about a presidential future, and led to the reissue of his memoir, Dreams from My Father. In July 2004, Obama delivered the keynote address at the 2004 Democratic National Convention, seen by 9.1 million

viewers. His speech was well received and elevated his status within the Democratic Party. Obama's expected opponent in the general election, Republican primary winner Jack Ryan, withdrew from the race in June 2004. Six weeks later, Alan Keyes accepted the Republican nomination to replace Ryan. In the November 2004 general election, Obama won with 70 percent of the vote. Obama cosponsored the Secure America and Orderly Immigration Act. He introduced two initiatives that bore his name: LugarObama, which expanded the NunnLugar cooperative threat reduction concept to conventional weapons; and the Federal Funding Accountability and Transparency Act of 2006, which authorized the establishment of USAspending.gov, a web search engine on federal spending. On June 3, 2008, Senator Obamaalong with three other senators: Tom Carper, Tom Coburn, and John McCain—introduced follow-up legislation: Strengthening Transparency and Accountability in Federal Spending Act of 2008."

The following questions do not require coreference resolution:

Q1: Who withdrew from the race in June 2004? **A:** Jack Ryan

Q2: What Act sought to build on the Federal Funding Accountability and Transparency Act of 2006? **A:** Strengthening Transparency and Accountability in Federal Spending Act of 2008

The following question has ambiguous answers:

Q1: Whose memoir was called Dreams from My Father? **A:** Barack Obama; Obama; Senator Obama

A.4 Worker Pool Management

Beyond training workers with the detailed instructions shown above, we ensured that the questions are of high quality by selecting a good pool of 21 workers using a two-stage selection process, allowing only those workers who clearly understood the requirements of the task to produce the final set of questions. Both the qualification and final HITs had 4 paragraphs per HIT for paragraphs from movie plot summaries, and 5 per HIT for the other domains, from which the workers could choose. For each HIT, workers typically spent 20 minutes, were required to write 10 questions, and were paid US$7.

B Experimental Setup Details

Unless otherwise mentioned, we adopt the original published procedures and hyperparameters used for each baseline.

BERT QA and XLNet QA We use uncased BERT, and cased XLNet, but lowercase our data while processing. We train our model with a batch size of 10, sequence length of 512 wordpieces, and a stride of 128. We use the AdamW optimizer, with a learning rate of 3^{-5}. We train for 10 epochs, checkpointing the model after 19399 steps. We report the performance of the checkpoint which is the best on the dev set.

QANet Durining training, we truncate paragraphs to 400 (word) tokens during training and questions to 50 tokens. During evaluation, we truncate paragraphs to 1000 tokens and questions to 100 tokens.

Passage-only baseline We keep the HPs setup used for training BERT QA and XLNet QA and replace questions with empty strings.

Zero-shot Reading Comprehension by Cross-lingual Transfer Learning with Multi-lingual Language Representation Model

Abstract

Because it is not feasible to collect training data for every language, there is a growing interest in cross-lingual transfer learning. In this paper, we systematically explore zero-shot cross-lingual transfer learning on reading comprehension tasks with a language representation model pre-trained on multi-lingual corpus. The experimental results show that with pre-trained language representation zero-shot learning is feasible, and translating the source data into the target language is not necessary and even degrades the performance. We further explore what does the model learn in zero-shot setting[0].

1 Introduction

Reading Comprehension (RC) has become a central task in natural language processing, with great practical value in various industries. In recent years, many large-scale RC datasets in English (Hermann et al., 2015; Hewlett et al., 2016; Rajpurkar et al., 2016; Nguyen et al., 2016; Trischler et al., 2017; Joshi et al., 2017; Rajpurkar et al., 2018) have nourished the development of numerous powerful and diverse RC models (Seo et al., 2016; Hu et al., 2018; Wang et al., 2017; Clark and Gardner, 2018; Huang et al., 2017). The state-of-the-art model (Devlin et al., 2018) on SQuAD, one of the most widely used RC benchmarks, even surpasses human-level performance. Nonetheless, RC on languages other than English has been limited due to the absence of sufficient training data. Although some efforts have been made to create RC datasets for Chinese (He et al., 2018; Shao et al., 2018) and Korean (Seungyoung Lim, 2018), it is not feasible to collect RC datasets for every language since annotation efforts to collect a new RC dataset are often far from trivial. Therefore, the setup of transfer learning, especially zero-shot learning, is of extraordinary importance.

Existing methods (Asai et al., 2018) of cross-lingual transfer learning on RC datasets often count on machine translation (MT) to translate data from source language into target language, or vice versa. These methods may not require a well-annotated RC dataset for the target language, whereas a high-quality MT model is needed as a trade-off, which might not be available when it comes to low-resource languages.

In this paper, we leverage pre-trained multilingual language representation, for example, BERT learned from multilingual un-annotated sentences (multi-BERT), in cross-lingual zero-shot RC. We fine-tune multi-BERT on the training set in source language, then test the model in target language, with a number of combinations of source-target language pair to explore the cross-lingual ability of multi-BERT. Surprisingly, we find that the models have the ability to transfer between low lexical similarity language pair, such as English and Chinese. Recent studies (Lample and Conneau, 2019; Devlin et al., 2018; Wu and Dredze, 2019) show that cross-lingual language models have the ability to enable preliminary zero-shot transfer on simple natural language understanding tasks, but zero-shot transfer of RC has not been studied. To our knowledge, this is the first work systematically exploring the cross-lingual transferring ability of multi-BERT on RC tasks.

2 Zero-shot Transfer with Multi-BERT

Multi-BERT has showcased its ability to enable cross-lingual zero-shot learning on the natural language understanding tasks including XNLI (Conneau et al., 2018), NER, POS, Dependency Parsing, and so on. We now seek to know if a pre-trained multi-BERT has ability to solve RC tasks in the zero-shot setting.

*Equal contribution

2.1 Experimental Setup and Data

We have training and testing sets in three different languages: English, Chinese and Korean. The English dataset is SQuAD (Rajpurkar et al., 2016). The Chinese dataset is DRCD (Shao et al., 2018), a Chinese RC dataset with 30,000+ examples in the training set and 10,000+ examples in the development set. The Korean dataset is KorQuAD (Seungyoung Lim, 2018), a Korean RC dataset with 60,000+ examples in the training set and 10,000+ examples in the development set, created in exactly the same procedure as SQuAD. We always use the development sets of SQuAD, DRCD and KorQuAD for testing since the testing sets of the corpora have not been released yet.

Next, to construct a diverse cross-lingual RC dataset with compromised quality, we translated the English and Chinese datasets into more languages, with Google Translate[1]. An obvious issue with this method is that some examples might no longer have a recoverable span. To solve the problem, we use fuzzy matching[2] to find the most possible answer, which calculates minimal edit distance between translated answer and all possible spans. If the minimal edit distance is larger than min(10, lengths of translated answer - 1), we drop the examples during training, and treat them as noise when testing. In this way, we can recover more than 95% of examples. The following generated datasets are recovered with same setting.

The pre-trained multi-BERT is the official released one[3]. This multi-lingual version of BERT were pre-trained on corpus in 104 languages. Data in different languages were simply mixed in batches while pre-training, without additional effort to align between languages. When fine-tuning, we simply adopted the official training script of BERT, with default hyperparameters, to fine-tune each model until training loss converged.

2.2 Experimental Results

Table 1 shows the result of different models trained on either Chinese or English and tested on Chinese. In row (f), multi-BERT is fine-tuned on English but tested on Chinese, which achieves competitive performance compared with QANet trained on Chinese. We also find that multi-BERT trained on English has relatively lower EM compared with the model with comparable F1 scores. This shows that the model learned with zero-shot can roughly identify the answer spans in context but less accurate. In row (c), we fine-tuned a BERT model pre-trained on English monolingual corpus (English BERT) on Chinese RC training data directly by appending fastText-initialized Chinese word embeddings to the original word embeddings of English-BERT. Its F1 score is even lower than that of zero-shot transferring multi-BERT (rows (c) v.s. (e)). The result implies multi-BERT does acquire better cross-lingual capability through pre-training on multilingual corpus.

Model	Train-set	EM	F1
(a) Shao et al. 2018	Chinese	-	53.78
(b) QANet[3]	Chinese	66.10	78.10
(c) English-BERT	Chinese	65.00	76.96
(d) Chinese-BERT	Chinese	82.00	89.10
(e) multi-BERT	Chinese	81.24	88.68
(f) multi-BERT	English	63.31	78.82
(g) multi-BERT	English +Chinese	82.63	90.10

Table 1: EM/F1 scores over Chinese testing set.

Train	Test		
	English	Chinese	Korean
En	**81.2/88.6**	63.3/78.8	49.2/69.3
Zh	34.1/53.8	**81.2/88.7**	56.4/78.2
Kr	58.5/68.4	73.4/82.7	**69.41/89.3**
En-Fr	67.5/76.4	56.5/72.5	37.2/56.3
En-Zh	59.7/71.4	**61.4/78.8**	49.0/72.7
En-Jp	53.3/64.9	62.4/76.7	50.4/72.0
En-Kr	41.7/50.1	56.7/71.6	**47.1/70.8**

Zh-Fr	23.4/39.8	44.9/62.0	39.6/59.9
Zh-Jp	25.5/42.6	60.9/72.4	44.9/65.7
Zh-Kr	26.5/42.2	58.2/69.5	**47.4/67.7**

Table 2: EM/F1 score of multi-BERTs fine-tuned on different training sets and tested on different languages (En: English, Fr: French, Zh: Chinese, Jp: Japanese, Kr: Korean, xx-yy: translated from xx to yy). The text in bold means training data language is the same as testing data language.

Table 2 shows the results of multi-BERT fine-tuned on different languages and then tested on English , Chinese and Korean. The top half of the table shows the results of training data without translation. It is not surprising that when the training and testing sets are in the same language, the best results are achieved, and multi-BERT shows transfer capability when training and testing sets are in different languages, especially between Chinese and Korean.

In the lower half of Table 2, the results are ob-

[1] https://translate.google.com/
[2] https://github.com/taleinat/fuzzysearch
[3] https://github.com/google-research/bert

tained by the translated training data. First, we found that when testing on English and Chinese, translation always degrades the performance (En v.s. En-XX, Zh v.s. Zh-XX). Even though we translate the training data into the same language as testing data, using the untranslated data still yield better results. For example, when testing on English, the F1 score of the model training on Chinese (Zh) is 53.8, while the F1 score is only 44.1 for the model training on Zh-En. This shows that translation degrades the quality of data. There are some exceptions when testing on Korean. Translating the English training data into Chinese, Japanese and Korean still improve the performance on Korean. We also found that when translated into the same language, the English training data is always better than the Chinese data (En-XX v.s. Zh-XX), with only one exception (En-Fr v.s. Zh-Fr when testing on KorQuAD). This may be because we have less Chinese training data than English. These results show that the quality and the size of dataset are much more important than whether the training and testing are in the same language or not.

2.3 Discussion

2.3.1 The Effect of Machine Translation

Table 2 shows that fine-tuning on un-translated target language data achieves much better performance than data translated into the target language. Because the above statement is true across all the languages, it is a strong evidence that translation degrades the performance.We notice that the translated corpus and untranslated corpus are not the same. This may be another factor that influences the results. Conducting an experiment between un-translated and back-translated data may deal with this problem.

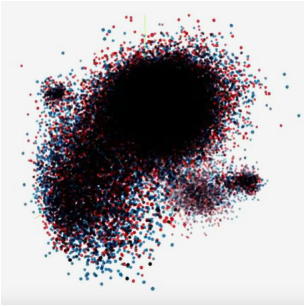
2.3.2 The Effect of Other Factors

Here we discuss the case that the training data are translated. We consider each result is affected by at least three factors: (1) training corpus, (2) data size, (3) whether the source corpus is translated into the target language. To study the effect of data-size, we conducted an extra experiment where we down-sampled the size of English data to be the same as Chinese corpus, and used the down-sampled corpus to train. Then We carried out one-way ANOVA test and found out the significance of the three factors are ranked as below: (1) $>$ (2) $>>$ (3). The analysis supports that the characteristics of training data is more important than translated into target language or not. Therefore, although translation degrades the performance, whether translating the corpus into the target language is not critical.

Train	Test	EM	F1
English	English-permuted	1.25	11.54
English	Chinese-permuted	5.02	17.49
Chinese	Chinese-permuted	8.91	25.67
Chinese	Chinese	81.24	88.68

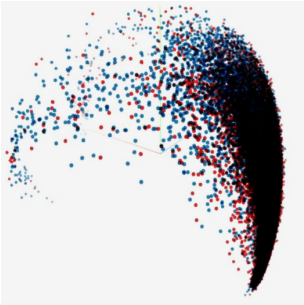
Table 3: EM/F1 scores over artificially created unseen languages (English-permuted and Chinese-permuted).

3 What Does Zero-shot Transfer Model Learn?



3.1 Unseen Language Dataset

It has been shown that extractive QA tasks like SQuAD may be tackled by some language independent strategies, for example, matching words in questions and context (Weissenborn et al., 2017). Is zero-shot learning feasible because the model simply learns this kind of language independent strategies on one language and apply to the other?



To verify whether multi-BERT largely counts on a language independent strategy, we test the model on the languages unseen during pre-training. To make sure the languages have never been seen before, we artificially make unseen languages by permuting the whole vocabulary of existing languages. That is, all the words in the sentences of a specific language are replaced by other words in the same language to form the sentences in the created unseen language. It is assumed that if multi-BERT used to find answers by language independent strategy, then multi-BERT should also do well on unseen languages. Table 4 shows that the performance of multi-BERT drops drastically on the dataset. It implies that multi-BERT might not totally rely on pattern matching when finding answers.

3.2 Embedding in Multi-BERT

PCA projection of hidden representations of the last layer of multi-BERT before and after fine-tuning are shown in Fig. 1. The red points represent Chinese tokens, and the blue points are for English. The results show that tokens from different languages might be embedded into the same

(a) Before Fine-tuning

(b) After Fine-tuning

gt:	second law of thermodynamics
pred:	エ レ ク ト リ ッ ク motors (Jp)
gt:	electric motors
pred:	fermionic nature des lectrons (Fr)
gt:	fermionic nature of electrons
pred:	the 차이점 in 잠재력 에너지 (Kr)
gt:	the difference in potential energy

Table 5: Answers inferenced on code-switching dataset. The predicted answers would be the same as the ground truths (gt) if we translate every word into English.

space with close spatial distribution. Even though during the fine-tuning only the English data is used, the embedding of the Chinese token changed accordingly. We also quantitatively evaluate the similarities between the embedding of the languages. The results can be found in the Appendix.

3.3 Code-switching Dataset

We observe linguistic-agnostic representations in the last subsection. If tokens are represented in a language-agnostic way, the model may be able to handle code-switching data. Because there is no code-switching data for RC, we create artificial code-switching datasets by replacing some of the words in contexts or questions with their synonyms in another language. The synonyms are found by word-by-word translation with given dictionaries. We use the bilingual dictionaries collected and released in facebookresearch/MUSE GitHub repository. We substitute the words if and only if the words are in the bilingual dictionaries.

Table 4 shows that on all the code-switching datasets, the EM/F1 score drops, indicating that the semantics of representations are not totally disentangled from language. However, the examples of the answers of the model (Table 5) show that multi-BERT could find the correct answer spans although some keywords in the spans have been translated into another language.

3.4 Typology-manipulated Dataset

There are various types of typology in languages. For example, in English the typology order is subject-verb-object (SVO) order, but in Japanese and Korean the order is subject-object-verb (SOV). We construct a typology-manipulated dataset to examine if the typology order of the training data influences the transfer learning results. If the model only learns the semantic mapping between different languages, changing English typology order from SVO to SOV should improve the transfer ability from English to Japanese. The method used to generate datasets is the same as Ravfogel et al. 2019.

The source code is from a GitHub repository named Shaul1321/rnn_typology, which labels given sentences to CoNLL format with Stanford-CoreNLP and then re-arranges them greedily.

Table 6 shows that when we change the English typology order to SOV or OSV order, the perfor-

Train/Test	English	Chinese	Korean
En	81.2/88.6	63.3/78.8	49.2/69.3
En-SOV	78.4/86.5	62.8/78.3	47.6/70.4
En-VOS	79.4/87.1	59.1/74.6	46.2/67.0
En-VSO	79.4/87.1	60.9/76.8	44.2/65.4
En-OSV	78.9/86.9	63.5/78.0	49.0/70.7
En-OVS	73.6/82.5	57.6/72.1	45.8/67.0

Table 6: EM/F1 scores over artificially created typology-manipulated dataset.

mance on Korean is improved and worsen on English and Chinese, but very slightly. The results show that the typology manipulation on the training set has little influence. It is possible that multi-BERT normalizes the typology order of different languages to some extent.

4 Conclusion

In this paper, we systematically explore zero-shot cross-lingual transfer learning on RC with multi-BERT. The experimental results on English, Chinese and Korean corpora show that even when the languages for training and testing are different, reasonable performance can be obtained. Furthermore, we created several artificial data to study the cross-lingual ability of multi-BERT in the presence of typology variation and code-switching. We showed that only token-level pattern matching is not sufficient for multi-BERT to answer questions and typology variation and code-switching only caused minor effects on testing performance.

A Supplemental Material

A.1 Internal Representation of multi-BERT

The architecture of multi-BERT is a Transformer encoder (Vaswani et al., 2017). While fine-tuning on SQuAD-like dataset, the bottom layers of multi-BERT are initialized from Google-pretrained parameters, with an added output layer initialized from random parameters. Tokens representations from the last layer of bottom-part of multi-BERT are inputs to the output layer and then the output layer outputs a distribution over all tokens that indicates the probability of a token being the START/END of an answer span.

A.1.1 Cosine Similarity

As all translated versions of SQuAD/DRCD are parallel to each other. Given a source-target language pair, we calculate cosine similarity of the mean pooling of tokens representation within corresponding answer-span as a measure of how much they look like in terms of the internal representation of multi-BERT. The results are shown in Fig. 2.

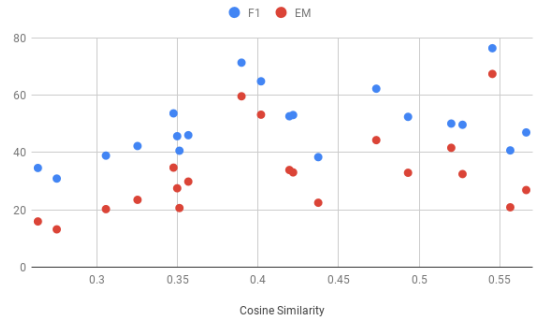

Figure 2: The relation of cosine similarity of answer words with EM/F1 scores in red and blue respectively. Each point represents a source-target language pair of datasets.

A.1.2 SVCCA

Singular Vector Canonical Correlation Analysis (SVCCA) is a general method to compare the correlation of two sets of vector representations. SVCCA has been proposed to compare learned representations across language models (Saphra and Lopez, 2018). Here we adopt SVCCA to measure the linear similarity of two sets of representations in the same multi-BERT from different translated datasets, which are parallel to each other. The results are shown in Fig 3.

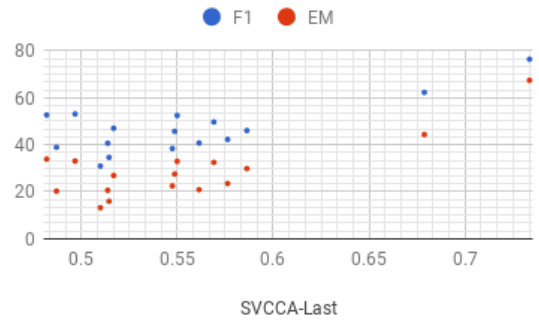

Figure 3: The relation of SVCCA similarity with EM/F1 scores in red and blue respectively. Each point represents a source-target language pair of datasets.

A.2 Improve Transfering

In the paper, we show that internal representations of multi-BERT are linear-mappable to some extent between different languages. This implies that multi-BERT model might encode semantic and syntactic information in language-agnostic ways and explains how zero-shot transfer learning could be done.

To take a step further, while transfering model from source dataset to target dataset, we align representations in two proposed way, to improve performance on target dataset.

A.2.1 Linear Mapping Method

Algorithms proposed in (Lample et al., 2018; Artetxe et al., 2018; Zhou et al., 2019) to unsupervisedly learn linear mapping between two sets of embeddings are used here to align representations of source (training data) to those of target. We obtain the mapping generated by embeddings from one specific layer of pre-trained multi-BERT then we apply this mapping to transform the internal representations of multi-BERT while fine-tuning on training data.

A.2.2 Adversarial Method

In Adversarial Method, we add an additional transform layer to transform representations and a discrimination layer to discriminate between transformed representations from source language (training set) and target language (development set). And the GAN loss is applied in the total loss of fine-tuning.

A.2.3 Discussion

As table 7 shows, there are no improvements among above methods. Some linear mapping

Approach	EM	F1
MUSE(Lample et al., 2018)	33.03	49.48
DeMa(Zhou et al., 2019)	55.64	72.59
Vecmap(Artetxe et al., 2018)	14.05	24.83
GAN-layer 8	54.26	71.04
GAN-layer 11	60.47	76.14

methods even causes devastating effect on EM/F1 scores.

QUARTZ: An Open-Domain Dataset of Qualitative Relationship Questions

Oyvind Tafjord, Matt Gardner, Kevin Lin, Peter Clark
Allen Institute for Artificial Intelligence, Seattle, WA
{oyvindt,mattg,kevinl peterc}@allenai.org

Abstract

We introduce the first open-domain dataset, called QUARTZ, for reasoning about textual qualitative relationships. QUARTZ contains general qualitative statements, e.g., "A sunscreen with a higher SPF protects the skin longer.", twinned with 3864 crowdsourced situated questions, e.g., "Billy is wearing sunscreen with a lower SPF than Lucy. Who will be best protected from the sun?", plus annotations of the properties being compared. Unlike previous datasets, the general knowledge is textual and not tied to a fixed set of relationships, and tests a system's ability to comprehend and apply textual qualitative knowledge in a novel setting. We find state-of-the-art results are substantially (20%) below human performance, presenting an open challenge to the NLP community.

1 Introduction

Understanding and applying qualitative knowledge is a fundamental facet of intelligence. For example, we may read that exercise improves health, and thus decide to spend more time at the gym; or that larger cars cause more pollution, and thus decide to buy a smaller car to be environmentally sensitive. These skills require understanding the underlying qualitative relationships, and being able to apply them in specific contexts.

To promote research in this direction, we present the first *open-domain* dataset of qualitative relationship questions, called QUARTZ ("Qualitative Relationship Test set")[1]. Unlike earlier work in qualitative reasoning, e.g., (Tafjord et al., 2019), the dataset is not restricted to a small, fixed set of relationships. Each question Q_i (2-way multiple choice) is grounded in a particular situation, and is paired with a sentence K_i expressing the general qualitative knowledge needed to answer it.

[1] Available at http://data.allenai.org/quartz/

Q: If Mona lives in a city that begins producing a greater amount of pollutants, what happens to the air quality in that city? (A) increases (B) decreases **[correct]**

K: More pollutants mean poorer air quality.

Annotations:

Q: [**MORE**, "greater", "amount of pollutants"]
→ (A) [**MORE**, "increases", "air quality"]
(B) [**LESS**, "decreases", "air quality"]

K: [**MORE**, "more", "pollutants"]
↔ [**LESS**, "poorer", "air quality"]

Figure 1: QUARTZ contains situated qualitative questions, each paired with a gold background knowledge sentence and qualitative annotations.

Q_i and K_i are also annotated with the properties being compared (Figure 1). The property annotations serve as supervision for a potential semantic parsing based approach. The overall task is to answer the Q_i given the corpus $K = \{K_i\}$.

We test several state-of-the-art (BERT-based) models and find that they are still substantially (20%) below human performance. Our contributions are thus (1) the dataset, containing 3864 richly annotated questions plus a background corpus of 400 qualitative knowledge sentences; and (2) an analysis of the dataset, performance of BERT-based models, and a catalog of the challenges it poses, pointing the way towards solutions.

2 Related Work

Despite rapid progress in general question-answering (QA), e.g., (Clark and Gardner, 2018), and formal models for qualitative reasoning (QR), e.g., (Forbus, 1984; Weld and De Kleer, 2013), there has been little work on reasoning with *textual* qualitative knowledge, and no dataset available in this area. Although many datasets include a few qualitative questions, e.g., (Yang et al., 2018; Clark et al., 2018), the only one directly probing

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5941–5946, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Differing Comparatives:	
Q_1	Jan is comparing stars, specifically a small star and the larger Sun. Given the size of each, Jan can tell that the Sun puts out heat that is (A) greater (B) lesser
K_1	Bigger stars produce more energy, so their surfaces are hotter.
Discrete Property Values:	
Q_2	What happens to a light car when it has the same power as a heavy car? (A) accelerates faster (B) accelerates slower
K_2	The smaller its mass is, the greater its acceleration for a given amount of force.
Numerical Property Values:	
Q_3	Will found water from a source 10m from shore. Eric found water from a source 2m from shore. Whose water likely contains the least nutrients? (A) Will's (B) Eric's
K_3	Most nutrients are washed into ocean water from land. Therefore, water closer to shore tends to have more nutrients.
Commonsense Knowledge:	
Q_4	Compared to a box of bricks a box of feathers would be (A) lighter (B) heavier
K_4	A given volume of a denser substance is heavier than the same volume of a less dense substance.
Multiple Entities ("Worlds"):	
Q_5	Jimbo liked to work out, while James never did. Which person would have weaker muscles? (A) Jimbo (B) James
K_5	Muscles that are exercised are bigger and stronger than muscles that are not exercised.
Complex Stories:	
Q_6	NASA has sent an unmanned probe to survey a distant solar system with four planets. Planet Zorb is farthest from the sun of this solar system, Planet Krakatoa is second farthest, Planet Beanbag is third, and Krypton is the closest. The probe visits the planets in order, first Zorb, then Krakatoa, then Beanbag and finally Krypton. Did the probe have to fly farther in its trip from (A) Zorb to Krakatoa or (B) from Beanbag to Krypton?
K_6	In general, the farther away from the Sun, the greater the distance from one planets orbit to the next.

Table 1: Examples of crowdsourced questions Q and corpus knowledge K in QUARTZ, illustrating phenomena.

QR is QuaRel (Tafjord et al., 2019). However, although QuaRel contains 2700 qualitative questions, its underlying qualitative knowledge was specified formally, using a small, fixed ontology of 19 properties. As a result, systems trained on QuaRel are limited to only questions about those properties. Likewise, although the QR community has performed some work on extracting qualitative models from text, e.g., (McFate et al., 2014; McFate and Forbus, 2016), and interpreting questions about identifying qualitative processes, e.g., (Crouse et al., 2018), there is no dataset available for the NLP community to study textual qualitative reasoning. QUARTZ addresses this need.

3 The Task

Examples of QuaRTz questions Q_i are shown in Table 1, along with a sentence K_i expressing the relevant qualitative relationship. The QUARTZ task is to answer the questions given a small (400 sentence) corpus K of general qualitative relationship sentences. Questions are crowdsourced, and the sentences K_i were collected from a larger corpus, described shortly.

Note that the task involves substantially more than matching intensifiers (more/greater/...) between Q_i and K_i. Answers also require some qualitative reasoning, e.g., if the intensifiers are inverted in the question, and entity tracking, to keep track of which entity an intensifier applies to. For example, consider the qualitative sentence and three questions (correct answers bolded):

K_n: People with greater height are stronger.
Q_n: Sue is taller than Joe so Sue is (A) **stronger** (B) weaker
Q'_n: Sue is shorter than Joe so Sue is (A) stronger (B) **weaker**
Q''_n: Sue is shorter than Joe so Joe is (A) **stronger** (B) weaker

Q'_n requires reasoning about intensifers that are flipped with respect to K (shorter $\rightarrow$ weaker), and Q''_n requires entities be tracked correctly (asking about Sue or Joe changes the answer).

4 Dataset Collection

QUARTZ was constructed as follows. First, 400 sentences[2] expressing general qualitative relations were manually extracted by the authors from a large corpus using keyword search ("increase", "faster", etc.). Examples (K_i) are in Table 1.

Second, crowdworkers were shown a seed sentence K_i, and asked to annotate the two properties

[2] In a few cases, a short paragraph rather than sentence was selected, where surrounding context was needed to make sense of the qualitative statement.

being compared using the template below, illustrated using K_2 from Table 1:

"The smaller its mass is, the greater its acceleration for a given amount of force."

What is being compared?

Less ▾ mass More ▾ acceleration

They were then asked to author a situated, 2-way multiple-choice (MC) question that tested this relationship, guided by multiple illustrations. Examples of their questions (Q_i) are in Table 1.

Third, a second set of workers was shown an authored question, asked to validate its answer and quality, and asked to annotate how the properties of K_i identified earlier were expressed. To do this, they filled a second template, illustrated for Q_2:

	Appears in question as:	
Relation:	More/Less phrase:	Changed property:
MORE mass:	-	heavy
LESS mass:	-	light
MORE acceleration:	faster	accelerates
LESS acceleration:	slower	accelerates

Finally these workers were asked to generate a new question by "flipping" the original so the answer switched. Flipping means inverting comparatives (e.g., "more" → "less"), values, and other edits as needed to change the answer, e.g.,

K: *More rain causes damper surfaces.*

Q:*More rain causes (A) wetter land (B) drier land*

Q-flipped: **Less** *rain causes (A) wetter land (B) drier land*

Flipped questions are created to counteract the tendency of workers to use the same comparison direction (e.g., "more") in their question as in the seed sentence K_i, potentially answerable by simply matching Q_i and K_i. Flipped questions are more challenging as they demand more qualitative reasoning (Section 7.1).

Questions marked by workers as poor quality were reviewed by the authors and rejected/modified as appropriate. The dataset was then split into train/dev/test partitions such that questions from the same seed K_i were all in the same partition. Statistics are in Table 2.

To determine if the questions are correct and answerable given the general knowledge, a human baseline was computed. Three annotators independently answered a random sample of 100 questions given the supporting sentence K_i for each. The mean score was 95.0%.

# questions Q_i	3864
flip/no flip	1932/1932
positive/negative qualitative influence (QR+/QR-)	2772/1092
train/dev/test	2696/384/784
av Q_i length (sents) min/avg/max	1/1.5/6
av K_i length (sents) min/avg/max	1/1.1/4

Table 2: Statistics of QUARTZ.

5 Models

The QUARTZ task is to answer the questions given the corpus K of qualitative background knowledge. We also examine a "no knowledge" (questions only) task and a "perfect knowledge" task (each question paired with the qualitative sentence K_i it was based on). We report results using two baselines and several strong models built with BERT-large (Devlin et al., 2019) as follows:

1. **Random:** always 50% (2-way MC).
2. **BERT-Sci:** BERT fine-tuned on a large, general set of science questions (Clark et al., 2018).
3. **BERT (IR):** This model performs the full task. First, a sentence K_i is retrieved from K using Q_i as a search query. This is then supplied to BERT as *[CLS] K_i [SEP] question-stem [SEP] answer-option [SEP]* for each option. The [CLS] output token is projected to a single logit and fed through a softmax layer across answer options, using cross entropy loss, the highest being selected. This model is fine-tuned using QUARTZ (only).
4. **BERT (IR upper bound):** Same, but using the ideal (annotated) K_i rather than retrieved K_i.
5. **BERT-PFT (no knowledge):** BERT first fine-tuned ("pre-fine-tuned") on the RACE dataset (Lai et al., 2017; Sun et al., 2019), and then fine-tuned on QUARTZ (questions only, no K, both train and test). Questions are supplied as *[CLS] question-stem [SEP] answer-option [SEP]*.
6. **BERT-PFT (IR):** Same as BERT (IR), except starting with the pre-fine-tuned BERT.

All models were implemented using AllenNLP (Gardner et al., 2018).

6 Results

The results are shown in Table 3, and provide insights into both the data and the models:

1. **The dataset is hard.** Our best model, BERT-PFT (IR), scores only 73.7, over 20 points behind human performance (95.0), suggesting there are significant linguistic and semantic challenges to overcome (Section 7).

Questions→ Model ↓	All Test	No-flip only	Flip only
Baselines:			
Random	50.0	50.0	50.0
BERT-Sci	54.6	76.0	33.2
Models:			
BERT (IR)	64.4	66.3	62.5
(BERT IR upper bound)	(67.7)	(68.1)	(67.3)
BERT-PFT (no knowledge)	68.8	70.4	67.1
BERT-PFT (IR)	**73.7**	77.3	70.2
(BERT-PFT IR upper bound)	(79.8)	(82.1)	(77.6)
Human	95.0		

Table 3: Performance of various models on QUARTZ.

2. **A general science-trained QA system has not learned this style of reasoning.** BERT-Sci only scores 54.6, just a little above random (50.0).

3. **Pre-Fine-Tuning is important.** Fine-tuning only on QUARTZ does signficantly worse (64.4) than pre-fine-tuning on RACE before fine-tuning on QUARTZ (73.7). Pre-fine-tuning appears to teach BERT something about multiple choice questions in general, helping it more effectively fine-tune on QUARTZ.

4. **BERT already "knows" some qualitative knowledge.** Interestingly, BERT-PFT (no knowledge) scores 68.8, significantly above random, suggesting that BERT already "knows" some kind of qualitative knowledge. To rule out annotation artifacts, we we experimented with balancing the distributions of positive and negative influences, and different train/test splits to ensure no topical overlap between train and test, but the scores remained consistent.

5. **BERT can apply general qualitative knowledge to QA, but only partially.** The model for the full task, BERT-PFT (IR) outperforms the no knowledge version (73.7, vs. 68.8), but still over 20 points below human performance. Even given the ideal knowledge (IR upper bound), it is still substantially behind (at 79.8) human performance. This suggests more sophisticated ways of training and/or reasoning with the knowledge are needed.

7 Discussion and Analysis

7.1 Qualitative Reasoning

Can models learn qualitative reasoning from QUARTZ? While QUARTZ questions do not require chaining, 50% involve "flipping" a qualitative relationship (e.g., K: "more X → more Y", Q: "Does less X → less Y?"). Training on just the original crowdworkers' questions, where they chose to flip the knowledge only 10% of the time, resulted in poor (less than random) performance on all the flipped questions. However, training on full QUARTZ, where no-flip and flip were balanced, resulted in similar score for both types of question, suggesting that such a reasoning capability can indeed be learned.

Comparatives:
"warmer" ↔ "increase temperature"
"more difficult" ↔ "slower"
"need more time" ↔ "have lesser amount"
"decreased distance" ↔ "hugged"
"cost increases" ↔ "more costly"
"increase mass" ↔ "add extra"
"more tightly packed" ↔ "add more"
Commonsense Knowledge:
"more land development" ↔ "city grow larger"
"not moving" ↔ "sits on the sidelines"
"caught early" ↔ 'sooner treated"
"lets more light in" ↔ "get a better picture"
"stronger electrostatic force" ↔ "hairs stand up more"
"less air pressure" ↔ "more difficult to breathe"
"more photosynthesis" ↔ "increase sunlight"
Discrete Values:
"stronger acid" ↔ "vinegar" vs. "tap water"
"more energy" ↔ "ripple" vs. "tidal wave"
"closer to Earth" ↔ "ball on Earth" vs. "ball in space"
"mass" ↔ "baseball" vs. "basketball"
"rougher" ↔ "notebook paper" vs. "sandpaper"
"heavier" ↔ "small wagon" vs. "eighteen wheeler"

Table 4: Examples of linguistic and semantic gaps between knowledge K_i (left) and question Q_i (right). A system needs to bridge such gaps for high performance.

7.2 Linguistic Phenomena

From a detailed analysis of 100 randomly sampled questions, the large majority (86%) involved the (overlapping) linguistic and semantic phenomena below, and illustrated in Tables 1 and 4:

1. **Differing comparative expressions** (≈68%) between K_i and Q_i occur in the majority of questions, e.g.,
   "increased altitude" ↔ "higher"
2. **Indirection and Commonsense knowledge** (≈35%) is needed for about 1/3 of the questions to relate K and Q, e.g.,
   "higher temperatures" ↔ "A/C unit broken"
3. **Multiple Worlds** (≈26%): 1/4 of the questions explicitly mention *both* situations being compared, e.g., Q_1 in Table 1. Such questions are known to be difficult because models can easily confuse the two situations (Tafjord et al., 2019).
4. **Numerical property values** (≈11%) require numeric comparison to identify the qualitative relationship, e.g., that "60 years" is older than "30 years".

5. **Discrete property values** (≈7%), often require commonsense to compare, e.g., that a "melon" is larger than an "orange".
6. **Stories** (≈15%): 15% of the questions are 3 or more sentences long, making comprehension more challenging.

This analysis illustrates the richness of linguistic and semantic phenomena in QUARTZ.

7.3 Use of the Annotations

QUARTZ includes a rich set of annotations on all the knowledge sentences and questions, marking the properties being compared, and the linguistic and semantic comparatives employed (Figure 1). This provides a laboratory for exploring semantic parsing approaches, e.g., (Berant et al., 2013; Krishnamurthy et al., 2017), where the underlying qualitative comparisons are extracted and can be reasoned about.

8 Conclusion

Understanding and applying textual qualitative knowledge is an important skill for question-answering, but has received limited attention, in part due the lack of a broad-coverage dataset to study the task. QUARTZ aims to fill this gap by providing the first *open-domain* dataset of qualitative relationship questions, along with the requisite qualitative knowledge and a rich set of annotations. Specifically, QuaRTz removes the requirement, present in all previous qualitative reasoning work, that a fixed set of qualitative relationships be formally pre-specified. Instead, QuaRTz tests the ability of a system to find and apply an arbitrary relationship on the fly to answer a question, including when simple reasoning (arguments, polarities) is required.

As the QUARTZ task involves using a general corpus K of textual qualitative knowledge, a high-performing system would be close to a fully general system where K was much larger (e.g., the Web or a filtered subset), encompassing many more qualitative relationships, and able to answer arbitrary questions of this kind. Scaling further would thus require more sophisticated retrieval over a larger corpus, and (sometimes) chaining across influences, when a direct connection was not described in the corpus. QUARTZ thus provides a dataset towards this end, allowing controlled experiments while still covering a substantial number of textual relations in an open setting. QuaRTz is available at http://data.allenai.org/quartz/.

Abstract

Reading comprehension models have been successfully applied to extractive text answers, but it is unclear how best to generalize these models to abstractive numerical answers. We enable a BERT-based reading comprehension model to perform lightweight numerical reasoning. We augment the model with a predefined set of executable 'programs' which encompass simple arithmetic as well as extraction. Rather than having to learn to manipulate numbers directly, the model can pick a program and execute it. On the recent Discrete Reasoning Over Passages (DROP) dataset, designed to challenge reading comprehension models, we show a 33% absolute improvement by adding shallow programs. The model can learn to predict new operations when appropriate in a math word problem setting (Roy and Roth, 2015) with very few training examples.

1 Introduction

End-to-end reading comprehension models have been increasingly successful at extractive question answering. For example, performance on the SQuAD 2.0 (Rajpurkar et al., 2018) benchmark has improved from 66.3 F1 to 89.5[1] in a single year. However, the Discrete Reasoning Over Passages (DROP) (Dua et al., 2019) dataset demonstrates that as long as there is quantitative reasoning involved, there are plenty of relatively straightforward questions that current extractive QA systems find difficult to answer. Other recent work has shown that even state-of-the-art neural models struggle with numerical operations and quantitative reasoning when trained in an end-to-end manner (Saxton et al., 2019; Ravichander et al., 2019). In other words, even BERT (Devlin et al., 2019) is not very good at doing simple calculations.

[1] https://rajpurkar.github.io/SQuAD-explorer/

How many more Chinese nationals are there than European nationals?
The city of Bangkok has a population of 8,280,925 ...the census showed that it is home to 81,570 Japanese and **55,893** Chinese nationals, as well as 117,071 expatriates from other Asian countries, **48,341** from Europe, 23,418 from the Americas,...
NAQANet: −55893 **Ours**: `Diff`(55893, 48341) = **7552**

Table 1: Example from the DROP development set. The correct answer is not explicitly stated in the passage and instead must be computed. The NAQANet model[2](Dua et al., 2019) predicts a negative number of people, whereas our model predicts that an operation `Diff` should be taken and identifies the two arguments.

In this work, we extend an extractive QA system with numerical reasoning abilities. We do so by asking the neural network to synthesize small programs that can be executed. The model picks among simple programs of the form `Operation`(args, ...), where the possible operations include span extraction, answering yes or no, and arithmetic. For math operations, the arguments are pointers to numbers in the text and, in the case of composition, other operations. In this way, the burden of actually doing the computation is offloaded from the neural network to a calculator tool. The program additionally provides a thin layer of interpretability that mirrors some of the reasoning required for the answer. For example, in Table 1, the model predicts subtraction (`Diff`) over two numbers in the passage, and executes it to produce the final answer.

We start with a simple extractive question answering model based on BERT (Devlin et al., 2019), and show the following:

1. Predicting unary and binary math operations

[2] https://demo.allennlp.org/reading-comprehension/NzQwNjg1

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5947–5952, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

with arguments resulted in significant improvements on the DROP dataset.

2. Our model can smoothly handle more traditional reading comprehension inputs as well as math problems with new operations. Co-training with the CoQA (Reddy et al., 2018) dataset improved performance on DROP. The DROP+CoQA trained model had never seen multiplication or division examples, but can learn to predict these two ops when appropriate in a math word problem setting (Roy and Roth, 2015) with very few training examples.

2 Background and Related Work

Discrete Reasoning over Paragraphs (DROP) (Dua et al., 2019) is a reading comprehension task that requires discrete reasoning. Inspired by semantic parsing tasks where models need to produce executable 'programs', it keeps the open-domain nature of reading comprehension tasks such as SQuAD 2.0 (Rajpurkar et al., 2018). As shown in Table 1, the system needs to perform fuzzy matching between *"from Europe"* and *"European nationals"* in order to identify the arguments.

Numerically-aware QANet (NAQANet) (Dua et al., 2019) is the current state-of-the-art[3] system for DROP. It extends the QANet model (Yu et al., 2018) with predictions for numbers (0–9) and summation operations. For the latter, it performs a 3-way classification (plus, minus, and zero) on all the numbers in the passage.

While certain binary operations are expressible efficiently with flat sign prediction, it is difficult to generalize the architecture. Moreover, each number is tagged independently, which can cause global inconsistencies; for instance, in Table 1 it assigns a single minus label and no plus labels, leading to a prediction of negative people.

Mathematical Word Problems have been addressed with a wide variety of datasets and approaches; see Zhang et al. (2018) for an overview. One such dataset of arithmetic problems is the Illinois dataset (Roy and Roth, 2015). The problems are posed in simple natural language that has a specific, narrow domain, For example: *"If there are 7 bottle caps in a box and Linda puts 7 more bottle caps inside, how many bottle caps are in the box?"*. Unlike DROP, the problems are typically 1–3 sentences long and do not require reading complex passages. Instead, the main challenge is mathematical reasoning. According to Zhang et al. (2018), the current state of the art uses syntactic parses and deterministic rules to convert the input to logical forms (Liang et al., 2016).

3 Model

We extend a BERT-based extractive reading comprehension model with a lightweight extraction and composition layer. For details of the BERT architecture see Devlin et al. (2019). We only rely on the representation of individual tokens that are jointly conditioned on the given question Q and passage P. Our model predicts an answer by selecting the top-scoring *derivation* (i.e. program) and executing it.

Derivations We define the space of possible derivations $\mathcal{D}$ as follows:

- *Literals*: $\{\text{YES}, \text{NO}, \text{UNKNOWN}, 0, \ldots 9\}$.
- *Numerical operations*: including various types of numerical compositions of numbers[4], such as `Sum` or `Diff`.
- *Text spans*: composition of tokens into text spans up to a pre-specified length.
- *Composition of compositions*: we only consider two-step compositions, including merging text spans and nested summations.

The full set of operations are listed in Table 2. For example, `Sum` is a numerical operation that adds two numbers and produces a new number. While we could recursively search for compositions with deep derivations, here we are guided by what is required in the DROP data and simplify inference by heavily restricting multi-step composition. Specifically, spans can be composed into a pair of merged spans (`Merge`), and the sum of two numbers (`Sum`) can subsequently be summed with a third (`Sum3`). The results in Table 3 show the dev set oracle performance using these shallow derivations, by answer type.

Representation and Scoring For each derivation $d \in \mathcal{D}$, we compute a vector representation $\mathbf{h}_d$ and a scalar score $\rho(d, P, Q)$ using the BERT output vectors. The scores ρ are used for computing the probability $P(d \mid P, Q)$ as well as for pruning. For brevity, we will drop the dependence on P and Q in this section.

[3] https://leaderboard.allenai.org/drop/submissions/public

[4] Numbers are heuristically extracted from the text.

	Derivations	Example Question	Answer Derivation
Literals	YES, NO, UNKNOWN, 0, 1 ..., 9	How many field goals did Stover kick?	4
Numerical	`Diff100` : $n_0 \rightarrow 100 - n_1$	How many percent of the national population does not live in Bangkok?	$100 - 12.6 = 87.4$
	`Sum` : $n_0, n_1 \rightarrow n_0 + n_1$ as well as: `Diff`, `Mul`, `Div`	How many from the census were in Ungheni and Cahul?	$32,828 + 28,763 = 61591$
Text spans	`Span` : $i, j \rightarrow s$	Does Bangkok have more Japanese or Chinese nationals?	"Japanese"
Compositions	`Merge` : $s_0, s_1 \rightarrow \{s_0, s_1\}$	What languages are spoken by more than 1%, but fewer than 2% of Richmond's residents?	"Hmong-Mien languages", "Laotian"
	`Sum3` : $n_0, n_1, n_2 \rightarrow (n_0 + n_1) + n_2$	How many residents, in terms of percentage, speak either English, Spanish, or Tagalog?	$\texttt{Sum}(64.56, 23.13) + 2.11 = 89.8$

Table 2: Operations supported by the model. s, n refer to arguments of type *span* and *number*, respectively. i, j are the start and end indices of span s. The omitted definitions of `Diff`, `Mul`, and `Div` are analogous to `Sum`.

Literals are scored as $\rho(d) = \mathbf{w}_d^\intercal \text{MLP}_{\text{lit}}(\mathbf{h}_{\texttt{CLS}})$, where $\mathbf{h}_{\texttt{CLS}}$ is the output vector at the `[CLS]` token of the BERT model (Devlin et al., 2019).

Numeric operations use the vector representations $\mathbf{h}_i$ of the first token of each numeric argument. Binary operations are represented as

$$\mathbf{h}_d = \text{MLP}_{\text{binary}}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_i \circ \mathbf{h}_j) \quad (1)$$

and scored as $\rho(d) = \mathbf{w}_{op}^\intercal \mathbf{h}_d$, where $\mathbf{h}_d$ represents the binary arguments and *op* is the operation type. $\circ$ is the Hadamard product. Unary operations such as `Diff100` are scored as $\mathbf{w}_{op}^\intercal \text{MLP}_{\text{unary}}(\mathbf{h}_i)$.

Text spans are scored as if they were another binary operation taking as arguments the start and end indices i and j of the span (Lee et al., 2017):

$$\mathbf{h}_d = \text{MLP}_{\text{span}}(\mathbf{h}_i, \mathbf{h}_j) \quad (2)$$

and scored as $\rho(d) = \mathbf{w}_{\text{span}}^\intercal \mathbf{h}_d$.

Compositions of compositions are scored with the vector representations of its children. For example, the ternary `Sum3`, comprising a `Sum` and a number, is scored with $\mathbf{w}_{\texttt{Sum3}}^\intercal \text{MLP}_{\texttt{Sum3}}(\mathbf{h}_{d0}, \mathbf{h}_k)$, where $\mathbf{h}_{d0}$ corresponds to the representation from the first `Sum`, and $\mathbf{h}_k$ is the representation of the third number. The *composition* of two spans is scored as $\mathbf{w}_{\texttt{Merge}}^\intercal \text{MLP}_{\texttt{Merge}}(\mathbf{h}_{d0}, \mathbf{h}_{d1}, \mathbf{h}_{d0} \circ \mathbf{h}_{d1})$, where $\mathbf{h}_{d0}$ and $\mathbf{h}_{d1}$ are span representations from (2). The intuition for including $\mathbf{h}_{d0} \circ \mathbf{h}_{d1}$ is that it encodes span similarity, and spans with similar types are more likely to be merged.

This strategy differs from the NAQANet baseline in a few ways. One straightforward difference is that we use BERT as the base encoder rather than QANet. A more meaningful difference is that we model all derivations in the unified op scoring framework described above, which allows generalizing to new operations, whereas NAQANet would require more large-scale changes to go beyond addition and subtraction. Generalizing the model to new ops is a case of extending the derivations and scoring functions. In Section 4, we will show the impact of incrementally adding `Diff100`, `Sum3`, and `Merge`.

3.1 Training

We used exhaustive pre-computed oracle derivations $\mathcal{D}^*$ following Dua et al. (2019). We marginalized out all derivations d^* that lead to the answer[5] and minimized:

$$\mathcal{J}(P, Q, \mathcal{D}^*) = -\log \sum_{d^* \in \mathcal{D}^*} P(d^* \mid P, Q)$$

$$P(d \mid P, Q) = \frac{\exp \rho(d, P, Q)}{\sum_{d'} \exp \rho(d', P, Q)}$$

If no derivation lead to the gold answer ($\mathcal{D}^*$ is empty), we skipped the example.

Pruning During inference, the `Merge` and `Sum3` operations are composed from the results of `Span` and `Sum` operations, respectively. The space of possible results of `Merge` is quadratic in the number $|\mathcal{S}|$ of possible spans. With $|\mathcal{S}| \sim 10^4$, the complete set of `Merge` instances becomes overwhelming. Similarly, with $|\mathcal{N}| \sim 100$ numbers in each passage, there are millions of possible `Sum3` derivations. To do training and inference efficiently, we kept only the top 128 `Span` and `Sum` results when computing `Merge` and `Sum3`.[6]

[5] In practice we capped the number of derivations at 64, which covers 98.7% of the training examples.

[6] During training, the pruned arguments had recall of 80–90% after 1 epoch and plateaued at 95–98%.

	Oracle	Overall Dev		Overall Test		Date (1.6%)		Number (62%)		Span (32%)		Spans (4.4%)

Table 3: Accuracies on the DROP dev and test set in terms of exact match (EM) and token-level F1. The right-hand columns show the performance breakdown with different answer types on the development set. The largest improvements come from *Date*, *Number*, and *Spans* (answers with multiple spans). *Oracle* rows and columns indicate the performance that could be achieved by perfect selections of derivations. The ensemble used 6 models.

Spurious ambiguities Of the answers for which we could find at least one oracle derivation, 36% had two or more alternatives. During training, the model became effective at resolving many of these ambiguities. We monitored the entropy of $P(d^* \mid P, Q)$ for the ambiguous examples as training progressed. At the start, the entropy was 2.5 bits, which matches the average ambiguous oracle length of $\sim$ 6 alternatives. By the end of 4 epochs, the average entropy had dropped to < 0.2 bits, comparable to a typical certainty of 95–99% that one of the derivations is the correct one.

4 Experiments

Our main experiments pertain to DROP (Dua et al., 2019), using DROP and, optionally, CoQA (Reddy et al., 2018) data for training. Preprocessing and hyperparameter details are given in the supplementary material. In addition to full DROP results, we performed ablation experiments for the incremental addition of the `Diff100`, `Sum3`, and `Merge` operations, and finally the CoQA training data. We ran on the CoQA dev set, to show that the model co-trained on CoQA can still perform traditional reading comprehension. To investigate our model's ability to do symbolic reasoning at the other extreme, we performed few-shot learning experiments on the Illinois dataset of math problems (Roy and Roth, 2015).

4.1 DROP Results

As shown in Table 3, our model achieves over 50% relative improvement (over 33% absolute) over the previous state-of-the-art NAQANet system. The ablations indicate that the improvements due to the addition of extra ops (`Diff100`, `Sum3`, `Merge`) are roughly consistent with their proportion in the data. Specifically, the `Diff100` and `Sum3` derivations increase the oracle performance by 8.7% and 1.4% respectively, corresponding to model improvements of roughly 9% and 1.1%, respectively. Answers requiring two spans occur about 2.8% of the time, which is a 60.4% proportion of the *Spans* answer type. `Merge` only improves the *Spans* answer type by 9%, which we think is due to the significant 11:1 class imbalance between competing single and multiple spans. As a result, multiple spans are under-predicted, leaving considerable headroom there.

Pre-training on CoQA then fine-tuning on DROP lead to our best results on DROP, reported in Table 3. After fine-tuning on DROP, the model forgot how to do CoQA, with an overall F1 score of 52.2 on the CoQA dev set. If one prefers a model competent in both types of input, then the forgetting can be prevented by fine-tuning on both CoQA and DROP datasets simultaneously. This resulted in dev set F1 scores of 82.2 on CoQA and 81.1 on DROP. The CoQA performance is decent and compares well with the pre-trained model performance of 82.5. The 0.5% drop in DROP performance is likely attributable to the difference between pre-training versus fine-tuning on CoQA.

We ensembled 6 models (3 seeds $\times$ 2 learning rates) for an additional 1% improvement.

4.2 Results on Math Word Problems

We trained our model on the Illinois math word problems dataset (Roy and Roth, 2015), which contains answers requiring multiplication and

[7] The "basic" model includes all $\mathcal{D}_{\text{direct}}$, all $\mathcal{S}$, and the simple binary operations `Sum` and `Diff`.

Roy et al. (2015)	73.9
Liang et al. (2016)	**80.1**
Wang et al. (2018)	73.3
Our basic: IL data	48.6 ± 5.3
+ `Mul` and `Div`	74.0 ± 6.0
+ DROP data	$\mathbf{83.2 \pm 6.0}$

Table 4: Accuracy on the Illinois (IL) dataset[8] of 562 single-step word problems, using the five cross-validation folds of Roy and Roth (2015). Standard deviations were computed from the five folds. Roughly half the questions require the use of `Sum` and `Diff`, and half require `Mul` and `Div`.

division—operations not present in DROP—as well as addition and subtraction, in roughly equal proportion. Given the small ($N = 562$) dataset size, training and evaluation is done with five-fold cross-validation on a standardized set of splits. As shown in Table 4, when we added `Mul` and `Div` to our basic DROP operations, the model was able to learn to use them. Transferring from the DROP dataset further improved performance beyond that of Liang et al. (2016), a model specific to math word problems that uses rules over dependency trees. Compared to other more general systems, our model outperforms the deep reinforcement learning based approach of Wang et al. (2018).

5 Conclusions and Future Work

We proposed using BERT for reading comprehension combined with lightweight neural modules for computation in order to smoothly handle both traditional factoid question answering and questions requiring symbolic reasoning in a single unified model. On the DROP dataset, which includes a mix of reading comprehension and numerical reasoning, our model achieves a 33% absolute improvement over the previous best. The same model can also do standard reading comprehension on CoQA, and focused numerical reasoning on math word problems. We plan to generalize this model to more complex and compositional answers, with better searching and pruning strategies of the derivations.

Abstract

Answer selection is an important research problem, with applications in many areas. Previous deep learning based approaches for the task mainly adopt the Compare-Aggregate architecture that performs word-level comparison followed by aggregation. In this work, we take a departure from the popular Compare-Aggregate architecture, and instead, propose a new gated self-attention memory network for the task. Combined with a simple transfer learning technique from a large-scale online corpus, our model outperforms previous methods by a large margin, achieving new state-of-the-art results on two standard answer selection datasets: TrecQA and WikiQA.

1 Introduction and Related Work

Answer selection is an important task, with applications in many areas (Lai et al., 2018). Given a question and a set of candidate answers, the task is to identify the most relevant candidate. Previous work on answer selection typically relies on feature engineering, linguistic tools, or external resources (Wang et al., 2007; Wang and Manning, 2010; Heilman and Smith, 2010; Yih et al., 2013; Yao et al., 2013). Recently, with the renaissance of neural network models, many deep learning based methods have been proposed to address the task (Tay et al., 2017b; Shen et al., 2017; Wang et al., 2017; Bian et al., 2017; Tymoshenko and Moschitti, 2018; Tay et al., 2018; Tayyar Madabushi et al., 2018; Yoon et al., 2019). They outperform traditional techniques. A common trait of a number of these deep learning methods is the use of the Compare-Aggregate architecture (Wang and Jiang, 2017). Typically in this architecture, contextualized vector representations of small units such as words of the question and the candidate are first *compared and aligned*. After that, these comparison results are then *aggregated* to calculate a score indicating the relevance between the question and the candidate. On standard answer selection datasets such as TrecQA (Wang et al., 2007) or WikiQA (Yang et al., 2015), Compare-Aggregate approaches achieve very competitive performance. However, they still have some limitations. For example, the first few layers of most previous Compare-Aggregate models encode the question-candidate pair into sequences of contextualized vector representations separately (Wang et al., 2017; Shen et al., 2017; Bian et al., 2017). These sequences are independent and completely ignore the information from the other sequence.

In this work, we take a departure from the popular Compare-Aggregate architecture, so instead, we propose a mix between two very successful architectures in machine comprehension and sequence modeling, the memory network (Sukhbaatar et al., 2015) and the self-attention architecture (Vaswani et al., 2017). In the context of answer selection, the self-attention architecture allows us to learn the contextual representation of elements in the sequence with respect to both the question and the answer, while the multi-hop reasoning memory network allows us to refine the decision over multiple steps. To this end, we propose a new memory-based, gated self-attention architecture for the task of answer selection. Combined with a simple transfer learning technique from a large-scale online corpus, our model achieves new state-of-the-art results on the TrecQA and WikiQA datasets.

In the following parts, we first describe our gated self-attention memory network for answer selection in Section 2. We then go into details our transfer learning approach in Section 3. After that, we describe the conducted experiments and their results in Section 4. Finally, we conclude this

work in Section 5.

2 Gated Self-Attention Memory Network

2.1 The gated self-attention mechanism

The gated attention mechanism (Dhingra et al., 2017; Tran et al., 2017) extends the popular scalar-based attention mechanism by calculating a real vector gate to control the flow of information, instead of a scalar value. Let's denote the sequence of input vectors as $X = [\mathbf{x}_1..\mathbf{x}_n]$. If we have context information $\mathbf{c}$, then in traditional attention mechanism, association score α_i is usually calculated as a normalized dot product between the two vectors $\mathbf{c}$ and $\mathbf{x}_i$ (Equation 1) where $i \in [1..n]$.

$$\alpha_i = \frac{\exp(\mathbf{c}^T \mathbf{x}_i)}{\sum_{j \in [1..n]} \exp(\mathbf{c}^T \mathbf{x}_j)} \tag{1}$$

For the gated attention mechanism, the association between two vectors $\mathbf{c}$ and $\mathbf{x}_i$ is represented by gate vector $\mathbf{g}_i$ as follows:

$$\mathbf{g}_i = \sigma\big(f(\mathbf{c}, \mathbf{x}_i)\big) \tag{2}$$

where σ denotes the element-wise sigmoid function. Function f is a parameterized function and thus, is more flexible in modelling the interaction between vectors $\mathbf{c}$ and $\mathbf{x}_i$.

In this work, we propose a new type of self-attention based on the gated attention mechanism described above, and we refer to it as the *gated self-attention* mechanism (GSAM). We want to condition the gate vector not only on a context vector and a single input vector but also on the entire sequence of inputs. Therefore, we design function f to be dependent on all the inputs in the sequence and the context vector. To calculate the gate for input $\mathbf{x}_i$, first, each of the inputs in the input sequence and the context vector will present an individual gate "vote". Then, the votes are aggregated to calculate gate $\mathbf{g}_i$ for $\mathbf{x}_i$. This process is illustrated in Equation 3:

$$\begin{aligned}
\mathbf{v}^j &= \mathbf{W}\mathbf{x}_j + \mathbf{b} \;;\; \mathbf{v}^c = \mathbf{W}\mathbf{c} + \mathbf{b} \\
s_i^j &= \mathbf{x}_i^T \mathbf{v}^j \;;\; s_i^c = \mathbf{x}_i^T \mathbf{v}^c \\
\alpha_i^j &= \frac{\exp(s_i^j)}{\sum_{k \in [1..n]} \exp(s_i^k) + \exp(s_i^c)} \\
\alpha_i^c &= \frac{\exp(s_i^c)}{\sum_{k \in [1..n]} \exp(s_i^k) + \exp(s_i^c)} \\
\mathbf{g}_i &= f_i(c, X) \\
&= \sigma\left(\sum_j \left(\alpha_i^j \, \mathbf{x}^j \right) + \alpha_i^c \, \mathbf{c} \right)
\end{aligned} \tag{3}$$

where $\mathbf{W}$ and $\mathbf{b}$ are learnable parameters shared among functions $f_1 ... f_n$. Vectors $\mathbf{v}$s are linear-transformed inputs which are used to calculate the self attentions. s_i^j is the unnormalized attention score of input $\mathbf{x}_j$ put on $\mathbf{x}_i$ and α_i^j is the normalized score. We use affine-transformed inputs $\mathbf{v}$ and $\mathbf{x}$ to calculate the self-attention instead of just $\mathbf{x}$ to break the attention symmetry phenomenon.

2.2 Combining with the memory network

In most previous memory network architectures, interactions between memory cells are relatively limited. At each hop, a single control vector is used to interpret each memory cell independently. To overcome this limitation, we combine GSAM described in Section 2.1 with the memory network architecture to create a new network called the Self-Attention Memory Network (GSAMN). Figure 1 shows the simplified computation flow of GSAMN. In each reasoning hop, instead of using only context vector $\mathbf{c}$ to interpret the inputs, we use GSAM. Let $\mathbf{c}_k$ be the controlling context and $\mathbf{x}_1^k ... \mathbf{x}_n^k$ be the memory values at the k^{th} reasoning hop. Each memory cell update from the k^{th} hop to the next hop is calculated as the gated self-attention update (Equation 4).

$$\begin{aligned}
\mathbf{g}_i &= f_i(\mathbf{c}_k, X) \\
\mathbf{x}_i^{k+1} &= \mathbf{g}_i \odot \mathbf{x}_i^k
\end{aligned} \tag{4}$$

The controller's update is a combination of the gated self-attention above, and the memory network's traditional aggregate update. As the memory state values have already been attended to by the gating mechanism, we only need to average them (not weighted average).

$$\begin{aligned}
\mathbf{g}_c &= f_c(\mathbf{c}_k, X) \\
\mathbf{c}_{k+1} &= \mathbf{g}_c \odot \mathbf{c}_k + \frac{1}{n} \sum_i \mathbf{x}_i^{k+1}
\end{aligned} \tag{5}$$

.

2.3 GSAMN for answer selection

In the context of answer selection, we concatenate question Q and candidate answer A to a single sequence and treat the task as a binary classification problem. Given the GSAMN architecture above, we can use final controller state $\mathbf{c}_T$ as the representation of the sequence. The matching probability $P(A \mid Q)$ is finally calculated as follows:

$$P(A \mid Q) = \sigma\Big(\mathbf{W}_c \, \mathbf{c}_T + \mathbf{b}_c \Big) \tag{6}$$

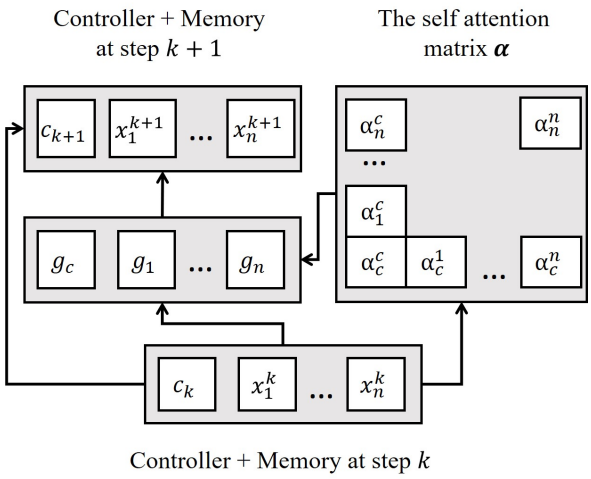

Figure 1: Simplified computation flow of the Gated Self-Attention Memory Network

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are learnable parameters. We can initialize the memory values $\mathbf{x}_1^0 \ldots \mathbf{x}_n^0$ using any representation model such as word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), ELMo (Peters et al., 2018), or BERT (Devlin et al., 2018). The control vector $\mathbf{c}$ is a randomly initialized learnable vector.

3 Transfer Learning

Previous studies on answer selection have focused mostly on small-scale datasets. On the other hand, many community question answering (CQA) platforms such as Yahoo Answers and Stack Exchange have become an essential source of information for many people. The amount of data (i.e., questions and answers) in these CQA platforms is huge and encompasses many domains and topics. This provides a great opportunity to apply transfer learning techniques to improve answer selection systems trained on limited datasets.

We crawled question-answer pairs related to various topics from Stack Exchange [1]. After that, we removed every pair that contains text written in a language different from English. Furthermore, to ensure that in each collected pair the answer is highly relevant to the question, we removed pairs whose answers have less than two up-votes from community users. Finally, because training answer selection models also require negative examples, for each question, we sampled several real answers not related to the question to build up negative pairs. In the end, our dataset has 628,706 positive pairs and 9,874,758 negative pairs in total. We refer to our newly collected dataset as StackExchangeQA. Table 1 shows some examples of positive question-answer pairs from the dataset. The dataset has question-answer pairs from many different domains and topics. The code for constructing the StackExchangeQA dataset is available online [2].

In this work, we employ a basic transfer learning technique. The first step is to pre-train our answer selection model on the StackExchangeQA dataset. Then, the second step is to fine-tune the same model on a target dataset of interest such as TrecQA or WikiQA. Despite the simplicity of the technique, the performance of our model improves substantially compared to not using transfer learning. Different from previous works which use source datasets that were manually annotated (Min et al., 2017; Chung et al., 2018), our source dataset required minimal effort to obtain and preprocess. The choice of crawling question-answer pairs from the Stack Exchange website was arbitrary. We could also have crawled data from websites such as Yahoo Answers instead.

4 Experiments and Results

To evaluate the effectiveness of our proposed answer selection model, we use two datasets: TrecQA and WikiQA. The TrecQA dataset (Wang et al., 2007) was created from the TREC Question Answering tracks. There are two versions of TrecQA: raw and clean. Both versions have the same training set but their development and test sets differ. In this study, we use the clean version of the dataset that removed questions in development and test sets with no answers or only positive/negative answers. The clean version has 1,229/65/68 questions and 53,417/1,117/1,442 question-answer pairs for the train/dev/test split. The WikiQA dataset (Yang et al., 2015) was constructed from real queries of Bing and Wikipedia. Following the literature (Yang et al., 2015; Bian et al., 2017; Shen et al., 2017), we removed all questions with no correct answers before training and evaluating answer selection models. The excluded WikiQA has 873/126/243 questions and 8,627/1,130/2,351 question-answer pairs for train/dev/test split.

Similar to previous work, we report the model

Domain	QA Pair
Academia	**Question**: Is it okay for a PhD student to go on holidays in breaks? **Answer**: Do you have an adviser? Have you talked to them about this? Most should be fine with you taking some time off to visit your family, but you should probably discuss longer breaks with them to work out all the details.
Apple Product	**Question**: What hidden features have you found in iOS 6? **Answer**: Newly downloaded apps have a "new" label on the home screen.
Chemistry	**Question**: Hydrochloric acid vs hydrogen chloride? **Answer**: Hydrochloric acid is an aqueous solution of hydrogen chloride.
Cooking	**Question**: How do I prevent tomatoes from falling in a green salad? **Answer**: I work around this by serving tomatoes on the top of the individual salads after they've been portioned out. I'm not sure of a way to keep them incorporated.
Philosophy	**Question**: What did Socrates teach which lead to his conviction that he spoiled youth and taught other Gods? **Answer**: I think in general one of the problems Socrates' contemporaries may have had with him was not so much what he taught but how he taught. Perhaps Socrates' method of philosophy was characterised more by testing propositions through questioning, than any strict concern with formulating a set of propositions on any one subject.

Table 1: Examples of positive question-answer pairs from the StackExchangeQA dataset

performance as the mean average precision (MAP) and mean reciprocal rank (MRR) [3]. In all experiments, we use the base version of BERT (Devlin et al., 2018) to initialize the memory of our proposed architecture. We fine-tune the BERT embeddings during training. We set the number of reasoning hops to be 2. We use the Adam optimizer with a learning rate of 5e-5, $\beta_1 = 0.9$, $\beta_2 = 0.999$, L2 weight decay of 0.01, learning rate warmup over the first 10 percent of the total number of training steps, and linear decay of the learning rate. We did hyper-parameter tuning on the development sets.

It is worth noting that, we have experimented with various values for the number of reasoning hops. We found that using 2 hops gives the best performance on the tested datasets while using larger number of hops decreases the performance slightly. We attribute the diminishing returns in increasing the number of hops to the limited size of the TrecQA and WikiQA datasets. Many previous works related to memory networks also use small number of memory hops (Weston et al., 2015; Sukhbaatar et al., 2015; Miller et al., 2016; Zhang et al., 2018).

4.1 Comparison with Previous Methods

Table 2 summarizes the performances of our proposed models and compares them to the baselines on the TrecQA and WikiQA datasets. The full model [BERT + GSAMN+ Transfer Learning] outperforms the previous state-of-the-art methods by a large margin. Note that by simply fine-tuning the pre-trained BERT embeddings, one can easily achieve very competitive performance on both datasets. This is expected as BERT has been pre-trained on a massive amount of unlabeled data. However, our proposed techniques do add a significant amount of performance. The gain from using all of our proposed techniques is larger than the difference between fine-tuning BERT model compared to previous systems in the TrecQA dataset.

4.2 Ablation Analysis

We aim to analyze the relative effectiveness of different components of our full model. From the original BERT baseline, we add one component at a time and evaluate the performance of the partial models on the datasets. From Table 2, we can see that both the variants [BERT + GSAMN] and [BERT + Transfer Learning] have better performance than the original BERT baseline. However, both of the partial variants still perform worse than the one with all the techniques. This shows that although each of our proposed components is effective by itself, we need to combine them together in order to achieve the best performance.

4.3 GSAMN versus Transformer

It was an iterative process to arrive at the current design of GSAMN. We aim to analyze whether the improvement in performance comes from the inductive bias that we introduced into the architec-

Table 2: Results on the TrecQA and WikiQA datasets

ture or simply from having more parameters due to added complexity. To this end, we evaluated the performances of two variants [BERT + Transformers] and [BERT + Transformers + Transfer Learning]. These model variants simply use two Transformer layers (Vaswani et al., 2017) on top of BERT instead of using our GSAMN architecture. Table 2 clearly shows that GSAMN outperforms the Transformer based variants, with or without the transfer learning component.

We have experimented with adding more Transformer layers on top of BERT but the performance did not improve. For example, using 6 extra Transformer layers only achieves a MAP score of 0.885 on the TrecQA dataset. This is reasonable because BERT by itself already contains 12 Transformer layers. Without a new kind of layer such as our proposed GSAMN architecture, stacking more Transformer layers will not be helpful, especially in this case where the tested datasets are not large.

4.4 GSAMN versus Compare-Aggregate

Finally, we have a comparison between our full model and the Compare-Aggregate framework. Most previous Compare-Aggregate architectures use traditional word embeddings such as word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014). In contrast, our full model uses BERT which is an arguably more powerful language representation model. To this end, we implemented a Compare-Aggregate variant that uses dynamic-clip attention (Bian et al., 2017). We use ELMo (Peters et al., 2018) to represent the input words to the implemented Compare-Aggregate architecture. We use ELMo instead of BERT because BERT is in subword-level while one of the intuitions behind the Compare-Aggregate variant is about comparing word-level representations. In addition, we have tested the variant [BERT + Compare-Aggregate] but found it to be worse than the version [ELMo + Compare-Aggregate]. The results in Table 2 show that our model significantly outperforms [ELMo + Compare-Aggregate] as well.

5 Conclusions

In this paper, we propose a new gated self-attention memory network architecture for answer selection. Combined with a simple transfer learning technique from a large-scale CQA corpus, the model achieves the state-of-the-art performance on two well-studied answer selection datasets: TrecQA and WikiQA. In the future, we plan to investigate more transfer learning techniques for utilizing the large volume of existing CQA data. In addition, we plan to apply our self-attention memory network on other sentence matching tasks such as natural language inference, paraphrase identification, or measuring semantic relatedness.

Polly Want a Cracker: Analyzing Performance of Parroting on Paraphrase Generation Datasets

Hong-Ren Mao, Hung-Yi Lee
Department of Electrical Engineering
National Taiwan University
ccm29cam@gmail.com, hungyilee@ntu.edu.tw

Abstract

Paraphrase generation is an interesting and challenging NLP task which has numerous practical applications. In this paper, we analyze datasets commonly used for paraphrase generation research, and show that simply parroting input sentences surpasses state-of-the-art models in the literature when evaluated on standard metrics. Our findings illustrate that a model could be seemingly adept at generating paraphrases, despite only making trivial changes to the input sentence or even none at all.

1 Introduction

The task of paraphrase generation has many important applications in NLP. It can be used to generate adversarial examples of input text, which can then be used to train neural networks so that they become less susceptible to adversarial attack (Iyyer et al., 2018). For knowledge-based QA systems, a paraphrasing step can produce multiple variations of a user query and match them with knowledge base assertions, enhancing recall (Yin et al., 2015; Fader et al., 2014). Relation extraction can also benefit from incorporating paraphrase generation into its processing pipeline (Romano et al., 2006). Manually annotating translation references is expensive, and automatically generating references through paraphrasing has been shown to be effective for evaluation of machine translation (Zhou et al., 2006; Kauchak and Barzilay, 2006).

Datasets used for paraphrase generation include QUORA[1], TWITTER (Lan et al., 2017) and MSCOCO (Lin et al., 2014). Previous work on paraphrase generation that used these datasets (Wang et al., 2019; Gupta et al., 2018; Li et al., 2018; Prakash et al., 2016) chose BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007) and TER (Snover et al., 2006) as evaluation metrics.

In this paper, we find that simply using the input sentence as output in an unsupervised manner (*i.e.* fully parroting the input) significantly outperforms the state-of-the-art on two metrics for TWITTER, and on one metric for QUORA. Even after changing part of the input sentence (*i.e.* partially parroting the input), state-of-the-art metric scores can still be surpassed.

Consequently, for future paraphrase generation research which achieve good evaluation scores, we suggest investigating whether their methods or models act differently from simple parroting behavior.

2 Method Description

Given an input sentence i, the goal of paraphrase generation is to generate an output sentence o which is semantically identical to i, but contain variations in lexicon or syntax. Full parroting simply uses the input as output ($o = i$).

Paraphrase generation models may not parrot the input sentence word for word, but it is possible that they only modify a few words of the input, thus we also experiment with simple methods of modifying i, such as replacing or cutting words from the head, from the tail or from random positions.

Both full parroting and the forms of partial parroting we use are fully unsupervised.

3 Datasets

QUORA. The QUORA dataset contains 149,263 paraphrase sentence pairs (positive examples) and 255,027 non-paraphrase sentence pairs (negative examples). Having both positive and negative ex-

[1] https://data.quora.com/First-Quora-Dataset-Release-Question-Pairs

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5960–5968, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

amples makes it appealing for research on paraphrase generation (Gupta et al., 2018; Li et al., 2018) and identification (Lan and Xu, 2018). After processing the dataset, there are 149,650 unique sentences that have reference paraphrases.

Gupta et al. (2018) sampled 4K sentences as their test set, but did not specify which sentences they used. Li et al.(2018) sampled 30K sentences as their test set, also not specifying which sentences they used. To avoid selecting a subset of data that is biased in favor of our method, we perform evaluation on the entire QUORA dataset. Although we evaluate on the entire dataset, the size of our training set is zero due to the fully unsupervised nature of full and partial parroting.

We group sentences by the number of reference paraphrases they have, and plot the relative counts in Appendix A. It can be seen that over 64% of entries have only a single reference paraphrase, which is problematic because even if a paraphrase of good quality is generated for any one of these entries, BLEU, METEOR and TER scores could still be inferior if the generated paraphrase differs too much from the single reference paraphrase. Previous paraphrase generation work on QUORA (Gupta et al., 2018; Li et al., 2018) did not mention removing these entries, thus we include them in our experiments for fair comparison. However, we strongly recommend future work which wishes to use BLEU, METEOR and TER as evaluation metrics to only consider entries that have multiple reference paraphrases.

TWITTER. There are 114,025 paraphrase sentence pairs in TWITTER, which were acquired by collecting tweets which contain identical URLs (Lan et al., 2017). As with QUORA, prior paraphrase generation work on this dataset (Li et al., 2018) did not provide their sampled test set sentences, so we evaluate parroting on the entire dataset to avoid bias. We follow the same data processing steps as QUORA, and plot the number of reference paraphrases in Appendix A.

MSCOCO. This is an image captioning dataset, with multiple captions provided for a single image (Lin et al., 2014). There have been multiple works which use it as a paraphrase generation dataset by treating captions of the same image as paraphrases (Wang et al., 2019; Gupta et al., 2018; Prakash et al., 2016). The training and testing sets are available, containing 331,163 and 162,016 input sentences respectively.

However, relevance scores for captions of the same image score only 3.38 out of 5 under human evaluation (in contrast, the score is 4.82 for QUORA) (Gupta et al., 2018), due to the fact that different captions for the same image often vary in the semantic information conveyed. This makes the use of MSCOCO as a paraphrase generation dataset questionable.

We plot the number of reference paraphrases in Appendix A.

4 Experiments

We evaluate the performance of full parroting on all three datasets and compare with state-of-the-art models.

We also study the performance of partial parroting. Whereas full parroting does not modify the input sentence, partial parroting replaces or cuts some of the input words. We try three different modes of choosing words to be cut or replaced: from the sentence head, from the tail or sampled randomly.

4.1 Evaluation

Following prior paraphrase generation research which used QUORA, TWITTER and MSCOCO, we use BLEU, METEOR and TER as evaluation metrics. When calculating metric scores, all available reference paraphrases for a given input sentence are considered.

4.2 Results

Full parroting. Our results are organized in Tables 1, 2 and 3. We see for TWITTER, parroting outperforms the state-of-the-art by significant margins on both BLEU and METEOR scores; for QUORA, parroting outperforms the state-of-the-art appreciably on METEOR while having comparable performance on BLEU.

The poor performance of full parroting on MSCOCO is due to higher edit distances between input sentences and their reference paraphrases. TER measures the edit distance of a sentence to a reference sentence, normalized by the average length of all references (Snover et al., 2006):

$$\text{TER} = \frac{\text{\# of edits}}{\text{average \# of reference words}}$$

We see that the TER score of full parroting is particularly high on MSCOCO compared to the other two datasets. Correspondingly, the BLEU and METEOR scores are lower by a wide margin.

Metric	STATE-OF-THE-ART			PARROT		
	paper	score	num_train	score	num_train	ΔSOTA
BLEU ↑	(Li et al., 2018)	**43.54**	100K	41.59	0	-4.47%
METEOR ↑	(Gupta et al., 2018)	33.6	150K	**38.60**	0	**+14.88%**
TER ↓	(Gupta et al., 2018)	**39.5**	150K	45.22	0	+14.47%

Table 1: Performance of full parroting v.s. state-of-the-art on QUORA. Higher BLEU and METEOR scores are better, while higher TER scores are worse. Bold text represents best results.

Metric	STATE-OF-THE-ART			PARROT		
	paper	score	num_train	score	num_train	ΔSOTA
BLEU ↑	(Li et al., 2018)	45.74	110K	**65.26**	0	**+42.67%**
METEOR ↑	(Li et al., 2018)	20.18	110K	**41.73**	0	**+106.77%**
TER ↓	-	-	-	**41.87**	0	-

Table 2: Performance of full parroting v.s. state-of-the-art on TWITTER.

Metric	STATE-OF-THE-ART			PARROT		
	paper	score	num_train	score	num_train	ΔSOTA
BLEU ↑	(Wang et al., 2019)	**44.0**	331K	19.0	0	-56.8%
METEOR ↑	(Wang et al., 2019)	**34.7**	331K	23.9	0	-31.0%
TER ↓	(Wang et al., 2019)	**37.1**	331K	70.4	0	+89.7%

Table 3: Performance of full parroting v.s. state-of-the-art on MSCOCO.

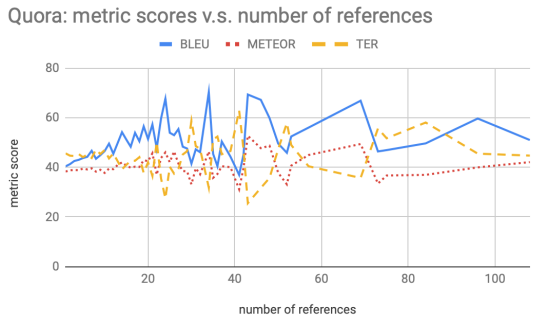

Figure 1: Metric scores v.s. number of reference paraphrases (Quora). For lower numbers of references, metric scores improve as the amount of references increases. For higher numbers of references, there does not appear to be a clear correlation.

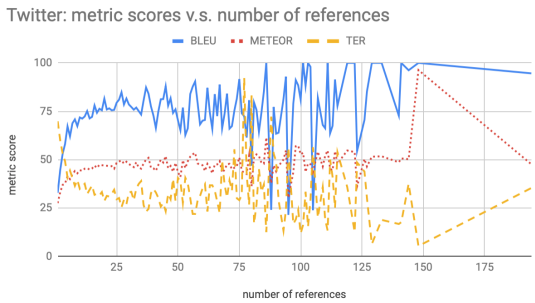

Figure 2: Metric scores v.s. number of reference paraphrases (Twitter). For lower numbers of references, metric scores improve as the amount of references increases. For higher numbers of references, there does not appear to be a clear correlation.

For further investigation of parroting on QUORA and TWITTER, we plot parroting performance versus the number of reference paraphrases available for a given input sentence (Figures 1 and 2). If the number of references is not too high, metric scores generally improve when the number of references rises. Once the number of references exceeds a certain threshold, we do not observe a clear correlation, showing that the probability of finding a reference sentence which bears higher resemblance to the input does not increase proportionally with the number of references.

The choice of testing on the entire dataset for QUORA and TWITTER experiments was to avoid bias in favor of parroting. Nevertheless, we also randomly sampled test sets of size 4K for QUORA in the same manner as (Gupta et al., 2018) (which holds the most state-of-the-art records on QUORA) and test sets of size 5K for TWITTER in the same manner as (Li et al., 2018) (which holds all state-

Statistic	QUORA (5K test set × 1200)			TWITTER (4K test set × 250)		
	BLEU ↑	METEOR ↑	TER ↓	BLEU ↑	METEOR ↑	TER ↓
Average	41.57	38.59	45.21	74.97	46.22	33.43
Std. Dev.	0.50	0.20	0.50	0.36	0.14	0.35
Max.	43.12	39.29	46.95	76.01	46.56	34.31
Min.	39.98	37.85	43.53	74.01	45.89	32.41

Table 4: Performance of full parroting on randomly sampled test sets. The test set size and sampling method is the same as that described in prior state-of-the-art work. Here, scores for sampled QUORA test sets are similar to those of the full dataset, and the scores for TWITTER test sets are better than scores achieved on the full dataset.

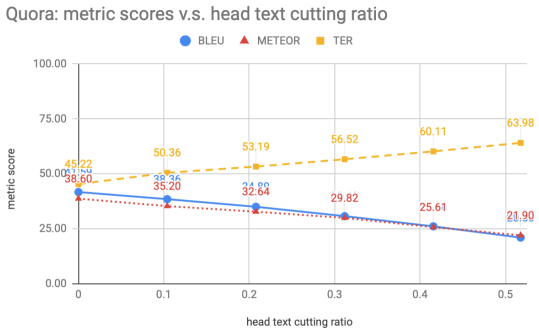

Figure 3: Metric scores v.s. ratio of text that is cut from the start of the input sentence (Quora).

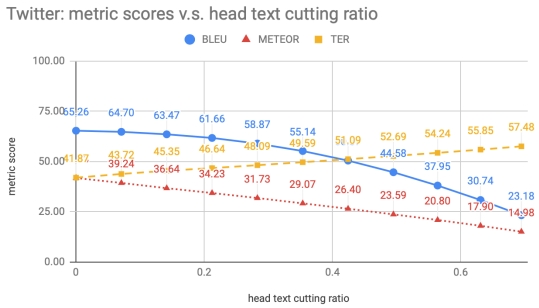

Figure 4: Metric scores v.s. ratio of text that is cut from the start of the input sentence (Twitter).

of-the-art records on TWITTER). In total, 1200 test sets of size 4K were sampled for QUORA and 250 test sets of size 5K were sampled for TWITTER. Parroting performance on these sampled test sets can be found in Table 4. It can be observed that the average metric scores for QUORA are similar to the scores in Table 1, whereas the average scores for TWITTER are noticeably better than those in Table 2. Furthermore, the score deviation between different samples is small. Consequently, although the exact test sets used by (Gupta et al., 2018) and (Li et al., 2018) are not available, it is logical to assume that parroting performance would still exceed or be on par with the state-of-the-art on those test sets.

Partial parroting. We also introduce lexical variation into our parroting method by replacing or cutting words of the input sentence. For replacement, we substitute input words with an out-of-vocabulary word not found in any of the input sentence's reference paraphrases. Paraphrase generation models are usually allowed to generate words which exist in reference paraphrases; we purposely use out-of-vocabulary words to give harsher scores to our method.

Figures 3 and 4 show performance of cutting words from the start of input sentences. For QUORA, when over 10% of the input sentence has been modified by being cut off, partial parroting underperforms the state-of-the-art by only 3.8% on METEOR. For TWITTER, the same form of partial parroting (cutting off words) still outperforms the state-of-the-art on BLEU when input sentences are modified by 42% , and does the same on METEOR when the input is modified by 56%. Additionally, we experiment with cutting words in other positions, and also replace words rather than cut them away. The results can be found in Appendix B.

Earlier work using QUORA and TWITTER (Gupta et al., 2018; Li et al., 2018) only provided a few examples of output paraphrases, and did not study in detail the paraphrasing behavior of their models, making it unclear whether the models achieve qualitatively better results than our simple rule-based parroting techniques, given that evaluation scores of the two are similar. We recommend future research to perform such an analysis if their metric scores are close to that of parroting.

5 Related Work

For the task of paraphrase generation, Wang et al. (2019) trained a Transformer network on

MSCOCO; Gupta et al. (2018) trained a seq2seq variational autoencoder (VAE) on QUORA and MSCOCO; Li et al. (2018) trained a seq2seq pointer network on QUORA and TWITTER, then fine-tuned it with an *evaluator* which was trained via inverse reinforcement learning; Prakash et al. (2016) trained a seq2seq model with residual connections on MSCOCO.

Work on paraphrase generation using other datasets can also be found. Methods include lexical substitution (Hassan et al., 2007; Bolshakov and Gelbukh, 2004), back-translation (Wieting and Gimpel, 2018) and sequence-to-sequence neural networks (Iyyer et al., 2018).

It is worth noting that paraphrase generation serves practical purposes, such as augmenting training data for NLP models to decrease their susceptibility to adversarial attack (Iyyer et al., 2018), or enhancing recall for QA systems (Yin et al., 2015; Fader et al., 2014). Improvement of downstream model performance is a valid evaluation metric for paraphrase generation, and future work wishing to use QUORA entries which only have a single reference paraphrase could choose such an evaluation metric instead of BLEU, METEOR or TER.

As a sidenote, we also ran experiments in which BLEU scores were calculated using non-reference dataset sentences. The results are in Appendix C.

6 Conclusion

In this work, we discover that various forms of simple parroting outperforms state-of-the-art results on QUORA and TWITTER when evaluated using BLEU and METEOR. An interpretation is that current models could simply be parroting input sentences, and researchers should perform qualitative analysis of such behavior. Another interpretation is that BLEU and METEOR are inappropriate for evaluating paraphrase generation models, in which case other metrics such as effectiveness of data augmentation (Iyyer et al., 2018), may be used instead.

C Calculating BLEU score using non-reference sentences

For an input sentence, BLEU scores are usually calculated by comparing the input sentence with a number of reference sentences. We ran experiments in which 5 reference and 100 randomly sampled non-reference sentences were used, and show part of our results below. It can be seen that sentences with higher BLEU scores are more similar to the input sentence, which is to be expected.

Input sentence: what would happen if you hired two private detectives to spy on each other ?

BLEU	
0.3 - 0.35	what will happen if i hire two private detectives to follow each other ? what would happen if i got two private investigators to follow each other ? what would happen if i sent two private investigators to find each other ?
0.25 - 0.3	(None)
0.2 - 0.25	what would happen if earth collided with a black hole ? what if i hired two private eyes and ordered them to follow each other ? what would happen if donald trump lost and refused to concede the election ?
0.15 - 0.2	would i be able to hire two private investigators and then get them to follow each other ? what would happen if donald trump turned out to be a plant for hillary to win the white house ?
0 - 0.15	do i need to pay again on coursera if i switch sessions ? is there anyway to tell if someone blocked you on facebook ? what song do you listen to when you are angry ? ..... what are bugs you noticed on quora ? if i eat a pot cookie , how long until i 'm able to pass a urine test ?

Input sentence: who do you think portrayed batman better : christian bale or ben affleck ?

BLEU	
0.4 - 0.45	according to you , whose batman performance was best : christian bale or ben affleck ?
0.35 - 0.4	(None)
0.3 - 0.35	no fanboys please , but who was the true batman , christian bale or ben affleck ?
0.25 - 0.3	(None)
0.2 - 0.25	(None)
0.15 - 0.2	what do you think about " chinese dream " ? what do you think about dota2 ? who was better as batman : bale or affleck ? did ben affleck shine more than christian bale as batman ? do you think that the demonetization policy will backfire for bjp in 2019 elections ?
0 - 0.15	biswapati sarkar : how do you overcome a writer 's block ? who is the better batman ? affleck or bale ? how do you stop your cat from spraying ? ..... do we always get what we deserve ? can a moon have a moon ?

Query-focused Sentence Compression in Linear Time

Abram Handler and **Brendan O'Connor**

{ahandler,brenocon}@cs.umass.edu

Abstract

Search applications often display shortened sentences which must contain certain query terms and must fit within the space constraints of a user interface. This work introduces a new transition-based sentence compression technique developed for such settings. Our query-focused method constructs length and lexically constrained compressions in linear time, by growing a subgraph in the dependency parse of a sentence. This theoretically efficient approach achieves an 11x empirical speedup over baseline ILP methods, while better reconstructing gold constrained shortenings. Such speedups help query-focused applications, because users are measurably hindered by interface lags. Additionally, our technique does not require an ILP solver or a GPU.

1 Introduction

Traditional study of extractive sentence compression seeks to create short, readable, single-sentence summaries which retain the most "important" information from source sentences. But search user interfaces often require compressions which must include a user's query terms and must not exceed some maximum length, permitted by screen space. Figure 1 shows an example.

This study examines the English-language compression problem with such length and lexical requirements. In our constrained compression setting, a source sentence S is shortened to a compression C which (1) must include all tokens in a set of query terms Q and (2) must be no longer than a maximum budgeted character length, $b \in \mathbb{Z}^+$. Formally, constrained compression maps $(S, Q, b) \rightarrow C$, such that C respects Q and b. We describe this task as query-focused compression because Q places a hard requirement on words from S which must be included in C.

Figure 1: A search user interface (boxed, top) returns a snippet consisting of three compressions which must contain a users' query Q (bold) and must not exceed $b = 75$ characters in length. The third compression C was derived from source sentence S (italics, bottom).

Existing techniques are poorly suited to constrained compression. While methods based on integer linear programming (ILP) can trivially accommodate such length and lexical restrictions (Clarke and Lapata, 2008; Filippova and Altun, 2013; Wang et al., 2017), these approaches rely on slow third-party solvers to optimize an NP-hard integer linear programming objective, causing user wait time. An alternative LSTM tagging approach (Filippova et al., 2015) does not allow practitioners to specify length or lexical constraints, and requires an expensive graphics processing unit (GPU) to achieve low runtime latency (access to GPUs is a barrier in fields like social science and journalism). These deficits prevent application of existing compression techniques in search user interfaces (Marchionini, 2006; Hearst, 2009), where length, lexical and latency requirements are paramount. We thus present a new stateful method for query-focused compression.

Our approach is theoretically and empirically faster than ILP-based techniques, and more accurately reconstructs gold standard compressions.

Approach	Complexity	Constrained
ILP	exponential	yes
LSTM tagger	linear	no
VERTEX ADDITION	**linear**	**yes**

Table 1: Our VERTEX ADDITION technique (§3) constructs constrained compressions in linear time. Prior work (§2) has higher computational complexity (ILP) or does not respect hard constraints (LSTM tagger).

(Knight and Marcu, 2000; Clarke and Lapata, 2008; Filippova et al., 2015; Wang et al., 2017).[1] To our knowledge, this work is the first to consider extractive compression under hard length and lexical constraints.

We compare our VERTEX ADDITION approach to ILP-based compression methods (Clarke and Lapata, 2008; Filippova and Altun, 2013; Wang et al., 2017), which shorten sentences using an integer linear programming objective. ILP methods can easily accommodate lexical and budget restrictions via additional optimization constraints, but require worst-case exponential computation.[2]

Finally, compression methods based on LSTM taggers (Filippova et al., 2015) cannot currently enforce lexical or length requirements. Future work might address this limitation by applying and modifying constrained generation techniques (Kikuchi et al., 2016; Post and Vilar, 2018; Gehrmann et al., 2018).

3 Compression via VERTEX ADDITION

We present a new transition-based method for shortening sentences under lexical and length constraints, inspired by similar approaches in transition-based parsing (Nivre, 2003). We describe our technique as VERTEX ADDITION because it constructs a shortening by *growing* a (possibly disconnected) subgraph in the dependency parse of a sentence, one vertex at a time. This approach can construct constrained compressions with a linear algorithm, leading to 11x lower latency than ILP techniques (§4). To our knowledge, our method is also the first to construct compressions by *adding* vertexes rather than *pruning* subtrees in a parse (Knight and Marcu, 2000; Almeida and Martins, 2013; Filippova and Alfonseca, 2015). We assume a boolean relevance model: S must contain Q. We leave more sophisticated relevance models for future work.

3.1 Formal description

VERTEX ADDITION builds a compression by maintaining a state (C_i, P_i) where $C_i \subseteq S$ is a set of added candidates, $P_i \subseteq S$ is a priority queue of vertexes, and i indexes a timestep during compression. Figure 2 shows a step-by-step example.

During initialization, we set $C_0 \leftarrow Q$ and $P_0 \leftarrow S \setminus Q$. Then, at each timestep, we pop some candidate $v_i = h(P_i)$ from the head of P_i and evaluate v_i for inclusion in C_i. (Neighbors of C_i in P_i get higher priority than non-neighbors; we break ties in left-to-right order, by sentence position). If we accept v_i, then $C_{i+1} \leftarrow C_i \cup v_i$; if not, $C_{i+1} \leftarrow C_i$. (Acceptance decisions are detailed in §4.3.) We continue adding vertexes to C until either P_i is empty or C_i is b characters long.[3] The appendix includes a formal algorithm.

VERTEX ADDITION is linear in the token length of S because we pop and evaluate some vertex from P_i at each timestep, after $P_0 \leftarrow S \setminus Q$. Additionally, because (1) we never accept v_i if the length of $C_i \cup v_i$ is more than b, and (2) we set $C_0 \leftarrow Q$, our method respects Q and b.

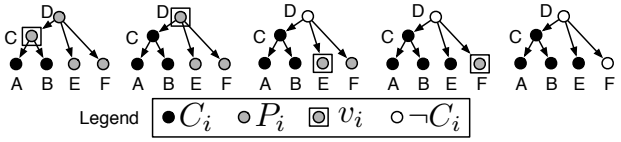

Figure 2: A dependency parse of a sentence S, shown across five timesteps of VERTEX ADDITION (from left to right). Each node in the parse is a vertex in S. Our stateful method produces the final compression {A,C,B,E} (rightmost). At each timestep, each candidate v_i is boxed; rejected candidates $\neg C_i$ are unshaded.

4 Evaluation

We observe the latency, readability and token-level F1 score of VERTEX ADDITION, using a standard dataset (Filippova and Altun, 2013). We compare our method to an ILP baseline (§2) because ILP methods are the only known technique for constrained compression. All methods have similar

[1] Some methods compress via generation instead of deletion (Rush et al., 2015; Mallinson et al., 2018). Our extractive method is intended for practical, interpretable and trustworthy search systems (Chuang et al., 2012). Users might not trust abstractive summaries (Zhang and Cranshaw, 2018), particularly in cases with semantic error.

[2] ILPs are exponential in $|V|$ when selecting tokens (Clarke and Lapata, 2008) and exponential in $|E|$ when selecting edges (Filippova et al., 2015).

[3] We linearize C by left-to-right vertex position in S, common for compression in English (Filippova and Altun, 2013).

compression ratios (shown in appendix), a well-known evaluation requirement (Napoles et al., 2011). We evaluate the significance of differences between VERTEX ADDITION$_{LR}$ and the ILP with bootstrap sampling (Berg-Kirkpatrick et al., 2012). All differences are significant ($p < .01$).

4.1 Constrained compression experiment

In order to evaluate different approaches to constrained compression, we require a dataset of sentences, constraints and known-good shortenings, which respect the constraints. This means we need tuples (S, Q, b, C_g), where C_g is a known-good compression of S which respects Q and b (§1).

To support large-scale automatic evaluation, we reinterpret a standard compression corpus (Filippova and Altun, 2013) as a collection of input sentences and constrained compressions. The original dataset contains pairs of sentences S and compressions C_g, generated using news headlines. For our experiment, we set b equal to the character length of the gold compression C_g. We then sample a small number of nouns[4] from C_g to form a query set Q, approximating both the observed number of tokens and observed parts of speech in real-world search (Jansen et al., 2000; Barr et al., 2008). Sampled Q include reasonable queries like "police, Syracuse", "NHS" and "Hughes, manager, QPR".

By sampling queries and defining budgets in this manner, we create 198,570 training tuples and 9949 test tuples, each of the form (S, Q, b, C_g). Filippova and Altun (2013) define the train/test split. We re-tokenize, parse and tag with CoreNLP v3.8.0 (Manning et al., 2014). We reserve 25,000 training tuples as a validation set.

4.2 Model: ILP

We compare our system to a baseline ILP method, presented in Filippova and Altun (2013). This approach represents each edge in a syntax tree with a vector of real-valued features, then learns feature weights using a structured perceptron trained on a corpus of (S, C_g) pairs.[5] Learned weights are used to compute a global compression objective, subject to structural constraints which ensure C is a valid tree. This baseline can easily perform constrained compression: at test time, we add optimization constraints specifying that C must include Q, and not exceed length b.

To our knowledge, a public implementation of this method does not exist. We reimplement from scratch using Gurobi Optimization (2018), achieving a test-time, token-level F1 score of 0.76 on the unconstrained compression task, lower than the result (F1 = 84.3) reported by the original authors. There are some important differences between our reimplementation and original approach (described in detail in the appendix). Since VERTEX ADDITION requires Q and b, we can only compare it to the ILP on the *constrained* (rather than traditional, unconstrained) compression task.

4.3 Models: VERTEX ADDITION

Vertex addition accepts or rejects some candidate vertex v_i at each timestep i. We learn such decisions $y_i \in \{0, 1\}$ using a corpus of tuples (S, Q, b, C_g) (§4.1). Given such a tuple, we can always execute an oracle path shortening S to C_g by first initializing VERTEX ADDITION and then, at each timestep: (1) choosing $v_i = h(P_i)$ and (2) adding v_i to C_i iff $v_i \in C_g$. We set $y_i = 1$ if $v_i \in C_g$; we set $y_i = 0$ if $v_i \notin C_g$. We then use decisions from oracle paths to train two models of inclusion decisions, $p(y_i = 1 | v_i, C_i, P_i, S)$. At test time, we accept v_i if $p(y_i > .5)$.

Model One. Our VERTEX ADDITION$_{NN}$ model broadly follows neural approaches to transition-based parsing (e.g. Chen and Manning (2014)): we predict y_i using a LSTM classifier with a standard max-pooling architecture (Conneau et al., 2017), implemented with a common neural framework (Gardner et al., 2017). Our classifier maintains four vocabulary embeddings matrixes, corresponding to the four disjoint subsets $C_i \cup \neg C_i \cup P_i \cup \{v_i\} = V$. Each LSTM input vector x_t comes from the appropriate embedding for $v_t \in V$, depending on the state of the compression system at timestep i. The appendix details network tuning and optimization.

Model Two. Our VERTEX ADDITION$_{LR}$ model uses binary logistic regression,[6] with 3 classes of features.

Edge features describe the properties of the edge (u, v_i) between $v_i \in P_i$ and $u \in C_i$. We

[4] 1 to 3 nouns; cardinality chosen uniformly at random.

[5] Another ILP (Wang et al., 2017) sets weights using a LSTM, achieving similar in-domain performance. This method requires a multi-stage computational process (i.e. run LSTM *then* ILP) that is poorly-suited to query-focused settings, where low latency is crucial.

[6] We implement with Python 3 using scikit-learn (Pedregosa et al., 2011). We tune the inverse regularization constant to $c = 10$ via grid search over powers of ten, to optimize validation set F1.

Approach	F1	SLOR	*Latency
RANDOM (lower bound)	0.653	0.377	0.5
ABLATED (edge only)	0.827	0.669	3.7
VERTEX ADDITION$_{NN}$	0.873	0.728	2929.1 (CPU)
ILP	0.852	0.756	44.0
VERTEX ADDITION$_{LR}$	0.881	0.745	4.1

Table 2: Test results for constrained compression. *Latency is the geometric mean of observed runtimes (in milliseconds per sentence). VERTEX ADDITION$_{LR}$ achieves the highest F1, and also runs 10.73 times faster than the ILP. Differences between all scores for VERTEX ADDITION$_{LR}$ and ILP are significant ($p < .01$).

use the edge-based feature function from Filippova and Altun (2013), described in detail in the appendix. This allows us to compare the performance of a vertex addition method based on local decisions with an ILP method that optimizes a global objective (§4.5), using the same feature set.

Stateful features represent the relationship between v_i and the compression C_i at timestep i. Stateful features include information such as the position of v_i in the sentence, relative to the rightmost and left-most vertex in C_i, as well as history-based information such as the fraction of the character budget used so far. Such features allow the model to reason about which sort of v_i should be added, given Q, S and C_i.

Interaction features are formed by crossing all stateful features with the type of the dependency edge governing v_i, as well as with indicators identifying if u governs v_i, if v_i governs u or if there is no edge (u, v_i) in the parse.

4.4 Metrics: F1, Latency and SLOR

We measure the token-level F1 score of each compression method against gold compressions in the test set. F1 is the standard automatic evaluation metric for extractive compression (Filippova et al., 2015; Klerke et al., 2016; Wang et al., 2017).

In addition to measuring F1, researchers often evaluate compression systems with human *importance* and *readability* judgements (Knight and Marcu, 2000; Filippova et al., 2015). In our setting Q determines the "important" information from S, so importance evaluations are inappropriate. To check readability, we use the automated readability metric SLOR (Lau et al., 2015), which correlates with human judgements (Kann et al., 2018).

We evaluate theoretical gains from VERTEX ADDITION (Table 1) by measuring empirical latency. For each compression method, we sample and compress $N = 300,000$ sentences, and record the runtime (in milliseconds per sentence). We observe that runtimes are distributed log-normally (Figure 3), and we thus summarize each sample using the geometric mean. ILP and VERTEX ADDITION$_{LR}$ share edge feature extraction code to support to fair comparison. We test VERTEX ADDITION$_{NN}$ using a CPU: the method is too slow for use in search applications in areas without access to specialized hardware (Table 2). The appendix further details latency and SLOR experiments.

4.5 Analysis: ABLATED & RANDOM

For comparison, we implement an ABLATED vertex addition method, which learns inclusion decisions using only edge features from Filippova and Altun (2013). ABLATED has a lower F1 score than ILP, which uses the same edge-level information to optimize a global objective: adding stateful and interaction features (i.e. VERTEX ADDITION$_{LR}$) improves F1 score. Nonetheless, strong performance from ABLATED hints that edge-level information alone (e.g. dependency type) can mostly guide acceptance decisions.

We also evaluate a RANDOM baseline, which accepts each v_i randomly in proportion to $p(y_i = 1)$ across training data. RANDOM achieves reasonable F1 because (1) $C_0 = Q \in C_g$ and (2) F1 correlates with compression rate (Napoles et al., 2011), and b is set to the length of C_g.

5 Future work: practical compression

This work presents a new method for fast query-focused sentence compression, motivated by the need for query-biased snippets in search engines (Tombros and Sanderson, 1998; Marchionini, 2006). While our approach shows promise in simulated experiments, we expect that further work will be required before the method can be employed for practical, user-facing search.

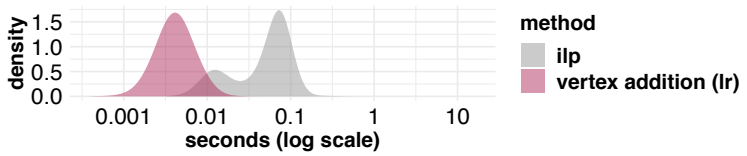

Figure 3: Density plot of log transformed latencies for VERTEX ADDITION$_{LR}$ (left) and ILP (right). Theoretical gains (Table 1) create real speedups. The ILP shows greater runtime variance, possibly reflecting varying approaches from Gurobi Optimization (2018).

To begin, both our technique and our evaluation ignore the conventions of search user interfaces, which typically display missing words using ellipses. This convention is important, because it allows snippet systems to transparently show users which words have been removed from a sentence. However, we observe that some well-formed compressions are difficult to read when displayed in this format. For instance the sentence "Aristide quickly fled Haiti in September 1991" can be shortened to the well-formed compression "Aristide fled in 1991." But this compression does not read fluidly when using ellipses ("Aristide...fled...in...1991"). Human experiments aimed at enumerating the desirable and undesirable properties of compressions displayed in ellipse format (e.g. compressions should minimize number of ellipses?) could help guide user-focused snippet algorithms in future work.

Our method also assumes access to a reliable, dependency parse, and ignores any latency penalties incurred from parsing. In practical settings, both assumptions are unreasonable. Like other NLP tools, dependency parsers often perform poorly on out-of-domain text (Bamman, 2017), and users looking to quickly investigate a new corpus might not wish to wait for a parser. Faster approaches based on low-latency part-of-speech tagging, or more cautious approaches based on syntactic uncertainty (Keith et al., 2018), each offer exciting possibilities for additional research.

Our approach also assumes that a user already knows a reasonable b and reasonable Q for a given sentence S.[7] However, in some cases, there is no well-formed shortening of which respects the requirements. For instance, if Q="Kennedy" and b=15 there is no reasonable shortening for the toy sentence "Kennedy kept running", because the compressions "Kennedy kept" and "Kennedy running" are not well-formed. We look forward to investigating which (Q, S, b) triples will never return well-formed compressions in later work.

Finally, some shortened sentences will modify the meaning of a sentence, but we ignore this important complication in this initial study. In the future, we hope to apply ongoing research into textual entailment (Bowman et al., 2015; Pavlick and Callison-Burch, 2016; McCoy and Linzen, 2018) to develop semantically-informed approaches to the task.

6 Conclusion

We introduce a query-focused VERTEX ADDITION$_{LR}$ method for search user interfaces, with much lower theoretical complexity (and empirical runtimes) than baseline techniques. In search applications, such gains are non-trivial: real users are measurably hindered by interface lags (Nielsen, 1993; Liu and Heer, 2014). We hope that our fast, query-focused method better enables snippet creation at the "pace of human thought" (Heer and Shneiderman, 2012).

Generating Personalized Recipes from Historical User Preferences

Bodhisattwa Prasad Majumder[*], **Shuyang Li**[*], **Jianmo Ni, Julian McAuley**

Abstract

Existing approaches to recipe generation are unable to create recipes for users with culinary preferences but incomplete knowledge of ingredients in specific dishes. We propose a new task of *personalized recipe generation* to help these users: expanding a name and incomplete ingredient details into complete natural-text instructions aligned with the user's historical preferences. We attend on technique- and recipe-level representations of a user's previously consumed recipes, fusing these 'user-aware' representations in an attention fusion layer to control recipe text generation. Experiments on a new dataset of 180K recipes and 700K interactions show our model's ability to generate plausible and personalized recipes compared to non-personalized baselines.

1 Introduction

In the kitchen, we increasingly rely on instructions from cooking websites: recipes. A cook with a predilection for Asian cuisine may wish to prepare chicken curry, but may not know all necessary ingredients apart from a few basics. These users with limited knowledge cannot rely on existing recipe generation approaches that focus on creating coherent recipes given all ingredients and a recipe name (Kiddon et al., 2016). Such models do not address issues of personal preference (e.g. culinary tastes, garnish choices) and incomplete recipe details. We propose to approach both problems via *personalized generation* of plausible, user-specific recipes using user preferences extracted from previously consumed recipes.

Our work combines two important tasks from natural language processing and recommender systems: data-to-text generation (Gatt and Krahmer, 2018) and personalized recommendation (Rashid et al., 2002). Our model takes as user input the name of a specific dish, a few key ingredients, and a calorie level. We pass these loose input specifications to an encoder-decoder framework and attend on user profiles—learned latent representations of recipes previously consumed by a user—to generate a recipe *personalized* to the user's tastes. We fuse these 'user-aware' representations with decoder output in an attention fusion layer to jointly determine text generation. Quantitative (perplexity, user-ranking) and qualitative analysis on user-aware model outputs confirm that personalization indeed assists in generating plausible recipes from incomplete ingredients.

While personalized text generation has seen success in conveying user writing styles in the product review (Ni et al., 2017; Ni and McAuley, 2018) and dialogue (Zhang et al., 2018) spaces, we are the first to consider it for the problem of recipe generation, where output quality is heavily dependent on the *content* of the instructions—such as ingredients and cooking techniques.

To summarize, our main contributions are as follows:

1. We explore a new task of generating plausible and personalized recipes from incomplete input specifications by leveraging historical user preferences;[1]
2. We release a new dataset of 180K+ recipes and 700K+ user reviews for this task;
3. We introduce new evaluation strategies for generation quality in instructional texts, centering on quantitative measures of coherence. We also show qualitatively and quantitatively that personalized models generate high-quality and specific recipes that align with historical user preferences.

2 Related Work

Large-scale transformer-based language models have shown surprising expressivity and fluency in creative and conditional long-text generation (Vaswani et al., 2017; Radford et al., 2019). Recent works have proposed hierarchical methods that condition on narrative frameworks to generate internally consistent long texts (Fan et al., 2018; Xu et al., 2018; Yao et al., 2018). Here, we generate procedurally structured recipes instead of free-form narratives.

Recipe generation belongs to the field of data-to-text natural language generation (Gatt and Krahmer, 2018), which sees other applications in automated journalism (Leppänen et al., 2017), question-answering (Agrawal et al., 2017), and abstractive summarization (Paulus et al., 2018), among others. Kiddon et al. (2015); Bosselut et al. (2018b) model recipes as a structured collection of ingredient entities acted upon by cooking actions. Kiddon et al. (2016) imposes a 'checklist' attention constraint emphasizing hitherto unused ingredients during generation. Yang et al. (2017) attend over explicit ingredient references in the prior recipe step. Similar hierarchical approaches that infer a full ingredient list to constrain generation will not help personalize recipes, and would be infeasible in our setting due to the potentially unconstrained number of ingredients (from a space of 10K+) in a recipe. We instead learn historical preferences to guide full recipe generation.

A recent line of work has explored user- and item-dependent aspect-aware review generation (Ni et al., 2017; Ni and McAuley, 2018). This work is related to ours in that it combines contextual language generation with personalization. Here, we attend over historical user preferences from previously consumed recipes to generate recipe content, rather than writing styles.

3 Approach

Our model's input specification consists of: the recipe name as a sequence of tokens, a partial list of ingredients, and a caloric level (high, medium, low). It outputs the recipe instructions as a token sequence: $\mathcal{W}_r = \{w_{r,0}, \ldots, w_{r,T}\}$ for a recipe r of length T. To personalize output, we use historical recipe interactions of a user $u \in \mathcal{U}$.

Encoder: Our encoder has three embedding layers: vocabulary embedding $\mathcal{V}$, ingredient embedding $\mathcal{I}$, and caloric-level embedding $\mathcal{C}$. Each token in the (length L_n) recipe name is embedded via $\mathcal{V}$; the embedded token sequence is passed to a two-layered bidirectional GRU (BiGRU) (Cho et al., 2014), which outputs hidden states for names $\{\mathbf{n}_{\text{enc},j} \in \mathbb{R}^{2d_h}\}$, with hidden size d_h. Similarly each of the L_i input ingredients is embedded via $\mathcal{I}$, and the embedded ingredient sequence is passed to another two-layered BiGRU to output ingredient hidden states as $\{\mathbf{i}_{\text{enc},j} \in \mathbb{R}^{2d_h}\}$. The caloric level is embedded via $\mathcal{C}$ and passed through a projection layer with weights W_c to generate calorie hidden representation $\mathbf{c}_{\text{enc}} \in \mathbb{R}^{2d_h}$.

Ingredient Attention: We apply attention (Bahdanau et al., 2015) over the encoded ingredients to use encoder outputs at each decoding time step. We define an attention-score function α with key K and query Q:

$$\alpha(K, Q) = \frac{\exp\left(\tanh\left(W_\alpha\left[K + Q\right] + \mathbf{b}_\alpha\right)\right)}{Z},$$

with trainable weights W_α, bias $\mathbf{b}_\alpha$, and normalization term Z. At decoding time t, we calculate the ingredient context $\mathbf{a}_t^i \in \mathbb{R}^{d_h}$ as:

$$\mathbf{a}_t^i = \sum_{j=1}^{L_i} \alpha\left(\mathbf{i}_{\text{enc},j}, \mathbf{h}_t\right) \times \mathbf{i}_{\text{enc},j}.$$

Decoder: The decoder is a two-layer GRU with hidden state h_t conditioned on previous hidden state h_{t-1} and input token $w_{r,t}$ from the original recipe text. We project the concatenated encoder outputs as the initial decoder hidden state:

$$\mathbf{h}_0\left(\in \mathbb{R}^{d_h}\right) = W_{h_0}\left[\mathbf{n}_{\text{enc},L_n}; \mathbf{i}_{\text{enc},L_i}; \mathbf{c}_{\text{enc}}\right] + \mathbf{b}_{h_0}$$
$$\mathbf{h}_t, \mathbf{o}_t = \text{GRU}\left(\left[w_{r,t}; \mathbf{a}_t^i\right], \mathbf{h}_{t-1}\right).$$

To bias generation toward user preferences, we attend over a user's previously reviewed recipes to jointly determine the final output token distribution. We consider two different schemes to model preferences from user histories: (1) recipe interactions, and (2) techniques seen therein (defined in Section 4). Rendle et al. (2009); Quadrana et al. (2018); Ueda et al. (2011) explore similar schemes for personalized recommendation.

Prior Recipe Attention: We obtain the set of prior recipes for a user u: R_u^+, where each recipe can be represented by an embedding from a recipe embedding layer $\mathcal{R}$ or an average of the name tokens embedded by $\mathcal{V}$. We attend over the k-most recent prior recipes, R_u^{k+}, to account for temporal drift of user preferences (Moore et al., 2013).

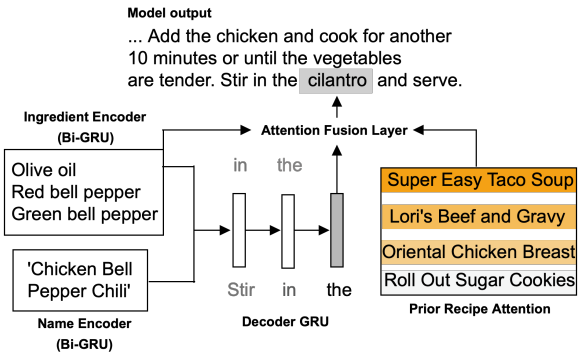

Figure 1: Sample data flow through model architecture. Emphasis on prior recipe attention scores (darker is stronger). Ingredient attention omitted for clarity.

These embeddings are used in the '**Prior Recipe**' and '**Prior Name**' models, respectively.

Given a recipe representation $\mathbf{r} \in \mathbb{R}^{d_r}$ (where d_r is recipe- or vocabulary-embedding size depending on the recipe representation) the *prior recipe attention* context $\mathbf{a}_t^{r_u}$ is calculated as

$$\mathbf{a}_t^{r_u} = \sum_{r \in R_u^{k+}} \alpha\left(\mathbf{r}, \mathbf{h}_t\right) \times \mathbf{r}.$$

Prior Technique Attention: We calculate prior technique preference (used in the '**Prior Tech**' model) by normalizing co-occurrence between users and techniques seen in R_u^+, to obtain a preference vector $\boldsymbol{\rho}_u$. Each technique x is embedded via a technique embedding layer $\mathcal{X}$ to $\mathbf{x} \in \mathbb{R}^{d_x}$. *Prior technique attention* is calculated as

$$\mathbf{a}_t^{x_u} = \sum_{x \text{ seen in } R_u^+} \left(\alpha\left(\mathbf{x}, \mathbf{h}_t\right) + \rho_{u,x}\right) \times \mathbf{x},$$

where, inspired by copy mechanisms (See et al., 2017; Gu et al., 2016), we add $\rho_{u,x}$ for technique x to emphasize the attention by the user's prior technique preference.

Attention Fusion Layer: We fuse all contexts calculated at time t, concatenating them with decoder GRU output and previous token embedding:

$$\mathbf{a}_t^f = \text{ReLU}\left(W_f\left[w_{r,t}; \mathbf{o}_t; \mathbf{a}_t^i; (\mathbf{a}_t^{r_u} \text{ or } \mathbf{a}_t^{x_u})\right] + \mathbf{b}_f\right).$$

We then calculate the token probability:

$$P(S_{r,t}) = \text{softmax}\left(W_P[\mathbf{a}_t^f] + \mathbf{b}_P\right),$$

and maximize the log-likelihood of the generated sequence conditioned on input specifications and user preferences. Figure 1 shows a case where the Prior Name model attends strongly on previously consumed savory recipes to suggest the usage of an additional ingredient ('cilantro').

Split	# Users	# Recipes	# Actions	Sparsity[3]

Dev	7,023	6,621	7,023	–
Test	12,455	11,695	12,455	–

Table 1: Statistics of Food.com interactions

4 Recipe Dataset: Food.com

We collect a novel dataset of 230K+ recipe texts and 1M+ user interactions (reviews) over 18 years (2000-2018) from Food.com.[2] Here, we restrict to recipes with at least 3 steps, and at least 4 and no more than 20 ingredients. We discard users with fewer than 4 reviews, giving 180K+ recipes and 700K+ reviews, with splits as in Table 1.

Our model must learn to generate from a diverse recipe space: in our training data, the average recipe length is 117 tokens with a maximum of 256. There are 13K unique ingredients across all recipes. Rare words dominate the vocabulary: 95% of words appear <100 times, accounting for only 1.65% of all word usage. As such, we perform Byte-Pair Encoding (BPE) tokenization (Sennrich et al., 2016; Radford et al., 2018), giving a training vocabulary of 15K tokens across 19M total mentions. User profiles are similarly diverse: 50% of users have consumed ≤6 recipes, while 10% of users have consumed >45 recipes.

We order reviews by timestamp, keeping the most recent review for each user as the test set, the second most recent for validation, and the remainder for training (sequential leave-one-out evaluation (Kang and McAuley, 2018)). We evaluate only on recipes not in the training set.

We manually construct a list of 58 cooking techniques from 384 cooking actions collected by Bosselut et al. (2018b); the most common techniques (*bake*, *combine*, *pour*, *boil*) account for 36.5% of technique mentions. We approximate technique adherence via string match between the recipe text and technique list.

5 Experiments and Results

For training and evaluation, we provide our model with the first 3-5 ingredients listed in each recipe. We decode recipe text via top-k sampling (Radford et al., 2019), finding $k = 3$ to produce satisfactory results. We use a hidden size $d_h = 256$

Table 2: Metrics on generated recipes from test set. D-1/2 = Distinct-1/2, UMA = User Matching Accuracy, MRR = Mean Reciprocal Rank, PP = Pairwise preference over baseline (evaluated for 310 recipe pairs per model).

Input	**Name:** Pomberrytini; **Ingredients:** pomegranate-blueberry juice, cranberry juice, vodka ; **Calorie:** Low
Gold	Place everything except the orange slices in a cocktail shaker. Shake until well mixed and well chilled. Pour into martini glasses and float an orange slice in each glass.
Enc-Dec	Combine all ingredients. Cover and refrigerate. Serve with whipped topping.
Prior Tech	Combine all ingredients. Store in refrigerator. Serve over ice. Enjoy!
Prior Recipe	Pour the ice into a cocktail shaker. Pour in the vodka and vodka. Add a little water and shake to mix. Pour into the glass and garnish with a slice of orange slices. Enjoy!
Prior Name	Combine all ingredients except for the ice in a blender or food processor. Process to make a smooth paste and then add the remaining vodka and blend until smooth. Pour into a chilled glass and garnish with a little lemon and fresh mint.

Table 3: Sample generated recipe. Emphasis on personalization and explicit ingredient mentions via highlights.

for both the encoder and decoder. Embedding dimensions for vocabulary, ingredient, recipe, techniques, and caloric level are 300, 10, 50, 50, and 5 (respectively). For prior recipe attention, we set $k = 20$, the 80th %-ile for the number of user interactions. We use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 10^{-3}, annealed with a decay rate of 0.9 (Howard and Ruder, 2018). We also use teacher-forcing (Williams and Zipser, 1989) in all training epochs.

In this work, we investigate how leveraging historical user preferences can improve generation quality over strong baselines in our setting. We compare our personalized models against two baselines. The first is a name-based Nearest-Neighbor model (**NN**). We initially adapted the Neural Checklist Model of Kiddon et al. (2016) as a baseline; however, we ultimately use a simple Encoder-Decoder baseline with ingredient attention (**Enc-Dec**), which provides comparable performance and lower complexity. All personalized models outperform baseline in BPE perplexity (Table 2) with Prior Name performing the best. While our models exhibit comparable performance to baseline in BLEU-1/4 and ROUGE-L, we generate more diverse (Distinct-1/2: percentage of distinct unigrams and bigrams) and acceptable recipes. BLEU and ROUGE are not the most appropriate metrics for generation quality. A 'correct' recipe can be written in many ways with the same main entities (ingredients). As BLEU-1/4 capture structural information via n-gram matching, they are not correlated with subjective recipe quality. This mirrors observations from Baheti et al. (2018); Fan et al. (2018).

We observe that personalized models make more diverse recipes than baseline. They thus perform better in BLEU-1 with more key entities (ingredient mentions) present, but worse in BLEU-4, as these recipes are written in a personalized way and deviate from gold on the phrasal level. Similarly, the 'Prior Name' model generates more unigram-diverse recipes than other personalized models and obtains a correspondingly lower BLEU-1 score.

Qualitative Analysis: We present sample outputs for a cocktail recipe in Table 3, and additional recipes in the appendix. Generation quality progressively improves from generic baseline output to a blended cocktail produced by our best performing model. Models attending over prior recipes explicitly reference ingredients. The Prior Name model further suggests the addition of lemon and mint, which are reasonably associated with previously consumed recipes like coconut mousse and pork skewers.

Personalization: To measure personalization, we evaluate how closely the generated text corresponds to a particular user profile. We compute the likelihood of generated recipes using identical input specifications but conditioned on ten different user profiles—one 'gold' user who consumed the original recipe, and nine randomly generated user profiles. Following Fan et al. (2018), we expect the highest likelihood for the recipe conditioned on the gold user. We measure user matching accuracy (UMA)—the proportion where the gold user is ranked highest—and Mean Reciprocal Rank (MRR) (Radev et al., 2002) of the gold user. All personalized models beat baselines in both metrics, showing our models personalize generated recipes to the given user profiles. The Prior Name model achieves the best UMA and MRR by a large margin, revealing that prior recipe names are strong signals for personalization. Moreover, the addition of attention mechanisms to capture these signals improves language modeling performance over a strong non-personalized baseline.

Recipe Level Coherence: A plausible recipe should possess a coherent step order, and we evaluate this via a metric for recipe-level coherence. We use the neural scoring model from Bosselut et al. (2018a) to measure recipe-level coherence for each generated recipe. Each recipe step is encoded by BERT (Devlin et al., 2019). Our scoring model is a GRU network that learns the overall recipe step ordering structure by minimizing the cosine similarity of recipe step hidden representations presented in the correct and reverse orders. Once pretrained, our scorer calculates the similarity of a generated recipe to the forward and backwards ordering of its corresponding gold label, giving a score equal to the difference between the former and latter. A higher score indicates better step ordering (with a maximum score of 2). Table 4 shows that our personalized models achieve average recipe-level coherence scores of 1.78-1.82, surpassing the baseline at 1.77.

Recipe Step Entailment: Local coherence is also crucial to a user following a recipe: it is crucial that subsequent steps are logically consistent with prior ones. We model local coherence as an entailment task: predicting the likelihood that a recipe step follows the preceding. We sample several consecutive (positive) and non-consecutive (negative) pairs of steps from each recipe. We train a BERT (Devlin et al., 2019) model to predict the entailment score of a pair of steps separated by a `[SEP]` token, using the final representation of the `[CLS]` token. The step entailment score is computed as the average of scores for each set of consecutive steps in each recipe, averaged over every generated recipe for a model, as shown in Table 4.

Model	Recipe Level Coherence	Recipe Step Entailment
Enc-Dec	1.77	0.72
Prior Tech	1.78	0.73
Prior Recipe	1.80	0.76
Prior Name	**1.82**	**0.78**

Table 4: Coherence metrics on generated recipes from test set.

Human Evaluation: We presented 310 pairs of recipes for pairwise comparison (Fan et al., 2018) (details in appendix) between baseline and each personalized model, with results shown in Table 2. On average, human evaluators preferred personalized model outputs to baseline 63% of the time, confirming that personalized attention improves the semantic plausibility of generated recipes. We also performed a small-scale human coherence survey over 90 recipes, in which 60% of users found recipes generated by personalized models to be more coherent and preferable to those generated by baseline models.

6 Conclusion

In this paper, we propose a novel task: to generate personalized recipes from incomplete input specifications and user histories. On a large novel dataset of 180K recipes and 700K reviews, we show that our personalized generative models can generate plausible, personalized, and coherent recipes preferred by human evaluators for consumption. We also introduce a set of automatic coherence measures for instructional texts as well as personalization metrics to support our claims. Our future work includes generating structured representations of recipes to handle ingredient properties, as well as accounting for references to collections of ingredients (e.g. "dry mix").

Generating Highly Relevant Questions

Jiazuo Qiu and **Deyi Xiong***
School of Computer Science and Technology, Soochow University, Suzhou, China
qjzhzw@163.com; dyxiong@suda.edu.cn

Abstract

The neural seq2seq based question generation (QG) is prone to generating generic and undiversified questions that are poorly relevant to the given passage and target answer. In this paper, we propose two methods to address the issue. (1) By a partial copy mechanism, we prioritize words that are morphologically close to words in the input passage when generating questions; (2) By a QA-based reranker, from the n-best list of question candidates, we select questions that are preferred by both the QA and QG model. Experiments and analyses demonstrate that the proposed two methods substantially improve the relevance of generated questions to passages and answers.

1 Introduction

Question generation is to generate a valid and fluent question according to a given passage and the target answer. In general, the answer is a span of words in the passage. QG can be used in many scenarios, such as automatical tutoring systems, improving the performance of QA models and enabling chatbots to lead a conversation.

In the early days, QG has been tackled mainly via rule-based approaches (Mitkov and Ha, 2003; Heilman and Smith, 2010). These methods rely on many handcrafted rules and templates. Constructing such rules is time-consuming and it is difficult to adapt them to other domains.

Very recently, neural networks have been used for QG. Specifically, the encoder-decoder seq2seq model (Du et al., 2017; Zhou et al., 2017; Song et al., 2018) is used to encode a passage and generate a question corresponding to the answer.

Such end-to-end neural models are able to generate better questions than traditional rule-based approaches. However, one issue with the current neural models is that the generated questions are not quite relevant to the corresponding passages and target answers. In other words, the neural QG models tend to generate generic questions (e.g., "what is the name of...?").

In this paper, we propose two methods to deal with this low-relevance issue for QG. First, we present a partial copy method to enhance the existing copy mechanism so that the QG model can not only copy a word as an entire unit from the passage to the generated question but also copy a part of a word (e.g., "start" in "started") to generate a new morphological form of the word in the question. The fine-grained partial copy mechanism enables the QG model to copy morphologically changed words from the passage, increasing the relevance of the generated question to the passage by sharing more words in different forms. Second, we propose a QA-based reranker to rerank QG results. Particularly, we use a neural QA model to evaluate the quality of generated questions, and rerank them according to the QA model scores. Normally, generic questions get low scores from the neural QA model, hence the reranker is able to select non-generic and highly relevant questions.

While alleviating the low-relevance issue, the proposed two methods alone and their combination have also improved the quality of generated questions in terms of both BLEU and METEOR in our experiments.

2 Methods

2.1 The Partial Copy Mechanism

The conventional copy mechanism (Gu et al., 2016; See et al., 2017) can allow the decoder to copy a word from the input passage to the generated question. However, such copy mechanism works at the word level. It cannot copy a part of a word to reproduce an appropriate form of the

*Corresponding author

word in the generated question. In other words, it cannot copy words with morphological changes. However, morphological changes frequently happen when we transform a passage into a question as grammatical functions of some words (e.g., verbs, nouns, adjectives, etc) change.

Let's consider the following example:

> Passage: Teaching started in 1794.
> Question: When did teaching start?

The morphological variants "start", "starts" of "started" in the passage may be used in the generated question.

In order to encourage the decoder to copy the inflected forms of a word from the passage to the generated question, we propose a partial copy mechanism that measures the character overlap rate of an original word in the passage with its copied form in the question. We first detect the overlapped subsequence of characters between words w_1 and w_2 according to the longest common subsequence (LCS) between them. For example, "start" and "started" have LCS "start". Then we calculate the overlap rate C between w_1 and w_2 as follows.

$$C = \frac{|LCS| * 2}{|w_1| + |w_2|} \quad (1)$$

According to this formula, the overlap rate between "start" and "started" is 0.71. The value range of C is $\in [0, 1]$. Full-word copy is of course encouraged as the value of C is 1.

One problem with C is that many unrelated words also have LCS. For example, "a" is the LCS of "append" and "start". The overlap rate of the two words is 0.18 instead of 0. To ensure the effectiveness of the method, we compute the final overlap rate with a threshold γ :

$$C = \begin{cases} C, & \text{if } C >= \gamma \\ 0, & \text{if } C < \gamma \end{cases} \quad (2)$$

Whenever we generate a word in the question, we find its corresponding word in the passage with the highest attention weight. We then calculate the overlap rate C between the two words and use C to re-adjust the probability of the generated word as follows:

$$P_{adj} = P * (1 + \lambda_1 * C) \quad (3)$$

where P is the original generation probability output by the decoder, λ_1 is a hyperparameter whose range is [0, $+\infty$). We normalize all these re-adjusted probabilities to get the final probability distribution.

2.2 The QA-Based Reranking

Since we use the beam search algorithm in the neural QG decoder, we can generate multiple question candidates. We find that the generated question with the highest probability according to the baseline neural QG model is not always the best question.

Partially inspired by Li et al. (2016), we propose a QA-based reranker to rerank the n-best questions generated by the baseline decoder.

In general, the task of the QG model is to estimate the probability $P(q|p, a)$ of a generated question q given the passage p and target answer a. In the QA-based reranker, we re-estimate the quality of a candidate question by calculating the probability of the target answer a given the passage and the generated question q, i.e., $P(a|p, q)$.

In theory, we can combine the two probabilities to rerank generated questions. But in practice, we take a more intuitive and straightforward way to use the F_1 score of a predicted answer by the trained QA model according to the generated question. The F_1 score is calculated at the character level by comparing the generated answer and gold answer (considering the answers as a set of characters). The idea behind this is that a good question allows the QA model to easily find an answer close to the ground truth answer.

The score used to rerank a question candidate is therefore computed as:

$$score = (1 - \lambda_2) * score_1 + \lambda_2 * score_2 \quad (4)$$

where $score_1$ is the log probability of the candidate question estimated by the baseline QG model, $score_2$ is the F_1 score of the predicted answer by the QA model, and λ_2 is a hyperparameter whose range is [0, 1].

3 Experiments

3.1 Datasets

Following previous work, we conducted our experiments on SQuAD (Rajpurkar et al., 2016), a QA dataset which can also be used for QG. The dataset contains 536 articles and over 100k questions. Since the test set is unavailable, Du et al. (2017) randomly divide the raw dataset into

models	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR
Du et al. (2017)	43.09	25.96	17.50	12.28	16.62
Song et al. (2018) (reported in paper)	–	–	–	13.98	18.77
Song et al. (2018) (our re-running)	42.15	27.21	19.53	14.56	19.15
partial copy (λ_1=0.5)	44.13	28.29	20.17	14.95	19.81
partial copy (λ_1=1)	44.33	28.34	20.17	14.95	20.00
partial copy (λ_1=2)	42.34	26.95	19.15	14.16	**20.16**
QA-based reranking (λ_2=0.2)	42.64	27.57	19.77	14.72	19.43
QA-based reranking (λ_2=0.5)	42.50	27.42	19.62	14.56	19.38
QA-based reranking (λ_2=0.8)	42.43	27.34	19.54	14.48	19.34
partial copy + QA-based reranking	**44.61**	**28.78**	**20.59**	**15.29**	20.13

Table 1: Experiment results on the test set.

train/dev/test set. In our experiments, we used the same data split as Du et al. (2017).

3.2 Baseline and Settings

Our baseline is based on the QG model proposed by Song et al. (2018). To be specific, it is a seq2seq model with attention and copy mechanism. The model consists of two encoders and a decoder. The two encoders encode a passage = (p_1,...,p_M) and an answer = (a_1,...,a_N) respectively. Additionally, multi-perspective matching strategies are used to combine the two encoders. With information from the encoders, the decoder generates a question word by word.

We retained the same values for most hyperparameters in our experiments as the baseline system (Song et al., 2018). We used Glove (Pennington et al., 2014) to initialize the word embeddings and trained the model for 10 epochs. Copy and coverage mechanism (See et al., 2017) were included while additional lexical features (POS, NER) were not. We used adam (Kingma and Ba, 2015) as the optimizer during training. The beam size was set to 20 for the decoder.

In the experiments of the partial copy mechanism, we set the threshold γ to 0.7. Three values (0.5, 1 and 2) were tried for λ_1.

In the experiments of the QA-based reranking, we used the SAN model (Liu et al., 2018) as the QA model. 0.2, 0.5 and 0.8 were tried for λ_2.

We used automatic evaluation metrics: BLEU-1, BLEU-2, BLEU-3, BLEU-4 (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014). The calculation script was provided by Du et al. (2017).

3.3 Results

Experiment results are shown in Table 1, from which we observe that our methods substantially improves the baseline in terms of all evaluation metrics.

The combination of the proposed two methods (λ_1 = 1, λ_2 = 0.2) achieve the best performance, gaining 0.73 BLEU-4 and nearly 1 METEOR point of improvements over the baseline (obtained by re-running the source code of the baseline, higher than the results reported in the paper (Song et al., 2018)). The proposed partial copy mechanism alone obtain substantial improvements over the baseline, especially in terms of BLEU-1 and BLEU-2. This is because this method is able to help the decoder copy morphologically changed words from passages. The application of the QA-based reranking obtain further improvements over the partial copy mechanism, indicating that the two methods are complementary to each other.

4 Analysis

Partial copy: We use the method to enhance the existing copy mechanism, making generated questions more relevant to passages and target answers. The average proportion of words (or their other morphological forms) that are copied from the passages in generated questions increases from 75.49% (the baseline) to 78.74%. Under such a mechanism, generic questions such as "what is the name of...?" will be penalized by our method as the overlap rate between words in these generic questions and those in passages is low. On the contrary, questions with higher overlap rate and therefore higher relevance to the input passage are rewarded by the new copy mechanism. In order to testify this hypothesis, we counted the numbers

Question templates	Song et al. (2018)	Our model
What is/was the name of ...?	8,180/13,740	5,618/9,990
What type of ...?	4,942	3,805
What is/was another name ...?	2,731/26	57/3
What is/was the total ...?	470/794	101/62
What is/was it ...?	251/57	111/32

Table 2: Frequency of generic questions generated by the baseline and our methods.

Passage: in the polytechnic sector : wellington polytechnic amalgamated with massey university .
Answer: wellington polytechnic
Question: what school did massey university combine with ?
Baseline: what is the name of the polytechnic sector in the polytechnic ?
Partial copy: who amalgamated with massey university in the polytechnic sector ?

Passage: in practice , catholic services in all provinces were quickly forbidden , and the reformed church became the " public " or " privileged " church in the republic .
Answer: catholic services
Question: what was forbidden in all provinces ?
Baseline: what was the " public " church in the republic ?
QA-based reranking: what was forbidden in all provinces in the republic ?

Table 3: QG examples.

of such generic questions generated by the baseline and our method, which are shown in Table 2. It is clearly seen that the number of generic questions is significantly decreased after the partial copy mechanism is used.

In the first example displayed in Table 3, the phrase "what school" is difficult to be generated as it does not appear in the input passage. The baseline model generates the generic question "what is the name of...?", which is not relevant to the passage and target answer. Such generic questions are generated because the templates of these questions occur frequently in the training data. The trained seq2seq model is prone to generating these "safe" questions, similar to the undiversified response generation in seq2seq-based dialogue model (Li et al., 2016). In contrast, our model is able to generate a more relevant question including a rare word "amalgamated" as the word has a high overlap rate.

QA-based reranking: In our experiments, a total of 2,099 questions were reranked. Among them, 1,117 examples achieve a higher BLEU-4 score after reranking, while only 821 examples have a lower BLEU-4 after reranking.

In the second example of Table 3, the question with the highest score generated by the baseline is "what church", while the ground truth question is asking "what was forbidden". Since the generated questions to be reranked are different to each other, the QA model naturally finds different answers to these questions. For "what church", the QA model detected "reformed church" as the answer while for "what was forbidden", the QA model correctly detected the target answer "catholic services". Therefore, the QA-based reranker is able to find the answer-relevant questions.

5 Related Work

The neural QG is an emerging task. Unlike the extractive QA, most neural QG models are generative. Du et al. (2017) pioneer the neural QG by proposing neural seq2seq models to deal with the task. Unfortunately, they do not use the target answer for QG. At the same time, Zhou et al. (2017) present a similar model for QG. They use answer position embeddings to represent target answers and explore a variety of lexical features.

After that, many QG studies have been conducted on the basis of the widely-used seq2seq architecture together with the attention and copy mechanism. Song et al. (2018) propose two encoders for both the passage and the target answer. Du and Cardie (2018) employ coreferences as an additional feature. Kim et al. (2019) propose a model of answer separation. Yuan et al. (2017) and Kumar et al. (2018) adopt reinforcement learning to optimize the generation process.

QA and QG are closely related to each other. Tang et al. (2017) treat QA and QG as dual tasks, and many other studies use QG to enhance QA or jointly learn QG and QA (Duan et al., 2017; Wang et al., 2017; Sachan and Xing, 2018).

6 Conclusion

In this paper, we have presented two methods to improve the relevance of generated questions to the given passage and target answer. Experiments and analyses on SQuAD show that both the partial copy mechanism and QA-based reranking improve the relevance of generated questions in terms of both BLEU and METEOR.

Improving Neural Story Generation by Targeted Common Sense Grounding

Huanru Henry Mao, Bodhisattwa Prasad Majumder,
Julian McAuley, Garrison W. Cottrell
Department of Computer Science and Engineering
UC San Diego
{hhmao, bmajumde, jmcauley, gary}@eng.ucsd.edu

Abstract

Stories generated with neural language models have shown promise in grammatical and stylistic consistency. However, the generated stories are still lacking in *common sense reasoning*, e.g., they often contain sentences deprived of world knowledge. We propose a simple multi-task learning scheme to achieve quantitatively better common sense reasoning in language models by leveraging auxiliary training signals from datasets designed to provide common sense grounding. When combined with our two-stage fine-tuning pipeline, our method achieves improved common sense reasoning and state-of-the-art perplexity on the *WritingPrompts* (Fan et al., 2018) story generation dataset.

1 Introduction

Story generation is the task of automatically producing compelling creative writing. Recent advances in language modeling have yielded thematic and stylistic coherence in story generation through large scale pretraining of Transformer models (Vaswani et al., 2017). The recent introduction of the General Pre-trained Transformer v2 (GPT2) (Radford et al., 2019)—a high-capacity Transformer trained on a large, diverse corpus of text crawled from the web (called WebText)—is capable of generating stylistically coherent text but commonly produces text with logical inconsistencies. For example, in one sample the model writes: "*It was a sunny, warm summer night*". Obviously, this writing is nonsense as it cannot be sunny at night. The lack of common sense reasoning in such a strong language model suggests that minimizing next-token perplexity alone may be insufficient in producing models that can compose sensible stories.

In this paper, we consider the challenge of *common sense reasoning* (CSR) in language modeling for story generation. Unlike other work in the CSR literature (Storks et al., 2019), which evaluates CSR in isolation, we are specifically interested in a generative model's likelihood of producing text that exhibits common sense. Evaluating common sense qualitatively in a model's samples is difficult, as it is subject to human bias and dependent on sampling procedure. We propose evaluating the common sense of a model automatically by ranking the model's perplexity on spurious (plausible, but nonsense) text completions from SWAG (Zellers et al., 2018) and Story Cloze (Mostafazadeh et al., 2016) datasets, which are designed for common sense grounding.

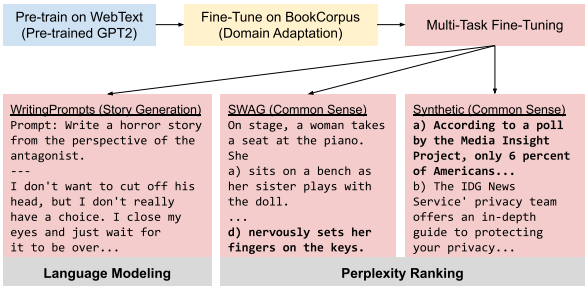

Figure 1: Our two-stage fine-tuning pipeline with auxiliary multi-task learning. For perplexity ranking examples, bolded text indicates the correct answer. For **synthetic**, the correct choice is written by a human, and the wrong choice is generated by a neural network.

Our contributions are as follows: We propose a simple way to define *better* CSR in generative models, which leads to an auxiliary multi-task objective to directly bias our model to generate text with better common sense. When fine-tuning is combined with multi-task learning in a two-stage pipeline, we improve the model's CSR and outperform state-of-the-art perplexity on the WritingPrompts (Fan et al., 2018) dataset.[1]

2 Tasks

2.1 Primary Task: Language Modeling

Our primary task is to perform language modeling (Elman, 1990; Bengio et al., 2003; Dai and Le, 2015) on the WritingPrompts dataset. A language model learns to assign the probability of a text sequence $X = x_1, \ldots, x_T$ using the conditional probability factorization:

$$P(X) = \prod_{t=1}^{T} P(x_t | x_{1:t-1}). \quad (1)$$

We train our model using a standard cross-entropy loss between next-step true tokens and predicted probabilities given current tokens.

WritingPrompts (Fan et al., 2018) is a dataset of prompts and short stories crawled from Reddit. The aim of the dataset is to produce a story given a free-text prompt. We reduce this conditional text generation task into a generic language modeling task by simply concatenating the prompt before the story and treating a prompt-story pair as one input to the Transformer decoder model. This human-readable format (example in Figure 1) is chosen because GPT2 may have been trained on similarly formatted text from the web. When sampling, we can either seed the model with a prompt or allow it to generate its own prompt.

2.2 Auxiliary Task: Perplexity Ranking

Our auxiliary task aims to bias the model to produce text with better common sense (which we refer to as *sensible* text). Given a set of text sequences $S = \{S_1, \ldots, S_N\}$, where S_1 is a sensible text sequence and the rest $S_2, \ldots, S_N$ are spurious text sequences, we operationally define *better* as the model assigning higher probability (Eq. 1) to S_1 versus the average probability over spurious text sequences $S_2, \ldots, S_N$. Using this definition, it is possible to directly optimize the model to assign $P(S_1)$ to be higher than any $P(S_i)$. Formally, we define the probability of the model choosing the correct sequence S_1 over spurious sequences as the softmax over the length-normalized log probabilities of all plausible sequences:

$$\frac{\exp(\frac{1}{T_1} \log P(S_1))}{\sum_{i=1}^{N} \exp(\frac{1}{T_i} \log P(S_i))} \quad (2)$$

where T_i refers to the length of the text sequence S_i. Thus, we can practically minimize the negative log-likelihood of Eq. 2 by reusing the same softmax layer used for the primary language modeling task. We refer to this objective as *perplexity ranking* as it constrains the model to rank sensible text to have lower perplexity than spurious ones.

Dataset	Size	Role
WritingPrompts	272K Stories	Story Generation
BookCorpus	10K Books	Domain Adaptation
SWAG	73K Questions	Common Sense
Synthetic	250K Pairs	Common Sense

Table 1: Datasets, training set sizes and their roles

SWAG: In order to train on this auxiliary objective, we need training examples in the format of multiple choice questions, where the correct choice corresponds to the text with the best common sense. We choose the SWAG dataset (Zellers et al., 2018), a dataset that provides 4-way multiple choice common sense questions that are adversarially filtered to seem plausible to language models. Unlike other CSR datasets (Talmor et al., 2018), SWAG forms its question and answer as two full sentences, which we can concatenate into a single string to find its probability. This makes it suitable for perplexity ranking.

Synthetic: To facilitate perplexity ranking on SWAG, we additionally use a synthetic dataset that consists of 250K pairs of human written text from WebText and samples generated by the original 1.5B parameter version of the GPT2 model.[2] These samples are many paragraphs long and truncated to a maximum of 1024 tokens. We frame these pairs as a 2-way classification problem and train the model by perplexity ranking to assign higher likelihood to human written text over synthetic examples. The assumption we make is that human written text is more sensible than text written by neural language models. Hence, on average, this promotes the model to assign higher probabilities to sensible text.

3 Training Pipeline

We introduce a two-stage training pipeline (Figure 1) to improve model performance both in terms of perplexity and CSR on story generation. Our pipeline uses four different datasets (Table 1), each of which plays a role in improving model performance. Our model architecture is the 117M parameter version of GPT2, using the pre-trained

[2]We obtained the samples from https://github.com/openai/gpt-2-output-dataset

weights provided by Radford et al. (2019). We refer readers to Vaswani et al. (2017) for details of the Transformer architecture.

We first perform intermediate fine-tuning (Phang et al., 2018; Howard and Ruder, 2018) of the pre-trained GPT2 on BookCorpus (Zhu et al., 2015) as a method of domain adaptation from WebText to the domain of stories. BookCorpus is a dataset that contains over 10,000 free books crawled from the web.[3] We train on this corpus using our language modeling objective. Next, we fine-tune on the target WritingPrompts dataset with a multi-task learning objective. We alternate training between the language modeling objective on WritingPrompts and perplexity ranking on SWAG and our synthetic dataset. Training details and hyperparameters are in the appendix.

4 Evaluation

We perform three types of evaluation on the model to assess its readability, reliance on the prompt (prompt ranking) and CSR.

Readability is measured in terms of model perplexity on the test set of WritingPrompts. Because GPT2 uses subword tokenization (Sennrich et al., 2016), it is not directly comparable to the word-level perplexity obtained in Fan et al. (2018). We estimate the corresponding word-level perplexity by taking the product of each subword's probabilities to obtain probabilities for each word. Both sub-word perplexity and word-level perplexities are reported in our experiments.

Prompt ranking (Fan et al., 2018) assesses how well a model matches a story to its given prompt. This is measured by computing the likelihood of stories conditioned under ten different prompts, nine of which are randomly sampled and one is the true prompt. Following Fan et al. (2018), we count a random story sample as correct when it ranks the true prompt with the lowest perplexity. We compute the accuracy from 1000 random samples.

CSR is evaluated on two multiple choice datasets – SWAG and Story Cloze (Mostafazadeh et al., 2016). We rank the perplexity computed by the model for each example and count it as correct if the lowest perplexity matches the answer. The SWAG validation set provides a proxy of how well the model generalizes in CSR to unseen examples. To ensure generalization beyond SWAG, we also perform *zero-shot* evaluation on the Winter 2018 Story Cloze validation set. Story Cloze consists of 5-sentence stories with correct and spurious endings. It is similar to SWAG but serves as an in-domain dataset to specifically test the model's performance at CSR in story telling.

[3]We crawled BookCorpus from https://www.smashwords.com/

Premise: *John and Billy became very skilled at beer pong. They entered a contest in college. They won the contest and advanced to the next level. The next level sent them to Vegas.*
GPT2 → BC → WP output:
1. They would fall.
2. Later, they figured out what it was all about.
GPT2 → BC → WP + SWAG + SYNTH output:
1. They have been ranked number one in their respective leagues and are considered the best in their respective countries.
2. They then moved to the bars.

Table 2: Top two highest likelihood story completions from 10 random completion samples generated by our models when primed with a premise from the Story Cloze validation set.

5 Results and Discussion

We analyze our pipeline and report the results in Table 3. We also generate stories by sampling from our model using nucleus sampling with $p = 0.9$ (Holtzman et al., 2019). We present example story completions in Table 2 and full sampled stories in our appendix and Table 4.

Pre-training: We compare our models with the attention-based Fusion Model (Fan et al., 2018), which has been designed for and trained on WritingPrompts. We observe that a pre-trained GPT2 performing zero-shot inference on WritingPrompts (GPT2 in Table 3) is a strong baseline. By fine-tuning GPT2 on WritingPrompts (GPT2 → WP), we outperform the Fusion Model in perplexity. All our models outperform the Fusion Model in prompt ranking, which suggests that task-specific models are unnecessary given pre-training.

Intermediate Fine-Tuning: The first stage in our pipeline performs intermediate fine-tuning of GPT2 on BookCorpus (GPT2 → BC in Table 3). To confirm that intermediate fine-tuning helps downstream performance, we evaluate the zero-shot performance of the model on WritingPrompts. This yields perplexity and prompt ranking improvements compared to GPT2, demonstrating successful domain adaptation. Perform-

Models	SW PPL	Word PPL	Prompt Ranking	SWAG	Story Cloze
Fusion Model (Fan et al., 2018)	-	36.6	16.3%	-	-
GPT2	35.57	51.29*	49.8%	48.1%	58.8%
GPT2 → BC	29.10	42.01*	62.7%	50.5%	59.6%
GPT2 → WP	21.68	30.65*	80.0%	49.8%	58.3%
GPT2 → BC → WP	20.79	29.56*	**80.6%**	51.4%	59.1%
GPT2 → BC → WP + SWAG	**20.78**	**29.52***	78.9%	75.3%	63.2%
GPT2 → BC → WP + SWAG + SYNTH	**20.78**	29.63*	80.1%	**76.3%**	**64.1%**

Table 3: Performance of models on the test set of WritingPrompts and validation set of SWAG and Story Cloze. **SW PPL** and **Word PPL** refer to sub-word and word-level perplexity on WritingPrompts respectively. WP refers to WritingPrompts, BC refers to BookCorpus and SYNTH refers to training with our 250K synthetic examples. The asterisk * refers to an estimated score derived from BPE PPL.

ing two-stage fine tuning (GPT2 → BC → WP) further improves perplexity and CSR. We hypothesize the improvement in CSR is due to BookCorpus being a higher quality dataset written by authors when compared against WebText.

Multi-tasking Fine-Tuning: Performing multi-task learning on WritingPrompts and SWAG (GPT2 → BC → WP + SWAG) unsurprisingly yields significant improvements on the SWAG validation set. More importantly, the zero-shot performance on Story Cloze also improved, indicating that it was able to generalize its common sense knowledge. We also see qualitatively improved results when generating story completions (Table 2). The addition of the synthetic dataset we introduced (GPT2 → BC → WP + SWAG + SYNTH) further boosts performance on CSR. Other metrics are negligibly affected by the auxiliary tasks.

6 Related Work

Story Generation: Recent work in neural story generation (Kiros et al., 2015; Roemmele, 2016) has shown success in using hierarchical methods (Yao et al., 2018; Fan et al., 2018) to generate stories. In these schemes, a neural architecture is engineered to first generate an outline or a prompt, then to expand the prompt into a full-length story. Our work performs hierarchical generation, but our main focus is on achieving better common sense in the generated text rather than engineering task-specific architectures.

Common Sense Reasoning: Common sense reasoning (CSR) has been studied through many benchmarks such as SWAG (Zellers et al., 2018), Story Cloze (Mostafazadeh et al., 2016), the Winograd Schema Challenge (Levesque et al., 2012), and CommonsenseQA (Talmor et al., 2018). Recent methods (Peters et al., 2018; Radford et al., 2018) on these benchmarks focus on large-scale pre-training of language models. They show that transfer learning is an effective means to improve CSR and our fine-tuning pipeline builds upon these techniques. Our results on SWAG and Story Cloze are far from state-of-the-art (Devlin et al., 2018). However, our aim is not to directly tackle SWAG or Story Cloze, but instead to use it as a constraint on our model and a proxy to estimate the likelihood of generating sensible text.

Multi-task Learning: Multi-task learning (MTL) introduces inductive bias in a model, helps reduce overfitting and increases robustness (Caruana, 1993; Ruder, 2017; McCann et al., 2018). Our work builds upon MTL principles as we introduce auxiliary tasks to specifically tackle CSR (Søgaard and Bingel, 2017). Contrary to conventional auxiliary multi-task learning (Howard and Ruder, 2018), which adds an additional classifier to the final representations of the model for learning auxiliary tasks, we use perplexity ranking, which does not introduce additional parameters. We argue that perplexity ranking, by definition, guarantees that the model will generate sensible text with a higher probability.

7 Conclusion

We demonstrated a simple way to improve the likelihood that a particular language model generates sensible text. We introduced a training pipeline that leverages transfer and multi-task learning to improve perplexity and CSR. One limitation of our approach is its dependence on SWAG, which only provides short-term common sense grounding. While our synthetic dataset may mitigate this issue, story-level coherence is unlikely to be achieved using this method alone. We leave this investigation for future work.

Prompt: Aliens start abducting humans.
Steve smashed his Xbox controller at the table. He lit a smoke and took another hit. Two exes were in the room, just outside the door. "What are you doing?" he said. "Get back in there." "I-I've never actually seen any of the aliens," he replied, dispelling the smoke from his mouth. The two aliens were smirking. "Is this your first time?" the ex asked. "The last one tried to kill us." The aliens looked at each other. "Are you sure you are ok? It looks like you are severely hurt." "Yeah, I'm fine. I just saw the door open. I'm just fine," he replied. "We're fine? You do that every day, Steve, but we still haven't gotten past this door," the ex said, resting a hand on the UFO that stood in the doorway. "I'm fine." "Good! I've never seen anything like it, have I Steve?" Steve stood up. "Yes I have." He picked up his controller. "Ok, shoot!" the aliens yelled. "This is no time to hesitate." Steve put the controller to his ear. "Who are you? What are you doing here?" The aliens pulled the gun towards him. "We-we're here to kidnap you." Steve put his hands on the UFO, and pulled the trigger. The gun went off. The aliens, scared, immediately realized where they were and ran towards the other two aliens. They kept running. Steve continued on his way towards his childhood toy house. When he was just a teen, he had built his own helicopter. He always felt they had lost. The abandoned building on the edge of the highway he and the ex had entered had been the perfect landing spot. He didn't know where they were. He didn't know how they were going to get out of there. There were bodies everywhere.

Table 4: Sample generated by GPT2 → BC → WP + SWAG + SYNTH primed with the same prompt as Fan et al. (2018).

Abstract

Text summarization is considered as a challenging task in the NLP community. The availability of datasets for the task of multilingual text summarization is rare, and such datasets are difficult to construct. In this work, we build an abstract text summarizer for the German language text using the state-of-the-art "Transformer" model. We propose an iterative data augmentation approach which uses synthetic data along with the real summarization data for the German language. To generate synthetic data, the Common Crawl (German) dataset is exploited, which covers different domains. The synthetic data is effective for the low resource condition and is particularly helpful for our multilingual scenario where availability of summarizing data is still a challenging issue. The data are also useful in deep learning scenarios where the neural models require a large amount of training data for utilization of its capacity. The obtained summarization performance is measured in terms of ROUGE and BLEU score. We achieve an absolute improvement of +1.5 and +16.0 in ROUGE1 F1 (R1_F1) on the development and test sets, respectively, compared to the system which does not rely on data augmentation.

1 Introduction

Automatic text summarization is considered as a challenging task because while summarizing a piece of text, we read it entirely to develop our understanding to prepare highlighting its main points. Due to the lack of human knowledge and language processing abilities in computers, automatic text summarization is a major non-trivial task (Allahyari et al., 2017).

Two major approaches for automatic summarization are: extractive and abstractive. The extractive summarization approach produces summaries by choosing a subset of sentences in the original text. The abstract text summarization approach aims to shorten the long text into a human-readable form that contains the most important fact from the original text (Allahyari et al., 2017; Kryściński et al., 2018).

The deep learning-based neural attention model when applying to abstract text summarization performs well compared to standard learning-based approaches (Rush et al., 2015). Abstract text summarization using the attentional encoder-decoder recurrent neural network approach shows a state-of-the-art performance and sets a baseline model (Nallapati et al., 2016). Further improvements are introduced to the baseline model by using the pointer generator network and coverage mechanism using reinforcement learning based training procedure (See et al., 2017; Paulus et al., 2017). There is an inherent limitation to natural language processing tasks such as text summarization for resource-poor and morphological complex languages owing to a shortage of quality linguistic data available (Kurniawan and Louvan, 2018). The use of synthetic data along with the real data is one of the popular approaches followed in machine translation domain for the low resource conditions to improve the translation quality (Bojar and Tamchyna, 2011; Hoang et al., 2018; Chinea-Rıos et al., 2017). The iterative back-translation (e.g. training back-translation systems multiple times) were also found effective in machine translation (Hoang et al., 2018). We explore similar approaches in our experiments for the text summarization task.

The organizations of this paper is as follows: Section 1 describes related work on abstract text summarization. Section 2 explains the techniques followed in our work. Section 3 describes the dataset used in our experiment. Section 4 explains the experimental settings: models and their parameters. Section 5 provides evaluation results with

analysis and discussion. Section 6 provides conclusion to the paper.

2 Method Description

Across all experiments performed in this paper, we have used the Transformer model as implemented in OpenNMT-py[1] (Vaswani et al., 2018; See et al., 2017). The Transformer model is based on encoder/decoder architecture. In context to summarize, it takes text as input and provides its summary.

We use synthetic data as shown in Figure 1 to increase the size of the training data.

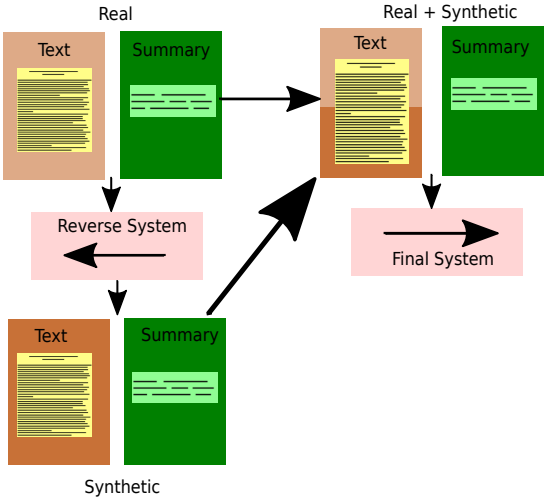

Figure 1: Generation of synthetic data using a reverse system. To generate synthetic data, first, a system in the reverse direction (i.e. source as summary and target as text) is trained and then used to generate text for the given summary. Then both the real and synthetic data acts as input to the final system.

3 Dataset Description

We use German wiki data (spread across different domain) collected from the SwissText 2019[2] (real data) and Common Crawl[3] data (synthetic data) in our experiment. The statistics of all the datasets are shown in Table 1.

3.1 SwissText datasets used as real data

We divide the 100K SwissText dataset (downloaded from SwissText 2019 website) into three subsets: train, dev, and test in 90:5:5 ratio (i.e. 90K for training, 5K for development and 5K for the test data). The experiments performed over these datasets are described in Section 4.3 (denoted as S1 experimental setup).

Dataset	#Text	#Summ
Train_Real(SwissText)	90K	90K
Train_RealSynth(Swiss+CC)	190K	190K
Train_RealSynthRegen(Swiss+CC)	190K	190K
Dev(SwissText)	5K	5K
Test(SwissText)	5K	5K

Table 1: Statistics of the experimental data which include the number of texts and their summaries.

3.2 Common Crawl dataset used as synthetic data

The data crawled from the Internet (Common Crawl) used to prepare synthetic data to boost the training. The steps followed to create the synthetic dataset as follows:

Step 1: **Build vocab:** We create vocabulary using SwissText based on the occurrence of the most frequent (top N) German words.

Step 2: **Sentence selection:** The sentences from the Common Crawl data are selected with respect to the vocabulary based on the threshold we provide (e.g. a sentence has 10 words and the threshold is 10% (0.1)). For a sentence to be selected, at least 1 out of 10 words should be in the vocabulary.

Step 3: **Filtering:** Select random sentences (e.g. 100K) from the selected Common Crawl data in the previous step.

Step 4: **Generate summary:** The 100K data obtained from the previous step are used as a summary and required to generate corresponding text. We use the reverse trained model where we provide the summary as source and target as text. This results in the text as well as the corresponding summary as additional data to be utilized along with real data (SwissText).

Eventually, the 190K dataset is created (denote as Train_RealSynth) as a combination of 90K SwissText train data (real) and 100K synthetic data. This dataset is used in the experimental setup S2 (described in details in Section 4.3).

4 Experimental Setup

This section describes our experiments conducted for the text summarization task.

[1] http://opennmt.net/OpenNMT-py/Summarization.html
[2] https://www.swisstext.org/
[3] http://commoncrawl.org/

Setting	Dataset	R1_F1	R2_F1	RL_F1	BLEU
S1	Dev	43.9	28.5	46.3	12.6
	Test	39.7	22.9	42.2	9.0
S2	Dev	45.4	29.8	47.4	14.0
	Test	55.7	41.8	57.6	20.8
S3	Dev	44.3	28.5	46.4	13.1
	Test	40.0	23.0	42.3	9.4

Table 2: Evaluation results of our models on development (dev) and testing (test) sets. The automatic evaluation scores in terms of Rouge (R1_F1, R2_F1, RL_F1) and BLEU for the output summaries are shown in the table.

4.1 Prepossessing

The preprocess step involves preprocessing the dataset such that source and target are aligned and use the same dictionary. Additionally, we truncate the source length at 400 tokens and the target length at 100 tokens to expedite training (See et al., 2017).

4.2 Model Parameters

The Transformer model is implemented in OpenNMT-py. To train the model, we use a single GPU. To fit the model to the GPU cluster, a batch size equal to 4,096 is selected for training. The validation batch size is set to 8. We use an initial learning rate of 2, drop out of 0.2 and 8,000 warm-up steps. Decoding uses a beam size of 10 and we did not set any minimum length of output summary.

4.3 Model Setup

We use 3 settings: (i) real data (we set this as the baseline in our experiment), (ii) real data and synthetic data, and (iii) real and regenerated synthetic data for the summarization task, described as follows:

1. *S1: Transformer model using Train_Real data*

   In this setup, we use the "Train_Real" data for training the Transformer model.

2. *S2: Transformer Model using Train_RealSynth data*

   In this setup, we use the "Train_RealSynth" data for training the Transformer model. As the balance between real and synthetic data is an important factor, we maintain a 1:1 ratio (e.g. 1 (real) :1 (synthetic)) for our experiment (Sennrich et al., 2016).

3. *S3: Transformer Model using Train_RealSynthRegen data*

   We propose an iterative approach to improve the quality of synthetic summaries. In this setup, after training a system with (real+synthetic) data, it is used to regenerate synthetic data for the final system. As a result, the input data to the final system is a combination of real and regenerated synthetic data as shown in Figure 2.

4.4 Training Procedure

The copying mechanism is applied during training. It allows the summarizer to fall back and copy the source text when encounters $< unk >$ tokens by referencing to the softmax of the multiplication between attention scores of the output with the attention scores of the source (See et al., 2017). The systems are trained for 300K iterations.

5 Evaluation and Discussion

We evaluate the results for every 10,000 iterations on the dev and test set. The automatic evaluation results based on the dev and test set are shown in Table 2 with sample summaries in Table 3. To evaluate the proposed algorithms, we use ROUGE (Recall-Oriented Understudy for Gisting Evaluation) score, which is a popular metric for text summarization task, and has several variants like ROUGE-N, and ROUGE-L, which measure the overlap of n-grams between the system and reference summary (LIN, 2004). We use ROUGE_1 F1 (R1_F1), ROUGE_2 F1 (R2_F1), and ROUGE_L F1 (RL_F1) for scoring the generated summary. In addition, we also use the SacreBLEU[4] evaluation metric (Post, 2018).

Figure 3 presents the learning curves for the models (S1 and S2) on the development set. It can be seen that there is a variance (e.g. word

selection, summary length) for model S2 generated summary as compared with model S1. During manual verification, we found that the summaries generated without a minimum length constraint appear better compared to summaries with minimum length constraint. Although we do not explicitly specify a minimum length parameter for generating summaries for the models, the average length of words generated by model S2 (e.g. 41.42 words) is longer than the model S1 (e.g. 39.81 words). Some data (e.g. name, year) were found inconsistent during a comparison of the generated summary with respect to the reference. There is a variance in summaries generated by model S3 as compared to S2 and S1. In terms of Rouge score model S3 outperforms model S1 but perform worse than model S2 (see Table 2).

6 Conclusion

In this paper, we highlighted the implementation of synthetic data for the abstract text summarization task under low resource condition, which helps improving the text summarization system in terms of automatic evaluation metrics. As the next step, we plan to investigate: i) synthetic summarization data, and ii) applying transfer learning on text summarization for the multilingual low resource data set with little or no ground truth summaries (Keneshloo et al., 2018).

Abstract

We present a novel approach for generating poetry automatically for the morphologically rich Finnish language by using a genetic algorithm. The approach improves the state of the art of the previous Finnish poem generators by introducing a higher degree of freedom in terms of structural creativity. Our approach is evaluated and described within the paradigm of computational creativity, where the fitness functions of the genetic algorithm are assimilated with the notion of aesthetics. The output is considered to be a poem 81.5% of the time by human evaluators.

1 Introduction

Poem generation is a challenging task for creative NLG (natural language generation) requiring structural integrity in the form of rhyming and meter, grammatical correctness and figurative expression. Poems are meant to be interpreted and therefore the meaning they convey cannot be fully explained by semantics, but they rather require an exploration into the notion of pragmatics.

In this paper, we present a novel approach based on a genetic algorithm for creating poetry in Finnish from the stand point of computational creativity. In addition to solving problems related to poems in general, the morphosyntactically complex Finnish sets additional requirements for producing grammatical output.

Computational creativity can be seen as a search for creative artefacts in a conceptual space (cf. Wiggins, 2006). Therefore the use of genetic algorithm for a creative task is reasonable as it conducts a search and picks out the most suitable candidates based on its fitness function. An important aspect for creativity is that the system should be able to assess its own creations, a notion called appreciation (Colton, 2008) or aesthetic function (Colton et al., 2011) in the literature. The fitness function of the genetic algorithm serves for this exact purpose, as it can score the output in terms of different aesthetic dimensions.

2 Related work

In the past, poetry generation has been studied both from the point of view of computational creativity and natural language generation. Poem generation has been tackled with a variety of different methods such as case-based reasoning (Gervás, 2001), templates (Colton et al., 2012), translation with WFSTs (weighted finite-state transducers) (Greene et al., 2010), text transformation via word embeddings (Bay et al., 2017) and conditional variational autoencoders (Li et al., 2018). As the field of poem generation has been broadly discussed by Oliveira (2017), we dedicate the rest of this section to describing the existing poetry generation work conducted for Finnish within the computational creativity paradigm. We also discuss some previous approaches using genetic algorithms.

One of the first takes on Finnish poem generation is the P. O. Eticus system (Toivanen et al., 2012). P. O. Eticus uses a corpus of human authored poems. These poems are used as templates for generating new poetry. In practice, the system takes a random poem from the corpus, conducts a morphological analysis on it and replaces some of the words in the existing poem. The replaced words are inflected to match the morphology of the original word.

Another take on the poetry generation in Finnish is that of Kantosalo et al. (2015). This approach is presented as a part of a poem authoring system. How this generator operates is that it takes sentences form children's books stored in its corpus based on a shared keyword. These sentences serve as verses, or poem fragments, and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5999–6004,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

they are output one after another forming a generated poem. As the system does not alter text at all, it does not have to deal with the complexities of the Finnish morphology.

The most recent work on Finnish poem generation is the work presented by Hämäläinen (2018a). This approach consists of individual rule-based verse generators, each of which produces structurally different verses with different types of figurative expression, such as metaphors, tautology, comparison and so on. The verse generators are applied in the order defined by hand-written poem structures. Semantic cohesion is achieved by the fact that each verse generator outputs a noun to the following verse generator in the poem structure. This guarantees that verses are always coherent to some extent with the verse that immediately precedes them. This generator is in use in the creative internet application Poem Machine tailored for co-creativity (Hämäläinen, 2018b).

The previous approaches in Finnish poem generation covered in this section are limited in terms of structural creativity. The approaches are either limited by the structure imposed by the existing poems or sentences, or the hand-written verse structures. The approach we present in our paper showcases more creative freedom on the structural level. This, however, is challenging due to the complicated morphosyntax of Finnish; structural changes can easily render the results nonsensical as wrong morphology in an incorrect syntactic position will make the entire sentence nongrammatical. We take this into account in our proposed method.

Genetic algorithms have been used in the generation of poetic language before. Although not full poem generation, Hervás et al. (2007) have used genetic algorithms for generating alliterations in Spanish. In terms of full poetry generation, Manurung et al. (2012) aim for *grammaticality*, *meaningfulness* and *poeticness* with their genetic algorithm approach. Their approach tires to maximize the similarity of the poem meter to the target meter, and the poem semantics to the target semantics, while still retaining grammaticality.

A recent approach to poem generation with genetic algorithms, TwitSong 3.0 (Lamb and Brown, 2019), is based on a mined corpus of sentences that are used as verses in poems based on their inter-compatibility in terms of rhyming. They base their fitness functions on the following metrics: (*meter, emotion, topicality* and *imagery)*. The fitness functions operate on verse level. They solve emotion and imagery with existing lexicons, topicality is assessed based on trigram and keyword similarity with the desired topic and meter is scored based on how close it is to a iambic meter.

3 Poem Generator

This section is dedicated to describing the data used for poem generation, the genetic algorithm and how the Finnish morphosyntax is solved by the system. Special attention is paid to describing the fitness functions, according to which the system can rank its creations.

3.1 Data

We crawl Wikisources[1] for Finnish poetry. This way we obtain 6,189 poems. We parse the poems by using the Finnish dependency parser (Haverinen et al., 2014) to obtain syntactic relations, morphological features, part of speech and lemma for each word. This constitutes our poem corpus, denoted as P, with verse-level syntactic parsing. These poems are used by the genetic algorithm for the initial population, where a stanza of a human authored poem is treated as one poem.

For semantics, we use the pretrained word2vec word embeddings[2] trained on the Finnish Internet Parsebank (Kanerva et al., 2014). This word2vec model has been trained on lemmatized data, which is important as we are interested in obtaining replacement words in an uninflected form.

3.2 Genetic Algorithm

Genetic algorithms are inspired by evolution taking place in the real world. They have an initial set of individuals forming a population. These individuals are then exposed to evolutionary processes such as mutation and crossover. After a generation, the fittest individuals survive to the next generation and the evolutionary process is repeated. For modeling this process, we use the Python library DEAP (Fortin et al., 2012) as the genetic algorithms framework.

We employ a standard $(\mu + \lambda)$ genetic algorithm, which has previously been used in computational creativity applications (see Alnajjar et al.,

[1] https://fi.wikisource.org

[2] http://bionlp-www.utu.fi/fin-vector-space-models/fin-word2vec-lemma.bin

2018). The method begins by constructing an initial population and then evolving it, while optimizing certain parameters, throughout G generations. At each generation step, the fittest μ individuals in the current population and the λ offspring are selected to represent the next population. We empirically set μ and λ to 100 and G to 25. Additionally, the algorithm takes two user-defined inputs, a poem p and a theme t. For our case, we considered a theme t as a single word representing an abstract concept such as *nature*; alternatively, a set of words could be used instead to represent a more focused theme (e.g. *tree*, *forest*, *flower*, ... etc).

3.2.1 Initial Population

To build an initial population containing poems with various syntactic structures, the method makes μ copies of the input poem p. For each poem, the method then replaces one verse in it with a random verse from a different poem existing in the poem corpus P.

3.2.2 Mutation and Crossover

In our method, we implement one type of mutation which selects a random content word in the poem. The term content word in this case refers to a word that belongs to an open class part-of-speech category. The selected word is substituted with another semantically similar word, which is determined as follows. Let w be the random content word selected to be replaced, the method retrieves the top 300 semantically similar words to w as candidate replacements from the word2vec model. Thereafter, the method uses UralicNLP (Hämäläinen, 2019) to perform morphological analysis on all candidate words. The candidate words that have a different part-of-speech tag than the original word w are omitted out. Out of the remaining candidate words, a random word is picked to substitute w.

We use a single-point crossover at the verse-level. In practice, this means that during the evolutionary process two poem individuals are selected and a single point at the beginning of their verses is chosen at random. Verses after that point are swapped between them.

3.2.3 Fitness Functions

The genetic algorithm assesses the individuals based on six metrics that evaluate the poem's structure and one metric that evaluates semantics. The difference in the number of syllables in verses and in the poetic foot, as measured by the distribution of long and short syllables, are contrasted to the original poem. The genetic algorithm is set to minimize these values to keep the difference minimal. As not changing the poem at all would result in the minimum difference in these values, we penalize identical verses by giving them a distance of 20. This way the genetic algorithm tries to make changes so that results following the original meter are preferred.

The number of full rhymes, assonance rhymes and consonance rhymes in between the verses of each generated poem are used as metrics to assess to overall poetic quality of the individuals. The number of alliterating words is counted within verses as this type of rhyme is traditionally occurring within verses in Finnish poetry. The values given by these four metrics are maximized by the genetic algorithm to get the maximum number rhyming words in the final outputs.

The last metric measures the average semantic similarity of the words in the poem to the input theme t with the word2vec model. Maximizing this function pushes the evolutionary process towards creating poems that are close in semantics to the desired input theme.

As we are employing multiple objective functions in our genetic algorithm, we resort to using a non-dominant sorting algorithm (NSGA-II) (Deb et al., 2002) for optimizing these functions. In short, the algorithm selects individuals that are not dominated by any other individual. An individual x is considered to be dominating another if its scores on all objective functions are greater than or equal to y's and it is always better than y on at least one objective.

3.3 Surface Generation

As the genetic algorithm does substitutions on the level of lemmas, it is important to be able to turn the verses with new lemmas into grammatical sentences. This is not only needed for presenting the final output produced by the genetic algorithm to people, but also for the fitness functions to work.

In Finnish, the surface form of a word (morphological realization) is affected by two mechanisms: agreement and government. The former means that certain words have to share morphological features in a sentence. For example, adjectives will have to follow the case and number of the noun they modify, like so: *punainen talo* (a

red house) and *punaisessa talossa* (in a red house). This can be accounted for just by inflecting the replacement word with the morphology of the original word. For this purpose we use Omorfi (Pirinen et al., 2017) which implements Finnish morphology as an FST (finite-state transducer).

Government, on the other hand, requires some additional work. In government, words affect on each other morphologically in a way that depends on the governor. This means that if a governor word is replaced by another one in the sentence, the morphology of the governed word needs to adapt to the change. In concrete, given an original verse *uneksin hatusta* (I dream of a hat) and a change of the verb to *näen hatun* (I see a hat), the case of the object for *hattu* has to change from elative to genitive. We resolve government with Syntax maker (Hämäläinen and Rueter, 2018), which resolves the required case based on corpus statistics.

4 Results and Evaluation

As evaluation of creative systems is one of the most difficult problems in the field of computational creativity, instead of trying to come up with an evaluation metric of our own, we opt for the evaluation method used to evaluate a previous Finnish poem generator. In practice, this means conducting a quantitative evaluation with human judges with the evaluation questions defined by Toivanen et al. (2012).

An additional reasoning for using human evaluators instead of automated evaluation metrics is the poor correlation observed in a previous study (Hämäläinen and Alnajjar, 2019) of automatic evaluation metrics such as BLEU (Papineni et al., 2002) and PINC (Chen and Dolan, 2011) scores with human judgments when evaluating creativity of a system.

We run the genetic algorithm to produce a final population for 20 different initial poems for four different themes *luonto* (nature), *perhe* (family), *lemmikki* (pet) and *ihminen* (human). From each of the 20 final populations, we pick one poem at random. We shuffle the order of poems to reduce the priming effect of poems appearing always in a given order. We divide the 20 poems into two batches of 10 poems to reduce the effort of an individual evaluator. Each batch of 10 is then evaluated by 10 different human evaluators recruited from the university campus. The total number of evaluators is 20 and all of them are native in Finnish.

We use the following evaluation questions from Toivanen et al. (2012): (1) *How typical is the text as a poem?* (2) *How understandable is it?* (3) *How good is the language?* (4) *Does the text evoke mental images?* (5) *Does the text evoke emotions?* (6) *How much do you like the text?*. These questions are evaluated in a 5 point Likert scale, where 1 represents the worst and 5 the best grade. In addition to these questions, one simple binary question is asked: *Is the text a poem?*.

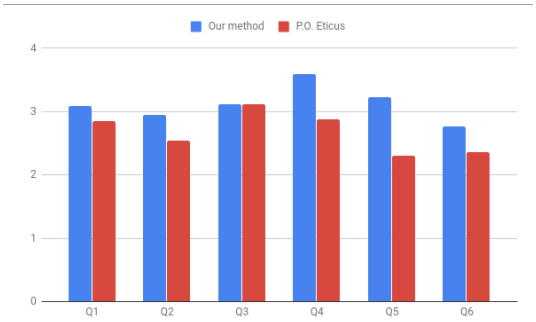

Figure 1: Evaluation results

Figure 1 represents the average values of the results of the human evaluation for each question. The plot also shows the evaluation results of P.O. Eticus as obtained in their study. As we can see, our method shows higher ratings on all the evaluation questions except for question 3. As for the binary question, the judges rated the output as a poem 81.5% of the time which is exactly the same result as P.O. Eticus got.

However, it is to remember that as a high level of subjectivity is involved in this evaluation setting, our results should not be directly compared to those of P.O. Eticus. The results form their study should taken more as a reference, rather than a definite proof that our system always outperforms P.O. Eticus.

	Q1	Q2	Q3	Q4	Q5	Q6
Average	3.10	2.94	3.11	3.60	3.23	2.77
Median	3	3	3	4	3	3
Mode	2	2	3	4	4	2

Table 1: The average, median and mode of the evaluation results

Table 1 shows the median and mode of the results in addition to the average values. The median values seems to correspond to the rounded average values. However, the mode deviates in the case

of the first, second, fifth and last questions as the most chosen answer by the judges was different from the average.

Ja kultaa, kuninkaankin saan.
Ja laulut ne kiertävät maata ja merta
Jos virkkaan kun orja
Aina, todella Herra pahankurisuutta antaa.

And gold, of a king I shall have.
And songs, they shall roam on the land and the sea
If I knit like a slave
Always, indeed the Lord shall wrack his mischief.

Above is an example of a poem generated by the system and its translation in English. The poems generated by the system are typically of this length as the genetic algorithm uses a stanza of an existing poem as its starting point.

5 Discussion and Conclusion

The method presented in this paper shows improvement on a previously used evaluation metric. However, based on the discussions we had with some of the human evaluators after they had given their judgment, it became evident that people have very different criteria for poetry. Some of the judges had guessed that they were reading computer generated poems, even though this detail was not revealed to them explicitly. Their judgments were the most critical towards the generated poetry. On the other hand, the evaluators, who were struck by a surprise that the poems were generated by a computer, were in general more generous in their judgments. One of the evaluators almost refused to believe the poems were generated by a computer instead of a person.

The high level of subjectivity that we could observe just by talking with people calls for a more robust qualitative study on the poem evaluation problem itself in the future. This would allow us to uncover additional factors that affect on the judgments given by people. Furthermore, conducting a study just on the evaluation itself makes it possible for us to evaluate the adequacy of the used evaluation metric in evaluating computer generated poetry.

Nevertheless, the scores achieved by our system, in relation to a previous method by following the same evaluation metric, are promising as they are indicative of potentially higher quality in the output. We have presented a solution for the Finnish morphosyntax in conjunction with employing a genetic algorithm to cater for computational creativity in poem generation.

Abstract

We propose SUM-QE, a novel Quality Estimation model for summarization based on BERT. The model addresses linguistic quality aspects that are only indirectly captured by content-based approaches to summary evaluation, without involving comparison with human references. SUM-QE achieves very high correlations with human ratings, outperforming simpler models addressing these linguistic aspects. Predictions of the SUM-QE model can be used for system development, and to inform users of the quality of automatically produced summaries and other types of generated text.

1 Introduction

Quality Estimation (QE) is a term used in machine translation (MT) to refer to methods that measure the quality of automatically translated text without relying on human references (Bojar et al., 2016, 2017). In this study, we address QE for summarization. Our proposed model, SUM-QE, successfully predicts linguistic qualities of summaries that traditional evaluation metrics fail to capture (Lin, 2004; Lin and Hovy, 2003; Papineni et al., 2002; Nenkova and Passonneau, 2004). SUM-QE predictions can be used for system development, to inform users of the quality of automatically produced summaries and other types of generated text, and to select the best among summaries output by multiple systems.

SUM-QE relies on the BERT language representation model (Devlin et al., 2019). We use a pre-trained BERT model adding just a task-specific layer, and fine-tune the entire model on the task of predicting linguistic quality scores manually assigned to summaries. The five criteria addressed are given in Figure 1. We provide a thorough evaluation on three publicly available summarization datasets from NIST shared tasks, and compare the performance of our model to a wide variety of baseline methods capturing different aspects of linguistic quality. SUM-QE achieves very high correlations with human ratings, showing the ability of BERT to model linguistic qualities that relate to both text content and form.[1]

Q1 – Grammaticality: The summary should have no datelines, system-internal formatting, capitalization errors or obviously ungrammatical sentences (e.g., fragments, missing components) that make the text difficult to read.

Q2 – Non redundancy: There should be no unnecessary repetition in the summary.

Q3 – Referential Clarity: It should be easy to identify who or what the pronouns and noun phrases in the summary are referring to.

Q4 – Focus: The summary should have a focus; sentences should only contain information that is related to the rest of the summary.

Q5 – Structure & Coherence: The summary should be well-structured and well-organized. The summary should not just be a heap of related information, but should build from sentence to sentence to a coherent body of information about a topic.

Figure 1: SUM-QE rates summaries with respect to five linguistic qualities (Dang, 2006a). The datasets we use for tuning and evaluation contain human assigned scores (from 1 to 5) for each of these categories.

2 Related Work

Summarization evaluation metrics like Pyramid (Nenkova and Passonneau, 2004) and ROUGE (Lin and Hovy, 2003; Lin, 2004) are recall-oriented; they basically measure the content from a model (reference) summary that is preserved in peer (system generated) summaries. Pyramid requires substantial human effort, even in its more recent versions that involve the use of word embeddings (Passonneau et al., 2013) and a lightweight crowdsourcing scheme (Shapira et al.,

[1] Our code is available at https://github.com/nlpaueb/SumQE

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6005–6011,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

2019). ROUGE is the most commonly used evaluation metric (Nenkova and McKeown, 2012; Allahyari et al., 2017; Gambhir and Gupta, 2017). Inspired by BLEU (Papineni et al., 2002), it relies on common n-grams or subsequences between peer and model summaries. Many ROUGE versions are available, but it remains hard to decide which one to use (Graham, 2015). Being recall-based, ROUGE correlates well with Pyramid but poorly with linguistic qualities of summaries. Louis and Nenkova (2013) proposed a regression model for measuring summary quality without references. The scores of their model correlate well with Pyramid and Responsiveness, but text quality is only addressed indirectly.[2]

Quality Estimation is well established in MT (Callison-Burch et al., 2012; Bojar et al., 2016, 2017; Martins et al., 2017; Specia et al., 2018). QE methods provide a quality indicator for translation output at run-time without relying on human references, typically needed by MT evaluation metrics (Papineni et al., 2002; Denkowski and Lavie, 2014). QE models for MT make use of large post-edited datasets, and apply machine learning methods to predict post-editing effort scores and quality (good/bad) labels.

We apply QE to summarization, focusing on linguistic qualities that reflect the readability and fluency of the generated texts. Since no post-edited datasets – like the ones used in MT – are available for summarization, we use instead the ratings assigned by human annotators with respect to a set of linguistic quality criteria. Our proposed models achieve high correlation with human judgments, showing that it is possible to estimate summary quality without human references.

3 Datasets

We use datasets from the NIST DUC-05, DUC-06 and DUC-07 shared tasks (Dang, 2006a,b; Over et al., 2007). Given a question and a cluster of newswire documents, the contestants were asked to generate a 250-word summary answering the question. DUC-05 contains 1,600 summaries (50 questions x 32 systems); in DUC-06, 1,750 summaries are included (50 questions x 35 systems); and DUC-07 has 1,440 summaries (45 questions x 32 systems).

[2]In the Responsiveness annotation instructions, annotators were asked to assess the linguistic quality of the summary only if it interfered with the expression of information and reduced the amount of conveyed information. See https://duc.nist.gov/duc2005/responsiveness.assessment.instructions

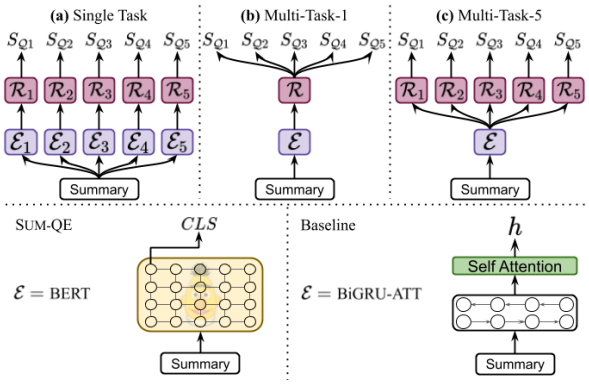

Figure 2: Illustration of different flavors of the investigated neural QE methods. An encoder ($\mathcal{E}$) converts the summary to a dense vector representation h. A regressor $\mathcal{R}_i$ predicts a quality score $S_{\mathcal{Q}i}$ using h. $\mathcal{E}$ is either a BiGRU with attention (BiGRU-ATT) or BERT (SUM-QE). $\mathcal{R}$ has three flavors, one single-task (a) and two multi-task (b, c).

The submitted summaries were manually evaluated in terms of content preservation using the Pyramid score, and according to five linguistic quality criteria ($\mathcal{Q}1, \ldots, \mathcal{Q}5$), described in Figure 1, that do not involve comparison with a model summary. Annotators assigned scores on a five-point scale, with 1 and 5 indicating that the summary is bad or good with respect to a specific $\mathcal{Q}$. The overall score for a contestant with respect to a specific $\mathcal{Q}$ is the average of the manual scores assigned to the summaries generated by the contestant. Note that the DUC-04 shared task involved seven $\mathcal{Q}$s, but some of them were found to be highly overlapping and were grouped into five in subsequent years (Over et al., 2007).[3] We address these five criteria and use DUC data from 2005 onwards in our experiments.

4 Methods

4.1 The SUM-QE Model

In SUM-QE, each peer summary is converted into a sequence of token embeddings, consumed by an encoder $\mathcal{E}$ to produce a (dense vector) summary representation h. Then, a regressor $\mathcal{R}$ predicts a quality score $S_{\mathcal{Q}}$ as an affine transformation of h:

$$S_{\mathcal{Q}} = \mathcal{R}(h) = W^{\mathcal{R}}h + b^{\mathcal{R}} \quad (1)$$

Non-linear regression could also be used, but a

[3]The complete guidelines given to annotators for DUC 2005 and subsequent years can be found at https://duc.nist.gov/duc2005/quality-questions.txt

linear (affine) $\mathcal{R}$ already performs well. We use BERT as our main encoder and fine-tune it in three ways, which leads to three versions of SUM-QE.

Single-task (BERT-FT-S-1): The first version of SUM-QE uses five separate estimators, one per quality score, each having its own encoder $\mathcal{E}_i$ (a separate BERT instance generating h_i) and regressor $\mathcal{R}_i$ (a separate linear regression layer on top of the corresponding BERT instance):

$$S_{\mathcal{Q}i} = \mathcal{R}_i(h_i), i = 1 \dots 5 \quad (2)$$

Multi-task with one regressor (BERT-FT-M-1): The second version of SUM-QE uses one estimator to predict all five quality scores at once, from a single encoding h of the summary, produced by a single BERT instance. The intuition is that $\mathcal{E}$ will learn to create richer representations so that $\mathcal{R}$ (an affine transformation of h with 5 outputs) will be able to predict all quality scores:

$$S_{\mathcal{Q}i} = \mathcal{R}(h)[i], i = 1 \dots 5 \quad (3)$$

where $\mathcal{R}(h)[i]$ is the i-th element of the vector returned by $\mathcal{R}$.

Multi-task with 5 regressors (BERT-FT-M-5): The third version of SUM-QE is similar to BERT-FT-M-1, but we now use five different linear (affine) regressors, one per quality score:

$$S_{\mathcal{Q}i} = \mathcal{R}_i(h), i = 1 \dots 5 \quad (4)$$

Although BERT-FT-M-5 is mathematically equivalent to BERT-FT-M-1, in practice these two versions of SUM-QE produce different results because of implementation details related to how the losses of the regressors (five or one) are combined.

4.2 Baselines

BiGRUs with attention: This is very similar to SUM-QE but now $\mathcal{E}$ is a stack of BiGRUs with self-attention (Xu et al., 2015), instead of a BERT instance. The final summary representation (h) is the sum of the resulting context-aware token embeddings ($h = \sum_i a_i h_i$) weighted by their self-attention scores (a_i). We again have three flavors: one single-task (BiGRU-ATT-S-1) and two multi-task (BiGRU-ATT-M-1 and BiGRU-ATT-M-5).

ROUGE: This baseline is the ROUGE version that performs best on each dataset, among the versions considered by Graham (2015). Although ROUGE focuses on surface similarities between peer and reference summaries, we would expect properties like grammaticality, referential clarity and coherence to be captured to some extent by ROUGE versions based on long n-grams or longest common subsequences.

Language model (LM): For a peer summary, a reasonable estimate of $\mathcal{Q}1$ (Grammaticality) is the perplexity returned by a pre-trained language model. We experiment with the pre-trained GPT-2 model (Radford et al., 2019), and with the probability estimates that BERT can produce for each token when the token is treated as masked (BERT-FR-LM).[4] Given that the grammaticality of a summary can be corrupted by just a few bad tokens, we compute the perplexity by considering only the k worst (lowest LM probability) tokens of the peer summary, where k is a tuned hyper-parameter.[5]

Next sentence prediction: BERT training relies on two tasks: predicting masked tokens and next sentence prediction. The latter seems to be aligned with the definitions of $\mathcal{Q}3$ (Referential Clarity), $\mathcal{Q}4$ (Focus) and $\mathcal{Q}5$ (Structure & Coherence). Intuitively, when a sentence follows another with high probability, it should involve clear referential expressions and preserve the focus and local coherence of the text.[6] We, therefore, use a pre-trained BERT model (BERT-FR-NS) to calculate the sentence-level perplexity of each summary:

$$\mathcal{H} = 2^{-\frac{1}{n}\sum_{i=2}^{n} \log_2 p(s_i|s_{i-1})} \quad (5)$$

where $p(s_i|s_{i-1})$ is the probability that BERT assigns to the sequence of sentences $\langle s_{i-1}, s \rangle$, and n is the number of sentences in the peer summary.

5 Experiments

To evaluate our methods for a particular $\mathcal{Q}$, we calculate the average of the predicted scores for the summaries of each particular contestant, and the average of the corresponding manual scores assigned to the contestant's summaries. We measure the correlation between the two (predicted vs.

[4] Here BERT parameters are frozen (not fine-tuned). We use the pre-trained masked LM model to obtain probability estimates for the tokens, which are then used to calculate the perplexity.

[5] Consult the supplementary material for details.

[6] We also found the three quality scores to be highly correlated. The reader may refer to the supplementary material for correlation heatmaps between the five quality scores.

Table 1: Spearman's ρ, Kendall's τ and Pearson's r correlations on DUC-05, DUC-06 and DUC-07 for $\mathcal{Q}1$–$\mathcal{Q}5$. BEST-ROUGE refers to the version that achieved best correlations and is different across years.

manual) across all contestants using Spearman's ρ, Kendall's τ and Pearson's r.

We train and test the SUM-QE and BiGRU-ATT versions using a 3-fold procedure. In each fold, we train on two datasets (e.g., DUC-05, DUC-06) and test on the third (e.g., DUC-07). We follow the same procedure with the three BiGRU-based models. Hyper-parameters are tuned on a held out subset from the training set of each fold.

6 Results

Table 1 shows Spearman's ρ, Kendall's τ and Pearson's r for all datasets and models. The three fine-tuned BERT versions clearly outperform all other methods. Multi-task versions seem to perform better than single-task ones in most cases. Especially for $\mathcal{Q}4$ and $\mathcal{Q}5$, which are highly correlated, the multi-task BERT versions achieve the best overall results. BiGRU-ATT also benefits from multi-task learning.

The correlation of SUM-QE with human judgments is high or very high (Hinkle et al., 2003) for all $\mathcal{Q}$s in all datasets, apart from $\mathcal{Q}2$ in DUC-05 where it is only moderate. Manual scores for $\mathcal{Q}2$ in DUC-05 are the highest among all $\mathcal{Q}$s and years (between 4 and 5) and with the smallest standard deviation, as shown in Table 2. Differences among systems are thus small in this respect, and although SUM-QE predicts scores in this range, it struggles to put them in the correct order, as illustrated in Figure 3.

	DUC-05	DUC-06	DUC-07
$\mathcal{Q}1$	3.77 (± 0.42)	3.58 (± 0.60)	3.54 (± 0.78)
$\mathcal{Q}2$	**4.41 (± 0.20)**	**4.23 (± 0.26)**	**3.71 (± 0.31)**
$\mathcal{Q}3$	2.99 (± 0.50)	3.11 (± 0.52)	3.20 (± 0.66)
$\mathcal{Q}4$	3.15 (± 0.41)	3.60 (± 0.39)	3.30 (± 0.47)
$\mathcal{Q}5$	2.18 (± 0.46)	2.39 (± 0.51)	2.42 (± 0.59)

Table 2: Mean manual scores (± standard deviation) for each $\mathcal{Q}$ across datasets. $\mathcal{Q}2$ is the hardest to predict because it has the highest scores and the lowest standard deviation.

BEST-ROUGE has a negative correlation with the ground-truth scores for $\mathcal{Q}2$ since it does not account for repetitions. The BiGRU-based models also reach their lowest performance on $\mathcal{Q}2$ in DUC-05. A possible reason for the higher relative performance of the BERT-based models, which achieve a moderate positive correlation, is that BiGRU captures long-distance relations less effectively than BERT, which utilizes Transformers (Vaswani et al., 2017) and has a larger receptive field. A possible improvement would be a stacked BiGRU, since the states of higher stack layers have a larger receptive field as well.[7]

The BERT multi-task versions perform better with highly correlated qualities like $\mathcal{Q}4$ and $\mathcal{Q}5$ (as illustrated in Figures 2 to 4 in the supplementary material). However, there is not a clear winner among them. Mathematical equivalence does not lead to deterministic results, especially when random initialization and stochastic learning algorithms are involved. An in-depth exploration of this point would involve further investigation, which will be part of future work.

7 Conclusion and Future Work

We propose a novel Quality Estimation model for summarization which does not require human references to estimate the quality of automatically produced summaries. SUM-QE successfully predicts qualitative aspects of summaries that recall-oriented evaluation metrics fail to approximate. Leveraging powerful BERT representations, it achieves high correlations with human scores for most linguistic qualities rated, on three different datasets. Future work involves extending the SUM-QE model to capture content-related aspects, either in combination with existing evaluation metrics (like Pyramid and ROUGE) or, preferably, by identifying important information in the original text and modelling its preservation in the proposed summaries. This would preserve SUM-QE's independence from human references, a property of central importance in real-life usage scenarios and system development settings.

[7] As we move up the stack, the states are affected directly by their neighbors and indirectly by the neighbors of their neighbors, and so on.

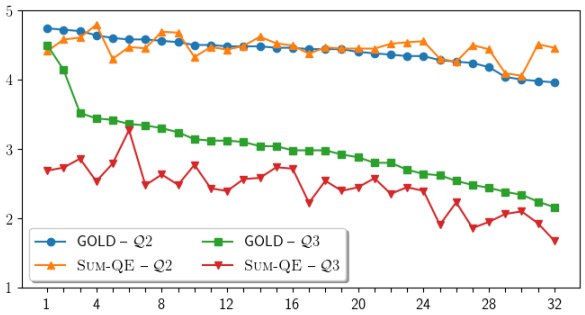

Figure 3: Comparison of the mean gold scores assigned for $\mathcal{Q}2$ and $\mathcal{Q}3$ to each of the 32 systems in the DUC-05 dataset, and the corresponding scores predicted by SUM-QE. Scores range from 1 to 5. The systems are sorted in descending order according to the gold scores. SUM-QE makes more accurate predictions for $\mathcal{Q}2$ than for $\mathcal{Q}3$, but struggles to put the systems in the correct order.

The datasets used in our experiments come from the NIST DUC shared tasks which comprise newswire articles. We believe that SUM-QE could be easily applied to other domains. A small amount of annotated data would be needed for fine-tuning – especially in domains with specialized vocabulary (e.g., biomedical) – but the model could also be used out of the box. A concrete estimation of performance in this setting will be part of future work. Also, the model could serve to estimate linguistic qualities other than the ones in the DUC dataset with mininum effort.

Finally, SUM-QE could serve to assess the quality of other types of texts, not only summaries. It could thus be applied to other text generation tasks, such as natural language generation and sentence compression.

Acknowledgments

We would like to thank the anonymous reviewers for their helpful feedback on this work. The work has been partly supported by the Research Center of the Athens University of Economics and Business, and by the French National Research Agency under project ANR-16-CE33-0013.

Abstract

Generating paraphrases from given sentences involves decoding words step by step from a large vocabulary. To learn a decoder, supervised learning which maximizes the likelihood of tokens always suffers from the exposure bias. Although both reinforcement learning (RL) and imitation learning (IL) have been widely used to alleviate the bias, the lack of direct comparison leads to only a partial image on their benefits. In this work, we present an empirical study on how RL and IL can help boost the performance of generating paraphrases, with the pointer-generator as a base model [1]. Experiments on the benchmark datasets show that (1) imitation learning is constantly better than reinforcement learning; and (2) the pointer-generator models with imitation learning outperform the state-of-the-art methods with a large margin.

1 Introduction

Generating paraphrases is a fundamental research problem that could benefit many other NLP tasks, such as machine translation (Bahdanau et al., 2014), text generation (Radford et al., 2019), document summarization (Chopra et al., 2016), and question answering (McCann et al., 2018). Although various methods have been developed (Zhao et al., 2009; Quirk et al., 2004; Barzilay and Lee, 2003), the recent progress on paraphrase generation is mainly from neural network modeling (Prakash et al., 2016). Particularly, the encoder-decoder framework is widely adopted (Cho et al., 2015), where the encoder takes source sentences as inputs and the decoder generates the corresponding paraphrase for each input sentence.

In supervised learning, a well-known challenge of generating paraphrases is the exposure bias: the current prediction is conditioned on the ground truth during training but on previous predictions during decoding, which may accumulate and propagate the error when generating the text. To address this challenge, prior work (Li et al., 2018) suggests to utilize the exploration strategy in reinforcement learning (RL). However, training with the RL algorithms is not trivial and often hardly works in practice (Dayan and Niv, 2008). A typical way of using RL in practice is to train the model with supervised learning (Ranzato et al., 2015; Shen et al., 2015; Bahdanau et al., 2016), which leverages the supervision information from training data and alleviate the exposure bias to some extent. In the middle ground between RL and supervised learning, a well-known category is imitation learning (IL) (Daumé et al., 2009; Ross et al., 2011), which has been used in structured prediction (Bagnell et al., 2007) and other sequential prediction tasks (Bengio et al., 2015).[2]

In this work, we conduct an empirical comparison between RL and IL to demonstrate the pros and cons of using them for paraphrase generation. We first propose a unified framework to include some popular learning algorithms as special cases, such as the REINFORCE algorithm (Williams, 1992) in RL and the DAGGER algorithm (Ross et al., 2011) in IL. To better understand the value of different learning techniques, we further offer several variant learning algorithms based on the RL framework. Experiments on the benchmark datasets show: (1) the DAGGER algorithm is better than the REINFORCE algorithm and its variants on paraphrase generation, (2) the DAGGER algorithm with a certain setting gives the best

[1] The data and code for this work can be obtained from: https://github.com/ddddwy/Reinforce-Paraphrase-Generation

[2] In this work, we view *scheduled sampling* (Bengio et al., 2015) as an imitation learning algorithm similar to DAGGER (Ross et al., 2011).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6012–6018,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

results, which outperform the previous state-of-the-art with about 13% on the average evaluation score. We expect this work will shed light on how to choose between RL and IL, and alleviate the exposure bias for other text generation tasks.

2 Method

Given an input sentence $\boldsymbol{x} = (x_1, x_2, \cdots, x_S)$ with length S, a paraphrase generation model outputs a new sentence $\boldsymbol{y} = (y_1, y_2, \cdots, y_T)$ with length T that shares the same meaning with $\boldsymbol{x}$. The widely adopted framework on paraphrase generation is the encoder-decoder framework (Cho et al., 2014). The encoder reads sentence $\boldsymbol{x}$ and represents it as a single numeric vector or a set of numeric vectors. The decoder defines a probability function $p(y_t \mid \boldsymbol{y}_{\leq t-1}, \boldsymbol{x}; \boldsymbol{\theta})$, where $\boldsymbol{y}_{\leq t-1} = (y_1, y_2, \ldots, y_{t-1})$ and $\boldsymbol{\theta}$ is the collection of model parameters,

$$p(y_t \mid \boldsymbol{y}_{\leq t-1}, \boldsymbol{x}; \boldsymbol{\theta}) = \text{softmax}\left(\mathbf{W}\boldsymbol{h}_t\right) \quad (1)$$

with $\boldsymbol{h}_t = \boldsymbol{f}(\boldsymbol{h}_{t-1}, y_{t-1}, \boldsymbol{x})$, where $\boldsymbol{f}$ as a nonlinear transition function and $\mathbf{W} \in \boldsymbol{\theta}$ as a parameter matrix. We use the *pointer-generator model* (See et al., 2017) as the base model, which is state-of-the-art model on paragraph generation (Li et al., 2018). We skip the detail explanation of this model and please refer to (See et al., 2017) for further information.

2.1 Basic Learning Algorithms

To facilitate the comparison between RL and IL, we propose a unified framework with the following objective function. Given a training example $(\boldsymbol{x}, \boldsymbol{y})$, the objective function is defined as

$$L(\boldsymbol{\theta}) = \Big\{ \sum_{t=1}^{T} \log \pi_\theta(\tilde{y}_t \mid \boldsymbol{h}_t) \Big\} \cdot r(\tilde{\boldsymbol{y}}, \boldsymbol{y}), \quad (2)$$

Following the terminology in RL and IL, we rename $P(\tilde{y}_t \mid \boldsymbol{y}_{\leq t-1}, \boldsymbol{x}; \boldsymbol{\theta})$ as the the policy function $\pi_\theta(\tilde{y}_t \mid \boldsymbol{h}_t)$. That implies taking an action based on the current observation, where the action is *picking* a word $\tilde{y}_t$ from the vocabulary $\mathcal{V}$. $r(\tilde{\boldsymbol{y}}, \boldsymbol{y})$ is a reward function with $r(\tilde{\boldsymbol{y}}, \boldsymbol{y}) = 1$ if $\tilde{\boldsymbol{y}} = \boldsymbol{y}$. In our experiments, We use the ROUGE-2 score (Lin, 2004) as the reward function. Algorithm 1 presents how to optimize $L(\boldsymbol{\theta})$ in the online learning fashion. As shown in the pseudocode, the **schedule rates** (α, β) and the **decoding function** $\texttt{Decode}(\cdot)$ are the keys to understand the special cases of this unified framework.

Algorithm 1 Online learning

Input: A training example $(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})$, current schedule rates $\alpha^{(i)}, \beta^{(i)} \in [0, 1]$, learning rate η
Initialize $L(\boldsymbol{\theta}) \leftarrow 0$
for $t = 1, \ldots, T$ **do**
  $p_1, p_2 \sim \text{Uniform}(0, 1)$
  $\tilde{y}_{t-1} \leftarrow y_{t-1}$ **if** $(p_1 < \alpha^{(i)})$ **else** $\hat{y}_{t-1}$
  $\boldsymbol{h}_t = \boldsymbol{f}(\boldsymbol{h}_{t-1}, \tilde{y}_{t-1}, \boldsymbol{x})$
  $\hat{y}_t \leftarrow \texttt{Decode}(\pi(y \mid \boldsymbol{h}_t))$
  $\tilde{y}_t \leftarrow y_t$ **if** $(p_2 < \beta^{(i)})$ **else** $\hat{y}_t$
  $L(\boldsymbol{\theta}) \leftarrow L(\boldsymbol{\theta}) + \log \pi(\tilde{y}_t \mid \boldsymbol{h}_t)$
end for
$\delta\boldsymbol{\theta} \leftarrow \nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}) \cdot r(\tilde{\boldsymbol{y}^{(i)}}, \boldsymbol{y}^{(i)})$
$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \eta \cdot \delta\boldsymbol{\theta}$

The REINFORCE Algorithm. When $\alpha = 0$, $\beta = 0$, and $\texttt{Decode}(\pi(y \mid \boldsymbol{h}_t))$ is defined as as:

$$\begin{aligned} &\texttt{Decode}(\pi_\theta(y \mid \boldsymbol{h}_{t-1})) \\ &\quad = \text{Random_Sampling}(\pi_\theta(y \mid \boldsymbol{h}_{t-1})), \end{aligned} \quad (3)$$

Specifically, when $\alpha = \beta = 0$, both $\tilde{y}_{t-1}$ and $\tilde{y}_t$ will choose the sampled values from the $\texttt{Decode}$ function with policy π_θ. It essentially samples a trajectory from the decoder $(\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_T)$ as in the REINFORCE algorithm. The reward is $r(\tilde{\boldsymbol{y}}, \boldsymbol{y}) = r(\hat{\boldsymbol{y}}, \boldsymbol{y})$ once it has the entire trajectory $\hat{\boldsymbol{y}}$.

The DAGGER Algorithm. When $0 < \alpha < 1$, $\beta = 1$, and $\texttt{Decode}(\pi(y \mid \boldsymbol{h}_t))$ is defined as as:

$$\texttt{Decode}(\pi_\theta(y \mid \boldsymbol{h}_{t-1})) = \operatorname*{argmax}_{y'} \pi_\theta(y' \mid \boldsymbol{h}_{t-1}). \quad (4)$$

Depending the value of α, $\tilde{y}_{t-1}$ will choose between the ground truth y_{t-1} and decoded value $\hat{y}_{t-1}$ with the function defined in Equation 4. On the other hand, $\tilde{y}_t$ will always choose the ground truth y_t as $\beta = 1$. Since $\tilde{\boldsymbol{y}} = \boldsymbol{y}$, we have $r(\tilde{\boldsymbol{y}}, \boldsymbol{y}) = 1$ and the reward can be ignored from Equation 2. In imitation learning, ground truth sequence $\boldsymbol{y}$ is called expert actions. The DAGGER algorithm (Ross et al., 2011) is also called scheduled sampling (Bengio et al., 2015) in recent deep learning literature. To be accurate, in the DAGGER and the scheduled sampling, the α is dynamically changed during training. Typically, it starts from 1 and gradually decays to a certain value along with iterations. As shown in our experiments, the selection of decay scheme has a big impact on model performance.

The MLE Algorithm. Besides, there is a trivial case when $\alpha = 1, \beta = 1$. In this case, $\tilde{y}_{t-1}$ and $\tilde{y}_t$ are equal to y_{t-1} and y_t respectively, and $r(\tilde{\boldsymbol{y}}, \boldsymbol{y}) = 1$. Optimizing the objective function in Equation 2 is reduced to the maximum likelihood estimation (MLE).

2.2 Other Variant Algorithms

Inspired by the previous three special cases, we offer other algorithm variants with different combinations of (α, β), while the decoding function $\texttt{Decode}(\pi(y \mid \boldsymbol{h}_t))$ in the same as Equation 3 in all following variants.

- **REINFORCE-GTI** (REINFORCE with Ground Truth Input): $\alpha = 1, \beta = 0$. Unlike the REINFORCE algorithm, REINFORCE-GTI restricts the input to the decoder can only be ground truth words, which means $\tilde{y}_{t-1} = y_{t-1}$. This is a popular implementation in the deep reinforcement learning for Seq2Seq models (Keneshloo et al., 2018).

- **REINFORCE-SO** (REINFORCE with Sampled Output): $\alpha = 1, 0 < \beta < 1$. In terms of choosing the value of $\tilde{y}_t$ as output from the decoder, REINFORCE-SO allows $\tilde{y}_t$ to select the ground truth y_t with probability β.

- **REINFORCE-SIO** (REINFORCE with Sampled Input and Output): $0 < \alpha < 1, 0 < \beta < 1$. Instead of always taking the ground truth y_{t-1} as input, REINFORCE-SIO further relaxes the constraint in REINFORCE-SO and allows $\tilde{y}_{t-1}$ to be the decoded value $\hat{y}_{t-1}$ with probability α.

Unless specified explicitly, an additional requirement when $0 < \alpha, \beta < 1$ is that its value decays to a certain value during training, which by default is 0.

3 Experiments

Dataset and Evaluation Metrics. We evaluate our models on the Quora Question Pair Dataset [3], and the Twitter URL Paraphrasing Dataset (Lan et al., 2017) [4]. Both datasets contain positive and negative examples of paraphrases, and we only keep the positive examples for our experiments as in prior work of paraphrase generation (Li et al., 2018; Patro et al., 2018). For the Quora dataset, we follows the configuration of (Li et al., 2018) and split the data into 100K training pairs, 30K testing pairs and 3K validation pairs. For the Twitter dataset, since our model cannot deal with the negative examples as (Li et al., 2018) do, we just obtain the 1-year 2,869,657 candidate pairs from https://languagenet.github.io, and filter out all negative examples. Finally, we divided the remaining dataset into 110K training pairs, 3K testing pairs and 1K validation pairs.

We use the following evaluation metrics to compare our models with other state-of-art neural networks: ROUGE-1 and ROUGE-2 (Lin, 2004), BLEU with up to bi-grams (Papineni et al., 2002). For the convenience of comparison, we also calculate the average of the scores.

Competitive Systems. We compare our results with four competitive systems on paraphrase generation: the sequence-to-sequence model (Bahdanau et al., 2014, Seq2seq), the Reinforced by Matching framework (Li et al., 2018, RbM), the Residual LSTM (Prakash et al., 2016, Res-LSTM), and the Discriminator LSTM model (Patro et al., 2018, Dis-LSTM). Among these competitive systems, the RbM (Li et al., 2018) is more closely related to our work, since we both use the pointer-generator as the base model and apply some reinforcement learning algorithms for policy learning.

Experimental Setup. We first pre-train the pointer-generator model with MLE, then fine-tune the models with various algorithms proposed in section 2. Pre-training is critical to make the REINFORCE algorithm and some variants to work. More implementation details are provided in Appendix A.

Result Analysis. Table 1 shows the model performances on the Quora test set, and Table 2 shows the model performances on the Twitter test set. For the Quora dataset, all our models outperform the competitive systems with a large margin. We suspect the reason is because we ran the development set during training on-the-fly, which is not the experimental setup used in (Li et al., 2018).

For both datasets, we find that DAGGER with a fixed (α, β) gives the best performance among all the algorithm variants. The difference between DAGGER and DAGGER* is that, in DAGGER, we use the decay function on α at each iteration,

6	Dagger	$\alpha \to 0$	$\beta = 1$	58.84	44.24	38.95	47.34
7	Dagger*	$\alpha = 0.2$	$\beta = 1$	**58.95**	**44.34**	**39.04**	**47.44**

Table 2: Performance on Twitter dataset. Since the dataset we obtained is different from (Li et al., 2018), we do not directly compare the results with the prior works.

$\alpha \leftarrow k \cdot \alpha$ with $k = 0.9999$. In our experiments, we also try different decaying rates, and present the best results we obtained (more details are provided in Table B). The selection of α depends on the specific task: for the Quora dataset, we find $\alpha = 0.5$ gives us the optimal policy; for the Twitter dataset, we find $\alpha = 0.2$ gives us the optimal policy.

As shown in line 6 – 11 from Table 1, the additional training with whichever variant algorithms can certainly enhance the generation performance over the pre-trained model (line 5). This observation is consistent with many previous works of using RL/IL in NLP. However, we also notice that the improvement of using the Reinforce algorithm (line 6) is very small, only 0.18 on the average score.

As shown in line 2 – 7 from Table 2, the additional training with variant algorithms also shows improved performance over the pre-trained model (line 1). However, for the pointer-generator model, it is more difficult to do paraphrase generation on the Twitter dataset. Since in the Twitter dataset, one source sentence shares several different paraphrases, while in the Quora dataset, one source sentence only corresponds to one paraphrase. This explains why the average improvement in the Twitter dataset is not as significant as in the Quora dataset. Besides, from Table 2, we also find that IL (line 6 – 7) outperforms RL (line 2 – 3), which is consist with the experimental results in Table 1.

Overall, in this particular setting of paraphrase generation, we found that Dagger is much easier to use than the Reinforce algorithm, as it always takes ground truth (expert actions) as its outputs. Although, picking a good decay function α can be really tricky. On the other hand, the Reinforce

algorithm (together with its variants) could only outperform the pre-trained baseline with a small margin.

4 Related Work

Paraphrase generation has the potential of being used in many other NLP research topics, such as machine translation (Madnani et al., 2007) and question answering (Buck et al., 2017; Dong et al., 2017). Early work mainly focuses on extracting paraphrases from parallel monolingual texts (Barzilay and McKeown, 2001; Ibrahim et al., 2003; Pang et al., 2003). Later, Quirk et al. (2004) propose to use statistical machine translation for generating paraphrases directly. Despite the particular MT system used in their work, the idea is very similar to the recent work of using encoder-decoder frameworks for paraphrase generation (Prakash et al., 2016; Mallinson et al., 2017). In addition, Prakash et al. (2016) extend the encoder-decoder framework with a stacked residual LSTM for paraphrase generation. Li et al. (2018) propose to use the pointer-generator model (See et al., 2017) and train it with an actor-critic RL algorithm. In this work, we also adopt the pointer-generator framework as the base model, but the learning algorithms are developed by uncovering the connection between RL and IL.

Besides paraphrase generation, many other NLP problems have used some RL or IL algorithms for improving performance. For example, structured prediction has more than a decade history of using imitation learning (Daumé et al., 2009; Chang et al., 2015; Vlachos, 2013; Liu et al., 2018). In addition, scheduled sampling (as another form of DAGGER) has been used in sequence prediction ever since it was proposed in (Bengio et al., 2015). Similar to IL, reinforcement learning, particularly with neural network models, has been widely used in many different domains, such as coreference resolution (Yin et al., 2018), document summarization (Chen and Bansal, 2018), and machine translation (Wu et al., 2018).

5 Conclusion

In this paper, we performed an empirical study on some reinforcement learning and imitation learning algorithms for paraphrase generation. We proposed a unified framework to include the DAGGER and the REINFORCE algorithms as special cases and further presented some variant learning algorithms. The experiments demonstrated the benefits and limitations of these algorithms and provided the state-of-the-art results on the Quora dataset.

Abstract

Sentence position is a strong feature for news summarization, since the lead often (but not always) summarizes the key points of the article. In this paper, we show that recent neural systems excessively exploit this trend, which although powerful for many inputs, is also detrimental when summarizing documents where important content should be extracted from later parts of the article. We propose two techniques to make systems sensitive to the importance of content in different parts of the article. The first technique employs 'unbiased' data; i.e., randomly shuffled sentences of the source document, to pretrain the model. The second technique uses an auxiliary ROUGE-based loss that encourages the model to distribute importance scores throughout a document by mimicking sentence-level ROUGE scores on the training data. We show that these techniques significantly improve the performance of a competitive reinforcement learning based extractive system, with the auxiliary loss being more powerful than pretraining.

1 Introduction

Extractive summarization remains a simple and fast approach to produce summaries which are grammatical and accurately represent the source text. In the news domain, these systems are able to use a dominant signal: the position of a sentence in the source document. Due to journalistic conventions which place important information early in the articles, the lead sentences often contain key information. In this paper, we explore how systems can look beyond this simple trend.

Naturally, automatic systems have all along exploited position cues in news as key indicators of important content (Schiffman et al., 2002; Hong and Nenkova, 2014; Liu, 2019). The 'lead' baseline is rather strong in single-document news summarization (Brandow et al., 1995; Nenkova, 2005), with automatic systems only modestly improving the results. Nevertheless, more than 20-30% of summary-worthy sentences come from the second half of news documents (Nallapati et al., 2016; Kedzie et al., 2018), and the lead baseline, as shown in Table 1, does not always produce convincing summaries. So, systems must balance the position bias with representations of the semantic content throughout the document. Alas, preliminary studies (Kedzie et al., 2018) suggest that even the most recent neural methods predominantly pick sentences from the lead, and that their content selection performance drops greatly when the position cues are withheld.

Lead-3: Bangladesh beat fellow World Cup quarter-finalists Pakistan by 79 runs in the first one-day international in Dhaka. Tamim Iqbal and Mushfiqur Rahim scored centuries as Bangladesh made 329 for six and Pakistan could only muster 250 in reply. Pakistan will have the chance to level the three-match series on Sunday when the second odi takes place in Mirpur.

Lead-3: Standing up for what you believe. What does it cost you? What do you gain?
Reference: Indiana town's Memories Pizza is shut down after online threat. Its owners say they'd refuse to cater a same-sex couple's wedding.

Table 1: 'Lead' (first 3 sentences of source) can produce extremely faithful (top) to disastrously inaccurate (bottom) summaries. Gold standard summaries are also shown.

In this paper, we verify that sentence position and lead bias dominate the learning signal for state-of-the-art neural extractive summarizers in the news domain. We then present techniques to improve content selection in the face of this bias. The first technique makes use of 'unbiased data' created by permuting the order of sentences in

the training articles. We use this shuffled dataset for pre-training, followed by training on the original (unshuffled) articles. The second method introduces an auxiliary loss which encourages the model's scores for sentences to mimic an estimated score distribution over the sentences, the latter computed using ROUGE overlap with the gold standard. We implement these techniques for two recent reinforcement learning based systems, RNES (Wu and Hu, 2018) and BanditSum (Dong et al., 2018), and evaluate them on the CNN/Daily Mail dataset (Hermann et al., 2015).

We find that our auxiliary loss achieves significantly better ROUGE scores compared to the base systems, and that the improvement is even more pronounced when the true best sentences appear later in the article. On the other hand, the pre-training approach produces mixed results. We also confirm that when summary-worthy sentences appear late, there is a large performance discrepancy between the oracle summary and state-of-the-art summarizers, indicating that learning to balance lead bias with other features of news text is a noteworthy issue to tackle.

2 Related Work

Modern summarization methods for news are typically based on neural network-based sequence-to-sequence learning (Kalchbrenner et al., 2014; Kim, 2014; Chung et al., 2014; Yin and Pei, 2015; Cao et al., 2015; Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018a; Zhou et al., 2018). In MLE-based training, extractive summarizers are trained with gradient ascent to maximize the likelihood of heuristically-generated ground-truth binary labels (Nallapati et al., 2017). Many MLE-based models do not perform as well as their reinforcement learning-based (RL) competitors that directly optimize ROUGE (Paulus et al., 2018; Narayan et al., 2018b; Dong et al., 2018; Wu and Hu, 2018). As RL-based models represent the state of the art for extractive summarization, we analyze them in this paper.

The closest work to ours is a recent study by Kedzie et al. (2018) which showed that MLE-based models learn a significant bias for selecting early sentences when trained on news articles as opposed to other domains. As much as 58% of selected summary sentences come directly from the lead. Moreover, when these models are trained on articles whose sentences are randomly shuffled, the performance drops considerably for news domain only. While this drop could be due to the destruction of position cues, it may also arise because the article's coherence and context were lost.

In this paper, we employ finer control on the distortion of sentence position, coherence, and context, and confirm that performance drops are mainly due to the lack of position cues. We also propose the first techniques to counter the effects of lead bias in neural extractive systems.

3 Base Models for Extractive Summarization

In supervised systems, given a document $D = \{s_1, ..., s_n\}$ with n sentences, a summary can be seen as set of binary labels $y_1, \ldots, y_n \in \{0, 1\}$, where $y_i = 1$ indicates that the i-th sentence is included in the summary.

We choose to experiment with two state-of-the-art RL-based extractive models: **RNES** (Wu and Hu, 2018) and **BanditSum** (Dong et al., 2018). Both employ an encoder-decoder structure, where the encoder extracts sentence features into fixed-dimensional vector representations $h_1, \ldots, h_n$, and a decoder produces the labels $y_1, \ldots, y_n$ based on these sentence representations. RNES uses a CNN+bi-GRU encoder, and BanditSum a hierarchical bi-LSTM. RNES's decoder is *auto-regressive*, meaning it predicts the current sentence's label based on decisions made on previous sentences; i.e., $y_t = f(D, h_t, y_{1:t-1})$. In BanditSum, there is no such dependence: it produces affinity scores for each sentence and the top scoring sentences are then selected.

4 Lead Bias of News Systems

First, we investigate the impact of sentence position on our models. We manipulate the **original** CNN/Daily Mail dataset to preserve sentence position information at different levels. In the **random** setting, sentences are shuffled randomly; in **reverse**, they are in reverse order; in **insert-lead** and **insert-lead3**, we insert an out-of-document sentence (chosen randomly from the corpus) as the first sentence or randomly as one of the first three sentences, respectively.

In Table 2, we show BanditSum's performance,[1] when trained and tested on the various datasets. All models (except random) perform

[1] We notice the same trends on RNES.

train setting \ test setting	original	random	reverse	insert-lead	insert-lead3	Mean	Std. Dev.
Lead-3 baseline	32.68	22.81	17.94	27.67	27.68	25.76	5.00
original	**33.85**	26.18	20.71	31.71	31.11	28.71	4.72
random	30.88	**29.70**	29.79	29.97	30.09	**30.09**	**0.42**
reverse	21.35	26.32	**33.59**	21.63	21.65	24.91	4.72
insert-lead	33.21	26.07	20.70	**33.41**	31.59	29.00	4.93
insert-lead3	32.29	25.57	20.22	32.92	**32.15**	28.63	4.98

Table 2: BanditSum's performance—calculated as the average between ROUGE-1,-2, and -L F1—on the validation set of the CNN/Daily Mail corpus. The sentence position information is perturbed at different levels, as explained in Section 4.

worse when tested on a mismatched data perturbation. Even when the distortion is at a single lead position in **insert-lead** and **insert-lead3**, the performance on the original data is significantly lower than when trained without the distortion. These results corroborate Kedzie et al. (2018)'s findings for RL-based systems. Interestingly, the **random** model has the best mean performance and the lowest variation indicating that completely removing the position bias may allow a model to focus on learning robust sentence semantics.

5 Learning to Counter Position Bias

We present two methods which encourage models to locate key phrases at diverse parts of the article.

5.1 Multi-Stage Training

This technique is inspired by the robust results from the **random** model in section 4. We implement a multi-stage training method for both BanditSum and RNES where in the first few epochs, we train on an 'unbiased' dataset where the sentences in every training document are randomly shuffled. We then fine-tune the models by training on the original training articles. The goal is to prime the model to learn sentence semantics independently of position, and then introduce the task of balancing semantics and positional cues.

5.2 ROUGE-based Auxiliary Loss

We observed that BanditSum tends to converge to a low-entropy policy, in the sense that the model's affinity scores are either 1 or 0 at the end of training. Furthermore, over 68% of its selections are from the three leading sentences of the source. Regularizing low-entropy policies can increase a model's propensity to explore potentially good states or stay close to a known good policy (Nachum et al., 2017; Galashov et al., 2019). We extend this idea to summarization by introducing a ROUGE-based loss which regularizes the model policy using an estimate of the value of individual sentences.

These sentence-level estimates are computed as a *distribution* P_R:

$$P_R(x = i) = \frac{r(s_i, \mathcal{G})}{\sum_{j=1}^{n} r(s_j, \mathcal{G})}, \tag{1}$$

where r is the average of ROUGE-1, -2 and -L F_1 scores between sentence s_i in the article and the reference summary $\mathcal{G}$. We would like the model's predictive distribution $P_\mathcal{M}$ to approximately match P_R. To compute $P_\mathcal{M}$, we normalize the predicted scores from a non-auto-regressive model. In an auto-regressive model such as RNES, the decision of including a sentence depends on those selected so far. So a straightforward KL objective is hard to implement, and we use this technique for BanditSum only.

Our auxiliary loss is defined as the KL divergence: $\mathcal{L}_{\text{KL}} = D_{\text{KL}}(P_R \parallel P_\mathcal{M})$. The update rule then becomes:

$$\theta^{(t+1)} = \theta^{(t)} + \alpha \left(\nabla \mathcal{L}_\mathcal{M}(\theta^{(t)}) + \beta \nabla \mathcal{L}_{\text{KL}}(\theta^{(t)}) \right) \tag{2}$$

where $\theta^{(t)}$ represents the model's parameters at time step t, $\mathcal{L}_\mathcal{M}$ is the original model's loss function, and β is a hyperparameter.

6 Experimental Setup

We use the CNN/Daily Mail dataset (Hermann et al., 2015) with the standard train/dev/test splits of 287,227/13,368/11,490. To avoid inconsistencies, we built on top of the author-provided implementations for BanditSum and our faithful reimplementation of RNES.

To reduce training time, we pre-compute and store the average of ROUGE-1, -2, and -L for every sentence triplet of each article, using a HDF5 table and PyTables (PyTables Developers Team, 2002-2019; The HDF Group, 1997-2019). This allows for a considerable increase in training speed.

Model	ROUGE			Overlp
	1	2	L	%
Lead-3	40.06	17.53	36.18	100.0
Oracle	56.53	32.65	53.12	27.24
Refresh	40.0	18.2	36.6	–
NeuSum	40.15	17.80	36.63	58.24
RNES	41.15	18.81	37.75	68.44

BanditSum	41.68	18.78	38.00	69.87
B.Sum+pretrain	41.68	18.79	37.99	70.77
B.Sum+entropy	41.71	18.87	38.04	64.83
BanditSum+KL	**41.81***	**18.96***	**38.16***	65.13

Table 3: ROUGE scores for systems. 'Overlp' denotes the model's overlap in extraction choices with the lead-3 baseline. Scores significantly higher than BanditSum with $p < 0.001$ (bootstrap resampling test) are marked with *.

We limit the maximum number of sentences considered in an article to the first 100.

All the models were trained for 4 epochs. For the multi-stage training, we pretrain for 2 epochs, then train on the original articles for 2 epochs. We set the auxiliary loss hyperparameters $\alpha = 1e-4$ and $\beta = 0.0095$ in eq. 2 based on a grid search using the Tune library (Liaw et al., 2018).

We also train a baseline **entropy** model by replacing $\mathcal{L}_{\text{KL}}$ with the negated entropy of $P_{\mathcal{M}}$ in eq. 2. This loss penalizes low entropy, helping the model explore, but it is 'undirected' compared to our proposed method. We present the results of Lead-3 baseline (first 3 sentences), and two other competitive models—Refresh[2] (Narayan et al., 2018a) and NeuSum (Zhou et al., 2018).

Lastly, we include results from an *oracle* summarizer, computed as the triplet of source sentences with the highest average of ROUGE-1, -2 and -L scores against the abstractive gold standard.

7 Results and Discussion

Table 3 reports the F1 scores for ROUGE-1,-2 and -L (Lin, 2004). We use the *pyrouge*[3] wrapper library to evaluate the final models, while training with a faster Python-only implementation[4].

We test for significance between the baseline models and our proposed techniques using the bootstrap method. This method was first recommended for testing significance in ROUGE scores by Lin (2004), and has subsequently been advocated as an appropriate measure in works such as Dror et al. (2018) and Berg-Kirkpatrick et al. (2012).

[2]We are unable to evaluate this model on the lead overlap measure due to lack of access to the model outputs.

[3]www.github.com/bheinzerling/pyrouge

[4]www.github.com/Diego999/py-rouge

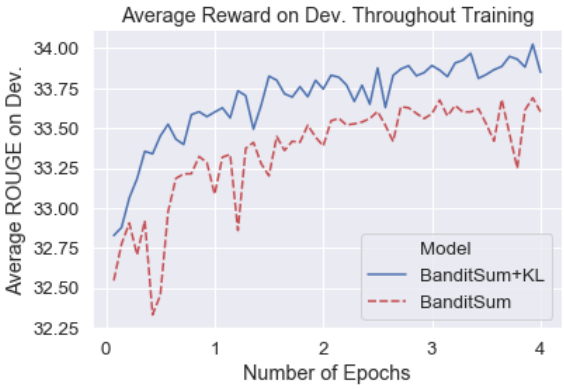

Figure 1: Training curves for BanditSum based models. Average ROUGE is the average of ROUGE-1, -2 and -L F1.

The simple entropy regularizer has a small but not significant improvement, and pretraining has a similar improvement only for RNES. But the auxiliary ROUGE loss significantly ($p < 0.001$) improves over BanditSum, obtaining an extra 0.15 ROUGE points on average. The last column reports the percentage of summary sentences which overlap with the lead. The auxiliary loss leads to a 4.7% absolute decrease in such selections compared to the base system, while also reaching a better ROUGE score. Figure 1 shows that the reward (average ROUGE-1,-2,-L) for the auxiliary loss model is consistently above the base.

We also examined the auxiliary loss model on documents where the summary is mostly comprised of lead sentences D_{early}, mostly sentences much later in the article D_{late}, and a dataset at the midway point, D_{med}. To create these sets, we rank test articles using the average index of its summary sentences in the source document. The 100 test articles with lowest average index are D_{early}, the 100 with highest value are D_{late} and the 100 closest to the median are D_{med}. In Table 4, we can see that the auxiliary loss model's improvements are even more amplified on D_{med} and D_{late}.

On the other hand, our pretraining results are mixed. We hope to employ more controlled multi-tasking methods (Kiperwasser and Ballesteros, 2018) in the future to deal with the issue.

The second line in Table 4 reports the oracle ROUGE scores of the best possible extractive summary. While all systems are quite close to the oracle on D_{early} they only reach half the performance on D_{late}. This gap indicates that our improvements only scratch the surface, but also that this problem is worthy and challenging to explore.

It is worth noting that we have attempted to build a single model which can summarize both

Model	D_{early}	D_{med}	D_{late}
Lead-3	46.17	30.90	20.18
Oracle	50.52	47.92	42.21
RNES	41.76	32.11	20.62
RNES+pretrain	41.66	32.38	20.64
BanditSum	43.10	32.65	21.63
BanditSum+entropy	41.96	32.59	22.12
BanditSum+KL	42.63	33.05	21.96

Table 4: Average ROUGE-1, -2 and -L F1 scores on D_{early}, and D_{med}, D_{late}. Each set contains 100 documents.

lead-biased articles and those whose information is spread throughout. Our aim was to encourage the model to explore useful regions as a way of learning better document semantics. But we hypothesize that our models can be further improved by learning to automatically predict when the lead paragraph suffices as a summary, and when the model should look further in the document.

8 Conclusion

In this paper, we have presented the first approaches for learning a summarization system by countering the strong effect of summary-worthy lead sentences. We demonstrate that recent summarization systems over-exploit the inherent lead bias present in news articles, to the detriment of their summarization capabilities. We explore two techniques aimed at learning to better balance positional cues with semantic ones. While our auxiliary loss method achieves significant improvement, we note that there is a large gap which better methods can hope to bridge in the future.

One approach, building on ours, is to examine other ways to combine loss signals (Finn et al., 2017), and to encourage exploration (Haarnoja et al., 2018). We will also carry out deeper study of the properties of D_{early} and D_{late} type documents and use them to inform new solutions. On cursory analysis, the most frequent terms in D_{early} tend to be about UK politics, while in D_{late} they are often related to British soccer.

Learning Rhyming Constraints using Structured Adversaries

Abstract

Existing recurrent neural language models often fail to capture higher-level structure present in text: for example, rhyming patterns present in poetry. Much prior work on poetry generation uses manually defined constraints which are satisfied during decoding using either specialized decoding procedures or rejection sampling. The rhyming constraints themselves are typically not learned by the generator. We propose an alternate approach that uses a structured discriminator to learn a poetry generator that directly captures rhyming constraints in a generative adversarial setup. By causing the discriminator to compare poems based only on a learned similarity matrix of pairs of line ending words, the proposed approach is able to successfully learn rhyming patterns in two different English poetry datasets (Sonnet and Limerick) without explicitly being provided with any phonetic information.

1 Introduction

Many existing approaches to text generation rely on recurrent neural networks trained using likelihood on sequences of words or characters. However, such models often fail to capture overall structure and coherency in multi-sentence or long-form text (Bosselut et al., 2018; Holtzman et al., 2018). To rectify this, prior work has proposed losses which encourage overall coherency or other desired behavior (Li et al., 2016; Zhang and Lapata, 2017; Bosselut et al., 2018). However, most of these approaches rely on manually provided definitions of what constitutes a good or suitable structure, thereby limiting their applicability. In this paper we propose a method for English poetry generation that directly learns higher-level rhyming constraints as part of a generator without requiring strong manual intervention. Prior works on poetry generation (Oliveira, 2017; Ghazvininejad et al., 2018) have focused mostly on ad-hoc decoding procedures to generate reasonable poetry, often relying on pruning from a set of candidate outputs to encourage desired behavior such as presence of explicitly-defined rhyming patterns.

We propose an adversarial approach to poetry generation that, by adding structure and inductive bias into the discriminator, is able to learn rhyming constraints directly from data without prior knowledge. The role of the discriminator is to try to distinguish between generated and real poems during training. We propose to add inductive bias via the choice of discriminator architecture: We require the discriminator to reason about poems through pairwise comparisons between line ending words. These learned word comparisons form a similarity matrix for the poem within the discriminator's architecture. Finally, the discriminator evaluates the poem through a 2D convolutional classifier applied directly to this matrix. This final convolution is naturally biased to identify spatial patterns across word comparisons, which, in turn, biases learned word comparisons to pick up rhyming since rhymes are typically the most salient spatial patterns.

Recent work by Lau et al. (2018) proposes a quatrain generation method that relies on specific domain knowledge about the dataset to train a classifier for learning the notion of rhyming: that a line ending word always rhymes with exactly one more ending word in the poem. This limits the applicability of their method to other forms of poetry with different rhyming patterns. They train the classifier along with a language model in a multi-task setup. Further, at generation time, they heavily rely on rejection sampling to produce quatrains which satisfy any valid rhyming pattern. In contrast, we find that generators trained using our structured adversary produce samples that satisfy rhyming constraints with much higher frequency.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6025–6031, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

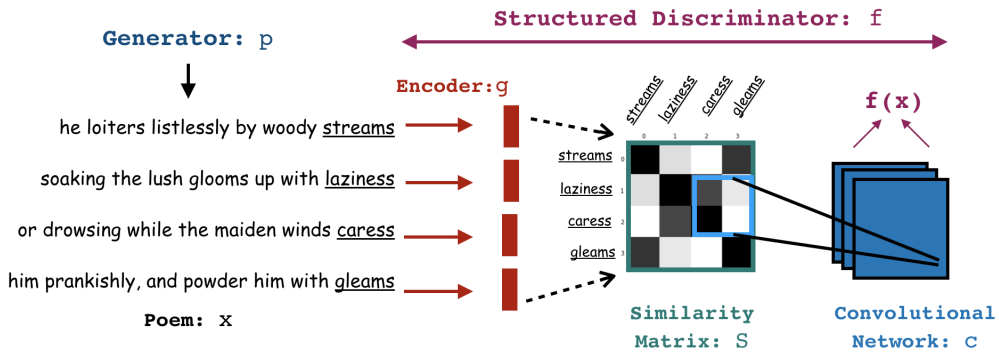

Figure 1: Model Overview: We propose a structured discriminator to learn a poetry generator in a generative adversarial setup. Similarities between pairs of end-of-line words are obtained by computing cosine similarity between their corresponding representations, produced by a learned character-level LSTM encoder. The discriminator operates on the resulting matrix S representing pair-wise similarities of end words. The proposed discriminator learns to identify rhyming word pairs as well as rhyming constraints present in the dataset without being provided phonetic information in advance.

Our main contributions are as follows: We introduce a novel structured discriminator to learn a poetry generation model in a generative adversarial setup. We show that the discriminator induces an accurate rhyming metric and the generator learns natural rhyming patterns without being provided with phonetic information. We successfully demonstrate the applicability of our proposed approach on two datasets with different structural rhyming constraints. Our poem generation model learned with the structured discriminator is more sampling efficient compared to prior work – many fewer generation attempts are required in order to obtain an valid sample which obeys the rhyming constraints of the corresponding poetry dataset.

2 Method

Many forms of poetry make use of rhyming patterns on line-ending words (Oliveira, 2017). Therefore, to characterize a rhyming poem, a model needs (1) to know what it means to rhyme (2) to identify the specific permissible rhyming patterns for a particular poem type. For example, a limerick is a 5 line poem with a rhyming constraint of the type AABBA, i.e. the ends of the first, second, and fifth lines rhyme. We consider an adversarial learning setup with a hierarchical language model and a structured discriminator, such that the discriminator is trained to distinguish between generated examples and training examples, and the generator is trained to *fool* the discriminator. Our novel structured discriminator operates on a matrix which encodes a *learned* pair-wise similarity function of the line ending words. We refer to our model as **RHYME-GAN**.

2.1 Neural Generation Model

Our generator is a hierarchical neural language model (Figure 1) that first generates a sequence of line-ending words, and thereafter generates the poem's lines conditioned on the ending words. We use recurrent neural networks for ending word generation as well line generation conditioned on ending words. Following prior work (Lau et al., 2018), we generate words in each line in reverse order (i.e. right to left), and begin generation with the last line first. Let $\hat{x}$ represent a sample from the current generator distribution, denoted by p_θ, where θ represents the generator parameters. We initialize the word embeddings in the generator with pre-trained word embeddings (Lau et al., 2018) trained on a separate non-sonnet corpus.

2.2 Structured Discriminator

We introduce a structured discriminator, denoted by function $f_\phi(x)$, which outputs the probability that x is a sample from the dataset as opposed to generated. Our architecture defines an intermediate matrix $S \in R^{T \times T}$, where T denotes the number of lines in the poem, which encodes pair-wise similarities between line ending words in order to capture rhyming structure. The discriminator's output is determined by a two layer 2D convolutional neural network applied to S. Convolutional neural networks have been shown to capture local as well as global patterns in 2D data – for example, images. Thus, our discriminator is composed of two main components: computation of a ma-

trix S, and a convolutional neural network to classify the computed matrix S. The pair-wise computation provides a useful inductive bias to identify the notion of rhyming, whereas the convolutional network is a suitable choice to capture overall rhyming patterns.

More specifically, let the words at the ends of lines in x be denoted by e. The number of ending words will be same as the number of lines in x, which we denote as T. We encode each ending word using a character-level LSTM (Hochreiter and Schmidhuber, 1997) denoted by g_{ϕ_g}, and use the last hidden state of the LSTM as a vector representation of the word. We let S_{ij} be the cosine similarity between the representations of ending words e_i, e_j, given by following equation:

$$S_{ij} = \frac{g(e_i)g(e_j)}{|g(e_i)||g(e_j)|} \quad (1)$$

The matrix S is passed through a convolutional neural network composed with a linear layer, together denoted by c_{ϕ_c}. The final output is passed through a sigmoid non-linearity, so that $f_\phi(x) \in [0, 1]$. The value of $f_\phi(x)$ represents the discriminator's assessment of the probability that datum x belongs to the *real* dataset, rather than being a generated sample. The discriminator's objective will train it to distinguish between a sample x from training data $\mathcal{X}$, and a generated sample $\hat{x}$, in a binary classification setup. Specifically, we define the discriminator loss for $x, \hat{x}$ as follows:

$$d(x, \hat{x}; \phi) = -\log(f_\phi(x)) - \log(1 - f_\phi(\hat{x})) \quad (2)$$

2.3 Learning

Generator parameters θ and discriminator parameters ϕ are trained together under following objective:

$$\min_\theta \left[\mathbb{E}_{x \in \mathcal{X}} \left[-\log p_\theta(x) + \lambda \max_\phi \mathbb{E}_{\hat{x} \sim p_\theta}[-d(x, \hat{x})] \right] \right] \quad (3)$$

Note, in addition to using a traditional adversarial objective, we also include a likelihood term to help stabilize the generator. λ is a hyperparameter which controls the relative weight of the two terms. Since sampling of $\hat{x}$ from generator involves discrete choices, we use the REINFORCE (Williams, 1992) algorithm to train the generator using learning signal from the adversarial loss term. The generator simultaneously gets an exact gradient from the likelihood portion of the objective. We observe training is more stable when we pretrain the LSTM word encoder $g_{\phi_g}(.)$ part of the discriminator, along with a separate LSTM decoder, using an auto-encoding objective on words in the vocabulary.

Model	Expected #Samples	
	SONNET	LIMERICK
DEEP-SPEARE	153.8	N/A
RHYME-LM	169.5	500
RHYME-GAN-NS	4.8	26.6
RHYME-GAN	**3.7**	**4.7**

Table 1: Sampling efficiency: We obtain 10K samples of poetry without additional intervention during decoding, and report the expected samples as inverse of the fraction of samples satisfying valid rhyming patterns for the corresponding dataset. Lower values are better.

3 Experiments and Results

3.1 Datasets

We work with the Shakespeare SONNET dataset (Lau et al., 2018) and a new LIMERICK corpus. Each sonnet in the Sonnet dataset is made up of 3 quatrains of 4 lines each, and a couplet. The dataset consists of 2685 sonnets in train, and 335 each in validation and test splits. The quatrains typically have one of the following rhyming structures: AABB, ABAB, ABBA, though some deviations are observed in the dataset. This may be because rhyming patterns are not always strictly followed in writing quatrains, and there are possible inaccuracies in the word pronunciation dictionaries used (e.g. some words can have multiple different pronunciations based on context).

A limerick is a form of verse with five lines. Limericks typically follow a rhyming pattern of AABBA. We collect limericks from an online collection[1]. Due to a large vocabulary in the full collection, we filter the dataset to retain only those limericks whose all the words are in a subset of 9K most frequent words. Our final dataset consists of $10,400$ limericks in train and 1300 each in validation and test splits. We train and evaluate the models separately on each corpus.

3.2 Poem Generator

Sampling efficiency We compute the expected number of samples needed before we sample a quatrain which satisfies one of the hand-defined rhyming patterns. Towards this end, we get 10K samples from each model without any constraints (except avoiding *UNK* - unknown tokens). Fol-

[1] http://hardsoft.us. Accessed May 2019.

lowing prior work (Lau et al., 2018), words are sampled with a temperature value between 0.6 and 0.8. We use CMU dictionary (Weide, 1998) to look up the phonetic representation of a word, and extract the sequence of phonemes from the last stressed syllable onward. Two words are considered to be rhyming if their extracted sequences match (Parrish, 2015). We consider a generated quatrain to have an acceptable pattern if the four ending words follow one of the three rhyming patterns: AABB, ABBA, ABAB. Similarly for LIMERICK, we consider only those samples to be acceptable which have line endings of the rhyming form AABBA.

We consider a baseline **RHYME-LM**, which has the same generator architecture as RHYME-GAN but is trained without the discriminator. We also compare with **RHYME-GAN-NS** which uses a simpler non-structured discriminator. Specifically, it uses a discriminator which first runs a character-level encoder for each ending word - similar to RHYME-GAN - but then instead of computing pairwise similarity matrix, it utilizes a LSTM on the sequence of the computed representations.

As can be observed from Table 1, RHYME-GAN needs fewer samples than other methods to produce an acceptable quatrain or a limerick, indicating that it has learned natural rhyming structures more effectively from data. Note we do not report DEEP-SPEARE on Limerick due to their SONNET specific assumption that for a given end-of-line word there is exactly one more rhyming word among other end-of-line words. Additionally, RHYME-GAN-NS performs worse than RHYME-GAN, and the difference in performance is more prominent in LIMERICK – demonstrating that the proposed structure in the discriminator provided useful inductive bias. Note that compared to 4 line quatrains in SONNET, LIMERICK has 5 line poems and has arguably more complex rhyming pattern constraints.

Likelihood on held out data We report negative log likelihood (NLL) on test splits (Table 2). For SONNET, RHYME-GAN achieves a test set NLL of 3.98. Our model without adversarial learning i.e. RHYME-LM, achieves a test set NLL of 3.97. DEEP-SPEARE reports a test set NLL of 4.38. Note that our language model is hierarchical while DEEP-SPEARE has a linear model. The NLL for RHYME-LM and RHYME-GAN are very similar, though RHYME-GAN gets much better sampling efficiency scores than RHYME-LM.

Model	NLL	
	SONNET	LIMERICK
DEEP-SPEARE	4.38	N/A
RHYME-LM	**3.97**	**3.48**
RHYME-GAN	3.98	3.49

Table 2: Held out negative log likelihood per token for poems in test split.

Our generator implementation is largely based on that of Lau et al. (2018). The main difference is that we first generate all the line-ending words and then condition on them to generate the remaining words. The change was made to make it more amenable to our proposed discriminator. However, our hierarchical language model (RHYME-LM) performs worse than DEEP-SPEARE as per sampling efficiency. Therefore, structured discriminator is the driving factor behind the observed improvement with RHYME-GAN. However, committing to the ending words of all lines before completing preceding lines can be a limitation, and addressing it is a possible future direction.

3.3 Analyzing Learned Discriminator

We probe the the word representations $g(.)$ to check if rhyming words are close-by in the learned manifold. We consider all pairs of words among the ending words in a quatrain/limerick, and label each pair to be rhyming or non-rhyming based on previously stated definition of rhyming. If the cosine similarity score between the representations of pairs of words is above a certain threshold, we predict that word pair as rhyming, else it is predicted as non-rhyming. We report F1 scores for the binary classification setup of predicting word-pairs to be rhyming or not. We consider some additional baselines: **RHYM-EM** (Reddy and Knight, 2011) uses latent variables to model rhyming schemes, and train parameters using EM. **GRAPHEME-K** baselines predict a word pair as rhyming only if the last $K = \{1, 2, 3\}$ characters of the two words are same.

For SONNET data, we observe that RHYME-GAN obtains a F1 score of 0.90 (Table 3) on the test split (threshold chosen to maximize f1 on dev split). We repeat the above analysis on the LIMERICK dataset and observe an F1 of 0.92 for RHYME-GAN. DEEP-SPEARE model reports F1

Model	SONNET	LIMERICK
GRAPHEME-1	0.71	0.79
GRAPHEME-2	0.78	0.79
GRAPHEME-3	0.69	0.67
RHYM-EM	0.71	0.73
DEEP-SPEARE/MAX-MARGIN	0.91	0.81
RHYME-GAN-NS	0.85	0.87
RHYME-GAN	**0.90**	**0.92**

Table 3: Rhyming probe: We use the cosine similarity score of the learned representations to predict a word pair as rhyming or not, and report F1 score for this classification task. RHYM-EM is an unsupervised rhyming pattern discovery method. GRAPHEME-K baselines predict based on exact match of last k characters.

of 0.91 on SONNET. As stated earlier, DEEP-SPEARE'S model is not amenable to LIMERICK - we do compare though with the max-margin classifier in DEEP-SPEARE model trained on LIMERICK which gets F1 score of 0.81. The scores are understandably lower since the AABBA pattern in limericks is not amenable to SONNET specific assumptions made in DEEP-SPEARE model. On the other hand, RHYME-GAN achieves high F1 scores for both the datasets without incorporating any domain specific rhyming pattern information.

RHYME-GAN performs much better than RHYM-EM and GRAPHEME-K baselines. RHYM-EM does not perform well - probably because it operates at word-level and fails to generalize. Note that **RHYME-GAN-NS** gets F1 score of 0.85 in case of SONNET dataset and 0.87 for LIMERICK. These values are lower than corresponding scores for RHYME-GAN, demonstrating that the proposed structure in the discriminator was useful in learning the notion of rhyming.

3.4 Human Evaluations

Following prior work (Lau et al., 2018), we requested human annotators to identify the human-written poem when presented with two samples at a time - a quatrain from the Sonnet corpus and a machine-generated quatrain, and report the annotator accuracy on this task. Note that a lower accuracy value is favorable as it signifies higher quality of machine-generated samples. Using 150 valid samples (i.e. samples belonging to one of the allowed rhyming patterns), we observe 56.0% annotator accuracy for RHYME-GAN, and 53.3% for DEEP-SPEARE – indicating that the post-rejection sampling outputs from the two methods are of comparable quality (the difference in annotator accuracy is not statistically significant as per McNemar's test under $p < 0.05$). If we use pre-rejection samples, we observe 60.0% annotator accuracy for RHYME-GAN, and 81.3% for DEEP-SPEARE (the difference being statistically significant as per McNemar's test under $p < 0.05$) – indicating that unfiltered samples from RHYME-GAN are of higher quality compared to DEEP-SPEARE.

4 Related Work

Early works on poetry generation mostly used rule based methods (Gervás, 2000; Wu et al., 2009; Oliveira, 2017). More recently, neural models for poetry generation have been proposed (Zhang and Lapata, 2014; Ghazvininejad et al., 2016, 2017; Hopkins and Kiela, 2017; Lau et al., 2018; Liu et al., 2019). Yan et al. (2013) retrieve high ranking sentences for a given user query, and repeatedly swap words to satisfy poetry constraints. Ghazvininejad et al. (2018) worked on poetry translation using an unconstrained machine translation model and separately learned Finite State Automata for enforcing rhythm and rhyme. Similar to rhyming and rhythm patterns in poetry, certain types of musical compositions showcase rhythm and repetition patterns, and some prior works model such patterns in music generation (Walder and Kim, 2018; Jhamtani and Berg-Kirkpatrick, 2019). Generative adversarial learning (Goodfellow et al., 2014) for text generation has been used in prior works (Fedus et al., 2018; Wang et al., 2018, 2019; Rao and Daumé III, 2019), though has not been explored with regard to the similarity structure proposed in this paper.

5 Conclusions

In this paper we have proposed a novel structured discriminator to learn a poem generator. The generator learned utilizing the structured adversary is able to identify rhyming structure patterns present in data, as demonstrated through the improved sampling efficiency. Through the rhyming classification probe, we demonstrate that the proposed discriminator is better at learning the notion of rhyming compared to baselines.

Question-type Driven Question Generation

Abstract

Question generation is a challenging task which aims to ask a question based on an answer and relevant context. The existing works suffer from the mismatching between question type and answer, i.e. generating a question with type *how* while the answer is a personal name. We propose to automatically predict the question type based on the input answer and context. Then, the question type is fused into a seq2seq model to guide the question generation, so as to deal with the mismatching problem. We achieve significant improvement on the accuracy of question type prediction and finally obtain state-of-the-art results for question generation on both SQuAD and MARCO datasets.

1 Introduction

Question generation (QG) can be effectively applied to many fields, including question answering (Duan et al., 2017), dialogue system (Shum et al., 2018) and education. In this paper, we focus on the answer-aware QG, which is to generate a question according to the given sentence and the expected answer.

Recently, the neural-based approaches on QG have achieved remarkable success, by applying large-scale reading comprehension datasets and employing the encoder-decoder framework. Most of the existing works are based on the seq2seq network incorporating attention mechanism and copy mode, which are first applied in Zhou et al. (2017). Later, Song et al. (2018) leverage multi-perspective matching methods, and Sun et al. (2018) propose a position-aware model to put more emphasis on answer-surrounded context words. Both works are trying to enhance the relevance between the question and answer. Zhao et al. (2018) aggregate paragraph-level context to provide sufficient information for question generation. Another direction is to integrate question answering and question generation as dual tasks (Tang et al., 2017). Beyond answer-aware QG, some systems try to generate questions from a text without answer as input (Du and Cardie, 2017; Subramanian et al., 2018).

Despite the progress achieved by the previous work, we found that the types of generated questions are often incorrect. According to experiments on SQuAD, one strong model (Zhou et al., 2017) we replicate only obtains 57.6% accuracy in question type. As we know, question type is vital for question generation, since it determines the question pattern and guides the generating process. If the question type is incorrect, the remained generated sequence would drift far away.

Several works have addressed this issue. Sun et al. (2018) incorporated a question word generation mode to generate question word at each decoding step, which utilized the answer information by employing the encoder hidden states at the answer start position. However, their method did not consider the structure and lexical features of answer. Meanwhile, the way they utilize the question word is not as effective as ours. Hu et al. (2018) proposed a model to generate question based on the given question type and aspect, and their work verifies the effect of question word but fails in the conventional QG task which does not give a question type, since their experimental results show poor performance when trying to generate question types automatically. Our work solves this problem as Section 3.3 shows. Wang et al. (2018) devised a type decoder which combines three type-specific generation distribution (including question type) with weighted sum. However, the results displayed in their paper show that questions in dialogue are far different from questions for reading comprehension, which indicates a gap

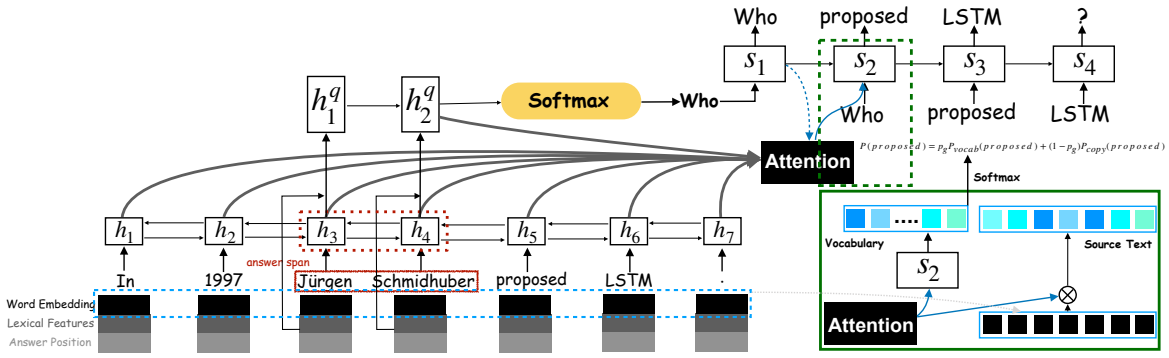

Figure 1: Structure of our unified model

between two tasks.

In this paper, we propose a unified model to predict the question type and to generate questions simultaneously. We conduct experiments on two reading comprehension datasets: SQuAD and MARCO, and obtain promising results. As for the auxiliary task, our unified model boosts the accuracy of question type prediction significantly, by 16.79% on SQuAD and 3.5% on MARCO. For question generation, our model achieves new state-of-the-art results on both datasets, with BLEU-4 16.31 on SQuAD and 21.59 on MARCO.

2 Model Description

The structure of our model is shown in Figure 1. A feature-rich encoder is used to encode the input sentence and corresponding answer that is a span of the sentence. Besides, the answer hidden states are used to predict the type of target question. This prediction will further be used to guide QG with a unified attention-based decoder.

2.1 Feature-rich Encoder

Follow Zhou et al. (2017), we exploit lexical features to enrich the encoder, where features are composed of POS tags, NER tags, and word case. We concatenate the word embedding e_t, answer position embedding a_t and lexical features embedding l_t as input $((x_1, ..., x_T), x_t = [e_t; a_t; l_t])$. Then a bidirectional LSTM is used to produce a sequence of hidden states $(h_1, ..., h_T)$.

2.2 Question Type Prediction

Since different types of questions are various in syntax and semantics, it is essential to predict an accurate type for generating a reasonable question. According to the statistics on SQuAD, 78% of questions in the training set begin with the 7 most common used question words as Table 1 shows. So we divide question types into 8 categories, including 7 question words and an additional type 'others'. It shows that the data distribution on different types is quite unbalanced, suggesting it is a hard task to predict the correct question type.

We use an unidirectional LSTM network to predict the expected question type. Assuming *m+1, ..., m+a* is the index of given answer span in the input sentence, based on the corresponding feature-rich hidden states $(h_{m+1}, ..., h_{m+a})$, we calculate the question type hidden states as follow:

$$h_j^q = LSTM^q([h_{m+j}; l_{m+j}], h_{j-1}^q), j \in [1, a] \quad (1)$$

$$h_0^q = h_T \quad (2)$$

where l_{m+j} is the corresponding lexical features. Besides, to make full use of the feature-rich encoder hidden states, we take the last hidden state as the initial hidden state of $LSTM^q$.

Then, the last output hidden state h_a^q are fed into a softmax layer to obtain the type distribution:

$$P(Q_w) = softmax(W_q h_a^q) \quad (3)$$

$$E^q = -log(P(Q_w^*)) \quad (4)$$

E^q is the loss of question type prediction, Q_w^* is the target type.

2.3 Unified Attention-based Decoder

The conventional attention-based decoder adopts a <BOS> token as the first input word at step 1, while we replace it with the predicted question word Q_w to guide the generation process. At step i, we calculate the decoder hidden state as follow:

$$s_i = LSTM([w_{i-1}; c_{i-1}], s_{i-1}) \quad (5)$$

Further, to fuse the type information in every step of question generation, our model takes h_a^q into consideration while calculating the context

Type	What	Who	How	When	Which	Where	Why	Others
SQuAD	43.26%	9.39%	9.12%	6.26%	4.78%	3.76%	1.37%	21.83%
MARCO	44.29%	1.47%	16.28%	1.52%	1.11%	4.16%	1.88%	29.29%

Table 1: Proportions of each type of questions on two datasets.

vector, i.e. the context vector is conditioned on $(h_1, ..., h_T, h_{T+1})$, where $h_{T+1} = h_a^q$.

$$c_i = \sum_{t=1}^{T+1} \alpha_{it} h_t \tag{6}$$

where α_{it} is calculated via attention mechanism (Bahdanau et al., 2014).

Then, s_i together with c_i will be fed into a two-layer feed-forward network to produce the vocabulary distribution P_{vocab}.

Following (See et al., 2017), the copy mode is used to duplicate words from the source via pointing:

$$P(w_i) = p_g P_{vocab}(w_i) + (1 - p_g) P_{copy}(w_i) \tag{7}$$

where P_{copy} is the distribution of copy mode, $p_g \in [0, 1]$ is a gate to dynamically assign weights.

The loss at step i is the negative log-likelihood of the target word w_i^*. To obtain a combined training objective of two tasks, we add the loss of question type prediction into the loss of question generation to form a total loss function:

$$E^{total} = \frac{1}{K} \sum_{i=1}^{K} -logP(w_i^*) + E^q \tag{8}$$

3 Experiment

3.1 Experiment Settings

Dataset Following the previous works, we conduct experiments on two datasets, SQuAD and MARCO. We use the data released by Zhou et al. (2017) and Sun et al. (2018), there are 86,635, 8,965 and 8,964 sentence-answer-question triples in the training, development and test set for SQuAD, and 74,097, 4,539 and 4,539 sentence-answer-question triples in the training, development and test set for MARCO, respectively. Lexical features are extracted using Stanford CoreNLP.

Implementation Details Our vocabulary is set to contain the most frequent 20,000 words in each training set. Word embeddings are initialized with the pre-trained 300-dimensional Glove vectors, and they are allowed to be fine-tuned during training. The representations of answer position, POS tags, NER tags, and word case are randomly initialized as 32-dimensional vectors, respectively. The feature-rich encoder consists of 2 layers BiLSTM, and the hidden size of all encoders and decoder is set to 512. The cutoff length of the input sequences is set to 10. In testing, we used beam search with a beam size of 12. The development set is used to search the best checkpoint. In order to decrease the volatility of the training procedure, we then average the nearest 5 checkpoints to obtain a single averaged model.

Following the existing work, we use BLUE (Papineni et al., 2002) as the metrics for automatic evaluation, with BLUE-4 as the main metric.

3.2 Upper Bound Analysis

To study the effectiveness of the question type for QG, we make an upper bound analysis. The experimental results are shown in Table 2.

First, we feed the decoder with the original first word of questions, regardless whether the first word is a question word or not. As shown in Table 2, comparing with the baseline model, the performance gets 3.41 and 3.32 points increment on SQuAD and MARCO, respectively, which is a large margin.

Since the beginning words which are not question words compose a large vocabulary while the number of each word is few, it is irrational to train a classifier to predict all types of these beginning words. Therefore, we reduce the question type vocabulary to only question words. In details, if the start of a targeted question is a question word, the corresponding question word will replace the <BOS> to feed into decoder, otherwise we just use the original <BOS> without any replacement. This experiment still gains a lot, as shown in Table 2 with "given the quetion type".

The above experiments verify the magnitude of using the proper question type to guide the generation process, suggesting us a promising direction for QG.

Dataset / Model	SQuAD BLEU-1	SQuAD BLEU-2	SQuAD BLEU-3	SQuAD BLEU-4	MARCO BLEU-1	MARCO BLEU-2	MARCO BLEU-3	MARCO BLEU-4
feature-rich pointer generator (baseline)	41.25	26.76	19.53	14.89	54.04	36.68	26.62	20.15
given the first word of question	47.00	31.82	23.69	18.30	59.51	41.42	30.70	23.47
given the question type	45.56	30.53	22.61	17.38	57.39	39.60	29.29	22.52

Table 2: Upper bound analysis by incorporating question words with different ways.

Dataset / Model	SQuAD BLEU-1	SQuAD BLEU-2	SQuAD BLEU-3	SQuAD BLEU-4	MARCO BLEU-1	MARCO BLEU-2	MARCO BLEU-3	MARCO BLEU-4
NQG++ (Zhou et al., 2017)	-	-	-	13.29	-	-	-	-
question word generate model (Sun et al., 2018)	42.10	27.52	20.14	15.36	46.59	33.46	24.57	18.73
Hybrid model (Sun et al., 2018)	43.02	28.14	20.51	15.64	48.24	35.95	25.79	19.45

Question-type driven model (Unified-model)	43.11	**29.13**	**21.39**	**16.31**	**55.67**	**38.16**	**28.12**	**21.59**

Table 3: Experimental results of our model comparing with previous methods on two datasets.

3.3 Results and Analysis

Main Results The experimental results on two datasets are shown in Table 3. By incorporating the question type prediction, our model obtains obvious performance gain over the baseline model, with 1.42 points gain on SQuAD and 1.44 on MARCO. Comparing with previous methods, our model outperforms the existing best methods, achieving new state-of-the-art results on both datasets, with 16.31 on SQuAD and 21.59 on MARCO.

Question Type Accuracy We evaluate different models in terms of Beginning Question Word Accuracy (BQWA). This metric measures the ratio of the generated questions that share the same beginning word with the references which begin with a question word. Table 4 displays the BQWA of two models on both datasets. It shows that our unified model brings significant performance gain in question type prediction.

Further, in Figure 2 we show the accuracy of different question words on both datasets in detail. Our unified model outperforms the baseline for all question types on SQuAD, and all but two types on MARCO.

Model	BQWA on SQuAD	BQWA on MARCO
Baseline	57.62%	76.98%
Unified model	**74.41%**	**80.48%**

Table 4: Experiments of the beginning question word accuracy.

Model Analysis We conduct experiments on different variants of our model, as shown in Table 5. "w/o answer hidden state" takes $(x_{m+1}, ..., x_{m+a})$ as the input of type decoder instead of answer hidden states; "w/o question word replace <BOS>" simply use <BOS> as the first input word of decoder. Experiments on SQuAD verify the effectiveness of our model setting.

Dataset / Model	SQuAD BLEU-1	SQuAD BLEU-2	SQuAD BLEU-3	SQuAD BLEU-4
Unified-model	43.11	29.13	21.39	16.31
w/o answer hidden states	41.91	27.77	20.37	15.54
w/o question word replace <BOS>	41.05	26.93	19.73	15.10

Table 5: Experiments on different settings of our model.

Case Study To show the effect of question words prediction on question generation, Table 6 lists some typical examples.

In the first example, the baseline fails to recognize *Len-shaped* as an adjective, while the unified-model succeeds by utilizing lexical features which are the input of question type prediction layer.

In the second example, the baseline assigns a location type for the generated question based on *American* and *Israel*, it fails to consider the whole answer span. Our unified model resolves it by encoding the answer hidden states sequence as a whole.

The third example shows another typical error, which fails to consider answer surrounding context. In this example the given answer only contains a number *66*. By taking *article 66* into account, we know the question should not be a nu-

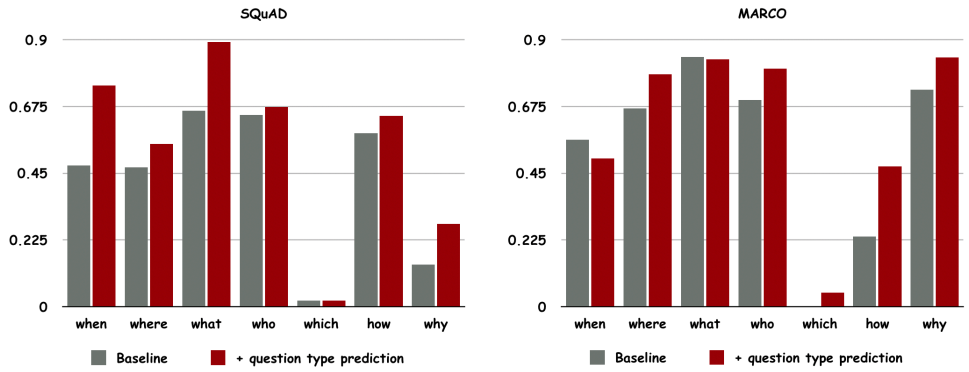

Figure 2: The accuracy on different question words.

merical type. Since the answer hidden states used as the input of type prediction contain surrounding information, our model resolves this problem.

Context: In land plants , chloroplasts are generally lens-shaped, 5–8 m in diameter and 1–3 m thick. **Reference:** How are chloroplasts in land plants usually shaped? **Baseline:** What are chloroplasts generally generally? **Unified-model:** How are chloroplasts in land plants?
Context: In response to American aid to Israel, on October 16, 1973, OPEC raised the posted price of oil by 70%, to $5.11 a barrel. **Reference:** Why did the oil ministers agree to a cut in oil production? **Baseline:** Where did OPEC receive the price of oil by 70%? **Unified-model:** Why did OPEC raised the posted price of oil by 70%?
Context: Article 65 of the agreement banned cartels and article 66 made provisions for concentrations, or mergers, and the abuse of a dominant position by companies. **Reference:** Which article made provisions for concentrations or mergers and the abuse of a dominant position by companies? **Baseline:** How many provisions made provisions for concentrations? **Unified-model:** Which article made provisions for concentrations, or mergers?

Table 6: Examples of generated questions. The underline words are the target answer.

4 Conclusion

In this paper, we discuss the challenge in question type prediction for question generation. We propose a unified model to predict the type and utilize it to guide the generation of question. Experiments on SQuAD and MARCO datasets verify the effectiveness of our model. We improve the accuracy of question type prediction by a large margin, and achieve new state-of-the-art results for question generation.

Abstract

Deep reinforcement learning (RL) has been a commonly-used strategy for the abstractive summarization task to address both the exposure bias and non-differentiable task issues. However, the conventional reward ROUGE-L simply looks for exact n-grams matches between candidates and annotated references, which inevitably makes the generated sentences repetitive and incoherent. In this paper, instead of ROUGE-L, we explore the practicability of utilizing the distributional semantics to measure the matching degrees. With distributional semantics, sentence-level evaluation can be obtained, and semantically-correct phrases can also be generated without being limited to the surface form of the reference sentences. Human judgments on Gigaword and CNN/Daily Mail datasets show that our proposed distributional semantics reward (DSR) has distinct superiority in capturing the lexical and compositional diversity of natural language.

1 Introduction

Abstractive summarization is a task of paraphrasing a long article with fewer words. Unlike extractive summarization, abstractive summaries can include tokens out of the article's vocabulary. There exists several encoder-decoder approaches such as attention-based architecture (Bahdanau et al., 2015; Rush et al., 2015; Nallapati et al., 2016; Chopra et al., 2016), incorporating graph techniques (Moawad and Aref, 2012; Ganesan et al., 2010), and adding pointer generator (Vinyals et al., 2015; Nallapati et al., 2016; See et al., 2017; Bello et al., 2017). However, long sentence generation suffers from exposure bias (Bahdanau et al., 2017) as the error accumulates during the decoding process.

Many innovative deep RL methods (Ranzato et al., 2016; Wu et al., 2016; Paulus et al., 2018; Lamb et al., 2016) are developed to alleviate this issue by providing sentence-level feedback after generating a complete sentence, in addition to optimal transport usage (Napoles et al., 2012). However, commonly used automatic evaluation metrics for generating sentence-level rewards count exact n-grams matches and are not robust to different words that share similar meanings since the semantic level reward is deficient.

Currently, many studies on contextualized word representations (Peters et al., 2018; Devlin et al., 2019) prove that they have a powerful capacity of reflecting distributional semantic. In this paper, we propose to use the distributional semantic reward to boost the RL-based abstractive summarization system. Moreover, we design several novel objective functions.

Experiment results show that they outperform the conventional objectives while increasing the sentence fluency. Our main contributions are three-fold:

• We are the first to introduce DSR to abstractive summarization and achieve better results than conventional rewards.
• Unlike ROUGE, our DSR does not rely on cross-entropy loss (XENT) to produce readable phrases. Thus, no exposure bias is introduced.
• DSR improves generated tokens' diversity and fluency while avoiding unnecessary repetitions.

2 Methodology

Background While sequence models are usually trained using XENT, they are typically evaluated at test time using discrete NLP metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005). Therefore, they suffer from both the exposure bias

*Equal contributions.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6038–6044, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

and non-differentiable task metric issues. To solve these problems, many resorts to deep RL with sequence to sequence model (Paulus et al., 2018; Ranzato et al., 2016; Ryang and Abekawa, 2012), where the learning agent interacts with a given environment. However, RL models have poor sample efficiency and lead to very slow convergence rate. Therefore, RL methods usually start from a pretrained policy, which is established by optimizing XENT at each word generation step.

$$L_{\text{XENT}} = -\sum_{t=1}^{n'} \log P(y_t|y_1, \ldots, y_{t-1}, x). \quad (1)$$

Then, during RL stage, the conventional way is to adopt self-critical strategy to fine-tune based on the target evaluation metric,

$$L_{\text{RL}} = \sum_{t=1}^{n'} \log P(\hat{y_t}|\hat{y_1}, \ldots, \hat{y_{t-1}}, x) \times (r_{metric}(y^b) - r_{metric}(\hat{y})) \quad (2)$$

Distributional Semantic Reward During evaluating the quality of the generated sentences, ROUGE looks for exact matches between references and generations, which naturally overlooks the expression diversity of the natural language. In other words, it fails to capture the semantic relation between similar words. To solve this problem, distributional semantic representations are a practical way. Recent works on contextualized word representations, including ELMO (Peters et al., 2018), GPT (Radford et al., 2018), BERT (Devlin et al., 2019), prove that distributional semantics can be captured effectively. Based on that, a recent study, called BERTSCORE (Zhang et al., 2019), focuses on sentence-level generation evaluation by using pre-trained BERT contextualized embeddings to compute the similarity between two sentences as a weighted aggregation of cosine similarities between their tokens. It has a higher correlation with human evaluation on text generation tasks comparing to existing evaluation metrics.

In this paper, we introduce it as a DSR for deep RL. The BERTSCORE is defined as:

$$R_{\text{BERT}} = \frac{\sum_{y_i \in y} \text{idf}(y_i) \max_{\hat{y}_j \in \hat{y}} \mathbf{y_i}^\top \hat{\mathbf{y}}_\mathbf{j}}{\sum_{y_i \in y} \text{idf}(y_i)} \quad (3)$$

$$P_{\text{BERT}} = \frac{\sum_{y_j \in y} \text{idf}(y_j) \max_{\hat{y}_i \in \hat{y}} \mathbf{y_j}^\top \hat{\mathbf{y}}_\mathbf{i}}{\sum_{y_j \in y} \text{idf}(y_j)} \quad (4)$$

$$F_{\text{BERT}} = 2\frac{R_{\text{BERT}} \cdot P_{\text{BERT}}}{R_{\text{BERT}} + P_{\text{BERT}}} \quad (5)$$

where $\mathbf{y}$ and $\hat{\mathbf{y}}$ represent BERT contextual embeddings of reference word y and candidate word $\hat{y}$, respectively. The function idf$(\cdot)$ calculates inverse document frequency (idf). In our DSR, we do not use the idf since Zhang et al. (2019) requires to use the entire dataset including test set for calculation. Besides, ROUGE do not use similar weight, so we do not include idf for consistency.

3 Experimental Setup

3.1 Datasets

Gigaword corpus It is an English sentence summarization dataset based on annotated Gigaword (Napoles et al., 2012). A single sentence summarization is paired with a short article. We use the OpenNMT provided version It contains 3.8M training, 189k development instances. We randomly sample 15k instances as our test data.

CNN/Daily Mail dataset It consists of online news articles and their corresponding multi-sentence abstracts (Hermann et al., 2015; Nallapati et al., 2016). We use the non-anonymized version provided by See et al. (2017), which contains 287k training, 13k validation, and 11k testing examples. We truncate the articles to 400 tokens and limit the summary lengths to 100 tokens.

3.2 Pretrain

We first pretrain a sequence-to-sequence model with attention using XENT and then select the best parameters to initialize models for RL. Our models have 256-dimensional hidden states and 128-dimensional word embeddings and also incorporates the pointer mechanism (See et al., 2017) for handling out of vocabulary words.

3.3 Baseline

In abstractive summarization, ROUGE (Lin, 2004) is a common evaluation metric to provide a sentence-level reward for RL. However, using ROUGE as a pure RL objective may cause too many repetitions and reduced fluency in outputs. Paulus et al. (2018) propose a hybrid learning objective that combines XENT and self-critical ROUGE reward (Paulus et al., 2018).

$$L_{\text{baseline}} = \gamma L_{\text{rouge}} + (1 - \gamma) L_{\text{XENT}} \quad (6)$$

where γ is a scaling factor and the F score of ROUGE-L is used as the reward to calculate L_{Rouge}. In our experiment, we select $\gamma = 0.998$ for Gigaword Corpus and $\gamma = 0.9984$ for CNN/Daily Mail dataset. [1] Note that we do not avoid repetition during the test time as Paulus et al. (2018) do, because we want to examine the repetition of sentence directly produced after training.

3.4 Proposed Objective Functions

Inspired by the above objective function (Paulus et al., 2018), we optimize RL models with a similar loss function as equation 2. Instead of ROUGE-L, we incorporate BERTSCORE, a DSR to provide sentence-level feedback.

In our experiment, L_{DSR} is the self-critical RL loss (equation 2) with F_{BERT} as the reward. We introduce the following objective functions:

DSR+ROUGE: A combined reward function of ROUGE and F_{BERT}

$$L_1 = \gamma L_{\text{DSR}} + (1 - \gamma) L_{\text{rouge}} \tag{7}$$

In our experiment, we select $\gamma = 0.5$ for both datasets to balance the influence of two reward functions.

DSR+XENT: F_{BERT} reward with XENT to make the generated phrases more readable.

$$L_2 = \gamma' L_{\text{DSR}} + (1 - \gamma') L_{\text{XENT}} \tag{8}$$

In our experiment, we select $\gamma' = 0.998$ for Gigaword Corpus and $\gamma' = 0.9984$ for CNN/Daily Mail dataset.

DSR: Pure F_{BERT} objective function without any teacher forcing.

$$L_3 = L_{\text{DSR}} \tag{9}$$

4 Results

For the abstractive summarization task, we test our models with different objectives on the Gigaword and CNN/Daily Mail datasets. We choose F_{BERT} and ROUGE-L as our automatic evaluation metrics. For multi-sentence summaries in CNN/Daily Mail dataset, we calculate ROUGE-L and F_{BERT} after concatenating the original abstract sentences or their BERT contextualized embeddings. The results are shown in Table 1. The model DSR+ROUGE (equation 7) achieves the best ROUGE performance on Gigaword and similar performance comparing to ROUGE model on CNN/Daily Mail. Training with DSR (equation 9) and DSR+XENT (equation 8) can obtain the best BERTScores as expected. It is also expected that ROUGE model will obtain worse BERTScores as simply optimizing ROUGE will generate less readable sentences (Paulus et al., 2018); however, DSR model without XENT as a teacher forcing can improve the performance of pretrained model in both F_{BERT} and ROUGE-L scale.

Note that DSR model's ROUGE-L is high in training time but does not have a good generalization on test set, and ROUGE-L is not our target evaluation metrics. In the next section, we will do human evaluation to analyze the summarization performance of different reward systems.

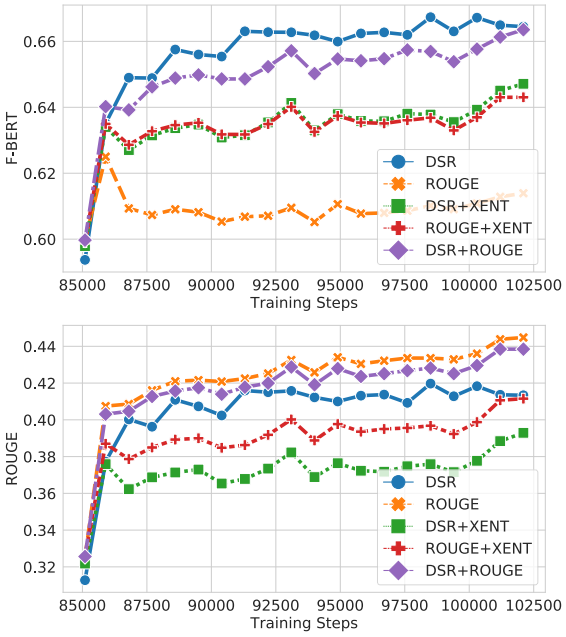

Figure 1: F_{BERT} (left) and ROUGE (right) on Gigaword Corpus during training time after pretraining with XENT. Note that ROUGE is not our target evaluation metrics.

5 Human Evaluation

We perform human evaluation on the Amazon Mechanical Turk to assure the benefits of DSR on output sentences' coherence and fluency. We randomly sample 500 items as an evaluation set us-

[1] γ is very close to 1 due to the difference in the scales of the two loss functions. For Gigaword Corpus, we tune the γ on the development set. For CNN/Daily Mail, we use the same γ as Paulus et al. (2018) does.

Model	Gigawords				CNN/Daily Mail			
	F_{BERT}	P_{BERT}	R_{BERT}	ROUGE	F_{BERT}	P_{BERT}	R_{BERT}	ROUGE
XENT	65.78	67.61	64.53	40.77	62.77	62.18	63.79	29.46
ROUGE	61.46	60.89	62.70	42.73	60.11	59.31	61.33	**33.89**
ROUGE+XENT	66.50	67.24	66.28	42.72	61.38	61.07	62.17	33.07
DSR+ROUGE	66.48	66.79	66.65	**42.95**	65.01	65.92	64.56	33.61
DSR+XENT	67.02	**67.69**	66.85	42.29	66.64	66.06	67.63	31.28
DSR	**67.06**	67.34	**67.28**	41.73	**66.93**	**66.27**	**67.98**	30.96

Table 1: Results on Gigawords and CNN/Daily Mail for abstractive summarization. Upper rows show the results of baselines. Rouge stands for the F score of Rouge-L.

Task	Model v. base	Gigawords			CNN/Daily Mail		
		Win	Lose	Tie	Win	Lose	Tie
Relevance	DSR + XENT	31.0%	25.2%	43.8%	51.1%	34.1%	14.8%
	DSR	45.4%	27.2%	27.4%	48.7%	38.5%	12.8%
Fluency	DSR + XENT	40.2%	19.6%	40.2%	55.8%	28.5%	15.6%
	DSR	45.4%	28.8%	25.8%	54.0%	31.7%	14.3%

Table 2: Human evaluation results on Gigaword and CNN/Daily Mail for abstractive summarization. ROUGE+XENT is the selected baseline model.

ing uniform distribution. During the evaluation, given the context without knowing the ground truth summary, judges are asked to decide two things between generations of ROUGE+XENT and DSR+XENT: 1. which summary is more relevant to the article. 2. which summary is more fluent. Ties are permitted. A similar test is also done between ROUGE+XENT and DSR model. As shown in Table 2, DSR and DSR+XENT models improve the relevance and fluency of generated summary significantly. In addition, using pure DSR achieve better performances on Gigaword Corpus and comparable results as DSR+XENT on CNN/Daily Mail. While Paulus et al.'s (2018) objective function requires XENT to make generated sentence readable, our proposed DSR does not require XENT and can limit the exposure bias originated from it.

6 Analysis

Diversity Other than extractive summarization, abstractive summarization allows more degrees of freedom in the choice of words. While simply selecting words from the article made the task easier to train, higher action space can provide more paths to potentially better results (Nema et al., 2017). Using the DSR as deep RL reward will support models to choose actions that are not n-grams of the articles. In Table 4, we list a few generated samples on Gigaword Corpus. In our first example in Table 4, the word "sino-german" provides an interesting and efficient way to express the relation between China and Germany. F_{BERT} is also improved by making this change. In addition, the second example in Table 4 shows that RL model with DSR corrects the sentence' grammar and significantly improves the F_{BERT} score by switching "down" to an unseen word "drops". On the other hand, when optimizing DSR to improve the diversity of generation, some semantically similar words may also be generated and harm the summarization quality as shown in the third example in Table 4. The new token "wins" reduces the scores of both metrics. We also evaluate the diversity of a model quantitively by averaging the percentage of out-of-article n-grams in generated sentences. Results can be found in Table 3. The DSR model achieves the highest diversity.

Model	Gigawords		CNN/Daily Mail	
	Rep(%)	Div(%)	Rep(%)	Div(%)
ROUGE+XENT	11.57	16.33	66.82	21.32
DSR+ROUGE	18.42	15.97	50.41	34.70
DSR+XENT	20.15	16.24	25.98	31.80
DSR	**7.20**	**19.17**	**22.03**	**41.35**

Table 3: Qualitative analysis on repetition(Rep) / diversity(Div). They are calculated by the percentage of repeat/out-of-article n-grams (unigrams for Gigaword and 5-grams for CNN/Daily Mail) in generated sentences.

1) Context	economic links between china and germany will be at the center of talks here next month between li peng and chancellor helmut kohl when the chinese premier makes a week-long visit to germany , sources on both sides said .
Groundtruth	li peng 's visit to germany to focus on economic ties
ROUGE+XENT	chinese premier to visit germany next month { F_{BERT}: 49.48, ROUGE:**18.64**}
DSR+XENT	chinese premier to visit germany next month { F_{BERT}: 49.48, ROUGE:**18.64**}
DSR	**sino-german** economic **links** to be at center of talks **with** germany {F_{BERT}: **50.77**, ROUGE:17.33}
2) Context	the sensitive index dropped by #.## percent friday on the bombay stock exchange -lrb- bse -rrb- following brisk inquiries from operators that generally pressed sales to square up positions on the last day of the current settlement .
Groundtruth	sensex falls in bombay stock exchange
ROUGE+XENT	sensitive index down on bombay stock exchange {F_{BERT}: 70.03, ROUGE:**45.62**}
DSR+XENT	sensitive index **drops** on bombay stock exchange {F_{BERT}: **73.92**, ROUGE:**45.62**}
DSR	sensitive index **drops** on bombay stock exchange {F_{BERT}: **73.92**, ROUGE:**45.62**}
3) Context	belgium 's rik verbrugghe took victory in tuesday 's prologue stage of the tour de romandie , with a confident ride through the streets of geneva 's old town .
Groundtruth	verbrugghe takes prologue victory in tour de romandie
ROUGE+XENT	verbrugghe **takes** victory in prologue stage of tour de romandie {F_{BERT}: 91.41, ROUGE:75.93}
DSR+XENT	verbrugghe **takes** victory in tour de romandie prologue stage {F_{BERT}: **91.56**, ROUGE:**81.79**}
DSR	verbrugghe **wins** victory in tour de romandie prologue stage {F_{BERT}: 89.45, ROUGE:70.10}
4) Context	european finance ministers on saturday urged swedes to vote " yes " to adopting the euro , saying entry into the currency bloc would be good for sweden and the rest of europe .
Groundtruth	european finance ministers urge swedes to vote yes to euro
ROUGE+XENT	**eu** finance ministers urge swedes to vote yes to euro {F_{BERT}: **96.63**, ROUGE:**93.47**}
DSR+XENT	**eu** finance ministers urge swedes to vote yes to adopting euro {F_{BERT}: 90.38, ROUGE:88.89}
DSR	**eu** finance ministers urge swedes to vote yes to euro euro {F_{BERT}: 95.05, ROUGE:**93.47**}

Table 4: Qualitative analysis of generated samples on Gigaword corpus. Generated words that do not appear in the context are marked blue. Repeated words are marked red. The first two examples represent DSR's generated tokens are more diverse. However, it may suffer from problems as shown in example 3 and 4.

Repetition Repetition will lead to lower F_{BERT} as shown in the last example in Table 4. Using DSR reduces the probability of producing repetitions. The average percentage of repeated n-grams in generated sentences are presented in the Table 3. As shown in this table, unlike ROUGE, the DSR model can achieve high fluency without XENT; moreover, it produces the fewest repetitions among all the rewards. Table 4 gives an example that DSR produces a repeated word (from example 4), but it does not reflect the overall distribution of repeated word generation for all evaluated models.

7 Conclusion

This paper demonstrates the effectiveness of applying the distributional semantic reward to reinforcement learning in abstractive summarization, and specifically, we choose BERTSCORE. Our experimental results demonstrate that we achieve better performance on Gigaword and CNN/Daily Mail datasets. Besides, the generated sentences have fewer repetitions, and the fluency is also improved. Our finding is aligned to a contemporaneous study (Wieting et al., 2019) on leveraging semantic similarity for machine translation.

Clause-Wise and Recursive Decoding for Complex and Cross-Domain Text-to-SQL Generation

Dongjun Lee
SAP Labs Korea
dongjun.lee01@sap.com

Abstract

Most deep learning approaches for text-to-SQL generation are limited to the WikiSQL dataset, which only supports very simple queries over a single table. We focus on the *Spider* dataset, a complex and cross-domain text-to-SQL task, which includes complex queries over multiple tables. In this paper, we propose a SQL clause-wise decoding neural architecture with a self-attention based database schema encoder to address the *Spider* task. Each of the clause-specific decoders consists of a set of sub-modules, which is defined by the syntax of each clause. Additionally, our model works recursively to support nested queries. When evaluated on the *Spider* dataset, our approach achieves 4.6% and 9.8% accuracy gain in the test and dev sets, respectively. In addition, we show that our model is significantly more effective at predicting complex and nested queries than previous work.

1 Introduction

Text-to-SQL generation is the task of translating a natural language question into the corresponding SQL. Recently, various deep learning approaches have been proposed based on the WikiSQL dataset (Zhong et al., 2017). However, because WikiSQL contains only very simple queries over just a single table, these approaches (Xu et al., 2017; Huang et al., 2018; Yu et al., 2018a; Dong and Lapata, 2018) cannot be applied directly to generate complex queries containing elements such as `JOIN`, `GROUP BY`, and nested queries.

To overcome this limitation, Yu et al. (2018c) introduced *Spider*, a new complex and cross-domain text-to-SQL dataset. It contains a large number of complex queries over different databases with multiple tables. It also requires a model to generalize to unseen database schema as different databases are used for training and testing. Therefore, a model should understand not only the natural language question but also the schema of the corresponding database to predict the correct SQL query.

In this paper, we propose a novel SQL-specific clause-wise decoding neural network model to address the *Spider* task. We first predict a sketch for each SQL clause (e.g., `SELECT`, `WHERE`) with text classification modules. Then, clause-specific decoders find the columns and corresponding operators based on the sketches. Our contributions are summarized as follows.

- We decompose the clause-wise SQL decoding process. We also modularize each of the clause-specific decoders into sub-modules based on the syntax of each clause. Our architecture enables the model to learn clause-dependent context and also ensures the syntactic correctness of the predicted SQL.
- Our model works recursively so that it can predict nested queries.
- We also introduce a self-attention based database schema encoder that enables our model to generalize to unseen databases.

In the experiment on the *Spider* dataset, we achieve 24.3% and 28.8% exact SQL matching accuracy on the test and dev set respectively, which outperforms the previous state-of-the-art approach (Yu et al., 2018b) by 4.6% and 9.8%. In addition, we show that our approach is significantly more effective compared to previous work at predicting not only simple SQL queries, but also complex and nested queries.

2 Related Work

Our work is related to the grammar-based constrained decoding approaches for semantic parsing (Yin and Neubig, 2017; Rabinovich et al., 2017;

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6045–6051,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Iyer et al., 2018). While their approaches are focused on general purpose code generation, we instead focus on SQL-specific grammar to address the text-to-SQL task. Our task differs from code generation in two aspects. First, it takes a database schema as an input in addition to natural language. To predict SQL correctly, a model should fully understand the relationship between the question and the schema. Second, as SQL is a non-procedural language, predictions of SQL clauses do not need to be done sequentially.

For text-to-SQL generation, several SQL-specific approaches have been proposed (Zhong et al., 2017; Xu et al., 2017; Huang et al., 2018; Yu et al., 2018a; Dong and Lapata, 2018; Yavuz et al., 2018) based on WikiSQL dataset (Zhong et al., 2017). However, all of them are limited to the specific WikiSQL SQL sketch, which only supports very simple queries. It includes only the `SELECT` and `WHERE` clauses, only a single expression in the `SELECT` clause, and works only for a single table. To predict more complex SQL queries, sequence-to-sequence (Iyer et al., 2017; Finegan-Dollak et al., 2018) and template-based (Finegan-Dollak et al., 2018; Lee et al., 2019) approaches have been proposed. However, they focused only on specific databases such as ATIS (Price, 1990) and GeoQuery (Zelle and Mooney, 1996). Because they only considered question and SQL pairs without requiring an understanding of database schema, their approaches cannot generalize to unseen databases.

SyntaxSQLNet (Yu et al., 2018b) is the first and state-of-the-art model for the *Spider* (Yu et al., 2018c), a complex and cross-domain text-to-SQL task. They proposed an SQL specific syntax tree-based decoder with SQL generation history. Our approach differs from their model in the following aspects. First, taking into account that SQL corresponds to non-procedural language, we develop a clause-specific decoder for each SQL clause, where SyntaxSQLNet predicts SQL tokens sequentially. For example, in SyntaxSQLNet, a single column prediction module works both in the `SELECT` and `WHERE` clauses, depending on the SQL decoding history. In contrast, we define and train decoding modules separately for each SQL clause to fully utilize clause-dependent context. Second, we apply sequence-to-sequence architecture to predict columns instead of using the sequence-to-set framework from SyntaxSQLNet, because correct ordering is essential for the `GROUP BY` and `ORDER BY` clauses. Finally, we introduce a self-attention mechanism (Lin et al., 2017) to efficiently encode database schema, which includes multiple tables.

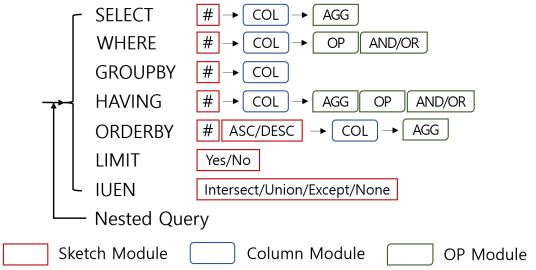

Figure 1: Clause-wise and recursive SQL generation process.

3 Methodology

We predict complex SQL clause-wisely as described in Figure 1. Each clause is predicted consecutively by at most three different types of modules (sketch, column, operator). The same architecture recursively predicts nested queries with temporal predicted SQL as an additional input.

3.1 Question and Schema Encoding

We encode a natural language question with a bi-directional LSTM. We denote $H_Q \in \mathbb{R}^{d \times |X|}$ as the question encoding, where d is the number of LSTM units and $|X|$ is the number of tokens in the question.

To encode a database schema, we consider each column in its tables as a concatenated sequence of words from the table name and column name with a separation token. (e.g., [student, `[SEP]`, first, name]). First, we apply bi-directional LSTM over this sequence for each column. Then, we apply the self-attention mechanism (Lin et al., 2017) over the LSTM outputs to form a summarized fixed-size vector for each column. For the ith column, its encoding $h_{col}^{(i)} \in \mathbb{R}^d$ is computed by a weighted sum of the LSTM output $o_{col}^{(i)} \in \mathbb{R}^{d \times |L|}$ as follows:

$$\alpha = \texttt{softmax}(w^T \texttt{tanh}(o_{col}^{(i)})) \quad (1)$$

$$h_{col}^{(i)} = o_{col}^{(i)} \alpha^T \quad (2)$$

where $|L|$ is the number of tokens in the column and $w \in \mathbb{R}^d$ is a trainable parameter. We denote $H_{col} = [h_{col}^{(1)}, ...h_{col}^{(|C|)}]$ as columns encoding where $|C|$ is the number of columns in the database.

3.2 Sketch Prediction

We predict the clause-wise sketch via 8 different text classification modules that include the number of SQL expressions in each clause, the presence of `LIMIT` clause, and the presence of `INTERSECT/UNION/EXCEPT` as described in Figure 1. All of them share the same model architecture but are trained separately. For the classification, we applied attention-based bi-directional LSTM following Zhou et al. (2016).

First, we compute sentence representation $r_s \in \mathbb{R}^d$ by a weighted sum of question encoding $H_Q \in \mathbb{R}^{d\times|X|}$. Then we apply the softmax classifier to choose the sketch as follows:

$$\alpha_s = \texttt{softmax}(w_s^T \texttt{tanh}(H_Q)) \quad (3)$$

$$r_s = H_Q\, \alpha_s^T \quad (4)$$

$$P_{sketch} = \texttt{softmax}(W_s r_s + b_s) \quad (5)$$

where $w_s \in \mathbb{R}^d, W_s \in \mathbb{R}^{n_s\times d}, b_s \in \mathbb{R}^{n_s}$ are trainable parameters and n_s is the number of possible sketches.

3.3 Columns and Operators Prediction

To predict columns and operators, we use the LSTM decoder with the attention mechanism (Luong et al., 2015) such that *the number of decoding steps are decided by the sketch prediction module*. We train 5 different column prediction modules separately for each SQL clause, but they share the same architecture.

In the column prediction module, the hidden state of the decoder at the t-th decoding step is computed as $d_{col}^{(t)} (\in \mathbb{R}^d) = \texttt{LSTM}(d_{col}^{(t-1)}, h_{col}^{(t-1)})$, where $h_{col}^{(t-1)} \in \mathbb{R}^d$ is an encoding of the predicted column in the previous decoding step. The context vector $r^{(t)}$ is computed by a weighted sum of question encodings $H_Q \in \mathbb{R}^{d\times|X|}$ based on attention weight as follows:

$$\alpha^{(t)} = \texttt{softmax}({d_{col}^{(t)}}^T H_Q) \quad (6)$$

$$r^{(t)} = H_Q\, {\alpha^{(t)}}^T \quad (7)$$

Then, the attentional output of the t-th decoding step $a_{col}^{(t)}$ is computed as a linear combination of $d_{col}^{(t)} \in \mathbb{R}^d$ and $r^{(t)} \in \mathbb{R}^d$ followed by `tanh` activation.

$$a_{col}^{(t)} = \texttt{tanh}(W_1 d_{col}^{(t)} + W_2 r^{(t)}) \quad (8)$$

where $W_1, W_2 \in \mathbb{R}^{d\times d}$ are trainable parameters. Finally, the probability for each column at the t-th decoding step is computed as a dot product between $a_{col}^{(t)} \in \mathbb{R}^d$ and the encoding of each column in $H_{col} \in \mathbb{R}^{d\times|C|}$ followed by softmax.

$$P_{col}^{(t)} = \texttt{softmax}({a_{col}^{(t)}}^T H_{col}) \quad (9)$$

To predict corresponding operators for each predicted column, we use a decoder of the same architecture as in the column prediction module. The only difference is that a decoder input at the t-th decoding step is an encoding of the t-th predicted column from the column prediction module.

$$d_{op}^{(t)} = \texttt{LSTM}(d_{op}^{(t-1)}, h_{col}^{(t)}) \quad (10)$$

Attentional output $a_{op}^{(t)} \in \mathbb{R}^d$ is computed identically to Eq. (8). Then, the probability for operators corresponding to the t-th predicted column is computed by the softmax classifier as follows:

$$P_{op}^{(t)} = \texttt{softmax}(W_o a_{op}^{(t)} + b_o) \quad (11)$$

where $W_o \in \mathbb{R}^{n_o\times d}$ and $b_o \in \mathbb{R}^{n_o}$ are trainable parameters and n_o is the number of possible operators.

3.4 From Clause Prediction

After the predictions of all the other clauses, we use a heuristic to generate the `FROM` clause. We first collect all the columns that appear in the predicted SQL, and then we `JOIN` tables that include these predicted columns.

3.5 Recursion for Nested Queries

To predict the presence of a sub-query, we train another module that has the same architecture as the operator prediction module. Instead of predicting corresponding operators for each column, it predicts whether each column is compared to a variable (e.g., `WHERE` age $>$ 3) or to a sub-query (e.g., `WHERE` age $>$ (`SELECT avg`(age) ..)). In the latter case, we add the temporal `[SUB_QUERY]` token to the corresponding location in the SQL output. Additionally, if the sketch prediction module predicts one of `INTERSECT/UNION/EXCEPT` operators, we add a `[SUB_QUERY]` token after the operator.

To predict a sub-query, our model takes the temporal generated SQL with a `[SUB_QUERY]` token as an input in addition to a natural language question with separate token `[SEP]` (e.g.,

Method	Dev Easy	Medium	Hard	Extra Hard	All	Test All
SQLNet	23.2%	8.6%	9.8%	0%	10.9%	12.4%
TypeSQL	18.8%	5.5%	4.6%	2.4%	8.0%	8.2%

Table 2: F1 scores of SQL component matching on the *dev* set.

What is ... `[SEP]` SELECT ... INTERSECT `[SUB_QUERY]`). This input is encoded in the same way as question encoding described in Section 3.1. Then, the rest of the SQL generation process is identical to that described in Section 3.2–3.4. After the sub-query is predicted, it replaces the `[SUB_QUERY]` token to form the final query.

4 Experiments

4.1 Experimental Setup

We evaluate our model with *Spider* (Yu et al., 2018c), a large-scale, complex and cross-domain text-to-SQL dataset. We follow the same database split as Yu et al. (2018c), which ensures that any database schema that appears in the training set does not appear in the dev or test set. Through this split, we examine how well our model can be generalized to unseen databases. Because the test set is not opened to the public, we use the *dev* set for the ablation analysis. For the evaluation metrics, we use 1) accuracy of exact SQL matching and 2) F1 score of SQL component matching, proposed by (Yu et al., 2018c). We also follow their query hardness criteria to understand the model performance on different levels of queries. Our model and all the baseline models are trained based on only the *Spider* dataset without data augmentation.

4.2 Model Configuration

We use the same hyperparameters for every module. For the word embedding, we apply deep contextualized word representations (ELMO) from Peters et al. (2018) and allow them to be fine-tuned during the training. For the question and column encoders, we use a 1-layer 512-unit bi-directional LSTM. For the decoders in the columns and operators prediction modules, we use a 1-layer 1024-unit uni-directional LSTM. For the training, we use Adam optimizer (Kingma and Ba, 2014) with a learning rate of 1e-4 and use early stopping with 50 epochs. Additionally, we use dropout (Hinton et al., 2012) with a rate of 0.2 for the regularization.

4.3 Result and Analysis

Table 1 shows the exact SQL matching accuracy of our model and previous models. We achieve 24.3% and 28.8% on the test and dev sets respectively, which outperforms the previous best model SyntaxSQLNet (Yu et al., 2018b) by 4.6% and 9.8%. Moreover, our model outperforms previous models on all different query hardness levels.

To examine how each technique contributes to the performance, we conduct an ablation analysis of three aspects: 1) without recursion, 2) without self-attention for database schema encoding, and 3) without sketch prediction modules that decide the number of decoding steps. Without recursive sub-query generation, the accuracy drops by 5.7% and 3.6% for hard and extra hard queries, respectively. This result shows that the recursion we use enables the model to predict nested queries. When using the final LSTM hidden state as in Yu et al. (2018b) instead of using self-attention for schema encoding, the accuracy drops by 4.0% on all queries. Finally, when using only an encoder-

decoder architecture without sketch generation for columns prediction, the accuracy drops by 4.7%.

For the component matching result for each SQL clause, our model outperforms previous approaches for all of the SQL components by a significant margin, as shown in Table 2. Examples of predicted SQL from different models are shown in Appendix A.

5 Conclusion

In this paper, we propose a recursive and SQL clause-wise decoding neural architecture to address the complex and cross-domain text-to-SQL task. We evaluate our model with the *Spider* dataset, and the experimental result shows that our model significantly outperforms previous work for generating not only simple queries, but also complex and nested queries.

Acknowledgments

We thank Yongsik Lee, Jaesik Yoon, and Donghun Lee (SAP) for their reviews and support. We also thank professor Sungroh Yoon, Jongyun Song, and Taeuk Kim (Seoul National University) for their insightful feedback and three anonymous reviewers for their helpful comments.

Abstract

How do adjectives project from a noun to its parts? If a motorcycle is red, are its wheels red? Is a nuclear submarine's captain nuclear? These questions are easy for humans to judge using our commonsense understanding of the world, but are difficult for computers. To attack this challenge, we crowdsource a set of human judgments that answer the English-language question "Given a whole described by an adjective, does the adjective also describe a given part?" We build strong baselines for this task with a classification approach. Our findings indicate that, despite the recent successes of large language models on tasks aimed to assess commonsense knowledge, these models do not greatly outperform simple word-level models based on pre-trained word embeddings. This provides evidence that the amount of commonsense knowledge encoded in these language models does not extend far beyond that already baked into the word embeddings. Our dataset will serve as a useful testbed for future research in commonsense reasoning, especially as it relates to adjectives and objects.

1 Introduction

We investigate the commonsense inference of the transitivity of an attribute of a whole object to its component parts. To illustrate this targeted reasoning by example, "is a sharp knife's handle sharp?" The ability to perform commonsense inference of this type enables a more complete understanding of the physical world and therefore may find use in a variety of tasks in pragmatics and at the interface of vision and language. Consider generating a story in which a slow car goes to the shop to get a new part. If the new part is a windshield, the car remains slow, whereas if the new part is an engine, the car may now be fast. This knowledge may also help a visual agent reason about unseen objects: it knows a brick house does not have a brick door without needing to see the door.

The past few years have seen a raft of data sets intended to test our ability to construct models with an understanding of commonsense knowledge. Standout examples are the Stanford Natural Language Inference (SNLI) and related Multi-Genre Natural Language Inference (MNLI) corpora (Bowman et al., 2015; Williams et al., 2018), the SemEval-2018 commonsense shared task (Ostermann et al., 2018), the Rochester Story Completion (ROCStories) corpus (Mostafazadeh et al., 2016), and the Situations with Adversarial Generations (SWAG) grounded inference corpus (Zellers et al., 2018). After their release, very large language models (LMs) were able to reach or surpass human-level performance on SNLI (Peters et al., 2018) and SWAG (Devlin et al., 2018).

However, researchers have found inadequacies in these datasets and the models trained on them. Despite the strong performance of recent systems on SNLI (e.g., Chen et al., 2017; Parikh et al., 2016), Glockner et al. (2018) show that by making trivial changes to the test set, these methods suffered. Further, Pavlick and Callison-Burch (2016) show that state-of-the-art models for natural language inference fail on a task requiring only reasoning over adjective-noun relations. Relatedly, in the shared task to predict sentence endings of ROCStories, Schwartz et al. (2017) show that by incorporating style features, with only the answer choices as input, it is possible to reach near state-of-the-art performance. These results point to implicit bias baked into the data sets.

Rudinger et al. (2017) demonstrate similar systematic and social bias in SNLI, attributing it to the fact that hypothesis sentences were written by crowd workers. The SWAG data set was specif-

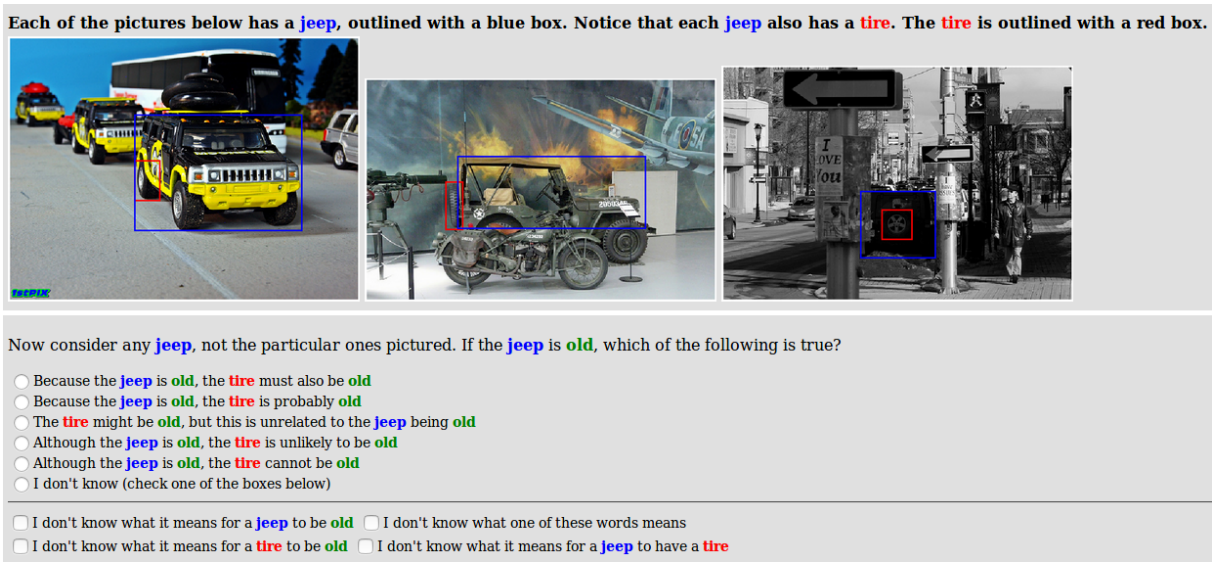

Figure 1: Visual annotation interface, excluding overall instructions.

ically constructed in an adversarial way with this in mind, but may be disadvantaged by the fact that continuation sentences are generated by computers. This may lead to patterns that are hard to detect but can nevertheless be picked up by other language models. We avoid the issue of elicitation bias by first collecting candidates grounded in natural sources of text and images, and then gathering only scaled judgments from crowd workers, as was done by Zhang et al. (2017).

To understand how to build truly intelligent agents, we should strive to create datasets with as little exploitable bias as possible, and to further investigate the landscape of current performance. We contribute a dataset which provides a focused evaluation, based on a specific task in commonsense reasoning. Gathering and validating data from crowd workers, we evaluate a number of approaches to performing these inferences, a three-way lexical entailment problem. We find that simple word embedding-based models perform adequately, but beneath humans, on this task, with recent large LM approaches (Devlin et al., 2018; Radford et al., 2018) providing only slight improvement over the purely lexical approach.

2 Related Work

Other researchers have constructed datasets investigating similar ideas in commonsense reasoning. Forbes and Choi (2017) develop a dataset and methods for inferring physical commonsense knowledge from verb usage, showing it is possible to learn the physical implications of unseen verbs from a small seed set. Zhang et al. (2017) create a large dataset for general commonsense inference in the form of premise-hypothesis pairs, equipped with ordinal labels ranging from "impossible" to "very likely". We adopt much of their methodology but for a targeted subset of commonsense reasoning. The SemEval 2018 Task 10 on Capturing Discriminative Attributes (Krebs et al., 2018) describes a similar lexical reasoning task involving triplets of words, though it focuses on finding attributes that *distinguish* two concepts, while in our work the adjective may well apply to both part and whole.

Past work has also evaluated commonsense capabilities in neural models. Pavlick and Callison-Burch (2016) investigate the related problem of entailment in adjective-nouns, and show surprising negative results for neural NLI models. Wang et al. (2018) showed that models based on distributional semantics without explicit external knowledge perform poorly at predicting physical plausibility of actions.

Lucy and Gauthier (2017) investigate perceptual properties of distributional embeddings and suggest that part–whole properties like *has_legs* are well encoded by embeddings. This may help explain why the simple word-based MLP models perform well without other sources of context. Rei et al. (2018) introduce an effective neural architecture for learning word-embedding based models for graded lexical entailment. Prior work (Bulat et al., 2016; Fagarasan et al., 2015) utilizes embeddings to predict real-world perceptual proper-

Whole	Part	Adjective	Label	NLI premise	NLI hypothesis
armchair	arm	black	Probably	On the back of the president's quaint black armchair there was emblazoned a half-sun, brilliant with its gilded rays.	The armchair's arm is black.
vanity	mirror	white	Impossible	A door to a bathroom half open and a white vanity.	The vanity's mirror is white.
bench	support	wooden	Unrelated	In front of me about five feet distance, stood a wooden bench.	The bench's support is wooden.

Table 1: Example triples and retrieved premise sentences, with labels, used for training word embedding-based models and language model fine-tuning.

ties, and we expect an approach that leverages this will help solve this task, but we leave it to future work.

3 Candidate collection

We seek to annotate examples of (*whole*, *part*, *adjective*) triples with answers to the question: "Does an ⟨*adjective*⟩ ⟨*whole*⟩ have an ⟨*adjective*⟩ ⟨*part*⟩?" As a major part of our contribution, we provide an annotated dataset that is visually grounded, with relations mined from Visual Genome (Krishna et al., 2017) and Google Syntactic N-grams (Goldberg and Orwant, 2013). We provide an overview here, with details in Appendix A.

3.1 Part–whole relations

Visual Genome (VG) is a large dataset of images annotated with objects, their attributes, and the relations between them. We start by considering all relationships in the VG dataset where the predicate is an underspecified *has* relation. We count the number of images in which a pair of objects appear in a *has* relation, and keep only those pairs appearing in at least three distinct images.

3.2 Adjectives

We gather adjectives from both Google Syntactic N-grams and VG. From Syntactic N-grams, we count the occurrences of an adjective modifying a noun with the *amod* relation. We remove common non-attributive (e.g., *awake*) and non-descriptive (e.g., *first*) adjectives using manually constructed lexicons. Then, for each whole noun, we gather its five most common adjectival modifiers, as well as its five most common adjective attributes from Visual Genome. Through pilot studies we observed that without further filtering, annotations were highly skewed towards non-entailment, thus we achieve a more balanced dataset by filtering out adjectives that are never observed attached to the part.

4 Collecting human annotations

We crowdsource annotations on Amazon Mechanical Turk (AMT) for each (*whole*, *part*, *adjective*) triple as follows:

4.1 Task overview

For each part–whole pair, we sample three random images from VG that contain the pair, and draw bounding boxes around both objects, provided by VG annotations. We present these to workers simply to provide context for the part–whole pair, since early tests showed that without visual cues workers often have trouble understanding the overall problem. Then, we ask a series of questions that each associates the pair with an adjective. To encourage the worker to imagine the prototypical version of the objects rather than the specific ones shown,[1] we use the template "Consider any ⟨*whole*⟩, not the particular ones pictured". Specific questions have the form: "If the ⟨*whole*⟩ is ⟨*adjective*⟩, which of the following is true?" The answers describe whether it is "impossible", "unlikely", "unrelated", "likely", or "guaranteed" that the identified part is also described by the adjective. The answers use causal language to encourage "conditional plausibility" thinking, as described by Zhang et al. (2017). This also allows for the "unrelated" answer, which covers spu-

[1] This is a necessary downside of displaying visual cues.

Label	Percentage
Guaranteed	44.2
Probably	19.8
Unrelated	23.7
Unlikely	5.6
Impossible	6.6

Table 2: Final label distribution

rious examples, such as a black guitar's cord being black, where the cord is likely black, but not *as a result* of the guitar being black. We also give an option for the worker to mark that one of the pairwise relations is nonsensical.

4.2 Qualification task

After manually annotating some examples, and conducting two AMT pilot studies, we found a non-trivial margin between our own agreement and that of workers, as measured by the quadratic-weighted Cohen's κ. To alleviate this, we followed Zhang et al. (2017) and conducted a pilot study to gather a pool of qualified workers. We launched a pilot task with two gold examples from each class on which our manual annotations agreed, and recruited 300 crowd workers to label them. By setting a κ threshold on agreement with the gold examples at 0.7, this resulted in 106 qualified workers, whom we requested to perform the rest of the annotations. We collected at least three annotations per triple. An example annotation interface is shown in Figure 1.

4.3 Filtering and statistics

From the total of 20,284 triples annotated, we filter out 4,040 (19.9%) that were reported to contain an invalid triple. We further remove instances without a majority vote from the workers. This results in a set of 13,684 triples with an inter-annotator agreement (quadratic-weighted Cohen's κ) of 0.624. (For reference, Zhang et al. (2017) report $\kappa = 0.54$ for general commonsense inference.) The label distribution is shown in Table 2. The dataset has 728 unique *part* nouns, 873 unique *whole* nouns, and 553 unique adjectives.

5 Inference baselines

We now describe several basic approaches for solving these commonsense inference problems, which we intend as a baseline to be built upon by future work. Formally, models answer the question: Given (**1**) a noun denoting a whole object that has (**2**), a component part also denoted by a noun, does (**3**), an adjective that describes **1** also describe **2**? The data is first split into training, validation, and test sets consisting of 70%, 10%, and 20% of the data respectively. Model selection and tuning details are described in Appendix C.

5.1 Word embedding models

We approach the problem as categorical classification and train a multi-layer perceptron (MLP) model to classify inputs consisting of word embeddings for the whole, part, and adjective words. The MLP takes as input the concatenation of these three word embeddings, obtained from GloVe (Pennington et al., 2014), and applies a single hidden layer with ReLU activation before the final softmax layer which predicts the class label.

5.2 Adjective projection as NLI

As we want to evaluate strong yet simple pre-existing language understanding models on this task, we now describe a method for obtaining the direct prediction described above via conversion to a form suitable for inference in the style of the SNLI and MNLI datasets (Bowman et al., 2015; Williams et al., 2018), which consist of *premise* and *hypothesis* sentence pairs. We first form simple hypothesis sentences from the tuples using the fixed template "The ⟨*whole*⟩'s ⟨*part*⟩ is ⟨*adjective*⟩." We then retrieve premise sentences that describe a ⟨*whole*⟩ ⟨*adjective*⟩. An example for (*bicycle, old*) is "He rode an old bicycle and brought fruits and vegetables home from Chinatown." We retrieve context sentences from five resources: Project Gutenberg books[2], the Gigaword news corpus (Parker et al., 2011), SNLI, MNLI, and MSCOCO image captions (Lin et al., 2014); premise sentence selection is described fully in Appendix D and examples are shown in Table 1.

5.3 Fine-tuning language models

We apply transfer learning from two recently developed large contextualized LMs to this task. Both are state-of-the-art on NLI and commonsense tasks.

Specifically, we test OpenAI GPT (Radford et al., 2018), and BERT (Devlin et al., 2018).

[2] https://gutenberg.org

OpenAI GPT is a unidirectional model that predicts the next word, while BERT is bidirectional and predicts randomly missing words, as well as the next sentence. Both train on the BooksCorpus, with BERT additionally trained on English Wikipedia. Both models are fine-tuned to perform NLI by applying a linear layer to the model's final output at one position of the input. The models are then trained in a multi-task way for the inference task and the language modeling objective(s), updating the whole network.

Method	Accuracy
Majority baseline	0.430
Majority-per-part baseline	0.485
GloVe embeddings	0.651
OpenAI GPT (Radford et al., 2018)	0.666
BERT (Devlin et al., 2018)	0.667
Human performance	0.785

Table 3: Test set results for multi-class prediction

Test set results for these methods are in Table 3. We also provide performance by two simple baselines, the first of which always predicts the majority class ("guaranteed"). To choose the second baseline, we evaluated choosing the majority class for the given whole, part, or adjective. Of these, predicting the majority-per-part had the best validation set performance, so we report that result on test.

We observe that the best model that operates on just word embeddings is within ≈ 0.02 of both language models in absolute accuracy points, and the best performing model still lags behind human accuracy[3] by nearly 0.12 absolute points, suggesting work remains to be done on incorporating this variety of common sense into intelligent models.

6 Conclusion

Inspired by recent commonsense dataset construction efforts and the speed with which researchers develop highly performant models for them, we develop a dataset that evaluates a type of inference that is specific but that agents with commonsense should be able to solve. We show that state-of-the-art language models perform well, but that models using just pretrained word embeddings perform comparably, and both fall short of human accuracy. We release our dataset to provide a challenging commonsense reasoning task for the community.

[3]Measured using the triplet, not NLI, version of the data.

Abstract

In this work, we propose an aggregation method to combine the **B**idirectional **E**ncoder **R**epresentations from **T**ransformer (BERT) with a MatchLSTM layer for Sequence Matching. Given a sentence pair, we extract the output representations of it from BERT. Then we extend BERT with a MatchLSTM layer to get further interaction of the sentence pair for sequence matching tasks. Taking natural language inference as an example, we split BERT output into two parts, which is from premise sentence and hypothesis sentence. At each position of the hypothesis sentence, both the weighted representation of the premise sentence and the representation of the current token are fed into LSTM. We jointly train the aggregation layer and pre-trained layer for sequence matching. We conduct an experiment on two publicly available datasets, WikiQA and SNLI. Experiments show that our model achieves significant improvement compared with state-of-the-art methods on both datasets.

1 Introduction

Text sequence matching aims to infer the relationship of two text sequences which is a critical problem used in many NLP tasks such as answer selection (Yang et al., 2015), natural language inference (Bowman et al., 2015), and paraphrase identification (Dolan et al., 2004).

Recent years, various deep learning models have been proposed for text sequence matching tasks (Wang and Jiang, 2016; Tay et al., 2018; Tymoshenko and Moschitti, 2018; Kim et al., 2018). Most previous works are learned from task specific supervised datasets, which are always limited to the amount, due to the cost of annotation. Recently, learning a general representation of words based on language models attracts great attention, and are successfully applied to a range of NLP tasks (McCann et al., 2017; Peters et al., 2018, 2017; Alec Radford, 2018; Devlin et al., 2018). In these works, they first learn general language representations through training a language model using large scale unlabeled data. Then they use these representations to the downstream tasks. Previous works show that the representations with linguistic information perform obvious effectiveness and robustness applied to downstream tasks.

In these methods, there are two typical strategies using pre-trained models, feature-based (Peters et al., 2017) and fine-tuning approach (Devlin et al., 2018; Radford et al., 2018). Our model is based on the fine-tuning approach and use BERT (Devlin et al., 2018) as our pre-trained language model. BERT has been directly used in many tasks and achieved significantly improvement compared with other methods. However, BERT only uses a standard softmax layer for many different specific tasks. Intuitively, for more complex tasks, like sequence matching in this work, we need a better strategy for extending the BERT to infer the relationship of the sequence pair. Thus, we incorporate a MatchLSTM layer (Wang and Jiang, 2015) to BERT, and make it better to adapt to sequence matching.

In our model, we design a MatchLSTM layer to aggregate representations of words in the sequences, and then we concatenate the hidden state of first token in BERT to the output of MatchLSTM (Wang and Jiang, 2015). This method can combine the features extracted from BERT and MatchLSTM effectively, and it is much better than directly using the outputs of BERT as pre-trained word representations to MatchLSTM.

The main contributions of this work are as follows:

- We extend BERT with a MatchLSTM layer. It can be applied to a variety of sequence matching tasks.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6059–6063,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- We compare various aggregation layers to extend BERT, with the MatchLSTM layer achieving the best performance. It gets more powerful representations than the original output from BERT for sequence matching.

- Experiments on WikiQA and SNLI datasets show that our model achieves better performance than state-of-the-art methods.

2 Related Work

Sequence Matching task has attracted lots of attention in the past decades. There are many related works on Question Answering(QA) (Yin et al., 2015; Tay et al., 2018; Wang et al., 2017; Tymoshenko and Moschitti, 2018; Min et al., 2017), Natural Language Inference(NLI) (Peters et al., 2018; Kim et al., 2018; Radford et al., 2018) and so on. (Yin et al., 2015) use attention mechanism with convolutional layer to model sentence pairs. In (Tymoshenko and Moschitti, 2018), they combine the similarity features of members within the same pair and traditional sentence pair similarity and achieve state-of-the-art results on several answer selection datasets including WikiQA (Yang et al., 2015). (Peters et al., 2018) and (Radford et al., 2018) incorporate pre-trained language models to text sequence matching task and achieve performance improvement on SNLI (Bowman et al., 2015).

Recently, pre-trained language models have been successfully used in NLP tasks. ELMo (Peters et al., 2017) is trained as a bidirectional language model. OpenAI GPT (Alec Radford, 2018) uses a basic left-to-right transformer to learn a language model. BERT, used in this paper, is based on the architecture of a bidirectional Transformer and per-trained on Masked Language Model task and Next Sentence Prediction. Using the pre-trained parameters, BERT (Devlin et al., 2018) achieves state-of-the-art performance on the GLUE benchmark (Wang et al., 2018) and SQuAD 1.1 (Rajpurkar et al., 2016) by fine-tuning in corresponding supervised data.

In this work, we design a sequence matching model based on BERT.

3 Our Model

In this section, we will introduce our sequence matching model. Our model is combined BERT encoder with the MatchLSTM layer.

3.1 BERT Encoder

Given two natural language sentences A, B, the tokens of both sentences are packed into a token sequence S as "[CLS] A [SEP] B [SEP]", where [CLS], [SEP] are special tokens. The representation of each token is the sum of three types of embedding: 1). **WordPiece embedding**(Wu et al., 2016) is used in BERT to represent the input sequence, which has 30000 token vocabulary. The tokens in S are split into several word pieces with "##". 2). **Position embedding** is used to cover position information in transformer. 3). **Segment embedding** is used to indicate whether the current token is from A or B.

Then the representation of S is fed into the BERT encoder which is a multi-layer bidirectional Transformer(Vaswani et al., 2017). The implement of its architecture can refer to (Vaswani et al., 2017; Devlin et al., 2018). BERT encodes the input token sequence S into a context aware representation $h = \{h_0, h_1, ..., h_{|S|-1}\}$. Then h is used to a match layer for downstream supervised tasks.

For downstream tasks of text sequence matching, BERT extract the final hidden state of the first token, h_0, corresponding to the special token [CLS]. The label probabilities are computed with h_0 by a standard softmax layer. Finally, all of the parameters of the model are fine-tuned to maximize the log-probability of the correct label in specific tasks.

3.2 MatchLSTM Layer

Although BERT has proved its effectiveness for text sequence matching tasks, there still exist two limitations. First, the two sentences can only interact through a general attention mechanism in the transformer, which is not enough for complex matching tasks. Secondly, BERT only uses the first token hidden state in sequence matching tasks such as QA, MNLI in (Devlin et al., 2018), ignoring the final hidden state $h_i, i > 0$ in other positions. To overcome the two limitations, we add a bidirectional MatchLSTM network (Wang and Jiang, 2015), which computes the word-by-word matching results at each position for input sentence pairs.

To get the representation of each input sentence, we first split the final hidden state h into h^A and h^B as the representations of the sentence pair, A and B, according to its position information. Then we apply a bidirectional MatchLSTM net-

work with the input of h^A and h^B. At each position i of the tokens in sentence B, the MatchLSTM layer first uses a standard word-by-word attention mechanism to obtain attention weight $a^i = \{a_0^i, a_1^i, ..., a_{|A|-1}^i\}$ over sentence A and compute a weighted sum of sentence A as c_i, which can be formulated as,

$$e_j^i = u^T tanh(W^A h_j^A + W^B h_i^B + W^s s_{i-1} + b_e)$$
$$a_j^i = \frac{e_j^i}{\sum_{k=1}^{|p|} e_k^i}; c_i = \sum_{j=0}^{|A|} a_j^i h_j \tag{1}$$

where u, W^A,W^B,W^s and b_e are trainable parameters, s_i is the hidden state at the ith position of B. The i,j in Equation 1 represents ith word in h^A and jth word in h^B, and e_j^i is the attention score between the two words. We concatenate c_i with the current token of sentence B as:

$$r_i = [h_i^B : c_i]$$
$$s_i = LSTM(r_i, s_{i-1}) \tag{2}$$

Then, we concatenate the last hidden state of MatchLSTM layer $s_{|B|}$ with the first hidden state h_0 of BERT encoder and feed it into the output softmax layer,

$$f = [s_{|B|} : h_0]$$
$$P = softmax(W^f f + b_f) \tag{3}$$

where W^f and b_f are trainable parameters, P is the label probability distribution.

3.3 Loss Function

Finally we compute the loss function to maximize the log-probability of corresponding label $y \in \{0, 1, .., m-1\}$, m is the number of target label types. It can be formulated as,

$$\mathcal{L} = -log(P_i)[i = y] \tag{4}$$

3.4 Other Aggregation Layers

In this section, we introduce two other general methods to utilize all the final hidden states of BERT encoder.

3.4.1 Average Layer

To incorporate all the hidden states of BERT, a basic idea is to sum all final hidden states h directly as the feature vector f_{avg}. It will be used to calculate the probability of final label by Eq.3.

3.4.2 Convolutional Layer

We also evaluate the performance using the convolutional layer with max pooling. We set several fixed window sizes to extract feature vectors. For each windows size l, we use a kernel matrix $W^l \in R^{l \times d}$ and a non-linear function to operate on the hidden vector h from BERT encoder. The output of one operation is a local feature which can be computed as follows:

$$z_i = g(W^l \cdot v[i : i + l] + b^l) \tag{5}$$

where W^l and b^l are trainable parameters, g is a non-linear function. We conduct this operation on different hidden vectors $v_{1:l}, v_{2:l+1}, ..., v_{n-l+1:n}$ and get a set of local features $z = \{z_1, z_2, ..., z_{n-l+1}\}$. We then extract a maximum feature from the local features z generated by one kernel through the max pooling layer and get feature vector f_{cnn}. We concatenate f_{cnn} with the first hidden state h_0 as above to get the final feature vector and calculate the probability distribution of labels.

4 Experiment

We conduct experiments on the WikiQA and SNLI corpuses. We use Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) as the evaluation metrics on WikiQA. On SNLI, we use accuracy(ACC) as our evaluation metric.

4.1 Datasets

WikiQA dataset (Yang et al., 2015) is a sentence-level QA dataset, containing 2.0k/0.3k/0.6k train/dev/test examples. Each sample contains a query in Bing's log and a snippet of a Wikipedia retrieved by Bing. Each query contains 18.6 candidate sentences on average. The task is to select an answer from candidate sentences for each query.

The Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) is a large-scale entailment classification task, containing 570K human annotated sentence pairs. Each sample consists of a sentence pair and a label from relationship class (entailment, neutral, contradiction, and -). We remove samples in "-" class same as previous works, since they do not have a consensus label among the annotators. For training, development and test sets, we use the same split with (Bowman et al., 2015) to report our results.

4.2 Settings

We use the pre-trained model of BERT$_{BASE}$ (Our goal is to prove the effectiveness of our aggregation method, so we do not use the BERT$_{LARGE}$ which is time and resource consuming), the number of Transformer blocks is 12, and dimension of all hidden state is 768 in our model. The batch size of the model is 32 and the initial learning rate is 2e-5. We set the dropout rate to 0.5.

Except for using state-of-the-art methods as our baseline, we also list variants of aggregated layers with BERT in the experiments. "BERT+AVG" is the model described in 3.4.1. "BERT+CNN" is the model proposed in 3.4.2. "BERT" represents the BERT with pre-trained parameters as initialization. "BERT$_{no\ init}$" denotes BERT using random parameters as initialization. The "-FHS" means the model does not use the hidden state of first token in BERT encoder.

4.3 Experiments on WikiQA

Methods	MAP	MRR
ABCNN (Yin et al., 2015)	69.21	71.08
MULT (Wang and Jiang, 2016)	74.33	75.45
HyperQA (Tay et al., 2018)	72.70	71.20
BiMPM (Wang et al., 2017)	71.80	73.10
PTK (Tymoshenko and Moschitti, 2018)	73.34	74.68
SQuAD* (Min et al., 2017)	83.20	84.58
BERT$_{no\ init}$	58.91	60.09
BERT (Devlin et al., 2018)	80.15	82.31
BERT+AVG	81.95	83.26
BERT+CNN	81.23	83.16
BERT+MatchLSTM	**83.53**	**85.13**
-FHS	70.46	72.44

Table 1: Performance for answer sentence selection on WikiQA dataset. Results of PTK are ensemble results and SQuAD* is trained with extra supervised corpus, SQuAD.

We first study the effectiveness of our method for answering on the WikiQA dataset. Our model achieves new state-of-the-art performance compared with previous methods. First, comparing "BERT+MatchLSTM" with "BERT", we find that "BERT+MatchLSTM" achieves significant improvement, which illustrates the effectiveness of our method using a MatchLSTM layer to extend "BERT". Moreover, from the results of "BERT+MatchLSTM", "BERT+AVG" and "BERT+CNN", we find that the MatchLSTM layer utilizes the output representations from the BERT encoder more efficiently than "AVG" and "CNN". We also see that "BERT$_{no\ init}$" does not perform well on this task, which shows that the architecture of BERT is not superior to existing architectures, thus using other architectures to boost the pre-trained BERT is meaningful and important. From the result of "-FHS" we find that the performance drops a lot, which illustrates the method we used to concatenate the hidden state of first token in BERT to the output of MatchLSTM is very important.

4.4 Experiments on SNLI

SNLI	train	test
SLRC (Zhang et al., 2018)	89.1	89.1
LMPT (Radford et al., 2018)	96.6	89.9
ESIM+ELMo (Peters et al., 2018)	91.6	88.7
+Ensemble	92.1	89.3
DRCN (Kim et al., 2018)	93.1	88.9
+Ensemble	95.0	90.1
BERT$_{no\ init}$	90.7	82.5
BERT (Devlin et al., 2018)	95.9	89.6
BERT+AVG	96.2	90.1
BERT+CNN	94.7	90.2
BERT+MatchLSTM	**96.8**	**90.9**
-FHS	91.4	88.3

Table 2: Accuracy on SNLI dataset. All compared results are from the SNLI Leaderboard.

Table 2 shows the comparisons of our method with the state-of-the-art methods on the SNLI dataset. The trends observed in this experiment are consistent with the former one. Compared with baseline methods, our "BERT+MatchLSTM" achieves the best performance on both training and test sets. Furthermore, compared with "BERT", "BERT+AVG" and "BERT+CNN", our model shows obvious superiority. Comparing the results of "BERT" and "BERT$_{no\ init}$", we also observe that the pre-training process is significantly helpful in this task.

5 Conclusion

In this work, we design an aggregation method to combine BERT with a MatchLSTM layer for sequence matching. We show that our model is more effective in computing the interaction features with the BERT encoder than the original BERT model. Experiments show that our method achieves new state-of-the-art performance on WikiQA and SNLI datasets.

What Does This Word Mean?
Explaining Contextualized Embeddings with Natural Language Definition

Abstract

Contextualized word embeddings have boosted many NLP tasks compared with traditional static word embeddings. However, the word with a specific sense may have different contextualized embeddings due to its various contexts. To further investigate what contextualized word embeddings capture, this paper analyzes whether they can indicate the corresponding sense definitions and proposes a general framework that is capable of explaining word meanings given contextualized word embeddings for better interpretation. The experiments show that both ELMo and BERT embeddings can be well interpreted via a readable textual form, and the findings may benefit the research community for a better understanding of what the embeddings capture[1].

1 Introduction

Contextualized word embeddings, such as ELMo, BERT, and OpenAI GPT, GPT-2 (Peters et al., 2018; Devlin et al., 2018; Radford et al., a,b) have been shown to yield richer representations of meaning and boosted many NLP tasks. To understand what contextualized word embeddings capture, Schuster et al. (2019) recently visualized the representations of ELMo and showed that 1) embeddings of the same word in different contexts can form a cluster, and 2) when a word has multiple senses, the embeddings can be separated into multiple distinct groups, one for each meaning. To further investigate the meanings contextualized word embeddings indicate, this paper focuses on analyzing whether a contextualized embedding is sense-informative enough to indicate the corresponding sense definition given a (target word, context) pair. We train and evaluate our model on the online Oxford dictionary dataset released by Chang et al. (2018).

To analyze if the embeddings are sense-informative, our work focuses on learning a mapping between the semantic space of contextualized word embeddings and the space of definition embeddings. Specifically, a better mapping indicates richer sense-specific cues in the contextualized word embedding.

Different from the definition modeling in the prior work (Noraset et al., 2017; Gadetsky et al., 2018; Chang et al., 2018), we reformulate the task from natural language generation (NLG) to classification, i.e., selecting the most reasonable definition according to the target word and its contexts. As recent work has shown the great success in encoding lexical resources into consistent representations (Tissier et al., 2017; Bahdanau et al., 2017; Bosc and Vincent, 2018), in this paper, we leverage pretrained sentence encoder (Cer et al., 2018) to project all definitions in the Oxford dictionary to a consistent embedding space, supporting our reformulation which requires to learn a mapping transforming from the contextualized word embedding space to the definition embedding space. Therefore, we can avoid some predicaments in NLG, such as troubles in generating fluent sequences, the exposure bias problem (Ranzato et al., 2015) and the difficulties in evaluation (Stent et al., 2005).

2 Methodology

The goal of this paper is to analyze whether we can distill sense-specific information from the pretrained contextualized word embeddings such as ELMo and BERT for better interpretation. Specifically, given the embedding of a (word, context) pair, our model learns a non-linear mapping network $f : X \rightarrow Y$ to project it into the desired

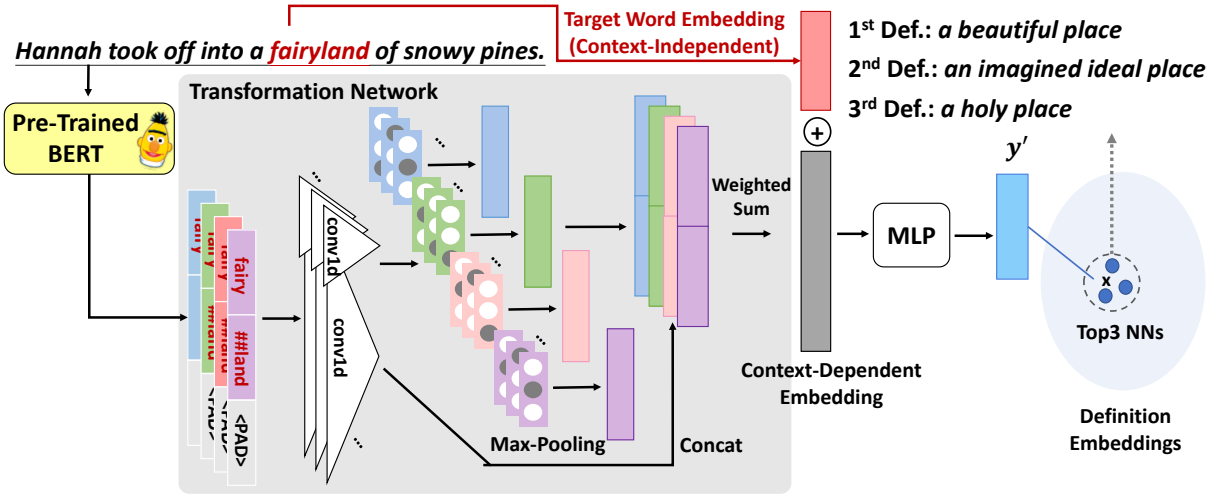

Figure 1: Illustration of the proposed model using contextualized embeddings from BERT as the context-dependent component. We use the one-dimensional convolution with its kernel sizes being 1 and 3.

definition space. Note that the mapping is many-to-one intrinsically because there exist some examples sharing the same definition, and their target words or contexts differ. This paper assumes that *contextualized word embeddings can be easily translated into their corresponding definitions if their semantics is well captured in the representations*. To validate the assumption, the following models are proposed for mapping the embeddings.

2.1 Model Objective

The whole framework of our proposed model is illustrated in Figure 1. Our goal is to learn the mapping that transforms contextualized word embeddings into their corresponding definition, which is to solve:

$$f^\star = \arg\min_f \|f(\mathbf{x}) - \mathbf{y}\|_2, \qquad (1)$$

where $\mathbf{x} = (\mathbf{u}, \mathbf{v}) \in X$ consists of the target word embedding $\mathbf{u}$, which is context-independent and serving as the target word identity, and a context-dependent component $\mathbf{v}$, which could be either the context embedding or the contextualized target word embedding; $\mathbf{y} \in Y$ is the embedding of the corresponding definition. Both the definition embedding and the context embedding are encoded by the pretrained transformer-based universal sentence encoder (Cer et al., 2018), and we utilize different types of contextualized word embeddings, such as ELMo, BERT-base, and BERT-large, by swapping the context-dependent component shown in the left part of Figure 1.

Note that though we model this task as a classification problem, we do not train a classifier that regards all definitions as discrete labels but learn a translation between two representation spaces, motivated by Lample et al. (2017, 2018), because different definitions may have semantic similarities. We first encode all ground truth definitions to a consistent embedding space and learn a mapping function f. During the inference stage, given a target word and its context, we retrieve the corresponding human-readable definitions of the top-k nearest neighbors of our predicted embedding in the definition embedding space, with consideration of the whole 79,030 definition candidates in the Oxford dictionary. Note that the candidates for each word are not restricted to its existing definitions in the dictionary, considering that words may go through semantic shift, such as the word *gay* has shifted its meaning from *happy* to *homosexual*.

2.2 Mapping Architecture

Our mapping architecture consists of a transformation network followed by the 7-layer MLP, with batch normalization (Ioffe and Szegedy, 2015) and ReLU. In order to incorporate diverse context-dependent embeddings (such as ELMo and BERT), different transformation nets are proposed, whose common goal is to map the input features to a fixed-dimension representation. Three variants are described in detail.

- **Context Embedding**: the target word embedding and its context embedding encoded

by a pretrained sentence encoder are concatenated as the input to the transformation net, which is simply implemented as a fully-connected layer with the ReLU activation.

- **ELMo**: we apply a weighted sum over 3 extracted contextualized word embeddings, i.e., the output of character CNN and two LSTMs, getting a single context-dependent vector for concatenating with the target word vector.

- **BERT**: the target word is tokenized into word pieces, and we use one-dimensional convolution (conv1d) (Kim, 2014) and max-pooling to tackle the variable-lengthed features. We extract the last 4 layers from BERT and jointly learn softmax-normalized weights corresponding to each layer similar to ELMo.[2] Figure 1 illustrates the mapping model leveraging features from BERT, which expresses the best capability of carrying sense-specific explanation among all variants.

2.3 Reverse Mapping

In order to analyze what the mapping captures for better interpretation, we examine the reverse direction of our mapping after training, motivated by Yuan et al. (2016). Given a context-dependent embedding $\mathbf{v}$ and its ground truth definition embedding $\mathbf{y}$, also the word embedding $\mathbf{u}_w$ for each target word w in the vocabulary V, and a pretrained mapping $\bar{f}$, the word that is the closest vector to the target definition after mapping is formulated as:

$$\arg\max_{w \in V} \cos(\bar{f}(\mathbf{u}_w, \mathbf{v}), \mathbf{y}). \quad (2)$$

In our experiments, the word set corresponding to the top-k highest cosine scores often contains the actual target word, also overlapping with a few synonyms provided by the Oxford dictionary. When applying to contextualized word embeddings from BERT-base, the model achieves the average recall of 23.7%, even though we do not incorporate any synonym information during training. This demonstrates that our models are capable of automatically capturing potential similarities. Examples of the generated synonyms can be found in the supplementary material.

[2]Note that our work focuses on analyzing the sense information encoded in the contextualized embeddings; thus, our model is stacked upon the frozen representations extracted from the pretrained BERT instead of fine-tuning them. More training details are given in the supplementary material.

3 Experiments

In order to examine whether the sense-specific information captured by contextualized word embeddings can be well disentangled, the following experiments are conducted.

3.1 Definition Retrieval

This is to analyze whether our proposed mapping indeed interprets the sense-specific definitions from contextualized word embeddings. Considering that the words can be seen and unseen, our experiments contain two levels of tasks (Chang et al., 2018).

- **Seen** is to test the pair with *(seen word, unseen context, seen definition)*, including 151,306 pairs of instances containing 9,276 target words.

- **Unseen** is to test the pair with *(unseen word, unseen context)*, including 15,959 pairs of instances corresponding to the 1,000 randomly selected target words held-out from training. Such a **zero-shot** setting challenges if the input feature is informative enough and if the mapping can generalize to the unseen but semantically consistent embeddings. Also, it is a practical and appealing task as many new words are coined every year.

We ensure both being polysemic tasks by sampling within instances whose target words have at least 3 definitions when building these two test sets.

3.1.1 Results

We measure the performance of various proposed architectures with average precision (@1, @5, @10) as well as the average cosine distance between the predicted definition embedding and the ground truth embedding (lower is better). Two baselines without using contextualized embeddings as context-dependent input features are proposed, 1) using the target word embedding only, which entirely ignores the contexts and thus being a lower bound of this task and 2) leveraging the context embedding from the pretrained Transformer-based universal-sentence encoder as

Task	Methods	P@1	P@5	P@10	Cosine Dist
Seen	target word embedding	33.27 / 18.29	50.77 / 31.92	56.06 / 36.69	0.251
	+ context embedding	59.36 / 45.19	71.43 / 58.17	74.95 / 62.42	0.178
	+ ELMo	67.00 / 53.91	77.32 / 65.69	80.35 / 69.58	0.149
	+ BERT-base	**74.83 / 63.34**	**83.28 / 73.97**	**85.46 / 77.06**	**0.123**
	+ BERT-large	73.89 / 62.36	82.61 / 73.24	84.92 / 76.28	0.126
Zero-Shot	target word embedding	1.84 / 1.06	6.54 / 4.22	9.67 / 6.44	0.388
	+ context embedding	1.97 / 1.29	7.00 / 4.77	10.78 / 7.50	0.383
	+ ELMo	2.04 / 1.38	6.79 / 4.65	10.21 / 7.06	0.387
	+ BERT-base	3.27 / 2.28	9.59 / 7.41	14.44 / 11.44	0.344
	+ BERT-large	**3.50 / 2.52**	**10.47 / 8.17**	**15.58 / 12.35**	**0.339**

Table 1: Precision@K (average within examples sharing the same target words / average within examples sharing the same (target word, definition)) and cosine distance for models using various input features.

Methods	Tasks	
	Seen	Unseen
Noraset et al. (2017)	21.6 / 36.7	1.7 / 15.8
Chang et al. (2018)	24.9 / 41.0	2.0 / 15.9
target word embedding	28.4 / 36.9	4.6 / 17.2
+ context embedding	58.5 / 62.8	5.1 / 16.8
+ ELMo	66.5 / 71.6	4.8 / 17.2
+ BERT-base	**74.7 / 78.3**	**7.1 / 19.3**

Table 2: BLEU@4 / ROUGE-L:F scores of NLG-based models and various proposed architectures.

described in Section 2.2. Note that the naive baseline is randomly guessing among the whole 79,030 definitions, with P@1 lower than 0.0013%, showing the difficulty of this task.

For **Seen** experiments, Table 1 shows that the context-dependent component contains abundant sense-informative cues, where contextualized word embeddings, especially BERT, expresses the strong capability of producing corresponding definitions with about 15% enhancement of P@1 comparing to the second baseline. For **Unseen** results, the trend is similar: all models with context-dependent input features outperform the first baseline, and the variants with BERT reach the best scores among all metrics. The above results demonstrate rich sense-informative cues captured by the contextualized word embeddings.

Furthermore, we evaluate the definitions by their natural language surfaces using BLEU (Papineni et al., 2002) and ROUGE-L (Lin, 2004) scores. The results are in Table 2, where both Noraset et al. (2017) and the first proposed baseline generates or selects definitions depending merely on the static target word embedding, and all other architectures are context-dependent. We initialize the target word embeddings for all models with pretrained `fasttext` (Joulin et al., 2016) on Wikipedia 2017, UMBC webbase corpus for a fair comparison. The results demonstrate that our mapping model can better explain the word representations than the prior work.

3.1.2 Analysis

An ablation study is conducted in which only the contextualized word embedding is used. While the scores of all 3 related variants drop dramatically due to the lack of the explicit, context-independent signal to the target word identity, the scores still outperform the first baseline by 7% (P@1) on the **Seen** task, showing the superiority of contextualized representations to their static counterparts. In addition, the reason about better performance of the models with contextualized embeddings compared to the one with context embeddings (the second baseline) is that two context embeddings sharing the same target word sense may differ a lot due to various words in the contexts, but they may have similar contextualized word embeddings produced from ELMo or BERT. This allows our proposed model to better interpret the sense information.

Despite the overall low performance under the zero-shot setting, it is found that all proposed models with context-dependent components are still able to disambiguate different senses. Table 3 shows a randomly-sampled example from the output of the BERT-base model. Although the model can only correctly answer the first definition of *draw*, which may be the most common usage so that it can be easily generated from the input embedding, we show that our model is still able to capture the other two very different word senses

Target	Contexts, Selected Definitions, Ground Truth
draw	The embodied capacity to write and *draw* seems to rule over the languid group of objects underneath. **1st Definition**: produce an image of someone or something by making lines and marks on paper **2nd Definition**: produce a picture or diagram by making lines and marks on paper with a pencil pen etc **3rd Definition**: compose or draw up something written or abstract **Ground Truth**: produce an image of someone or something by making lines and marks on paper
	When it came to the end of the day, though, I was more than happy to *draw* the curtains and shut the day out. **1st Definition**: arrange something carefully into a particular shape or position **2nd Definition**: arrange objects or parts in a zigzag formation or so that they are not in line **3rd Definition**: draw a circle round something especially to focus attention on it **Ground Truth**: pull curtains shut or open
	... hinders your ability to impart spin on the ball, reducing your ability to *draw* and fade the shot on command. **1st Definition**: put the ball in play by throwing it up between two opponents **2nd Definition**: strike the ball in the direction of ones followthrough so that it travels to the left ... **3rd Definition**: propel a ball with a bat racket stick etc to score runs or points in a game **Ground Truth**: hit the ball so that it deviates slightly usually as a result of spin

Table 3: The analysis of the top 3 selected definitions on the **Unseen** task.

Model	Accuracy (%)
Lee and Chen (2017)	52.14
Neelakantan et al. (2015)	54.00
Mancini et al. (2016)	54.56
Guo et al. (2019)	55.27
Chang et al. (2018)	57.00
Pilehvar and Collier (2016)	58.55
Proposed (BERT-base)	**68.64**

Table 4: The results on Word-in-Context (WiC) data.

according to the selected definitions. More output samples on both **Seen** and **Unseen** tasks can be found in the supplementary material.

Moreover, unlike the prior work that required discrete token generation to interpret the pretrained word embeddings (Noraset et al., 2017; Gadetsky et al., 2018; Chang et al., 2018), we reformulate the definition modeling task from an NLG problem to a classification problem via learning a mapping between two semantically continuous spaces, which greatly simplifies the hardness, making significant improvement as shown in Table 2. Specifically, as the input representations of Noraset et al. (2017) and the first proposed baseline are the same, i.e., they both are context-agnostic and utilize the same pretrained static word embeddings, the better performance of our model demonstrates the direct benefits of not requiring sequence generation.

3.2 Word Sense Selection in Context

We further examine if the captured sense-specific cues help word sense disambiguation via Word-in-Context data (WiC) (Pilehvar and Camacho-Collados, 2018), in which each instance contains a pair of two contexts sharing a target word, and the task is to decide whether their word senses are the same.[3] To justify that the models are capable of selecting senses encoded in the embeddings, for each pair, our model outputs 10 candidate definitions (top-10 nearest neighbors), and we output TRUE if any definition occurs in both candidate sets, otherwise FALSE. Table 4 shows that the proposed model with contextualized word embeddings outperforms all previous models. We conclude that contextualized word embeddings indeed capture sense-informative cues and our proposed model is capable of interpreting the corresponding senses via definition.

4 Conclusion

This paper proposes a framework that can well interpret the contextualized word embeddings by human-readable sense definitions. The experiments demonstrate that contextualized word embeddings capture the sense-informative cues and the proposed model can better explain the semantics encoded in the representations.

Abstract

Pre-trained BERT contextualized representations have achieved state-of-the-art results on multiple downstream NLP tasks by fine-tuning with task-specific data. While there has been a lot of focus on task-specific fine-tuning, there has been limited work on improving the pre-trained representations. In this paper, we explore ways of improving the pre-trained contextual representations for the task of automatic short answer grading, a critical component of intelligent tutoring systems. We show that the pre-trained BERT model can be improved by augmenting data from the domain-specific resources like textbooks. We also present a new approach to use labeled short answering grading data for further enhancement of the language model. Empirical evaluation on multi-domain datasets shows that task-specific fine-tuning on the enhanced pre-trained language model achieves superior performance for short answer grading.

1 Introduction

Intelligent tutoring system (ITS) is one of the tools to facilitate personalized learning. Automatic short answer grading (ASAG) is an important component of a dialog-based tutoring (DBT) system; especially, to enable Socratic tutoring. Automatic grading is the task of evaluating the correctness of a student answer for a specific question by comparing it to a reference answer. In short answer grading, the reference answers are typically one or two sentences long and close ended. A broad range of approaches from simple bag-of-words to transfer learning and deep neural networks have been explored to address the short answer grading problem (Mueller and Thyagarajan, 2016; Saha et al., 2018; Marvaniya et al., 2018).

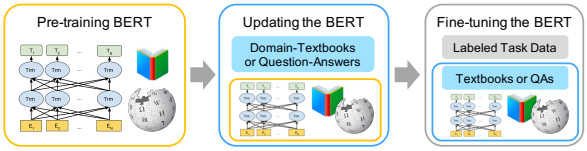

Figure 1: In this work, we propose to update the pre-trained BERT language model by utilizing the textbook or question-answer data to improve short answer grading.

For a variety of natural language processing (NLP) tasks, state-of-the-art results have been reported with pre-trained deep language models, such as BERT (Devlin et al., 2018), GPT (Radford et al., 2018), and ULMFit (Howard and Ruder, 2018). In these approaches, pre-trained language models are utilized for down-stream NLP tasks by means of task-specific *fine-tuning*.

A typical DBT, and therefore a short answer grading system, is often used across various subjects or domains (e.g., Science, Sociology, and Psychology). A pre-trained language model, such as that of BERT, is typically trained on generic English language corpus. Thus, there may be a scope for updating and improving the pre-trained language model on available textual resources for the domains of short answer grading. Textbooks used to create questions and reference answers are mostly available in digital form. Moreover, the labeled data for short answer grading have question and reference answer pairs available but contextual information between the pairs and even just questions are easily ignored. Thus, in this research, we aim to explore and evaluate various methods of updating the pre-trained BERT language model (LM)[*] on such domain-specific

[*]Corresponding author.

[†]The work was done when the author was an employee at IBM Research, India.

[*]We prefer the phrase *to update LM* to imply further training or modifying the pre-trained LM. In some literature, the term *LM fine-tuning* is also used to refer to the update of pre-trained language model. However, we reserve the term *fine-tuning* for task-specific classifier training in sync with BERT terminology.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6071–6075,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

available resources in the context of ASAG to answer the following research questions.

RQ1 Is updating pre-trained BERT LM helpful in improving short answer grading performance?

RQ2 What is the effect of unsupervised domain corpora (i.e. domain textbooks) in updating LM for short answer grading?

RQ3 How generalizable are the pre-trained and the updated BERT models to unseen domains, in case, where textbooks are not available?

RQ4 How can labeled Question-Answer data be exploited to update LM for short answer grading, in addition to fine-tuning?

Our evaluations are performed on four subjects (Physiology, American Government, and two on Psychology). In addition to the empirical analysis, we also propose a novel approach to effectively utilize the question-answer data as part of the pre-trained model update.

2 Related Work

The problem of short answer grading has attracted significant attention of the researchers over the years. Various approaches, starting from traditional hand-crafted features (Mohler et al., 2011; Sultan et al., 2016) to more recent deep learning models (Riordan et al., 2017; Kumar et al., 2017) and their combination (Saha et al., 2018) have been explored. However, similar to most downstream NLP tasks, ASAG also suffers from the overhead of task-specific architectures and thus scalability across different subjects has proven to be hard.

In a step towards alleviating this overhead, the NLP community has recently proposed multiple generic pre-trained language models which can be transferred seamlessly and fine-tuned for any end task. Universal Language Model Fine-Tuning (ULMFiT) (Howard and Ruder, 2018) method is one of the first such initiatives to illustrate the effectiveness of language model fine-tuning. Embeddings from Language Models, commonly referred to as ELMo (Peters et al., 2018) also learns deep contextualized word representations using the internal states of a deep bidirectional language model. Finally, Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) improves on all previous pre-training techniques by training a deep language model that jointly conditions on both the left and right context simultaneously through all the layers. BERT's effectiveness has been widespread and Sung *et al.* (Sung et al., 2019) have shown that fine-tuning BERT for ASAG also outperforms all existing techniques.

While BERT has been fine-tuned to achieve state-of-the-art results on a large number of tasks, the idea of further pre-training of the language model to incorporate more domain knowledge has been explored less. BioBERT (Lee et al., 2019) for biomedical tasks and SciBERT (Beltagy et al., 2019) for science domains have shown the effectiveness of language model pre-training for tasks in specific domains. Motivated by these prior works, we propose two pre-training techniques for BERT in the context of short answer grading that improve over the generic BERT.

3 Method

Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) is a deep bidirectional pre-trained language model that is fine-tuned for downstream NLP tasks. As illustrated in Figure 1, we describe the usage of BERT in two parts: firstly the proposed enhancements in the pre-training step and secondly, the fine-tuning step for short answer grading.

3.1 Pre-Training BERT

We start with the pre-trained BERT language model, trained using the English Wikipedia and BooksCorpus and propose two methods to further improve it.

3.1.1 Usage of Textbooks

Our first approach relies on the usage of textbooks from specific domains of short answer grading. Specifically, we collect textbooks corresponding to the domains and chunk them into paragraphs and feed each paragraph as a document for pre-training. Since our task at hand is short answer grading, we assume that the answers to questions do not overlap between paragraphs and thus we treat each paragraph as an independent document.

To validate our assumption, we randomly sampled 60 question-answer pairs from Physiology domain, and manually examined these whether the answer is contained in the same paragraph of the question. We observe that for about 90% of these

samples, that is indeed the case. Further details on the textbooks and their pre-processing steps for data preparation is provided in the experiments section.

3.1.2 Usage of Question-Answer Pairs

Our second approach leverages the labeled (question, reference answer, student answer) data triples as unsupervised data for pre-training the language model. We consider the triples with correct labels only and create pairs of the following form for each of the correct student answers.

Question-Reference Answer pair
What does the telencephalon contain? The telencephalon contains most of the cerebral cortex.
Question-Correct Answer pair
What does the telencephalon contain? It contains the cerebral cortex, limbic system, and basal ganglia.

Each of these pairs is fed as documents to the BERT architecture. Since one of the training objectives for BERT is next sentence prediction, the answer in a (question, answer) pair provides an immediate context to the question. Incorrect and partially correct student answers, apart from being factually incomplete, are often grammatically incorrect and thus may harm the language model learning. Hence, we ignore those triples for pre-training.

3.2 Fine-tuning for ASAG

The BERT fine-tuning step using labeled short answer grading data proceeds similar to any sentence pair classification task. The (reference answer, student answer) pair is converted to a single sequence of tokens by using a separator token `[SEP]` between the pair and a classification token `[CLS]` at the beginning. The input pair's representation, as obtained from the embedding of the `[CLS]` token, is then fed into a dense layer, which along with the language model is updated during fine-tuning.

4 Experiments

The experiments section is organized as follows. We start by providing a brief description of the dataset, followed by a discussion about the implementation details. In the concluding two subsections, we analyze the effect of the two proposed pre-training methodologies for short answer grading.

Textbook	Train			Test		
	Correct	Incorrect	Partial	Correct	Incorrect	Partial
Phy	9,676	1,197	2,524	4,784	593	1,321
Gov	9,405	3,483	2,433	4,784	1,699	1,177

Table 2: Size and domain of pre-training text corpora.

4.1 Dataset

We show results on a proprietary large-scale industry dataset consisting of three domains - (1) Physiology of Behavior (Phy), (2) American Government (Gov), and (3) Psychology – Human Development (Psy-I) and Abnormal Psychology (Psy-II). Given a question, reference answer and student answer, we address a 3-way classification task into `correct`, `incorrect` and `partially correct` classes. Table 1 shows the train-test splits for each of the domains.

We obtain three textbooks for each of the Physiology and American Government domains. These include our own textbooks and additional ones downloaded from Lumen Learning[†] and Gutenberg[‡] websites. We do not use any textbooks for the Psychology domain, to show the effect of BERT pre-training on out-of-domain data. We combine the data from all the textbooks for further pre-training of BERT. Table 2 summarizes the sizes of the textbook corpora (1.1M words) and question-answer corpora (1.3M words) used in our experiments. Note that, the original BERT model is learned with about 3.3B words corpora.

4.2 Implementation Details

We leverage the TensorFlow implementation of BERT-Base[§] for all our experiments. It is further pre-trained for 240K, 150K, and 240K epochs for BERT+Textbook$_{\text{Phy+Gov}}$, BERT+QA$_{\text{Phy+Gov}}$, and BERT+QA$_{\text{Phy+Gov+Psy-I,II}}$ respectively using the same hyperparameters until the accuracy of the two pre-training objectives converges to 100%.

	BERT	(+Textbook)	(+QA)	(+Textbook+QA)
Phy	81.35	82.28	83.95	83.64
Gov	74.55	76.25	75.43	77.28
Psy-I	78.69	78.05	77.71	77.89
Psy-II	80.06	79.10	79.46	80.74

Table 3: Effect of domain data. Textbook and Question-Answer data from only Phy and Gov domains are used in the pre-trained model update; making Psy-I and Psy-II unseen domains.

Note that the corpus size for Phy+Gov is smaller, leading to faster convergence. Once the pre-training is done, we fine-tune the model with the short answer grading labeled data for 3 epochs using a learning rate of 3e-5. All results are reported in terms of macro-averaged F1.

4.3 Effect of Domains Textbook Data

In this set of experiments, we aim to understand the effect of updating the pre-trained BERT LM on textbook data. We take the textbooks from only two domains (Physiology and American Government), for designing a scenario where textbooks are not available. Such a scenario helps us understand the generalizability of BERT (for which all the domains are unseen), and BERT+Textbook data (for which Psy-I and Psy-II are unseen domains). We combine the data from both the domains and pre-train a single BERT model as pre-training per-domain models is computationally expensive and almost impossible to scale.

Table 3 shows the results. The pre-trained BERT model, as is, performs fairly well (74-81% M-F1). The LM updated with textbook data (BERT+Textbook), improves performance on the domains included in additional pre-training (Phy and Gov). However, we suspect that the updated model becomes more specialized towards seen domains, which leads to performance degradation on the unseen domain of Psychology.

- RQ1 and RQ2 can be answered as *LM update using domain textbook data positively affects the short answer grading performance on the corresponding domains.*
- RQ3 can be answered as *the updated BERT LM model does not appear to generalize well on unseen domains, as the evidence suggests that LM becomes more domain-specific.*

4.4 Effect of Question-Answer Data

In this set of experiments, we aim to understand effectiveness of the Question-Answer (QA) data to update the LM. As explained earlier, for each reference answer and correct answer, question-answer pairs are created and utilized as documents.

In Table 3, a combined QA dataset from Psy and Gov subjects is used for running additional steps of LM pre-training. This again simulates the unseen domain scenario for Psy-I and Psy-II in pre-training update. It can be observed that the proposed approach utilizing QA data (BERT+QA) improves the performance consistently in both the seen subjects of Phy and Gov. Akin to textbook data experiments, the performance is degrading for unseen domains as the model becomes more specialized. Interestingly enough, the updated LM on both strategies (BERT+Textbook+QA) also positively impacts on in-domain performance.

Additionally, another set of results is obtained by utilizing the QA dataset of *all four* domains; simulating an all seen-domain scenario. Table 4 reports the corresponding results showing that the QA data helps improve the model for all the domains, consistently.

	BERT	BERT+QA
Phy	81.35	**83.36**
Gov	74.55	**76.25**
Psy-I	78.69	**78.73**
Psy-II	80.06	**81.41**

Table 4: Effect of Question-Answer data in seen-domains scenario. All four domains are included in the Question-Answer data.

These observations suggest that the proposed approach re-purposes the `Next Sentence Prediction` task to effectively encode the latent features of ASAG. Further, RQ1 can be answered affirmatively; and RQ4 can be answered as *it is advisable to use the QA corpora for LM model update in addition to fine-tuning.*

5 Conclusion

In this paper, we proposed two ways to update the pre-trained BERT language model for the short answer grading task. We illustrate utilization of unstructured textbook data and labeled question answer data for the model update. We show that by adding a step of updating BERT using these domain-related resources, we can achieve better results than directly fine-tuning pre-trained BERT on the end task. We also observed that the updated model becomes more specialized towards the corresponding domains, adversely affecting the per-

formance on unseen domains.

We limited the scope of this paper to the task of automatic short answer grading only. However, our findings of the sensitivity of domain-specific BERT models appear generic. We believe that any multi-domain text classification task should exhibit similar behavior. We also note that our strategies for improving the BERT model should be directly applicable to other QA tasks as well. Future directions include trying our method on different tasks and different relevant data.

WIQA: A dataset for "What if..." reasoning over procedural text

Niket Tandon*, **Bhavana Dalvi Mishra***, **Keisuke Sakaguchi**,
Antoine Bosselut, **Peter Clark**
Allen Institute for Artificial Intelligence, Seattle, WA
{nikett,bhavanad,keisukes,antoineb,peterc}@allenai.org

Abstract

We introduce WIQA, the first large-scale dataset of "What if..." questions over procedural text. WIQA contains three parts: a collection of paragraphs each describing a process, e.g., beach erosion; a set of crowdsourced *influenct graphs* for each paragraph, describing how one change affects another; and a large (40k) collection of "What if...?" multiple-choice questions derived from the graphs. For example, given a paragraph about beach erosion, would stormy weather result in more or less erosion (or have no effect)? The task is to answer the questions, given their associated paragraph. WIQA contains three kinds of questions: perturbations to steps mentioned in the paragraph; external (out-of-paragraph) perturbations requiring commonsense knowledge; and irrelevant (no effect) perturbations. We find that state-of-the-art models achieve 73.8% accuracy, well below the human performance of 96.3%. We analyze the challenges, in particular tracking chains of influences, and present the dataset as an open challenge to the community.

1 Introduction

Procedural text is common in language, but challenging to comprehend because it describes a dynamically changing world. While recent systems for procedural text comprehension can answer questions about what events happen, e.g., (Bosselut et al., 2018; Henaff et al., 2017; Dalvi et al., 2018), the extent to which they understand the influences *between* those events remains unclear.

One important test of understanding is to predict what would happen if a process was *perturbed* in some way, requiring understanding and tracing the chain of influences through a paragraph. However, to date there is no dataset available to help develop this capability. We aim to fill this gap with WIQA[1], the first large-scale dataset testing "What if..." reasoning over procedural text.

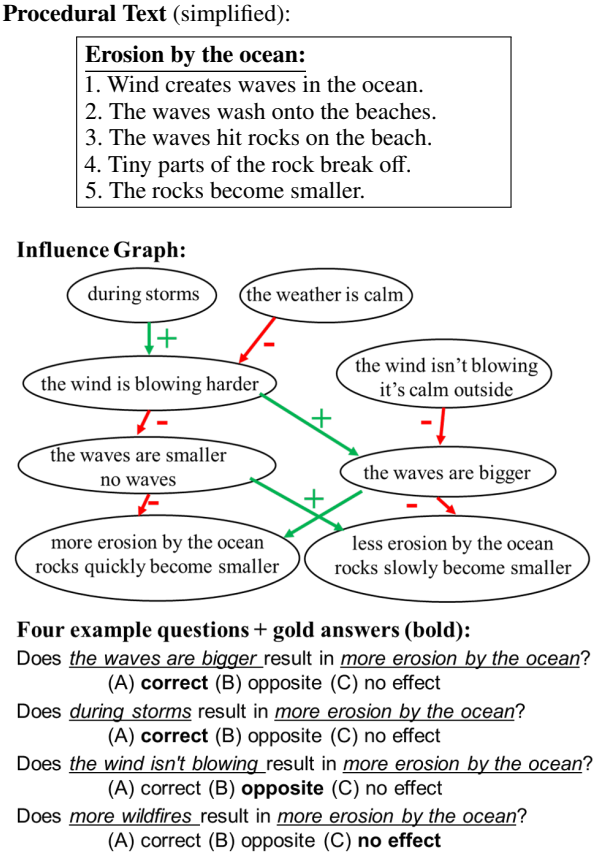

Figure 1: WIQA contains procedural paragraphs, crowdsourced influence graphs associated with them, and a large collection of "Does *changeX* result in *changeY*?" (what-if) questions, derived from the graphs.

WIQA contains 40.7K questions, for 379 process paragraphs. To efficiently create the questions, crowdworkers created 2107 *influence graphs* (IGs) for the paragraphs, describing how one perturbation positively or negatively influences another (Fig-

*Niket Tandon and Bhavana Dalvi Mishra contributed equally to this work.

[1]The dataset is available at http://data.allenai.org/wiqa/

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ure 1). Questions were then derived from paths in the graphs, each asking how the change described in one node affects another. Each question is a templated, multiple choice (MC) question of the form *Does changeX result in changeY? (A) Correct (B) Opposite (C) No effect*, where *Opposite* indicates a negative influence between *changeX* and *changeY*. To bound the task, perturbations are typically qualitative (e.g., "the wind is blowing harder"), and possible effects are restricted to changes to entities and events mentioned in the paragraph (e.g., "the waves are bigger"). Perturbations themselves include in-paragraph, out-of-paragraph, and irrelevant (no effect) changes. The WIQA task is to answer the questions, given the paragraph (but not the IG).

We first describe the task and how the dataset was constructed, and then present results from baselines and strong BERT-based models. We find that the best model is still 23% behind human performance and the gap further widens with indirect and out-of-paragraph effects, illustrating that the dataset is hard. We present a detailed analysis showing WIQA is rich in linguistic and semantic phenomena. Our contributions are: (1) the new dataset (2) performance measures and an analysis of its challenges, to support research on counterfactual, textual reasoning over procedural text.

2 Related Work

While there are several NLP datasets now available for procedural text understanding, e.g., (Kiddon et al., 2016; Dalvi et al., 2018; Weston et al., 2015), these have all targeted the task of tracking entity states throughout the text. WIQA takes the next step of asking how states might *change* if a perturbation was introduced.

Predicting the effects of qualitative change has been studied in the qualitative reasoning (QR) community, but primarily using formal models (Forbus, 1984; Weld and De Kleer, 2013). Similarly, counterfactual reasoning has been studied in the logic community (Lewis, 2013), but again using formal frameworks. In contrast, WIQA treats the task as a mixture of reading comprehension and commonsense reasoning, creating a new NLP challenge.

3 Dataset Construction

To efficiently generate questions, we first asked crowdworkers to create *influence graphs* (IGs) for each paragraph. We then create questions from the IGs using paths in the IGs. We now describe this process.

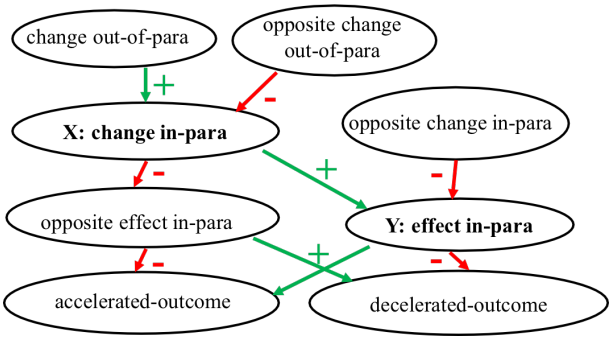

Figure 2: The template used to acquire influence graphs

Influence Graphs An influence graph $\mathcal{G}(V, E)$ for a procedural text T is an unweighted directed graph. Each vertex v_i is labeled with one or more text strings, each describing a change to the original conditions described or assumed in T, such that all those changes have the same influence on a connected node v_j. Each edge is labeled with a *polarity*, **+** or **-**, indicating whether the influence is positive (causes/increases) or negative (prevents/ reduces). Indirect effects can be found by traversing $\mathcal{G}$.
It is useful to distinguish two kinds of nodes:
1. **Out-of-para nodes:** denoting events or changes to entities/events not mentioned in the paragraph, e.g, "during storms" in Figure 1.
2. **In-para nodes:** denoting events or changes to entities/events mentioned in the paragraph, e.g, "the wind is blowing harder" in Figure 1.

Acquiring influence graphs For a source of paragraphs, we used the 377 training set paragraphs from the ProPara dataset (Tandon et al., 2018). (Multiple) influence graphs were then crowdsourced for each. To do this, we use an *influence graph template*, shown in Figure 2. Workers were asked to populate this (hidden) template using a sequence of five questions, where the later questions were automatically constructed from their answers to the earlier questions. The first question asks the worker to supply an X and Y in: "If [X] occurs, it will have the intermediate effect [Y] resulting in *accelerated_outcome*" (where the *accelerated outcome* phrase was pre-authored for each paragraph). For X and Y, workers were asked to describe a change in some property/phenomonon mentioned in the paragraph, e.g., if a paragraph sentence x_i is "Wind creates waves.", they may author an X saying "the wind is blowing harder" (Figure 1).

(The alignment of X and x_i, and whether X describes an increase or decrease of x_i, denoted by $d_X \in \{+, -\}$, was also recorded.). This fills X and Y in Figure 2. Similar questions populate the remaining nodes (see Appendix). 2107 influence graphs were collected in this way.

Generating Questions from Graphs Each path in a graph forms a *"change→effect?"* question, whose answer is either "correct" or "opposite" depending on the product of the polarities of the traversed edges. Questions are labeled with the number of edges traversed (1 = "1-hop", etc.). We also distinguish *in-para* and *out-of-para* questions depending on the type of node they originated from. We then created a third category of question, whose answer is "no effect", by selecting out-of-para changes from *other* paragraphs and asking for their effect on nodes in the current graph. Occasionally these changes did affect the selected node, resulting in an erroneous label of "no effect", but this was rare (and such cases were removed from the test partition, as we now describe).

Using a separate crowdsourcing task, questions in the test set were filtered to improve the test set quality. First, five workers independently answered each question, given the paragraph. The inter-annotator agreement between workers, using Krippendorff's alpha, was moderately high (0.6). We then retained only questions with majority agreement (i.e., at least 3 out of 5 workers agreed), resulting in 88% of questions being retained.

Balancing the Dataset From the (many) questions thus generated, we (randomly) selected a subset that approximately balanced the numbers of (a) in-para, out-of-para, and no-effect questions, and (b) questions with each answer (correct, opposite, no-effect), resulting in 40,695 questions. Train, dev, and test partitions do not share paragraphs about the same topic. Statistics are shown in Table 1.

Explanations As each question is derived from a path in an IG, we can also generate *explanations* for each answer using that path. Although explanation is not part of the WIQA task, we create an explanation database to support a possible explanation task at a future date.

Consider a question "Does perturbation q_p result in q_e?" with answer $d_e \in \{+, -\}$ (as a shorthand for $\{correct, opposite\}$), created from an IG path:

$$q_p \xrightarrow{r_{pX}} X \xrightarrow{r_{XY}} Y \xrightarrow{r_{Ye}} q_e$$

Here, r_{pX}, r_{XY}, and r_{Ye} denote the polarities (+/-) of the edges q_pX, XY, and Xq_e in the IG respectively. (As described earlier, answer d_e is the product of the polarities $r_{pX}.r_{XY}.r_{Ye}$). To define an explanation in terms of the paragraph's sentences $x_1, ..., x_K$, we define the gold explanation E_{gold} as the structure:

$$q_p \rightarrow d_i x_i \rightarrow d_j x_j \rightarrow d_e q_e$$

where x_i is the sentence corresponding to X, x_j is the sentence corresponding to Y, and d_i, d_j, and d_e denote the directions of influence (+/-, denoting {more,correct}/{less,opposite}). As workers already annotated the alignment between X and x_i (similarly Y and x_j) we know x_i and x_j. Similarly, as workers also annotated whether X describes an increase of decrease of x_i, denoted by $d_X \in \{+, -\}$, we can straightforwardly compute the directions of influence:

$d_i = r_{pX}.d_X$
$d_j = d_i$ (in-paragraph influence[2])
$d_e = r_{pX}.r_{XY}.r_{Ye}$ = the answer

We can similarly generate explanations for answers derived from 1-hop and 2-hop paths.

We generated a full database of explanations for all the questions with answer "correct" or "opposite" (For "no effect" answers, there is no explanation as there is by definition no path of influence). We then removed the (occasional) explanation where worker annotations were contradictory (e.g., $j < i$) or had no majority decision for an annotation. This database is available for a possible future explanation task (given question + paragraph, produce the answer + explanation).

4 Experiments

4.1 Models

We measured the performance of two baselines and three strong neural models on WIQA, to understand how it stresses these models:

Majority predicts the most frequent label, *correct*, in the training dataset.

Polarity is a rule-based baseline that assumes influences of the form "*more X → more Y*" (similarly for "less") are *correct*, hence "*more X → less Y*" are *opposite*. A small lexicon of positive (*"more"*) and negative (*"less"*) words is used to assign the more/less polarities. A random class label is chosen when assignments

[2]Paragraph sentences always describe correct, not opposite, influences on later sentences, HENCE if x_i is more/accelerated, x_j will be too (similarly for less/decelerated).

Table 1: Dataset statistics

cannot be made.

Adaboost (Freund and Schapire, 1995) was used to make the 3-way classification using several bag-of-word features computed from *change* and *effect*.

Decomp-Attn applies the Decomposable Attention (DA) model of (Parikh et al., 2016) to our task. The original DA model computes entailment, i.e., the confidence that a *premise* entails (or contradicts) a *hypothesis*. We recast WIQA as an entailment task where cause-effect becomes premise-hypothesis, and (correct/opposite/no-effect) correspond to (entailment/contradiction/neutral). We retrain the DA model on WIQA using this mapping.

BERT (Devlin et al., 2018) is a pre-trained transformer-based language model that has achieved state of the art performance on many NLP tasks. We supply questions to BERT as *[CLS] paragraph [SEP] question [SEP] answer-option* for each of the three options. The [CLS] token is then projected to a single logit and fed through a softmax layer across the three options, using cross entropy loss, and the highest-scoring option selected. We fine-tune BERT on the WIQA training data in this way. We also measure an ablated version where the paragraph is omitted (train and test).

Human Performance was estimated by having three people independently answering the same 100 questions (with paragraphs) drawn randomly from the test set. Krippendorff's alpha (nominal metric) for these answers was 0.908 (high agreement) (Krippendorff, 1970).

Question Type	in-para	out-of-para	no-effect	Total
# questions	935	1598	1460	3993

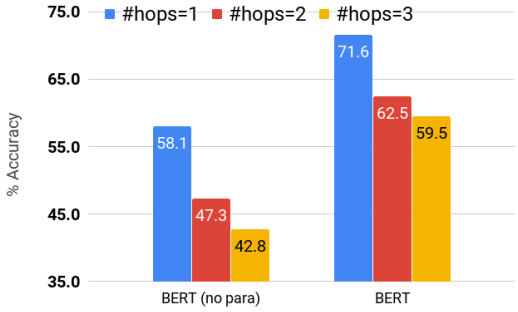

Figure 3: Accuracy of the best baselines drops as number of hops increase, quicker for 'no para' version.

5 Results and Analysis

5.1 Prediction Accuracy

The results (Table 2) provide several insights:

1. **The dataset is hard.** Our strongest model (73.8) is over 20 points behind human performance, suggesting WIQA poses significant challenges. Prediction of out-of-para effects is particularly challenging, 37 points behind human performance.

2. **BERT already "knows" some change-effect knowledge.** Even without the paragraph, and even though the test paragraphs are on topics unseen in training, BERT scores substantially above the baselines. This suggests BERT has some type of cause-effect information embedded in it.

3. **Supplying the paragraph helps,** resulting in 10 points higher score, illustrating that WIQA contains questions that require understanding of the paragraph. This suggests more sophisticated reading strategies may further improve results.

5.2 Predicting Indirect Effects

In-para and out-of-para questions were derived from chains of different lengths ("hops") in the influence graphs. Figure 3 shows how performance varies with respect to those lengths, and shows that

"indirect" (2/3-hop) effects are harder to predict than "direct" (1-hop) effects. For example, it is easier to predict "cloudy day" results in "less sunshine" (direct) than "less photosynthesis" (indirect). This suggests that some form of reasoning along influence chains may be needed to predict indirect effects reliably, as those effects are less likely to be explicitly stated in corpora and embedded in pre-trained language models.

5.3 Consistency

Are the models making consistent predictions? If a model predicts both X→Y and Y→Z are correct, it should, if it were consistent, also predict *X* →Z is correct. To measure a model's *transitivity consistency*, for each influence graph, we measure how often its indirect predictions (2/3-hop) are consistent[3] with its 1-hop predictions. Similarly, we measure *disjunctive consistency* by how often its predictions for edges known to be opposite (eg X→Y and X→*opp-effect-in-para* in Fig 2) are indeed so[4]. The results in Figure 4 illustrate that the **models are far from consistent**. This suggests that reasoning with global consistency constraints may improve results, e.g., (Ning et al., 2017; Tandon et al., 2018).

5.4 Linguistic and Semantic Phenomena

We analyzed 200 descriptions of changes in 100 random questions, and observe the following challenging (overlapping) phenomena to handle:

1. Qualitative Language: ≈65% of the change statements are expressed qualitatively, using a broad vocabulary of comparatives (e.g., more, fewer, smaller, larger, cooler, slower, higher, harder, decreased, hotter) or their corresponding adjectives (small, cool, etc.). In addition, whether the change is a positive or negative influence on the process is context-dependent ("more X" can be positive or negative, depending on X, and sometimes depending on the paragraph topic itself).

2. Commonsense (≈45%): Exogenous influences are (by definition) not stated in the paragraph, and so require substantial commonsense to understand, e.g., that "heavy rainfall" (out of para) negatively influences "more wild fires" (in para); or that "overfishing" (out of para) negatively influences "fish lay eggs" (in para).

[3]i.e., the polarity (+/-, for correct/opposite) of edge XZ = the product of the polarities of edges chaining from X to Z. As models can also predict "no effect", random score is 1/3.

[4]Only edge pairs with labels +&-, or -&+, are disjunctively consistent (of 9 possible labelings), hence random is 2/9.

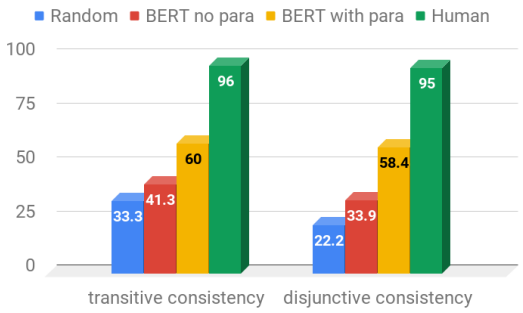

Figure 4: The best models (red,yellow) make substantially less consistent predictions than humans (green).

3. Lexical matching ≈15% of the in-para changes refer to paragraph entities using different terms, e.g., "insect" (para) ↔ "bee" (question), "becomes" ↔ "forms", "removes" ↔ "expels", complicating aligning questions with the paragraph.

4. Negation (≈6%): Negation occurs in about 6% of the changes, e.g., "drought does not occur", "soil is not fertile", "magma does not get larger".

5. Juxtaposed polarities (≈3%): Sometimes positive- and negative-related terms are juxtaposed, (e.g., "much less", "increased deforestation", "less severe") again challenging to process.

These all illustrate the diversity of linguistic and semantic challenges in WIQA.

6 Conclusion

An important test of understanding procedural text is whether the effects of *perturbations* to the process can be predicted. To that end, we have introduced WIQA, the first large-scale dataset for "what if" reasoning over text. While our experiments suggest language models have some built-in knowledge of influences, and some ability to identify influences in paragraphs, these capabilities are limited, producing predictions that are over 20 points worse than humans, often inconsistent, and particularly erroneous about indirect (multi-hop) effects. WIQA aims to improve this state of affairs, offering a new challenge and resource to the community. The dataset is available at http://data.allenai.org/wiqa/.

Appendix A: Topicwise consistency

We study trends in topic-wise accuracy of models as they read more context information. Bert no-para model does not have access to any context or paragraph, except the language model's background knowledge from Wikipedia. By reading the paragraph context Bert with-para model performs much better on certain topics such as `Pollination, blood, mountain, evaporation` but the impact of reading is much less on topics such as `Igneous rocks, plant crops, solar eclipse, DNA replication`. Topics such as `blood` are very popular on Wikipedia and distributed across several very different articles. These topics are harder for BERT as it requires additional paragraph context to understand the question.

topic	BERT (no para)	BERT
igneous rock	0.66	0.64
plant crops	0.61	0.61
solar eclipse	0.43	0.43
frog	0.59	0.62
DNA replication	0.58	0.63
water cycle	0.63	0.69
fish	0.5	0.57
pumpkin	0.61	0.69
pollination	0.62	0.75
blood	0.62	0.76
mountain	0.57	0.72
evaporation	0.42	0.67

Table 3: As the Bert model (that has access to the paragraph in context) reads more paragraphs in context, its accuracy is better. Reading helps certain topics such as `Pollination, blood, mountain, evaporation` more than others

Appendix B: Crowdsourcing Influence Graphs

We crowdsource influence graphs by getting the graphs constructed progressively, with the help of five questions stated in Figure 7. At first, the turkers see an empty graph in Figure 5.

When the annotators answer the first question (shown in Fig. 7), two nodes of the partial influence graph are filled (depicted in Fig. 6).

Once all the questions are answered, the influence graph will be ready. During the process of annotation, there are appropriate validations for quality control.

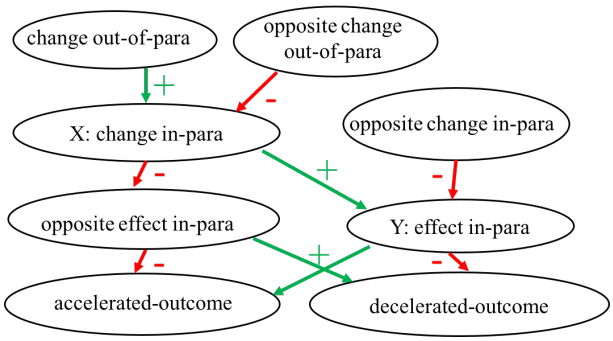

Figure 5: At the start of the process to annotate an influence graph for a given paragraph, the annotators see a blank influence graph with the basic structure.

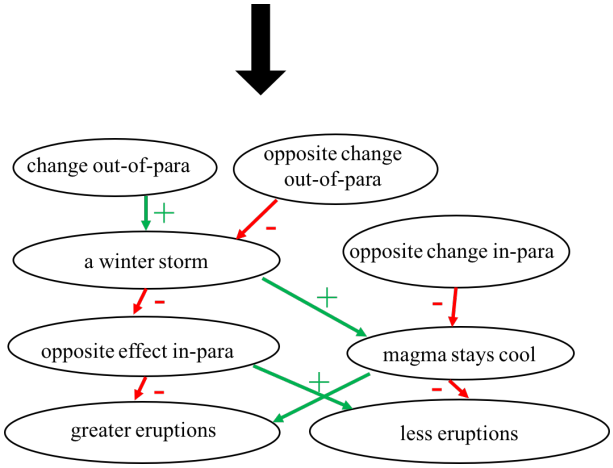

Figure 6: As the annotators answer questions in Fig. 7, a partial influence graph emerges. As they answer questions, the annotators found it useful to validate their answers by examining the emerged influence graph.

Appendix C: Sample Influence Graphs

To get an impression of our crowdsourced influence graph repository, we display four paragraphs (not hand picked) in Figures 8, 9, 10, 11. These range from natural process, to human body process and mechanical process.

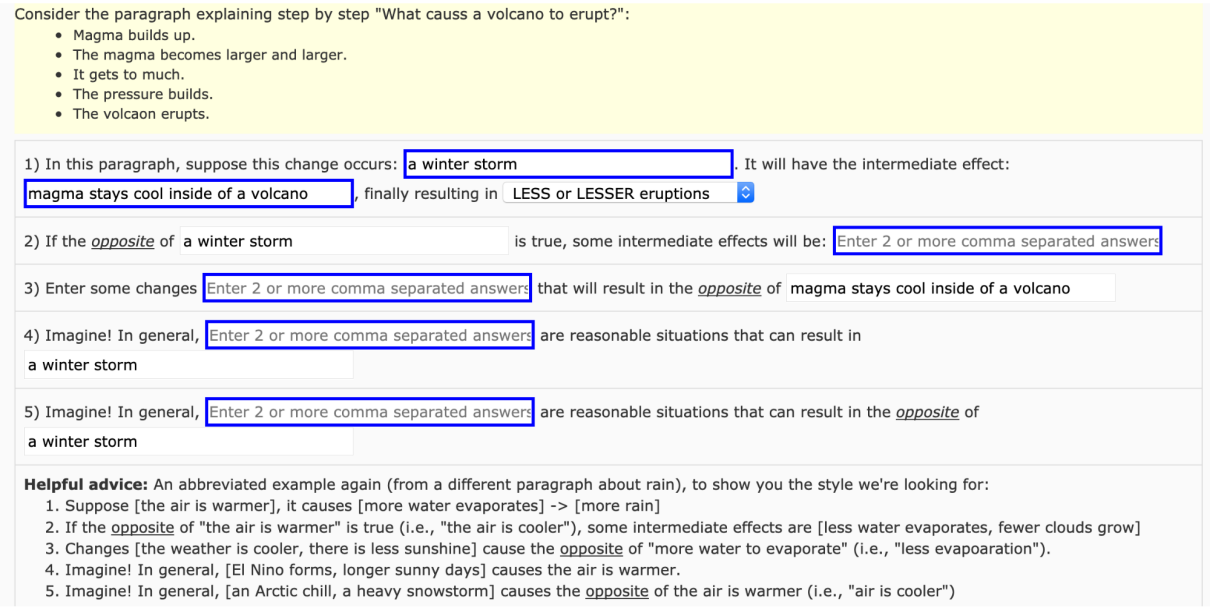

Figure 7: The interface shown to the annotators on Mechanical turk platform. Given a paragraph in yellow background, the annotators answer the five questions and an influence graph emerges from their answers.

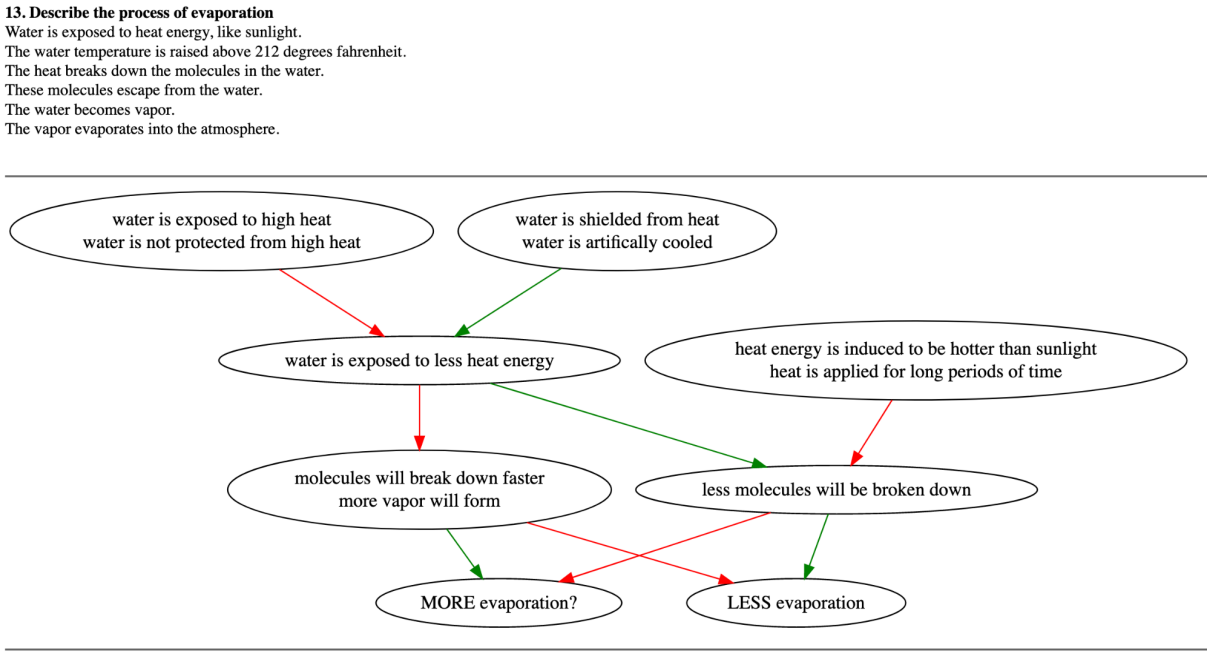

Figure 8: Influence graph for a paragraph from the topic `evaporation`

Evaluating BERT for natural language inference: A case study on the CommitmentBank

Nanjiang Jiang and **Marie-Catherine de Marneffe**
Department of Linguistics
The Ohio State University
{jiang.1879, demarneffe.1}@osu.edu

Abstract

Natural language inference (NLI) datasets (e.g., MultiNLI) were collected by soliciting hypotheses for a given premise from annotators. Such data collection led to annotation artifacts: systems can identify the premise-hypothesis relationship without observing the premise (e.g., negation in hypothesis being indicative of contradiction). We address this problem by recasting the CommitmentBank for NLI, which contains items involving reasoning over the extent to which a speaker is committed to complements of clause-embedding verbs under entailment-canceling environments (conditional, negation, modal and question). Instead of being constructed to stand in certain relationships with the premise, hypotheses in the recast CommitmentBank are the complements of the clause-embedding verb in each premise, leading to no annotation artifacts in the hypothesis. A state-of-the-art BERT-based model performs well on the CommitmentBank with 85% F1. However analysis of model behavior shows that the BERT models still do not capture the full complexity of pragmatic reasoning, nor encode some of the linguistic generalizations, highlighting room for improvement.

1 Introduction

Natural language inference (NLI), the task of identifying whether a hypothesis can be inferred from, contradicted by, or not related to a premise, has become one of the standard benchmark tasks for natural language understanding. NLI datasets, such as SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018), are typically built by asking annotators to compose sentences based on premises extracted from corpora, so that the composed sentences stand in entailment/contradiction/neutral relationship to the premise. The hypotheses collected this way have been found to contain annotation artifacts – clues allowing systems to identify the relationship between a premise and a hypothesis without observing the premise. For instance, Gururangan et al. (2018) found that in SNLI and MultiNLI, negation is highly indicative of contradiction and generic nouns (e.g., *animal, something*) of entailment.

Premise: A: Boy that's scary, isn't it. B: Oh, can you imagine, because it happens in the middle of the night, so you know, these parents didn't know the kid was gone until the kid is knocking on the door screaming, let me in. *Hypothesis:* the kid was gone.	`Entailment (1.92)`
Premise: "Clever". Klug means "clever". Would you say that Abie was clever? *Hypothesis:* Abie was clever.	`Neutral (0)`
Premise: GM confirmed it received U.S. antitrust clearance to boost its holding. Sansui Electric agreed to sell a 51% stake to Polly Peck of Britain for $110 million. Still, analysts said the accord doesn't suggest Japan is opening up to more foreign takeovers. *Hypothesis:* Japan is opening up to more foreign takeovers.	`Contradiction (-1.2)`

Table 1: Examples from the CommitmentBank, with NLI class and original annotation mean.

To address this issue, we recast the CommitmentBank (CB henceforth) (de Marneffe et al., 2019), an English dataset of speaker commitment/event factuality, for NLI.[1] The original CommitmentBank includes naturally occurring discourses annotated with speaker commitment towards the content of complements of clause-embedding verbs under entailment-canceling environments (negation, modal, question and conditional). CB does not suffer from the drawback of annotation artifacts in the hypotheses, since the hypotheses are the complement of a clause-embedding verb in the premise. It thus tests for

[1]The recast CommitmentBank is part of the SuperGLUE benchmark (Wang et al., 2019a), at `https://super.gluebenchmark.com`.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6086–6091,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

inferences involving a particular kind of syntactic construction and contains no annotation artifacts in the hypothesis, making it suitable to test for robust language understanding.

CB has many challenging aspects which are highlighted in various adversarial NLI datasets. It can be thought of as a variant of HANS (McCoy et al., 2019), which contains examples where the hypothesis is a subsequence or a constituent of the premise. It contains several phenomena in the "stress tests" (Naik et al., 2018) including word overlap, negation, and length mismatch. However these datasets are artificially constructed while CB data are naturally occurring.

Here we evaluate BERT, the state-of-the-art model in NLI, on CB. While BERT models achieve good performance with supervision from both CB and MultiNLI, they still struggle with items involving pragmatic reasoning and lag behind human performance. Experiments show that BERT does not use the linguistic generalizations for speaker commitment to make predictions, although BERT can learn them with direct supervision. CB is thus a useful benchmark for measuring progress on robust natural language understanding and specifically speaker commitment inferences.

2 The CommitmentBank

To study the linguistic correlates of speaker commitment in English, de Marneffe et al. (2019) introduced the CommitmentBank dataset.[2] It consists of naturally occurring English items with up to two sentences of preceding context and one target sentence, from three genres: newswire (Wall Street Journal), fiction (British National Corpus), and dialogue (Switchboard). The target sentences contain a clause-embedding verb (such as *think*) in an entailment-canceling environment (negation, modal, question, or conditional). Each item has at least 8 annotations indicating the extent to which the speaker of the sentences are committed to the truth of the embedded clause ($+3$/speaker is certain that it is true, 0/speaker is not certain about its truth, -3/speaker is certain that it is false).

2.1 Recast for NLI

For each item, we take the context and target sentence to be the premise, and the embedded clause in the target sentence to be the hypothesis.

[2]The original CommitmentBank is available at https://github.com/mcdm/CommitmentBank

	Entailment	Neutral	Contradiction	Total
Train	115	16	119	250
Dev	23	5	28	56
Test	113	16	121	250
Total	251	37	268	556

Table 2: Number of items with each gold label in each split. Split are from Wang et al. (2019a).

We identified a subset of the CommitmentBank with high annotator agreement, and assigned categorical labels (entailment/neutral/contradiction) to them according to their mean annotations in $[-3, 3]$. We label an item as entailment if at least 80% of its annotations are within $[1, 3]$, where the speaker is committed to the complement p, as neutral if within $[0]$, where the speaker is uncommitted toward p, as contradiction if within $[-3, -1]$ where the speaker is committed to $\neg p$. We discard the item if less than 80% of the annotations are within one of the three sub-ranges. Table 1 contains examples from CB with the original mean annotation and the gold NLI label. The number of items in each class is in Table 2.

2.2 Possible Annotation Artifacts

Since the hypotheses in CB are extracted from the premises instead of generated by annotators, we expect CB to contain less annotation artifacts compared to SNLI or MultiNLI.

Length Gururangan et al. (2018) found that entailed hypotheses in SNLI tend to be shorter and neutral ones longer.[3] The hypothesis length in the CB train set is distributed evenly across the three classes (mean length 8.5 tokens for entailment, 6.6 for neutral and 7.3 for contradiction).

Lexical Features Following Gururangan et al. (2018), we computed the PMI between each unigram/4-gram and class in the training set,[4] capturing the extent to which an expression is associated with each class. Table 3 gives the five unigrams and 4-grams with the highest PMI values. For hypotheses, there don't seem to be any discriminating expressions. In particular, negation words are not features for contradiction, in contrast to SNLI and MultiNLI. For premises, we find some expressions that are strongly associated with

[3]In SNLI, about half of the entailed hypotheses have token length less than 5, while a similar portion of the neutral hypothesis have length under 12 tokens.

[4]We applied add-one smoothing to the raw counts.

Hypothesis					
Entailment		Neutral		Contradiction	
Mr	C ##rois ##set by	pretty	the cat was well	really	' s going to
been	the language was peeled	cat	at any given moment	people	a de ##ter ##rent
.	language was peeled down	moment	any given moment a	can	de ##ter ##rent to
had	no women are allowed	response	given moment a response	go	is going to be
-	women are allowed to	ban	moment a response of	parents	it was too long
Premise					
Entailment		Neutral		Contradiction	
g	might have known that	clever	Do you think that	mean	. B : I
herself	. You could say	Nicky	. Do you think	five	don ' t think
perhaps	Mr . An ##tar	pressure	you know , what	care	B : Uh ,
wrong	. An ##tar '	Base	' ' I hope	guy	: I don '
notice	An ##tar ' s	radio	' I hope you	jury	, I mean ,

Table 3: Unigrams and 4-grams with top 5 PMI with each class for the hypotheses and premises. We used the BERT cased tokenizer, which marks split word pieces with ##. The 4-grams in the hypotheses listed here share the same PMI values with many other 4-grams in the same class (745 for entailment, 60 for neutral, 6 for contradiction).

a particular class. But most of these expressions align with linguistic generalizations about these particular constructions, as elaborated on below.

Entailment The most discriminating expressions for the entailment premises include modal operators *perhaps*, *could* and *might*. This is because 63 out of the 115 entailment items in the train set involve the modal environment. Factive verbs *notice* and *know* are also discriminating features of entailment, indicating that factive verbs tend to suggest the truths of their complement (Karttunen, 1971).

Neutral The most discriminating expressions for the neutral class include questions: *Do you think*. This is due to the fact that 10 out of 16 neutral items are under the question environment.

Contradiction For contradiction, the most discriminating expressions involve neg-raising constructions (*I don't think/know/believe that p*, where the speaker is committed to *p* being false), filler phrases *Uh* and *I mean*, and indicator of speakers in dialogues *B:*. These are all characteristic of the Switchboard genre, which makes up 80% of the contradictions in the training set.

3 Predicting NLI labels

We evaluate BERT, the state-of-the-art model for NLI, on CB.[5] The BERT model follows the standard practice for sentence-pair tasks as in Devlin et al. (2019). We concatenate the premise and the hypothesis with `[SEP]`, prepend the sequence with `[CLS]`, and feed the input to BERT. The representation for `[CLS]` is fed into a softmax layer for a three-way classification.

For all experiments, we used the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 1e-5, a batch size of 8, and fine-tuned with at most 10 epochs on each dataset. We fine-tuned BERT with three different sets of training data: CB only (CB^B), MultiNLI only (MNLI^B), and MultiNLI first then CB (MNLI+CB^B).[6] For comparison, we also included the models' performance on the MultiNLI dev set.

Baselines We included two baselines: a bag-of-words baseline (CBOW) in which each item is represented as the average of its tokens' GloVe (Pennington et al., 2014) vectors; a Heuristics baseline, only applicable to the CB dataset, which uses five rules based on the observations in Section 2.2: 1. items under modals are entailments, 2. neg-raising items of the form *I don't think/know/believe* are contradictions, 3. items with factive verbs are entailments, 4. items under negation are contradictions, 5. all other items are neutral.

Human Performance We included human performance on CB from Wang et al. (2019a) obtained by asking crowdworkers to re-annotate a part of the test set. The MultiNLI human performance accuracy is for the matched/mismatched test set from Nangia and Bowman (2019).

Results Table 4 shows the results. CBOW does not perform well on either datasets. On the CB

[5] We used `jiant` (Wang et al., 2019b) with the `bert_large_cased` model for all our experiments.

[6] Superscript ^{B} denotes BERT model tuned on the corresponding dataset to distinguish them from the actual datasets.

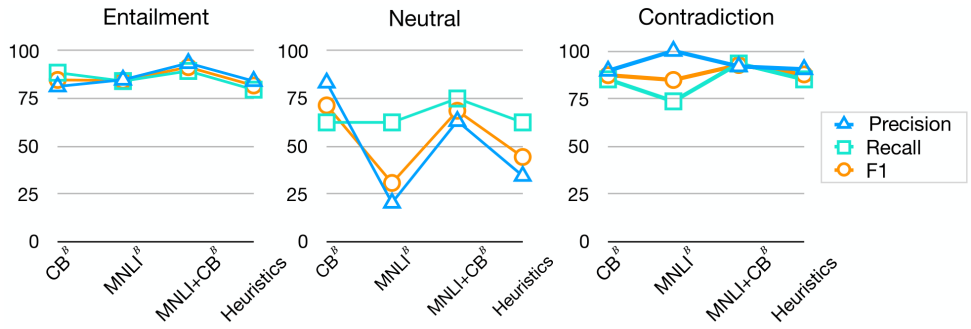

Figure 1: Precision, recall and F1 of each class on the CB test set for three BERT variants and Heuristics.

	CB		MultiNLI	
	Acc.	F1	Acc.	F1
CBOW	69.2	47.6	71.2	71.2
MNLI^B	77.6	66.7	**83.6**	**83.6**
Heuristics	81.2	71.3	-	-
CB^B	85.2	81.2	41.1	30.6
MNLI+CB^B	**91.2**	**85.3**	72.3	74.4
Human	98.9	95.8	92.0/92.8	-

Table 4: Performance on the CB test set and the MultiNLI dev set.

data, the heuristics based on linguistic generalizations is a strong baseline, performing better than MNLI^B. We gain a lot of performance with supervision from CB only (CB^B), which aligns with McCoy et al.'s observation that BERT performs very well when trained with in-domain data. The best results are obtained by MNLI+CB^B on CB and by MNLI^B on MultiNLI, but still lag behind human performance. While MNLI+CB^B gives the best performance on CB, it does not perform well on MultiNLI. This is in line with Liu et al. (2019) who found that fine-tuning on datasets that test for a specific linguistic phenomenon decrease the performance on the original dataset.

4 Analysis

Figure 1 shows the precision, recall and F1 scores of each class on the CB test set for the three BERT variants and the Heuristics baseline. Heuristics performs similarly as CB^B on all classes. Compared with CB^B, MNLI+CB^B improves the overall performance of contradiction and the recall of neutral. MNLI^B identifies contradictions with perfect precision but poor recall. All models do poorly on the neutral class, which has very few items in the dataset and no clear linguistic generalizations.

Correct label with Heuristics?	Yes (203)	No (47)
CB^B	88.7	55.8
MNLI^B	68.9	55.7
MNLI+CB^B	89.4	68.5

Table 5: F1 scores of the three BERT models on the CB test set divided by whether Heuristics predicts the correct label (size of each subset in parentheses).

Linguistic Generalizations and Beyond 80% of the predictions of both CB^B and MNLI+CB^B are the same as the predictions of the Heuristics baseline, while it drops to 69.6% for MNLI^B. We divided the test set by whether Heuristics predicts the correct label. Table 5 reports the models' F1 scores on the two subsets. CB^B and MNLI+CB^B performances on the Yes-items are similar and both outperforming MNLI^B (statistically significant improvements, McNemar's test, $p < 0.01$). There is no statistical difference between the models' performance for the No-items. There is thus a performance gap between items requiring more pragmatic reasoning in general (No-items) and items which can be correctly predicted by identifying certain structures (Yes-items), suggesting that there is still work to achieve robust language understanding. Table 6 shows some items on which MNLI+CB^B still fails.

Feature Probing To investigate whether BERT actually learns the linguistic features from the Heuristics baseline and uses them to make NLI predictions, we trained two probing models to predict 1. whether the clause-embedding verb is factive and 2. the type of entailment-canceling environment. Following Tenney et al. (2019), we take the weighted sum of BERT layers (fine-tuned for NLI) to produce a pooled representation for each token. Unlike Tenney et al. (2019), in which the

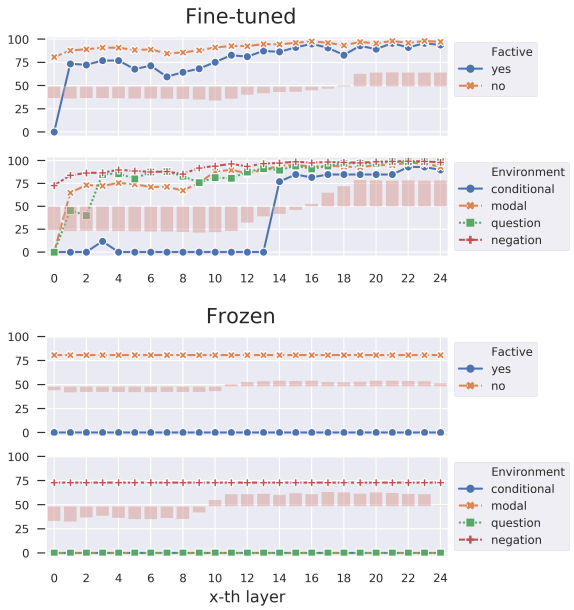

Figure 2: Results on the two probing tasks using parameters from MNLI+CB^B. Lineplots show model's F1 scores when using encoding layers up to the x-th layer. Barplots show the scalar mixing weights.

representations for the word tokens are used, we take the representation of the `[CLS]` token for each item and fed it into a MLP classifier to predict whether the discourse has certain features. We extracted the trained scalar mixing weights to see the importance of the different layers. For each layer k, we trained a series of classifiers using all previous layers up to k, to measure at which layer the feature can be correctly predicted.[7]

We did the above experiments in two settings: 1. fine-tune all BERT layers to learn the feature-specific representations, and 2. freeze BERT layers tuned for NLI and only train the probing classifier. The results are shown in Figure 2.

When fine-tuning BERT layers for each feature task, we see that performance increases as more layers are added. Factives, conditionals, and modals are correctly predicted at later layers than nonfactives and negation. For conditionals and modals, this might be due to the fact that they are rare in the dataset. Factives possibly require more contextual information in order to be learned: the scalar weights indicate that factivity is processed at higher layers than entailment-canceling environment. This is consistent with the language acquisition literature (Hacquard and Lidz, 2019) which suggests that rich syntactic/pragmatic information is required to learn the semantics of factive verbs.

However, when we freeze the BERT parameters from MNLI+CB^B, the models always give the highest probability to negation environment and nonfactive verb, resulting in zero F1s on every other feature. The scalar mixing weights are smaller than the weights from the fine-tuned model. This suggests that, although BERT can learn these features with direct supervision, training BERT for NLI does not result in representations that encode these features: the model relies on other statistical clues to make decisions.

[7] The code and data are available at https://github.com/njjiang/jiant/tree/cb_emnlp19.

Premise: B: Yeah, it's called VCX or something like that. Also called Delta Clipper, which is a decent name for something like that. A: Wow. Well, I don't know. you think you'd, uh, go up in space if you had a chance? *Hypothesis:* speaker B would go up in space if he had a chance H: `neutral` B: `contradiction` Gold: `neutral`
Premise: Those people... Not a one of them realized I was not human. They looked at me and they pretend I'm someone called Franz Kafka. Maybe they really thought I was Franz Kafka. *Hypothesis:* he was Franz Kafka H & B: `entailment` Gold: `contradiction`

Table 6: Items in the test set with predictions the by Heuristics baseline (H) and MNLI+CB^B (B). The first one is correctly predicted by Heuristics, while the second one is not.

5 Conclusion

We introduce CB as a dataset for NLI, and show that it does not contain annotation artifacts in the hypotheses in contrast to previous NLI datasets. Our evaluation shows that despite the high F1 scores, BERT models have systematic error patterns, suggesting that they still do not capture the full complexity of human pragmatic reasoning. There is much room for improvement, and the CB dataset will be a useful testbed to assess models' progress on such reasoning.

Abstract

Recently, biomedical version of embeddings obtained from language models such as BioELMo have shown state-of-the-art results for the textual inference task in the medical domain. In this paper, we explore how to incorporate structured domain knowledge, available in the form of a knowledge graph (UMLS), for the Medical NLI task. Specifically, we experiment with fusing embeddings obtained from knowledge graph with the state-of-the-art approaches for NLI task, which mainly rely on contextual word embeddings. We also experiment with fusing the domain-specific sentiment information for the task. Experiments conducted on MedNLI dataset clearly show that this strategy improves the baseline BioELMo architecture for the Medical NLI task[1].

1 Introduction

Natural language inference (NLI) is one of the basic natural language understanding tasks which deals with detecting inferential relationship such as entailment or contradiction, between a given premise and a hypothesis. In recent years, with the availability of large annotated datasets like SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), researchers have come up with several neural network based models which could be trained with these large annotated datasets and are able to produce state-of-the-art performances (Bowman et al., 2015, 2016; Munkhdalai and Yu, 2017; Sha et al., 2016; Chen et al., 2017; Tay et al., 2018). With these attempts, even though NLI in domains like fiction, travel etc. has progressed a lot, NLI in medical domain is yet to be explored extensively. With the introduction of MedNLI (Romanov and Shivade, 2018), an expert annotated dataset for NLI in the clinical domain, researchers have started pursuing the problem of clinical NLI. Modeling informal inference is one of the basic tasks towards achieving natural language understanding, and is considered very challenging. MedNLI is a dataset that assists in assessing how good a sentence or word embedding method is for downstream uses in medical domain.

Recently, with the emergence of advanced contextual word embedding methods like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), performances of many NLP tasks have improved, setting state-of-the-art performances. Following this stream of literature, Lee et al. (2019) introduce BioBERT, which is a BERT model pretrained on English Wikipedia, BooksCorpus and fine-tuned on PubMed (7.8B tokens in total) corpus, PMC full-text articles. Jin et al. (2019) propose BioELMo which is a domain-specific version of ELMo trained on 10M PubMed abstracts, and attempt to solve medical NLI problem with these domain specific embeddings, leading to state-of-the-art performance. These two attempts show a direction towards solving medical NLI problem where the pretrained embeddings are fine-tuned on medical corpus and are used in the state-of-the-art NLI architecture.

Chen et al. (2018) proposed the use of external knowledge to help enrich neural-network based NLI models by applying Knowledge-enriched co-attention, Local inference collection with Exter-

[*] equal contribution

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6092–6097, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

nal Knowledge, and Knowledge-enchanced inference composition components. Another line of solution tries to bring in the extra domain knowledge from sources like Unified Medical Language System (UMLS) (Bodenreider, 2004). Romanov and Shivade (2018) used the knowledge-directed attention based methods in (Chen et al., 2018) for Medical NLI. Another such attempt is made by Lu et al. (2019), where they incorporate domain knowledge in terms of the definitions of medical concepts from UMLS with the state-of-the-art NLI model ESIM (Chen et al., 2017) and vanilla word embeddings of Glove (Pennington et al., 2014) and fastText (Bojanowski et al., 2017). Even though, the authors achieve significant improvement by incorporating only concept definitions from UMLS, the features of this clinical knowledge graph are yet to be fully utilized. Motivated by the emerging trend of embedding knowledge graphs to encode useful information in a high dimensional vector space, we propose the idea of applying state-of-the-art knowledge graph embedding algorithm on UMLS and use these embeddings as a representative of additional domain knowledge with the state-of-the-art medical NLI models like BioELMo, to investigate the performance improvement on this task. Additionally, we also incorporate the sentiment information for medical concepts given by MetaMap (Aronson and Lang, 2010) leading to further improvement of the performance. Note that, as state-of-the-art baselines, we use the models proposed by Jin et al. (2019) and Lu et al. (2019). Since, both of these studies consider ESIM as the core NLI model which makes it more convenient for us to incorporate extra domain knowledge and to have a fair performance comparison with these state-of-the-art models. Our contributions are two-fold.

- We incorporate domain knowledge via knowledge graph embeddings applied on UMLS. We propose an intelligent path-way to combine contextual word embeddings with the domain specific embeddings learnt from the knowledge graph, and feed them to the state-of-the-art NLI models like ESIM. This helps to improve the performance of the base architecture.

- We further show the usefulness of the associated sentiments per medical concept from UMLS in boosting the performance further, which in a way shows that if we can carefully use the domain knowledge present in sources like UMLS, it can lead to promising results as far as the medical NLI task is concerned.

2 Dataset

In this study, we use the MedNLI dataset (Romanov and Shivade, 2018), a well-accepted dataset for natural language inference in clinical domain. The dataset is sampled from doctors' notes in the clinical dataset MIMIC-III (Alistair EW Johnson and Mark., 2016) and is arguably the largest publicly available database of patient records. The entire dataset consists of 14,049 premise-hypothesis pairs divided into 11,232 train pairs, 1,395 validation pairs and 1,422 test pairs. Each such pair consists of a gold label which could be either entailment (true), contradiction (false), or neutral (undetermined). The average (maximum) sentence lengths of premises and hypotheses are 20 (202) and 5.8 (20), respectively.

3 Proposed Approach

The task is to classify the given premise (p) and hypothesis (h) sentence pair into one of the three classes: entailment, contradiction and neutral. Following the approach by Jin et al. (2019), we use the BioELMo embedding model where authors bring in contextual information in terms of embeddings obtained via applying ELMo trained on 10M PubMed abstracts, and use these with the state-of-the-art ESIM model (Chen et al., 2017) for the NLI task. The architecture includes two sentence encoders each of which takes in as input the word embeddings of p and h. The inputs are run through corresponding bi-directional LSTM encoder layers. Pairwise attention matrix is computed between encoded p and h, which forms the attention layer followed by a second bi-directional LSTM layer run separately over p and h. Max and average pooling are performed over the outputs of LSTM layers and the output of pooling operations is run through a softmax model. We feed this architecture an additional domain knowledge from UMLS as vector representations obtained via knowledge graph embeddings, the details of which are described below.

UMLS: Unified Medical Language System (UMLS) is a compendium which includes many health and biomedical vocabularies and standards. It provides a mapping structure between these

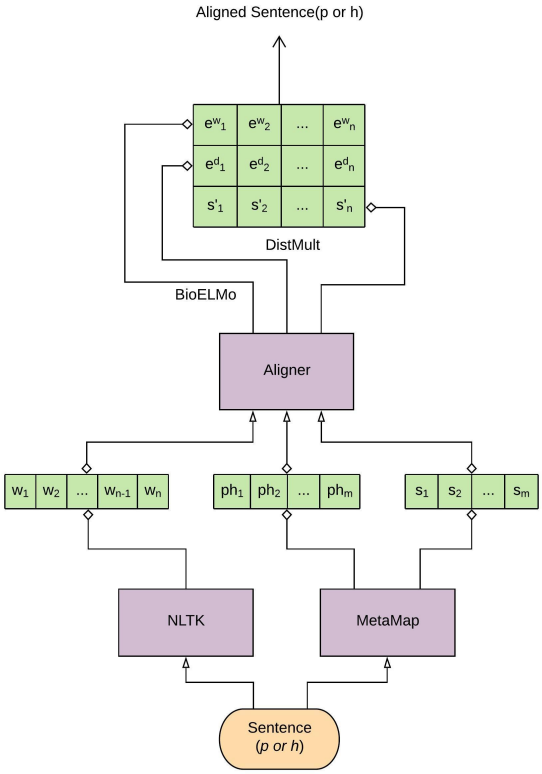

Figure 1: **BioELMo w/ KG pipeline** Here w is the NLTK tokenized form of premise (p) or hypothesis (h), ph is the MetaMap tokenized form of sentence (p or h). s signifies the sentiment vector. e^w and e^d signify the aligned word embeddings and DistMult embeddings, respectively. s' signifies the aligned sentiment vector.

vocabularies and is a comprehensive thesaurus and ontology of biomedical concepts. UMLS contains 3 knowledge sources: Metathesaurus, Semantic Network, and Specialist Lexicon and Lexical Tools. We use two of these sources: the Metathesaurus and the Semantic Network. The Metathesaurus comprises of over 1 million biomedical concepts and 5 million concept names. Each concept has numerous relationships with each other. Each concept in the Metathesaurus is assigned one or more Semantic Type linked to other Semantic Types through a semantic relationship. This information is provided in the Semantic Network of UMLS. There are 127 semantic types and 54 relationships in total. Semantic types include "disease", "symptom", "laboratory test" and semantic relationships include "is-a", "part-of", "affects".

MetaMap: MetaMap is a tool for effective entity mapping of biomedical text to the concepts and

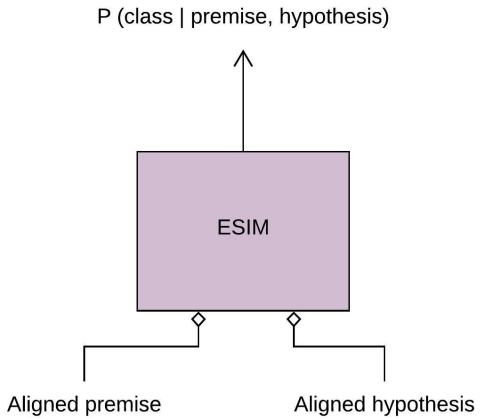

Figure 2: Aligned premise and hypothesis embeddings are obtained using the method described in Figure 1 and become inputs to the ESIM model.

semantic type in UMLS Metathesaurus. On feeding a sentence to MetaMap, it divides the sentence into phrases based on medical concepts found in the sentence and for each medical concept it provides its unique ID in Metathesaurus, its position in the sentence, the list of semantic types the concept is mapped to, the preferred medical name and unique ID for the preferred concept (such as a concept called "chest pain" would be mapped to its preferred medical term "angina"). We also get a boolean value associated with each concept denoting whether the medical concept occurs in a negative sentiment (1) or not (0). For example, in the sentence, "The patient showed no signs of pain", the medical concept 'pain' would appear with a negative sentiment. Note that, for each extracted phrase, there may be more than one related medical concepts and each concept may have more than one possible mapping. For our study, we only consider the mapping with the highest MetaMap Indexing (MMI) score, a metric provided by MetaMap. As a result, every word in a sentence has zero or one corresponding medical concept.

Constructing the appropriate knowledge graph: We use the MetaMap tool to process the complete MedNLI dataset and extract the relevant information from UMLS into a smaller knowledge graph.

First, we use MetaMap to extract medical concepts from p and h, and map them to the standard terminology in UMLS. We choose to map each medical concept to its preferred medical term.

E.g., "blood clots" would map to "thrombus". This helps us to map different synonymous surface forms to the same concept. This results in 7,496 unique medical concepts from UMLS matched to various words and phrases in the MedNLI dataset. Each unique concept in UMLS becomes a node in our knowledge graph. The relations in our knowledge graph come from two sources: The Metathesaurus and the Semantic Network of UMLS.

Using relations extracted from these two sources, we connect the filtered medical concepts from UMLS to build a smaller Knowledge Graph (subgraph of UMLS).

We get 117,467 triples from the Metathesaurus and 23,824,105 triples from the Semantic Network, which constitute the edgelists in the prepared knowledge graph.

Knolwedge Graph Embeddings: To obtain the embedding from this graph, we use state-of-the-art DistMult model (Bishan Yang and Deng, 2015). The choice is inspired by Kadlec et al. (2017), which reports that an appropriately tuned DistMult model can produce similar or better performance while compared with the competing knowledge graph embedding models. DistMult model embeds entities (nodes) and relations (edges) as vectors. It uses a matrix dot product to measure compatibility between head (h) and tail (t) entities, connected by a relation (r). Logistic loss is used for training the model.

$$\sigma_{DistMult}(h, r, t) = r^T(h \cdot t) \quad (1)$$

Combining Knolwedge Graph Embeddings with BioELMo: As explained in Figure 1, each sentence (p or h) is tokenized using the simple module of NLTK[2] as well as processed using MetaMap to get UMLS concepts. To align these, we copy the UMLS concept for a phrase to all the constituent words.

Once we have aligned the tokens obtained via NLTK and MetaMap, we apply BioELMo and DistMult to get the embedding vectors, $e_{BioELMo,w}$ and $e_{DistMult,w}$ for each word w. We concatenate these vectors as $e_w = e_{BioELMo,w} \oplus e_{DistMult,w}$, to obtain the word representation for w. We call the proposed model which uses these embeddings as *BioELMo w/ KG*.

Combining Sentiment Information: We further enhance the domain knowledge by incorporating sentiment information for a concept separately. For that purpose, we use the sentiment boolean provided by MetaMap and create a 1-d vector $(sent_w)$ containing 0 for positive medical concepts or non-medical concept and 1 for negative concept. This 1-d vector is aligned with the $e_{DistMult,w}$ in the same fashion as explained above. We concatenate this single dimension with our concatenated resultant embeddings. Thus $e_w = e_{BioELMo,w} \oplus e_{DistMult,w} \oplus sent_w$. We call the proposed model which uses these embeddings as *BioELMo w/ KG + Sentiment*.

We use the vanilla ESIM model (Chen et al., 2017) and feed the obtained concatenated embeddings for each word in the premise and hypothesis to the model, to be trained for the inference task (see Figure 2).

Model	Accuracy
fastText	68.7%
GloVe	73.1%
$BioELMo$ (Jin et al., 2019)	78.2%
$ESIMw/K$ (Lu et al., 2019)	77.8%
fastText w/ KG+Sentiment	73.67%
GloVe w/ KG+Sentiment	74.46%
BioELMo w/ KG	78.76%
BioELMo w/ KG+Sentiment	**79.04%**

Table 1: Performance of our models (bottom four) along with the state-of-the-art baseline models (top four). Baseline results for fastText, GloVe are obtained from Romanov and Shivade (2018). Adding knowledge graph information to the base models showed an absolute improvement of 4.97% in case of fastText and 1.36% in case of GloVe. The baseline model utilizing BioELMo as base embeddings (Jin et al., 2019) showed an accuracy of 78.2%. On adding knowledge graph information, we were able to improve these results to 78.76% and on further addition of sentiment information, the accuracy rose to 79.04%

4 Experimental Results and Analysis

As discussed earlier, we mainly consider the models presented by Jin et al. (2019) [$BioELMo$] and Lu et al. (2019) [$ESIMw/K$] as our baselines. We report accuracy as the performance metric. Table 1 represents the performance comparison of our proposed models and the baselines, which shows that incorporation of knowledge graph embeddings helps to improve the model performance. All the results reported use ESIM as their base model. Further, incorporating sentiment of medical concepts gives further improvements,

[2] https://www.nltk.org/

achieving an overall 1% improvement over the baseline model.

We also see from (Jin et al., 2019) that BERT and BioBERT show an accuracy of 77.8% and 81.7%, respectively. However, they also showcase through a probing task that BioELMo is a better feature extractor than BioBERT, even though the latter has higher performance when fine tuned on MedNLI. Due to this reason, we take BioELMo as our base architecture and use our enhancements over BioELMo instead of BioBERT.

We also experimented with using fastText and GloVe as our base general embeddings. With addition of Knowledge Graph embeddings and sentiment information, the results showed an absolute improvement from 68.7% to 73.67% in case of fastText, and 73.1% to 74.46% in case of GloVe. All results are summarized in Table 1.

Training Details: For *DistMult*, we use word embeddings dimensions to be 100. SGD was used for optimization with an initial learning rate of 10^{-4}. The batch size was set to 100. For *ESIM*, we take the dimension of hidden states of BiLSTMs to be 500. We set the dropout to 0.5 and choose an initial learning rate of 10^{-3}. We choose a batch size of 32 and run for a maximum of 64 epochs. The training is stopped when the development loss does not decrease after 5 subsequent epochs.

Qualitative Analysis: We explain the efficacy of our model with the help of a few examples. Consider the sentence pair, p: "History of CVA" and h: "patient has history of stroke". In medical terms, 'CVA' means 'Cerebrovascular accident' which is another term for 'stroke'. By Using MetaMap, we are able to find that the preferred term for 'stroke' is 'Cerebrovascular accident' and hence our model classified the sample pair correctly as entailment.

In many cases, our baseline models fail to capture negative sentiment present in the premise or hypothesis. For example, in case of p: Watermelon stomach with gastric varices, without bleed in more than 2 years, h: Patient has no active bleeding, BioELMo predicts this as contradiction, whereas the gold label is entailment. But, by using the negative sentiment, captured by Metamap, for the word 'bleed' in both premise and hypothesis, our model is able predict the label correctly.

On the other hand, even though our model produces promising improvement over state-of-the-art performance, there are cases for which our model is not able to classify correctly. For the sentence pair p: "She was speaking normally at that time" and h: "The patient has no known normal time where she was speaking normally." contradicting each other, our model predicts this to be entailment. The probable reason could be that, the negative sentiment associated with "speaking normally" is not captured by MetaMap and the noise in MetaMap is percolated further. In another example case, p: "He had no EKG changes and first set of enzymes were negative." and h: "the patient has negative enzymes." our model classifies this pair as entailment while the gold label is neutral. While the premise says that the first set of enzymes was negative, it gives no information about the current state. This leads us to believe that a sense of timeline is extremely important for examples like this which is not already being captured by our model. Taking care of these cases would be our immediate future work.

5 Conclusion

In this paper, we showed that knowledge graph embeddings obtained through applying state-of-the-art model like DistMult from UMLS could be a promising way towards incorporating domain knowledge leading to improved state-of-the-art performance for the medical NLI task. We further showed that sentiments of medical concepts can contribute to medical NLI task as well, opening a new direction to be explored further. With the emergence of knowledge graphs in different domains, the proposed approach can be tried out in other domains as well for future exploration.

Abstract

For machine translation, a vast majority of language pairs in the world are considered low-resource because they have little parallel data available. Besides the technical challenges of learning with limited supervision, it is difficult to *evaluate* methods trained on low-resource language pairs because of the lack of freely and publicly available benchmarks. In this work, we introduce the FLORES evaluation datasets for Nepali–English and Sinhala–English, based on sentences translated from Wikipedia. Compared to English, these are languages with very different morphology and syntax, for which little out-of-domain parallel data is available and for which relatively large amounts of monolingual data are freely available. We describe our process to collect and cross-check the quality of translations, and we report baseline performance using several learning settings: fully supervised, weakly supervised, semi-supervised, and fully unsupervised. Our experiments demonstrate that current state-of-the-art methods perform rather poorly on this benchmark, posing a challenge to the research community working on low-resource MT. Data and code to reproduce our experiments are available at https://github.com/facebookresearch/flores.

1 Introduction

Research in Machine Translation (MT) has seen significant advances in recent years thanks to improvements in modeling, and in particular neural models (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2016; Vaswani et al., 2017), as well as the availability of large parallel corpora for training (Tiedemann, 2012; Smith et al., 2013; Bojar et al., 2017). Indeed, modern neural MT systems can achieve near human-level translation performance on language pairs for which sufficient parallel training resources exist (e.g., Chinese–English translation (Hassan et al., 2018) and English–French translation (Gehring et al., 2016; Ott et al., 2018a).

Unfortunately, MT systems, and in particular neural models, perform poorly on *low-resource* language pairs, for which parallel training data is scarce (Koehn and Knowles, 2017). Improving translation performance on low-resource language pairs could be very impactful considering that these languages are spoken by a large fraction of the world population.

Technically, there are several challenges to solve in order to improve translation for low-resource languages. First, in face of the scarcity of clean parallel data, MT systems should be able to use any source of data available, namely monolingual resources, noisy comparable data, as well as parallel data in related languages. Second, we need reliable public evaluation benchmarks to track progress in translation quality.

Building evaluation sets on low-resource languages is both expensive and time-consuming because the pool of professional translators is limited, as there are few fluent bilingual speakers for these languages. Moreover, the quality of professional translations for low-resource languages is not on par with that of high-resource languages, given that the quality assurance processes for the low-resource languages are often lacking or under development. Also, it is difficult to verify the quality of the human translations as an non-native speaker, because the topics of the documents in these low-resource languages may require knowl-

edge and context coming from the local culture.

In this work, we introduce new evaluation benchmarks on two very low-resource language pairs: Nepali–English and Sinhala–English. Sentences were extracted from Wikipedia articles in each language and translated by professional translators. The datasets we release to the community are composed of a tune set of 2559 and 2898 sentences, a development set of 2835 and 2766 sentences, and a test set of 2924 and 2905 sentences for Nepali–English and Sinhala–English respectively.

In §3, we describe the methodology we used to collect the data as well as to check the quality of translations. The experiments reported in §4 demonstrate that these benchmarks are very challenging for current state-of-the-art methods, yielding very low BLEU scores (Papineni et al., 2002) even using all available parallel data as well as monolingual data or Paracrawl[1] filtered data. This suggests that these languages and evaluation benchmarks can constitute a useful test-bed for developing and comparing MT systems for low-resource language pairs.

2 Related Work

There is ample literature on low-resource MT. From the modeling side, one possibility is to design methods that make more effective use of monolingual data. This is a research avenue that has seen a recent surge of interest, starting with semisupervised methods relying on back-translation (Sennrich et al., 2015), integration of a language model into the decoder (Gulcehre et al., 2017; Stahlberg et al., 2018) all the way to fully unsupervised approaches (Lample et al., 2018b; Artetxe et al., 2018), which use monolingual data both for learning good language models and for fantasizing parallel data. Another avenue of research has been to extend the traditional supervised learning setting to a *weakly supervised* one, whereby the original training set is augmented with parallel sentences mined from noisy comparable corpora like Paracrawl. In addition to the challenge of learning with limited supervision, low-resource language pairs often involve distant languages that do not share the same alphabet, or have very different morphology and syntax; accordingly, recent work has begun to explore language-independent lexical representations to improve transfer learning (Gu et al., 2018).

In terms of low-resource datasets, DARPA programs like LORELEI (Strassel and Tracey, 2016) have collected translations on several low-resource languages like English–Tagalog. Unfortunately, the data is only made available to the program's participants. More recently, the Asian Language Treebank project (Riza et al., 2016) has introduced parallel datasets for several low-resource language pairs, but these are sampled from text originating in English and thus may not generalize to text sampled from low-resource languages.

In the past, there has been work on extracting high quality translations from crowd-sourced workers using automatic methods (Zaidan and Callison-Burch, 2011; Post et al., 2012). However, crowd-sourced translations have generally lower quality than professional translations. In contrast, in this work we explore the quality checks that are required to filter *professional* translations of low-resource languages in order to build a high quality benchmark set.

In practice, there are very few publicly available datasets for low-resource language pairs, and often times, researchers *simulate* learning on low-resource languages by using a high-resource language pair like English–French, and merely limiting how much labeled data they use for training (Johnson et al., 2016; Lample et al., 2018a). While this practice enables a framework for easy comparison of different approaches, the real practical implications deriving from these methods can be unclear. For instance, low-resource languages are often distant and often times corresponding corpora are not comparable, conditions which are far from the simulation with high-resource European languages, as has been recently pointed out by Neubig and Hu (2018).

3 Methodology & Resulting Datasets

For the construction of our benchmark sets we chose to translate between Nepali and Sinhala into and out of English. Both Nepali and Sinhala are Indo-Aryan languages with a subject-object-verb (SOV) structure. Nepali is similar to Hindi in its structure, while Sinhala is characterized by extensive omissions of arguments in a sentence.

Nepali is spoken by about 20 million people if we consider only Nepal, while Sinhala is spo-

[1] https://paracrawl.eu/

ken by about 17 million people just in Sri Lanka[2]. Sinhala and Nepali have very little publicly available parallel data . For instance, most of the parallel corpora for Nepali–English originate from GNOME and Ubuntu handbooks, and account for about 500K sentence pairs.[3] For Sinhala–English, there are an additional 600K sentence pairs automatically aligned from from OpenSubtitles (Lison et al., 2018). Overall, the domains and quantity of the existing parallel data are very limited. However, both languages have a rather large amount of monolingual data publicly available (Buck et al., 2014), making them perfect candidates to track performance on unsupervised and semi-supervised tasks for Machine Translation.

3.1 Document selection

To build the evaluation sets, we selected and professionally translated sentences originating from Wikipedia articles in English, Nepali and Sinhala from a Wikipedia snapshot of early May 2018. To select sentences for translation, we first selected the top 25 documents that contain the largest number of *candidate* sentences in each source language. To this end, we defined candidate sentences[4] as: (*i*) being in the intended source language according to a language-id classifier (Bojanowski et al., 2017)[5], and (*ii*) having sentences between 50 and 150 characters. Moreover, we considered sentences and documents to be inadequate for translation when they contained large portions of untranslatable content such as lists of entities[6]. To avoid such lists we used the following rules: (*i*) for English, sentences have to start with an uppercase letter and end with a period; (*ii*) for Nepali and Sinhala, sentences should not contain symbols such as bullet points, repeated dashes, repeated periods or ASCII characters. The document set, along with the categories of documents is presented in the Appendix, Table 8.

After the document selection process, we randomly sampled 2,500 sentences for each language. From English, we translated into Nepali and Sinhala, while from Sinhala and Nepali, we only translated into English. We requested each string to be translated twice by different translators.

3.2 Quality checks

Translating domain-specialized content such as Wikipedia articles from and to low-resource languages is challenging: the pool of available translators is limited, there is limited context available to each translator when translating one string at a time, and some of the sentences can contain code-switching (e.g. text about Buddhism in Nepali or Sinhala can contain Sanskrit or Pali words). As a result, we observed large variations in the level of translation quality, which motivated us to enact a series of automatic and manual checks to filter out poor translations.

We first used automatic methods to filter out poor translations and sent them for rework. Once the reworked translations were received, we sent all translations (original or reworked) that passed the automatic checks to human quality checks. Translations which failed human checks, were disregarded. Only the translations that passed all checks were added to the evaluation benchmark, although some source sentences may have less than two translations. Below, we describe the automatic and manual quality checks that we applied to the datasets.

Automatic Filtering. The guiding principles underlying our choice of automatic filters are: (*i*) translations should be fluent (Zaidan and Callison-Burch, 2011), (*ii*) they should be sufficiently different from the source text, (*iii*) translations should be similar to each other, yet not equal; and (*iv*) translations should not be transliterations. In order to identify the vast majority of translation issues we filtered by: (*i*) applying a count-based n-gram language model trained on Wikipedia monolingual data and removing translations that have perplexity above 3000.0 (English translations only), (*ii*) removing translations that have sentence-level char-BLEU score between the two generated translations below 15 (indicating disparate translations) or above 90 (indicating suspiciously similar translations), (*iii*) removing sen-

[2]See https://www.ethnologue.com/language/npi and https://www.ethnologue.com/language/sin.

[3]Nepali has also 4K sentences translated from English Penn Tree Bank at http://www.cle.org.pk/software/ling_resources/UrduNepaliEnglishParallelCorpus.htm, which is valuable parallel data.

[4]We first used HTML markup to split document text into paragraphs. We then used regular expressions to split on punctuation, e.g. full-stop, poorna virama (\u0964) and exclamation marks.

[5]This is a necessary step as many sentences in foreign language Wikipedias may be in English or other languages.

[6]For example, the Academy Awards page: https://en.wikipedia.org/wiki/Academy_Award_for_Best_Supporting_Actor.

tences that contain at least 33% transliterated words, (*iv*) removing translations where at least 50% of words are copied from the source sentence, and (*v*) removing translations that contain more than 50% out-of-vocabulary words or more than 5 total out-of-vocabulary words in the sentences (English translations only). For this, the vocabulary was calculated on the monolingual English Wikipedia described in Table 2.

Manual Filtering. We followed a setup similar to *direct assessment* (Graham et al., 2013). We asked three different raters to rate sentences from 0–100 according to the perceived translation quality. In our guidelines, the 0–10 range represents a translation that is completely incorrect and inaccurate, the 70–90 range represents a translation that closely preserves the semantics of the source sentence, while the 90–100 range represents a *perfect* translation. To ensure rating consistency, we rejected any evaluation set in which the range of scores among the three reviewers was above 30 points, and requested a fourth rater to break ties, by replacing the most diverging translation rating with the new one. For each translation, we took the average score over all raters and rejected translations whose scores were below 70.

To ensure that the translations were as fluent as possible, we also designed an Amazon Mechanical Turk (AMT) monolingual task to judge the *fluency* of English translations. Regardless of content preservation, translations that are not fluent in the target language should be disregarded. For this task, we then asked five independent human annotators to rate the fluency of each English translation from 1 (bad) to 5 (excellent), and retained only those above 3.Additional statistics of automatic and manual filtering stages can be found in Appendix.

3.3 Resulting Datasets

We built three evaluation sets for each language pair using the data that passed our automatic and manual quality checks: *dev* (tune), *devtest* (validation) and *test* (test). The tune set is used for hyperparameter tuning and model selection, the validation set is used to measure generalization during development, while the test set is used for the final blind evaluation.

To measure performance in both directions (e.g. Sinhala–English and English–Sinhala), we built test sets with mixed original-*translationese* (Baroni and Bernardini, 2005) on the source side. To reduce the effect of the source language on the quality of the resulting evaluation benchmark, direct and reverse translations were mixed at an approximate 50-50 ratio for the *devtest* and *test* sets. On the other hand, the *dev* set was composed of the remainder of the available translations, which were not guaranteed to be balanced. Before selection, the sentences were grouped by document, to minimize the number of documents per evaluation set.

orig lang	*dev*		*devtest*		*test*	
	uniq	tot	uniq	tot	uniq	tot
Nepali–English						
English	693	1,181	800	1,393	850	1,462
Nepali	825	1,378	800	1,442	850	1,462
	1,518	**2,559**	**1,600**	**2,835**	**1,700**	**2,924**
Sinhala–English						
English	1,123	1,913	800	1,395	850	1,465
Sinhala	565	985	800	1,371	850	1,440
	1,688	**2,898**	**1600**	**2,766**	**1700**	**2,905**

Table 1: Number of unique sentences (*uniq*) and total number of sentence pairs (*tot*) per FLORES test set grouped by their original languages.

In Table 1 we present the statistics of the resulting sets. For Sinhala–English, the *test* set is composed of 850 sentences originally in English, and 850 originally in Sinhala. We have approximately 1.7 translations per sentence. This yielded 1,465 sentence pairs originally in English, and 1,440 originally in Sinhalese, for a total of 2,905 sentences. Similarly, for Nepali–English, the *test* set is composed of 850 sentences originally in English, and 850 originally in Nepali. This yielded 1,462 sentence pairs originally in English and 1,462 originally in Nepali, for a total of 2,924 sentence pairs. The composition of the rest of the sets can be found in Table 1.

In Appendix Table 6, we present the aggregate distribution of topics per sentence for the datasets in Nepali–English and Sinhala–English, which shows a diverse representation of topics ranging from General (e.g. documents about tires, shoes and insurance), History (e.g. documents about history of the radar, the Titanic, etc.) to Law and Sports. This richness of topics increases the difficulty of the set, as it requires models that are rather domain-independent. The full list of documents and topics is also in Appendix, Table 8.

4 Experiments

In this section, we first describe the data used for training the models, we then discuss the learning settings and models considered, and finally we report the results of these baseline models on the new evaluation benchmarks.

4.1 Training Data

Small amounts of parallel data are available for Sinhala–English and Nepali–English. Statistics can be found in Table 2. This data comes from different sources. Open Subtitles and GNOME/KDE/Ubuntu come from the OPUS repository[7]. Global Voices is an updated version (2018q4) of a data set originally created for the CASMACAT project[8]. Bible translations come from the bible-corpus[9]. The Paracrawl corpus comes from the Paracrawl project[10]. The filtered version (Clean Paracrawl) was generated using the LASER model (Artetxe and Schwenk, 2018) to get the best sentence pairs having 1 million English tokens as specified in Chaudhary et al. (2019). We also contrast this filtered version with a randomly filtered version (Random Paracrawl) with the same number of English tokens. Finally, our multilingual experiments in Nepali use Hindi monolingual (about 5 million sentences) and English-Hindi parallel data (about 1.5 million parallel sentences) from the IIT Bombay corpus[11].

Table 2: Parallel, comparable, and monolingual data used in experiments in §4. The number of tokens for parallel and comparable corpora are reported over the English tokens. Monolingual and comparable corpora do not include any sentences from the evaluation sets. *Comparable data from Paracrawl is used only in the weakly-supervised experiments since alignments are noisy.

4.2 Training Settings

We evaluate models in four training settings. First, we consider a fully *supervised* training setting using the parallel data listed in Table 2.

Second, we consider a fully *unsupervised* setting, whereby only monolingual data on both the source and target side are used to train the model (Lample et al., 2018b).

Third, we consider a *semi-supervised* setting where we also leverage monolingual data on the target side using the standard back-translation training protocol (Sennrich et al., 2015): we train a backward MT system, which we use to translate monolingual target sentences to the source language. Then, we merge the resulting pairs of noisy (back-translated) source sentences with the original target sentences and add them as additional parallel data for training source-to-target MT system. Since monolingual data is available for both languages, we train backward MT systems in both directions and repeat the back-translation process iteratively (He et al., 2016; Lample et al., 2018a). We consider up to two back-translation iterations. At each iteration we generate back-translations using beam search, which has been shown to perform well in low-resource settings (Edunov et al., 2018); we use a beam width of 5 and individually tune the length-penalty on the *dev* set.

Finally, we consider a *weakly supervised* setting by using a baseline system to filter out Paracrawl data using LASER (Artetxe and Schwenk, 2018) by following the approach similar to Chaudhary et al. (2019), in order to augment the original training set with a possibly larger but noisier set of parallel sentences.

[9] https://github.com/christos-c/bible-corpus/

[10] https://paracrawl.eu/

[11] http://www.cfilt.iitb.ac.in/iitb_parallel/

For Nepali only, we also consider training using Hindi data, both in a joint supervised and semi-supervised setting. For instance, at each iteration of the joint semi-supervised setting, we use models from the previous iteration to back-translate English monolingual data into both Hindi and Nepali, and from Hindi and Nepali monolingual data into English. We then concatenate actual parallel data and back-translated data of the same language pair together, and train a new model. We also consider using English-Hindi data in the unsupervised scenario. In that setting, a model is pretrained in an unsupervised way with English, Hindi and Nepali monolingual data using the unsupervised approach by Lample and Conneau (2019), and it is then jointly trained on both the Nepali–English unsupervised learning task and the Hindi-English supervised task (in both directions).

4.3 Models & Architectures

We consider both phrase-based statistical machine translation (PBSMT) and neural machine translation (NMT) systems in our experiments. All hyper-parameters have been cross-validated using the dev set. The PBSMT systems use Moses (Koehn et al., 2007), with state-of-the-art settings (5-gram language model, hierarchical lexicalized reordering model, operation sequence model) but no additional monolingual data to train the language model.

The NMT systems use the Transformer (Vaswani et al., 2017) implementation in the Fairseq toolkit (Ott et al., 2019); preliminary experiments showed these to perform better than LSTM-based NMT models. More specifically, in the supervised setting, we use a Transformer architecture with 5 encoder and 5 decoder layers, where the number of attention heads, embedding dimension and inner-layer dimension are 2, 512 and 2048, respectively. In the semi-supervised setting, where we augment our small parallel training data with millions of back-translated sentence pairs, we use a larger Transformer architecture with 6 encoder and 6 decoder layers, where the number of attention heads, embedding dimension and inner-layer dimension are 8, 512 and 4096, respectively. When we use multilingual data, the encoder is shared in the {Hindi, Nepali}–English direction, and the decoder is shared in the English–{Hindi, Nepali}direction. We regularize our models with dropout, label smoothing and weight decay, with the corresponding hyper-parameters tuned independently for each language pair. Models are optimized with Adam (Kingma and Ba, 2015) using $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 1e-8$. We use the same learning rate schedule as Ott et al. (2018b). We run experiments on between 4 and 8 Nvidia V100 GPUs with mini-batches of between 10K and 100K target tokens following Ott et al. (2018b). Code to reproduce our results can be found at https://github.com/facebookresearch/flores.

4.4 Preprocessing and Evaluation

We tokenize Nepali and Sinhala using the Indic NLP Library.[12] For the PBSMT system, we tokenize English sentences using the Moses tokenization scripts. For NMT systems, we instead use a vocabulary of 5K symbols based on a joint source and target Byte-Pair Encoding (BPE; Sennrich et al., 2015) learned using the sentencepiece library[13] over the parallel training data. We learn the joint BPE for each language pair over the raw English sentences and tokenized Nepali or Sinhala sentences. We then remove training sentence pairs with more than 250 source or target BPE tokens.

We report detokenized SacreBLEU (Post, 2018) when translating into English, and tokenized BLEU (Papineni et al., 2002) when translating from English into Nepali or Sinhala.

4.5 Results

In the supervised setting, PBSMT performed quite worse than NMT, achieving BLEU scores of 2.5, 4.4, 1.6 and 5.0 on English–Nepali, Nepali–English, English–Sinhala and Sinhala–English, respectively. Table 3 reports results using NMT in all the other learning configurations described in §4.2. There are several observations we can make.

First, these language pairs are very difficult, as even supervised NMT baselines achieve BLEU scores less than 8. Second and not surprisingly, the BLEU score is particularly low when translating into the more morphologically rich Nepali and Sinhala languages. Third, unsupervised NMT approaches seem to be ineffective on these distant language pairs, achieving BLEU scores close to 0. The reason for this failure is due to poor initialization of the word embeddings.

[12] https://github.com/anoopkunchukuttan/indic_nlp_library

[13] https://github.com/google/sentencepiece

	Supervised		Unsupervised		Semi-supervised				Weakly supervised
		+mult.		+ mult.	it. 1	it. 2	it 1. + mult.	it 2. + mult.	
English–Nepali	4.3	6.9	0.1	8.3	6.8	6.8	8.8	8.8	5.8
Nepali–English	7.6	14.2	0.5	18.8	12.7	15.1	19.8	21.5	9.6
English–Sinhala	1.2	-	0.1	-	5.2	6.5	-	-	3.1
Sinhala–English	7.2	-	0.1	-	12.0	15.1	-	-	10.9

Table 3: BLEU scores of NMT using various learning settings on *devtest* (see §3). We report detokenized SacreBLEU (Post, 2018) for {Ne,Si}→En and tokenized BLEU for En→{Ne,Si}.

Poor initialization can be attributed to to the monolingual corpora used to train word embeddings which do not have sufficient number of overlapping strings, and are not comparable (Neubig and Hu, 2018; Søgaard et al., 2018).

Fourth, the biggest improvements are brought by the semi-supervised approach using back-translation, which nearly doubles BLEU for Nepali–English from 7.6 to 15.1 (+7.5 BLEU points) and Sinhala–English from 7.2 to 15.1 (+7.9 BLEU points), and increases +2.5 BLEU points for English–Nepali and +5.3 BLEU points for English–Sinhala.

Fifth, additional parallel data in English-Hindi further improves translation quality in Nepali across all settings. For instance, in the Nepali–English supervised setting, we observe a gain of 6.5 BLEU points, while in the semi-supervised setting (where we back-translate also to and from Hindi) the gain is 6.4 BLEU points. Similarly, in the unsupervised setting, multilingual training with Hindi brings Nepali–English to 3.9 BLEU and English–Nepali to 2.5 BLEU; if however, the architecture is pretrained as prescribed by Lample and Conneau (2019), BLEU score improves to 18.8 BLEU for Nepali–English and 8.3 BLEU for English–Nepali.

Finally, the weakly supervised baseline using the additional noisy parallel data described in §4.1 improves upon the supervised baseline in all four directions. This is studied in more depth in Table 4 for Sinhala–English and Nepali–English. Without any filtering or with random filtering, BLEU score is close to 0 BLEU. Applying the a filtering method based on LASER scores (Artetxe and Schwenk, 2018) provides an improvement over using the unfiltered Paracrawl, of +5.5 BLEU points for Nepali–English and +7.3 BLEU points for Sinhala–English. Adding Paracrawl Clean to the initial parallel data improves performance by +2.0 and +3.7 BLEU points, for Nepali–English and Sinhala–English, respectively.

Corpora	BLEU	
	ne–en	si–en
Parallel	7.6	7.2
Unfiltered Paracrawl	0.4	0.4
Paracrawl Random	0.1	0.4
Paracrawl Clean	5.9	7.7
Parallel + Paracrawl Clean	9.6	10.9

Table 4: Weakly supervised experiments: Adding noisy parallel data from filtered Paracrawl improves translation quality in some conditions. "Parallel" refers to the data described in Table 2.

5 Discussion

In this section, we provide an analysis of the performance on the Nepali to English *devtest* set using the semi-supervised machine translation system, see Figure 1. Findings on other language directions are similar.

Fluency of references: we observe no correlation between the fluency rating of human references and the quality of translations as measured by BLEU. This suggests that the difficulty of the translation task is not related to the fluency of the references, at least at the current level of accuracy.

Document difficulty: we observe that translation quality is similar across all document ids, with a difference of 10 BLEU points between the document that is the easiest and the hardest to translate. This suggests that the random sampling procedure used to construct the dataset was adequate and that no single Wikipedia document produces much harder sentences than others.

Original vs translationese: we noticed that documents originating from Nepali are harder to translate than documents originating in English. This holds when performing the evaluation with the supervised MT system: translations of original Nepali sentences obtain 4.9 BLEU while Nepali translationese obtain 9.1 BLEU. This suggests that the existing parallel corpus is closer to English Wikipedia than Nepali Wikipedia.

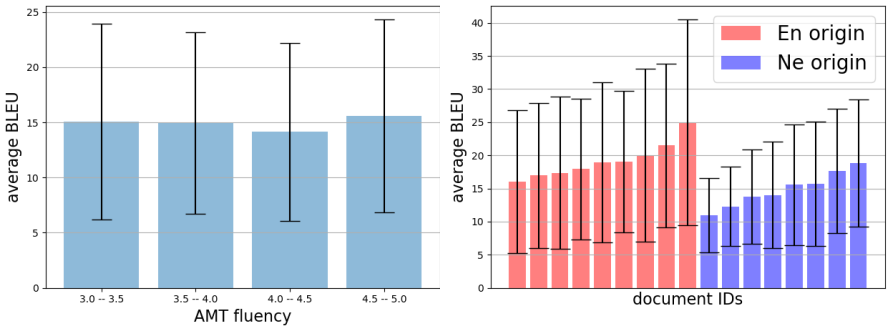

Figure 1: Analysis of the Ne→En *devtest* set using the semi-supervised machine translation system. **Left**: sentence level BLEU versus AMT fluency score of the reference sentences in English; source sentences that have received more fluent human translations are not easier to translate by machines. **Right**: average sentence level BLEU against Wikipedia document id from which the source sentence was extracted; sentences have roughly the same degree of difficulty across documents since there is no extreme difference between shortest and tallest bar. However, source sentences originating from Nepali Wikipedia (blue) are translated more poorly than those originating from English Wikipedia (red). Documents are sorted by BLEU for ease of reading.

5.1 Domain drift

To better understand the effect of domain mismatch between the parallel dataset and the Wikipedia evaluation set, we restricted the Sinhala–English training set to only the Open Subtitles portion of the parallel dataset, and we held out 1000 sentences for "in-domain" evaluation of generalization performance. Table 5 shows that translation quality on in-domain data is between 10 and 16 BLEU points higher. This may be due to both domain mismatch as well as sensitivity of the BLEU metric to sentence length. Indeed, there are on average 6 words per sentences in the Open Subtitles test set compared to 16 words per sentence in the FLORES *devtest* set. However, when we train semi-supervised models on back-translated Wikipedia data whose domain better matches the "Out-of-domain" *devtest* set, we see much larger gains in BLEU for the "Out-of-domain" set than we see on the "In-domain" set, suggesting that domain mismatch is indeed a major problem.

	Open Subtitles	**FLORES (*devtest*)**
Sinhala–English		
Supervised	23.5	7.2
Semi-sup.	28.1 (+20%)	15.1 (+210%)
English–Sinhala		
Supervised	11.0	1.2
Semi-sup.	11.8 (+7%)	6.5 (+542%)

Table 5: In-domain vs. out-of-domain translation performance (BLEU) for supervised and semi-supervised NMT models. We report BLEU on a held-out subset of 1,000 sentences from the Open Subtitles training data (see Table 2) and on *devtest* (see §3). Semi-supervised models are trained on back-translated Wikipedia data.

6 Conclusions

One of the biggest challenges in MT today is learning to translate low-resource language pairs. Research in this area not only faces formidable technical challenges, from learning with limited supervision to dealing with very distant languages, but it is also hindered by the lack of freely and publicly available evaluation benchmarks.

In this work, we introduce and freely release to the community FLORES benchmarks for Nepali–English and Sinhala–English . Nepali and Sinhala are languages with very different syntax and morphology than English; also, very little parallel data in these language pairs is publicly available. However, a good amount of monolingual data, parallel data in related languages, and Paracrawl data exist in both languages, making these two language pairs a perfect candidate for research on low-resource MT.

Our experiments show that current state-of-the-art approaches perform rather poorly on these new evaluation benchmarks, with semi-supervised and in particular multi-lingual neural methods outperforming all the other model variants and training settings we considered. We perform additional analysis to probe the quality of the datasets. We find no evidence of poor construction quality, yet observe that the low BLEU scores are partly due to the domain mismatch between the training and test datasets. We believe that these benchmarks will help the research community on low-resource MT make faster progress by enabling free access to evaluation data on actual low-resource languages and promoting fair comparison of methods.

B Statistics of automatic filtering and manual filtering

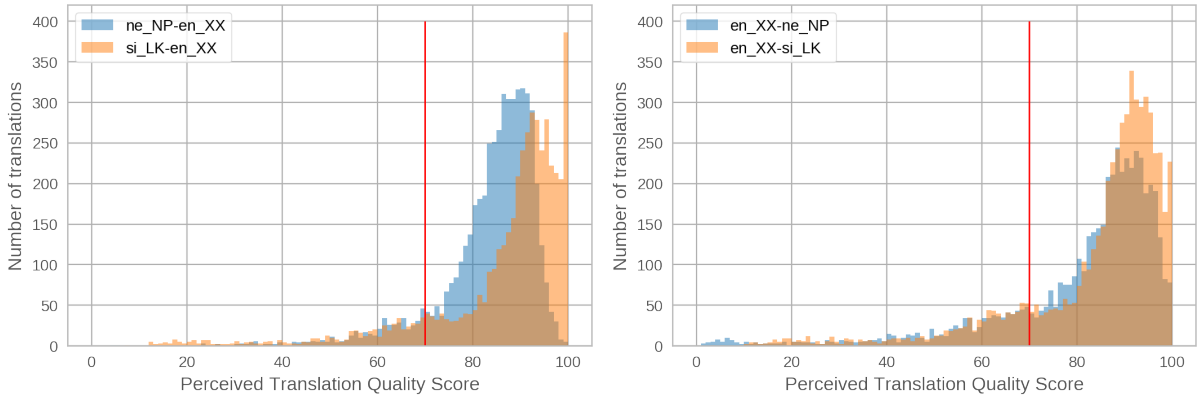

Figure 2: Histogram of averaged translation quality score. We ask three different raters to rate each sentence from 0–100 according to the perceived translation quality. In our guidelines, the 0–10 range represents a translation that is completely incorrect and inaccurate; the 11–29 range represents a translation with few correct keywords, but the overall meaning is different from the source; the 30–50 range represents a translation that contains translated fragments of the source string, with major mistakes; the 51–69 range represents a translation which is understandable and conveys the overall meaning of source string but contains typos or grammatical errors; the 70–90 range represents a translation that closely preserves the semantics of the source sentence; and the 90–100 range represents a *perfect* translation. Translations with averaged translation score less than 70 (red line) are removed from the dataset.

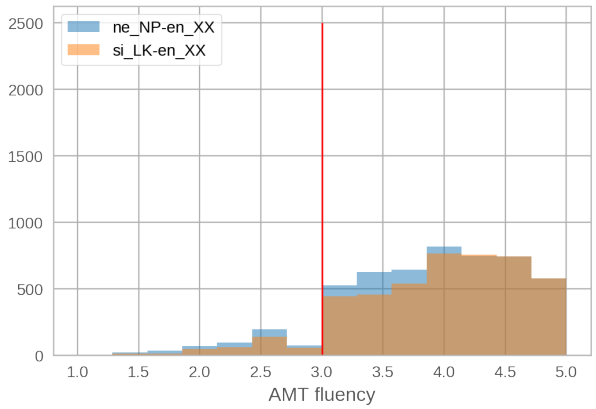

Figure 3: Histogram of averaged AMT fluency score of English translations. We ask five different raters to rate each sentence from 1–5 according to its fluency. In our guidelines, the 1–2 range represents a sentence that is not fluent, 3 is neutral, while the 4–5 range is for fluent sentences that raters can easily understand. Translations with averaged fluency score less than 3 (red line) are removed from the dataset.

	Nepali–English	English–Nepali	Sinhala–English	English–Sinhala
Automatic filtering	14%	18%	24%	7%
Manual filtering				
Translation quality	10%	19%	13%	16%
Fluency	10%	-	17%	-

Table 7: Percentage of translations that did not pass the automatic and manual filtering checks. We first use automatic methods to filter out poor translations and send those translations back for rework. We then collect translations that pass the automatic filtering and send them to two human quality checks, one for adequacy and the other for fluency. Note that the percentage of sentences that did not pass manual filtering is among those sentences that passed the automatic filtering.

Mask-Predict: Parallel Decoding of Conditional Masked Language Models

Marjan Ghazvininejad* **Omer Levy*** **Yinhan Liu*** **Luke Zettlemoyer**
Facebook AI Research
Seattle, WA

Abstract

Most machine translation systems generate text autoregressively from left to right. We, instead, use a masked language modeling objective to train a model to predict any subset of the target words, conditioned on both the input text and a partially masked target translation. This approach allows for efficient iterative decoding, where we first predict all of the target words non-autoregressively, and then repeatedly mask out and regenerate the subset of words that the model is least confident about. By applying this strategy for a constant number of iterations, our model improves state-of-the-art performance levels for non-autoregressive and parallel decoding translation models by over 4 BLEU on average. It is also able to reach within about 1 BLEU point of a typical left-to-right transformer model, while decoding significantly faster.[1]

1 Introduction

Most machine translation systems use sequential decoding strategies where words are predicted one-by-one. In this paper, we present a model and a parallel decoding algorithm which, for a relatively small sacrifice in performance, can be used to generate translations in a *constant* number of decoding iterations.

We introduce conditional masked language models (CMLMs), which are encoder-decoder architectures trained with a masked language model objective (Devlin et al., 2018; Lample and Conneau, 2019). This change allows the model to learn to predict, in parallel, any arbitrary subset of masked words in the target translation. We use transformer CMLMs, where the decoder's self attention (Vaswani et al., 2017) can attend to the entire sequence (left and right context) to predict each masked word. We train with a simple masking scheme where the number of masked target tokens is distributed uniformly, presenting the model with both easy (single mask) and difficult (completely masked) examples. Unlike recently proposed insertion models (Gu et al., 2019; Stern et al., 2019), which treat each token as a separate training instance, CMLMs can train from the entire sequence in parallel, resulting in much faster training.

We also introduce a new decoding algorithm, *mask-predict*, which uses the order-agnostic nature of CMLMs to support highly parallel decoding. Mask-predict repeatedly masks out and re-predicts the subset of words in the current translation that the model is least confident about, in contrast to recent parallel decoding translation approaches that repeatedly predict the entire sequence (Lee et al., 2018). Decoding starts with a completely masked target text, to predict all of the words in parallel, and ends after a constant number of mask-predict cycles. This overall strategy allows the model to repeatedly reconsider word choices within a rich bi-directional context and, as we will show, produce high-quality translations in just a few cycles.

Experiments on benchmark machine translation datasets show the strengths of mask-predict decoding for transformer CMLMs. With just 4 iterations, BLEU scores already surpass the performance of the best non-autoregressive and parallel decoding models.[2]

With 10 iterations, the approach outperforms the current state-of-the-art parallel decod-

*Equal contribution, sorted alphabetically.

[1]Our code is publicly available at: https://github.com/facebookresearch/Mask-Predict

[2]We use the term "parallel decoding" to refer to the family of approaches that can generate the entire target sequence in parallel. These are often referred to as "non-autoregressive" approaches, but both iterative refinement (Lee et al., 2018) and our mask-predict approach condition on the model's past predictions.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6112–6121,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing model (Lee et al., 2018) by gaps of 4-5 BLEU points on the WMT'14 English-German translation benchmark, and up to 3 BLEU points on WMT'16 English-Romanian, but with the same model complexity and decoding speed. When compared to standard autoregressive transformer models, CMLMs with mask-predict offer a trade-off between speed and performance, trading up to 2 BLEU points in translation quality for a 3x speed-up during decoding.

2 Conditional Masked Language Models

A conditional masked language model (CMLM) predicts a set of target tokens Y_{mask} given a source text X and part of the target text Y_{obs}. It makes the strong assumption that the tokens Y_{mask} are conditionally independent of each other (given X and Y_{obs}), and predicts the individual probabilities $P(y|X, Y_{obs})$ for each $y \in Y_{mask}$. Since the number of tokens in Y_{mask} is given in advance, the model is also implicitly conditioning on the length of the target sequence $N = |Y_{mask}| + |Y_{obs}|$.

2.1 Architecture

We adopt the standard encoder-decoder transformer for machine translation (Vaswani et al., 2017): a source-language encoder that does self-attention, and a target-language decoder that has one set of attention heads over the encoder's output and another set for the target language (self-attention). In terms of parameters, our architecture is identical to the standard one. We deviate from the standard decoder by removing the self-attention mask that prevents left-to-right decoders from attending on future tokens. In other words, our decoder is bi-directional, in the sense that it can use both left and right contexts to predict each token.

2.2 Training Objective

During training, we randomly select Y_{mask} among the target tokens. We first sample the number of masked tokens from a uniform distribution between one and the sequence's length, and then randomly choose that number of tokens. Following Devlin et al. (2018), we replace the inputs of the tokens Y_{mask} with a special `MASK` token.

We optimize the CMLM for cross-entropy loss over every token in Y_{mask}. This can be done in parallel, since the model assumes that the tokens in Y_{mask} are conditionally independent of each other. While the architecture can technically make predictions over all target-language tokens (including Y_{obs}), we only compute the loss for the tokens in Y_{mask}.

2.3 Predicting Target Sequence Length

In traditional left-to-right machine translation, where the target sequence is predicted token by token, it is natural to determine the length of the sequence dynamically by simply predicting a special `EOS` (end of sentence) token. However, for CMLMs to predict the entire sequence in parallel, they must know its length in advance. This problem was recognized by prior work in non-autoregressive translation, where the length is predicted with a fertility model (Gu et al., 2018) or by pooling the encoder's outputs into a length classifier (Lee et al., 2018).

We follow Devlin et al. (2018) and add a special `LENGTH` token to the encoder, akin to the `CLS` token in BERT. The model is trained to predict the length of the target sequence N as the `LENGTH` token's output, similar to predicting another token from a different vocabulary, and its loss is added to the cross-entropy loss from the target sequence.

3 Decoding with Mask-Predict

We introduce the mask-predict algorithm, which decodes an entire sequence in parallel within a constant number of cycles. At each iteration, the algorithm selects a subset of tokens to mask, and then predicts them (in parallel) using an underlying CMLM. Masking the tokens where the model has doubts while conditioning on previous high-confidence predictions lets the model re-predict the more challenging cases, but with more information. At the same time, the ability to make large parallel changes at each step allows mask-predict to converge on a high quality output sequence in a sub-linear number of decoding iterations.

3.1 Formal Description

Given the target sequence's length N (see Section 3.3), we define two variables: the target sequence $(y_1, \ldots, y_N)$ and the probability of each token $(p_1, \ldots, p_N)$. The algorithm runs for a predetermined number of iterations T, which is either a constant or a simple function of N. At each iteration, we perform a *mask* operation, followed by *predict*.

src	Der Abzug der franzsischen Kampftruppen wurde am 20. November abgeschlossen .
$t = 0$	The departure of the French combat completed completed on 20 November .
$t = 1$	The departure of French combat troops was completed on 20 November .
$t = 2$	The withdrawal of French combat troops was completed on November 20th .

Figure 1: An example from the WMT'14 DE-EN validation set that illustrates how mask-predict generates text. At each iteration, the highlighted tokens are masked and repredicted, conditioned on the other tokens in the sequence.

Mask For the first iteration ($t = 0$), we mask all the tokens. For later iterations, we mask the n tokens with the lowest probability scores:

$$Y^{(t)}_{mask} = \arg\min_i(p_i, n)$$
$$Y^{(t)}_{obs} = Y \setminus Y^{(t)}_{mask}$$

The number of masked tokens n is a function of the iteration t; specifically, we use linear decay $n = N \cdot \frac{T-t}{T}$, where T is the total number of iterations. For example, if $T = 10$, we will mask 90% of the tokens at $t = 1$, 80% at $t = 2$, and so forth.

Predict After masking, the CMLM predicts the masked tokens $Y^{(t)}_{mask}$, conditioned on the source text X and the unmasked target tokens $Y^{(t)}_{obs}$. We select the prediction with the highest probability for each masked token $y_i \in Y^{(t)}_{mask}$ and update its probability score accordingly:

$$y^{(t)}_i = \arg\max_w P(y_i = w|X, Y^{(t)}_{obs})$$
$$p^{(t)}_i = \max_w P(y_i = w|X, Y^{(t)}_{obs})$$

The values and the probabilities of unmasked tokens $Y^{(t)}_{obs}$ remain unchanged:

$$y^{(t)}_i = y^{(t-1)}_i$$
$$p^{(t)}_i = p^{(t-1)}_i$$

We tried updating or decaying these probabilities in preliminary experiments, but found that this heuristic works well despite the fact that some probabilities are stale.

3.2 Example

Figure 1 illustrates how mask-predict can generate a good translation in just three iterations.

In the first iteration ($t = 0$), the entire target sequence is masked ($Y^{(0)}_{mask} = Y$ and $Y^{(0)}_{obs} = \emptyset$), and is thus generated by the CMLM in a purely non-autoregressive process:

$$P(Y^{(0)}_{mask}|X, Y^{(0)}_{obs}) = P(Y|X)$$

This produces an ungrammatical translation with repetitions ("completed completed"), which is typical of non-autoregressive models due to the multi-modality problem (Gu et al., 2018).

In the second iteration ($t = 1$), we select 8 of the 12 tokens generated in the previous step; these token were predicted with the lowest probabilities at $t = 0$. We mask them and repredict with the CMLM, while conditioning on the 4 unmasked tokens $Y^{(1)}_{obs} = \{$"The", "20", "November", "."$\}$. This results in a more grammatical and accurate translation. Our analysis shows that this second iteration removes most repetitions, perhaps because conditioning on even a little bit of the target sequence is enough to collapse the multi-modal target distribution into a single output (Section 5.1).

In the last iteration ($t = 2$), we select the 4 of the 12 tokens that had the lowest probabilities. Two of those tokens were predicted at the first step ($t = 0$), and not repredicted at the second step ($t = 1$). It is quite common for earlier predictions to be masked at later iterations because they were predicted with less information and thus tend to have lower probabilities. Now that the model is conditioning on 8 tokens, it is able to produce an more fluent translation; "withdrawal" is a better fit for describing troop movement, and "November 20th" is a more common date format in English.

3.3 Deciding Target Sequence Length

When generating, we first compute the CMLM's encoder, and then use the `LENGTH` token's encoding to predict a distribution over the target sequence's length (see Section 2.3). Since much of the CMLM's computation can be batched, we select the top ℓ length candidates with the highest probabilities, and decode the same example with different lengths in parallel. We then select the sequence with the highest average log-probability as our result:

$$\frac{1}{N}\sum \log p^{(T)}_i$$

Our analysis reveals that translating multiple candidate sequences of different lengths can improve performance (see Section 5.3).

4 Experiments

We evaluate CMLMs with mask-predict decoding on standard machine translation benchmarks. We find that our approach significantly outperforms prior parallel decoding machine translation methods and even approaches the performance of standard autoregressive models (Section 4.2), while decoding significantly faster (Section 4.3).

4.1 Experimental Setup

Translation Benchmarks We evaluate on three standard datasets, WMT'14 EN-DE (4.5M sentence pairs), WMT'16 EN-RO (610k pairs) and WMT'17 EN-ZH (20M pairs) in both directions. The datasets are tokenized into subword units using BPE (Sennrich et al., 2016). We use the same preprocessed data as Vaswani et al. (2017) and Wu et al. (2019) for WMT'14 EN-DE and WMT'17 EN-ZH respectively, and use the data from Lee et al. (2018) for WMT'16 EN-RO. We evaluate performance with BLEU (Papineni et al., 2002) for all language pairs, except from EN to ZH, where we use SacreBLEU (Post, 2018).[3]

Hyperparameters We follow most of the standard hyperparameters for transformers in the base configuration (Vaswani et al., 2017): 6 layers per stack, 8 attention heads per layer, 512 model dimensions, 2048 hidden dimensions. We also experiment with 512 hidden dimensions, for comparison with previous parallel decoding models (Gu et al., 2018; Lee et al., 2018). We follow the weight initialization scheme from BERT (Devlin et al., 2018), which samples weights from $\mathcal{N}(0, 0.02)$, initializes biases to zero, and sets layer normalization parameters to $\beta = 0, \gamma = 1$. For regularization, we use 0.3 dropout, 0.01 L_2 weight decay, and smoothed cross validation loss with $\varepsilon = 0.1$. We train batches of 128k tokens using Adam (Kingma and Ba, 2015) with $\beta = (0.9, 0.999)$ and $\varepsilon = 10^{-6}$. The learning rate warms up to a peak of $5 \cdot 10^{-4}$ within 10,000 steps, and then decays with the inverse square-root schedule. We trained all models for 300k steps, measured the validation loss at the end of each epoch, and averaged the 5 best checkpoints to create the final model. During decoding, we use a beam size of $b = 5$ for autoregressive decoding, and similarly use $\ell = 5$ length candidates for mask-predict decoding. We trained with mixed precision floating point arithmetic on two DGX-1 machines, each with eight 16GB Nvidia V100 GPUs interconnected by Infiniband (Micikevicius et al., 2018).

Model Distillation Following previous work on non-autoregressive and insertion-based machine translation (Gu et al., 2018; Lee et al., 2018; Stern et al., 2019), we train CMLMs on translations produced by a standard left-to-right transformer model (large for EN-DE and EN-ZH, base for EN-RO). For a fair comparison, we also train standard left-to-right base transformers on translations produced by large transformer models for EN-DE and EN-ZH, in addition to the standard baselines. We analyze the impact of distillation in Section 5.4.

4.2 Translation Quality

We compare our approach to three other parallel decoding translation methods: the fertility-based sequence-to-sequence model of Gu et al. (2018), the CTC-loss transformer of Libovický and Helcl (2018), and the iterative refinement approach of Lee et al. (2018). The first two methods are purely non-autoregressive, while the iterative refinement approach is only non-autoregressive in the first decoding iteration, similar to our approach. In terms of speed, each mask-predict iteration is virtually equivalent to a refinement iteration.

Table 1 shows that among the parallel decoding methods, our approach yields the highest BLEU scores by a considerable margin. When controlling for the number of parameters (i.e. considering only the smaller CMLM configuration), CMLMs score roughly 4 BLEU points higher than the previous state of the art on WMT'14 EN-DE, in both directions. Another striking result is that a CMLM with only 4 mask-predict iterations yields higher scores than 10 iterations of the iterative refinement model; in fact, only 3 mask-predict iterations are necessary for achieving a new state of the art on both directions of WMT'14 EN-DE (not shown).

The translations produced by CMLMs with mask-predict also score competitively when compared to strong transformer-based autoregressive models. In all 4 benchmarks, our base CMLM reaches within 0.5-1.2 BLEU points from a well-tuned base transformer, a relative decrease of less

Table 2: The performance (BLEU) of CMLMs with mask-predict, compared to the standard (sequential) transformer on WMT' 17 EN-ZH.

than 4% in translation quality. In many scenarios, this is an acceptable price to pay for a significant speedup from parallel decoding.

Table 2 shows that these trends also hold for English-Chinese translation, in both directions, despite major linguistic differences between the two languages.

4.3 Decoding Speed

Because CMLMs can predict the entire sequence in parallel, mask-predict can translate an entire sequence in a constant number of decoding iterations. Does this appealing theoretical property translate into a wall-time speed-up in practice? By comparing the actual decoding times, we show that, for some sacrifice in performance, our parallel method can translate much faster than standard sequential transformers.

Setup As the baseline system, we use the base transformer with beam search ($b = 5$) to translate WMT'14 EN-DE; we also use greedy search ($b = 1$) as a faster but less accurate baseline. For CMLMs, we vary the number of mask-predict iterations ($T = 4, \ldots, 10$) and length candidates ($\ell = 1, 2, 3$). For both models, we decode batches of 10 sentences.[4] For each decoding run, we measure the performance (BLEU) and wall time (seconds) from when the model and data have been loaded until the last example has been translated, and calculate the relative decoding speed-up (CMLM time / baseline time) to assess the speed-performance trade-off.

The implementation of both the baseline transformer and our CMLM is based on `fairseq` (Gehring et al., 2017), which efficiently decodes left-to-right transformers by caching the state. Caching reduces the baseline's decoding speed from 210 seconds to 128.5; CMLMs do not use cached decoding. All experiments used exactly the same machine and the same single GPU.

[4]The batch size was chosen arbitrarily; mask-predict can scale up to much larger batch sizes.

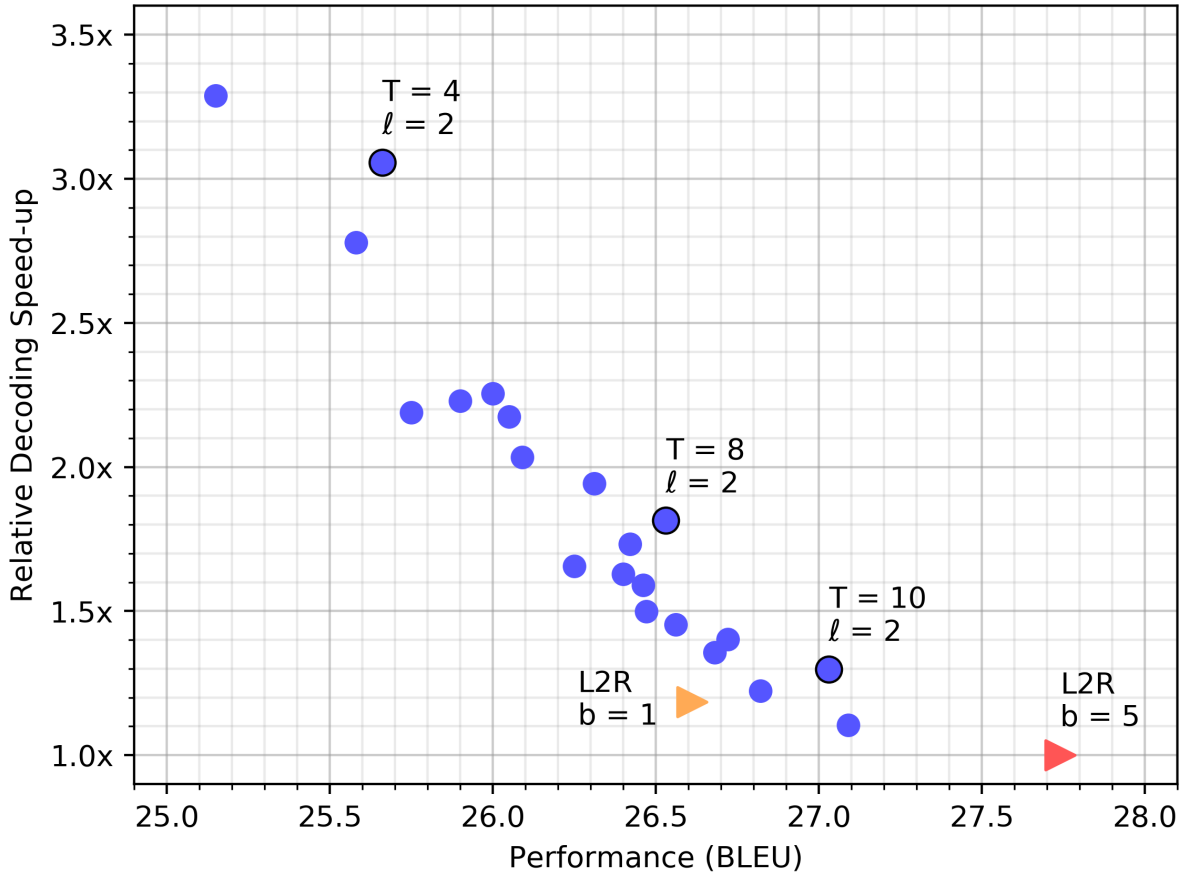

Figure 2: The trade-off between speed-up and translation quality of a base CMLM with mask-predict, compared to the standard sequentially-decoded base transformer on the WMT'14 EN-DE test set, with beam sizes $b = 1$ (orange triangle) and $b = 5$ (red triangle). Each blue circle represents a mask-predict decoding run with a different number of iterations ($T = 4, \ldots, 10$) and length candidates ($\ell = 1, 2, 3$).

Results Figure 2 shows the speed-performance trade-off. We see that mask-predict is versatile; on one hand, we can translate over 3 times faster than the baseline at a cost of 2 BLEU points ($T = 4$, $\ell = 2$), or alternatively retain a high quality of 27.03 BLEU while gaining a 30% speed-up ($T = 4$, $\ell = 2$). Surprisingly, this latter configuration outperforms an autoregressive transformer with greedy decoding ($b = 1$) in both quality and speed. We also observe that more balanced configurations (e.g. $T = 8$, $\ell = 2$) yield similar performance to the single-beam autoregressive transformer, but decode much faster.

5 Analysis

To complement the quantitative results in Section 4, we present qualitative analysis that provides some intuition as to why our approach works and where future work could potentially improve it.

5.1 Why Are Multiple Iterations Necessary?

Various non-autoregressive translation models, including our own CMLM, make the strong assumption that the individual token predictions are conditionally independent of each other. Such a model might consider two or more possible translations, A and B, but because there is no coordination mechanism between the token predictions, it could predict one token from A and another token from B. This problem, known as the multi-modality problem (Gu et al., 2018), often manifest as *token repetitions* in the output when the model has multiple hypotheses that predict the same word w with high confidence, but at different positions.

We hypothesize that multiple mask-predict iterations alleviate the multi-modality problem by allowing the model to condition on parts of the input, thus collapsing the multi-modal distribution into a sharper uni-modal distribution. To test our

Iterations	WMT'14 EN-DE BLEU	WMT'14 EN-DE Reps	WMT'16 EN-RO BLEU	WMT'16 EN-RO Reps
$T = 1$	18.05	16.72%	27.32	9.34%
$T = 2$	22.91	5.40%	31.08	2.82%
$T = 3$	24.99	2.03%	32.19	1.26%
$T = 4$	25.94	1.07%	32.53	0.87%
$T = 5$	26.30	0.72%	32.62	0.61%

Table 3: The performance (BLEU) and percentage of repeating tokens when decoding with a different number of mask-predict iterations (T).

	$T = 4$	$T = 10$	$T = N$
$1 \leq N < 10$	21.8	22.4	22.4
$10 \leq N < 20$	24.6	25.9	26.0
$20 \leq N < 30$	24.9	26.7	27.1
$30 \leq N < 40$	24.9	26.7	27.6
$40 \leq N$	25.0	27.5	28.1

Table 4: The performance (BLEU) of base CMLM with different amounts of mask-predict iterations (T) on WMT'14 EN-DE, bucketed by target sequence length (N). Decoding with $\ell = 1$ length candidates.

hypothesis, we measure the percentage of repetitive tokens produced by each iteration of mask-predict as a proxy metric for the multi-modality problem.

Table 3 shows that, indeed, the proportion of repetitive tokens drops drastically during the first 2-3 iterations. This finding suggests that the first few iterations are critical for converging into a uni-modal distribution. The decrease in repetitions also correlates with the steep rise in translation quality (BLEU), supporting the conjecture of Gu et al. (2018) that multi-modality is a major roadblock for purely non-autoregressive machine translation.

5.2 Do Longer Sequences Need More Iterations?

A potential concern with using a constant amount of decoding iterations is that it may be effective for short sequences (where the number of iterations T is closer to the output's length N), but insufficient for longer sequences. To determine whether this is the case, we use `compare-mt` (Neubig et al., 2019) to bucket the evaluation data by target sentence length and compute the performance with different values of T.

Table 4 shows that increasing the number of decoding iterations (T) appears to mainly improve the performance on longer sequences. Having said that, the performance differences across length buckets are not very large, and it seems that even 4 mask-predict iterations are enough to produce decent translations for long sequences ($40 \leq N$).

5.3 Do More Length Candidates Help?

Traditional autoregressive models can dynamically decide the length of the target sequence by generating a special `END` token when they are done, but that is not true for models that decode multiple tokens in parallel, such as CMLMs. To address this problem, our model predicts the length of the target sequence (Section 2.3) and decodes multiple length candidates in parallel (Section 3.3). We compare our model's performance with a varying number of length candidates to its performance when conditioned on the reference (gold) target length in order to determine how accurate it is at predicting the correct length and assess the relative contribution of decoding with multiple length candidates.

Length Candidates	WMT'14 EN-DE BLEU	WMT'14 EN-DE LP	WMT'16 EN-RO BLEU	WMT'16 EN-RO LP
$\ell = 1$	26.56	16.1%	32.75	13.8%
$\ell = 2$	27.03	30.6%	33.06	26.1%
$\ell = 3$	**27.09**	43.1%	**33.11**	39.6%
$\ell = 4$	**27.09**	53.1%	32.13	49.2%
$\ell = 5$	27.03	62.2%	33.08	57.5%
$\ell = 6$	26.91	69.5%	32.91	64.3%
$\ell = 7$	26.71	75.5%	32.75	70.4%
$\ell = 8$	26.59	80.3%	32.50	74.6%
$\ell = 9$	26.42	83.8%	32.09	78.3%
Gold	27.27	—	33.20	—

Table 5: The performance (BLEU) of base CMLM with 10 mask-predict iterations ($T = 10$), varied by the number of length candidates (ℓ), compared to decoding with the reference target length (Gold). Length precision (LP) is the percentage of examples that contain the correct length as one of their candidates.

Table 5 shows that having multiple candidates can increase performance almost as much as conditioning on the gold length. Surprisingly, adding too many candidates can even degrade performance. We suspect that because CMLMs are implicitly conditioned on the target length, producing a translation that is too short (i.e. high precision, low recall) will have a high average log probability. In preliminary experiments, we tried to address this issue by weighting the different candidates according to the model's length prediction, but this approach gave too much weight to the top candidate and resulted in lower performance.

Iterations	WMT'14 EN-DE		WMT'16 EN-RO	
	Raw	Dist	Raw	Dist
$T = 1$	10.64	**18.05**	21.22	**27.32**
$T = 4$	22.25	**25.94**	31.40	**32.53**
$T = 10$	24.61	**27.03**	32.86	**33.08**

Table 6: The performance (BLEU) of base CMLM, trained with either raw data (Raw) or knowledge distillation from an autoregressive model (Dist).

5.4 Is Model Distillation Necessary?

Previous work on non-autoregressive and insertion-based machine translation reported that it was necessary to train their models on text generated by an autoregressive teacher model, a process known as distillation. To determine CMLM's dependence on this process, we train a models on both raw and distilled data, and compare their performance.

Table 6 shows that in every case, training with model distillation substantially outperforms training on raw data. The gaps are especially large when decoding with a single iteration (purely non-autoregressive). Overall, it appears as though CMLMs are heavily dependent on model distillation.

On the English-Romanian benchmark, the differences are much smaller, and after 10 iterations the raw-data model can perform comparably with the distilled model. A possible explanation is that our teacher model was weaker for this dataset due to insufficient hyperparameter tuning. Alternatively, it could also be the case that the English-German dataset is much noisier than the English-Romanian one, and that the teacher model essentially cleans the training data. Unfortunately, we do not have enough evidence to support or refute either hypothesis at this time.

6 Related Work

Training Masked Language Models with Translation Data Recent work by Lample and Conneau (2019) shows that training a masked language model on sentence-pair translation data, as a pre-training step, can improve performance on cross-lingual tasks, including autoregressive machine translation. Our training scheme builds on their work, with the following differences: we use separate model parameters for source and target texts (encoder and decoder), and we also use a different masking scheme. Specifically, we mask a varying percentage of tokens, only from the target, and do not replace input tokens with noise. Most importantly, the goal of our work is different; we do not use CMLMs for pre-training, but to directly generate text with mask-predict decoding.

Concurrently with our work, Song et al. (2019) extend the approach of Lample and Conneau (2019) by using separate encoder and decoder parameters (as in our model) and pre-training them jointly in an autoregressive version of masked language modeling, although with monolingual data. While this work demonstrates that pre-training CMLMs can improve autoregressive machine translation, it does not try to leverage the parallel and bi-directional nature of CMLMs to generate text in a non-left-to-right manner.

Generating from Masked Language Models One such approach for generating text from a masked language model casts BERT (Devlin et al., 2018), a *non*-conditional masked language model, as a Markov random field (Wang and Cho, 2019). By masking a sequence of length N and then iteratively sampling a single token at each time from the model (either sequentially or in arbitrary order), one can produce grammatical examples. While this sampling process has a theoretical justification, it also requires N forward passes of the model; mask-predict decoding, on the other hand, can produce text in a constant number of iterations.

Parallel Decoding for Machine Translation There have been several advances in parallel decoding machine translation by training non-autoregressive models. Gu et al. (2018) introduce a transformer-based approach with explicit word fertility, and identify the multi-modality problem. Libovický and Helcl (2018) approach the multi-modality problem by collapsing repetitions with the Connectionist Temporal Classification training objective (Graves et al., 2006). Perhaps most similar to our work is the iterative refinement approach of Lee et al. (2018), in which the model corrects the original non-autoregressive prediction by passing it multiple times through a denoising autoencoder. A major difference is that Lee et al. (2018) train their noisy autoencoder to deal with corrupt inputs by applying stochastic corruption heuristics on the training data, while we simply mask a random number of input tokens. We also show that

our approach outperforms all of these models by wide margins.

Arbitrary Order Language Generation Finally, recent work has developed insertion-based transformers for arbitrary, but fixed, word order generation (Gu et al., 2019; Stern et al., 2019). While they do not decode in a constant number of iterations, Stern et al. (2019) show strong results in logarithmic time. Both models treat each token insertion as a separate training example, which cannot be computed in parallel with every other insertion in the same sequence. This makes training significantly more expensive that standard transformers (which use causal attention masking) and our CMLMs (which can predict all of the masked tokens in parallel).

7 Conclusion

This work introduces conditional masked language models and a novel mask-predict decoding algorithm that leverages their parallelism to generate text in a constant number of decoding iterations. We show that, in the context of machine translation, our approach substantially outperforms previous parallel decoding methods, and can approach the performance of sequential autoregressive models while decoding much faster. While there are still open problems, such as the need to condition on the target's length and the dependence on knowledge distillation, our results provide a significant step forward in non-autoregressive and parallel decoding approaches to machine translation. In a broader sense, this paper shows that masked language models are useful not only for representing text, but also for *generating* text efficiently.

Abstract

Automatic post-editing (APE), which aims to correct errors in the output of machine translation systems in a post-processing step, is an important task in natural language processing. While recent work has achieved considerable performance gains by using neural networks, how to model the copying mechanism for APE remains a challenge. In this work, we propose a new method for modeling copying for APE. To better identify translation errors, our method learns the representations of source sentences and system outputs in an interactive way. These representations are used to explicitly indicate which words in the system outputs should be copied, which is useful to help CopyNet (Gu et al., 2016) better generate post-edited translations. Experiments on the datasets of the WMT 2016-2017 APE shared tasks show that our approach outperforms all best published results. [1]

1 Introduction

Automatic post-editing (APE) is an important natural language processing (NLP) task that aims to automatically correct errors made by machine translation systems (Knight and Chander, 1994). It can be considered as an efficient way to modify translations to a specific domain or to incorporate additional information into translations rather than translating from scratch (McKeown et al., 2012; Chatterjee et al., 2015, 2018).

Approaches to APE can be roughly divided into two broad categories: *statistical* and *neural* approaches. While early efforts focused on statistical approaches relying on manual feature engineering (Simard et al., 2007; Béchara et al., 2011), neural network based approaches capable of learning representations from data have shown remarkable superiority over their statistical counterparts (Varis and Bojar, 2017; Chatterjee et al., 2017; Junczys-Dowmunt and Grundkiewicz, 2017; Unanue et al., 2018). Most of them cast APE as a multi-source sequence-to-sequence learning problem (Zoph and Knight, 2016): given a source sentence (src) and a machine translation (mt), APE outputs a post-edited translation (pe).

src	I ate a cake yesterday
mt	**Ich** esse **einen** Hamburger
pe	**Ich** hatte gestern **einen** Kuchen gegessen

Table 1: Example of automatic post-editing (APE). Given a source sentence (src) and a machine translation (mt), the goal of APE is to post-edit the erroneous translation to obtain a correct translation (pe). Our work aims to explicitly model how to copy words from mt to pe (highlighted in bold), which is a common phenomenon in APE.

A common phenomenon in APE is that many words in mt can be **copied** to pe. As shown in Table 1, two German words "Ich" and "einen" occur in both mt and pe. Note that the positions of copied words in mt and pe are not necessarily identical (e.g., "einen" in Table 1). Our analysis on the datasets of the WMT 2016 and 2017 APE shared tasks shows that over 80% of words in mt are copied to pe. As APE models not only need to decide which words in mt should be copied correctly, but also should place the copied words in appropriate positions in pe, it is challenging to model copying for APE. Our experiments show that the state-of-the-art APE method (Junczys-Dowmunt and Grundkiewicz, 2018) only achieves a copying accuracy of 64.63% (see Table 7).

We believe that existing approaches to APE (Varis and Bojar, 2017; Chatterjee et al., 2017; Junczys-Dowmunt and Grundkiewicz, 2017; Unanue et al., 2018) suffer from two major

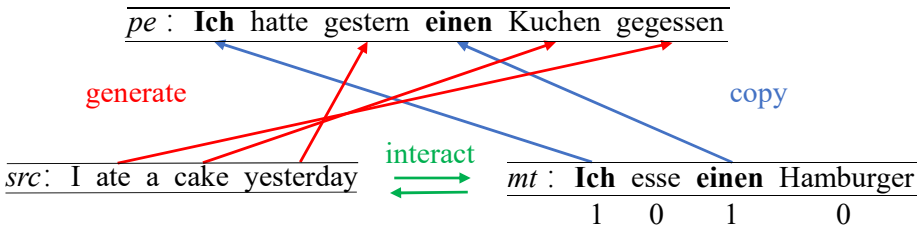

Figure 1: Learning to copy for APE. Our work is based on two key ideas. As both src and mt play important roles in APE, the first idea is that src and mt should "interact" with each other during representation learning to better generate words from src and copy words from mt during inference. The second idea is to predict which target words in mt should be copied since it is easy to obtain labeled data automatically by comparing mt and pe. The words to be copied (e.g., "Ich") in mt are labeled with 1's and other words (e.g., "esse") with 0's.

drawbacks when modeling the copying mechanism. First, the representations of src and mt are learned separately. APE is a two-source sequence-to-sequence learning problem in which both src and mt play important roles. On the one hand, if src is ignored, it is difficult to identify translation errors related to adequacy in mt, especially for fluent but inadequate translations (e.g., mt in Figure 1). On the other hand, mt serves as a major source for generating pe since many words (e.g., "Ich" and "einen" in Figure 1) are copied from mt to pe. Intuitively, it is likely to be easier to decide which words in mt should be copied if src and mt fully "interact" with each other during representation learning. Although CopyNet (Gu et al., 2016) can be adapted for explicitly modeling the copying mechanism in multi-source sequence-to-sequence learning, the lack of the interaction between src and mt still remains a problem.

Second, there is no explicit labeling that indicates which target words in mt should be copied. Existing approaches only rely on the attention between the encoder and decoder to implicitly choose target words to be copied. Given mt and pe, it is easy to decide whether a target word in mt should be copied or not. In Figure 1, the words in mt that should be copied are labeled with 1's. Other words are labeled with with 0's, which should be re-generated from src. These labels can served as useful supervision signals to help better copy words from mt to pe, even when CopyNet is used.

In this work, we propose a new method for modeling the copying mechanism for APE. As shown in Figure 1, our work is based on two key ideas. First, our method is capable of learning the representations of input in an interactive way by enabling src and mt to attend to each other during representation learning. This might be useful for deciding when to generate words from src and when to copy words from mt during post-editing. Second, it is possible to predict which words in mt should be copied because it is easy to automatically construct labeled data by comparing mt and pe. Such predictions can be combined with CopyNet to better model copying for APE. Experiments show that our approach outperforms the best published results on the datasets of the WMT 2016-2017 APE shared tasks.

2 Background

2.1 Multi-source Sequence-to-Sequence Learning

Multi-source sequence-to-sequence learning has been widely used in APE in recent years (Junczys-Dowmunt and Grundkiewicz, 2018; Pal et al., 2018; Tebbifakhr et al., 2018; Shin and Lee, 2018). The architecture of multi-source Transformer is shown in Figure 2(a). It can be equipped with CopyNet (see Section 2.2) to serve as a baseline in our experiments. It is worth noting that src and mt are encoded separately.

Let $\mathbf{x} = x_1 \dots x_I$ be a source sentence (i.e., src) with I words, $\tilde{\mathbf{y}} = \tilde{y}_1 \dots \tilde{y}_K$ be a translation output by a machine translation system (i.e., mt) with K words, and $\mathbf{y} = y_1 \dots y_J$ be the post-edited translation (i.e., pe) with J words. The APE model is given by

$$P(\mathbf{y}|\mathbf{x}, \tilde{\mathbf{y}}; \boldsymbol{\theta}) = \prod_{j=1}^{J} P(y_j|\mathbf{x}, \tilde{\mathbf{y}}, \mathbf{y}_{<j}; \boldsymbol{\theta}), \quad (1)$$

where y_j is the j-th target word in pe, $\mathbf{y}_{<j} = y_1 \dots y_{j-1}$ is a partial translation, $\boldsymbol{\theta}$ is a set of model parameters, and $P(y_j|\mathbf{x}, \tilde{\mathbf{y}}, \mathbf{y}_{<j}; \boldsymbol{\theta})$ is a word-level translation probability.

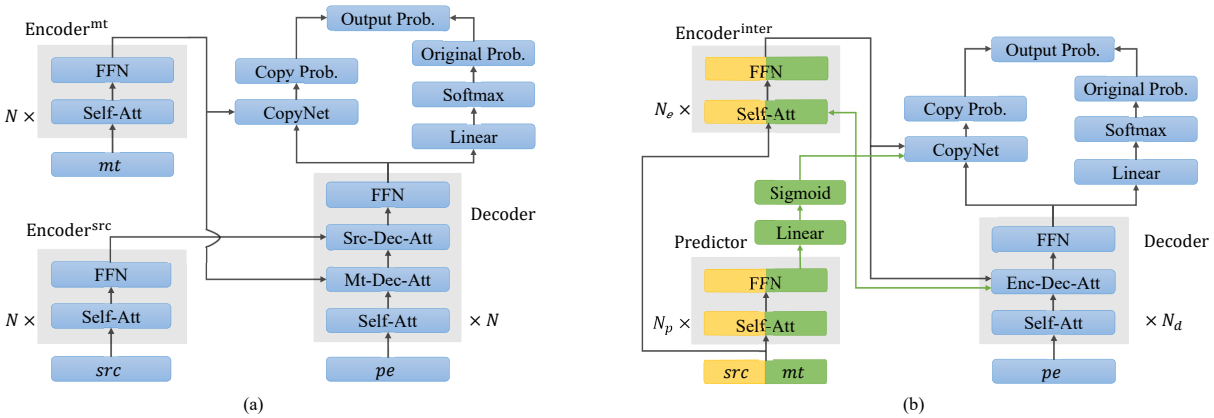

Figure 2: (a) The architecture of multi-source Transformer (Junczys-Dowmunt and Grundkiewicz, 2018) equipped with CopyNet (Gu et al., 2016) and (b) the architecture of our approach. While the existing work learns the representations of src and mt separately, our approach allows for learning the representations of src and mt in an interactive way by concatenating them as a single input. In addition, our approach introduces a Predictor module to explicitly indicate which words in mt should be copied.

The word-level translation probability in Eq. (1) is computed as

$$\mathbf{H}^{\text{src}} = \text{Encoder}^{\text{src}}(\mathbf{x}, \boldsymbol{\theta}), \quad (2)$$

$$\mathbf{H}^{\text{mt}} = \text{Encoder}^{\text{mt}}(\tilde{\mathbf{y}}, \boldsymbol{\theta}), \quad (3)$$

$$\mathbf{h}_j^{\text{pe}} = \text{Decoder}(\mathbf{y}_{<j}, \mathbf{H}^{\text{src}}, \mathbf{H}^{\text{mt}}, \boldsymbol{\theta}), \quad (4)$$

$$P(y_j|\mathbf{x}, \tilde{\mathbf{y}}, \mathbf{y}_{<j}; \boldsymbol{\theta}) \propto \exp(\mathbf{h}_j^{\text{pe}} \mathbf{W}_g), \quad (5)$$

where $\text{Encoder}^{\text{src}}(\cdot)$ is the encoder for src, $\mathbf{H}^{\text{src}}$ is the real-valued representation of src, $\text{Encoder}^{\text{mt}}(\cdot)$ is the encoder for mt, $\mathbf{H}^{\text{mt}}$ is the representation of mt, $\text{Decoder}(\cdot)$ is the decoder, $\mathbf{h}_j^{\text{pe}}$ is the representation of the j-th target word y_j in pe. $\mathbf{W}_g \in \mathbb{R}^{d \times \mathcal{V}_y}$ is a weight matrix, d is the dimension of hidden states, and $\mathcal{V}_y$ is the target vocabulary size.

A limitation of the aforementioned model is that src and mt are encoded separately without interacting with each other, which might lead to the inability to find which src word is untranslated and which mt word is incorrect. For example, the mt sentence in Figure 1 is fluent and meaningful. Without src, the APE system is unable to identify translation errors. In addition, the multi-source Transformer does not explicitly model the copying between mt and pe in neither the Encoder nor the Decoder.

2.2 CopyNet

CopyNet (Gu et al., 2016) is a widely used method for modeling copying in sequence-to-sequence learning. It has been successfully applied to single-turn dialogue (Gu et al., 2016), text summarization (See et al., 2017), and grammar error correction (Zhao et al., 2019).

It is possible to extend the multi-source Transformer with CopyNet to explicitly model the copying mechanism, as shown in Figure 2(a). CopyNet defines the word-level translation probability in Eq. (1) as a linear interpolation of copying and generating probabilities:

$$P(y_j|\mathbf{x}, \tilde{\mathbf{y}}, \mathbf{y}_{<j}; \boldsymbol{\theta}) = \gamma_j \times P^{\text{copy}}(y_j) + (1 - \gamma_j) \times P^{\text{gen}}(y_j), \quad (6)$$

where $P^{\text{copy}}(y_j)$ is the copying probability for y_j, $P^{\text{gen}}(y_j)$ is the generating probability for y_j, and γ_j is a gating weight. They are defined as follows:

$$P^{\text{copy}}(y_j) \propto \exp(g(\mathbf{H}^{\text{mt}}, \mathbf{h}_j^{\text{pe}})), \quad (7)$$

$$P^{\text{gen}}(y_j) \propto \exp(\mathbf{h}_j^{\text{pe}} \mathbf{W}_g), \quad (8)$$

$$\gamma_j = u(\mathbf{H}^{\text{mt}}, \mathbf{h}_j^{\text{pe}}), \quad (9)$$

where $g(\cdot)$ and $u(\cdot)$ are non-linear functions. See (Zhao et al., 2019) for more details.

Copying in APE involves two kinds of decisions: (1) choosing words in mt to be copied and (2) placing the copied words in appropriate positions in pe. CopyNet makes the two kinds of decisions simultaneously. We conjecture that if which words in mt should be copied can be explicitly indicated, it might be easier for CopyNet to copy words from mt to pe correctly. Therefore, it is necessary to design a new method for identifying words to be copied.

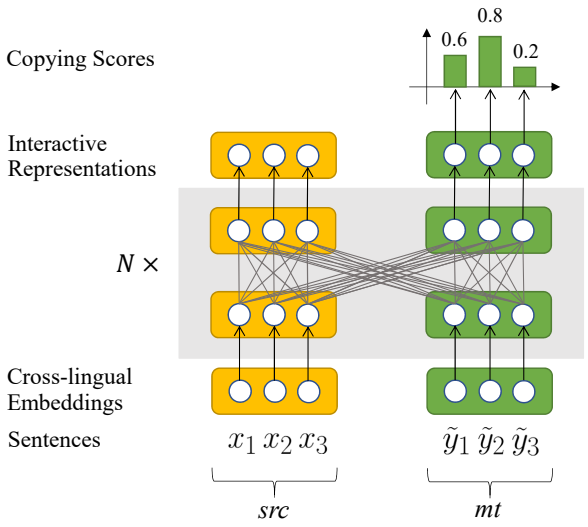

Figure 3: Interactive representation learning. Concatenated to serve as a single input, src and mt attend to each other during representation learning. Note that learnable weights of src and mt are shared. Interactive representation learning is used in both Predictor and Encoder. For example, copying scores are predicted based on the learned representations (see Eq. (13)).

3 Approach

Figure 2(b) shows the overall architecture of our approach. It differs from previous work in two aspects. First, we propose to let src and mt "interact" with each other to learn better representations (Section 3.1). Second, our approach introduces a Predictor module to predict words to be copied (Section 3.2). Section 3.3 describes how to train our APE model.

3.1 Interactive Representation Learning

We propose an interactive representation learning method by making src and mt attend to each other. Following Lample and Conneau (2019) and He et al. (2018), we concatenate src and mt in the dimension of sentence length with additional position and language embeddings:

$$\mathbf{X}_i = \mathbf{E}^{\text{token}}[x_i] + \mathbf{E}^{\text{pos}}[i] + \mathbf{E}^{\text{lang}}[0], \quad (10)$$

$$\tilde{\mathbf{Y}}_k = \mathbf{E}^{\text{token}}[\tilde{y}_k] + \mathbf{E}^{\text{pos}}[k] + \mathbf{E}^{\text{lang}}[1], \quad (11)$$

where $\mathbf{X}_i$ is the embedding of the i-th source word x_i, $\tilde{\mathbf{Y}}_k$ is the embedding of the k-th target word $\tilde{y}_k$, and $\mathbf{E}^{\text{token}}$, $\mathbf{E}^{\text{pos}}$, and $\mathbf{E}^{\text{lang}}$ are the token, position and language embedding matrices.

As shown in Figure 3, the representation of src and mt can be learned jointly:

$$\mathbf{H}^{\text{inter}} = \text{Encoder}^{\text{inter}}([\mathbf{X}; \tilde{\mathbf{Y}}], \boldsymbol{\theta}), \quad (12)$$

where $\text{Encoder}^{\text{inter}}(\cdot)$ is the interactive Encoder and $[\mathbf{X}; \tilde{\mathbf{Y}}]$ is the concatenation of $\mathbf{X}$ and $\tilde{\mathbf{Y}}$ in the dimension of sentence length.

As shown in Figure 2(b), the multi-source Encoders are replaced by the interactive Encoder, which enables src and mt to attend to each other.[2] We expect that enabling the interactions between them can help to strengthen the ability of the model to find which words in src is untranslated and which words in mt is correct. Note that interactive representation learning is used both in Predictor and Encoder. In the following, we will describe how to predict which words in mt should be copied based on these learned representations.

3.2 Predicting Words to be Copied

Given mt and pe, we can label each word in mt as 0 or 1. We use 1 to denote that the word is to be copied (e.g. "Ich" and "einen" in Figure 1) and 0 not to be copied (e.g. "esse" and "Hamburger" in Figure 1). It is possible to use the Longest Common Sequence (LCS) (Wagner and Fischer, 1974) algorithm to obtain common sequences between mt and pe. If the word in mt also appears in the common sequences, it will be labeled 1; otherwise, it will be labeled 0. We denote these labels as $l_1 \dots l_K$.

We propose a Predictor module to predict words to be copied. As discrete labels are non-differentiable during training, the Predictor module outputs **copying scores** instead for the target words in mt:

$$\mathbf{s} = \text{sigmoid}([\mathbf{H}^{\text{pred}}_{I+1}; \cdots; \mathbf{H}^{\text{pred}}_{I+K}]\mathbf{W}_s), \quad (13)$$

where $\mathbf{s} \in \mathbb{R}^{K\times 1}$ is a vector of copying scores corresponding to the K words in mt, $\mathbf{H}^{\text{pred}} \in \mathbb{R}^{(I+K)\times d}$ is the representation of src and mt:

$$\mathbf{H}^{\text{pred}} = \text{Predictor}([\mathbf{X}; \tilde{\mathbf{Y}}]; \boldsymbol{\theta}), \quad (14)$$

and $\mathbf{W}_s \in \mathbb{R}^{d\times 1}$ is a weight matrix. Only the representation of mt (i.e., $[\mathbf{H}^{\text{pred}}_{I+1}; \cdots; \mathbf{H}^{\text{pred}}_{I+K}]$) is used for calculating copying scores. [3]

As shown in Figure 2(b), copying scores can be incorporated into three parts of our model: the

[2] Note that the Predictor and Encoder do not share their weights because we found that sharing leads to degraded performance in experiments.

[3] It is also possible to predict which source words in src should be used to generate non-copied words in pe (e.g., "Kuchen" in Figure 1). This can be done by generating explicit labels using bilingual word alignment. We leave this for future work.

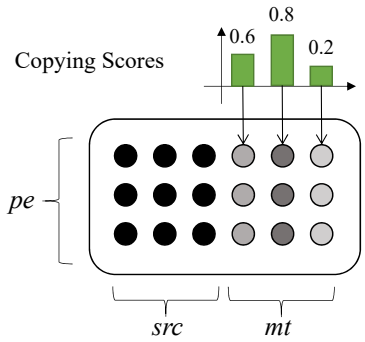

Figure 4: Copying scores as scaling masks. The copying scores are used to modify the attention layers of the Encoder, Decoder, and CopyNet.

Encoder, the Decoder, and the CopyNet. Inspired by Yang et al. (2018)'s strategy to integrate localness to self-attention, we propose to incorporate copying scores into our model by modifying attention weights involved in the aforementioned three modules.

The original scaled dot-product attention (Vaswani et al., 2017) is defined as

$$\text{energy} = \frac{\mathbf{q}\mathbf{K}^\top}{\sqrt{d}}, \tag{15}$$

$$\text{Att}(\mathbf{q}, \mathbf{K}) = \text{softmax}(\text{energy}), \tag{16}$$

where $\mathbf{q} \in \mathbb{R}^{1\times d}$ is the query vector, $\mathbf{K} \in \mathbb{R}^{(I+K)\times d}$ is the key matrix, and $\text{energy} \in \mathbb{R}^{1\times(I+K)}$ is the "energy" vector.

As shown in Figure 4, the copying scores can be used to form a scaling mask on the attention sub-layer:[4]

$$\text{Att}(\mathbf{q}, \mathbf{K}) = \text{softmax}\left(\text{energy} \odot [\mathbf{m}; \mathbf{s}]^\top\right), \tag{17}$$

where $\mathbf{m} = \{1.0\}^I$ is a masking vector corresponding to src and $\mathbf{s} \in \mathbb{R}^{K\times 1}$ is the vector of copying scores calculated by Eq. (13) corresponding to mt. Note that copying scores are used to only change the attention weights related to mt while the src part is unchanged.

3.3 Training

The training objective of our approach $L_{\text{all}}(\boldsymbol{\theta})$ consists of three parts:

$$L_{\text{all}}(\boldsymbol{\theta}) = (1-\alpha) \times (L_{\text{ape}}(\boldsymbol{\theta}) + \lambda \times L_{\text{copy}}(\boldsymbol{\theta})) + \alpha \times L_{\text{pred}}(\boldsymbol{\theta}), \tag{18}$$

where α and λ are hyper-parameters.

The first part is the original log-likelihood loss function of APE: [5]

$$L_{\text{ape}}(\boldsymbol{\theta}) = -\log P(\mathbf{y}|\mathbf{x}, \tilde{\mathbf{y}}; \boldsymbol{\theta}). \tag{19}$$

The second part is related to the CopyNet:

$$L_{\text{copy}}(\boldsymbol{\theta}) = \frac{1}{K}\sum_{k=1}^{K}(l_k - c_k)^2, \tag{20}$$

where l_k is the ground-truth label (see Section 3.2) and c_k is a quantity that measures how likely the k-th word in mt to be copied by CopyNet:

$$c_k = \sum_{j=1}^{J} \gamma_j \times P^{\text{copy}}(\tilde{y}_k). \tag{21}$$

Note that $\gamma \times P^{\text{copy}}(y)$ is the term related to copying the target word y in Eq. (6).

The third part is a cross-entropy loss related to the Predictor:

$$L_{\text{pred}}(\boldsymbol{\theta}) = -\sum_{k=1}^{K}\Big[l_k \log(s_k) + (1-l_k)\log(1-s_k)\Big], \tag{22}$$

where s_k is the copying score of the k-th word $\tilde{y}_k$ in mt.

Finally, we use an optimizer to find the model parameters that minimize the overall loss function:

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\text{argmin}}\left\{L_{\text{all}}(\boldsymbol{\theta})\right\}. \tag{23}$$

4 Experiments

4.1 Setup

Datasets

We evaluated our approach on the WMT APE datasets, which often distinguish between two tasks: phrase-based statistical machine translation (i.e., PBSMT) and neural machine translation (i.e., NMT). All these APE datasets consist of English-German triplets containing source text (src), the translations (mt) from a "black-box" MT system and the corresponding human-post-edits (pe). The statistics for the WMT APE datasets are shown in Table 2. In addition to the official dataset, the organizers also recommend using additional datasets

[4] Actually, we let "energy" vector minus its minimum value to keep it non-negative.

[5] For simplicity, we use sentence-level loss functions here. In practice, we use corpus-level loss functions.

Category	Dataset	# Sent.
PBSMT	training set	23,000
	dev2016	1,000
	test2016	2,000
	test2017	2,000
NMT	training set	13,442
	dev2018	1,000
Additional	artificial-small	526,368
	artificial-big	4,391,180
	eSCAPE-PBSMT	7,258,533
	eSCAPE-NMT	7,258,533

Table 2: Statistics of the English-German datasets in the WMT APE task. Note that the NMT official data only contains training and development sets.

(Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2014).

We used the WMT official dataset for the PBSMT task and the NMT task separately. The artificial training data (Junczys-Dowmunt and Grundkiewicz, 2016) was also used for both tasks. More precisely, we used the concatenation of the official training data and the artificial-small data to learn a truecasing model (Koehn et al., 2007) and obtain sub-word units using byte-pair encoding (BPE) (Sennrich et al., 2015) with 32k merges. Then, we applied truecasing and BPE to all datasets. We oversampled the official training data 20 times and concatenated them with both artificial-small and artificial-big datasets (Junczys-Dowmunt and Grundkiewicz, 2018). Finally, we obtained a dataset containing nearly 5M triplets for both tasks. To test our approach on a larger PBSMT dataset, we used the eSCAPE synthetic dataset (Negri et al., 2014), which contains 7.2M sentences. By including the eSCAPE dataset, the training set is enlarged to nearly 12M sentences.

Hyper-Parameter Settings

For the original Transformer model, CopyNet and our approach, the hidden size was set to 512 and the filter size was set to 2,048. The number of individual attention heads was set to 8 for multi-head attention. We set $N = N_e = N_d = 6$, $N_p = 3$ and we tied all three src, mt, pe embeddings for saving memory. The embeddings and softmax weights were also tied. In training, we used Adam (Kingma and Ba, 2014) for optimization. Each mini-batch contains approximately 25K tokens. We used the learning rate decay policy described by (Vaswani et al., 2017). In decoding, the beam size was set to 4. We used the length penalty (Wu et al., 2016) and set the hyper-parameter to 1.0. The other hyper-parameter settings were the same as the Transformer model (Vaswani et al., 2017). We implemented our approach on top of the open-source toolkit THUMT (Zhang et al., 2017).[6]

α	λ	TER↓	BLEU↑
0.1	1.0	18.83	72.59
0.5	1.0	18.45	72.83
0.9	0.1	18.89	72.27
0.9	0.5	18.47	72.83
0.9	1.0	**18.38**	**72.99**

Table 3: Effect of α and λ. The TER and BLEU scores are calculated on the WMT 2016 APE official development set.

Evaluation Metrics

We used the same evaluation metrics as the official WMT APE task (Chatterjee et al., 2018): case-sensitive BLEU and TER. BLEU is computed by *multi-bleu.perl* (Koehn et al., 2007). TER is calculated using TERcom.[7]

Baselines

We compared our approach with the following seven baselines:

1. ORIGINAL: the original mt without any post-editing.
2. COPYNET (Gu et al., 2016; Zhao et al., 2019): the multi-source Transformer equipped with CopyNet (see Figure 2(a)).
3. NPI-APE (Vu and Haffari, 2018): a neural programmer-interpreter approach.
4. MS_UEDIN (Junczys-Dowmunt and Grundkiewicz, 2018): a multi-source Transformer-based APE system that shares the encoders of src and mt. It is the champion of the WMT 2018 APE shared task.
5. USAAR_DFKI (Pal et al., 2018): a multi-source Transformer-based APE system with a joint encoder that attends over a combination of two encoded sequences. It is a participant of the WMT 2018 APE shared task.

Table 4: Results on the English-German PBSMT sub-task. "TEST16+17" is the concatenation of "TEST16" and "TEST17". MS_UEDIN$_{\text{ensemble}}$ and Ours$_{\text{ensemble}}$ used ensembles of four models.

6. POSTECH (Shin and Lee, 2018): a multi-source Transformer-based APE system with two encoders. It is a participant of the WMT 2018 APE shared task.

7. FBK (Tebbifakhr et al., 2018): a multi-source Transformer-based APE system with two encoders. It is a participant of the WMT 2018 APE shared task.

We implemented COPYNET also on top of THUMT (Zhang et al., 2017). The results of all other baselines were taken from the corresponding original papers.

4.2 Effect of Hyper-parameters

We first investigated the effect of the hyper-parameters α and λ in Eq. (18). As shown in Table 3, using $\alpha = 0.9$ and $\lambda = 1.0$ achieves the best performance in terms of TER and BLEU on the WMT 2016 development set, suggesting that both the Predictor and CopyNet play important roles in our approach. Therefore, we set $\alpha = 0.9$ and $\lambda = 1.0$ in the following experiments.

4.3 Main Results

Results on the PBSMT Sub-task

Table 4 shows the results of the PBSMT sub-task. We used the development set of the WMT 2016 APE PBSMT sub-task for model selection for our approach.

Under the small-data training condition (i.e., 5M), our single model (i.e., System 7) outperforms all single-model baselines on all test sets. The superiority over COPYNET (i.e., System 6) suggests that interactive representation learning and incorporating copying scores are effective in improving APE. Our approach that uses the ensemble of four models (i.e., System 8) also improves over the best published result (i.e., System 5).

Under the large-data training condition (i.e., 12M), we find that our single (i.e., System 12) and ensemble (i.e., System 13) models still outperform the best single (i.e., System 11) and ensemble (i.e., System 10) models of baselines.

Table 6: Ablation study. "Interactive" denotes interactive representation learning (Section 3.1), "Predictor" denotes detecting correct words (Section 3.2), "CopyNet" denotes the CopyNet used in our approach (Section 2.2), and "Joint Training" denotes the combination of three loss functions (Section 3.3).

Results on the NMT Sub-task

Table 5 shows the results on the NMT sub-task. Besides ORIGINAL and COPYNET, we also compared our approach with POSTECH (Shin and Lee, 2018), which is the only participating system that released the results on the development set of the WMT 2018 NMT sub-task.[8] We find that our approach also outperforms all baselines.

4.4 Ablation Study

Table 6 shows the results of ablation study. It is clear that interactive representation learning plays a critical role since removing it impairs post-editing performance (line 3). As shown in line 4, the Predictor is also an essential part of our approach. CopyNet and joint training are also shown to be beneficial for improving APE (lines 5 and 6) but seem to have relatively smaller contributions than interactive representation learning and predicting words to be copied.

4.5 Results on Prediction Accuracy

The Predictor is an important module in our approach as it predicts which words in mt should be copied. Given the ground-truth labels, it is easy to calculate *prediction accuracy* by casting the prediction as a binary classification problem. We find that the Predictor achieves a prediction accuracy of 85.09% on the development set.

4.6 Comparison of Copying Accuracies

A target word y in a machine translation $\tilde{\mathbf{y}}$ is called to be *correctly* copied to an automatic edited translation $\hat{\mathbf{y}}$ if and only if the positions where y occurs in $\hat{\mathbf{y}}$ and $\mathbf{y}$ (i.e., the ground-truth edited translation) are identical. Therefore, it is easy to define copying accuracy to measure how well the copying mechanism works.

System	Accuracy
MS_UEDIN	64.63
COPYNET	64.72
Ours	**65.61**

Table 7: Comparison of copying accuracies.

Table 7 shows the comparison of copying accuracies between MS_UEDIN, COPYNET, and our approach. We find that our approach outperforms the two baselines. However, the copying accuracy of our approach is almost 20% lower than the prediction accuracy (i.e., 65.61% vs. 85.09%), indicating that it is much more challenging to place the copied words in correct positions.

4.7 Visualization

Figure 5 gives an example that illustrates how copying scores influence attention. It shows the heatmap of the Enc-Dec-Attention, which averages over 8 different heads. Only the attention weights beween pe and mt are included. We take the second layer of Enc-Dec-Attention for example. The x-axis represents mt and the y-axis represents pe. The darker the color, the higher the copying scores.

We find that words "mit" and "dem" are identified by the Predictor. Accordingly, the attention weights corresponding to these words are decreased since the columns corresponding to these words have lighter color. As a result, all words in mt other than "mit" and "dem" are copied to pe.

[8] As POSTECH only used small data for training, the eSCAPE datasets were not used in this experiment for a fair comparison.

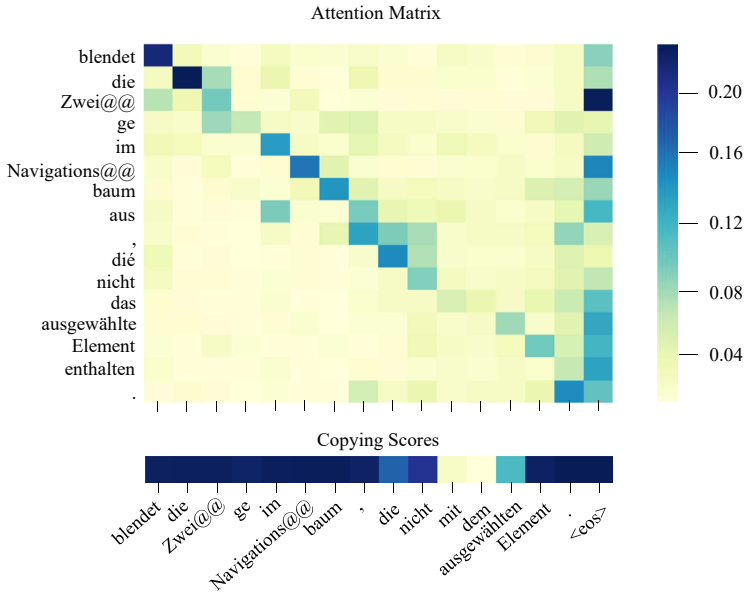

Figure 5: Example of the heatmap of attention and copying scores. The x-axis is mt and the y-axis is pe. The Predictor successfully detects the incorrect word "mit" and "dem" and gives low copying scores to these words and then decrease the importance of them in attention. Other words in mt are correctly copied to pe.

5 Related Work

5.1 Multi-source Sequence-to-Sequence Learning

Recently, multi-source Transformer-based APE systems (Junczys-Dowmunt and Grundkiewicz, 2018; Pal et al., 2018; Tebbifakhr et al., 2018; Shin and Lee, 2018) have achieved the state-of-the-art results on the datasets of the WMT APE shared task. Our work differs from prior studies by enabling interactions between src and mt and explicitly detecting words to be copied.

5.2 The Copying Mechanism

Zhao et al. (2019) apply CopyNet (Gu et al., 2016) to grammar error correction. Their approach generates labels similar to ours, but only uses them to perform mutli-task learning. Libovický et al. (2016) first introduce CopyNet to APE but do not provide a detailed description of their method and experimental results. We show that interactive representation learning and explicit indication of words are important for modeling copying in APE.

5.3 Interactive Representation Learning

Niehues et al. (2016) simply concatenate the output of the PBSMT system and the source sentence to serve as the input the NMT system without enabling multi-layer interactive learning. Lample and Conneau (2019) used cross-lingual setting to enable cross-lingual language model pre-training. We propose to let src and mt fully interact with each other to make it easier to decide which words in mt should be copied.

6 Conclusion

We have presented a new method for modeling the copying mechanism for automatic post-editing. By making the source sentence and machine translation attend to each other, representations learned in such an interactive way help to identify whether a target word should be copied or be re-generated. We also find that explicitly predicting words to be copied is beneficial for improving the performance of post-editing. Experiments show that our approach achieves new state-of-the-art results on the WMT 2016 & 2017 APE PBSMT sub-tasks.

Exploring Human Gender Stereotypes with Word Association Test

Yupei Du , Yuanbin Wu , and Man Lan

Abstract

Word embeddings have been widely used to study gender stereotypes in texts. One key problem regarding existing bias scores is to evaluate their validities: do they really reflect true bias levels? For a small set of words (e.g. occupations), we can rely on human annotations or external data. However, for most words, evaluating the correctness of them is still an open problem. In this work, we utilize word association test, which contains rich types of word connections annotated by human participants, to explore how gender stereotypes spread within our minds. Specifically, we use random walk on word association graph to derive bias scores for a large amount of words. Experiments show that these bias scores correlate well with bias in the real world. More importantly, comparing with word-embedding-based bias scores, it provides a different perspective on gender stereotypes in words.[1]

1 Introduction

Consciously or not, gender stereotypes can be found in many places in our life. From proportions of female in certain occupations, to students' choices on their majors, from the stories people been told in books and movies, to the decisions they make every day, researchers try to build different stereotype models, to understand patterns behind various gender-related social and psychological phenomena.

Here, we investigate gender bias using the lens of language, especially, the words. Recent studies have shown that, by learning from large amounts of texts, low dimensional word embeddings (Mikolov et al., 2013) can exhibit human gender bias: the vector of "engineer" is more close to "he" than "she" (Bolukbasi et al., 2016). What's more insightful is that the revealed bias correlates well with census data, and its trends on historical texts matches women's movements in 1960-1970s (Garg et al., 2017). Thus word embeddings might be a reasonable tool in the study of gender stereotypes.

In this work, we try to resolve two problems regarding existing word-embedding-based bias scores. First, most embeddings are trained on word co-occurrence information in texts: "engineer" co-occurs with "he" more often than "she" in corpus. Since co-occurrence is only one of the various relations among words, it is natural to ask whether other types of relations can also reflect gender bias. Second, the validity of word-embedding-based bias scores are often examined using a small set of occupation words (i.e., how they correlate with occupation statistics in the real world) or a small set of human annotated words. How to evaluate validities of bias scores on the remaining large amount of words is still an open problem.

In order to answer these questions, we depart from existing models and explore a new tool for quantifying gender bias of words. Our method utilizes a recent result of large-scale word association test (De Deyne et al., 2018). In this test, participants are given a *cue* word and asked to write down most related words (*responses*) in their minds. Comparing with the co-occurrence relation, which subjects to contexts and topics of a document, word association test bears a more direct interaction with human brains. Therefore, it may provide a more detailed profile on human gender stereotypes.

We build a word association graph based on records of cue-response pairs. The vertices represent words, and an edge indicates whether two words are associated in some tests. With this

graph, we can study how gender bias propagates among words using various graph-based algorithms. For example, a random walk starting from "he" and "she" can be applied to model the stochastic behaviors in real association tests, and the probabilities of reaching a word can be seen as its distances to "he" and "she". One advantage of graph-based models is that the derived bias scores are characterized by the intrinsic structure of the word association graph. Therefore, if we roughly assume the word association graph is an externalization of concept networks in human brains, as properties of the graph, the bias scores can be seen as a benchmark to help examining validities of other models.

In empirical evaluations, we compare the word-embedding-based bias scores with our word-association-based bias scores. First, regarding the real world census data and human annotations, word-association-based scores show stronger correlations than vanilla word-embedding-based scores. Second, as embeddings could also be applied for building graphs, we investigate such graphs and look into their differences with the word association graph. It turns out that both kinds of graphs exhibit "small world" properties, but they have different hub words and connecting mechanisms. We then run the same stereotype propagation algorithm and compare the derived gender bias scores. Third, as a case study, we use word-association-based scores as a benchmark to see the effectiveness of existing de-bias algorithms on word embeddings (Bolukbasi et al., 2016; Zhao et al., 2018). The results suggest that it is hard for both de-bias algorithms to remove gender stereotypes in word embeddings completely, which matches the conclusion in (Gonen and Goldberg, 2019).

2 Word Association Test

Word association test is a simple and sometimes entertaining game in which participants are asked to respond with the first several words that come out in their mind (the response) after being presented with a word (the cue)[2]. Table 1 lists some examples of the test. It is considered to be one of the most straightforward approaches for gaining insight into our semantic knowledge (Steyvers and Tenenbaum, 2005), and is also a common approach to measure words' meanings in our mind (so called mental lexicons (Jackendoff and Jackendoff, 2002)). For studies of gender stereotypes, word association test provides a way to inspect how a gender-specific word (e.g., "he", "she") connecting with other words, and the patterns of the connections may help us to probe gender stereotypes in our brains.

Cue	R1	R2	R3
way	path	via	method
extra	plus	special	additional
i	you	me	eye
come	go	closer	on
than	then	there	though
son	daughter	sun	boy
mind	brain	cognition	thinking

Table 1: Examples of word association test records in SWOWEN datasets (De Deyne et al., 2018). R1, R2, R3 are participants' responses.

Several collections of English word association test records are publicly available (Nelson et al., 2004; Moss et al., 1996; Kiss et al., 1973). In this work, we focus on SWOWEN (De Deyne et al., 2018), which is currently the largest English word association database. The dataset is collected from 2011 to 2018, and contains more than 12000 cues and responses from over 90000 participants. The collection process begins with a small number of words as a word pool. Every time a participant starts a new test, a cue word is sampled randomly from the word pool. Once a new word not in the word pool is associated, it is added into the pool. This snowball sampling method helps to include both frequent and less-frequent cues at the same time.

3 Word Association Graph

Based on a table of word association test results, we try to figure out a complete picture on how gender biases are embedded in the test. We build a word association graph $G = (V, E)$ whose vertices V are cues and responses, edges E encode associations in the test, and weights of edges represent the strength of associations. Specifically, we take the following steps.

Pre-Processing Our pre-processing steps are mostly based on De Deyne et al. (2018)[3]. These

[2] https://en.wikipedia.org/wiki/Word_Association

[3] Raw word association test results and pre-process scripts are available in https://github.com/SimonDeDeyne/SWOWEN-2018. We re-implement

procedures consist of spell-check, unifying cue forms, removing untrustworthy participants, and Americanize all non-American spellings. Through these steps, we reduce word association records from 88722 participants, 12292 cues, and 4069086 responses to 83863 participants, 12217 cues, and 3665100 responses.

Counting Association Pairs We set all preprocessed cues and responses as vertices. An edge is added if it corresponds to a cue-response pair (directions of pairs are ignored for simplicity), and we count the occurrence numbers for edges as their weights. The final graph G contains 12217 nodes and 1283047 edges.

Next, we will study how the gender bias propagates in G. More concretely, we investigate how gender information transit from a set of *gender-specific words* (i.e., words related with a gender by definition, such as "he", "she", "man", "woman") to other words. We obtain bias scores for *every* word based on the propagation and the graph structure, then we use them as a benchmark for evaluating validities of other models.

4 Stereotype Propagation

In the literature of psychology, Dell (1986) proposes a mental process in which words can spread its meaning by word associations. This theory suggests that once a gender-specific word in word association graph is activated, its influence will propagate along graph edges and form gender stereotypes. If a gender-neutral word (e.g. *nurse*) has stronger connections with gender-specific words in one gender (e.g. feminine words) than the other one, this gender-neutral word will receive imbalanced gender information, leading to unnecessary gender tendency. We thus tend to relate *nurse* more tightly with a woman than a man.

To characterize stereotypes of words, we simulate this mental process by spreading gender information from a set of commonly used gender-specific words $\mathcal{L}$ to the whole graph, using a random walk approach (Zhou et al., 2003). After enough iterations, gender information received by each word will eventually converge. Then we can calculate bias scores by seeing how much gender information they have received. We call this method *stereotype propagation*.

First, we build the set of gender-specific words

he / she	brother / sister
father / mother	man / woman
son / daughter	boy / girl
husband / wife	uncle / aunt
grandfather / grandmother	gentleman / lady

Table 2: Gender-specific word pairs in $\mathcal{L}$.

$\mathcal{L}$. In order to balance influence from different genders and avoid their heterogeneity, we collect them pair-by-pair. Specifically, $\mathcal{L} = \{(w_m^k, w_f^k)\}_{k=1}^{|\mathcal{L}|}$, where w_m^k (a *masculine word*) and w_f^k (a *feminine word*) are semantically related but different in gender. Table 2 is the $\mathcal{L}$ we use by default.

For each word, we use a 2-dimension vector (b_m, b_f) to record the amount of gender information they will receive from masculine words (b_m) and feminine words (b_f). Let $P \in \mathbb{R}^{|V|\times 2}$ be the matrix containing vectors of all words, and P_0 be the initial state of P. For the gender-specific words in $\mathcal{L}$, we set their vectors in P_0 with $(1, 0)$ (masculine words) and $(0, 1)$ (feminine words). Vectors of other words are initialized with $(0, 0)$.

Next, following (Zhou et al., 2003), we iteratively update all words' masculine and feminine information until reaching a stationary P^*,

$$P_{t+1} = \alpha T P_t + (1-\alpha) P_0, \qquad (1)$$

where $T \in \mathbb{R}^{|V|\times|V|}$ is a normalization of G's adjacent matrix S (entries are edge weights),

$$T = D^{-\frac{1}{2}} S D^{-\frac{1}{2}}, \;\; D = \mathrm{diag}_i\Big(\sum_{j=1}^{N} S_{ij}\Big),$$

and α is a hyper parameter in range (0, 1), controlling the balance between *global* and *local* consistency. When α is small, we will pay more attention to keep the initial vectors of words (i.e., global consistency). When α gets larger, we will emphasize the smoothness between connected words: close words should have similar labels (i.e., local consistency).

We have a closed-form solution of Equation 1

$$P^* = (1-\alpha)(I - \alpha T)^{-1} P_0. \qquad (2)$$

It is worth noting that the solution only depends on the graph structure (T), gender-specific words (P_0), and a hyper parameter α. We think that by minimizing the influence of parameters (only P_0

their R codes with Python.

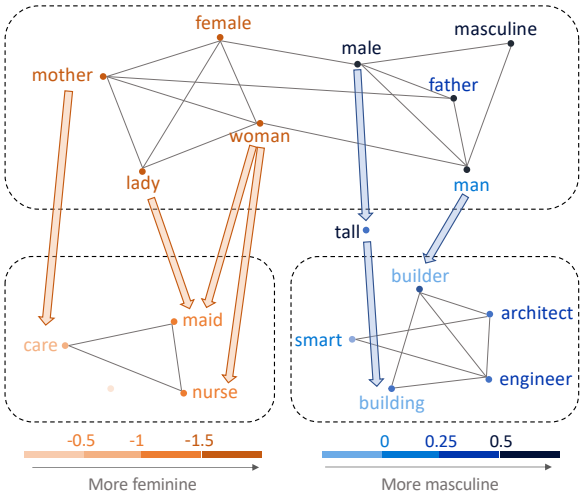

Figure 1: A snapshot on how stereotypes propagate in word association graph. Darker color on nodes means higher bias (visualize b). Colored arrows indicate how gender information propagate.

and α), vectors in P^* could be more robustly tied to the intrinsic properties of the word association graph and thus can be applied to (in)validate other bias scores.

Finally, we define a word's bias score b, from vectors in P^*,

$$b = \log \frac{\bar{b}_m}{\bar{b}_f},$$

where

$$\bar{b}_m = \frac{e^{b_m}}{e^{b_m} + e^{b_f}}, \quad \bar{b}_f = \frac{e^{b_f}}{e^{b_m} + e^{b_f}}.$$

We snapshot a sub-graph of G with P^* in Figure 1 to show how stereotype propagates. We first observe that words in the association graph are clustered. Those clusters are connected by some hubs (i.e., high degree words), through which gender information is able to spread quickly. As a result, words in a cluster usually have a same gender polarity. In Section 5.4, we will further show that G enjoys some key small-word properties. Thus, inherently, people may be "lazy" at carefully bounding gender biases. Another finding in Figure 1 is that "building" bears a male bias since both buildings and men are "tall". This kind of connections are hard to observe in co-occurrences (word embeddings). We will also discuss details in Section 5.4.

5 Empirical Evaluation and Application

In this section, we first evaluate the word-association-based bias scores by examining whether it correlates to other real-world data. Then, we perform various controlled comparisons on settings of the stereotype propagation, including different graph structures, gender specific word sets $\mathcal{L}$ and propagation algorithms. Finally, as a case study, we use our proposed scores as a benchmark to evaluate the performances of two recent de-bias methods for word embeddings.

5.1 Alignments with Real-world Data

In this section, we perform two experiments to validate the feasibility and reliability of studying gender stereotypes using the word association test.

In the first experiment, we examine whether the bias detected from word association test can correlate with gender stereotypes in the real world. We adopt two data sources here, namely the gender proportion of occupations in U.S. census data (*census data* in Table 3) [4] (Ruggles et al., 2015), and manually annotated professions stereotypes by U.S. based crowd workers (*human judgments* in Table 3) (Bolukbasi et al., 2016). We measure the strengths of correlations by Pearson's r[5] and significance p in Table 3.

Our second experiments compare average bias scores of words between different concepts using *Implicit Association Test* from (Caliskan et al., 2017). We adopt three pairs of concepts, namely *career vs. family*, *math vs. arts*, and *science vs. arts*[6]. Words in each pair are thought to have different gender tendencies. For example, we often relate *career* with a man but relate *family* with a woman. Words we use are shown in Table 4. For each pair, we report Cohen's d [7] and significance p.

For comparison, we also conduct a similar analysis for word-embedding-based stereotype scores. We take two widely used settings, namely *we-cos* (Bolukbasi et al., 2016) and *we-norm* (Garg et al.,

[4]Follow Levanon et al. (2009), we choose the log proportions, log-prop(p) = $\log \frac{p}{1-p}$, where p = percentage of women in an occupation, similar with the way we calculate words' stereotype scores.

[5]Pearson's r is a measure of the linear correlation between two variables. It has a value between 1 and -1, where 1 means total positive linear correlation, 0 means no linear correlation, and -1 means total negative linear correlation.

[6]Three words are not included in our word association graph, we thus substitute them by similar words, they are *cousins* to *cousin*, *equations* to *equation* and *computation* to *compute*.

[7]Cohen's d is an effect size used to indicate the standardized difference between two means. Conventional small, medium, and large values of d are 0.2, 0.5, and 0.8 respectively.

Method	Correlation Analysis				Implicit Association Test					
	Census data		Human Judgments		career vs. family		math vs. arts		science vs. arts	
	r	p	r	p	d	p	d	p	d	p
we-cos	0.58	10^{-7}	0.57	$< 10^{-10}$	**1.42**	.00	**1.30**	.01	1.37	.01
we-norm	**0.59**	10^{-7}	0.57	$< 10^{-10}$	1.18	.02	**1.30**	.01	1.37	.01
G	0.58	10^{-7}	**0.66**	$< 10^{-10}$	0.89	.10	0.98	.06	**1.55**	.00
G^e_{global}	0.04	.60	-0.01	.85	-0.20	.60	-0.08	.88	-0.31	.51
G^e_{local}	-0.08	.49	0.03	.72	-0.07	.87	-0.13	.74	-0.01	.98

Table 3: Validation of stereotype scores. r is the Pearson's r in correlation analysis, d is the effect size, and p is the significance. G, G^e_{global}, G^e_{local} represent stereotype propagation on different graphs. α is set to 0.99 by default.

concept	**words**
career	executive, professional, corporation, salary, office, business, career
family	home, parents, children, family, cousin, marriage, wedding, relatives
maths	math, algebra, geometry, calculus, equation, compute, numbers, addition
arts	poetry, art, dance, literature, novel, symphony, drama
science	science, technology, physics, chemistry, Einstein, NASA, experiment, astronomy

Table 4: Words in each concept.

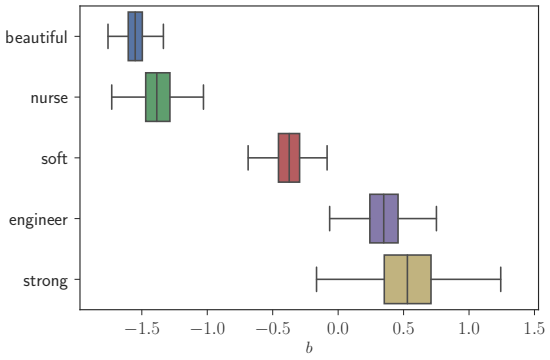

Figure 2: Examples of words' bias scores with confidence intervals (95%).

2017). They are both obtained by comparing a word w's embedding similarities with masculine and feminine words in gender word pairs $\mathcal{L}$.

The bias scores in "we-cos" are defined as [8],

$$b = \frac{1}{|\mathcal{L}|}\sum_{k=1}^{|\mathcal{L}|}\Big(\frac{w^\intercal w_m^k}{||w||\cdot||w_m^k||} - \frac{w^\intercal w_f^k}{||w||\cdot||w_f^k||}\Big), \quad (3)$$

and in "we-norm", the scores are

$$b = -\frac{1}{|\mathcal{L}|}\sum_{k=1}^{|\mathcal{L}|}\big(||w - w_m^k||^2 - ||w - w_f^k||^2\big), \quad (4)$$

where w_m, w_f is the embeddings of masculine and feminine words in $\mathcal{L}$. We re-train *word2vec* embeddings (Mikolov et al., 2013) on a Wikipedia dump.

Table 3 lists the correlation and implicit association test results. We find that

- Word-association-based bias scores have strong performances in both experiments. In correlation analysis, they exhibit similar or stronger relationships with real-world bias comparing to word-embedding-based bias scores. In implicit association test, our method still show large effects (Cohen's $d > 0.8$). It means that word association test is reliable in detecting human gender stereotypes.

- More importantly, although both word-embedding-based and word-association-based bias scores align well with real-world bias, gender stereotypes discovered from texts and human brains are different. The key evidence is that the word-association-based bias scores align much better on human annotated words.[9] Therefore, it is valuable and helpful to introduce a different perspective for lexical-level bias analyses.

5.2 The Influence of $\mathcal{L}$

To test the robustness of the proposed scores, we are interested in how $\mathcal{L}$ influences the results. We apply a bootstrap sampling strategy on the entire $\mathcal{L}$. Specifically, we sample 8 gender word pairs each time from $\mathcal{L}$. For all 45 possible combinations of the 8 gender words, we compute their bias scores to get confidence intervals w.r.t. to the full $\mathcal{L}$. We assume bias scores of a word to follow Gaussian distribution for easy calculation of confidence interval. We set the confidence level at 95%. Figure 2 illustrates some examples of words' bias scores with confidence intervals. We further

[8] We reuse symbol w as word w's embedding vector.

[9] Significantly higher correlation with human judgments than word-embedding-based methods (standard score Z=2.05).

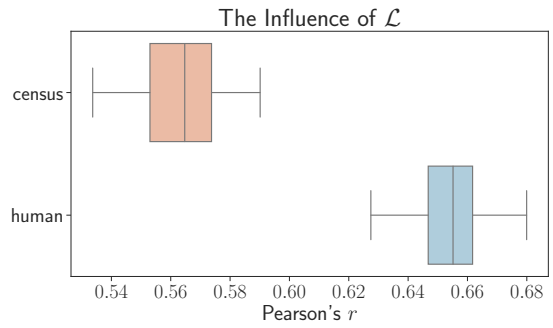

Figure 3: Confidence intervals (95%) of correlations between stereotype propagation results and real-world bias. Census stands for the census data dataset and human stands for the human judgments dataset.

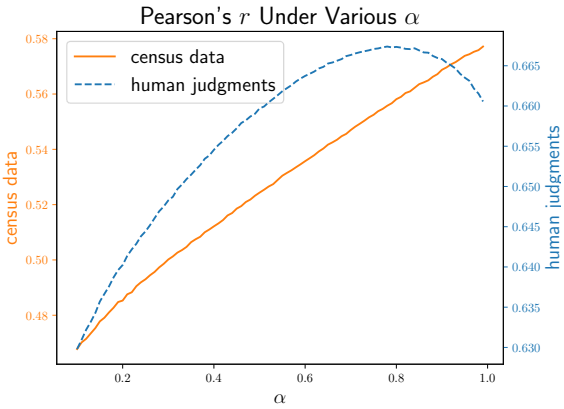

Figure 4: Correlation analysis under various α.

calculate the confidence intervals of correlations between our results and gender stereotypes in the real world in Figure 3. The results show that the words' bias scores are stable with respect to reasonable settings of $\mathcal{L}$.

5.3 Variants of Stereotype Propagation

There are many variants of the random walk method in previous literature (Zhou et al., 2003; Zhu et al., 2003; Velikovich et al., 2010; Vicente et al., 2017). We experiment with another approach in (Zhu et al., 2003), to test whether bias scores of words are insensitive towards random walk algorithms. In this method, we consider only local consistency (without the second term of Equation 1). As a result, we find high consistency between their bias scores (Pearson's $r = 0.789$, $p = 0.0$).

We also examine the influence of hyper parameter α. Here, we conduct similar correlation analysis in Section 5.1 under various α (Figure 4). We find that stereotype propagation has a stable performance regarding different α, while a proper α (close to 1, allowing information to spread more freely) do helps.

5.4 Comparing with Word Embedding Graphs

Word embeddings can also be applied to build graphs on words: edges and weights can be defined based on similarities among word vectors. Previous work Hamilton et al. (2016) has adopted these kind of approaches to study the propagation of words' sentiment. Therefore, it is natural to compare the graphs built from word embeddings with the word association graph here.

5.4.1 Word Embedding Graphs

We take two strategies, namely local and global, to construct two word embedding graphs G^e_{local} and G^e_{global}. The local strategy is to connect a word with its k nearest neighbors (same as Hamilton et al. (2016)). The global strategy is to find e most similar word pairs in all possible word pairs as graph edges. To ensure that information will not be interrupted during propagation, we rectify both $G^e_{local}, G^e_{global}$ to their largest connected components [10]. To make a fair comparison, we make the two word embedding graphs have the same average node degree with the word association graph (105), hence, we set $k = 105$ and $e = 1235178$. We use the same word2vec embeddings in Section 5.

We run stereotype propagation on both embedding based graphs. As reported in Figure 3, unfortunately, both of them can hardly capture gender bias of words. To understand the reasons, we further compare the two types of graphs in detail.

5.4.2 Graph Properties

We summarize some descriptive statistics of the three graphs in Table 5, where L is the average shortest path length between every possible word pair. D is the longest shortest path between two words in the graph. C is the clustering coefficient, which is the average proportion of two arbitrary neighbors of a random word being themselves neighbors. When $C = 0$, no words have neighbors that are also each others' neighbors and when $C = 1$, the graph should be a fully connected graph. It measures how tightly words are

[10] We won't have the same problem in the word association graph, because a word will be added only when it is associated from another word.

	Definition	G^e_{local}	G^e_{global}	G
$\|V\|$	number of words	11870	11758	12217
K	average in degree	104.69	105.05	105.02
L	average shortest path length	2.89	3.43	2.12
D	diameter of the graph	5	10	3
C	clustering coefficient	0.27	0.40	0.24

Table 5: Descriptive statistics of graphs. G is the word association graph.

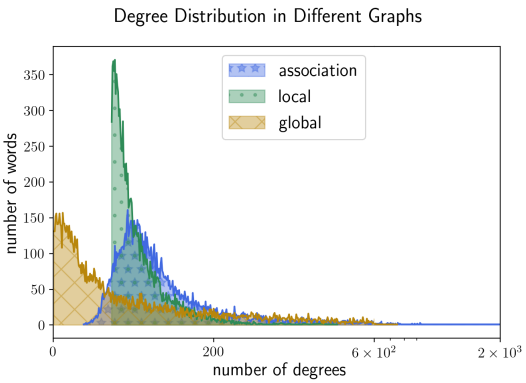

Figure 5: Distributions of node degrees.

organized as clusters.

Small world graphs are defined to be graphs where the distance between two arbitrary nodes follows a logarithmic distribution ($L \propto \log |V|$). In these graphs, node degree distributions follow power laws (Jeong et al., 2000), which means the degree of most nodes' are small, while a few nodes (*hubs*) have much larger degree number. Most nodes in the graph are organized as clusters connected by hubs, resulting in a relatively large clustering coefficient. These attributes work together to accelerate information flow within graphs.

From Table 5, we find that all three graphs exhibit small world properties. First, all three graphs have a quite small L and D ($L = 2.89, D = 5$, $L = 3.43, D = 10$, and $L = 2.12, D = 3$ for local, global, and word association graph respectively, while $\log 10000 = 9.21$). Second, their clustering coefficient C are relatively large (> 0.2), while that of a typical random network is 10^{-3} (Steyvers and Tenenbaum, 2005). Third, as shown in in Figure 5, the distributions of node degrees have shapes of power laws (e.g., long tails). It's worth noting that in word association graph, words with an extremely small number (< 10) of degrees are rare. We think that one reason might be the strategy token in data collection. The word association test records are collected using a snowball sampling method (Section 2), and words with few degrees are new comers in the test, which have not been sampled as cue words for enough times. Another difference is that the curve of word association graph has a significant longer tail which may imply that it has more powerful hubs. This feature allows gender information to spread more quickly (L is smaller) than the word embedding based graphs.

5.4.3 Types of Graph Edge

We also give a finer analysis on the two types of graphs to show their different ways on connecting gender specific words and other words. We examine *gender bias paths* which are all shortest paths [11] connecting words in $\mathcal{L}$ and other words in all three graphs.

According to semantic network theory (Collins and Loftus, 1975), there are three types of connections in human word association, namely *semantic priming* (Traxler, 2011), *neighborhood effects* and *frequency effects* (Andrews, 1989). Later, *co-occurrence* relation has also been found to hold a correlation with word association tests (Spence and Owens, 1990).

Our main observation is that, regarding the gender bias paths, we can find all of these connection types in bias paths of the word association graph. However, neighborhood effects and frequency effects are missed in word embedding graphs. This observation reveals that word association graph has a richer variety of connections, which may help the stereotype propagation. Examples of different connection types in both kind of graphs are exhibited in Table 6. We discuss each edge types in the following.

Semantic priming refers to the effect that word associations can happen between semantically related words. This is observed in bias paths on both word association graph and word embedding graphs, like *potential-maybe* in word association graph and *really-actually* in word embedding graphs. A more profound semantic relationship is hierarchical, including generic to specific and partitive relationships, such as *energy-carbohydrate* and *girl-person*.

Neighborhood effects refer to word associations between words that are highly confusable due to overlapping features, like spelling and pro-

[11] If several paths are equally short, we pick the one with highest cumulative weight.

Type	Word Association Graph	Word Embedding Graph
semantic priming	boy - *energy* - *carbohydrate* girl - *potential* - *maybe*	boy - kid - *really* - *actually* *girl* - *person*
neighborhood effects	*son* - *some* she - *pronoun* - *pro* - *projection*	X
frequency effects	husband - married - *a* - few girl - lady - *the* - article	X
co-occurrence	father - *respect* - *others* mother - *birth* - *day*	he - *even* - *more* she - *cook* - *pickle*

Table 6: Examples of different connection types between words. These words are shown in italics. Blue words refer to masculine word while red words refer to feminine word.

nunciation. Representative examples include *pronoun-pro-programmer* (spelling) and *son* to *some* (pronunciation). We manually check more than 100 bias paths on word embedding graphs, and didn't find this kind of connections, indicating its inability in modeling such effects.

Frequency effects suggest that human tends to associate commonly used words with higher possibility, making hubs in word association graph more likely to be frequent words. We pick top 2% words with largest node degrees as the representatives of hub words, and count the average occurrence of them in Wikipedia. As a result, the hubs of word association graph (297868) appears much more frequently than hubs in word embedding graphs (12931 of G^e_{local}, 3373 of G^e_{local}). It implies a stronger frequency effects in the word association graph.

To investigate how frequency effects influence stereotype propagation, we check the composition of these hub words. It turns out that most gender-specific words (except for *he*, *she*, *daughter*, *aunt*) in $\mathcal{L}$ are contained in the hub words of the word association graph, while none of them lie within those of the embedding-based graphs. Therefore, there is no wonder that $\mathcal{L}$ in the word association graph could distribute its gender information to other words in the graph more efficiently, leading to better performance in detecting gender bias of words.

Co-occurrence Due to the fact that most commonly used word embedding models are trained on word co-occurrence (Mikolov et al., 2013; Pennington et al., 2014), we observe lots of connections with such type in bias paths on word embedding graphs, which also widely exists in those on the word association graph, such as *birth-day* and *even-more*.

To summarize, frequency effects, neighborhood effects, and more concentrated hubs may work together to help spread gender stereotypes. It shows the value of introducing word association test into gender stereotype research.

5.5 Case Study: Do De-bias Methods Really Remove Gender Bias?

Some works have proposed approaches to reduce gender stereotypes in word embeddings. They can mainly be divided into two categories: post-processing step (Bolukbasi et al., 2016) and training goal modification (Zhao et al., 2018). Recent work (Gonen and Goldberg, 2019) has argued that those de-bias procedures only cover up but do not remove stereotypes. In this section, we utilize the bias scores from the word association graph to examine whether those de-bias methods work.

We experiment with de-bias methods of both categories, *Hard-Debias* refers to the method in (Bolukbasi et al., 2016) and *Gn-Glove* refers to the method in (Zhao et al., 2018). For each method, we compare it with an unde-biased version. For Hard-Debias, we compare with embeddings before these procedures [12] and for Gn-Glove, we compare with the original Glove (Pennington et al., 2014) offered in its project homepage [13].

For stereotype in word embeddings, we use the same measurements in Section 5, we-cos and we-norm. We examine whether those word embeddings still contain human-like stereotypes by con-

[12] We use the same word2vec embeddings in Section 5.

[13] https://github.com/uclanlp/gn_glove

		Original		De-biased	
		r	p	r	p
Hard-Debias	we-norm	0.36	.00	0.06	10^{-9}
	we-cos	0.35	.00	0.05	10^{-8}
Gn-Glove	we-norm	0.38	.00	0.34	$< 10^{-10}$
	we-cos	0.38	.00	0.34	$< 10^{-10}$

Table 7: Correlation analysis between word association bias scores and bias scores from de-biased word embeddings. r is Pearson's r and p is the significant value.

ducting a correlation analysis between their word-embedding-based bias scores and our word association bias scores. We expected that word association bias scores would have proper alignments with original word embeddings but poor alignments with de-biased versions if those de-bias procedures have done their jobs.

After removing a set of gender-specific words whose gender information are not removed in Hard-Debias, we extract the words appears both in our word association graph and the word embeddings vocabulary, 11311 words in total, as the word list for this case study.

Experiment results are shown in Table 7. We have three main observations:

- Both methods work to some extent, since Pearson's rs of both de-biased versions decrease compared with the original version.
- Neither Hard-Debias nor Gn-Glove removes gender stereotypes in word embeddings entirely, because bias scores derived from de-biased embeddings still exhibit significant correlations with the word association bias scores.
- Hard-Debias outperforms Gn-Glove. As we can see, Gn-Glove can hardly remove gender bias, which matches the conclusion in (Gonen and Goldberg, 2019).

6 Related Work

Studying gender stereotypes by language analysis (Hamilton and Trolier, 1986; Basow, 1992; Wetherell and Potter, 1993; Holmes and Meyerhoff, 2008; Coates, 2015) is now an import research topic. Although traditional methods like survey (Williams and Best, 1990) are quite effective, they are expensive and time-consuming. Therefore, Garg et al. (2017) use word embeddings as a quantitative lens to investigate historical trends of gender stereotypes. However, due to the limitations in word embedding training, existing methods have constrained effects in this field.

Word association test, as a product of psychology research, has been proven reliable on studying human implicit memory (Cañs, 1990; Playfoot et al., 2016). Different from word embeddings, word association test not only have a correlation with the co-occurrence of words (Spence and Owens, 1990) but also can reflect richer relationships like hierarchical relationships (Nuopponen, 2014), making it an excellent material in studying human stereotypes.

7 Conclusion

We utilize a recent large-scale word association test to explore how gender stereotypes propagate within our mind by constructing a word association graph from it, and derive gender bias scores of words. Experiments suggest that our approach is effective in detecting human stereotypes, and is tied robustly to graph structure. Therefore, these bias scores could be used to validate other methods. What's more, our results indicate that gender bias learned from large-scale texts is different from that within our minds, introducing a new perspective for lexical-level stereotype-related research.

A Modular Architecture for Unsupervised Sarcasm Generation

Abhijit Mishra, Tarun Tater, Karthik Sankaranarayanan
IBM Research
{abhijimi,ttater24,kartsank}@in.ibm.com

Abstract

In this paper, we propose a novel framework for sarcasm generation; the system takes a literal *negative opinion* as input and translates it into a sarcastic version. Our framework does not require any paired data for training. Sarcasm emanates from *context-incongruity* which becomes apparent as the sentence unfolds. Our framework introduces incongruity into the literal input version through modules that: (a) filter factual content from the input opinion, (b) retrieve incongruous phrases related to the filtered facts and (c) synthesize sarcastic text from the filtered and incongruous phrases. The framework employs reinforced neural sequence to sequence learning and information retrieval and is trained only using unlabeled non-sarcastic and sarcastic opinions. Since no labeled dataset exists for such a task, for evaluation, we manually prepare a benchmark dataset containing literal opinions and their sarcastic paraphrases. Qualitative and quantitative performance analyses on the data reveal our system's superiority over baselines, built using known unsupervised statistical and neural machine translation and style transfer techniques.

1 Introduction

Sarcasm[1] is an intensive, ironic construct that is intended to express contempt or ridicule. It is often linked with intelligence, creativity, and wit, and therefore empowering machines to generate sarcasm is in line with the key goals of *Strong AI*[2]. From the perspective of Natural Language Generation (NLG), sarcasm generation remains an important problem and can prove useful in downstream applications such as conversation systems, recommenders, and online content generators. For instance, in a conversational setting, a more natural and intriguing form of conversation between humans and machines could happen if machines can intermittently generate sarcastic responses, like their human counterparts.

Over the years, a lot of research and development efforts have gone into the problem of detecting sarcasm in text, which aims to classify whether a given text contains sarcasm or not (Joshi et al. (2017b) provide an overview). However, systems for generation of sarcasm have been elusive. This is probably due to the fact that in sarcasm generation both *selection of contents* for sarcastic opinion generation and *surface realization of contents* in natural language form are highly nuanced.

In the broader area of style transformation of texts, most of the existing works have focused narrowly on transformations at lexical and syntax levels, *i.e.,* text simplification (Siddharthan, 2014), text formalization (Jain et al., 2018), sentiment style transfer (Shen et al., 2017; Xu et al., 2018), sentiment flipping (Li et al., 2018) and understanding humor (West and Horvitz, 2019). However, very little work has been done ((Piwek, 2003),(Hovy, 1987)) on incorporating *pragmatics* into generation tasks such as sarcasm. Sarcasm generation offers a rich playground to study this challenge and push the state-of-the-art in text transformation. Moreover, being a pragmatic task, sarcasm construction offers diverse ways to convey the same intent, based on cultural, social and demographic backgrounds. Hence, a supervised treatment of sarcasm generation using paired labeled data (such as parallel sentences) will be highly restrictive. This further motivates the need for exploring unsupervised approaches as the one we propose in this paper.

We make the first attempt towards automatic sarcasm generation where the generation is conditioned on a literal input sentence. For example, the literal opinion *"I hate it when my bus is late."*

[1] https://www.thefreedictionary.com/Sarcasm

[2] https://en.wikipedia.org/wiki/Artificial_general_intelligence

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6144–6154, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

should be transformed into *"Absolutely love waiting for the bus"*. As sarcasm conveys a negative sentiment, our system expects a negative sentiment opinion as input. Out of various possible theories proposed to explain the phenomenon of sarcasm construction (Joshi et al., 2017b), our framework relies on the theory of *context incongruity* (Campbell and Katz, 2012). Context incongruity is prevalent in textual sarcasm (Riloff et al., 2013; Joshi et al., 2015b). The theory presents sarcasm as a contrast between positive sentiment context (*e.g., absolutely loved it*) and negative situational context (*e.g., my bus is late*).

In our framework, translation of literal sentences to sarcastic ones happens in four stages *viz.*, (1) **Sentiment Neutralization**, during which sentiment-bearing words and phrases are filtered from the input, (2) **Positive Sentiment Induction**, where the neutralized input is translated into phrases conveying a strong positive sentiment, (3) **Negative Situation Retrieval**, during which a negative situation related to the input is retrieved, and (4) **Sarcasm Synthesis**, where appropriate sarcastic constructs are formed from the positive sentiment and negative situation phrases gathered in the first three stages.

Training and development of these modules require only three unpaired corpora of positive, negative, and sarcastic opinions. For evaluating the system, we manually prepare a small benchmark dataset which contains a set of literal opinions and their corresponding sarcastic paraphrases. Quantitative evaluation of our system is done using popular translation-evaluation metrics, and document similarity measurement metrics. For qualitative evaluation, we consider the human judgment of sarcastic intensity, fluency, and adequacy of the generated sentences. As baselines, we consider some of our simplistic model variants and existing systems for unsupervised machine translation and style transfer. Our overall observation is that our system often generates sarcasm of better quality than the baselines. The code, data, and resources are available at https://github.com/TarunTater/sarcasm_generation.

2 Challenges in Sarcasm Generation

Generation of sarcasm, unlike other language generation tasks, is highly nuanced. If we reconsider the example in the introductory section, the output sentence is sarcastic as it presents an unusual situation where the opinion holder has liked the rather boring act of *waiting for a bus*. The unusualness (and hence, the sarcasm) arises from two implicitly opposing (*incongruous*) contexts: *love* and *waiting for the bus*. Such a form of sarcasm, based on the *context incongruity* theory (Campbell and Katz, 2012), is more common in text than other forms such as prepositional, embedded or illocutionary sarcasm (Camp, 2012). For any textual sarcasm generator, figuring out contextually incongruous phrases will be as difficult as generating a fluent sentence. Moreover, most of the existing language generators are known to work on large scale literal/non-sarcastic texts (*e.g.,* language models trained on Wikipedia articles), and are agnostic of the possible collocations of contextually incongruous phrases (Joshi et al., 2017a). We try to overcome these challenges through our modular system design, discussed as follows.

3 System Architecture

The overall system architecture is presented in Figure 1. For development of the modules three corpora are needed: (a) a corpus of positive sentiment sentences ($\boldsymbol{\mathcal{P}}$), (b) a corpus of negative sentiment sentences ($\boldsymbol{\mathcal{N}}$), and (c) a corpus of sarcastic sentences ($\boldsymbol{\mathcal{S}}$). The framework performs transformation of literal text into sarcastic ones in four stages as given below:

3.1 Sentiment Neutralization

The neutralization module is designed to filter sentiment information out from the input text. For example, the input *hate when my bus is late* should be filtered to produce a neutral statement like *bus is late*. Neutralization is performed by a neural sentiment classification module. Each word in the input sentence of length N ($\boldsymbol{x} = \{x_1, x_2, ..., x_N\}$) (in *one-hot* representation, padded wherever necessary) is transformed into K-dimensional embedding. The embeddings are then passed through a layer of recurrent units such as Long Short Term Memory (LSTM)(Hochreiter and Schmidhuber, 1997). The output of the LSTM layers are then sent to a *self-attention* layer before passing through a `softmax` based classifier. The classifier is trained with the supervision from sentiment positive/negative labels using corpora $\boldsymbol{\mathcal{P}}$ and $\boldsymbol{\mathcal{N}}$.

During testing, for a given input of length N, the self attention vector $\boldsymbol{\alpha} = \alpha_1, \alpha_2, ..., \alpha_N$ is first extracted (details skipped for brevity, refer Xu

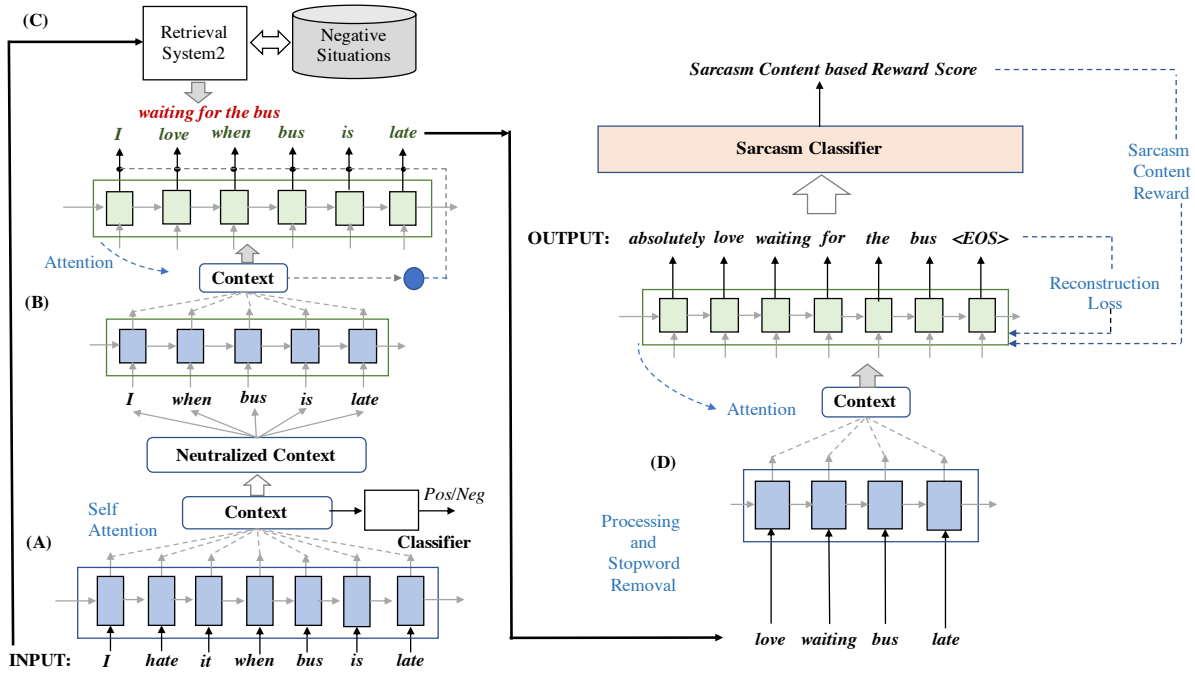

Figure 1: System Architecture. Input to the system are literal sentences. The blue and green boxed represent layers of embedding and LSTMs. The components are (A) Sentiment Neutralizer (B) Positive Sentiment Inducer (C) Negative Situation Retriever , and (D) Sarcasm Synthesizer.

et al. (2018)). We then inverse and discretize the self attention vector as follows:

$$\hat{\alpha_i} = \begin{cases} 0, & \text{if } \alpha_i > \mu + 2\sigma \\ 1, & \text{otherwise} \end{cases} \quad (1)$$

where α_i is the attention weight for the i^{th} word, μ and σ are the mean and standard deviation for the attention vector. For each word in the input, if the discretized attention weight is 0, it is filtered out.

The motivation behind such a design is that if the classifier is trained well, the attention weights will represent the contribution of each word to the overall sentiment decision (Xu et al., 2018). Sentiment bearing words will receive higher attention whereas neutral words will have lower attention weights. It is worth noting that neutralization can be done in several other ways such as filtering based on a sentiment lexicon. However, such operations would require additional resources such as sentiment dictionary, sense disambiguation tools, whereas the neural classification based filtering can only work with binary sentiment labeled data. Also, for computing word-level sentiment contributions, recent techniques (such as gradient-based methods (Sundararajan et al., 2017)) can be used. For simplicity, we use attention based filtering.

3.2 Positive Sentiment Induction

Once the neutralized output is extracted, it is passed to the positive sentiment induction module which transforms it into a positive sentiment sentence. For this, we use a traditional sequence to sequence pipeline (Bahdanau et al., 2014) with attention and copy mechanisms (Gulcehre et al., 2016). The input is a set of words coming from the neutralization module. These are transformed into embeddings and are then encoded with the help of LSTM layers. The decoder attends over the encoded output and produces the output tokens based on the attended vector and the previously generated tokens. This is a standard technique, typically used in neural machine translation.

As the output from the system is expected to be positive in sentiment, for training the framework, we use only a set of positive sentences from $\mathcal{P}$. Each sentence in the data is filtered using the neutralization module. The filtered version, and the original positive sentence are used as $\langle source, target \rangle$ pairs.

3.3 Negative Situation Retrieval

Negative situations present in sarcastic opinions are typically extrinsic and are loosely related to the semantics of its literal version. Hence, a sequence to sequence module analogous to Section

5-grams: getting up for school facts, getting yelled at by people, trying to schedule my classes, feeling like every single person, walking to class in pouring, making people who already hate, working on my last day, spending countless hours at doctors, getting overdraft statements in mail
4-grams: talking about world politics, stuck in a generation, sitting in class wondering, canceled at short notice, distancing myself from certain, wipe my own tears
3-grams: born not breathing, paid to sleep, scared those faces, taking a shower, starting your monday, accused of everything, worrying about someone, fight jealousy arguments, license to trill, awarded literature prize
2-grams: scratching itchy, looking chair, getting hiv, shot first, collecting death, lost respect
1-gram: canceled, sleeping, trying, buying, stapling

Table 1: Example negative situations extracted using bootstrapping technique (Riloff et al., 2013)

3.2 may not be very useful. Moreover, for sarcasm generation, for a certain topic, it is safe to assume that there can be a finite set of negative situations. From this set appropriate situation phrases can be *"retrieved"* depending on the given input. Thus, finding out appropriate negative situations boils down to two sub-problems of (a) preparing a finite set of negative situations, and (b) setting up the negative situation retrieval process. We discuss each of these two steps below.

3.3.1 Building *Negative Situation* Gazetteer

This is a one-time process and is done using the unsupervised bootstrapping technique similar to Riloff et al. (2013). For each sentence in the sarcasm corpus $\boldsymbol{\mathcal{S}}$, a candidate negative situation phrase is extracted. A candidate negative situation phrase is a word n-gram ($n \leq 5$) that follows a positive sentiment phrase in a sarcastic sentence [3]. After the candidates for a positive phrase are obtained, their Part of Speech tags are extracted with the help of a POS tagger. Specific patterns of n-gram are then obtained using the POS tags. This ensures that the phrases extracted are mostly *verb phrases*, *noun-phrases*, and *to-infinitive* verb phrases that describe situations. In our setting we use 30 predefined POS n-gram patterns following Riloff et al. (2013).

Once the candidate negative situation phrases are extracted, they are filtered based on a scoring function as given below:

$$score_i = \frac{\#ns_i \; in \; \boldsymbol{\mathcal{S}}}{\#ns_i \; in \; \boldsymbol{\mathcal{S}}, \boldsymbol{\mathcal{P}}, \boldsymbol{\mathcal{N}}} \qquad (2)$$

where ns_i is the i^{th} negative situation extracted for a certain positive phrase.

The scoring function returns a real value indicating the exclusiveness of the negative situation w.r.t the sarcastic sentences. If the score exceeds a threshold (*i.e.,* $p > 0.5$), the candidate phrase is added to the gazetteer. Once all the possible negative situation phrases are extracted, each phrase is used to extract more positive sentiment phrases similarly as above. This process of positive phrase and negative situation extraction is repeated until no new phrases are found. Table 1 shows some example negative situation phrases extracted from our dataset.

3.3.2 Retrieval Process

The idea is to find negative situations relevant to the input sentence. We implement an information retrieval system based on PyLucene. All the negative situations from the gazetteer (Sec. 3.3.1) are first indexed. The input sentence is considered as the query for which the most relevant negative situation is retrieved from the indexed list. The factors involved in PyLucene's retrieval algorithm include *tf-idf*, number of matching terms in the query sentence and the retrieved sentence, and importance measure of a term according to the total number of terms in the search.

Once the positive sentiment and negative situations are generated for the input sentence, they undergo a post-processing step where stopwords and redundant words are removed and given as input to the sarcasm synthesis module.

3.4 Sarcasm Synthesis

The sarcasm synthesis module is a sequence-to-sequence network that expects a set of keywords related to positive sentiment and negative situation phrases. For training this module, the sarcasm corpus $\boldsymbol{\mathcal{S}}$ is used. To prepare the input, we implement a keyword extraction technique based on POS tagging. Sentences in $\boldsymbol{\mathcal{S}}$ are POS-tagged and then stopwords are removed, and then based on the POS tags noun, verb, adjective and adverbs are retained. This way, the input keywords to the system would somewhat be similar to the keywords expected in real time scenario.

[3] the word "love" is considered as the seed positive sentiment phrase to begin the bootstrapping procedure

The module follows an encode-attend-decode style architecture like the positive sentiment induction module, but with a different learning objective. Keywords in the input (in *one-hot* representation, padded wherever necessary) are transformed into a sequence of embeddings and then encoded by layers of LSTMs, which produces a hidden representations for each input word. The decoder, consisting of a single layer of LSTMs stacked on the top of a decoder embedding layer, attend over the encoded hidden representations and generate target words. In general, for T training instances of keywords and sarcastic texts, $\{x^i, y^i\}_{i=1}^{T}$, the training objective is to maximize the likelihood of a target y^i given x^i, which is similar to minimizing the *cross entropy* between the target distribution and the predicted output distribution. For training the neural network, the cross-entropy loss is back propagated. In other words, the gradient of the negative cross-entropy loss is considered to update the model parameters. The gradient is given by:

$$\nabla_\theta L(\theta) = \nabla_\theta \sum_{i=1}^{T} y^i log\ P_{M_\theta}(\hat{y^i}|x^i) \qquad (3)$$

where L is the loss function and M_θ is the translation system with parameter θ. $\hat{y^i}$ is the predicted sentence. In our setting, where the input is not a proper sentence, the problem with the above objective is that it does not strongly enforce the decoder to learn and produce sarcastic output. We speculate that minimizing the token-level cross entropy loss in Eq. 3 may help produce an output that is grammatically correct but not sarcastic enough. For instance, the decoder may incur insignificant cross-entropy loss after generating a sentence like *absolutely loved it*, as this sentence has considerable overlap with the reference sarcastic text that provides supervision.

One possible idea to tackle such problems is to employ a sarcasm scorer that can determine the sarcasm content in the generated output, and use the scores given by the sarcasm scorer for better training of the generator. However, the sarcasm scorer may be external to the sequence-to-sequence pipeline, and the scoring function may not be differentiable with respect to the model M_θ. For this, we apply reinforcement learning which considers sarcasm content score as a form of *reward* and use it to fine-tune the learning process. For learning, the *policy gradient theorem* (Williams, 1992) is used. The system is trained under a modified learning objective *i.e.,* to maximize the expected reward score for a set of produced candidate sentences. The generator, operating with a policy of $P_{M_\theta}(\hat{y^i}|x^i)$, producing an output $\hat{y^i}$ with an *expected* reward score computed using a scorer, will thus have the following gradient:

$$\begin{aligned} \nabla_\theta RL(\theta) &= \nabla_\theta \mathbb{E}_{\hat{y_i} \sim P_{M_\theta}(\hat{y^i}|x^i)}[R(\hat{y^i})] \\ &= \mathbb{E}[R(\hat{y^i}) \nabla_\theta log(P_{M_\theta}(\hat{y^i}|x^i))] \end{aligned} \qquad (4)$$

where RL is the modified learning objective which has to be maximized and R is a reward function that is computed using an external scorer. In practice, the expected reward is computed by (a) sampling candidate outputs from the policy P_{M_θ}, (b) computing the reward score for each candidate and (c) averaging the rewards so obtained. In typical RL settings, the learner is typically initialized to a random policy distribution. However, in our case, since some supervision is already available in the form of target sarcastic sentences, we pretrain the model with the loss minimization objective given in Eq. 3 and then fine-tune the model based on the policy gradient scheme following Eq. 4. Thus, the learner gets initialized with a better policy distribution.

For reward calculation, we consider the confidence score of a sarcasm classifier (probability of being sarcastic) trained using $\boldsymbol{\mathcal{S}}$ as positive examples and $\boldsymbol{\mathcal{P}}$ and $\boldsymbol{\mathcal{N}}$ taken as negative examples. For our setting, the classifier is analogous to the classifier used for neutralization. The classifier is based on embedding, LSTM and softmax layers.

Since the input to the system is a list of words, it may seem that the sarcasm synthesis module may not require sequence to sequence learning, and a much simpler approach like bag-of-words to sequence generation could have been used. However, note that the input to the generator is obtained after dropping words during neutralization and later appending the negative situation phrase. The sequentiality is, thus, not completely lost. This makes sequence to sequence model an intuitive choice.

We now explain our experimental setup.

4 Experiment Setup

4.1 Datasets

As stated earlier, our system does not rely on any paired data for training. It requires three corpora of positive sentences, negative sentences, and sarcastic sentences collected independently.

For positive and negative sentiment corpora $\mathcal{P}$ and $\mathcal{N}$, we considered short sentences/snippets from the following well-known sources such as (a) Stanford Sentiment Treebank Dataset, (b) Amazon Product Reviews, (c) Yelp Reviews (d) Sentiment 140 dataset (See Kotzias et al. (2015) for sources). The above datasets primarily contain tweets and short snippets. Tweets are normalized by removing hashtags, usernames, and performing spell checking and lexical normalization using NLTK (Loper and Bird, 2002). We then filtered out sentences with more than 30 words. Approximately $50,000$ sentences from each category are retained. Then, based on the vocabulary overlap with our sarcasm corpus $\mathcal{S}$, $47,827$ sentences are finally retained from each category (total number of instances is 95654).

For the unlabelled sarcasm corpus $\mathcal{S}$, we relied on popular datasets used for sarcasm detection tasks such as the ones by Ghosh and Veale (2016), Riloff et al. (2013), and the Reddit Sarcasm Corpus[4]. Sentences are denoised, spell corrected and normalized. Average sentence length is kept as 30 words. A total number of $306,141$ sentences are thus collected. A common vocabulary of size $20,000$ is extracted (based on frequency) for all the modules from the three corpora. Each corpus is divided into a train-valid-test split of 80%-10%-10%.

4.1.1 Benchmark Dataset for Evaluation

Since no dataset containing paired examples of literal and sarcastic utterances are available, we created a small test-set for evaluating our system. From the test split of the sarcasm corpus $\mathcal{S}$, 250 sentences on diverse topics are selected and are manually translated into literal versions by two linguists. From this, only 203 sentences could be selected by the linguists who mutually decided whether the sentences were sarcastic enough to keep in the test dataset or not.

[4]https://www.kaggle.com/danofer/sarcasm

4.2 Model Configuration

For the neutralization module, the embedding dimension size is set to 128, two layers of LSTMs of hidden dimension of 200 are used. The classifier trains for 10 epochs with a batch size of 32, and achieves a validation accuracy of 96% and training accuracy of 98%.

For positive sentiment induction module, the embedding dimensions for both encoder and decoder are set to 500. Both the encoder and decoder have only one layer of LSTM, with a hidden dimension of 500. The module is built on top of the OpenNMT (Klein et al., 2017) framework. Training happens in $100,000$ iterations and the batch size is set to 64. The positive sentiment induction module, at the end of the training, produces a bigram BLEU (Papineni et al., 2002) score of 62.25%. For bootstrapping negative situations and other purposes, the POS tagger from Spacy[5] is used. The Lucene-IR framework is set up to retrieve negative situations.

The model configuration and training parameters for the sarcasm synthesizer is the same as the positive sentiment induction module. For the RL scheme, for each instance, the expected reward is computed over 100 candidate samples. At the end of the training, the bigram BLEU score on the validation set turns out to be 59.3%. For reward computation, we use a classifier similar to the one used for neutralization. The embedding size for this classifier is 300 and it uses two layers of unidirectional LSTMs with a hidden dimension of 300. It trains with a batch size of 64 and produces a validation accuracy of 78.3%. The probability estimates given by the classifier for any input text are taken as reward scores. For optimization, cross entropy loss criterion is used.

4.3 Evaluation Criteria

Absence of automatic evaluation metrics capable of capturing subtleties of sarcasm makes it difficult to evaluate sarcasm generators. For evaluation, we still use the popular translation and summarization evaluation metrics METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004). Additionally, to check the semantic relatedness between the input and output, we use Skip-thought sentence similarity metric[6]. Note that using BLEU (Papineni et al., 2002) will be futile here as direct

[5]http://spacy.io

[6]https://github.com/Maluuba/nlg-eval

n-gram overlaps between the predicted and gold-standard sentences are not expected to be significantly higher for such a task. We still include it as an evaluation metric for completion.

We employ an additional metric to judge the percentage of length increment (abbreviated as WL) to see the if the length of the output is generally more than that of the input (for the reference text it is 67%). The notion behind this metric is that sarcasm typically requires more context than its literal version, requiring to have more words present at the target side.

4.3.1 Human Judgement based Evaluation

We also consider human judgment scores indicating whether the generated output is non-sarcastic/sarcastic (0/1 labels), how fluent it is (in a scale of 1-5, 1 being lower), and to what extent it is related to the input (in a scale of 1-5). The relatedness measure is important as the objective of the task is to produce a sarcastic version of the input text without altering the semantics much. For human evaluation, we consider only the 30 sentences randomly picked from the benchmark (test) dataset. Sarcasm is a difficult topic, so we stuck to only two annotators who had a better understanding of the language and socio-cultural diversities.

4.4 Systems for Comparison

For comparison, we consider the following four systems:

1. **SarcasmBot**: This is an open-sourced sarcasm generation chatbot released by Joshi et al. (2015a). The system generates a sarcastic response to an input utterance.

2. **UNMT:** This system is based on Unsupervised Neural Machine Translation technique by Artetxe et al. (2017), which can be extended to any translation task. In our setting, the source and target side are literal and sarcastic utterances, *i.e.* the direction of translation is non-sarcastic to sarcastic.

3. **Monoses:** This is similar to UNMT but based on unsupervised Statistical Machine Translation (Artetxe et al., 2018).

4. **ST:** This is based on the cross alignment technique proposed by Shen et al. (2017), used for the task of sentiment translation.

5. **FLIP:** This is based on heuristics for sentiment reversal. For this, the input sentence is first dependency-parsed. The root verb is determined along with its tense and aspects with the help of its part-of-speech tags[7]. The sentiment of root verb is determined using sentiment lexicon[8]. If the verb has non-zero positive or negative sentiment score, its antonym is found using WordNet. Appropriate tense and aspect form of the antonym is then obtained[9]. The modified antonym replaces the original root verb. Similarly, we replace adjective and adverbs with words carrying opposite sentiment.

For training the above systems (except FLIP), we used $\mathcal{S}$ at one side and a larger version of combined $\mathcal{P}$ and $\mathcal{N}$ containing $558,235$ sentences on the other side, curated from the same sources as mentioned earlier. Apart from this system, we also tested some of our model variants, which are presumably inferior and can be considered as baselines. These are termed as:

1. **SG_NORMAL:** a system with only the sarcasm synthesizer module which takes the input directly (after removing stopwords from the input),

2. **SG_RL:**, same as *SG_NORMAL* but also applies reinforcement learning,

3. **ALL_NORMAL:**, the complete system, with sarcasm synthesizer trained without reinforcement learning strategy.

4. **ALL_RL:**, the complete system with reinforcement learning.

5 Results and Analysis

Tables 2 and 3 present evaluation results. While it was expected that the automatic metrics may not be able to capture the subtleties of sarcasm, the WL measure indicates that a carefully designed modular approach like ours often generates longer sentences with more context. This is also corroborated by the human evaluation where annotators have judged that the output generated from

ALL_NORM	63.3%	3.7	3.9
ALL_RL	73.3%	3.7	3.8

Table 3: Human judgment scores for various systems

our system are more sarcastic than the comparison systems. *SarcasmBot*, being a heuristic driven sarcasm generator produces sarcastic responses but is not related to the input topic. Moreover, it ends up generating only 20 different responses for our entire test dataset making its output redundant and unrelated to the input. Other existing systems such as *UNMT* and *Monoses* converge to autoencoding and end up replicating the input as output. *FLIP*, performs transformations at lexical level, hence achieves better fluency but certainly fails to induce sarcasm in most of the cases.

Table 4 presents example generations from different systems. It is quite interesting to note that due to the RL, the model tends to produce longer sentences and brings additional context necessary for sarcasm. The fluency is however compromised. A close inspection of the outputs from each module suggests that the overall error committed by the system is due to accumulation of different types of errors, mainly (a) error during neutralization due to inappropriate assignment of weights to the words in the input, (b) dropping of words and/or insertion of spurious words during positive sentiment induction, and (c) error in scoring the sarcasm content in the RL setting. These can be addressed through better hyper-parameter tuning, gathering more training data for training the individual modules (especially the sarcasm synthesizer), and fine-tuning the sarcasm scorer.

Input: worrying because did not finish my homework.
Reference: *did not finish any homework & i still need to shower ! lol ! love stressing out.* **SarcasmBot:** How exciting! $\star rolls\ eyes \star$. **Monoses:** whining because actually finish my homework. **UNMT:** worrying because i did not finish my homework. **ST**: if do not work my mom hurts. **FLIP**: reassuring because did not finish my homework. **SG (NORMAL)**: i am worrying about the worrying of homework. **SG (RL)**: worrying about finish homework. **ALL (NORMAL):** no worrying , i finish doing homework great. **ALL (RL):** worrying about finish homework is great.
Input: swimming lessons are very costly in nyc.
Reference: *you have to sacrifice your first born child for swimming lessons in nyc.* **SarcasmBot:** That is a very useful piece of information! Yawn! **Monoses:** Dry lessons are very costly financially. **UNMT:** swimming lessons are very costly in nyc. **ST:** a will was in bed. **FLIP**: swimming lessons are very costly in nyc. **SG (NORMAL)**: this is so costly to me swimming lessons in nyc. **SG (RL)**: swimming lessons is so costly in nyc. **ALL (NORMAL):** loving the swimming lessons in nyc ch. **ALL (RL):** i am loving the swimming lessons . going to be a very costly in nyc ch.

6 Related Work

As stated earlier, not many systems for sarcasm generation exist today. The closest work to ours is the one by Joshi et al. (2015a) which employs a heuristic driven approach for generating a sarcastic response to an input utterance. Since, the output of the system is a response, the system is not suitable for translating a literal input text into a sarcastic version. Unlike sarcasm generation, sar-

casm detection has been a well-known problem with several available solutions. For this problem, traditional supervised and deep neural network based solutions have been proposed. The supervised approaches rely on: (a) Unigrams and Pragmatic features (González-Ibánez et al., 2011; Barbieri et al., 2014; Joshi et al., 2015b) (b) Stylistic patterns (Davidov et al., 2010) and patterns related to *situational disparity* (Riloff et al., 2013) and (c) Cognitive features extracted from gaze patterns (Mishra et al., 2016, 2017). Recent systems are based on variants of deep neural networks built on the top of embeddings. Deep neural networks based solutions for sarcasm detection include (Ghosh and Veale, 2016) who uses a combination of RNNs and CNNs for sarcasm detection, and (Tay et al., 2018), who propose a variant of CNN for extracting features related to context incongruity.

A few works exist in the domains of irony, pun and humour generation and are summarized by Wallace (2015), Ritchie (2005) and Strapparava et al. (2011) respectively. However, most of these are heuristic driven and, hence, may not be easily scaled to new domains and languages. From the perspective of language style transfer. Shen et al. (2017) propose an unsupervised scheme to learn latent content distribution across different text corpora and use it for sentiment style transfer. Xu et al. (2018) introduce an unsupervised sentiment translation technique through sentiment neutralization and reinforced sequence generation. Zhang et al. (2018) propose a style transfer technique based on unsupervised MT inspired by Artetxe et al. (2017). Artetxe et al. (2018) have recently proposed an unsupervised statistical machine translation scheme. We adopt some of these modules for the task of sarcasm generation. As far as we know, our proposed model is the first of its kind for end-to-end neural sarcasm generation.

7 Conclusion and Future Work

We proposed a first of its kind approach for textual sarcasm generation from literal opinionated texts. We designed a modular framework for extracting facts from the input, generating incongruous positive and negative situational phrases related to the facts, and finally generating sarcastic variations. For evaluation, we prepared a benchmark dataset containing literal opinions and their sarcastic versions. Through qualitative and quantitative analysis of the system's performance on the benchmark dataset, we observed that our system often generates better sarcastic sentences compared to some of our trivial model variants, and unsupervised systems used for machine translation and sentiment style transfer. In the future, we would like to extend this framework for cross-lingual and cross-cultural sarcasm and irony generation.

Generating Classical Chinese Poems from Vernacular Chinese

Abstract

Classical Chinese poetry is a jewel in the treasure house of Chinese culture. Previous poem generation models only allow users to employ keywords to interfere the meaning of generated poems, leaving the dominion of generation to the model. In this paper, we propose a novel task of generating classical Chinese poems from vernacular, which allows users to have more control over the semantic of generated poems. We adapt the approach of unsupervised machine translation (UMT) to our task. We use segmentation-based padding and reinforcement learning to address under-translation and over-translation respectively. According to experiments, our approach significantly improve the perplexity and BLEU compared with typical UMT models. Furthermore, we explored guidelines on how to write the input vernacular to generate better poems. Human evaluation showed our approach can generate high-quality poems which are comparable to amateur poems.

1 Introduction

During thousands of years, millions of classical Chinese poems have been written. They contain ancient poets' emotions such as their appreciation for nature, desiring for freedom and concerns for their countries. Among various types of classical poetry, *quatrain poems* stand out. On the one hand, their aestheticism and terseness exhibit unique elegance. On the other hand, composing such poems is extremely challenging due to their phonological, tonal and structural restrictions.

Most previous models for generating classical Chinese poems (He et al., 2012; Zhang and Lapata, 2014) are based on limited keywords or characters at fixed positions (e.g., acrostic poems). Since users could only interfere with the semantic of generated poems using a few input words, models control the procedure of poem generation. In this paper, we proposed a novel model for classical Chinese poem generation. As illustrated in Figure 1, our model generates a classical Chinese poem based on a vernacular Chinese paragraph. Our objective is not only to make the model generate aesthetic and terse poems, but also keep rich semantic of the original vernacular paragraph. Therefore, our model gives users more control power over the semantic of generated poems by carefully writing the vernacular paragraph.

Although a great number of classical poems and vernacular paragraphs are easily available, there exist only limited human-annotated pairs of poems and their corresponding vernacular translations. Thus, it is unlikely to train such poem generation model using supervised approaches. Inspired by unsupervised machine translation (UMT) (Lample et al., 2018b), we treated our task as a translation problem, namely translating vernacular paragraphs to classical poems.

However, our work is not just a straight-forward application of UMT. In a training example for UMT, the length difference of source and target languages are usually not large, but this is not true in our task. Classical poems tend to be more concise and abstract, while vernacular text tends to be detailed and lengthy. Based on our observation on gold-standard annotations, vernacular paragraphs usually contain more than twice as many Chinese characters as their corresponding classical poems. Therefore, such discrepancy leads to two main problems during our preliminary experiments: (1) **Under-translation**: when summarizing vernacular paragraphs to poems, some vernacular sentences are not translated and ignored by our model. Take the last two vernacular sentences in Figure

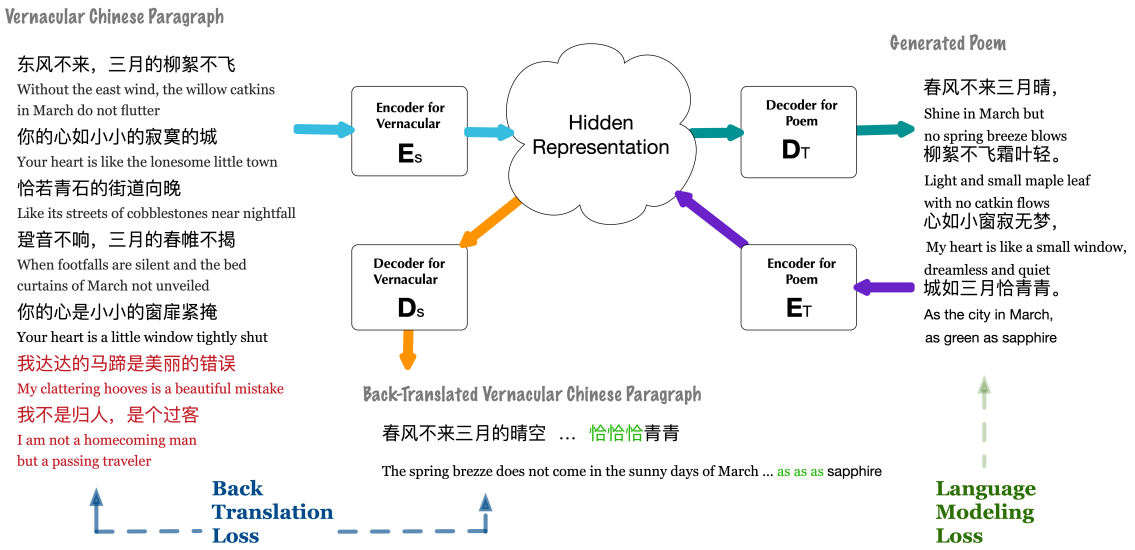

Figure 1: An example of the training procedures of our model. Here we depict two procedures, namely back translation and language modeling. Back translation has two paths, namely $\mathbf{E}_S \rightarrow \mathbf{D}_T \rightarrow \mathbf{E}_T \rightarrow \mathbf{D}_S$ and $\mathbf{D}_T \rightarrow \mathbf{E}_S \rightarrow \mathbf{D}_S \rightarrow \mathbf{E}_T$. Language modeling also has two paths, namely $\mathbf{E}_T \rightarrow \mathbf{D}_T$ and $\mathbf{E}_S \rightarrow \mathbf{D}_S$. Figure 1 shows only the former one for each training procedure.

1 as examples, they are not covered in the generated poem. (2) **Over-translation**: when expanding poems to vernacular paragraphs, certain words are unnecessarily translated for multiple times. For example, the last sentence in the generated poem of Figure 1, *as green as sapphire*, is back-translated as *as green as as as sapphire*.

Inspired by the phrase segmentation schema in classical poems (Ye, 1984), we proposed the method of phrase-segmentation-based padding to handle with under-translation. By padding poems based on the phrase segmentation custom of classical poems, our model better aligns poems with their corresponding vernacular paragraphs and meanwhile lowers the risk of under-translation. Inspired by Paulus et al. (2018), we designed a reinforcement learning policy to penalize the model if it generates vernacular paragraphs with too many repeated words. Experiments show our method can effectively decrease the possibility of over-translation.

The contributions of our work are threefold:

(1) We proposed a novel task for unsupervised Chinese poem generation from vernacular text.

(2) We proposed using phrase-segmentation-based padding and reinforcement learning to address two important problems in this task, namely under-translation and over-translation.

(3) Through extensive experiments, we proved the effectiveness of our models and explored how to write the input vernacular to inspire better poems. Human evaluation shows our models are able to generate high quality poems, which are comparable to amateur poems.

2 Related Works

Classical Chinese Poem Generation Most previous works in classical Chinese poem generation focus on improving the semantic coherence of generated poems. Based on LSTM, Zhang and Lapata (2014) purposed generating poem lines incrementally by taking into account the history of what has been generated so far. Yan (2016) proposed a polishing generation schema, each poem line is generated incrementally and iteratively by refining each line one-by-one. Wang et al. (2016) and Yi et al. (2018) proposed models to keep the generated poems coherent and semantically consistent with the user's intent. There are also researches that focus on other aspects of poem generation. (Yang et al. (2018) explored increasing the diversity of generated poems using an unsupervised approach. Xu et al. (2018) explored generating Chinese poems from images. While most previous works generate poems based on topic words, our work targets at a novel task: generating poems from vernacular Chinese paragraphs.

Unsupervised Machine Translation Compared

with supervised machine translation approaches (Cho et al., 2014; Bahdanau et al., 2015), unsupervised machine translation (Lample et al., 2018a,b) does not rely on human-labeled parallel corpora for training. This technique is proved to greatly improve the performance of low-resource languages translation systems. (e.g. English-Urdu translation). The unsupervised machine translation framework is also applied to various other tasks, e.g. image captioning (Feng et al., 2019), text style transfer (Zhang et al., 2018), speech to text translation (Bansal et al., 2017) and clinical text simplification (Weng et al., 2019). The UMT framework makes it possible to apply neural models to tasks where limited human labeled data is available. However, in previous tasks that adopt the UMT framework, the abstraction levels of source and target language are the same. This is not the case for our task.

Under-Translation & Over-Translation Both are troublesome problems for neural sequence-to-sequence models. Most previous related researches adopt the coverage mechanism (Tu et al., 2016; Mi et al., 2016; Sankaran et al., 2016). However, as far as we know, there were no successful attempt applying coverage mechanism to transformer-based models (Vaswani et al., 2017).

3 Model

3.1 Main Architecture

We transform our poem generation task as an unsupervised machine translation problem. As illustrated in Figure 1, based on the recently proposed UMT framework (Lample et al., 2018b), our model is composed of the following components:

- Encoder $\mathbf{E}_s$ and decoder $\mathbf{D}_s$ for vernacular paragraph processing
- Encoder $\mathbf{E}_t$ and decoder $\mathbf{D}_t$ for classical poem processing

where $\mathbf{E}_s$ (or $\mathbf{E}_t$) takes in a vernacular paragraph (or a classical poem) and converts it into a hidden representation, and $\mathbf{D}_s$ (or $\mathbf{D}_t$) takes in the hidden representation and converts it into a vernacular paragraph (or a poem). Our model relies on a vernacular texts corpus $\boldsymbol{S}$ and a poem corpus $\boldsymbol{T}$. We denote S and T as instances in $\boldsymbol{S}$ and $\boldsymbol{T}$ respectively.

The training of our model relies on three procedures, namely *parameter initialization*, *language modeling* and *back-translation*. We will give detailed introduction to each procedure.

Parameter initialization As both vernacular and classical poem use Chinese characters, we initialize the character embedding of both languages in one common space, the same character in two languages shares the same embedding. This initialization helps associate characters with their plausible translations in the other language.

Language modeling It helps the model generate texts that conform to a certain language. A well-trained language model is able to detect and correct minor lexical and syntactic errors. We train the language models for both vernacular and classical poem by minimizing the following loss:

$$\begin{aligned}\mathcal{L}^{lm} = &\mathop{\mathbb{E}}_{S\in\boldsymbol{S}}[-\log P(S|\mathbf{D}_s(\mathbf{E}_s(S_N))]+\\ &\mathop{\mathbb{E}}_{T\in\boldsymbol{T}}[-\log P(T|\mathbf{D}_t(\mathbf{E}_t(T_N))],\end{aligned} \tag{1}$$

where S_N (or T_N) is generated by adding noise (drop, swap or blank a few words) in S (or T).

Back-translation Based on a vernacular paragraph S, we generate a poem T_S using $\mathbf{E}_s$ and $\mathbf{D}_t$, we then translate T_S back into a vernacular paragraph $S_{T_S} = \mathbf{D}_s(\mathbf{E}_t(T_S))$. Here, S could be used as gold standard for the back-translated paragraph S_{T_s}. In this way, we could turn the unsupervised translation into a supervised task by maximizing the similarity between S and S_{T_S}. The same also applies to using poem T as gold standard for its corresponding back-translation T_{S_T}. We define the following loss:

$$\begin{aligned}\mathcal{L}^{bt} = &\mathop{\mathbb{E}}_{S\in\boldsymbol{S}}[-\log P(S|\mathbf{D}_s(\mathbf{E}_t(T_S))]+\\ &\mathop{\mathbb{E}}_{T\in\boldsymbol{T}}[-\log P(T|\mathbf{D}_t(\mathbf{E}_s(S_T))].\end{aligned} \tag{2}$$

Note that $\mathcal{L}^{bt}$ does not back propagate through the generation of T_S and S_T as we observe no improvement in doing so. When training the model, we minimize the composite loss:

$$\mathcal{L} = \alpha_1\mathcal{L}^{lm} + \alpha_2\mathcal{L}^{bt}, \tag{3}$$

where α_1 and α_2 are scaling factors.

3.2 Addressing Under-Translation and Over-Translation

During our early experiments, we realize that the naive UMT framework is not readily applied to our task. Classical Chinese poems are featured for

its terseness and abstractness. They usually focus on depicting broad poetic images rather than details. We collected a dataset of classical Chinese poems and their corresponding vernacular translations, the average length of the poems is 32.0 characters, while for vernacular translations, it is 73.3. The huge gap in sequence length between source and target language would induce over-translation and under-translation when training UMT models. In the following sections, we explain the two problems and introduce our improvements.

3.2.1 Under-Translation

By nature, classical poems are more concise and abstract while vernaculars are more detailed and lengthy, to express the same meaning, a vernacular paragraph usually contains more characters than a classical poem. As a result, when summarizing a vernacular paragraph S to a poem T_S, T_S may not cover all information in S due to its length limit. In real practice, we notice the generated poems usually only cover the information in the front part of the vernacular paragraph, while the latter part is unmentioned.

To alleviate under-translation, we propose phrase segmentation-based padding. Specifically, we first segment each line in a classical poem into several sub-sequences, we then join these sub-sequences with the special padding tokens <p>. During training, the padded lines are used instead of the original poem lines. As illustrated in Figure 2, padding would create better alignments between a vernacular paragraph and a prolonged poem, making it more likely for the latter part of the vernacular paragraph to be covered in the poem. As we mentioned before, the length of the vernacular translation is about twice the length of its corresponding classical poem, so we pad each segmented line to twice its original length.

According to Ye (1984), to present a stronger sense of rhythm, each type of poem has its unique phrase segmentation schema, for example, most seven-character quatrain poems adopt the 2-2-3 schema, i.e. each quatrain line contains 3 phrases, the first, second and third phrase contains 2, 2, 3 characters respectively. Inspired by this law, we segment lines in a poem according to the corresponding phrase segmentation schema. In this way, we could avoid characters within the scope of a phrase to be cut apart, thus best preserve the semantic of each phrase.(Chang et al., 2008)

Figure 2: A real example to show the effectiveness of our phrase-segmentation-based padding. Without padding, the vernacular paragraph could not be aligned well with the poem. Therefore, the text *in South Yangtze ends but the grass and trees have not withered* in red is not covered in the poem. By contrast, they are covered well after using our padding method.

3.2.2 Over-Translation

In NMT, when decoding is complete, the decoder would generate an <EOS>token, indicating it has reached the end of the output sequence. However, when expending a poem T into a vernacular Chinese paragraph S_T, due to the conciseness nature of poems, after finishing translating every source character in T, the output sequence S_T may still be much shorter than the expected length of a poem's vernacular translation. As a result, the decoder would believe it has not finished decoding. Instead of generating the <EOS>token, the decoder would continue to generate new output characters from previously translated source characters. This would cause the decoder to repetitively output a piece of text many times.

To remedy this issue, in addition to minimizing the original loss function $\mathcal{L}$, we propose to minimize a specific discrete metric, which is made possible with reinforcement learning.

We define *repetition ratio* $RR(S)$ of a paragraph S as:

$$RR(S) = 1 - \frac{vocab(S)}{len(S)}, \tag{4}$$

where $vocab(S)$ refers to the number of distinctive characters in S, $len(S)$ refers the number of all characters in S. Obviously, if a generated sequence contains many repeated characters, it would have high *repetition ratio*. Following the self-critical policy gradient training (Rennie et al.,

	Training set	Validation set	Test set
# Poems	163K	19K	487
Average length of poems	32.0	32.0	32.0
# vernacular paragraphs	337K	19K	487
Average length of vernacular paragraphs	71.8	76.8	73.3

Table 1: Statistics of our dataset

2017), we define the following loss function:

$$\mathcal{L}^{rl} = \mathop{\mathbb{E}}_{S \in \boldsymbol{S}}[(RR(S_{T_S}) - \tau) \log P(S|\mathbf{D}_s(\mathbf{E}_t(T_S))], \tag{5}$$

where τ is a manually set threshold. Intuitively, minimizing $\mathcal{L}^{rl}$ is equivalent to maximizing the conditional likelihood of the sequence S given S_{T_S} if its *repetition ratio* is lower than the threshold τ. Following (Wu et al., 2016), we revise the composite loss as:

$$\mathcal{L}' = \alpha_1 \mathcal{L}^{lm} + \alpha_2 \mathcal{L}^{bt} + \alpha_3 \mathcal{L}^{rl}, \tag{6}$$

where $\alpha_1, \alpha_2, \alpha_3$ are scaling factors.

4 Experiment

The objectives of our experiment are to explore the following questions: (1) How much do our models improve the generated poems? (Section 4.4) (2) What are characteristics of the input vernacular paragraph that lead to a good generated poem? (Section 4.5) (3) What are weaknesses of generated poems compared to human poems? (Section 4.6) To this end, we built a dataset as described in Section 4.1. Evaluation metrics and baselines are described in Section 4.2 and 4.3. For the implementation details of building the dataset and models, please refer to supplementary materials.[1]

4.1 Datasets

Training and Validation Sets We collected a corpus of poems and a corpus of vernacular literature from online resources. The poem corpus contains 163K quatrain poems from *Tang Poems* and *Song Poems*, the vernacular literature corpus contains 337K short paragraphs from 281 famous books, the corpus covers various literary forms including prose, fiction and essay. Note that our poem corpus and a vernacular corpus are not aligned. We further split the two corpora into a training set and a validation set.

[1]Our data and code is publicly available at https://github.com/whaleloops/interpoetry

Test Set From online resources, we collected 487 seven-character quatrain poems from *Tang Poems* and *Song Poems*, as well as their corresponding high quality vernacular translations. These poems could be used as gold standards for poems generated from their corresponding vernacular translations. Table 1 shows the statistics of our training, validation and test set.

4.2 Evaluation Metrics

Perplexity Perplexity reflects the probability a model generates a certain poem. Intuitively, a better model would yield higher probability (lower perplexity) on the gold poem.

BLEU As a standard evaluation metric for machine translation, BLEU (Papineni et al., 2001) measures the intersection of n-grams between the generated poem and the gold poem. A better generated poem usually achieves higher BLEU score, as it shares more n-gram with the gold poem.

Human evaluation While perplexity and BLEU are objective metrics that could be applied to large-volume test set, evaluating Chinese poems is after all a subjective task. We invited 30 human evaluators to join our human evaluation. The human evaluators were divided into two groups. The expert group contains 15 people who hold a bachelor degree in Chinese literature, and the amateur group contains 15 people who holds a bachelor degree in other fields. All 30 human evaluators are native Chinese speakers.

We ask evaluators to grade each generated poem from four perspectives: 1) *Fluency*: Is the generated poem grammatically and rhythmically well formed, 2) *Semantic coherence*: Is the generated poem itself semantic coherent and meaningful, 3) *Semantic preservability*: Does the generated poem preserve the semantic of the modern Chinese translation, 4) *Poeticness*: Does the generated poem display the characteristic of a poem and does the poem build good poetic image. The grading scale for each perspective is from 1 to 5.

ID	Vernacular paragraph	Generated poem
1	青山隐隐约约绿水千里迢迢，秋时已尽江南草木还未枯凋。二十四桥明月映照幽幽清夜，你这美人现在何处教人吹箫？	青山隐隐绿水光，千里秋时已尽藏。江南草木还未枯，二十四桥幽夜香。
1	Blue peak is blur and faint, green river meaders thousands miles, the southern grass has not dried up in the autumn. Twenty-four hole bridges and bright moons shine in the clear night. where do you beautifully teach people to flute?	Blue peak blurs and green river shines, thousands miles away, autumn has been hidden. the southern grass has not dried up in the autumn. Twenty-four hole bridges smells beautiful and quiet tonight.
2	拂袖起舞于梦中徘徊，相思蔓上心扉。她眷恋梨花泪，静画红妆等谁归，空留伊人徐徐憔悴。	拂袖起舞梦徘徊，相思蔓上心扉开。玉眷梨花泪痕静，画红等谁归去来。
2	The sleeves danced in the dream, and the lovesickness was on the heart. She is in love with the tears of pears, and who is quietly wearing red makeup, only left alone to be languished slowly.	The sleeves danced in the dream, the lovesickness appeared in the heart. Jade concerns tears of pears but the mark is still, wearing red makeup waiting for the one to come and go.
3	窗外的麻雀在电线杆上多嘴，你说这一句很有夏天的感觉。手中的铅笔在纸上来来回回，我用几行字形容你是我的谁。	窗下麻姑灯火多，闲中说与万缘何。夏频手把铅华纸，来往回头用几多。
3	The sparrow outside the window is talking on the pole. You say this sentence makes you feel very summer. The pencil in my hand is writing back and forth on the paper. I only use a few lines to describe who you are to me.	Under the window lie sparrow girls in this prosperous city, chit chatting about the destiny of the world. Summer hands over many drawing canvas, Looking back and forth, how many do you need?
4	雨天的屋瓦，浮漾湿湿的流光，灰而温柔，迎光则微明，背光则幽黯，对于视觉，是一种低沉的安慰。	雨余屋瓦浮漾湿，流光灰色暖相迎。光则微明背则色，幽人黯黯对风清。
4	The rainy days of the roof tiles are soaking wet and wet, gray and gentle, Facing the light, it is slightly bright, Against the light, it is pitch dark, For the concept of vision, it is a deep comfort.	The excess rain makes roof tiles rippling, ambilight gray is warm and welcoming. Light is slightly bright, against is pure color. The person hides in dark but faces wind breeze.
5	只要历史不阻断，时间不倒退，一切都会衰老。老就老了吧，安详地交给世界一副慈祥美。假饰天真是最残酷的自我糟践。	只要谐公不阻时，不倒退食一尘埃。会衰老矣安分世，一副慈祥假此来。
5	As long as history does not block, time does not go backwards, everything will age. It is fine to get old, and handing it to the world with kindness. Faking innocence is the cruelest self-destruction.	As long as people do not block time, it will not go backwards and absorbs into a dust. People should stay chill and get old. Faking innocence is not the way to go.

Table 2: A few poems generated by our model from their corresponding vernacular paragraphs.

4.3 Baselines

We compare the performance of the following models: (1) *LSTM* (Hochreiter and Schmidhuber, 1997); (2)*Naive transformer* (Vaswani et al., 2017); (3)*Transformer + Anti OT* (RL loss); (4)*Transformer + Anti UT* (phrase segmentation-based padding); (5)*Transformer + Anti OT&UT*.

4.4 Reborn Poems: Generating Poems from Vernacular Translations

As illustrated in Table 2 (ID 1). Given the vernacular translation of each gold poem in test set, we generate five poems using our models. Intuitively, the more the generated poem resembles the gold poem, the better the model is. We report mean perplexity and BLEU scores in Table 3 (Where +Anti OT refers to adding the reinforcement loss to mitigate over-fitting and +Anti UT refers to adding phrase segmentation-based padding to mitigate under-translation), human evaluation results in Table 4.[2]

According to experiment results, perplexity, BLEU scores and total scores in human evaluation are consistent with each other. We observe all BLEU scores are fairly low, we believe it is reasonable as there could be multiple ways to compose a poem given a vernacular paragraph. Among transformer-based models, both +Anti OT and +Anti UT outperforms the naive transformer, while Anti OT&UT shows the best performance, this demonstrates alleviating under-translation and over-translation both helps generate better poems. Specifically, +Anti UT shows bigger improvement than +Anti OT. According to human evaluation, among the four perspectives, our Anti OT&UT brought most score improvement in *Semantic preservability*, this proves our improvement on semantic preservability was most obvious to human evaluators. All transformer-

[2]We did not use LSTM in human evaluation since its performance is worse as shown in Table 3.

Model	Perplexity	BLEU	BLEU-1	BLEU-2	BLEU-3	BLEU-4
LSTM	118.27	3.81	39.16	6.93	1.58	0.49
Transformer	105.79	5.50	40.92	8.02	2.46	1.11
+Anti OT	77.33	6.08	41.22	8.72	2.82	1.36
+Anti UT	74.21	6.34	42.20	**9.04**	**2.96**	1.44
+Anti OT&UT	**65.58**	**6.57**	**42.53**	8.98	**2.96**	**1.46**

Table 3: Perplexity and BLEU scores of generating poems from vernacular translations. Since perplexity and BLEU scores on the test set fluctuates from epoch to epoch, we report the mean perplexity and BLEU scores over 5 consecutive epochs after convergence.

Model	Fluency	Semantic coherence	Semantic preservability	Poeticness	Total
Transformer	2.63	2.54	2.12	2.46	9.75
+Anti OT	2.80	2.75	2.44	2.71	10.70
+Anti UT	2.82	2.82	2.86	2.85	11.35
+Anti OT&UT	**3.21**	**3.27**	**3.27**	**3.28**	**13.13**

Table 4: Human evaluation results of generating poems from vernacular translations. We report the mean scores for each evaluation metric and total scores of four metrics.

based models outperform LSTM. Note that the average length of the vernacular translation is over 70 characters, comparing with transformer-based models, LSTM may only keep the information in the beginning and end of the vernacular. We anticipated some score inconsistency between expert group and amateur group. However, after analyzing human evaluation results, we did not observed big divergence between two groups.

4.5 Interpoetry: Generating Poems from Various Literature Forms

Chinese literature is not only featured for classical poems, but also various other literature forms. *Song lyric*(宋词), or *ci* also gained tremendous popularity in its palmy days, standing out in classical Chinese literature. *Modern prose*, *modern poems* and *pop song lyrics* have won extensive praise among Chinese people in modern days. The goal of this experiment is to transfer texts of other literature forms into quatrain poems. We expect the generated poems to not only keep the semantic of the original text, but also demonstrate terseness, rhythm and other characteristics of ancient poems. Specifically, we chose 20 famous fragments from four types of Chinese literature (5 fragments for each of modern prose, modern poems, pop song lyrics and Song lyrics). We try to As no ground truth is available, we resorted to human evaluation with the same grading standard in Section 4.4.

Comparing the scores of different literature forms, we observe Song lyric achieves higher scores than the other three forms of modern literature. It is not surprising as both Song lyric and quatrain poems are written in classical Chinese, while the other three literature forms are all in vernacular.

Comparing the scores within the same literature form, we observe the scores of poems generated from different paragraphs tends to vary. After carefully studying the generated poems as well as their scores, we have the following observation:

1) In classical Chinese poems, poetic images (意象) were widely used to express emotions and to build artistic conception. A certain poetic image usually has some fixed implications. For example, *autumn* is usually used to imply sadness and loneliness. However, with the change of time, poetic images and their implications have also changed. According to our observation, if a vernacular paragraph contains more poetic images used in classical literature, its generated poem usually achieves higher score. As illustrated in Table 2, both paragraph 2 and 3 are generated from pop song lyrics, paragraph 2 uses many poetic images from classical literature (e.g. pear flowers, makeup), while paragraph 3 uses modern poetic images (e.g. sparrows on the utility pole). Obviously, compared with poem 2, sentences in poem 3 seems more confusing, as the poetic images in modern times may not fit well into the language model of classical poems.

2) We also observed that poems generated from descriptive paragraphs achieve higher scores than from logical or philosophical paragraphs. For example, in Table 2, both paragraph 4 (more descriptive) and paragraph 5 (more philosophical) were

Literature form	Fluency	Semantic coherence	Semantic preservability	Poeticness	Total
Prose	2.52	2.30	2.30	2.32	9.44
Modern poem	2.37	2.34	2.01	2.16	8.88
Pop song lyric	2.40	2.31	2.24	2.42	9.37
Song lyric	**2.62**	**2.54**	**2.26**	**2.49**	**9.91**

Table 5: Human evaluation results for generating poems from various literature forms. We show the results obtained from our best model (Transformer+Anti OT&UT).

selected from famous modern prose. However, compared with poem 4, poem 5 seems semantically more confusing. We offer two explanations to the above phenomenon: **i**. Limited by the 28-character restriction, it is hard for quatrain poems to cover complex logical or philosophical explanation. **ii**. As vernacular paragraphs are more detailed and lengthy, some information in a vernacular paragraph may be lost when it is summarized into a classical poem. While losing some information may not change the general meaning of a descriptive paragraph, it could make a big difference in a logical or philosophical paragraph.

4.6 Human Discrimination Test

We manually select 25 generated poems from vernacular Chinese translations and pair each one with its corresponding human written poem. We then present the 25 pairs to human evaluators and ask them to differentiate which poem is generated by human poet.[3]

As demonstrated in Table 6, although the general meanings in human poems and generated poems seem to be the same, the wordings they employ are quite different. This explains the low BLEU scores in Section 4.3. According to the test results in Table 7, human evaluators only achieved 65.8% in mean accuracy. This indicates the best generated poems are somewhat comparable to poems written by amateur poets.

We interviewed evaluators who achieved higher than 80% accuracy on their differentiation strategies. Most interviewed evaluators state they realize the sentences in a human written poem are usually well organized to highlight a theme or to build a poetic image, while the correlation between sentences in a generated poem does not seem strong. As demonstrated in Table 6, the last two sentences in both human poems (marked as red) echo each other well, while the sentences in machine-generated poems seem more independent. This gives us hints on the weakness of generated poems: While neural models may generate poems that resemble human poems lexically and syntactically, it's still hard for them to compete with human beings in building up good structures.

[3]We did not require the expert group's participation as many of them have known the gold poems already. Thus using their judgments would be unfair.

Human	黄沙磧里客行迷，四望云天直下低。 Within yellow sand moraine guest travels lost, looking around found sky and clouds low. 为言地尽天还尽，行到安西更向西。 It is said that earth and sky ends here, however I need to travel more west than anxi.
Machine	异乡客子黄沙迷，雁路迷寒云向低。 Guest in yellow sand gets lost, geese are lost because clouds gets low. 只道山川到此尽，安西还要更向西。 It is said that mountains end here, however anxi is even more west.
Human	绝域从军计惘然，东南幽恨满词笺。 It's hard to pay for the ambition of the military field, the anxiety of situation in southeast is all over poems. 一箫一剑平生意，负尽狂名十五年。 A flute and sword is all I care about in my life, 15 years have failed the reputation of "madman".
Machine	从军疆场志难酬，令人怅望东南州。 It's hard to fulfill my ambition on the military field, the situation in the southeast states are troublesome. 形容仗剑敌平戎，情怀注满赋雪愁。 I would like to use my sword to conquer my enemy, yet my feelings are full of worry like the snow.

Table 6: Examples of generated poems and their corresponding gold poems used in human discrimination test.

5 Discussion

Addressing Under-Translation In this part, we wish to explore the effect of different phrase segmentation schemas on our phrase segmentation-based padding. According to Ye (1984), most seven-character quatrain poems adopt the 2-2-3 segmentation schema. As shown in examples in Figure 3, we compare our phrase segmentation-based padding (2-2-3 schema) to two less common schemas (i.e. 2-3-2 and 3-2-2 schema) we report our experiment results in Table 8.

Accuracy	Value
Min	52.0
Max	84.0
Mean	65.8

Table 7: The performance of human discrimination test.

Padding schema	Perplexity	BLEU
2-2-3	**74.21**	**6.34**
2-3-2	83.12	5.49
3-2-2	85.66	5.75

Table 8: Perplexity and BLEU scores of different padding schemas.

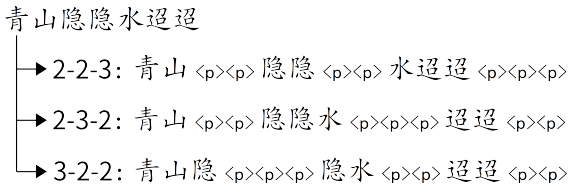

Figure 3: Examples of different padding schemas.

The results show our 2-2-3 segmentation-schema greatly outperforms 2-3-2 and 3-2-2 schema in both perplexity and BLEU scores. Note that the BLEU scores of 2-3-2 and 3-2-2 schema remains almost the same as our naive baseline (Without padding). According to the observation, we have the following conclusions: 1) Although padding better aligns the vernacular paragraph to the poem, it may not improve the quality of the generated poem. 2) The padding tokens should be placed according to the phrase segmentation schema of the poem as it preserves the semantic within the scope of each phrase.

Addressing Over-Translation To explore the effect of our reinforcement learning policy on alleviating over-translation, we calculate the *repetition ratio* of vernacular paragraphs generated from classical poems in our validation set. We found *naive transformer* achieves 40.8% in repetition ratio, while our +Anti OT achieves 34.9%. Given the repetition ratio of vernacular paragraphs (written by human beings) in our validation set is 30.1%, the experiment results demonstrated our RL loss effectively alleviate over-translation, which in turn leads to better generated poems.

6 Conclusion

In this paper, we proposed a novel task of generating classical Chinese poems from vernacular paragraphs. We adapted the unsupervised machine translation model to our task and meanwhile proposed two novel approaches to address the under-translation and over-translation problems. Experiments show that our task can give users more controllability in generating poems. In addition, our approaches are very effective to solve the problems when the UMT model is directly used in this task. In the future, we plan to explore: (1) Applying the UMT model in the tasks where the abstraction levels of source and target languages are different (e.g., unsupervised automatic summarization); (2) Improving the quality of generated poems via better structure organization approaches.

Set to Ordered Text: Generating Discharge Instructions from Medical Billing Codes

Litton J Kurisinkel, Nancy F. Chen
Institute for Infocomm Research, A*STAR
{Litton_Kurisinkel, nfychen}@i2r.a-star.edu.sg

Abstract

We present set to ordered text, a natural language generation task applied to automatically generating discharge instructions from admission ICD (International Classification of Diseases) codes. This task differs from other natural language generation tasks in the following ways: (1) The input is a set of identifiable entities (ICD codes) where the relations between individual entities are not explicitly specified. (2) The output text is not a narrative description (e.g. news articles) composed from the input. Rather, inferences are made from the input (ICD codes, which represent diagnoses and clinical procedures) to generate the output (instructions). (3) There is an optimal order in which each sentence (instruction) should appear in the output. Unlike most other tasks, neither the input (ICD codes) nor their corresponding text representations of diagnoses and clinical procedures appear in the output, so the ordering of the output instructions needs to be learned in an unsupervised fashion. We hypothesize that each instruction in the output is mapped to a subset of ICD codes specified in the input. We propose a neural architecture that jointly models (a) subset selection: choosing relevant subsets from a set of input entities; (b) content ordering: learning the order of instructions; (c) text generation: representing the instructions corresponding to the selected subsets in natural language. In addition, we penalize redundancy during beam search to improve tractability for long text generation. We formulate the problem setup and conducted experiments using the MIMIC-III dataset. Our model outperforms baseline models in both BLEU scores and human evaluations.

1 Introduction

1.1 Problem Statement

Many healthcare applications exhibit a strong mapping between numerical or categorical information and clinical instructions. To develop language generation capabilities for these settings, we define a task where discharge instructions are automatically generated using admission ICD (International Classification of Diseases) codes[1] to potentially streamline clinical workflow. We define a task where the input is a set of identifiable items (ICD codes) and the output consists of ordered text sequences (instructions), which are inferred from the input (see Figure 1).

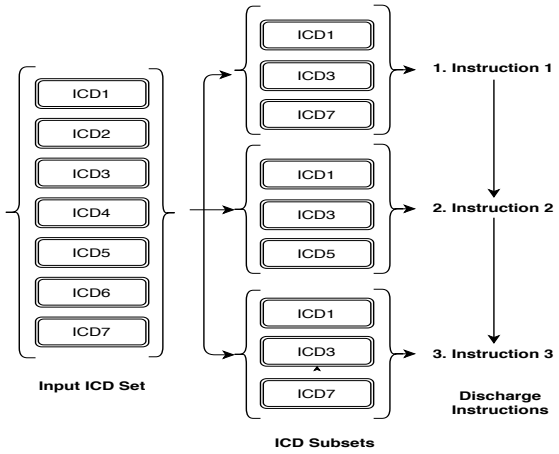

Figure 1: Set to Ordered Text: Problem Definition

1.2 Proposed Approach

We hypothesize that each discharge instruction in the output is mapped to a subset of ICD codes specified in the input. Our proposed approach thus models the correlations between individual entities in the input set to choose the most relevant subsets, and learn to generate their corresponding textual outputs in the appropriate order. We also incorporate explicit means for reducing redundancy during decoding. We empirically verify

[1]It is standard practice for healthcare providers to assign ICD codes to represent information regarding diagnosis and/or procedures for each hospital visit for medical billing purposes.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6165–6175,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the proposed approach by generating discharge instructions from ICD codes assigned during hospital admissions.

1.3 Relation to Other Work

For most natural language generation tasks, the relations between the input entities are specified in one way or another. For text-to-text generation (e.g. news articles), the relation between entities are semantically encoded in sequences of words (Paulus et al., 2017). For graph-to-text generation, relations between the nodes in a graph are characterized through labeled or unlabeled edges (Liu et al., 2019b). For text generation with database inputs, relations are usually specified through the attributes of each data entry (Lebret et al., 2016). In our problem setup, there is no explicit characterization of the relations between the input ICD codes assigned to a patient's visit.

Most natural language generation problems focus on generating descriptions, which often include the entities specified in the input. Examples include summarization or text generation from database records (Cheng and Lapata, 2016; Jhamtani et al., 2018). In our case, both the content and the ordering of the output need to be inferred from the input data.

Our work is closest to the line of research on text expansion, where the generated text is conditioned on a set of entities (Clark et al., 2018; Zhao et al., 2018; Kiddon et al., 2016). Although in this line of work the relations between the entity input set are not specified, as in our case, these input entities often appear in the output text, making it more straightforward to model the order of the input entities appearing in the output. In our case, neither the input entity set (ICD codes) nor their corresponding text representations (diagnoses and clinical procedures) occur in the generated output (instructions).

2 Approach

2.1 Task Definition

For input set S, the generation task can be specified as follows,

$$x \leftarrow F(S, X)$$
$$o \leftarrow Gen(x),$$

where F represents the mechanism to choose the next subset x given input S and the already chosen sequence of subsets X; Gen generates the output sentence o from the chosen subset x.

2.2 Neural Architecture

The proposed neural architecture is shown in Figure 2. The major components of the network are a lookup table for ICD codes, gates for content and subset selection, one RNN for content ordering and another one for decoding each discharge instruction. The network also posses two attention layers for finding the correlations between input ICD codes and for attending to the chosen content at each stage of instruction generation. The instruction ordering RNN is initialized with a zero vector. Below we elaborate on the major components of the proposed neural architecture in more detail. Bold symbols in equations represent parameter matrices.

2.2.1 Content and Subset Selection

The content selection gate selects the relevant content from each ICD code during each instruction generation phase. The gate takes the ICD code embedding, the previous state of the content ordering RNN H_{t-1} and the correlations among ICD codes into account for selecting the content. The content correlation vector C_j for each ICD code embedding icd_j in the input is computed as follows:

$$\alpha_{j,k} = \exp(icd_j^T \mathbf{W_a} icd_k)$$
$$C_j = \sum_{k \neq j} \alpha_{j,k} icd_k$$

The content gate value computation and the subsequent content selection is conducted as follows:

$$gc_j = \text{sigmoid}(\mathbf{W_{gc}}[icd_j; C_j; H_{t-1}])$$
$$icd_j^{'} = gc_j \odot icd_j$$

The selected content from each of the input ICD code passes through a subset selection gate. Each subset is selected as a probability distribution over the input set of ICD codes as follows:

$$gs_j = \text{sigmoid}(\mathbf{W_{gs}}[icd_j; C_j; H_{t-1}])$$
$$gs_j = \text{softmax}(gs_j)\ \forall j$$

$gs_j, \forall j$ represents the distribution of ICD codes in the subset chosen at the current time step of content ordering RNN. The subset selection gate updates the output from content selection gate as follows:

$$icd_j^{''} = gs_j icd_j^{'} \quad (1)$$

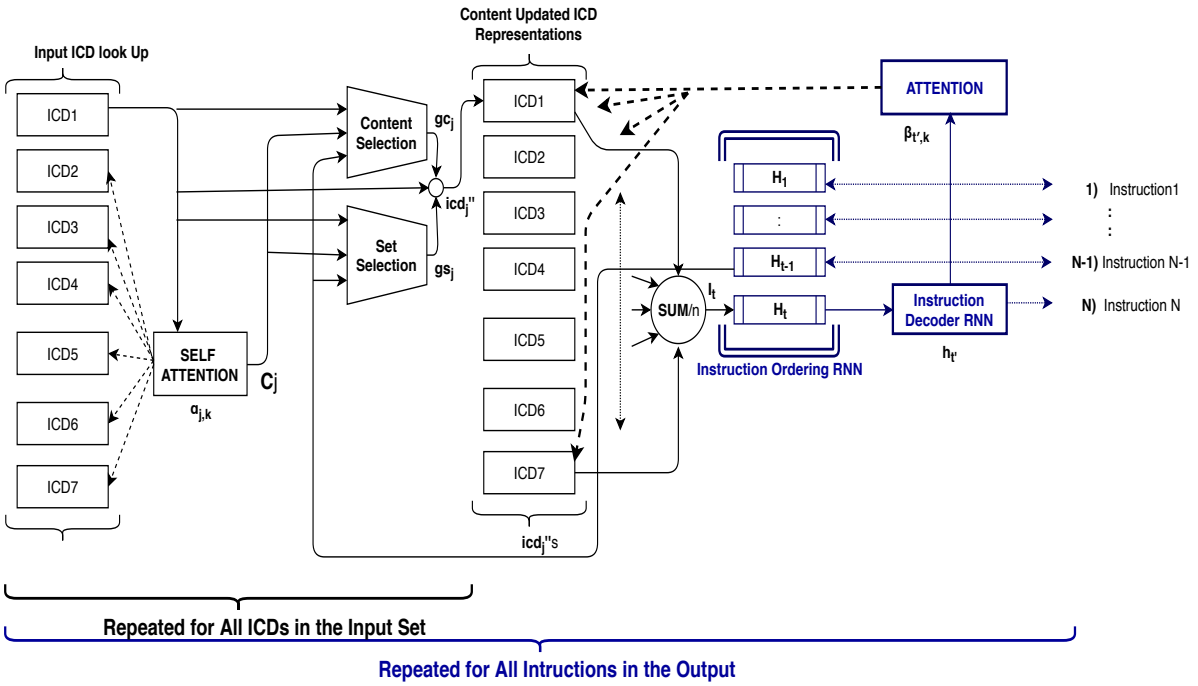

Figure 2: Proposed Neural Architecture

In the Figure 2, trapezoids represent the content and subset selection gates. During each stage of content and subset selection, the gates receive information regarding content and order of already selected subsets from the instruction ordering RNN. The figure also depicts the self attention layer which computes C_j.

2.2.2 Content Ordering and Instruction Generation

We use a GRU recurrent neural network (Chung et al., 2014) for content ordering. The RNN is initialized with a zero vector before the network activity begins and it takes the selected content of ICD codes as input during each time step. At time-step t,

$$H_t = \mathbf{GRU}(I_t, H_{t-1}), \tag{2}$$

where I_t is the mean vector of $icd_j^{"}$s computed using the Equation 1. The instruction decoder RNN (also a GRU) is initialized with H_t to generate the instruction at the current time step of content ordering RNN. During each time step of decoding, the decoder RNN attends over the current set of $icd_j^{"}$ to generate the sequence of words $w_{t'}$ in the instruction as formulated below.

$$\beta_{t',k} = \exp(h_{t'}^T \mathbf{W_c} icd_k^{"})$$
$$c_{t'} = \sum \beta_{t',k} icd_k^{"}$$
$$h_{t'}^{'} = \tanh(\mathbf{W_h}[h_{t'}, c_{t'}])$$

where $h_{t'}$ is the hidden state of the decoder at time-step $t^{'}$. The probability distribution over the output vocabulary for generating the word $w_{t'}$ at time step $t^{'}$ of the instruction generating decoder is computed as below,

$$P(w_{t'}|w_{<t'}, \{icd_i^{"}, .., icd_n^{"}\}) = \text{softmax}(\mathbf{W_o} h_{t'}^{'} + b_o) \tag{3}$$

The portion of Figure 2 marked in blue, represents the set of computations detailed in the current section.

2.2.3 Beam Search with Redundancy Penalization

In our approach, instructions are decoded one after another, corresponding to each hidden state of the content ordering RNN, as generating one single long text sequence could lead to intractability. In addition, we include a penalization factor for reducing redundancy in the cost function $\mathcal{C}$ of beam search:

$$\mathcal{C} = -\sum_{i=1}^{t} \log P_i + \lambda * J_{sim}(q_t, Q_I) \tag{4}$$

where q_t is the set of words currently chosen into the instruction under generation, Q_I represents the set of words in the previously generated instructions, J_{sim} computes Jaccard's Similarity(Hamers et al., 1989) and λ is a constant tuned to obtain a maximum BLEU score on development set.

Model	Accuracy
SVM	73 %
Logistic Regression	91 %

Table 1: Instruction vs. non-instruction classification results

3 Experiments

In this section, empirical evaluation is conducted to quantify the accuracy of our model regarding text generation, content ordering, correctness of grammar and informativeness.

3.1 Corpus: ICD Codes to Discharge Instructions[2]

Our dataset consisting of admission ICD codes and their corresponding discharge instructions is derived from MIMIC-III[3]. MIMIC-III is a database containing clinical information regarding patients, admission details, lab tests and medical notes (Ew et al., 2016). For each patient admitted to the hospital, there is a recorded set of ICD codes assigned for billing purposes to specify the diagnoses and clinical procedures related to the patient's admission. We assigned unique IDs for diagnoses and procedure codes and did not distinguish between them. Patients receive a list of discharge instructions written by clinical staff before they return home. These discharge instructions are embedded in larger documents called discharge reports.

We trained statistical models (SVM and logistic regression) to classify instruction sentences (e.g. commands) from non-instruction sentences in the discharge reports using TF-IDF vectors computed from sentences in the discharge reports as features. The dataset is split into the training set, developmental set and test set, each comprising 2,000, 500 and 500 sentences, respectively. The accuracy of this binary classification is in Table 1. The logistic regression classifier was used to construct the corpus that maps ICD codes to discharge instructions, resulting in 18,900 of input output pairs for training and 900 each for testing and development. Manual verification was performed to ensure data quality for testing and developmental sets. Following customary data post-processing protocols, named entities such as numerical values and person names were replaced by place holder tags such as [num] and [person name].

3.2 Implementation Details

We chose different base models and different settings of our model to evaluate the efficiency of our method. In this section we describe each of the models in detail.

3.2.1 Seq2Seq

In this setting we use sequence to sequence model with the attention mechanism (Bahdanau et al., 2014). The set of input ICD codes are arranged as a single sequence in random order and the model generates the entire set of instructions as a single sequence. The learning algorithm minimizes negative log-likelihood. Beam search decoding with beam size of 9 is used during testing.

3.2.2 Set2SingleSeq

In this setup, the model is a variant of (Zhou et al., 2017), where input is a set and content selection is conducted by learning correlations between the input items. This is also a variant of our method, where the output is treated as a single sequence instead of a set of instructions. Any icd_j in the input set of ICD codes are updated to selected content $icd_j^{'}$ using the content selection gate. The content correlation vector C_j for each icd_j is computed below:

$$\alpha_{j,k} = \exp(icd_j^T \mathbf{W_a} icd_k)$$
$$C_j = \sum_{k \neq j} \alpha_{j,k} icd_k$$

The content gate value computation and subsequent content selection is conducted as follows:

$$gc_j = \text{sigmoid}(\mathbf{W_{gc}}[icd_j; C_j])$$
$$icd_j^{'} = gc_j \odot icd_j$$

The entire sequence of instructions is decoded using the computed set of $icd_j^{'}$. For this purpose, the decoder is initialized with the mean vector of $icd_j^{'}$ and the decoder attends over all the set of $icd_j^{'}$ during each time-step of decoding. The learning algorithm minimizes negative log likelihood for optimizing parameters. Beam search decoding with beam size of 9 is used during testing.

3.2.3 Set2MultipleSeq

This setting represents the method explained in the Section 2.2. In this setup, instructions are generated one after another in the learned order. The optimized size for ICD embedding, content ordering RNN, and decoder RNN is 600. Sizes of network parameter matrices $\mathbf{W_a}$, $\mathbf{W_{gc}}$, $\mathbf{W_{gs}}$, $\mathbf{W_c}$ and $\mathbf{W_o}$ are adjusted accordingly. The learning algorithm minimizes negative log likelihood for optimizing parameters. Error is averaged for all instruction decoder time steps for the set of instructions generated. Beam search with beam size of 9 is used during testing.

3.2.4 Set2MultipleSeq+Opt

This setup is an enhanced version of *Set2MultipleSeq* (Section 3.2.3), but during beam search decoding redundancy is penalized (see Section 2.2.3). The value of λ in Equation 4 is set to 2.7 to obtain maximum content coverage on the development set.

4 Evaluation Study

4.1 Evaluation I: Content Generation

Instruction generation is quantitatively estimated by measuring the N-gram match of the generated content with ground-truth in test set using the BLEU metric (Papineni et al., 2002). We did not set any stopping criteria for the number of instructions to be generated for simplicity sake. However, we generated as many number of instructions in the corresponding test record. The results are shown in Table 2. *Set2MultipleSeq* yields a better score than *Seq2Seq*, indicating the effectiveness of content selection and self attention for modeling the correlation between ICD codes. The proposed *Set2MultipleSeq* approach yields even more improvement, validating that the introduction of subset selection and content selection helped in defining the content and context of an instruction during generation. This resulted in more accurate generation of instructions one after the other. When penalizing redundancy during decoding (*Set2MultipleSeq+Opt*), it explicitly forces the instruction decoder to generate an instruction with novel content during each stage of the content ordering RNN, thereby reducing errors caused by repeated content.

Method	Content Generation	
	BLEU	**BLEU-2**
Seq2Seq	6.3	22.30
Set2SingleSeq	7.6	27.00
Set2MultipleSeq	9.6	33.30
Set2MultipleSeq+Opt	**12.6**	**36.30**

Seq2Seq	0.06	0.07	0.07
Set2SingleSeq	0.07	0.09	0.08
Set2MultipleSeq	0.18	0.19	0.18
Set2MultipleSeq+Opt	**0.22**	**0.23**	**0.22**

Table 3: Evaluation II: Content Ordering: P is Precision, R is Recall and F is F- Measure. The values are approximated to two decimal points

4.2 Evaluation II: Content Ordering

For evaluating content ordering, we use a variant of the metric used by Gong et al. (2016). In this scheme, we compare the order of words in generated sequence of instructions with ground-truth: We take the set of all order bigrams S_o from the generated sequence of instructions where the first word in each bigram is from a preceding instruction and the second word is from any instruction succeeding it in the sequence. Precision and recall is computed as:

$$Precision = \frac{|S_o \bigcap S_0'|}{|S_0|}$$

$$Recall = \frac{|S_o \bigcap S_0'|}{|S_0'|}$$

S_0' is the order bigrams in the corresponding human written set of instructions in testset. Thus the metric scores the ordering better when the right content is generated in the right order. F-Measure is computed as the harmonic mean of precision and recall. The results in Table 3 show that there is a considerable improvement in the quality of ordering with after introducing content ordering mechanism in the neural architecture. Better ordering score for $Set2MultipleSeq + Opt$ is obvious as redundant content adversely affect instruction ordering.

Method	%

Set2MultipleSeq	38
Set2MultipleSeq+opt	61
Ambigous	1

Table 6: Evaluation III: Informativeness: The values represent percentage of times instructions generated by the model is chosen

4.3 Evaluation III: Human Analysis

We conduct human evaluations to measure if the generated instructions are grammatically correct and how informative they are. Four human evaluators who are post graduate students in linguistics were recruited and each given 30 sets of instructions from the testset.

4.3.1 Grammaticality

For each of the 30 instructions chosen for human evaluation, the evaluators were given a number of choices, each generated from a different model, and asked to choose the option that was the most grammatically correct. For each question, the instructions from the different models were shown to the evaluators in a random order to avoid any kind of bias. Instructions generated by *Set2SingleSeq* and *Set2MultipleSeq*. *Set2MultipleSeq+Opt* is excluded as it is an optimization for avoiding redundancy without any direct influence on the grammatical quality of text generated by neural models.

Results aggregated across evaluators through majority voting are shown in Table 4. The results show that incorporating neural network components for content selection and ordering helps in defining the context of an instruction and generating the right content in the right form. *Set2MultipleSeq* generates one instruction at a time, while *Set2SingleSeq* generates the entire set of instructions as one sequence. Grammaticality is shown to improve *Set2MultipleSeq* when only one (shorter) instruction needs to be decoded at a time .

4.3.2 Informativeness

We also conducted human experiments to evaluate the informativeness of generated instructions. The evaluators were asked to read the reference set of instructions prior to examining the instructions generated by competing methods. They were then asked to choose the model that generated instructions retaining the most information from the reference instructions. If two models present instructions that are equally informative, then the model providing richer information density is chosen.

We conducted separate evaluations for two pairs of competing systems (*Set2SingleSeq*, *Set2MultipleSeq*) and (*Set2SingleSeq*, *Set2MultipleSeq+Opt*). The results are shown in Tables 5 and 6 respectively. Results shown in Table 5 explains that incorporating neural components for subset selection and content ordering helps in improving informative instruction generation. We observe that conducting content selection multiple times during each time step through content ordering RNN helps in generating a discrete set of instructions (*Set2MultipleSeq*). Table 6 shows that penalizing redundancy during beam search decoding reduces noise and helps in generating instructions with rich information density. Inter-evaluator agreement for the entire set of human evaluation is reasonably high: Cohen's kappa coefficient is 0.79.

5 Discussions

5.1 Qualitative Comparison Across Models

Table 7 shows an example of instructions generated by the different approaches we investigated. Though *Set2SingleSeq* generates relevant instructions, it repeats the same content, misses out on instructions, and is less grammatically correct.

Set2MultipleSeq shows qualitative improvement over *Set2SingleSeq*, where the repeated content is largely reduced and the grammaticality is improved. However, for *Set2MultipleSeq*, there is

Method	Generated Content
Set2SingleSeq	shower daily including washing incisions gently with mild soap , no baths or swimming until cleared by surgeon. shower daily and pat incisions dry no lotions , creams or powders on incisions no driving for [num]. shower daily , let water flow over wounds , pat dry with a towel towel , do no
Set2MultipleSeq	**1)** shower daily and pat incisions dry no lotions , creams or powders on incisions, no baths or swimming until cleared by surgeon. **2)** no lifting greater then [num] pounds for [num] weeks , do not drive or operate heavy machinery while taking any narcotic pain medication such as percocet **3)** call for any fever , redness or drainage from wounds or weight gain more than [num] pounds **4)** call your doctor for any fever , redness or drainage from wounds
Set2MultipleSeq+Opt	**1)** shower daily and pat incisions dry no lotions , creams or powders on incisions, no baths or swimming until cleared by surgeon. **2)** no lifting greater then [num] pounds for [num] weeks , do not drive or operate heavy machinery while taking any narcotic pain medication such as percocet **3)** call for any fever , redness or drainage from wounds or weight gain more than [num] pounds **4)** follow up with your primary care doctor , dr [person name] , in the next week as well
Nurse Written Instructions	**1)** shower, no baths, no lotions,creams or powders to incisions **2)** no lifting more than [num] pounds for [num] weeks from surgery **3)** do not drive or drink alcohol while taking narcotic pain medications **4)** call with fever, redness or drainage from incision or weight gain more than [num] pounds in one day or five in one week.

Table 7: Examples from Evaluation II: Content Ordering. Person names and numeric values are specified as [person name] and [num] respectively. Repetitive content is color coded in blue for *Set2SingleSeq* and in purple for *Set2MultipleSeq*.

still repeated content in the 3rd and 4th instructions.

Set2MultipleSeq+Opt brings more tractability in the neural model by penalizing redundancy and preventing noisy content generation. In the example shown, *Set2MultipleSeq+Opt* improves over *Set2MultipleSeq*, as the content in the 3rd instruction is no longer repeated in the 4th instruction.

5.2 Variability in Groundtruth References

Variability stemming from communication style differences across clinicians could potentially be one reason why the overall scores for content generation (BLEU scores) and content ordering (F-measure) are on the low end. We observed that for the same set of ICD codes, different clinicians have different writing styles, even when the underlying content of the instructions are the same. Consider the following examples:

(a) shower daily and pat incisions dry no lotions , creams or powders on incisions, no baths or swimming until cleared by surgeon

(b) shower, no baths, no lotions,creams or powders to incisions

In (a), a more detailed way of representing the in-

struction is presented, while in (b) the same information is represented in a more succinct manner.

If a clinician decides to be more detailed in writing the instructions, the clinician might also include specific information such as medication details: "Please be sure to take aspirin and plavix everyday as directed." Such inconsistency of how information such as medication details are specified in the instructions can potentially lead the models to generate noisy content.

6 Related Prior Work

6.1 Natural Language Generation

Here we define natural language generation as the task of generating text from textual input or non-linguistic input (e.g. graphs, data records). Previous work on text generation span across various input types and methods. Initial models used learned rules (Reiter et al., 2003, 2005) and manually engineered templates (Kukich, 1983; McRoy et al., 2000; McKeown, 1985) for constructing the output text. There is also work using automatic means for generating templates (Angeli et al., 2010; Howald et al., 2013).

Such template approaches could be inherently less efficient in modeling semantics when compared to neural networks, especially if there is ample training data. Initial neural models for text generation were first motivated by machine translation (Bahdanau et al., 2014; Cho et al., 2014; Srivastava et al., 2014). However, such approaches are less suitable in comprehending the semantics of structures that are more complex than short sequences and in generating longer sequences (Paulus et al., 2017; Wiseman et al., 2018). Recent advancement in text to text generation has primarily focused on news document summarization (Cheng and Lapata, 2016; Nallapati et al., 2017; See et al., 2017; Paulus et al., 2017).

A portion of related work focuses on generating text from an input graph (Koncel-Kedziorski et al., 2019; Song et al., 2018, 2017): Graphs with labeled edges (e.g., knowledge graphs or abstract meaning representation) are used to generate a direct description of the information characterized in the input graph.

Text generation methods from data records has been investigated for different datasets such as wikipedia infobox (Lebret et al., 2016; Liu et al., 2018; Sha et al., 2018; Perez-Beltrachini and Lapata, 2018), weather predictions (Mei et al., 2016) or sport game summaries (Wiseman et al., 2017). There is a subset of work on text generation from data records which relies on content planning for generating a single sentence (Liu et al., 2018), while some other researchers generate multi-sentence outputs from structured data inputs (Puduppully et al.; Jhamtani et al., 2018). Puduppully et al. generated basketball game summaries by explicitly learning the order in which information should be mentioned in the output by generating an intermediate content plan.

6.2 Text Generation in Healthcare

A lot of NLP work in the medical domain has focused on information extraction (see (Wang et al., 2018) for a review). Driven by healthcare application demands, recently there is emerging interest in areas such as automatic ICD code assignment (Zhang et al., 2017; Scheurwegs et al., 2017; Mullenbach et al., 2018), risk prediction (Ma et al., 2018), and dialogue comprehension (Liu et al., 2019a). One of the earliest work on text generation in the medical domain dates back to more than two decades ago, where interactive systems generate summaries of the patient status for physicians and tailored explanations of clinical information for individual patients (Buchanan et al., 1995). Recent advances of neural modeling has rekindled interest in text generation. Text generation has had more presence in the media and journalism domain, ranging from image captioning (Kinghorn et al., 2018) to news reports on weather (Reiter et al., 2005) and sports (Wiseman et al., 2017). For the medical domain, interest in neural text generation has been springing up, with a primary focus on document summarization (Moradi and Ghadiri, 2018). For interested readers, Pauws et al. (2019) provides a recent review on how data-to-text technology can be applied in healthcare settings.

7 Conclusion

We proposed a neural architecture that learns to generate content in a specific order (discharge instructions for patients) without explicit specifications of the relations between input entities (ICD codes representing diagnoses and procedures) and how the input entities relate to the output. Our approach yields encouragingly better results in comparison with strong baselines. We further improved performance by penalizing redundancy during decoding.

Abstract

Phonological processes are context-dependent sound changes in natural languages. We present an unsupervised approach to learning human-readable descriptions of phonological processes from collections of related utterances. Our approach builds upon a technique from the programming languages community called *constraint-based program synthesis*. We contribute a novel encoding of the learning problem into Satisfiablity Modulo Theory constraints, which enables both data efficiency and fast inference. We evaluate our system on textbook phonology problems and lexical databases, and show that it achieves high accuracy at speeds two orders of magnitude faster than state-of-the-art approaches.

1 Introduction

Phonological processes govern the way speech sounds in natural languages change depending on the context. For example, in English verbs, the past tense suffix /d/ turns into [t] after voiceless consonants (so the word "zipped" is pronounced [zɪp**t**], while "begged" is pronounced [bɛg**d**]). Linguists routinely face the task of inferring phonological processes by observing and contrasting *surface forms* (pronunciations) of morphologically related words. To aid linguists with this task, we consider the problem of learning phonological processes automatically from collections of related surface forms.

This problem setting imposes four core requirements, which guide the design of our approach:

1. Inference results must be **fully interpretable**: our goal is to *explain* phonological processes exhibited by the data, not merely *predict* pronunciations of unseen words. Hence, our model takes the form of discrete, conditional rewrite rules from rule-based phonology (Chomsky and Halle, 1968).

2. Inference must be **unsupervised**: phonological processes are formalized as transformations from (latent) *underlying forms* to surface forms (rather than *between* surface forms).

3. Inference must be **data-efficient**: typically only a handful of data points are available.

4. Inference must be **fast**: we envision linguists using our system interactively, tweaking the data and being able to see the inferred rules within minutes.

Recently *program synthesis* has emerged as a promising approach to interpretable and data-efficient learning (Ellis et al., 2015; Singh et al., 2017; Verma et al., 2018; Ellis et al., 2018). In program synthesis, models are represented as programs in a domain-specific language (DSL), which allows domain experts to impose a strong prior by designing an appropriate DSL. Program synthesis uses powerful constraint solvers to perform combinatorial optimization and find the least-cost program in the DSL that fits the data. Program synthesis has been previously used to tackle the problem of phonological rule learning (Ellis et al., 2015), however their work uses global inference which scales poorly and hence does not satisfy requirement 4 (their system takes an hour on average to solve a phonology textbook problem).

In this work, we propose a novel inference technique that satisfies all four core requirements. Our key insight is that the problem of learning conditional rewrite rules can be decomposed into three steps: inference of the latent *underlying forms*, learning the *changes* (rewrites), and learning the *conditions*. Moreover, each of these problems can be encoded as a constrained optimization problem that can be solved efficiently by modern *satisfiability modulo theories* (SMT) solvers (de Moura and Bjørner, 2008). Both the decomposition and the encoding into constraints are contributions of this work. We implement this

approach in a system called SYPHON and show that it is capable of generating accurate phonological rules in under a minute and from just 5–30 data points.

2 Background and Problem Definition

In this section, we illustrate phonological processes and the problem of phonological rule induction using our running example of English verbs.

2.1 Rule-Based Phonology

Phonological features. *Phones* (speech sounds) are described using a feature system that groups similar-sounding phones together. For instance, voiced consonants (consonants produced with vibrating vocal cords, like [z], [d], [b]) possess the features +consonant and +voice, while voiceless consonants (like [s], [t], [p]) possess the features +consonant and −voice. Each phone can be uniquely identified by a feature vector: for example [−voice −strident +anterior −distributed] uniquely identifies the sound [t]. However, some phones may be uniquely identified by several feature vectors, and not all feature vectors correspond to phones (the feature system is redundant). For example, the feature vector [+low +high] does not correspond to any phones, as no phone can have both a raised and a lowered tongue body.

Phonological rules. In rule-based phonology, a phonological process is formalized as a conditional rewrite rule that transforms an *underlying form* of a word (roughly, the unique stored form of the word) into its *surface form* (the word as it is intended to be pronounced). In our English past tense example, the underlying form /zɪpd/—formed by concatenating the stem /zɪp/ and past tense suffix /d/—is transformed into the surface form [zɪpt] by a rule that makes an obstruent voiceless when it occurs after a voiceless obstruent:

$$[-\text{sonorant}] \rightarrow [-\text{voice}] \,/\, [-\text{voice}] _$$

In general, phonological rules have the form $A \rightarrow B \,/\, L _ R$, where all of A, B, L, and R are feature vectors. The rule means that any phone that matches A and occurs between two phones that match L and R, respectively, will be rewritten to match B (leaving the features not mentioned by B intact). A is called the *target* of the rule, B is called the *structural change*, and L and R are the left and the right *contexts*.[1] In the example above, the right context is omitted, because it is irrelevant to the rule's application; formally, A, L, and R may each be empty feature vectors, which are defined to match any phone.

Hereafter, we refer to the sequence LAR of the target and the context as the *condition* of the rule. If the condition is empty, the rule applies unconditionally. In addition to + and −, the values of features in the condition of the rule may be *variables*, which enforce that features have the same value in different parts of the condition. For example,

$$A \rightarrow B \,/\, [\alpha\text{consonant}] _ [\alpha\text{consonant}]$$

describes a rule which applies between pairs of consonants and pairs of vowels, but not between a consonant and a vowel.

2.2 Problem Definition

The input to our problem is a matrix of surface forms, such as the one shown in Fig. 1, left. These forms are arranged into rows, corresponding to different stems, and columns, corresponding to different inflections (in this case, the third-person singular and past tense of English verbs). In the interest of space, we only show four rows from this data set, but a typical input in a phonology textbook problem is only slightly larger and ranges from 5 to 30 rows.

Given these data, our task is to infer the latent underlying forms for each of the words in the input such that the resulting matrix of underlying forms factorizes into stems and suffixes, and to learn a sequence of phonological rules which, when applied elementwise to the matrix of underlying forms, reproduces the matrix of surface forms.

This learned sequence of phonological rules is generative in the following sense: given the underlying form for a new word, such as /æskz/, we can deterministically apply these rules to generate the surface form of that word, [æsks]. We use this property to evaluate the accuracy of the rule set we learned by holding out a portion of the words from the data, and then applying the rule to the underlying forms of those words, which were determined through phonological research.

2.3 Phonological Intuition

The design of our system is informed by how linguists solve the problem of phonological rule induction. When a phonologist analyzes these data, they begin by positing underlying forms that are likely to result in the simplest set of rules. For example, they observe that the substring shared in each row is most likely the stem, which surfaces without change; the underlying suffix in the first column in Fig. 1 is likely

[1] In this work we only consider a subset of *strictly local* k=3 rules (Chandlee et al., 2014), where either side of the context is restricted to at most a single phone.

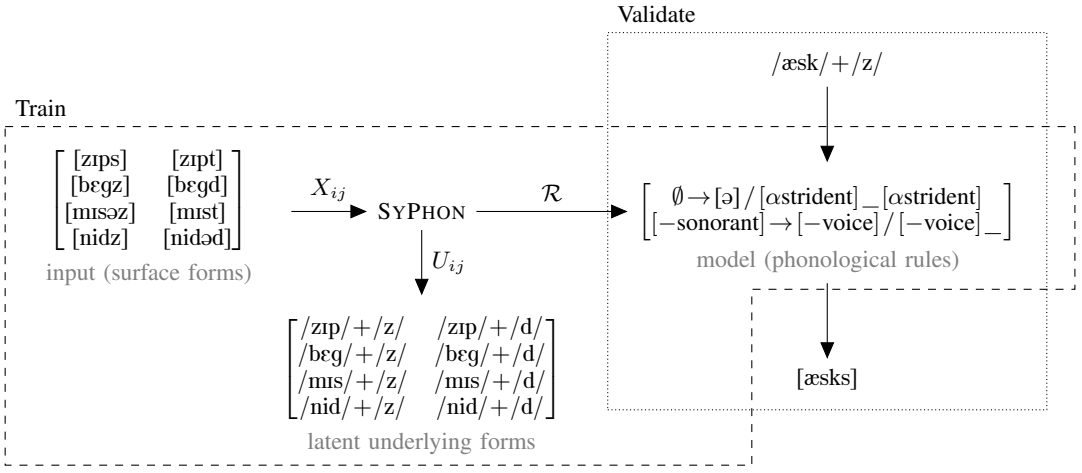

Figure 1: The general structure of the problem, shown concretely for English verbs.

/z/, which sometimes surfaces as [s] and other times as [əz]; and similarly, the underlying suffix in the second column is likely /d/, which can change to [t] or [əd]. The choice of /z/ and /d/ as the underlying suffixes is preferred to, say, /s/ and /t/, because this choice lets us explain all the observed data using only three edits: /z/ → [s], /d/ → [t], and ∅ → [ə].

The next step is to merge and generalize individual edits: the first two edits are both devoicing an obstruent, so they can be merged into [−sonorant] → [−voice], while the last edit is an insertion and cannot be generalized.

The final step of the analysis is to infer the conditions under which each of the two structural changes occurs. By contrasting examples in the first column, we infer that the insertion happens when the suffix /z/ occurs after a strident (like /s/ in /mɪs/); otherwise, /z/ and /d/ are devoiced whenever they occur after a voiceless obstruent (like /p/ in /zɪp/). The full data set can be explained using the two rules in Fig. 1, right. Note that in order to capture the data in both columns, the insertion rule says that [ə] is inserted whenever the stridency of the left and right context matches. Note also that in this case the order of rules matters: for words like /mɪsz/, insertion is applied first, which prevents the devoicing rule from applying.

3 Learning Phonological Rules

As illustrated in Fig. 1, the input to our learning problem is a matrix of surface forms X_{ij} with I rows and J columns. The goal is to learn a discrete rule set $\mathcal{R}$, while jointly inferring the latent set of I stems S_i and J affixes A_j.

Hypothesis space. The hypothesis space for $\mathcal{R}$ can be formalized as a context-free grammar:

$$\begin{aligned} &\mathcal{R} \Rightarrow R^* && R \Rightarrow C \rightarrow C \,/\, C_C \\ &C \Rightarrow (VF)^* && V \Rightarrow + \,|\, - \\ & && F \Rightarrow \text{consonant} \,|\, \text{voice} \,|\, \ldots \end{aligned} \tag{1}$$

According to this grammar, $\mathcal{R}$ is a sequence of rules R; each R is defined in terms of four feature vectors C; each feature vector is a sequence of pairs of feature values V and feature names F.

Rewriting. We use $\mathcal{C}_R$ and $\mathcal{B}_R$ to denote the condition and structural change of a rule R, respectively. A feature vector C can be interpreted as a Boolean formula that holds of a phone a if a possesses all features in C; we denote by $|C|$ the number of models of this formula, *i.e.* phones in the inventory Φ that satisfy C. Similarly, $\mathcal{C}_R$ is a Boolean formula over *trigrams* of phones. A *rewrite* of a trigram abc by rule R is defined as:

$$R(abc) = \begin{cases} \mathcal{B}_R(b) & \text{if } \mathcal{C}_R(abc) \\ b & \text{otherwise} \end{cases}$$

The notion of rewrites can be extended to words and rule sets.

Learning as constrained optimization. We can now formalize our problem as a hard *correctness constraint* over rules and underlying forms U_{ij}:

$$\mathcal{R}(U_{ij}) = X_{ij} \quad \text{where } U_{ij} \triangleq A_j[S_i] \tag{2}$$

Here, $A_j[S_i]$ denotes a concatenation of the prefix/suffix A_j with the stem S_i.

There might be many rule sets $\mathcal{R}$ that are consistent with all the data, and what we would like is to pick one that generalizes to other data that exhibits the same phonological process (for example, the rule inferred in Fig. 1 should generalize to other regular English verbs). Hence we frame the learning problem

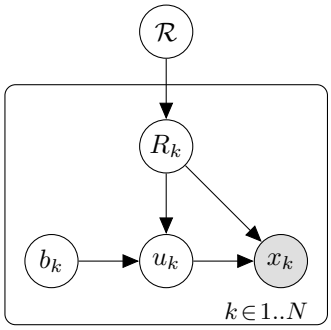

Figure 2: Probabilistic model of a phonological process. A rule set $\mathcal{R}$ is sampled from a description length prior. We observe a set of N surface phonemes x_k; each x_k is generated by sampling a rule R_k from $\mathcal{R}$ and an underlying trigram u_k, and deterministically applying R_k to u_k (coin flip b_k decides whether u_k should match R_k's condition).

as a constrained optimization problem and derive the objective function using a Bayesian model.

3.1 Bayesian Model

Generative process. Intuitively, to generate surface forms X_{ij}, we must sample a single rule set $\mathcal{R}$, I stems S_i, and J affixes A_j, and then deterministically apply $\mathcal{R}$ to each $A_j[S_i]$. Prior work on phonological rule learning (Ellis et al., 2015) assumed that S_i and A_j are sampled uniformly from the language and independently of $\mathcal{R}$. We observe, however, that in most data sets of interest, underlying forms are in fact sampled to contrast the contexts in which $\mathcal{R}$ does and does not apply. We model this intuition as a *strong sampling* process depicted in Fig. 2.

For simplicity, in this model each observation corresponds to an individual rule application to an underlying trigram u that produces a surface phoneme x. For example, the rewrite /zɪpz/ → [zɪps] is represented as four observations: /#zi/ → [z], /zɪp/ → [ɪ], /ipz/ → [p], and /pz#/ → [s] (where # encodes word boundary).

Our generative process first samples a ruleset $\mathcal{R}$ from the description length prior over the hypothesis space (1):

$$P(\mathcal{R}) \propto 2^{-w_s \cdot \sum_{R \in \mathcal{R}} \ell(R)}$$

where $\ell(R)$ is the length of rule R and $w_s > 0$ is a model hyperparameter. For each observation $k \in 1..N$, we pick a rule R_k uniformly from $\mathcal{R}$. Before sampling the underlying trigram u_k, we flip a coin b_k to decide whether we want to sample a *positive* or a *negative* trigram, *i.e.* whether $\mathcal{C}_{R_k}(u_k)$ should hold true; we then sample u_k uniformly from the set of all positive (resp. negative) trigrams (subject to the hard constraint that they form a factorizable matrix U_{ij}). Finally, we deterministically compute $x_k \triangleq R_k(u_k)$. Hence we can define:

$$P(x_k, u_k \mid R_k) = \begin{cases} 0 & \text{if } R_k(u_k) \neq x_k \\ \frac{P(b_k = \top)}{|\mathcal{C}_{R_k}|} & \text{if } \mathcal{C}_{R_k}(u_k) \\ \frac{P(b_k = \bot)}{|\neg\mathcal{C}_{R_k}|} & \text{otherwise} \end{cases}$$

Our goal is to maximize

$$P(\mathcal{R}, R_1, ..., R_N, u_1, ..., u_N \mid x_1, ..., x_N)$$
$$\propto P(\mathcal{R}) \prod_{k=1}^{N} P(x_k, u_k \mid R_k) P(R_k \mid \mathcal{R})$$

Objective function. Taking logs, we can derive the following approximate minimization objective for our constrained optimization problem:

$$w_s \sum_{R \in \mathcal{R}} \ell(R) + N_R^+ \cdot \log(|\mathcal{C}_R|) \qquad (3)$$

where N_R^+ is the number of positive examples for this rule. (Note that this objective ignores $P(R_k \mid \mathcal{R})$ and b_k, which are assumed to be uniform. It also ignores the negative examples. This provides a reasonable approximation, under the assumption that $|\neg\mathcal{C}_R| \gg |\mathcal{C}_R|$ for each rule R, which holds in the current setting.) This function includes a *simplicity term*, which favors rules with shorter (and hence, more general) conditions, and a *likelihood term*, which favors more specific conditions if there are sufficient positive examples to support them. This likelihood term stems from our strong sampling assumption; we demonstrate its importance for inferring accurate rules in Sec. 5.

3.2 Inference by Program Synthesis

To solve the constrained optimization problem we build upon a technique from programming languages called *constraint-based program synthesis* (Solar-Lezama, 2013).

Constraint-based synthesis. The input to (inductive) program synthesis is a DSL that defines the space of possible programs and a set of input-output examples $E = \overrightarrow{\langle i, o \rangle}$; the goal is to find a program whose behavior is consistent with the examples. In constraint-based synthesis, this search problem is reduced to solving a boolean constraint. To this end, we index the DSL by a bitvector c, called a *control vector*. We then define a mapping from control vectors to program behaviors via an *evaluation relation* $\varphi(c, y, z)$—a boolean formula that holds if and only if a program indexed by c produces output z on input y. Given the evaluation relation, the synthesis problem reduces to solving the following boolean constraint:

$$\exists c. \bigwedge_{\langle i,o \rangle \in E} \varphi(c, i, o)$$

An SMT solver (de Moura and Bjørner, 2008) is then used to find a satisfying assignment for c, which allows us to recover the corresponding program. For this approach to succeed, the evaluation relation has to be designed carefully so that it only uses constraints that the solver can efficiently reason about.

Synthesis of phonological rules. In our setting, the DSL is the space of all rule sets $\mathcal{R}$ (up to a certain size), and the evaluation relation $\varphi(c,U,X)$ is the correctness condition (2). Importantly, our setting differs from traditional program synthesis in two ways: first, we have to search for both the control vector and the inputs, and second, in addition to satisfying the correctness condition, we also seek to minimize the objective function (3). If we encode the objective function as $\psi(c,\overrightarrow{\langle U,X\rangle})$, we can reduce rule learning to the following constrained optimization:

$$\textbf{minimize} \quad \psi(c,\overrightarrow{\langle A_j[S_i],X_{ij}\rangle})$$
$$\textbf{subject to} \quad \bigwedge_{i,j=1,1}^{N,M} \varphi(c,A_j[S_i],X_{ij})$$

Given a proper encoding of φ and ψ, this constraint can be solved by an optimizing SMT solver (Bjørner et al., 2015); this is the approach used in prior work (Ellis et al., 2015). However, this is a very computationally intensive problem. The reason is the astronomical size of the search space: for a problem of factorizing a 10×2 matrix X_{ij} into stems of length $\ell_S = 3$ and affixes of length $\ell_A = 2$, if we limit the maximum number of rules $N_{\mathcal{R}}$ to 2 and consider an inventory Φ with 90 phones and a feature set F with 30 features, we can estimate the size of the search space as $3^{|F|N_{\mathcal{R}}}|\Phi|^{I\ell_S+J\ell_A} \approx 2^{600}$.

Decomposition. To achieve scalable inference, we decompose the global constrained optimization problem into three steps, inspired by phonological intuition we described in Sec. 2.3:

1. *Underlying form inference.* In the first step we use an SMT solver to generate likely underlying stems and suffixes. We rank them based on the heuristic that underlying forms U_{ij} that have a smaller edit distance from surface forms X_{ij} are more likely to produce simple rules (Sec. 3.3).

2. *Change inference.* Given the set of edits between each U_{ij} and the corresponding X_{ij}, we identify the smallest set of structural changes B that can describe all the edits (Sec. 3.4).

3. *Condition inference.* Finally, for each structural change B, we use program synthesis to infer the condition under which this change occurs (Sec. 3.5). If this step fails, we go back to step 1 and generate the next candidate matrix U_{ij}.

In the rest of this section we detail these three steps. For illustration purposes, in all examples we will assume that our feature set has just three features: voice v, sonorant s, and continuant c.

3.3 Underlying Form Inference

The input to this step is the matrix of surface forms X_{ij} and the output is a set of aligned pairs $\langle U,X\rangle_{ij}$. Tab. 1 illustrates this for a 2×2 matrix of English verbs. For example, $\langle U,X\rangle_{11} = \langle$[zɪpz],[zɪps]$\rangle$; we use red to show alignment information (in this case, a single substitution $z \to s$). Insertions and deletions are represented by alignment with null segments.

Input		Output	
[zɪps]	[zɪpt]	[zɪpz] [zɪps]	[zɪpd] [zɪpt]
[nidz]	[nidəd]	[nidz] [nidz]	[nid_d] [nidəd]

Table 1: Underlying form inference on English verbs.

The output matrix $\langle U, X\rangle_{ij}$ has to satisfy two properties: (i) the matrix U_{ij} can be factorized into stems S_i and affixes A_j, and (ii) each pair $\langle U,X\rangle$ has a small edit distance. Our intuition is that underlying forms that have a small edit distance from surface forms are likely to produce simpler rules. Hence we generate candidate matrices $\langle U,X\rangle_{ij}$ in the order of increasing edit distance, until rule inference succeeds for one of them. This strategy will always eventually find a matrix of underlying forms which can be related to the surface forms by a rule set we can infer as long as one exists. This process is not guaranteed to find the global minimum of the objective function (3), but we show empirically that it produces good results.

We can encode the properties (i) and (ii) as a boolean constraint over unknown strings with concatenation and length, which can be solved efficiently by the Z3STR2 solver (Zheng et al., 2017). From the solutions for those unknowns it is straightforward to recover not only the stems and suffixes, but also the required alignment information between the underlying and surface forms.

3.4 Change Inference

The input to change inference is the set of all edits in the aligned pairs $\langle U,X\rangle_{ij}$, computed in the previous step, and the output is a set of structural changes

that captures all the edits. Tab. 2 illustrates this for the edits from Tab. 1; columns LHS and RHS show relevant features of the left- and and right-hand sides of the edit.

Edit	LHS	RHS	Change
/z/ → [s]	[+v −s +c]	[−v −s +c]	[−v]
/d/ → [t]	[+v −s −c]	[−v −s −c]	
∅ → [ə]	∅	[ə]	[ə]

Table 2: Change inference on English verbs.

For each edit, we compute the set of all possible structural changes which are consistent with the edit. For example, the edit /z/ → [s] is consistent with four possible changes: [−v], [−v −s] [−v +c], and [−v −s +c]. Next, we greedily merge change-sets of different edits if their intersection is nonempty. This merging step allows us to identify a small set of distinct structural changes which together describe all the edits. For example, the change-sets of the first two edits in Tab. 2 can be merged to produce the change-set: {[−v],[−v −s]}. The third edit in Tab. 2 is an insertion, which changes the values of *all* features present in [ə], and hence cannot be merged. When no more merges are possible, we pick the simplest change from every change set (in this case, we end up with changes $B_1 = [-\text{v}]$ and $B_2 = [\text{ə}]$). This greedy process bounds the maximum number of rules to the number of change sets.

3.5 Condition Inference

For each structural change B inferred in the previous step, we now attempt to determine the condition LAR under which the change applies. If successful, a rule $A \rightarrow B \;/\; L _ R$ is added to the inferred rule set $\mathcal{R}$; otherwise we go back to underlying form inference and try the next candidate matrix U_{ij}.

For a given change B, the input to condition inference is the set of pairs $\langle u, \ell \rangle_k$, where u_k is a phone trigram in some underlying form and the label ℓ_k can be *positive* ($\top$), *negative* ($\bot$), or *unknown* (?). Tab. 3 illustrates this for trigrams from $U = /\text{zɪpz}/$. A trigram is labeled positive if its middle phone undergoes the change B in the data, negative if it does not undergo B, and unknown if B has no effect on this phone. In our example, neither /ɪ/ nor /p/ in /zɪps/ actually changed, however /zɪp/ is labeled $\bot$ while /ɪpz/ is labeled ?, because /p/ is already [−v], and hence devoicing has no effect on it. Our goal is to infer a condition consistent with the labels of all the positive and negative trigrams (unknown trigrams are ignored).

u	ℓ	Features		
/#zɪ/	$\bot$	[+#]	[+v −s]	[+v +s]
/zɪp/	$\bot$	[+v −s]	[+v +s]	[−v −s]
/ɪpz/	?	[+v +s]	[−v −s]	[+v −s]
/pz#/	$\top$	[−v −s]	[+v −s]	[+#]

Table 3: Input to condition inference for change [−v] on /zɪpz/ → [zɪps]

Inference by program synthesis. To frame condition inference as a program synthesis problem we need to define the control vector that indexes the space of all possible conditions, and a corresponding evaluation relation. In our control vector, for each feature f, we use six control variables, which represent the three positions that a feature can appear in a rule (left context, target, and right context) and the two values it can take on (+ and −). We denote these variables by f_p^v for v in $V = \{+,-\}$ and p in $P = \{l,t,r\}$.

Our evaluation relation takes the form $\varphi(c,u,\ell) \triangleq \text{matches}(c,u) \Leftrightarrow \ell$, where matches is a relation specifying whether the condition indexed by c matches the trigram u. The matches relation is further defined as follows:

$$\text{matches}(c,u) \triangleq \bigwedge_{(f,v,p)\in F\times V\times P} f_p^v \Rightarrow (u_{p,f} = v)$$

where $u_{p,f}$ is the value of feature f at position p in trigram u.

3.6 Inductive Bias

In addition to being consistent with the data, we also want the condition to minimize the objective function (3). We encode the objective function as

$$w_s s(c) + l(c),$$

where $s(c)$ encodes the simplicity of the condition indexed c (its size), $l(c)$ encodes the likelihood, and w_s is a model hyperparameter which determines the relative importance of simplicity.

The challenge is to encode the likelihood term in a solver-friendly way. To count the number of models of $|\mathcal{C}_R|$, we observe that $|\mathcal{C}_R| = |\mathcal{C}_R^l||\mathcal{C}_R^t||\mathcal{C}_R^r|$, *i.e.* we can independently count the models of the target, and the left and right contexts, so

$$l(c) \triangleq N^+ \sum_{p\in P} \log(|\mathcal{C}_R^p|)$$

We also observe that $|\mathcal{C}_R^p|$ can be encoded efficiently using a constraint whose size is *linear* in the size of the phone inventory Φ:

$$|\mathcal{C}_R^p| \triangleq \sum_{a\in\Phi} \text{if} \Big(\bigwedge_{\substack{(f,v)\in F\times V \\ a_f \neq v}} \neg f_p^v \Big) \text{ then } 1 \text{ else } 0$$

Finally, as the solver does not support logarithms, we encode log using a lookup table. This is tractable, since we only need to evaluate the log of each $|\mathcal{C}_R^p|$, which is at most the size of our inventory, roughly 100 phones.

3.7 Current limitations

SYPHON currently leverages three simplifying assumptions about rules for domain-specific problem decomposition and SMT encoding, which are crucial to making learning computationally tractable.

Conjunctive conditions. Rule conditions are conjunctions of equalities over feature values, and each rule has a unique change. We can thus decompose the learning process into change inference and condition inference: change inference greedily groups all observed edits into changes, and from then on we assume that each change uniquely corresponds to a rule.

Local context. The condition of each rule is only a function of the target phone and two surrounding phones. This allows us to encode condition inference as learning a formula over *trigrams* of phones, which has a compact encoding as SMT constraints.

Rule interaction. One rule's change does not create conditions for another. This allows us to perform condition inference for each rule independently.

Many attested patterns in real languages go beyond these limitations. We believe that it is possible to lift these restrictions, and still leverage the structure of conditional rewrite rules to retain most of the benefits of our problem decomposition. We leave this extension to future work.

4 Data

We evaluate our system on two broad categories of datasets: lexical databases and textbook problems.

4.1 Lexical Databases

We use large lexical databases to investigate two (morpho)phonological processes in English: flapping (6457 rows) and regular verb inflections (2756 rows). We process the CMU pronouncing dictionary (Weide, 2014) to create underlying and surface form pairs exemplifying flapping, as in Gildea and Jurafsky (1996). For verb inflections, we combine morphological information extracted from CELEX-2 (Baayen et al., 1993) with CMU transcriptions to create a database of regular verbs, where each row of the database contains the third-person singular present tense wordform and past tense wordform for a given verb. For both datasets we have gold standard solutions for both rule sets and underlying forms, provided by one of our coauthors, who is a phonologist.

4.2 Textbook Problems

For this category, we curated a set of 34 problems from phonology textbooks (Gussenhoven and Jacobs, 2017; Odden, 2005; Roca and Johnson, 1999) by selecting problems with local, non-interacting rules. For each problem, the input data set is tailored (by the textbook author) to illustrate a particular phonological process, and contains 20-50 surface forms. For all of these problems we have gold standard solutions, either provided with the textbook or inferred by a phonologist. Gold standard solutions range in complexity from one to two rules. Out of the 34, 21 problems are shared with (Ellis et al., 2019), which we use as the baseline for inference times.

Following the textbooks, these problems are further subdivided into 10 *matrix problems*, 20 *alternation problems*, and 4 *supervised problems*. The matrix problems follow the format presented in Sec. 2. The alternation and supervised problems are easier, as we are given more information about the underlying form. For alternation problems, we are essentially given a set of choices for what the underlying form might be, and for supervised problems the underlying form is given exactly. These problems include examples of phones in complementary distribution. Our problem decomposition allows us to switch out underlying forms inference to handle different kinds of input. According to this classification, the flapping lexical database is an alternation problem and verbs is a matrix problem.

5 Experiments

We evaluate our system on the two categories of data sets discussed in Sec. 4. We split the 34 textbook problems into 24 development and 10 test problems. Our system has several free parameters (most importantly, the simplicity weight w_s). These were hand-tuned on all of the data except the test problems. For the test problems, we only added missing sounds to the inventory as needed. The 10 test problems are all alternation problems. We leave for future work the investigation of these hyperparameter settings on new matrix problems.

5.1 Lexical Database Experiments

We evaluate our system on two large English datasets, one demonstrating flapping, and the other verbs. For each dataset, we learn a rule set from 20, 50 and 100

	Accuracy		Rule Match				UF
			Precision		Recall		
	SP	SP-	SP	SP-	SP	SP-	
Flap 20	76	52	50	66	31	25	100
Flap 50	93	79	86	71	86	71	100
Flap 100	100	79	100	71	100	71	100
Verb 20	86	73	48	42	83	61	100
Verb 50	88	78	52	50	92	80	100
Verb 100	95	81	62	58	100	82	100

Table 4: Accuracy results for the English flapping and verbs corpora data sets on 20, 50 and 100 training examples. SYPHON (SP) and SYPHON- (SP-) are two variants of our model, with and without likelihood, resp. Accuracy reports the generalization accuracy on unseen inputs, rule match and UF indicate how well the inferred rule and underlying form resp. match the gold standard.

	Data Set	Inferred Rule
1	Flap 20	$\begin{bmatrix}+\text{cor}\\-\text{voi}\end{bmatrix} \rightarrow [+\text{approx}] \,/\, [+1\text{stress}]_$
2	Flap 50	$\begin{bmatrix}+\text{cor}\\-\text{voi}\\-\text{del. rel.}\end{bmatrix} \rightarrow \begin{bmatrix}+\text{voi}\\+\text{approx}\end{bmatrix} \,/\, [+\text{stress}]_[+\text{syll}]$
3	Flap 100	$\begin{bmatrix}+\text{ant}\\-\text{voi}\\-\text{del. rel.}\end{bmatrix} \rightarrow \begin{bmatrix}+\text{voi}\\+\text{approx}\end{bmatrix} \,/\, [+\text{stress}]_[+\text{syll}]$
4	Russian	$[-\text{son}] \rightarrow [-\text{voi}] \,/\, _\#$
5	Scottish	$[+\text{syll}] \rightarrow [+\text{long}] \,/\, _ \begin{bmatrix}+\text{cons}\\+\text{voi}\\+\text{cont}\end{bmatrix}$
6	Korean	$\begin{bmatrix}-\text{cont}\\-\text{voi}\end{bmatrix} \rightarrow \begin{bmatrix}-\text{c.g.}\\-\text{s.g.}\end{bmatrix} \,/\, _[+\text{c.g.}]$
7	Farsi	$\begin{bmatrix}-\text{cont}\\+\text{dors}\end{bmatrix} \rightarrow \emptyset \,/\, [+\text{ATR}]_\#$
8	Hungarian	$[-\text{son}] \rightarrow [\alpha\text{voi}] \,/\, _ \begin{bmatrix}\alpha\text{voi}\\-\text{del. rel.}\end{bmatrix}$
9	Kishambaa	$[+\text{nas}] \rightarrow [-\text{voi}] \,/\, _[+\text{s.g.}]$
10	Persian	$\begin{bmatrix}+\text{approx}\\-\text{voi}\end{bmatrix} \rightarrow [+\text{voi}] \,/\, _[-\text{nas}]$
11	Ganda	$[+\text{lat}] \rightarrow [+\text{cont}] \,/\, \begin{bmatrix}-\text{lab}\\+\text{ATR}\end{bmatrix} _$
12	Limbu	$\begin{bmatrix}+\text{back}\\+\text{syll}\end{bmatrix} \rightarrow [+\text{rnd}] \,/\, \begin{bmatrix}+\text{lab}\\-\text{cont}\end{bmatrix} _$
13	Kongo	$\begin{bmatrix}-\text{son}\\+\text{cor}\end{bmatrix} \rightarrow \begin{bmatrix}-\text{ant}\\+\text{dist}\\+\text{strid}\end{bmatrix} \,/\, _ \begin{bmatrix}-\text{rnd}\\+\text{high}\end{bmatrix}$

Table 5: Selected inferred rules: English flapping trained on 20, 50 and 100 examples (1–3); textbook development problems (4–8); textbook test problems (9–13).

data points, and evaluate its accuracy on the remaining data. We also perform a syntactic comparison of the rule set against the gold standard rules, which we report as average precision and recall among the sets of features in the two rules. Finally, we compare the latent underlying forms we inferred for each problem to the known correct underlying forms. Tab. 4 summarizes the results. Tab. 5 (rows 1–3) shows the actual rules inferred on the three flapping training sets.

To examine the importance of likelihood in our system, we repeat this experiment for a variant of our system SYPHON-, which does not consider likelihood and simply optimizes our simplicity prior. As the number of data points increases, the effect of the likelihood grows, and so for SYPHON the recall compared to the gold standard quickly climbs. By contrast, the recall of SYPHON- plateaus, which shows that likelihood is indeed important for finding good rules.

5.2 Textbook Problem Experiments

We evaluate the textbook problems under the following three experimental conditions. First, to evaluate the generalization accuracy for unseen inputs, for each of the problems, we hold out a randomly sampled 20% of the data. We then learn a rule set on the remaining data, and validate it against the held out data. We repeat this process three times, and report the average accuracy for each class of problems in Tab. 6. We also evaluate syntactic accuracy of the rules and of underlying forms, in the same way as for the lexical databases. Additionally, we evaluate our system on 10 test problems, which were left out entirely when tuning the system hyperparameters. We report the same metrics for these problems. Tab. 5 shows inferred rules for selected development problems (rows 4–8) and test problems (rows 9–13).

The accuracy of our inferred rules and underlying forms is 100% for all textbook problems. This is not surprising: the combination of hard constraints and a restrictive DSL makes inferring incorrect rules or underlying forms very difficult. More interesting is the syntactic comparison to the gold standard. This measure is intended to estimate how well the rules SYPHON produces match phonologists' intuition. The results in Tab. 6 confirm that without the likelihood term, inference tends to exclude important features from the rule condition: the recall for held out problems goes down by 21%.

Finally, we compare inference times of SYPHON with the prior work of Ellis et al. (2019), which is also based on constraint-based program synthesis but does not perform problem decomposition, instead using the global encoding outlined in Sec. 3.2. As shown in Tab. 7, the decomposition makes SYPHON at least *two orders of magnitude* faster, with an average inference time of just 30 seconds for matrix problems, thus enabling phonologists to use the tool interactively.

	Accuracy		Rule Match				UF
			Precision		Recall		
	SP	SP-	SP	SP-	SP	SP-	SP
MAT	100	100	70	69	77	69	100
ALT	100	100	66	61	71	62	100
SUP	100	100	63	60	71	64	-
TEST	100	100	54	52	61	48	100

Table 6: Accuracy of textbook problems. We use (-) for supervised problems without underlying form inference.

	Inference Time (secs)		
	SYPHON	Baseline	Speedup
MAT	30.0	3100	124.6
ALT	10.7	N/A	N/A
SUP	5.3	6333	378.3
TEST	8.3	N/A	N/A

Table 7: Comparison of the inference times of textbook problems with baseline. We report the median execution times and geometric mean of the speedups. N/A indicates examples where baseline results are unavailable.

6 Related Work

Learning (morpho-)phonology is a rich and active area of research; in this overview, we focus on approaches that share our goal of inferring fully interpretable models of phonological processes.

Most closely related to ours is the work of Ellis et al. (2015) and its (unpublished) follow-up (Ellis et al., 2019) on using program synthesis to infer phonological rules. As mentioned above, the main difference is that SYPHON is two orders of magnitude faster than their system thanks to a novel decomposition and efficient SMT encoding. On the other hand, we impose extra restrictions on the hypothesis space (*i.e.* we only support local rules), which means that SYPHON is unable to solve some of the harder textbook problems that Ellis et al. (2019) can solve. In addition, Ellis et al. (2019) propose a method for inducing phonological representations which are universal across languages.

Beyond program synthesis, Rasin et al. (2017) use a comparable description length-based approach to unsupervised joint inference of underlying phonological forms and rewrite rule representations of phonological processes, but use a genetic algorithm to find approximate solutions. Gildea and Jurafsky (1996) and Chandlee et al. (2014) discuss supervised learning of restricted classes of finite-state transducer representations of several phonological processes (including English flapping). To date, such work either requires thousands of training observations (Gildea and Jurafsky, 1996) or has used abstracted and greatly simplified symbol inventories and training data (Chandlee et al., 2014).

Hayes and Wilson (2008), Goldsmith and Riggle (2012), and Futrell et al. (2017) propose different methods for learning probabilistic models of phonotactics, which represent gradient co-occurrence restrictions between surface segments within a word. Unlike the current implementation of SYPHON, these models include representational structures that enable them to capture certain non-local phenomena. However, because these models focus on phonotactics, they do not infer underlying forms or rules which relate underlying forms to surface forms.

Finally, much work has focused on learning representations of phonological processes as mappings that minimally violate a set of ranked or weighted constraints (Prince and Smolensky, 2004; Legendre et al., 1990), but such work has generally taken the constraint definitions as given and focused on learning rankings or weights (see *e.g.* Goldwater and Johnson, 2003; Tesar and Smolensky, 2000; Boersma and Hayes, 2001), with some exceptions (Doyle et al., 2014; Doyle and Levy, 2016).

7 Conclusion

We have presented a new approach to learning fully interpretable phonological rules from sets of related surface forms. We have shown that our approach produces rules that largely match linguists' intuition from a handful of examples and within minutes. The contributions of this paper are a novel decomposition of the global inference problem into three local problems, as well as an encoding of these problems into constraints that can be efficiently solved by an SMT solver.

Abstract

The task of Chinese text spam detection is very challenging due to both glyph and phonetic variations of Chinese characters. This paper proposes a novel framework to jointly model Chinese variational, semantic, and contextualized representations for Chinese text spam detection task. In particular, a Variation Family-enhanced Graph Embedding (VFGE) algorithm is designed based on a Chinese character variation graph. The VFGE can learn both the graph embeddings of the Chinese characters (local) and the latent variation families (global). Furthermore, an enhanced bidirectional language model, with a combination gate function and an aggregation learning function, is proposed to integrate the graph and text information while capturing the sequential information. Extensive experiments have been conducted on both SMS and review datasets, to show the proposed method outperforms a series of state-of-the-art models for Chinese spam detection.

1 Introduction

Chinese orchestrates over tens of thousands of characters by utilizing their morphological information, e.g., pictograms, simple/compound ideograms, and phono-semantic compounds (Norman, 1988). Different characters, however, may share the similar glyph and phonetic "root". For instance, from glyph perspective, character "裸 (naked)" looks like "课 (course)" (homographs), while from phonetic viewpoint, it shares the similar pronunciation with "锣 (gong)" (homophones). The form of variations can also be compounded, for instance, "账 (account)"and "帐 (curtain)" have the similar structure and pronunciation (homonyms). Unfortunately, in the context of spam detection, as shown in Figure 1, spammers are able to take advantage of these variations to escape from the detection algorithms (Jindal and Liu, 2007). For instance, in the e-commerce ecosystem, variation-based Chinese spam mutations thrive to spread illegal, misleading, and harmful information[1]. In this study, we propose a novel problem - Chinese Spam Variation Detection (CSVD), a.k.a. investigating an effective Chinese character embedding model to assist the classification models to detect the variations of Chinese spam text, which needs to address the following key challenges.

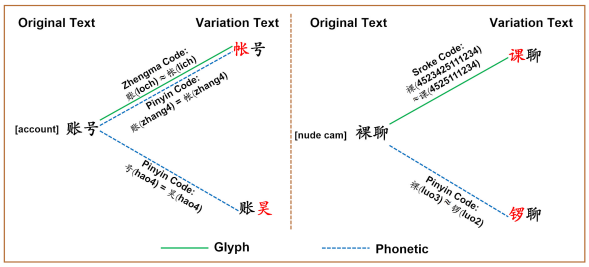

Figure 1: Character Variations in Chinese Spam Texts (the pinyin codes provide phonetic information and the stroke and Zhengma codes provide glyph information).

Diversity: the variation patterns of Chinese characters can be complex and subtle, which are difficult to generalize and detect. For instance, in the experimental dataset, one Chinese character can have 297 (glyph and phonetic) variants averagely and 2,332 maximally. The existing keyword based spam detection approaches, e.g., (Ntoulas et al., 2006), can hardly address this problem. **Sparseness, Zero-shot, and Dynamics**:

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6187–6196, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

when competing with classification models, spammers are constantly creating new Chinese characters combinations for spam texts (that can be a "zero/few shot learning" problem (Socher et al., 2013)). The labelling cost can be inevitably high in such dynamic circumstance. Data driven approaches, e.g., (Zhang et al., 2015), will perform poorly for unseen data. **Camouflage**: with the common cognition knowledge of Chinese and the contextual information, users are able to consume the spam information, even when some characters in the content are intentionally mutated into their similar variations (Spinks et al., 2000; Shu and Anderson, 1997). However, the variation-based spam text are highly camouflaged for machines. It is important to propose a novel Chinese character representation learning model that can synthesize character variation knowledge, semantics, and contextualized information.

To address these challenges, we propose a novel solution, **S**tone**S**kipping (**SS**) model to enable Chinese variation representation learning via graph and text joint embedding. SS is able to learn the Chinese character variation knowledge and predict the new variations not appearing in the training set by utilizing sophisticated heterogeneous graph mining method. For a piece of text (a character sequence), with the proposed model, each candidate character can probe character variation graph (like stone bouncing cross the water surface), and explore its glyph and phonetic variation information (like the ripples caused by the stone hitting the water). Algorithmically, a Variation Family-enhanced Graph Embedding (VFGE) algorithm is proposed to extract the heterogeneous Chinese variation knowledge while learning the (local) graph representation of a Chinese character along with the (global) representation of the latent variation families. Finally, an enhanced bidirectional language model, with a combination gate function and an aggregation learning function, is proposed to comprehensively learn the variation, semantic, and sequential information of Chinese characters. To the best of our knowledge, this is the first work to use graph embedding to learn the heterogeneous variation knowledge of Chinese characters for spam detection.

The major contributions of this paper can be summarized as follows:

1. We propose an innovative CSVD problem, in the context of text spam detection, to address the diversity, sparseness, and text camouflage problems.

2. A novel joint embedding SS model is proposed to learn the variational, semantic, and contextual representations of Chinese characters. SS is able to predict unseen variations.

3. A Chinese character variation graph is constructed for encapsulating the glyph and phonetic relationships among Chinese characters. Since the graph can be potentially useful for other NLP tasks, we share the graph/embeddings to motivate further investigation.

4. Through the extensive experiments on both SMS and review datasets[2], we demonstrate the efficacy of the proposed method for Chinese spam detection. The proposed method outperforms the state-of-the-art models.

2 Related Work

Neural Word Embeddings. Unlike traditional word representations, low-dimensional distributed word representations (Mikolov et al., 2013; Pennington et al., 2014) are able to capture in-depth semantics of text content. More recently, ELMo (Peters et al., 2018) employed learning functions of the internal states of a deep bidirectional language model to generate the character embeddings. BERT (Devlin et al., 2018) utilized bidirectional encoder representations from transformers (Vaswani et al., 2017) and achieved improvements for multiple NLP tasks. However, all the prior models only focused on learning the context, whereas the text variation was ignored. Moreover, CSVD problem can be different from other NLP tasks: the intentional character mutations and unseen variations (zero-shot learning (Socher et al., 2013)) can threaten prior models' performances.

Chinese Word and Sub-word Embeddings. A number of studies explored Chinese representation learning methodologies. CWE (Chen et al., 2015) learned the character and word embeddings to improve the representation performance. GWE (Su and Lee, 2017) introduced the features extracted from the images of traditional Chinese characters. JWE (Yu et al., 2017) used deep learning to generate character embedding based on an extended radical collection. Cw2vec (Cao et al., 2018) in-

[2]In order to help other scholars reproduce the experiment outcome, we will release the datasets via GitHub (https://github.com/Giruvegan/stoneskipping)

vestigated Chinese character as a sequence of n-gram stroke order to generate its embedding. Although these models had considered the nature of Chinese characters, they only utilized glyph features while the phonetic information was ignored. In CSVD problem, the forms of variations can be heterogeneous, and a single kind of features cannot cover all mutation patterns. More importantly, all these models are not designed for spam detection, and the task-oriented model should be able to highlight the most important variations for spam text.

Graph Embedding. Graph (a.k.a. information network) is a natural data structure for characterizing the multiple relationships between the objects. Recently, multiple graph embedding algorithms are proposed to learn the low dimensional feature representations of vertexes in graphs. DeepWalk (Perozzi et al., 2014) and Node2vec (Grover and Leskovec, 2016) are random walk based models. LINE (Tang et al., 2015) modeled 1st and 2nd order graph neighbourhood. Meanwhile, metapath2vec++ (Dong et al., 2017) was designed for heterogeneous graph embedding with human defined metapath rules. HEER (Shi et al., 2018) is a recent state-of-the-art heterogeneous graph embedding model. Though the techniques utilized in these models are different, most existing graph embedding models focus more on local graph structure representation, e.g., modelling of a fixed-size graph neighbourhood. CSVD problem requires graph embedding conducted from a more global perspective, to characterize comprehensive variation patterns.

Spelling Correction. Spelling correction may serve as an alternative to address CSVD problem, e.g., using dictionary-based (Yeh et al., 2014) or language model-based method (Yu and Li, 2014) to restore the content variations to their regular format. However, because spammers intentionally mutate the spam text to escape from the detection model, training data sparseness and dynamics may challenge this approach.

3 StoneSkipping Model

Figure 2 depicts the proposed SS model. There are three core modules in SS: a **Chinese character variation graph** to host the heterogeneous variation information; a **variation family-enhanced graph embedding** for Chinese character variation knowledge extraction and graph representation learning; an **enhanced bidirectional language model** for joint representation learning. In the remaining of this section, we will introduce them in detail.

3.1 Chinese Character Variation Graph

A Chinese character variation graph[3] can be denoted as $G = (C, R)$. C denotes the Chinese character set, and each character is represented as a vertex in G. R denotes the variation relation (edge) set, and edge weight is the similarity of two characters given the target relation (variation) type. To accurately characterize both phonetic and glyph information of Chinese character, we utilize three different encoding methods:

Pinyin system provides phonetic-based information, which is widely used for representing the pronunciations of Chinese characters (Chen and Lee, 2000). In this system, each Chinese character has one syllable which consists of three components: an initial (consonant), a final (vowel), and a tone. There are four types of tones in Modern Standard Mandarin Chinese. Different tones with the same syllable can have different meanings. For instance, the pinyin code of "裸 (naked)" is "luo3" and "锣 (gong)" is 'luo2". The pinyin-based variation similarity is calculated based on their pinyin syllables with tones[4].

Stroke is a basic glyph pattern for writing Chinese character (Cao et al., 2018). All Chinese characters are written in a certain stroke order and can be represented as a stroke code, e.g., the stroke code of "裸 (naked)" is "4523425111234" and '课 (course)" is "4525111234". The stroke-based variational similarity is calculated based on *longest common substring* and *longest common subsequence* metrics[4].

Zhengma is another important means for glyph character encoding, which encodes character at radical level (Yu et al., 2017). For instance, the Zhengma code of "裸 (naked)" is "WTKF" and '课 (course)" is "SKF". The Zhengma-based variational similarity is calculated based on the *Jaccard Index* metric[4].

Unlike previous works (Cao et al., 2018; Yu et al., 2017) only employ one kind of glyph-based information, we utilize two different glyph pat-

[3]We will release Chinese character variation graph via GitHub (https://github.com/Giruvegan/stoneskipping).

[4]Because of the space limitation, the detailed operations of relation generation will be provided on https://github.com/Giruvegan/stoneskipping.

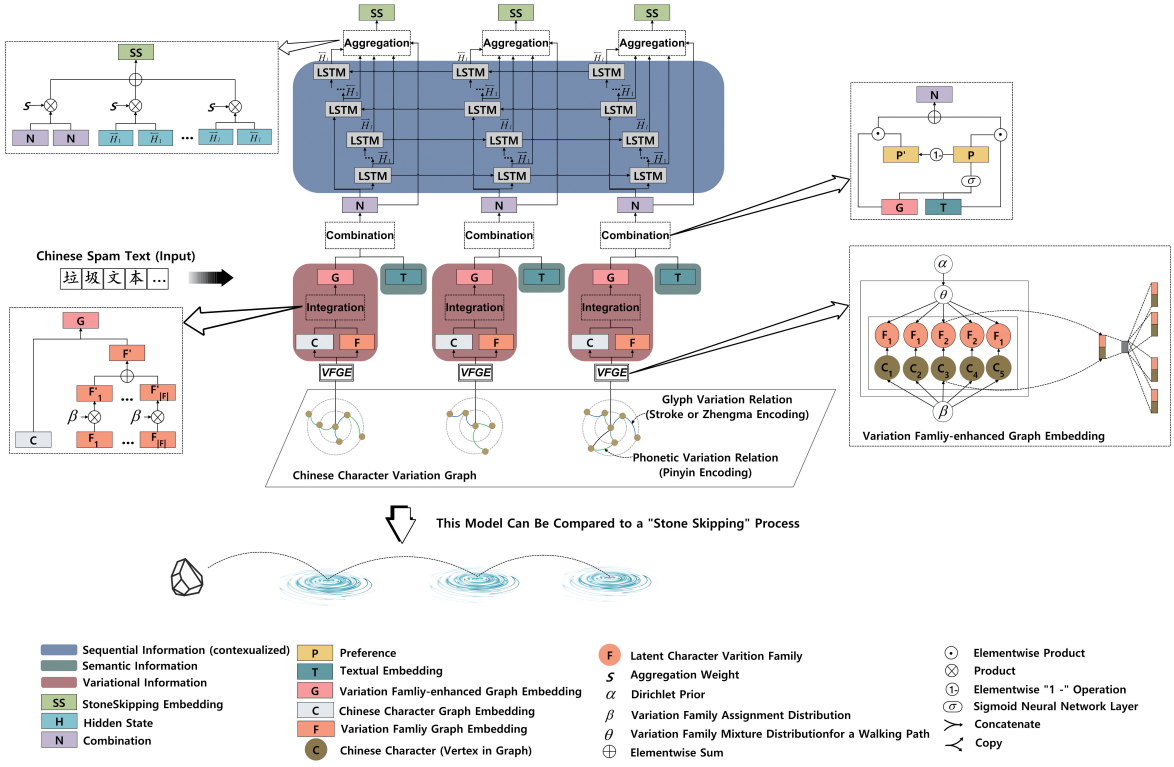

Figure 2: An Illustration of "StoneSkipping" Framework

terns (stroke and Zhengma) to encode the Chinese character. Because these two patterns can characterize Chinese characters from different internal structural levels, and complement each other to enable an enhanced glyph representation learning. Furthermore, the pinyin encoder provides phonetic information. The constructed character variation graph integrates these three kinds of variation relations, which can be significant for camouflaged spam detection.

3.2 Variation Family-enhanced Graph Embedding

While the variation graph can provide comprehensive knowledge of Chinese character variations, efforts need to be made to address these two problems: (1) the variation patterns can be very flexible, and the compounded (long-range) variation information transfer may exist. Therefore, short-range (local) graph information, e.g., character vertex's neighbors, may be insufficient for spam detection. Meanwhile, it is impractical to exhaust all the possible variation patterns. (2) To oblige users to consume the text content, spammers cannot make the variation patterns to be too complex/confusing, they usually focus on the most sensitive words in a spam message. Hence, some random infrequent variation patterns could be "noisy" for CSVD while polluting the detection outcomes.

Latent Character Variation Family. In this study, we propose a VFGE model to address these problems. As depicted in Figure 2, in VFGE model, we introduce a set of latent variables "*character variation family*" $F = \{F_1, ..., F_{|F|}\}$ at a graph schema (global) level to capture the critical information for spam detection. Each F_i is defined as *a distribution of characters*, which aims to estimate the global frequent variation dependencies in G. By learning F, VFGE is able to highlight the useful variations, eliminate the noisy patterns, and predict the unseen variation forms w.r.t. the spam detection task.

Random Walk based Character Family Representation Co-Learning . VFGE is a random walk based graph embedding model, and we employ a hierarchical random walk strategy (Jiang et al., 2018b) on G to generate the optimized walking paths (character vertex sequences) for each character. The model can sample the most possible variation context vertexes for each character. Based on generated walking paths, VFGE executes the following two processes iteratively:

(1) **Family Assignment**. By leveraging both lo-

cal context and global family distributions, we assign a discrete family for each character vertex in a particular walking path to form a character-family pair $\langle C, F\rangle$. As shown in Figure 2, we assume different walking paths tend to emerge various character variation patterns which can be represented as mixtures over latent variation families. Given a character C_i in a $path$, C_i has a higher chance to be assigned to a dominant family F_i. The assignment probability can be calculated as:

$$\begin{aligned} &Pr(F_i|C_i, path) \\ \propto &Pr(C_i, F_i, path) \\ = &Pr(path)Pr(F_i|path)Pr(C_i|F_i) \end{aligned} \tag{1}$$

As depicted in Figure 2, α is the parameter of the Dirichlet prior on the per-path family distributions ($Pr(path)$); β is the family assignment distribution ($Pr(C|F)$); and θ is the family mixture distribution for a walking path ($Pr(F|path)$). The distribution learning can be considered as a Bayesian inference problem, and we use Gibbs sampling (Porteous et al., 2008) to address this problem.

(2) **Character-Family Representation Co-Learning**. Given the assigned character-family pairs, the proposed method aims to obtain the representations of character C and latent variation family F by mapping them into a low-dimensional space $\mathbb{R}^d$ (d is a parameter specifying the number of dimensions). Motivated by (Liu et al., 2015), we propose a novel representation learning method to optimize characters and families ***separately*** and ***simultaneously***.

The objective is defined to maximize the following log probability:

$$\mathcal{L} = \max_f \sum_{C_i \in C} \sum_{C_j \in \mathbb{N}(C_i)} log Pr(\langle C_j, F_j\rangle \,|\mathbf{C_i^{F_i}}) \tag{2}$$

We use $f(\cdot)$ as the embedding function. $\mathbf{C_i} = f(C_i)$ represents the character graph embedding and $\mathbf{F_i} = f(F_i)$ represents the family graph embedding. $\mathbf{C_i^{F_i}}$ denotes the concatenation of $\mathbf{C_i}$ and $\mathbf{F_i}$, whereas $\mathbb{N}(C_i)$ is C_i's neighborhood (context). As Figure 2 shows, the feature representation learning method is an upgraded version of the skip-gram architecture. Compared with merely using the target vertex C_i to predict context vertexes in original skip-gram model (Mikolov et al., 2013), the proposed approach employs the character-family pair $\langle C_i, F_i\rangle$ to predict context character-family pairs. From variation viewpoint, character vertex's context will encapsulate both local (vertex) and global (variation family) information. Hence, the learned representations are able to comprehensively preserve the variation information in G.

$Pr(\langle C_j, F_j\rangle \,|\mathbf{C_i^{F_i}})$ is modeled as a softmax function:

$$Pr(\langle C_j, F_j\rangle \,|\mathbf{C_i^{F_i}}) = \frac{exp(\mathbf{C_j^{F_j}} \cdot \mathbf{C_i^{F_i}})}{\sum_{C_k \in C} exp(\mathbf{C_k^{F_k}} \cdot \mathbf{C_i^{F_i}})} \tag{3}$$

Stochastic gradient ascent is used for optimizing the model parameters of f. Negative sampling (Mikolov et al., 2013) is applied for optimization efficiency. Note that, the parameters of each character embedding and family embedding are shared over all the character-family pairs, which, as suggested in (Liu et al., 2015), can address the training data sparseness problem and improve the representation quality.

Family-enhanced Embedding Integration. As shown in Figure 2, the family-enhanced character graph embedding can be calculated as:

$$\mathbf{G_i} = \left[\mathbf{C_i}, \sum_{F_j \in F} Pr(F_j|C_i)\mathbf{F_j}\right] \tag{4}$$

where $\mathbf{G_i}$ is family-enhanced graph embedding for C_i, and $[\cdot]$ is concatenating operation. $Pr(F_j|C_i)$ can be inferred from family assignment distribution β.

3.3 Enhanced Bidirectional Language Model

As shown in Figure 2, SS model utilizes an enhanced bidirectional language model to jointly learn variation, semantic and contextualized representation of Chinese character.

Combination Gate Function. This gate function is utilized for combining the variation and semantic representations, which is the input function for bidirectional language model. The formulations of the gate function are listed as follows:

$$\begin{aligned} \mathbf{P} &= \sigma(\mathbf{W}_P \cdot [\mathbf{G}, \mathbf{T}] + \mathbf{b}_P) \\ \mathbf{N} &= (\mathbf{P} \odot \mathbf{T}) + ((\mathbf{1} - \mathbf{P}) \odot \mathbf{G}) \end{aligned} \tag{5}$$

$\mathbf{P} \in \mathbb{R}^d$ is the preference weights for controlling the contributions from $\mathbf{G} \in \mathbb{R}^d$ (variation graph embedding) and $\mathbf{T} \in \mathbb{R}^d$ (Skip-Gram textual embedding). $\mathbf{W}_P \in \mathbb{R}^{2d \times d}$. $\mathbf{N} \in \mathbb{R}^d$ is the combination representation. $\odot$ is elementwise product, and $+$ is elementwise sum.

Table 1: Chinese Text Spam Detection Performance Comparison of Different Models

Aggregation Learning Function. With the combination representation $\mathbf{N}$ as input, we train a bidirectional language model for capturing the sequential information. There could be multiple layers of forward and backward LSTMs in bidirectional language model. For k_{th} character, $\overrightarrow{\mathbf{H}_l^k}$ is the forward LSTM unit's output for layer l, where $l = 1, 2, ..., L$, and $\overleftarrow{\mathbf{H}_l^k}$ is the output of the backward LSTM unit.

The output $\mathbf{SS}$ embedding is learned from an aggregation function, which aims to aggregate the intermediate layer representations of the bidirectional language model and the input embedding $\mathbf{N}$. For k_{th} character, if we denote $\mathbf{H}_0^k = [\mathbf{N}^k, \mathbf{N}^k]$ (self concatenation), and $\mathbf{H}_l^k = [\overleftarrow{\mathbf{H}_l^k}, \overrightarrow{\mathbf{H}_l^k}]$, the output can be:

$$\mathbf{SS^k} = \omega\Big(\underbrace{s_0 \mathbf{H}_0^k}_{\text{(Variational \& Semantic)}} + \underbrace{\sum_{l=1}^{L} s_l \mathbf{H}_l^k}_{\text{Contextualized}} \Big) \quad (6)$$

where ω is the scale parameter, and s_l is a weight parameter for the combination of each layer, which can be learned through the training process. Similar aggregation operation has been proven useful to model the contextualized word representation (Peters et al., 2018).

4 Experiment

4.1 Dataset and Experiment Setting

Dataset[5]. In Table 2, we summarize the statistics of the two real-world spam datasets (in Chinese). One is a SMS dataset, the other is a product review dataset. Both datasets were manually labeled (spam or regular labels) by professionals. False advertising and scam information are the most common forms of spam information for SMS dataset, while abuse information dominates review spam dataset.

Dataset	Part	All	Spam	Normal
SMS	Train	48,884	23,891	24,993
	Test	48,896	23,891	25,005
Review	Train	37,299	17,299	20,000
	Test	37,299	17,299	20,000

Table 2: Statistics of Two Chinese Spam Text Datasets

In the constructed variation graph, there are totally 25,949 Chinese characters (vertexes) and 7,705,051 variation relations. For all the variation relations, there are 1,508,768 pinyin relations (phonetic), 373,803 stroke relations (glyph), and 5,822,480 Zhengma relations (glyph).

Experimental Set-up. We validated the proposed model in Chinese text spam detection task. In order to simulate the "diversity", "sparseness" and " zero-shot" problems under real business scenarios, we made a challenging restriction on the

Table 3: Case Study: given the target character, we list the top 3 similar characters from each algorithm. The characters are selected from a frequently used candidate character set whose size is 8238.

training and testing sets, i.e., the character variations were only included in testing set, and all samples in training set were using the original characters.

For the proposed SS model, we utilized the following setting: layers of LSTMs: 2; dimension of hidden (output) state in LSTM: 128; dimension of pre-trained character text embedding: 128; dimension of VFGE embedding: 128; batch size: 64; Dropout: 0.1. For training VFGE embedding[6], the walk length was 80, the number of walks per vertex was 10. These parameters were adopted in (Peters et al., 2018; Jiang et al., 2018a; Perozzi et al., 2014; Grover and Leskovec, 2016). The variation family number[7] was 500. SS model was pre-trained for parameter initialization as suggested in (Peters et al., 2018).

Baselines and Comparison Groups. We chose 13 strong baseline algorithms, from text or graph viewpoints, to comprehensively evaluate the performance of the proposed method.

General Textual Based Baselines: **Skip-gram** (Mikolov et al., 2013), **GloVe** (Pennington et al., 2014), and **ELMo** (Peters et al., 2018).

Chinese Specific Textual Based Baselines: **CWE** (Chen et al., 2015), **GWE** (Su and Lee, 2017), **JWE** (Yu et al., 2017), and **Cw2vec** (Cao et al., 2018).

Graph Embedding Based Baselines: **DeepWalk** (Perozzi et al., 2014), **LINE** (Tang et al., 2015), **Node2vec** (Grover and Leskovec, 2016), **Metapath2vec++** (Dong et al., 2017), and **HEER** (Shi et al., 2018). We applied this group of baselines on constructed Chinese character variation graph to get graph based character embeddings. Specifically, **Metapath2vec++** required a human-defined metapath scheme to guide the random walks. We tried 4 different metapaths for this experiment:(1) $\mathbf{M2V_P}$ (only walking on pinyin (phonetic) relations); (2) $\mathbf{M2V_S}$ (only walking on stroke (glyph) relations); (3) $\mathbf{M2V_Z}$ (only walking on Zhengma (glyph) relations); (4) $\mathbf{M2V_C}$ (alternately walking on glyph and phonetic relations). We reported the best results from these four metapaths, denoted as $\mathbf{M2V_{Max}}$.

Spelling Correction Baseline: **Pycorrector**[8] based on n-gram language model (Yu and Li, 2014).

Comparison Group: we compared the performances of several variants of the proposed method in order to highlight our technical contributions. There were 3 comparison groups conducted. $\mathbf{SS_{Graph}}$: we only used VFGE graph embedding. $\mathbf{SS_{Naive}}$: we simply concatenated VFGE graph embedding and skip-gram textual embedding (a naive version). $\mathbf{SS_{Original}}$: the proposed SS model.

For a fair comparison, the dimension[9] of all embedding models was 128. A single layer of CNN classification model[10] was used for spam detection task.

4.2 Experiment Result and Analysis

The text spam detection task performances of different models were reported in Table 1. Based on the experiment results, we had the following ob-

[6]For the experiment fairness, all the random walk based graph embedding baselines shared the same parameters with VFGE.

[7]Based on the parameter sensitive analysis, the proposed method was not very sensitive to number of variation families.

[8]https://github.com/shibing624/pycorrector

[9]The initial dimension of $\mathrm{SS_{Naive}}$ and $\mathrm{SS_{Original}}$ is 256, so we used a fully connected layer to reduce its dimension to 128.

[10]The filter sizes of CNN is 3, 4, 5, and the filter number is 128, dropout ratio is 0.1.

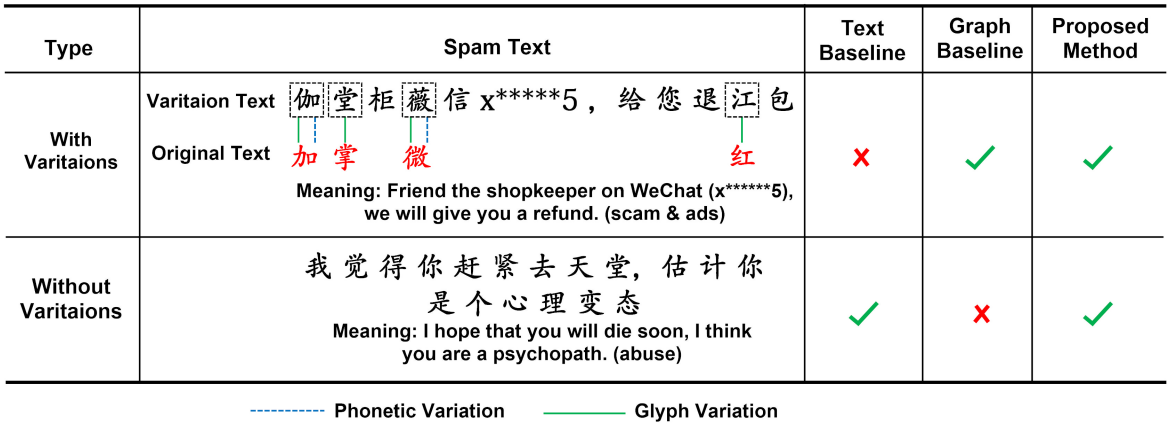

Figure 3: Two typical examples for CSVD task

servations:

SS vs. Baselines. (1) $\text{SS}_{\text{Original}}$ outperformed the baseline models for all evaluation metrics on both datasets, which indicated the proposed SS model can effectively address the CSVD problem. (2) On review dataset, the leading gap between $\text{SS}_{\text{Original}}$ and other baselines was greater. A possible explanation was that, the review spam text usually had richer content and more complex variation patterns than SMS spam text. Therefore, a good variation representation model may have certain advantages.

Chinese vs. General. (1) Compared to classical textual embedding models (Skipgram and GloVe), the Chinese embedding models showed their advantages, especially on review dataset. This result indicated that the characteristic knowledge of Chinese can help to detect spam text. (2) ELMo was able to learn both the semantic and contextualized information, and it achieved a good performance in text baseline group.

Graph vs. Text. Generally, the graph based baselines outperformed the textual based baselines (including general and Chinese). This observation indicated: (1) the variation knowledge of Chinese character can be critical for CSVD problem. (2) The proposed character variation graph can provide critical information for Chinese character representation learning. (3) Compared to other graph based baselines, SS_{Graph} was superior, which proved the effectiveness of VFGE algorithm, and the proposed variation family can characterize and predict useful variation patterns for CSVD problem.

Chinese Character Encodings. (1) In Chinese textual embedding baseline group, JWE (radical based) and Cw2vec (stroke based) didn't perform well, which indicated employing a single kind of glyph-based information can be insufficient for Chinese variation representation learning. Similarly, in graph based baseline group, the performances of M2V_{P}, M2V_{S} and M2V_{Z} (employed only one encoding relation on the constructed graph) were still unsatisfactory. The results revealed that an individual encoding method cannot comprehensively encode a character, we should consider various kinds of variation information simultaneously. (2) The performance of M2V_{C} (integrated all relations based on a predefined metapath pattern) was still inferior. This result indicated a human-defined rule cannot effectively integrate all relationships in a complex graph.

Representation vs. Spelling Correction. Pycorrector performed poorly in experiment, and other baselines outperformed this approach, which proved the spelling correction method is not capable for CSVD problem.

Variants of SS model. For variants of the proposed method, the results showed that (1) by combining the semantic and sequential information, the task performances can improve; (2) simply concatenating graph and text embeddings cannot generate a satisfactory joint representation. (3) The proposed SS model can successfully capture the variation, semantic, and sequential information for character representation learning.

4.3 Case Study

To gain an insightful understanding regarding the variation representation of the proposed method, we conduct qualitative analysis by performing the case studies of character similarities. As shown in Table 3, for exemplary characters, the most

similar characters, based on skipgram embedding (general textual based baseline), are all semantically similar or/and context-related. Meanwhile, based on Cw2vec embedding (most recent Chinese embedding baseline), all similar characters for target characters are also semantically similar or/and context-related. Unsurprisingly, for each target character, all similar characters based on VFGE model (best performed graph embedding model), are glyph and phonetic similar characters. The proposed SS model can achieve a comprehensive coverage from variation, semantic and context viewpoints. For instance, in its top 3 similar characters for "运(move)", "转(transmit)" is a semantic and context similar character, and "云(cloud)" is a glyph and phonetic similar character. Furthermore, SS model can capture complicated compound similarity between Chinese characters, for instance, "悚(afraid)" is a glyph, semantic, and context similar character for "惊(shock)". This also explains why SS model performs well to address the CSVD problem.

Figure 3 depicts two typical examples in the experimental datasets. For the spam text with variations, spammers used character variations to create camouflaged expressions. For instance, using glyph variation "江(river)" to replace "红(red)", and glyph-phonetic compound variation "薇(osmund)" to replace "微(micro)". The classical text embedding models may fail to identify this kind of spam texts. With the mining of character variation graph, the graph based approaches can be successful to capture these changes. For spam text without variations, classification models need more semantic and contextual information, and the text based methods can be suitable for this kind of spam texts. The proposed SS model is able to detect both two kinds of spam texts effectively, and experiment results proved SS can successfully model Chinese variational, semantic and contextualized representations for CSVD task.

5 Conclusion

In this paper, we propose a StoneSkipping model for Chinese spam detection. The performance of the proposed method is comprehensively evaluated in two real world datasets with challenging experimental setting. The results of experiments show that the proposed model significantly outperforms a number of state-of-the-art methods. Meanwhile, the case study empirically proves that the proposed model can successfully capture the Chinese variation, semantic, and contextualized information, which can be essential for CSVD problem. In the future, we will investigate more sophisticated methods to improve SS's performance, e.g., enable self-attention mechanism for contextualized information modelling.

Abstract

We propose a fine-grained entity typing model with a novel attention mechanism and a hybrid type classifier. We advance existing methods in two aspects: feature extraction and type prediction. To capture richer contextual information, we adopt contextualized word representations instead of fixed word embeddings used in previous work. In addition, we propose a two-step mention-aware attention mechanism to enable the model to focus on important words in mentions and contexts. We also present a hybrid classification method beyond binary relevance to exploit type interdependency with latent type representation. Instead of independently predicting each type, we predict a low-dimensional vector that encodes latent type features and reconstruct the type vector from this latent representation. Experiment results on multiple data sets show that our model significantly advances the state-of-the-art on fine-grained entity typing, obtaining up to 6.6% and 5.5% absolute gains in macro averaged F-score and micro averaged F-score respectively. [1]

1 Introduction

Fine-grained entity typing aims to assign one or more types to each entity mention given a certain context. For example, in the following sentence, "*If **Rogers** is in the game, the Huskies will be much better equipped to match the Cougars in that aspect*", the mention "Rogers" should be labeled as `athlete` in addition to `person` according to the context (e.g., game, Huskies). These fine-grained entity types are proven to be effective in supporting a wide range of downstream applications such as relation extraction (Yao et al., 2010), question answering (Lin et al., 2012), and coreference resolution (Recasens et al., 2013).

Fine-grained entity typing is usually formulated as a multi-label classification problem. Previous approaches (Ling and Weld, 2012; Choi et al., 2018; Xin et al., 2018) typically address it with binary relevance that decomposes the problem into isolated binary classification subproblems and independently predicts each type. However, this method is commonly criticized for its label independence assumption, which is not valid for fine-grained entity typing. For example, if the model is confident at predicting the type `artist`, it should promote its parent type `person` but discourage `organization` and its descendant types. In order to capture inter-dependencies between types, we propose a hybrid model that incorporates latent type representation in addition to binary relevance. Specifically, the model learns to predict a low-dimensional vector that encodes latent type features obtained through Principle Label Space Transformation (Tai and Lin, 2012) and reconstruct the sparse and high-dimensional type vector from this latent representation.

Another major challenge in fine-grained entity typing is to differentiate similar types, such as `director` and `actor`, which requires the model to capture slightly different nuances in texts. Previous neural models (Shimaoka et al., 2016; Xin et al., 2018; Choi et al., 2018; Xu and Barbosa, 2018) generally extract features from pre-trained word embeddings. Instead, we adopt contextualized word representations (Peters et al., 2018), which can capture context-aware word semantics and better represent out-of-vocabulary words. We further propose a two-step attention mechanism to actively extract the most relevant information from the sentence. Particularly, we calculate the attention for context words in a mention-aware manner, allowing the model to focus on different parts of the sentence for different mentions. For example, in the following sentence, "*In 2005 two fed-*

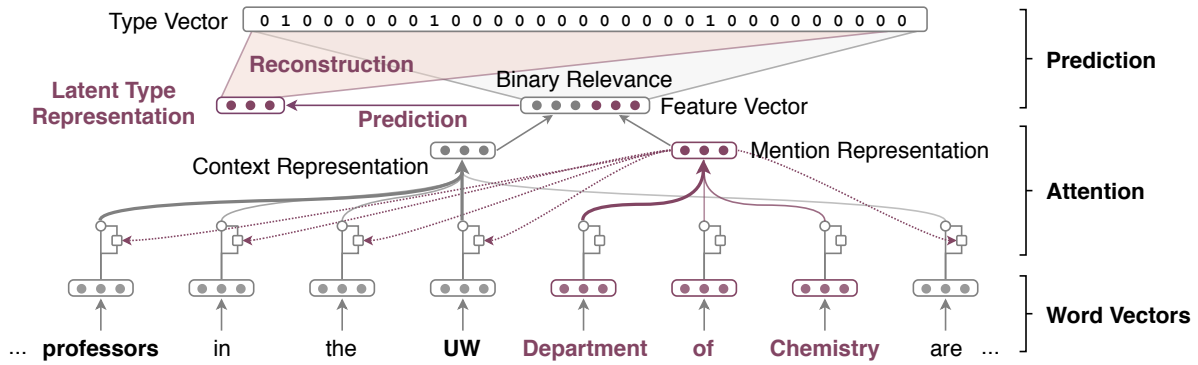

Figure 1: An illustration of our fine-grained entity typing framework.

eral agencies, the ***US Geological Survey*** *and the* ***Fish and Wildlife Service****, began to identify fish in the* ***Potomac*** *and tributaries ...*", the model should use "federal agencies" to help classify "US Geological Survey" and "Fish and Wildlife Service" as `government_agency`, but focus on "fish" and "tributaries" to determine that "Potomac" should be a `body_of_water` (river) instead of a `city`.

2 Methodology

Figure 1 illustrates our fine-grained entity typing framework. We represent the input sentence using pre-trained contextualized word representations. Next, we apply a two-step mention-aware attention mechanism to extract the most relevant features from the sentence to form the feature vector. On top of the model, we employ a hybrid classifier to predict the types of each mention.

2.1 Sentence Encoder

Contextual information plays a key role as we often need to determine the types especially subtypes according to the context. Hence, unlike previous neural models that generally use fixed word embeddings, we employ contextualized word representations (ELMo, Peters et al. 2018) that can capture word semantics in different contexts. Furthermore, because ELMo takes as input characters instead of words, it can better represent out-of-vocabulary words that are prevalent in entity mentions by leveraging sub-word information. Given a sentence of S words, the encoder generates a sequence of word vectors $\{\boldsymbol{r}_1, ..., \boldsymbol{r}_S\}$, where $\boldsymbol{r}_i \in \mathbb{R}^{d_r}$ is the representation of the i-th word.

2.2 Mention Representation

Previous attentive models (Shimaoka et al., 2017; Xu and Barbosa, 2018; Xin et al., 2018; Choi et al., 2018) only apply attention mechanisms to the context. However, some words in an entity mention may provide more useful information for typing, such as "Department" in Figure 1. To allow the model to focus on more informative words, we represent a mention m consisting of M words as a weighted sum of its contextualized word representations with an attention mechanism (Bahdanau et al., 2015) as

$$\boldsymbol{m} = \sum_i^M a_i^m \boldsymbol{r}_i,$$

where the attention score a_i^m is computed as

$$a_i^m = \text{Softmax}(e_i^m) = \frac{\exp(e_i^m)}{\sum_k^M \exp(e_k^m)},$$

$$e_i^m = \boldsymbol{v}^{m\top} \tanh(\boldsymbol{W}^m \boldsymbol{r}_i),$$

where parameters $\boldsymbol{W}^m \in \mathbb{R}^{d_a \times d_r}$ and $\boldsymbol{v}^m \in \mathbb{R}^{d_a}$ are learned during training, and the hidden attention dimension d_a is set to d_r in our experiments.

2.3 Context Representation

Given the context of mention m, we form its representation from involved contextualized word vectors with a mention-aware attention mechanism

$$\boldsymbol{c} = \sum_i^C a_i^c \boldsymbol{r}_i,$$

where C is the number of contextual words, and a_i^c is defined as $a_i^c = \text{Softmax}(e_i^c)$, where

$$e_i^c = \boldsymbol{v}^{c\top} \tanh(\boldsymbol{W}^c(\boldsymbol{r}_i \oplus \boldsymbol{m} \oplus p_i)),$$

where $\oplus$ represents concatenation, and $\boldsymbol{v}^c \in \mathbb{R}^{d_a}$ and $\boldsymbol{W}^c \in \mathbb{R}^{d_a \times (2d_r+1)}$ are trainable parameters. We introduce a relative position term p_i to indicate the distance from the i-th word to the mention as

$$p_i = \left(1 - \mu\Big(\min(|i-a|, |i-b|) - 1\Big)\right)^+,$$

where a and b are indices of the first and last words of the mention, and μ is set to 0.1.

Finally, the feature vector of mention m is formed by concatenating its mention representation $\boldsymbol{m}$ and context representation $\boldsymbol{c}$.

2.4 Hybrid Classification Model

We propose a hybrid type classification model consisting of two classifiers as Figure 1 shows. We first learn a matrix $\boldsymbol{W}^b \in \mathbb{R}^{d_t \times 2d_r}$ to predict type scores by

$$\tilde{\boldsymbol{y}}^b = \boldsymbol{W}^b(\boldsymbol{m} \oplus \boldsymbol{c}),$$

where $\tilde{y}_i^b$ is the score for the i-th type and d_t is the number of types. However, this method independently predicts each type and does not consider their inter-dependencies. To tackle this issue, we introduce an additional classifier inspired by Principle Label Space Transformation (Tai and Lin, 2012). Under the hypercube sparsity assumption that the number of training examples is much smaller than 2^{d_t}, Tai and Lin (2012) project high-dimensional type vectors into a low-dimensional space to find underlying type correlations behind the first order co-occurrence through Singular Value Decomposition (SVD)

$$\boldsymbol{Y} \approx \tilde{\boldsymbol{Y}} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{L}^\top,$$

where $\boldsymbol{U} \in \mathbb{R}^{d_t \times d_l}$, $\boldsymbol{\Sigma} \in \mathbb{R}^{d_l \times d_l}$, $\boldsymbol{L} \in \mathbb{R}^{N \times d_l}$, and $d_l \ll d_t$. This low-dimensional space is similar to the hidden concept space in Latent Semantic Analysis (Deerwester et al., 1990). The i-th row of $\boldsymbol{L}$ is the latent representation of the i-th type vector. After that, we learn to predict the latent type representation from the feature vector using

$$\boldsymbol{l} = \boldsymbol{V}^l(\boldsymbol{m} \oplus \boldsymbol{c}),$$

where $\boldsymbol{V}^l \in \mathbb{R}^{2d_r \times d_l}$ is trainable. We then reconstruct the type vector from $\boldsymbol{l}$ using a linear projection $\tilde{\boldsymbol{y}}^l = \boldsymbol{W}^l\boldsymbol{l} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{l}$. Next, by combining scores from both classifiers, we have

$$\tilde{\boldsymbol{y}} = \sigma(\boldsymbol{W}^b(\boldsymbol{m} \oplus \boldsymbol{c}) + \gamma\boldsymbol{W}^l\boldsymbol{l}),$$

where γ is a scalar initialized to 0.1 and updated during training. Finally, our training objective is to minimize the following cross-entropy-based loss function

$$J(\theta) = -\frac{1}{N}\sum_i^N \boldsymbol{y}_i \log \tilde{\boldsymbol{y}}_i + (1 - \boldsymbol{y}_i)\log(1 - \tilde{\boldsymbol{y}}_i).$$

In the test phase, we predict each type with a probability $\tilde{y}_i > 0.5$ or $\arg\max \tilde{y}_i$ if all probabilities are lower than 0.5.

3 Experiments

3.1 Data Sets

In our experiments, we evaluate the proposed model on the following data sets.

OntoNotes fine-grained entity typing data set is derived from the OntoNotes corpus (Weischedel et al., 2013) and annotated by Gillick et al. (2014) using a three-layer set of 87 types. We use the augmented data set created by Choi et al. (2018).

FIGER (Ling and Weld, 2012) contains 2.7 million automatically labeled training instances from Wikipedia and 434 manually annotated sentences from news reports. We use ground truth mentions in our experiments and sample 0.1M training instances as the development set.

KNET (Xin et al., 2018) is another data set derived from Wikipedia. It consists of an automatically annotated subset (WIKI-AUTO) and a manually annotated (WIKI-MAN) test set.

BBN Pronoun Coreference and Entity Type Corpus (BBN, Weischedel and Brunstein, 2005) annotates 2,311 Wall Street Journal articles in Treebank-2 (LDC95T7) with fine-grained entity types. We use the version processed by Ren et al. (2016a).

Data set	Train	Dev	Test	Label	Depth
OntoNotes	3.4M	2,202	8,963	87	3
FIGER	2.7M	-	563	113	2
KNET (Wiki-Auto)	1M	0.1M	0.1M	74	2
KNET (Wiki-Man)	-	-	100	74	2
BBN	32,739	-	6,430	56	2

Table 1: Data set statistics: Numbers of train/dev/test instances, label set size, max hierarchy depth.

3.2 Experimental Setup

We use the pre-trained `original-5.5b` ELMo model [2] and freeze its weights during training. We use an Adam optimizer with learning rate of 5e-5, L2 weight decay of 0.01, warmup rate of 0.1, and linear learning rate decay. We use a mini-batch size of 200. To reduce overfitting, we apply dropout (Srivastava et al., 2014) to the word representation, relative position term, and the final feature vector with probability 0.5, 0.2, and 0.2.

We evaluate the performance by strict accuracy (Acc), macro-average F-score (Macro F1), and micro-average F-score (Micro F1) (Ling and Weld, 2012).

Our Model	29.0	**77.6**	**75.3**

Table 4: Results on KNET test sets. KNET-KA and KNET-KAD use additional entity embeddings.

Model	Acc	Macro F1	Micro F1
Ling and Weld (2012)	46.7	67.2	61.2
Yosef et al. (2012)	52.3	57.6	58.7
Ren et al. (2016a)	**67.0**	72.7	73.5
Our Model	55.9	**79.3**	**78.1**
Our Model*	55.4	76.1	75.7

Table 5: Results on the BBN test set. Our Model* is a variant of our model that uses Bert contextualized word representations.

We compare the outputs of both classifiers ($\tilde{\boldsymbol{y}}^b$ and $\tilde{\boldsymbol{y}}^l$). The reconstructed type vector $\tilde{\boldsymbol{y}}^l$ alone doesn't predict entity types accurately, while adding this classifier substantially improves the performance of the model.

We show results on the BBN dataset in Table 5. Our Model* is a variant where we replace ELMo embeddings with Bert (large cased model) contextualized word representations.

	Acc	Marco F1	Micro F1
Shimaoka et al. (2017)	54.5	74.8	71.6
+ ELMo	59.3	81.7	79.0
+ latent	57.7	77.5	75.2
+ two-step attention	59.7	78.8	76.3
+ ELMo	62.9	83.0	79.8

Table 6: Ablation study on the FIGER (Gold) test set.

To evaluate the influence of individual components of our model, we conduct an ablation study as shown in Table 6. We implement a baseline model similar to (Shimaoka et al., 2017) (no hand-crafted features), the state-of-the-art on this data set. We observe that each component added to the model improves its performance.

We visualize mention and context attention in Figure 2. The first example shows the impact of mention attention. The baseline model mistakenly classifies the mention as `location` probably because "Asian" generally appears in location mentions, while our model successfully predicts `organization` by assigning higher weights to "Student Commission". In Example #2 and #3, we compare context attention between "Terry Martino" and "APA". Although they occur in the same sentence, our model is able to focus on different context words for different mentions with the mention-aware attention mechanism.

#1 ... *left out of the* [ORGANIZATION *Asian Student Commission*] *and that they don't feel like they are being represented well...*

#2 *After Executive Director* [PERSON *Terry Martino*] *announced ... applause packed into the APA 's board room*

#3 *After Executive Director Terry Martino announced ... applause packed into the* [ORGANIZATION *APA*] *'s board room*

Figure 2: Mention and context attention visualization.

4 Related Work

As entity types are usually organized as a forest of hierarchies, several models are proposed to leverage this structure. In (Yosef et al., 2012), the authors build a set of classifiers based on the taxon-

omy of YAGO (Hoffart et al., 2013) and perform top-down hierarchical classification. Shimaoka et al. (2017) propose a hierarchical label encoding method to share parameters between types in the same hierarchy. Xu and Barbosa (2018) propose a hierarchy-aware loss function to reduce the penalty when predicted types are related. By contrast, our model automatically find type inter-dependency via matrix factorization and is able to capture inter-dependencies between types regardless of whether they are in the same hierarchy.

Attention mechanisms are widely used in neural fine-grained entity typing models (Shimaoka et al., 2016, 2017; Xu and Barbosa, 2018; Xin et al., 2018; Choi et al., 2018) to weight context words. We also apply it to mention words and introduce a position term to make attentions for context words more mention-aware.

5 Conclusions and Future Work

We propose an attentive architecture for fine-grained entity typing with latent type representation. Experiments on multiple data sets demonstrate that our model achieves state-of-the-art performance. In the future, we will further improve the performance of fine-grained types, which is still lower than that of general types due to less training instances and distant supervision noise. We also plan to utilize fine-grained entity typing results in more downstream applications, such as coreference resolution and event extraction.

Abstract

Determining temporal relations (e.g., *before* or *after*) between events has been a challenging natural language understanding task, partly due to the difficulty to generate large amounts of high-quality training data. Consequently, neural approaches have not been widely used on it, or showed only moderate improvements. This paper proposes a new neural system that achieves about 10% absolute improvement in accuracy over the previous best system (25% error reduction) on two benchmark datasets. The proposed system is trained on the state-of-the-art MATRES dataset and applies contextualized word embeddings, a Siamese encoder of a temporal common sense knowledge base, and global inference via integer linear programming (ILP). We suggest that the new approach could serve as a strong baseline for future research in this area.

1 Introduction

Temporal relation (TempRel) extraction has been considered as a major component of understanding time in natural language (Do et al., 2012; UzZaman et al., 2013; Minard et al., 2015; Llorens et al., 2015; Ning et al., 2018a). However, the annotation process for TempRels is known to be time consuming and difficult even for humans, and existing datasets are usually small and/or have low inter-annotator agreements (IAA); e.g., UzZaman et al. (2013); Chambers et al. (2014); O'Gorman et al. (2016) reported Kohen's κ and F_1 in the 60's. Albeit the significant progress in deep learning nowadays, neural approaches have not been used extensively for this task, or showed only moderate improvements (Dligach et al., 2017; Lin et al., 2017; Meng and Rumshisky, 2018). We think it is important for to understand: is it because we missed a "magic" neural architecture, because the training dataset is small, or because the quality of the dataset should be improved?

Recently, Ning et al. (2018c) introduced a new dataset called *Multi-Axis Temporal RElations for Start-points* (MATRES). MATRES is still relatively small in its size (15K TempRels), but has a higher annotation quality from its improved task definition and annotation guideline. This paper uses MATRES to show that a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) system can readily outperform the previous state-of-the-art system, CogCompTime (Ning et al., 2018d), by a large margin. The fact that a standard LSTM system can significantly improve over a feature-based system on MATRES indicates that neural approaches have been mainly dwarfed by the quality of annotation, instead of specific neural architectures or the small size of data.

To gain a better understanding of the standard LSTM method, we extensively compare the usage of various word embedding techniques, including word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), FastText (Bojanowski et al., 2016), ELMo (Peters et al., 2018), and BERT (Devlin et al., 2018), and show their impact on TempRel extraction. Moreover, we further improve the LSTM system by injecting knowledge from an updated version of TEMPROB, an automatically induced temporal common sense knowledge base that provides *typical* TempRels between events[1] (Ning et al., 2018b). Altogether, these components improve over CogCompTime by about 10% in F_1 and accuracy. The proposed system is public[2] and can serve as a strong baseline for future research.

2 Related Work

Early computational attempts to TempRel extraction include Mani et al. (2006); Chambers et al.

[1]For example, "explode" typically happens *before* "die".

(2007); Bethard et al. (2007); Verhagen and Pustejovsky (2008), which aimed at building classic learning algorithms (e.g., perceptron, SVM, and logistic regression) using *hand-engineered features* extracted for each pair of events. The frontier was later pushed forward through continuous efforts in a series of SemEval workshops (Verhagen et al., 2007, 2010; UzZaman et al., 2013; Bethard et al., 2015, 2016, 2017), and significant progresses were made in terms of data annotation (Styler IV et al., 2014; Cassidy et al., 2014; Mostafazadeh et al., 2016; O'Gorman et al., 2016), structured inference (Chambers and Jurafsky, 2008a; Do et al., 2012; Chambers et al., 2014; Ning et al., 2018a), and structured machine learning (Yoshikawa et al., 2009; Leeuwenberg and Moens, 2017; Ning et al., 2017).

Since TempRel is a specific relation type, it is natural to borrow recent neural relation extraction approaches (Zeng et al., 2014; Zhang et al., 2015; Zhang and Wang, 2015; Xu et al., 2016). There have indeed been such attempts, e.g., in clinical narratives (Dligach et al., 2017; Lin et al., 2017; Tourille et al., 2017) and in newswire (Cheng and Miyao, 2017; Meng and Rumshisky, 2018; Leeuwenberg and Moens, 2018). However, their improvements over feature-based methods were moderate (Lin et al. (2017) even showed negative results). Given the low IAAs in those datasets, it was unclear whether it was simply due to the low data quality or neural methods inherently do not work well for this task.

A recent annotation scheme, Ning et al. (2018c), introduced the notion of multi-axis to represent the temporal structure of text, and identified that one of the sources of confusions in human annotation is asking annotators for TempRels across different axes. When annotating only same-axis TempRels, along with some other improvements to the annotation guidelines, MATRES was able to achieve much higher IAAs.[3] This dataset opens up opportunities to study neural methods for this problem. In Sec. 3, we will explain our proposed LSTM system, and also highlight the major differences from previous neural attempts.

3 Neural TempRel Extraction

One major disadvantage of feature-based systems is that errors occurred in feature extraction propagate to subsequent modules. Here we study the usage of LSTM networks[4] on the TempRel extraction problem as an end-to-end approach that only takes a sequence of word embeddings as input (assuming that the position of events are known). Conceptually, we need to feed those word embeddings to LSTMs and obtain a vector representation for a particular pair of events, which is followed by a fully-connected, feed-forward neural network (FFNN) to generate confidence scores for each output label. Based on the confidence scores, global inference is performed via integer linear programming (ILP), which is a standard procedure used in many existing works to enforce the transitivity property of time (Chambers and Jurafsky, 2008b; Do et al., 2012; Ning et al., 2017). An overview of the proposed network structure and corresponding parameters can be found in Fig. 1. Below we also explain the main components.

3.1 Handling Event Positions

Each TempRel is associated with two events, and for the same text, different pairs of events possess different relations, so it is critical to indicate the positions of those events when we train LSTMs for the task. The most straightforward way is to concatenate the hidden states from both time steps that correspond to the location of those events (Fig. 1b). Dligach et al. (2017) handled this issue differently, by adding XML tags immediately before and after each event (Fig. 1a). For example, in the sentence, *After **eating** dinner, he **slept** comfortably*, where the two events are bold-faced, they will convert the sequence into *After <e1> eating </e1> dinner, he <e2> slept </e2> comfortably.* The XML markups, which was initially proposed under the name of *position indicators* for relation extraction (Zhang and Wang, 2015), uniquely indicate the event positions to LSTM, such that the final output of LSTM can be used as a representation of those events and their context. We compare both methods in this paper, and as we show later, the straightforward concatenation method is already as good as XML tags for this task.

3.2 Common Sense Encoder (CSE)

In naturally occurring text that expresses TempRels, connective words such as *since*,

[3] Between experts: Kohen's $\kappa \approx 0.84$. Among crowdsourcers: accuracy 88%. More details in Ning et al. (2018c).

[4] We also tried convolutional neural networks but did not observe that CNNs improved performance significantly compared to the LSTMs. Comparison between LSTM and CNN is also not the focus of this paper.

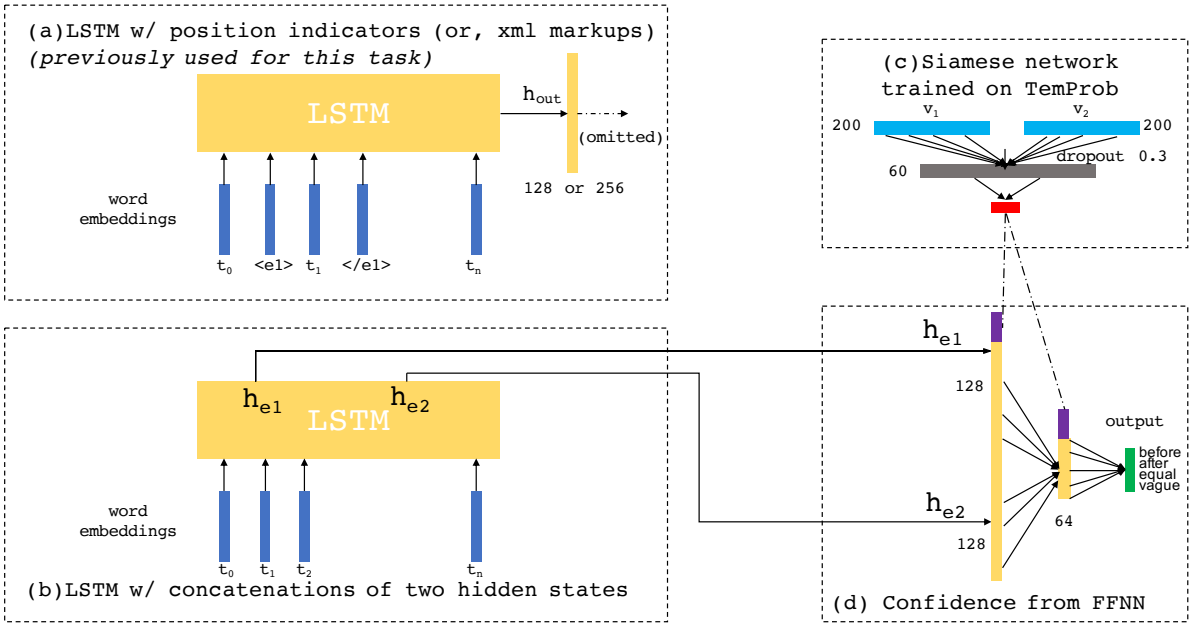

Figure 1: Overview of the neural network structures studied in this paper. Networks (a) and (b) are two ways to handle event positions in LSTMs (Sec. 3.1). (c) The Siamese network used to fit TemProb (Sec. 3.2). Once trained on TemProb, the Siamese network is fixed when training other parts of the system. (d) The FFNN that generates confidence scores for each label. Sizes of hidden layers are already noted. Embeddings of the same color share the same matrix.

when, or *until* are often not explicit; nevertheless, humans can still infer the TempRels using common sense with respect to the events. For example, even without context, we know that *die* is typically after *explode* and *schedule* typically before *attend*. Ning et al. (2018b) was an initial attempt to acquire such knowledge, by aggregating automatically extracted TempRels from a large corpus. The resulting knowledge base, TEMPROB, contains observed frequencies of tuples $(v1, v2, r)$ representing the probability of verb 1 and verb 2 having relation r and it was shown a useful resource for TempRel extraction.

However, TEMPROB is a simple counting model and fails (or is unreliable) for unseen (or rare) tuples. For example, we may see (ambush, die) less frequently than (attack, die) in a corpus, and the observed frequency of (ambush, die) being *before* or *after* is thus less reliable. However, since "ambush" is semantically similar to "attack", the statistics of (attack, die) can actually serve as an auxiliary signal to (ambush, die). Motivated by this idea, we introduce common sense encoder (CSE): We fit an updated version of TEMPROB via a Siamese network (Bromley et al., 1994) that generalizes to unseen tuples through the resulting embeddings for each verb (Fig. 1c). Note that the TEMPROB we use is reconstructed using the same method described in Ning et al. (2018b) with the base method changed to CogCompTime. Once trained, CSE will remain fixed when training the LSTM part (Fig. 1a or b) and the feedforward neural network part (Fig. 1d). We only use CSE for its output. In the beginning, we tried to directly use the output (i.e., a scalar) and the influence on performance was negligible. Therefore, here we discretize the CSE output, change it to categorical embeddings, concatenate them with the LSTM output, and then produce the confidence scores (Fig. 1d).

4 Experiments

4.1 Data

The MATRES dataset[5] contains 275 news articles from the TempEval3 workshop (UzZaman et al., 2013) with newly annotated events and TempRels. It has 3 sections: TimeBank (TB), AQUAINT (AQ), and Platinum (PT). We followed the official split (i.e., TB+AQ for training and PT for testing), and further set aside 20% of the training data as the development set to tune learning rates and epochs. We also show our performance on another dataset,

[5] http://cogcomp.org/page/publication_view/834

TCR[6] (Ning et al., 2018a), which contains both temporal and causal relations and we only need the temporal part. The label set for both datasets are *before*, *after*, *equal*, and *vague*.

	Purpose	#Doc	#Events	#TempRels
TB+AQ	Train	255	8K	13K
PT	Test	20	537	837
TCR	Test	25	1.3K	2.6K

Table 1: TimeBank (TB), AQUAINT (AQ), and Platinum (PT) are from MATRES (Ning et al., 2018c) and TCR from Ning et al. (2018a).

4.2 Results and Discussion

We compare with the most recent version of CogCompTime, the state-of-the-art on MATRES.[7] Note that in Table 2, CogCompTime performed slightly different to Ning et al. (2018d): CogCompTime reportedly had F_1=65.9 (Table 2 Line 3 therein) and here we obtained F_1=66.6. In addition, Ning et al. (2018d) only reported F_1 scores, while we also use another two metrics for a more thorough comparison: classification accuracy (acc.) and temporal awareness F_{aware}, where the awareness score is for the graphs represented by a group of related TempRels (more details in the appendix). We also report the average of those three metrics in our experiments.

Table 2 compares the two different ways to handle event positions discussed in Sec. 3.1: position indicators (P.I.) and simple concatenation (Concat), both of which are followed by network (d) in Fig. 1 (i.e., without using Siamese yet). We extensively studied the usage of various pretrained word embeddings, including conventional embeddings (i.e., the medium versions of word2vec, GloVe, and FastText provided in the Magnitude package (Patel et al., 2018)) and contextualized embeddings (i.e., the original ELMo and large uncased BERT, respectively); except for the input embeddings, we kept all other parameters the same. We used cross-entropy loss and the StepLR optimizer in PyTorch that decays the learning rate by 0.5 every 10 epochs (performance not sensitive to it).

Comparing to the previously used P.I. (Dligach et al., 2017), we find that, with only two exceptions (underlined in Table 2), the Concat system saw consistent gains under various embeddings and metrics. In addition, contextualized embeddings (ELMo and BERT) expectedly improved over the conventional ones significantly, although no statistical significance were observed between using ELMo or BERT (more significance tests in Appendix).

System	*Emb.*	*Acc.*	F_1	F_{aware}	Avg.
P.I.	word2vec	63.2	67.6	60.5	63.8
	GloVe	64.5	69.0	61.1	64.9
	FastText	60.5	64.7	59.5	61.6
	ELMo	67.5	73.9	63.0	**68.1**
	BERT	68.8	73.6	61.7	68.0
Concat	word2vec	65.0	69.5	59.4	64.6
	GloVe	64.9	69.5	60.9	65.1
	FastText	64.0	68.6	60.1	64.2
	ELMo	67.7	74.0	63.3	68.3
	BERT	69.1	74.4	63.7	**69.1**
Concat+CSE	ELMo	71.7	76.7	66.0	**71.5**
	BERT	71.3	76.3	66.5	71.4
CogCompTime	-	61.6	66.6	60.8	**63.0**

Table 2: Performances on the MATRES test set (i.e., the PT section). CogCompTime (Ning et al., 2018d) is the previous state-of-the-art feature-based system. Position indicator (P.I.) and concatenation (Concat) are two ways to handle event positions in LSTMs (Sec. 3.1). Concat+CSE achieves significant improvement over CogCompTime on MATRES.

Given the above two observations, we further incorporated our common sense encoder (CSE) into "Concat" with ELMo and BERT in Table 2. We split TEMPROB into train (80%) and validation (20%). The proposed Siamese network (Fig. 1c) was trained by minimizing the cross-entropy loss using Adam (Kingma and Ba, 2014) (learning rate 1e-4, 20 epochs, and batch size 500). We first see that CSE improved on top of Concat for both ELMo and BERT under all metrics, confirming the benefit of TEMPROB; second, as compared to CogCompTime, the proposed Concat+CSE achieved about 10% absolute gains in accuracy and F_1, 5% in awareness score F_{aware}, and 8% in the three-metric-average metric, with $p < 0.001$ per the McNemar's test. Roughly speaking, the 8% gain is contributed by LSTMs for 2%, contextualized embeddings for 4%, and CSE for 2%. Again, no statistical significance were observed between using ELMo and BERT. Table 3 furthermore applies CogCompTime and the proposed Concat+CSE system on a different test set called TCR (Ning et al., 2018a). Both systems achieved better scores (suggesting that TCR is easier than MATRES), while the proposed sys-

[6] http://cogcomp.org/page/publication_view/835

[7] http://cogcomp.org/page/publication_view/844

tem still outperformed CogCompTime by roughly 8% under the three-metric-average metric, consistent with our improvement on MATRES.

System	*Emb.*	*Acc.*	F_1	F_{aware}	Avg.
CogCompTime	-	68.1	70.7	61.6	**66.8**
Concat+CSE	ELMo	80.8	78.6	69.9	**76.4**
	BERT	78.4	77.0	69.0	74.9

Table 3: Further evaluation of the proposed system, i.e., Concat (Table 3.1) plus CSE (Sec. 3.2), on the TCR dataset (Ning et al., 2018a).

5 Conclusion

Temporal relation extraction has long been an important yet challenging task in natural language processing. Lack of high-quality data and difficulty in the learning problem defined by previous annotation schemes inhibited performance of neural-based approaches. The discoveries that LSTMs readily improve the feature-based state-of-the-art CogCompTime on the MATRES and TCR datasets by a large margin not only give the community a strong baseline, but also indicate that the learning problem is probably better defined by MATRES and TCR. Therefore, we should move along that direction to collect more high-quality data, which can facilitate more advanced learning algorithms in the future.

Abstract

Fine-grained entity typing is a challenging problem since it usually involves a relatively large tag set and may require to understand the context of the entity mention. In this paper, we use entity linking to help with the fine-grained entity type classification process. We propose a deep neural model that makes predictions based on both the context and the information obtained from entity linking results. Experimental results on two commonly used datasets demonstrates the effectiveness of our approach. On both datasets, it achieves more than 5% absolute strict accuracy improvement over the state of the art.

1 Introduction

Given a piece of text and the span of an entity mention in this text, fine-grained entity typing (FET) is the task of assigning fine-grained type labels to the mention (Ling and Weld, 2012). The assigned labels should be context dependent (Gillick et al., 2014). For example, in the sentence "Trump threatens to pull US out of World Trade Organization," the mention "Trump" should be labeled as /person and /person/politician, although Donald Trump also had other occupations such as businessman, TV personality, etc.

This task is challenging because it usually uses a relatively large tag set, and some mentions may require the understanding of the context to be correctly labeled. Moreover, since manual annotation is very labor-intensive, existing approaches have to rely on distant supervision to train models (Ling and Weld, 2012; Ghaddar and Langlais, 2018).

Thus, the use of extra information to help with the classification process becomes very important. In this paper, we improve FET with entity linking (EL). EL is helpful for a model to make typing decisions because if a mention is correctly linked to its target entity, we can directly obtain the type information about this entity in the knowledge base (KB). For example, in the sentence "There were some great discussions on a variety of issues facing Federal Way," the mention "Federal Way" may be incorrectly labeled as a company by some FET models. Such a mistake can be avoided after linking it to the city Federal Way, Washington. For cases that require the understanding of the context, using entity linking results is also beneficial. In the aforementioned example where "Trump" is the mention, obtaining all the types of Donald Trump in the knowledge base (e.g., politician, businessman, TV personality, etc.) is still informative for inferring the correct type (i.e., politician) that fits the context, since they narrows the possible labels down.

However, the information obtained through EL should not be fully trusted since it is not always accurate. Even when a mention is correctly linked to an entity, the type information of this entity in the KB may be incomplete or outdated. Thus, in this paper, we propose a deep neural fine-grained entity typing model that flexibly predicts labels based on the context, the mention string, and the type information from KB obtained with EL.

Using EL also introduces a new problem for the training process. Currently, a widely used approach to create FET training samples is to use the anchor links in Wikipedia (Ling and Weld, 2012; Ren et al., 2016a). Each anchor link is regarded as a mention, and is weakly labeled with all the types of its referred entity (the Wikipedia page the anchor link points to) in KB. Our approach, when links the mention correctly, also uses all the types of the referred entity in KB as extra information. This may cause the trained model to overfit the weakly labeled data. We design a variant of the hinge loss and introduce noise during training to address this problem.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6210–6215, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

We conduct experiments on two commonly used FET datasets. Experimental results show that introducing information obtained through entity linking and having a deep neural model both helps to improve FET performance. Our model achieves more than 5% absolute strict accuracy improvement over the state of the art on both datasets.

Our contributions are summarized as follows:

- We propose a deep neural fine-grained entity typing model that utilizes type information from KB obtained through entity linking.
- We address the problem that our model may overfit the weakly labeled data by using a variant of the hinge-loss and introducing noise during training.
- We demonstrate the effectiveness of our approach with experimental results on commonly used FET datasets.

Our code is available at `https://github.com/HKUST-KnowComp/IFETEL`.

2 Related Work

An early effort of classifying named entities into fine-grained types can be found in (Fleischman and Hovy, 2002), which only focuses on person names. Latter, datasets with larger type sets are constructed (Weischedel and Brunstein, 2005; Ling and Weld, 2012; Choi et al., 2018). These datasets are more preferred by recent studies (Ren et al., 2016a; Murty et al., 2018).

Most of the existing approaches proposed for FET are learning based. The features used by these approaches can either be hand-crafted (Ling and Weld, 2012; Gillick et al., 2014) or learned from neural network models (Shimaoka et al., 2017; Xu and Barbosa, 2018; Xin et al., 2018). Since FET systems usually use distant supervision for training, the labels of the training samples can be noisy, erroneous or overly specific. Several studies (Ren et al., 2016b; Xin et al., 2018; Xu and Barbosa, 2018) address these problems by separating clean mentions and noisy mentions, modeling type correction (Ren et al., 2016a), using a hierarchy-aware loss (Xu and Barbosa, 2018), etc.

(Huang et al., 2016) and (Zhou et al., 2018) are two studies that are most related to this paper. Huang et al. (2016) propose an unsupervised FET system where EL is an importat component. But they use EL to help with clustering and type name selection, which is very different from how we use it to improve the performance of a supervised FET model. (Zhou et al., 2018) finds related entities based on the context instead of directly applying EL. The types of these entities are then used for inferring the type of the mention.

3 Method

Let T be a predefined tag set, which includes all the types we want to assign to mentions. Given a mention m and its context, the task is to predict a set of types $\boldsymbol{\tau} \subset T$ suitable for this mention. Thus, this is a multi-class, multi-label classification problem (Ling and Weld, 2012). Next, we will introduce our approach for this problem in detail, including the neural model, the training of the model, and the entity linking algorithm we use.

3.1 Fine-grained Entity Typing Model

Input Each input sample to our FET system contains one mention and the sentence it belongs to. We denote $w_1, w_2, ..., w_n$ as the words in the current sentence, $w_{p_1}, w_{p_2}, ..., w_{p_l}$ as the words in the mention string, where n is the number of words in the sentence, $p_1, ..., p_l$ are the indices of the words in the mention string, l is the number of words in the mention string. We also use a set of pretrained word embeddings.

Our FET approach is illustrated in Figure 1. It first constructs three representations: *context representation*, *mention string representation*, and *KB type representation*. Note that the KB type representation is obtained from a knowledge base through entity linking and is independent of the context of the mention.

Context Representation To obtain the context representation, we first use a special token w_m to represent the mention (the token "[Mention]" in Figure 1). Then, the word sequence of the sentence becomes $w_1, ..., w_{p_l-1}, w_m, w_{p_l+1}, ..., w_n$. Their corresponding word embeddings are fed into two layers of BiLSTMs. Let $\boldsymbol{h}_m^1$ and $\boldsymbol{h}_m^2$ be the output of the first and the second layer of BiLSTMs for w_m, respectively. We use $\boldsymbol{f}_c = \boldsymbol{h}_m^1 + \boldsymbol{h}_m^2$ as the context representation vector.

Mention String Representation Let $\boldsymbol{x}_1, ..., \boldsymbol{x}_l$ be the word embeddings of the mention string words $w_{p_1}, ..., w_{p_l}$. Then the mention string representation $\boldsymbol{f}_s = (\sum_{i=1}^{l} \boldsymbol{x}_i)/l$.

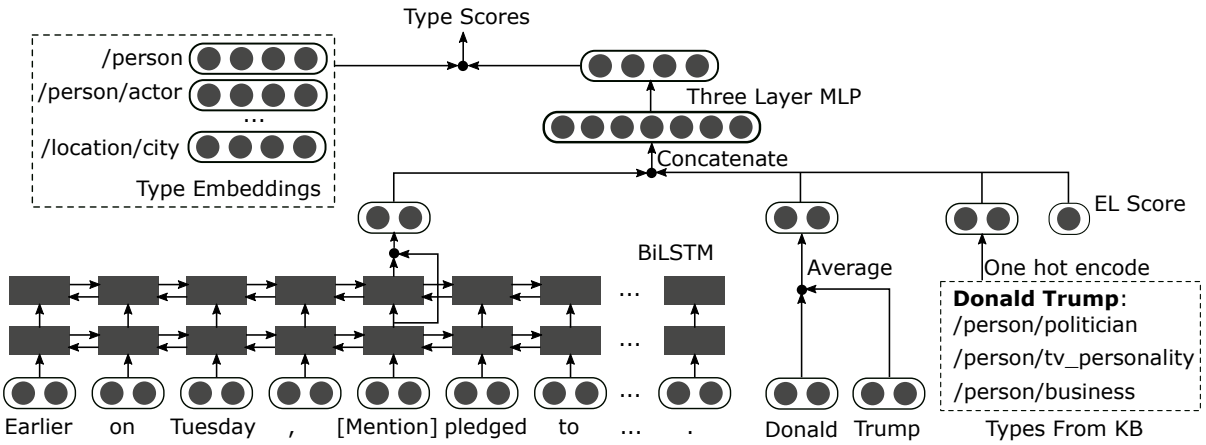

Figure 1: Our approach. The example sentence is "Earlier on Tuesday, *Donald Trump* pledged to help hard-hit U.S. farmers caught in the middle of the escalating trade war." Here, the correct label for the mention *Donald Trump* should be /person, /person/politician. "[Mention]" is a special token that we use to represent the mention.

KB Type Representation To obtain the KB type representation, we run an EL algorithm for the current mention. If the EL algorithm returns an entity, we retrieve the types of of this entity from the KB. We use Freebase as our KB[1]. Since the types in Freebase is different from T, the target type set, they are mapped to the types in T with rules similar to those used in (Zhou et al., 2018). Afterwards, we perform one hot encoding on these types to get the KB Type Representation $\boldsymbol{f}_e$. If the EL algorithm returns NIL (i.e., the mention cannot be linked to an entity), we simply one hot encode the empty type set.

Prediction Apart from the three representations, we also obtain the score returned by our entity linking algorithm, which indicates its confidence on the linking result. We denote it as a one dimensional vector $\boldsymbol{g}$. Then, we get $\boldsymbol{f} = \boldsymbol{f}_c \oplus \boldsymbol{f}_s \oplus \boldsymbol{f}_e \oplus \boldsymbol{g}$, where $\oplus$ means concatenation. $\boldsymbol{f}$ is then fed into an MLP that contains three dense layers to obtain $\boldsymbol{u}_m$, out final representation for the current mention sample m. Let $t_1, t_2, ..., t_k$ be all the types in T, where $k = |T|$. We embed them into the same space as $\boldsymbol{u}_m$ by assigning each of them a dense vector (Yogatama et al., 2015). These vectors are denoted as $\boldsymbol{t}_1, ..., \boldsymbol{t}_k$. Then the score of the mention m having the type $t_i \in T$ is calculated as the dot product of $\boldsymbol{u}_m$ and $\boldsymbol{t}_i$:

$$s(m, t_i) = \boldsymbol{u}_m \cdot \boldsymbol{t}_i. \quad (1)$$

We predict t_i as a type of m if $s(m, t_i) > 0$.

[1]We use Freebase mainly because it is widely used by existing studies. Wikidata is an alternative.

3.2 Model Training

Following existing studies, we also generate training data by using the *anchor links* in Wikipedia. Each anchor link can be used as a mention. These mentions are labeled by mapping the Freebase types of the target entries to the tag set T (Ling and Weld, 2012).

Since the *KB type representations* we use in our FET model are also obtained through mapping Freebase types, they will perfectly match the automatically generated labels for the mentions that are correctly linked (i.e., when the entity returned by the EL algorithm and the target entry of the anchor link are the same). For example, in Figure 1, suppose the example sentence is a training sample obtained from Wikipedia, where "Donald Trump" is an anchor link points to the Wikipedia page of *Donald Trump*. After mapping the Freebase types of *Donald Trump* to the target tag set, this sample will be weakly annotated as /person/politician, /person/tv_personality, and /person/business, which is exactly the same as the type information (the "Types From KB" in Figure 1) obtained through EL. Thus, during training, when the EL system links the mention to the correct entity, the model only needs to output the types in the *KB type representation*. This may cause the trained model to overfit the weakly labeled training data. For most types of entities such as locations and organizations, it is fine since they usually have the same types in different contexts. But it is problematic for person mentions, as their types can be context dependent.

To address this problem, during training, if a

mention is linked to a person entity by our entity linking algorithm, we add a random fine-grained person type label that does not belong to this entity while generating the *KB type representation*. For example, if the mention is linked to a person with types /person/actor and /person/author, a random label /person/politician may be added. This will force the model to still infer the type labels from the context even when the mention is correctly linked, since the *KB type representation* no longer perfectly match the weak labels.

To make it more flexible, we also propose to use a variant of the hinge loss used by (Abhishek et al., 2017) to train our model:

$$L = \sum_{m} [\sum_{t \in \tau_m} \max(0, 1 - s(m,t)) + \sum_{t \in \bar{\tau}_m} \lambda(t) \max(0, 1 + s(m,t))] \quad (2)$$

where τ_m is the correct type set for mention m, $\bar{\tau}_m$ is the incorrect type set. $\lambda(t) \in [1, +\infty)$ is a predefined parameter to impose a larger penalty if the type t is incorrectly predicted as positive. Since the problem of overfitting the weakly annotated labels is more severe for person mentions, we set $\lambda(t) = \lambda_P$ if t is a fine-grained person type, and $\lambda(t) = 1$ for all other types.

During training, we also randomly set the EL results of half of the training samples to be NIL. So that the model can perform well for mentions that cannot be linked to the KB at test time.

3.3 Entity Linking Algorithm

In this paper, we use a simple EL algorithm that directly links the mention to the entity with the greatest commonness score. Commonness (Pan et al., 2015; Medelyan and Legg, 2008) is calculated base on the anchor links in Wikipedia. It estimates the probability of an entity given only the mention string. In our FET approach, the commonness score is also used as the confidence on the linking result (i.e., the $\boldsymbol{g}$ used in the prediction part of Subsection 3.1). Within a same document, we also use the same heuristic used in (Ganea and Hofmann, 2017) to find coreferences of generic mentions of persons (e.g., "Matt") to more specific mentions (e.g., "Matt Damon").

We also tried other more advanced EL methods in our experiments. However, they do not improve the final performance of our model. Experimental results of using the EL system proposed in (Ganea and Hofmann, 2017) is provided in Section 4.

4 Experiments

4.1 Setup

We use two datasets: FIGER (GOLD) (Ling and Weld, 2012) and BBN (Weischedel and Brunstein, 2005). The sizes of their tag sets are 113 and 47, respectively. FIGER (GOLD) allows mentions to have multiple type paths, but BBN does not. Another commonly used dataset, OntoNotes (Gillick et al., 2014), is not used since it contains many pronoun and common noun phrase mentions such as "it," "he," "a thrift institution," which are not suitable to directly apply entity linking on.

Following (Ling and Weld, 2012), we generate weakly labeled datasets for training with Wikipedia anchor links. Since the tag sets used by FIGER (GOLD) and BBN are different, we create a training set for each of them. For each dataset, $2,000$ weakly labeled samples are randomly picked to form a development set. We also manually annotated 50 person mentions collected from news articles for tuning the parameter λ_P.

We use the 300 dimensional pretrained GloVe word vectors provided by (Pennington et al., 2014). The hidden layer sizes of the two layers of BiLSTMs are both set to 250. For the three-layer MLP, the size of the two hidden layers are both set to 500. The size of the type embeddings is 500. λ_P is set to 2.0. We also apply batch normalization and dropout to the input of each dense layer in our three-layer MLP during training.

We use strict accuracy, Macro F1, and Micro F1 to evaluate fine-grained typing performance (Ling and Weld, 2012).

4.2 Compared Methods

We compare with the following existing approaches: AFET (Ren et al., 2016a), AAA (Abhishek et al., 2017), NFETC (Xu and Barbosa, 2018), and CLSC (Chen et al., 2019).

We use **Ours (Full)** to represent our full model, and also compare with five variants of our own approach: **Ours (DirectTrain)** is trained without adding random person types while obtaining the KB type representation, and λ_P is set to 1; **Ours (NoEL)** does not use entity linking, i.e., the KB type representation and the entity linking confidence score are removed, and the model is trained in DirectTrain style; **Ours (NonDeep)** uses one BiLSTM layer and replaces the MLP with a dense layer; **Ours (NonDeep NoEL)** is the NoEL version of *Ours (NonDeep)*; **Ours (LocAttEL)** uses

Dataset	FIGER (GOLD)			BBN		
Approach	Accuracy	Macro F1	Micro F1	Accuracy	Macro F1	Micro F1
AFET	53.3	69.3	66.4	67.0	72.7	73.5
AAA	65.8	81.2	77.4	73.3	79.1	79.2
NFETC	68.9	81.9	79.0	72.1	77.1	77.5
CLSC	-	-	-	74.7	80.7	80.5
Ours (NonDeep NoEL)	65.9	81.7	78.0	69.3	81.4	81.5
Ours (NonDeep)	72.3	85.4	82.6	79.1	87.9	88.4
Ours (DirectTrain)	69.1	85.2	82.2	-	-	-
Ours (NoEL)	69.8	82.7	80.4	80.5	87.5	88.0
Ours (LocAttEL)	75.1	86.3	83.9	**82.8**	88.9	89.5
Ours (Full)	**75.5**	**87.1**	**84.6**	82.5	**89.2**	**89.6**

Table 1: Fine-grained entity typing performance. The performance of "Ours (DirectTrain)" on BBN is omitted since this dataset does not have fine-grained types for person.

the entity linking approach proposed in (Ganea and Hofmann, 2017) instead of our own commonness based approach. *Ours (Full)*, *Ours (DirectTrain)*, and *Ours (NonDeep)* all use our own commonness based entity linking approach.

4.3 Results

The experimental results are listed in Table 1. As we can see, our approach performs much better than existing approaches on both datasets.

The benefit of using entity linking in our approach can be verified by comparing *Ours (Full)* and *Ours (NoEL)*. The performance on both datasets decreases if the entity linking part is removed. Especially on FIGER (GOLD), the strict accuracy drops from 75.5 to 69.8. Using entity linking improves less on BBN. We think this is because of three reasons: 1) BBN has a much smaller tag set than FIGER (GOLD); 2) BBN does not allow a mention to be annotated with multiple type paths (e.g., labeling a mention with both /building and /location is not allowed), thus the task is easier; 3) By making the model deep, the performance on BBN is already improved a lot, which makes further improvement harder.

The improvement of our full approach over *Ours (DirectTrain)* on FIGER (GOLD) indicates that the techniques we use to avoid overfitting the weakly labeled data are also effective.

Ours (LocAttEL), which uses a more advanced EL system, does not achieve better performance than *Ours (Full)*, which uses our own EL approach. After manually checking the results of the two EL approaches and the predictions of our model on FIGER (GOLD), we think this is mainly because: 1) Our model also uses the context while making predictions. Sometimes, if it "thinks" that the type information provided by EL is incorrect, it may not use it. 2) The performances of different EL approaches also depends on the dataset and the types of entities used for evaluation. We find that on FIGER (GOLD), the approach in (Ganea and Hofmann, 2017) is better at distinguishing locations and sports teams, but it may also make some mistakes that our simple EL method does not. For example, it may incorrectly link "March," the month, to an entity whose Wikipedia description fits the context better. 3) For some mentions, although the EL system links it to an incorrect entity, the type of this entity is the same with the correct entity.

5 Conclusions

We propose a deep neural model to improve fine-grained entity typing with entity linking. The problem of overfitting the weakly labeled training data is addressed by using a variant of the hinge loss and introducing noise during training. We conduct experiments on two commonly used dataset. The experimental results demonstrates the effectiveness of our approach.

Abstract

In medical documents, it is possible that an entity of interest not only contains a discontiguous sequence of words but also overlaps with another entity. Entities of such structures are intrinsically hard to recognize due to the large space of possible entity combinations. In this work, we propose a neural two-stage approach to recognizing discontiguous and overlapping entities by decomposing this problem into two subtasks: 1) it first detects all the overlapping spans that either form entities on their own or present as segments of discontiguous entities, based on the representation of segmental hypergraph, 2) next it learns to combine these segments into discontiguous entities with a classifier, which filters out other incorrect combinations of segments. Two neural components are designed for these subtasks respectively and they are learned jointly using a shared encoder for text. Our model achieves the state-of-the-art performance in a standard dataset, even in the absence of external features that previous methods used.

1 Introduction

Named entity recognition (NER) aims at identifying shallow semantic elements in text and has been a crucial step towards natural language understanding (Tjong Kim Sang and De Meulder, 2003). Extracted entities can facilitate various downstream tasks like question answering (Abney et al., 2000), relation extraction (Mintz et al., 2009; Liu et al., 2017), event extraction (Riedel and McCallum, 2011; Lu and Roth, 2012; Li et al., 2013), and coreference resolution (Soon et al., 2001; Ng and Cardie, 2002; Chang et al., 2013).

The underlying assumptions behind most NER systems are that an entity should contain a contiguous sequence of words and should not overlap with each other. However, such assumptions do not always hold in practice. First, entities or mentions[1] with overlapping structures frequently exist in news (Doddington et al., 2004) and biomedical documents (Kim et al., 2003). Second, entities can be discontiguous, especially in clinical texts (Pradhan et al., 2014b). For example, Figure 3 shows three entities where two of them are discontiguous ("*laceration ... esophagus*" and "*stomach ... lac*"), and the second discontiguous entity also overlaps with another entity ("*blood in stomach*").

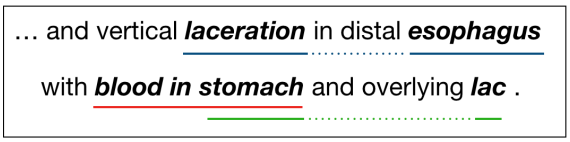

Figure 1: Entities are highlighted with colored underlines. "*laceration ... esophagus*" and "*stomach ... lac*" contain discontiguous sequence of words and the latter also overlaps with another entity "*blood in stomach*".

Such discontiguous entities are intrinsically hard to recognize considering the large search space of possible combinations of entities that have discontiguous and overlapping structures. Muis and Lu (2016a) proposed a hypergraph-based representation to compactly encode discontiguous entities. However, this representation suffers from the ambiguity issue during decoding – one particular hypergraph corresponds to multiple interpretations of entity combinations. As a result, it resorted to heuristics to deal with such an issue.

Motivated by their work, we take a novel approach to resolve the ambiguity issue in this work. Our core observation is that though it is hard to exactly encode the exponential space of all possible discontiguous entities, recent work on extracting overlapping structures (Wang and Lu, 2018) can be employed to efficiently explore the space

[1]Mentions are defined as references to entities that could be named, nominal or pronominal (Florian et al., 2004).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6216–6224, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of all the span combinations of discontiguous entities. Based on this observation, we decompose the problem of recognizing discontiguous entities into two subtasks: 1) *segment extraction*: learning to detect all (potentially overlapping) spans that either form entities on their own or present as parts of a discontiguous entity; 2) *segment merging*: learning to form entities by merging certain spans into discontiguous entities.

Our contributions are summarized as follows:

- By decomposing the problem of extracting discontiguous entities into two subtasks, we propose a two-stage approach that does not have the ambiguity issue.
- Under this decomposition, we design two neural components for these two subtasks respectively. We further show that the joint learning setting where the two components use a shared text encoder is beneficial.
- Empirical results show that our system achieves a significant improvement compared with previous methods, even in the absence of external features that previous methods used. [2]

Though we only focus on discontiguous entity recognition in this work, our model may find applications in other tasks that involve discontiguous structures, such as detecting gappy multiword expressions (Schneider et al., 2014).

2 Related Work

The task of extracting overlapping entities has long been studied (Zhang et al., 2004; Zhou et al., 2004; Zhou, 2006; McDonald et al., 2005; Alex et al., 2007; Finkel and Manning, 2009; Lu and Roth, 2015; Muis and Lu, 2017). As neural models (Collobert et al., 2011; Lample et al., 2016; Huang et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016) are proven effective for NER, there have been several neural systems recently proposed to handle entities of overlapping structures (Ju et al., 2018; Katiyar and Cardie, 2018; Wang et al., 2018; Sohrab and Miwa, 2018; Wang and Lu, 2018; Straková et al., 2019; Lin et al., 2019; Fisher and Vlachos, 2019). Our system is based on the model of neural segmental hypergraphs (Wang and Lu, 2018) which encodes all the possible combinations of overlapping entities using a compact hypergraph representation without ambiguity. Note that other system for extracting overlapping structures can also fit into our two-stage system.

For discontiguous and overlapping entity recognition, Tang et al. (2013); Zhang et al. (2014); Xu et al. (2015) extended the BIO tagging scheme to encode such complex structures so that traditional linear-chain CRF (Lafferty et al., 2001) can be employed. However, the model suffers greatly from ambiguity during decoding due to the use of the extended tagset. Muis and Lu (2016a) proposed a hypergraph-based representation to reduce the level of ambiguity. Essentially, these systems trade expressiveness for efficiency: they inexactly encoded the whole space of discontiguous entities with ambiguity for training, and then relied on some heuristics to handle the ambiguity during decoding. [3] Considering it is intrinsically hard to exactly identify discontiguous entities in one stage using a structured model, our work tries to decompose the task into two sub-tasks to resolve the ambiguity issue.

This task is also related to joint entity and relation extraction (Kate and Mooney, 2010; Li and Ji, 2014; Miwa and Sasaki, 2014) where the discontiguous entities can be viewed as relation links between segments. The major difference is that discontiguous entities require explicitly modeling overlapping entities and linking multiple segments.

3 Model

Our goal is to extract a set of entities that may have overlapping and discontiguous structures given a natural language sentence. We use $\boldsymbol{x} = x_1 \dots x_{|\boldsymbol{x}|}$ to denote a sentence, and use $\boldsymbol{y} = \{[b_{i:j} \dots b_{m:n}]^k\}$ to denote a set of discontiguous entities where each entity of type k contains a list of spans, e.g., $b_{i:j}$ and $b_{m:n}$, with subscripts indicating the starting and ending positions of the span. Hence, this task can be viewed as extracting and labelling a sequence of spans as an entity.

Our two-stage approach first extracts spans of interest like $b_{i:j}$, which are parts of discontiguous entities. Then it merges these extracted spans into discontiguous entities. In the more general setting where discontiguous entities are typed, our

[2] Our code is available at https://github.com/berlino/disco_em19.

[3] We will briefly introduce them and their heuristics later as our baselines in our experiments for comparison.

approach is designed to jointly extract and label the spans at the first stage, then only merge the spans of the same type at the second stage. We call the intermediate typed span $b^k_{i:j}$ a *segment* in the rest of the paper.

Formally, our model aims at maximizing the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$, which is decomposed as:

$$p(\boldsymbol{y}|\boldsymbol{x}) = p(\boldsymbol{s}|\boldsymbol{x})p(\boldsymbol{y}|\boldsymbol{s},\boldsymbol{x}) \quad (1)$$

where $\boldsymbol{s} = \{b^k_{i:j}\}$ denotes the set of segments that leads to $\boldsymbol{y}$ through a specific combination. [4] That is, we divide the problem of extracting discontiguous entities into two subtasks, namely *segment extraction* and *segment merging*.

3.1 Segment Extraction

The entity segments $\boldsymbol{s}$ of interest in a given sentence could also overlap with each other. For example, in Figure 3 the entity "*blood in stomach*" contains another segment "*stomach*". To make our model capable of extracting such overlapping segment combinations, we employ the model of neural segmental hypergraphs from Wang and Lu (2018), which uses a hypergraph-based representation to encode all the possible combinations of segments without ambiguity. Specifically, the segmental hypergraphs adopt a log-linear approach to model the conditional probability of each segment combination for a given sentence:

$$p(\boldsymbol{s}|\boldsymbol{x}) = \frac{\exp f(\boldsymbol{x},\boldsymbol{s})}{\sum_{\boldsymbol{s}'} \exp f(\boldsymbol{x},\boldsymbol{s}')} \quad (2)$$

where $f(\boldsymbol{x},\boldsymbol{s})$ is the score function for any pair of input sentence $\boldsymbol{x}$ and output segment combination $\boldsymbol{s}$.

In segmental hypergraphs, each segment combination $\boldsymbol{s}$ corresponds to a hyperpath. Following Wang and Lu (2018), the score for a hyperpath is the sum of the scores for each hyperedge, which are based on the word-level and span-level representations through LSTM (Graves and Schmidhuber, 2005):

$$\mathbf{h}^w_i = [\text{biLSTM}_1(\mathbf{x}_0, ..., \mathbf{x}_n)]_i \quad (3)$$
$$\mathbf{h}^s_{i:j} = \text{biLSTM}_2(\mathbf{h}^w_i, ..., \mathbf{h}^w_j) \quad (4)$$

where $\mathbf{x}_k$ is the corresponding word embedding for word x_k, $\mathbf{h}^w_i$ denotes the representation for the i-th word and $\mathbf{h}^s_{i:j}$ denotes the representation for the span from the i-th to the j-th word.

[4] We note that each $\boldsymbol{y}$ corresponds to one unique $\boldsymbol{s}$.

	# *sents*	# *entities* (%)			# *o.l.* (%)
		1 *segment*	2 *segments*	3 *segments*	
Train	534	544 (46)	607 (51)	44 (4)	205 (17)
Dev	303	357 (45)	421 (53)	18 (2)	240 (30)
Test	430	584 (48)	610 (50)	16 (1)	327 (27)

Table 1: Statistics of the dataset. *o.l.*: overlapping entities, *sents*: sentences.

On top of the segmental hypergraph representation, the partition function which is the denominator of Equation 2 can be computed using dynamic programming. The inference algorithm has a quadratic time complexity in the number of words, which can be further reduced to linear time complexity if we introduce the maximal length c of a segment. We regard c as a hyperparameter.

3.2 Segment Merging

Given a set of segments, our next subtask is to merge them into entities. First, we enumerate all the valid segment combinations, denoted as $\mathbf{E}$, based on the assumption that the segments in the same entity should have the same type and not overlap with each other. Our model then independently decides whether each valid segment combination forms an entity. We call these valid segment combinations *entity candidates*. For brevity, let us use $\boldsymbol{t}^k$ to denote an entity candidate $[b_{i:j} \ldots b_{m:n}]^k$ where each segment like $b^k_{i:j}$ belongs to $\boldsymbol{s}$.

Formally, given segments $\boldsymbol{s}$, the probability of generating entities $\boldsymbol{y}$ can be represented as:

$$p(\boldsymbol{y}|\boldsymbol{s},\boldsymbol{x}) = \prod_{\boldsymbol{t}^k \in \mathbf{E}} \big(\mathbb{1}[\boldsymbol{t}^k \in \boldsymbol{y}] p(\boldsymbol{t}^k \in \boldsymbol{y}) + \mathbb{1}[\boldsymbol{t}^k \notin \boldsymbol{y}](1 - p(\boldsymbol{t}^k \in \boldsymbol{y}))\big) \quad (5)$$

where $\mathbb{1}$ is an indicator function. We use a binary classifier to model $p(\boldsymbol{t}^k \in \boldsymbol{y})$.

To capture the interactions between segments within the same combination, we employ yet another LSTM on top of segments as follows:

$$\mathbf{h}^e_{\boldsymbol{t}^k} = \text{biLSTM}_3(\mathbf{h}^s_{i:j}, ..., \mathbf{h}^s_{m:n}) \quad (6)$$

where $\mathbf{h}^e_{\boldsymbol{t}^k}$ denotes the representation of the segment combination $\boldsymbol{t}^k$, which then serves as a feature vector for a binary classifier to determine whether it is an entity. Note that we reuse the span

representation from Equation 4, meaning that encoder for words and spans are shared in both segment extraction and merging.

The binary classifier for each $\boldsymbol{t}^k$ in Equation 5 is computed as:

$$p(\boldsymbol{t}^k \in \boldsymbol{y}) = \text{sigmoid}(\mathbf{W} \cdot \text{relu}(\mathbf{h}^e_{\boldsymbol{t}^k}) + b) \quad (7)$$

where we use a rectified linear unit (ReLU) (Glorot et al., 2011) and a linear layer, parameterized by $\mathbf{W}$ and b, to map the representation from Equation 6 to a scalar score. This score is normalized into a distribution by the sigmoid function.

In the joint model, we stack three separate LSTMs to encode text at different levels from words to spans, then discontiguous entities. Intuitively, the word and span level LSTM try to capture the lower-level information for segment extraction while the entity level LSTM captures the higher-level information for segment merging.

3.3 Learning and Decoding

For a dataset $\mathcal{D}$ consisting of sentence-entities pairs $(\boldsymbol{x}, \boldsymbol{y})$, our objective is to minimize the negative log-likelihood as follows:

$$\mathcal{L}(\theta) = -\sum_{(\boldsymbol{x}_i, \boldsymbol{y}_i) \in \mathcal{D}} \log p(\boldsymbol{y}_i | \boldsymbol{x}_i) + \frac{\lambda}{2}\|\theta\|^2 \quad (8)$$

where θ denotes model parameters and λ is the ℓ_2 coefficient. $p(\boldsymbol{y}_i|\boldsymbol{x}_i)$ is computed by $p(\boldsymbol{s}_i|\boldsymbol{x}_i)p(\boldsymbol{y}_i|\boldsymbol{s}_i, \boldsymbol{x}_i)$ where $\boldsymbol{s}_i$ is inferred from $\boldsymbol{y}_i$.

During the decoding stage, the system first predicts the most probable segments from the neural segmental hypergraph by $\hat{\boldsymbol{s}} = \arg\max_{\boldsymbol{s}'} p(\boldsymbol{s}'|\boldsymbol{x})$. Then it feeds the prediction to the next stage of merging segments and outputs the discontiguous entities by $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y}'} p(\boldsymbol{y}'|\hat{\boldsymbol{s}}, \boldsymbol{x})$.

4 Experiments

4.1 Setup

Data We evaluated our model on the task of recognizing mentions in clinical text from ShARe/CLEF eHealth Evaluation Lab (SHEL) 2013 (Suominen et al., 2013) and SemEval-2014 (Pradhan et al., 2014a). The task is defined to extract mentions of *disorders* from clinical documents according to the Unified Medical Language System (UMLS). The original dataset only has a small percentage of discontiguous entities, making it not suitable for comparing the effectiveness of different models when handling discontiguous entities. Following Muis and Lu (2016a), we use a subset of the original data where each sentence contains at least one discontiguous entity.

We split the dataset according to the setting of SemEval 2014. Statistics are shown in Table 1. In this subset, 53.6% of entities are discontiguous. Overlapping entities also frequently appear. Since an entity has three segments at most, we make the constraint that an entity candidate has no more than three segments during segment merging.

Note that all entities hold the same type of *disorder* in this dataset. Our model is intrinsically able to handle discontiguous entities of multiple types. Recall that segments are typed as $b^k_{i:j}$ during segment extraction, and only segments of the same type can be merged into an entity $\boldsymbol{t}^k$ where k indicates the entity type. To assess its ability to deal with multiple entity types, we conducted a further analysis (see section 4.2).

Hyperparameters We use the pretrained word embeddings from Chiu et al. (2016) which are trained on the PubMed corpus. A dropout layer (Srivastava et al., 2014) is used after each word is mapped to its embedding. The dropout rate and the number of hidden units in LSTMs are tuned based on the performance on the development set. We set the maximal length of a segment to be 6 during segment extraction. Our model is trained with Adam (Kingma and Ba, 2014). [5]

Baselines The first baseline we consider is to extend the traditional BIO tagging scheme to seven tags following Tang et al. (2013). With this tagging scheme, each word in a sentence is assigned a label. Then a linear-chain CRF is built to model the sequence labelling process. The next baseline is a hypergraph-based method by Muis and Lu (2016a). It encodes each entity combination into a directed graph based on six types of nodes; each has its specific semantics.

Since these baselines are both ambiguous, heuristics are required during decoding. Following Muis and Lu (2016a), we explored two heuristics: given a model's ambiguous output, either a tag sequence or a hypergraph, the "enough" heuristic finds the minimal set of entities that corresponds to it, while "all" decodes the union of all the possible set of entities. Please refer to Muis and Lu (2016a) for details. We also describe them in the Appendix for self-containedness.

[5] See Appendix C for the full hyperparameters.

	Model	P	R	F_1
Non-Neural	CRF (enough)	54.7	41.2	47.0
	CRF (all)	15.2	44.9	22.7
	Graph (enough)	**76.9**	40.1	52.7
	Graph (all)	76.0	40.5	52.8
	Our model	76.3	41.4	53.7
Neural	CRF (enough)	43.7	54.3	48.4
	CRF (all)	15.7	55.8	24.5
	Our model	48.4	**66.5**	**56.1**
	w.o. shared encoder	46.2	65.1	54.0

Table 2: Main results. Graph: the hypergraph based model by Muis and Lu (2016a). "enough" and "all" denotes the heuristics used in ambiguous model. *w.o. shared encoder*: without using shared encoder.

We compare our approach to these baselines in two settings. In the non-neural setting, we compare models using the same set of handcrafted features, including external features from POS tagger and Brown cluster following (Muis and Lu, 2016a). In the neural setting, we implement a linear-chain CRF model using the same neural encoder. We are trying to see our model can perform better in both settings. Note that all neural models in our experiments do not leverage any handcrafted features.

4.2 Results and Analysis

The main results are listed in Table 2. In both non-neural and neural settings, our model achieves the better result in terms of F_1 compared with other baselines, revealing the effectiveness of our methodology of decomposing the task into two stages. Our neural model achieves the best performance even without using any external handcrafted features.

We also assess the performance when our model uses separate encoders for segment extraction and merging. From the results, we observe that the setting of using a shared encoder is very beneficial for our two-stage system.

Compared with non-neural models, neural models are better in terms of F_1, both for CRF and our models. The gain mostly comes from the ability to recall more entities. Handcrafted features in non-neural models lead to high precisions but do not seem to be general enough to recall most entities.

The "enough" heuristic works better than "all" in most cases. Hence we use it for evaluating models' ability in handling multiple entity types.

Handling Multiple Entity Types To assess the effectiveness of handling entities of multiple types, we further categorize each entity into three types based on its Concept Unique Identifier (CUI), following Muis and Lu (2016a). [6] In this setting, segments are jointly extracted and labelled using these three categories during segment extraction. During segment merging, an entity candidate can only contain segments of the same type during merging.

	Model	P	R	F_1
Non-Neural	CRF (enough)	55.3	37.4	44.6
	Graph (enough)	**67.3**	37.5	48.2
Neural	CRF (enough)	41.6	52.3	46.3
	Our model	43.3	**65.8**	**52.2**

Table 3: Results on handling multiple entity types.

The results are listed in Table 3. Our neural model again achieves the best performance among all models in terms of F_1. Compared with neural CRF, our model is significantly better at recalling entities. Similar to the previous observation, the neural encoder consistently boosts the performance of the CRF by recalling more entities, compared with its non-neural counterpart.

5 Conclusion and Future Work

In this work, we propose a neural two-stage approach for recognizing discontiguous entities, which learns to extract and merge segments jointly without suffering from ambiguity issue. Empirically, it achieves a significant improvement compared with previous methods that rely heavily on handcrafted features.

During training, the classifier of merging segments is only exposed to correct segments, making it unable to recover from errors of segment exaction during decoding. This issue is similar to *exposure bias* (Wiseman and Rush, 2016) and it might be beneficial if the classifier of segment merging is exposed to incorrect segments during training. We leave this for future work.

A Segment Extraction

Neural segmental hypergraphs (Wang and Lu, 2018) were proposed for modeling overlapping structures in entity mentions. We directly adopt their approach to model the segments of overlapping structures. Note that our segment also holds the information of entity type, so the resulting system for segment extraction can also be viewed as performing sub-mention recognition. Next, we illustrate how the segmental hypergraph encodes the overlapping segments by a concrete example.

For brevity, we only show the example that is annotated with one entity type, and it is able to be trivially extended to the case of multiple entity types.

Given a phrase "He had blood in his mouth and on his tongue", there exist two disorder mentions: '*blood in his mouth*' and '*blood ... on his tongue*' where the second mention has a discontiguous sequence of words. Our two-stage approach first extracts segments that lead to these two mentions. In this example, the segments consist of '*blood*', '*blood in his mouth*' and '*on his tongue*'. We observe that the first two segments overlap with each other.

Segmental hypergraph encodes this segment combination based on five types of nodes:

- $\mathbf{A}_i$ encodes all segments that start with the i-th or a later word
- $\mathbf{E}_i$ encodes all segments that start exactly with the i-th word
- $\mathbf{T}_i^k$ represents all segments of type k starting with the i-th word
- $\mathbf{I}_{i,j}^k$ represents all segments of type k that contain the j-th word and start with the i-th word
- $\mathbf{X}$ marks the end of a segment.

Each segment can be expressed in terms of these five nodes and corresponds with a path in the segmental hypergraph. As a result, each segment combination corresponds with a *hyperpath* where hyperedges are designated to connect multiple nodes so as to model overlapping segments. Figure 2 shows such a hyperpath for the segment combination in our example phrase. Since we only have one entity type in this example, we eliminate the superscript k in $\mathbf{T}$ and $\mathbf{I}$ nodes that indicates the information of entity type.

Starting from the third word 'blood', there exist two segments '*blood*' and '*blood in his mouth*'. The brown hyperedge with the parent node being $\mathbf{I}_{3,3}$ is responsible for connecting these two overlapping segments. This hyperedge means that there exists a segment that ends at the third word (the link from $\mathbf{I}_{3,3}$ to $\mathbf{X}$) and there also exists a segment that continues to the next word (the link from $\mathbf{I}_{3,3}$ to $\mathbf{I}_{3,4}$). The segment '*on his tongue*' is directly mapped to the path from $\mathbf{T}_8$ to $\mathbf{X}$.

The score for each hyperpath is the sum of the scores that are computed over each hyperedge. Since $\mathbf{T}$ nodes encode word-level information and $\mathbf{I}$ nodes encode span-level information, two LSTMs are employed to capture the interactions at both word level and span level respectively. We use their original implementation that is publicly available[7].

B Heuristics for Handling Ambiguity

This section tries to explain the two heuristics "enough" and "all" when ambiguous tag sequences occur. We use the extended BIO tagging scheme (Tang et al., 2013; Muis and Lu, 2016a) for example.

To encode the three discontiguous entities in Figure 3, this tagset has seven tags:

- B/I: **B**eginning and **I**nside of contiguous entities
- BH/IH: **B**eginning and **I**nside of *head* where head refers to segments shared by multiple discontiguous entities.
- BD/ID: **B**eginning and **I**nside of *body* where body refers to segments that are not shared across entities.
- O: **O**utside of entities.

The resulting tag sequence is shown in Figure 4. Since this tagging scheme cannot model the correspondence between different tags, tagging sequences are very likely to have multiple interpretations. For instance, it is not clear that "laceration" should be combined with "esophagus" or with "stomach".

The "all" heuristics extracts all the possible entities that could exist in the tagging sequence. In this case, "all" heuristics will produce "*laceration ... esophagus*" , "*stomach ... lac*", "*blood in stomach*", "*laceration ... lac*", "*esophagu ... lac*", "*laceration ...esophagus ... lac*", "*laceration ... stomach*", "*esophagus ... stomach*", "*laceration... stomach ... lac*", "*esophagus ... stomach...lac*".

The "enough" heuristics tries to find the minimal set of entities that corresponds to this tagging sequence. In this case, "enough" heuristics would produce at least three entities like: "*laceration ... esophagus*" , "*stomach ... lac*" and "*blood in stomach*"; "*laceration ... lac*" , "*blood in stomach*" and

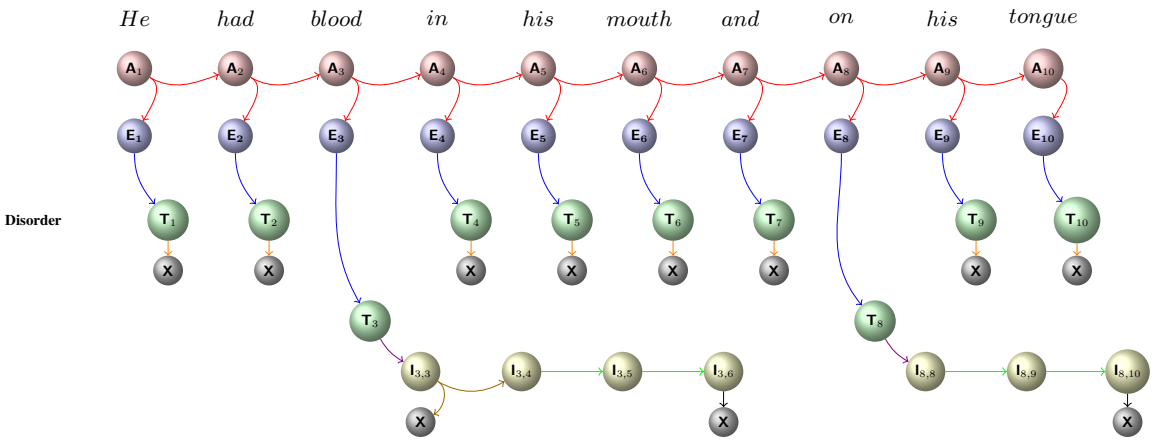

Figure 2: A hyperpath that encodes three mention segments: '*blood*', '*blood in his mouth*' and '*on his tongue*'.

Figure 3: Entities are highlighted with colored underlines. "*laceration ... esophagus*" and "*stomach ... lac*" contain discontiguous sequence of words and the latter also overlaps with another entity "*blood in stomach*".

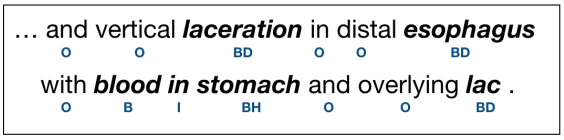

Figure 4: Entities annotated using seven tags.

"*esophagus ... stomach*". We make further constraints to generate only one combination following Muis and Lu (2016b).

C Hyperparameters

The hyperparameters used in our neural two-stage model are listed in Table 4. Since the size of our dataset is relatively small, the dropout is crucial to prevent overfitting considering that the pre-traind word embeddings have the dimension of 200. The length of most segments is not greater than 6, so we set the maximal length c to be 6 to improve the efficiency of segment extraction.

We also tried to incorporate a character-level component (Lample et al., 2016) to capture morphological and orthographic information. However, it does not have a significant effect on the performance in term of F_1.

word embedding dim	200
LSTM(word) hidden size	128
LSTM(span) hidden size	128
LSTM(entity) hidden size	64
maximal length c	6
dropout	0.8
l_2	0.0001

Table 4: Hyperparameters of our joint model.

Cross-Sentence N-ary Relation Extraction using Lower-Arity Universal Schemas

Abstract

Most existing relation extraction approaches exclusively target binary relations, and n-ary relation extraction is relatively unexplored. Current state-of-the-art n-ary relation extraction method is based on a supervised learning approach and, therefore, may suffer from the lack of sufficient relation labels. In this paper, we propose a novel approach to cross-sentence n-ary relation extraction based on *universal schemas*. To alleviate the sparsity problem and to leverage inherent decomposability of n-ary relations, we propose to learn relation representations of lower-arity facts that result from decomposing higher-arity facts. The proposed method computes a score of a new n-ary fact by aggregating scores of its decomposed lower-arity facts. We conduct experiments with datasets for ternary relation extraction and empirically show that our method improves the n-ary relation extraction performance compared to previous methods.

1 Introduction

Relation extraction is a core natural language processing task which is concerned with the extraction of relations between entities from text. It has numerous applications ranging from question answering (Xu et al., 2016) to automated knowledge base construction (Dong et al., 2014).

While the vast majority of existing research focuses on extracting *binary* relations, there exists only few recent approaches to extract n-ary relations, that is, relations among $n \geq 2$ entities (Li et al., 2015; Ernst et al., 2018). In n-ary relation extraction, relation mentions tend to span multiple sentences more frequently as n increases. Thus, Peng et al. (2017) recently extended the problem to cross-sentence n-ary relation extraction in which n-ary relations are extracted from multiple sentences. As a motivating example, consider the following text from Wikipedia: "*Revis started off the* **2009 season** *matched up against some of football's best wide receivers. In Week 1, he helped limit Houston* **Texans** *Pro-bowler* **Andre Johnson** *to four receptions for 35 yards.*" In this example, two sentences collectively describes that Andre Johnson is a player of the football team the Texans during 2009 season, and thus we need cross-sentence information to correctly extract this ternary interaction among the three entities, i.e. `Player`(Andre Johnson, Texans, 2009 season).

Previous methods (Peng et al., 2017; Song et al., 2018) capture cross-sentence n-ary relation mentions by representing texts with a *document graph* which consists of both intra- and cross-sentence links between words. With this graphical representation, they applied graph neural networks to predict ternary relations in the medical domain. However, these methods train the neural networks in a supervised manner using distant supervision (Mintz et al., 2009) and, therefore, may suffer from the lack of sufficient positive labels when a well-populated knowledge base is not available.

On the other hand, for binary relation extraction, the problem of insufficient positive labels can be mitigated with *universal schemas* (Riedel et al., 2013). In a universal schema approach, textual representations (surface patterns) of entities and their relations are encoded into the same vector space as the canonical knowledge base relations. Thus, semantically similar surface patterns can share information of relation labels in a semi-supervised manner. This reduces the amount of required labeled training data. Applying the universal schema approach to n-ary ($n > 2$) relation extraction is, however, not straight-forward due to the sparsity of higher-order relation mentions among a specific set of $n > 2$ entities.[1] This is be-

[1] In our Wiki-90k dataset (see §4.1), only 12.5% of ternary entity tuples have at least two relations among the entities, while 77.3% of entities appear at least twice.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6225–6231, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

cause the universal schema approach (Riedel et al., 2013) and its extensions (Toutanova et al., 2015; Verga et al., 2016, 2017) utilize co-occurring patterns of relation types between specific pair of entities. Also, prior work has only addressed binary relations, and it is not trivial to define surface patterns among $n > 2$ entities and to encode these patterns into a vector representation.

To mitigate the aforementioned sparsity problem and utilize existing encoders for binary and unary surface patterns, we propose to train universal schema models on more dense lower-arity (unary and binary) facts instead of original sparse n-ary facts. Since most n-ary relations can be decomposed into a set of k-ary relations ($k = 1, 2$) which are implied by the n-ary relation,[2] we can easily acquire lower-arity facts by decomposing n-ary facts. Our model learns representations of these lower-arity relations using the universal schema framework, and predicts new n-ary facts by aggregating scores of lower-arity facts.

To evaluate the proposed method, we create new cross-sentence n-ary relation extraction datasets with multiple ternary relations.[3] The new datasets contain more entity tuples with known relational facts appeared in a knowledge base than the existing dataset (Peng et al., 2017), and, therefore, these datasets can be used to more effectively evaluate methods which predict relation labels for each individual entity tuple. We show empirically that by jointly training lower-arity models and an n-ary score aggregation model, the proposed method improves the performance of n-ary relation extraction. To the best of our knowledge, this is the first attempt to apply universal schemas to n-ary relation extraction, taking advantage of the compositionality of higher-arity facts.

2 Task Definition and Notation

The cross-sentence n-ary relation extraction task (Peng et al., 2017) is defined as follows. Let $\mathcal{E}$ be a set of entities, $\mathcal{R}_{\text{KB}}$ be a set of relation types of an external knowledge base $\mathcal{KB}$, and $\mathcal{O}_{\text{KB}} = \{\langle r, (e_1, ..., e_n)\rangle : r(e_1, ..., e_n) \in \mathcal{KB}, r \in \mathcal{R}_{\text{KB}}, e_i \in \mathcal{E}\}$ be the set of facts in $\mathcal{KB}$. We collect a set of candidate entity tuples among which KB relation $r \in \mathcal{R}_{\text{KB}}$ possibly holds.[4] Here, all entities in each candidate tuple $(e_1, ..., e_n)$ are mentioned in the same text section T in a given set of documents. We define a set of these entity mentions as $\mathcal{O}_{\text{text}} = \{\langle T, (e_1, ..., e_n)\rangle : e_i \in \mathcal{E} \text{ is mentioned in } T\}$. Here, text section T is a (short) span in a document which can describes relational facts among entities. In the cross-sentence n-ary relation extraction task, text section T can contain multiple sentences. In this paper, following (Peng et al., 2017), we define M consecutive sentences ($M \geq 1$) which contain n target entities as a text section in the cross-sentence n-ary relation extraction task. We use the term "relation" to refer to both relations $r \in \mathcal{R}_{\text{KB}}$ and sections T.

The goal of the cross-sentence n-ary relation extraction task is to predict new facts $\langle r, (e_1, ..., e_n)\rangle \notin \mathcal{O}_{\text{KB}}$ for relation $r \in \mathcal{R}_{\text{KB}}$ given $\mathcal{O} = \mathcal{O}_{\text{KB}} \cup \mathcal{O}_{\text{text}}$, where $n \geq 2$.

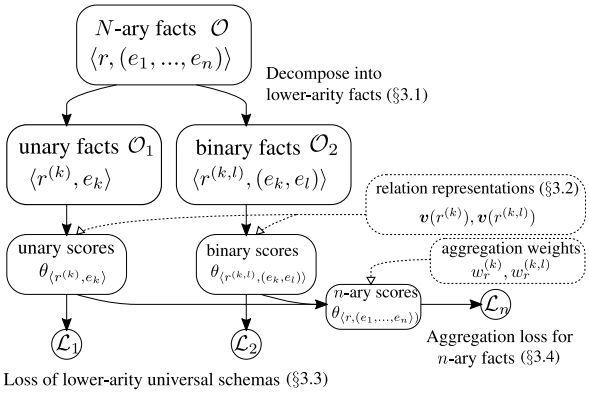

Figure 1: An overview of the proposed method.

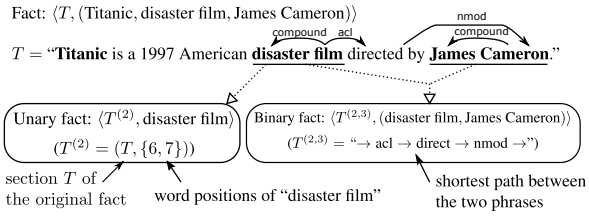

Figure 2: An example of decomposed textual facts.

3 Proposed Method

3.1 Lower-Arity Facts

To alleviate the sparsity problem of facts among n entities ($n > 2$) and to utilize well-studied encoders for binary and unary surface patterns, we

[2] For example, the ternary relation `AwardedFor`$(director, movie, award)$ can be decomposed into the binary relations `DirectorOf`$(director, movie)$ and `WonAward`$(director, award)$. Note that a similar idea is introduced in (Ernst et al., 2018) as *partial facts* or *partial patterns*.

[3] Our codes and datasets are available at https://github.com/aurtg/nary-relation-extraction-decomposed.

[4] It is allowed that multiple KB relations hold among the same set of entities.

decompose a set of original n-ary facts, $\mathcal{O}$, into a set of unary facts $\mathcal{O}_1$ and a set of binary facts $\mathcal{O}_2$ (Figure 1).

Unary Facts: Given an n-ary fact $\langle r, (e_1, ..., e_k)\rangle \in \mathcal{O}$, we decompose it into a set of n unary facts $\{\langle r^{(k)}, e_k\rangle : k = 1, ..., n\}$, where $r^{(k)}$ is a tentative unary relation w.r.t. the k-th argument of the original relation r. If r is a KB relation, we define unary relation $r^{(k)}$ as a new canonicalized relation. If r is section T, we define unary relation $r^{(k)}$ as a tuple $r^{(k)} = (T, pos(e_k))$, where $pos(e_k)$ is a set of word position indices of entity e_k in section T (Figure 2). We denote a set of all decomposed unary facts by $\mathcal{O}_1$. Intuitively, these unary relations represent semantic roles or types of corresponding arguments of the original relation r (Yao et al., 2013).

Binary Facts: Given an n-ary fact $\langle r, (e_1, ..., e_k)\rangle \in \mathcal{O}$, we decompose it into a set of $n(n-1)$ binary facts $\{\langle r^{(k,l)}, (e_k, e_l)\rangle : k, l = 1, ..., n, k \neq l\}$, where $r^{(k,l)}$ is a tentative binary relation between the k-th and l-th argument of the original relation r. If r is a KB relation, we define binary relation $r^{(k,l)}$ as a new canonicalized relation. If r is a section T, we represent it by the shortest path between e_k and e_l on the *document graph* (Quirk and Poon, 2017) of T (Figure 2), and denote it by $path(T; e_k, e_l)$. We denote the set of all decomposed binary facts by $\mathcal{O}_2$.

3.2 Lower-Arity Relation Representations

We learn a vector representation $\boldsymbol{v}(r) \in \mathbb{R}^{d_r}$ for each unary or binary relation in $\mathcal{O}_1$ or $\mathcal{O}_2$. For $r^{(k)}$ or $r^{(k,l)}$ derived from a KB relation, we represent it by a trainable parameter vector. On the other hand, for the one derived from a textual relation, we use the following encoders to compute its representations.

Unary encoder: For an unary textual relation $r^{(k)} = (T, pos(e_k))$, we represent each section T by a sequence of word vectors and use a bidirectional LSTM (Bi-LSTM) (Schuster and Paliwal, 1997) to compute a hidden representation $\boldsymbol{h}_l \in \mathbb{R}^{d_r}$ at each word position l. Following recent works (Zhang et al., 2018; He et al., 2018; Lee et al., 2017), we aggregate $\boldsymbol{h}_l$ within a phrase of entity e_k to compute $\boldsymbol{v}(T^{(k)})$. We use element-wise mean as aggregation function:

$$\boldsymbol{v}(r^{(k)}) = \text{mean}(\{\boldsymbol{h}_l : l \in pos(e_k)\}). \quad (1)$$

Binary encoder: For a binary textual relation $r^{(k,l)} = path(T; e_k, e_l)$, we represent each token (word or edge label) in $path(T; e_k, e_l)$ by an embedding vector (Toutanova et al., 2015; Verga et al., 2016). We use a Bi-LSTM to compute a hidden representation $\boldsymbol{h}'_l \in \mathbb{R}^{d_r}$ at each token position l, and max-pool along the path to compute the relation representation:

$$\boldsymbol{v}(T^{(k,l)}) = \max(\{\boldsymbol{h}'_l : l = 1, ..., L\}). \quad (2)$$

3.3 Learning Relation Representations

We follow Verga et al. (2017) to train relation representations (§3.2). We define a score $\theta_{\langle r,p\rangle}$ for each lower-arity fact $\langle r, p\rangle \in \mathcal{O}_1 \cup \mathcal{O}_2$, and minimize the following loss (3) for each arity $i = 1, 2$. Here, placeholder p refers to either an entity (if $\langle r, p\rangle \in \mathcal{O}_1$) or an entity tuple (if $\langle r, p\rangle \in \mathcal{O}_2$), and we simply refer to both as entity tuple. The loss functions contrast a score of an original fact $\langle r, p^+\rangle \in \mathcal{O}_i$ and those of K sampled negative facts $\langle r, p_k^-\rangle \notin \mathcal{O}_i$. We sample negative facts by randomly replacing entity tuple p^+ in the original fact by different entity tuples p_k^-.

$$\mathcal{L}_i = \mathop{\mathbb{E}}_{\substack{\langle r,p^+\rangle \in \mathcal{O}_i \\ \langle r,p_k^-\rangle \notin \mathcal{O}_i}} [-\log(\frac{\exp(\theta_{\langle r,p^+\rangle})}{\exp(\theta_{\langle r,p^+\rangle}) + \sum_k \exp(\theta_{\langle r,p_k^-\rangle})})]. \quad (3)$$

The score of fact $\langle r, p\rangle$ is defined as $\theta_{\langle r,p\rangle} = \boldsymbol{v}(r)^T \boldsymbol{v}(p; r)$. Entity tuple representations $\boldsymbol{v}(p; r)$ are computed with a weighted average of the representations $\{\boldsymbol{v}(r') : r' \in V(p)\}$ as shown in (4) and (5) where $a(r', r; V(p))$ is the attention weight for each relation $r' \in V(p)$.[5]

$$\boldsymbol{v}(p; r) = \sum_{r' \in V(p)} a(r', r; V(p)) \boldsymbol{v}(r'),$$
$$a(r', r; V(p)) = \frac{\exp(\boldsymbol{v}(r')^T \boldsymbol{v}(r))}{\sum_{r'' \in V(p)} \exp(\boldsymbol{v}(r'')^T \boldsymbol{v}(r))}. \quad (4)$$

$$V(p) = \begin{cases} \{r : \langle r, e_k\rangle \in \mathcal{O}_1\} & (\text{if } p = e_k) \\ \{r : \langle r, (e_k, e_l)\rangle \in \mathcal{O}_2\} & (\text{if } p = (e_k, e_l)) \end{cases}. \quad (5)$$

3.4 Aggregating Lower-Arity Scores

To predict n-ary facts of KB relation $r \in \mathcal{R}_{\text{KB}}$, we compute its score $\theta_{\langle r,(e_1,...,e_n)\rangle}$ by aggregating lower-arity scores as in (6), where $w_r^{(\cdot)}$ is a positive scalar weight defined for each KB relation which sum to one: $\sum_k w_r^{(k)} + \sum_{k \neq l} w_r^{(k,l)} = 1$.

[5] During training, as in (Verga et al., 2017), we aggregate sub-sampled M relations from $V(p)$ if $|V(p)| > M$. We set $M = 2$ for all experiments.

We can set all weights $w_r^{(k)}$ and $w_r^{(k,l)}$ to $1/n^2$, or train these weights to give higher scores to positive n-ary facts by minimizing additional loss function $\mathcal{L}_n$. Note that $\mathcal{L}_n$ directly contrasts n-ary scores associated with KB relations $r \in \mathcal{R}_{\text{KB}}$ in a more supervised manner than both $\mathcal{L}_1$ and $\mathcal{L}_2$.[6]

$$\theta_{\langle r,(e_1,\ldots,e_n)\rangle} = \sum_{k=1}^{n} w_r^{(k)} \theta_{\langle r^{(k)},e_k\rangle} + \sum_{\substack{k=1,\ldots,n \\ l=1,\ldots,n \\ k\neq l}} w_r^{(k,l)} \theta_{\langle r^{(k,l)},(e_k,e_l)\rangle}. \quad (6)$$

$$\mathcal{L}_n = \mathop{\mathbb{E}}_{\substack{\langle r,p^+\rangle\in\mathcal{O}_{\text{KB}} \\ \langle r,p^-\rangle\notin\mathcal{O}_{\text{KB}}}} [\max(0, 1 - \theta_{\langle r,p^+\rangle} + \theta_{\langle r,p^-\rangle})] \quad (7)$$

The overall loss function is now $\mathcal{L} = \mathcal{L}_1 + \mathcal{L}_2 + \alpha\mathcal{L}_n$. By changing α, we can balance the semi-supervised effect of lower-arity universal schemas ($\mathcal{L}_1, \mathcal{L}_2$) and that of the supervision with n-ary relation labels ($\mathcal{L}_n$).

4 Experiments

4.1 Dataset

The cross-sentence n-ary relation extraction dataset from Peng et al. (2017) contains only 59 distinct ternary KB facts including the train and test set. Since our proposed method and universal schemas baselines predict KB relations for each *entity tuple* instead of each *surface pattern*, the number of known facts of KB relations is crucial to reliably evaluate and compare these methods. Thus, we created two new n-ary cross-sentence relation extraction datasets (dubbed with **Wiki-90k** and **WF-20k**) that contain more known facts retrieved from public knowledge bases.

To create the Wiki-90k and WF-20k datasets, we used Wikidata and Freebase respectively as external knowledge bases. Since these knowledge bases store only binary relational facts, we defined multiple ternary relations by combining a few binary relations.[7,8] For both datasets, we collected paragraphs from the English Wikipedia, and used Stanford CoreNLP (Manning et al., 2014) to extract dependency and co-reference links. Entity mentions are detected using DBpedia Spotlight (Daiber et al., 2013). We followed (Peng et al., 2017) to extract co-occurring entity tuples and their surface patterns, that is, we selected tuples which occurred in a *minimal span* within at most $M \leq 3$ consecutive sentences. Entity tuples without a known KB relation are subsampled, since the number of such tuples are too large. We randomly partitioned all entity tuples into train, development (dev), and test sets.

4.2 Baselines

(Song et al., 2018): The state-of-the-art cross-sentence n-ary relation extraction method proposed by Song et al. (2018) represents each surface pattern by the concatenation of entity vectors from the last layer of a Graph State LSTM, a variant of a graph neural network. The concatenated vector is then fed into a classifier to predict the relation label. Since their method directly predicts a relation label for each surface pattern, it is more robust to the sparsity of surface patterns among a specific higher arity entity tuple. However, due to their purely supervised training objective, its performance may degrade if the number of available training labels is small.

Universal schemas: We compared our method with semi-supervised methods based on universal schemas (Toutanova et al., 2015; Verga et al., 2017). In our experiments, we used the same encoder as (Song et al., 2018) to encode each surface pattern.[9] We tested two types of scoring functions, Model F and Model E, as in (Toutanova et al., 2015).[10,11]

4.3 Evaluation

We compared the methods in the held-out evaluation as in (Mintz et al., 2009) and report (weighted) mean average precision (MAP) (Riedel et al., 2013). Unless otherwise noted, reported values are average values over six experiments, in which network parameters are randomly initialized. All reported p-values are calculated based on Wilcoxon rank sum test (Wilcoxon, 1945) with

[6] The loss function (7) performs better than a log-likelihood based loss, $-\log\sigma(\theta_{\langle r,p^+\rangle} - \theta_{\langle r,p^-\rangle})$.

[7] See the appendix A for details about defined ternary relations.

[8] For about half of the defined ternary relations, combined original binary relations in KB are different from decomposed binary relations of the ternary relations in the proposed method (§3.1).

[9] Using linear projection instead of simple concatenation did not improve performance in our preliminary experiments.

[10] It is not trivial to apply Model E scoring function with Verga et al. (2017) method, since their aggregation method calculates a representation for each row, i.e. entity tuple.

[11] DistMult scoring function in (Toutanova et al., 2015) showed poor performance compared to the other two scoring functions in our preliminary experiments.

Method	Wiki-90k		WF-20k	
	average	weighted	average	weighted
Proposed	**0.584**	**0.634**	**0.821**	**0.842**
(Song et al., 2018)	0.471	0.536	0.639	0.680
(Toutanova et al., 2015) with Graph State LSTM (Song et al., 2018) encoder				
Model F	0.240	0.262	0.341	0.380
Model E	0.399	0.414	0.725	0.752
(Verga et al., 2017) with Graph State LSTM (Song et al., 2018) encoder				
Model F	0.443	0.482	0.610	0.653

Table 1: Mean average precisions (MAPs) on **test** data.

multiple-test adjustment using Holm's method (Holm, 1979).

4.4 Results

Table 1 illustrates the performance of each method.[12] Compared to the baseline methods, our proposed method achieves higher weighted MAP for both datasets. Interestingly, Model F performs well in Verga et al. (2017) baseline, while it shows low performance in Toutanova et al. (2015) baseline.

Ablation Study: Table 2 illustrates the performance of various settings of our proposed method. **U**,**B**, and **N** stand for using the loss functions $\mathcal{L}_1$, $\mathcal{L}_2$, and $\alpha\mathcal{L}_n$ respectively. In the result, **U+B** performs significantly better ($p < 0.005$) than **U** and **B**, and this shows effectiveness of combining scores of both binary facts and unary facts. On the other hand, there was no significant difference between **U+B+N** and **N** ($p > 0.9$). Note that we used all positive labels in this experiment, that is, sufficient amount of positive labels are used for calculating the loss **N**.

Data efficiency: Furthermore, we also investigated the influence of the training data size (the number of positive labels) of our proposed method and baseline methods.[13] Here, $\alpha = \infty$ stands for optimizing $\mathcal{L}_n$ instead of $\mathcal{L}_1 + \mathcal{L}_2 + \alpha\mathcal{L}_n$. As shown in Figure 3, $\alpha = 1$ achieved higher performance than $\alpha = \infty$, showing that introducing lower-arity semi-supervised loss ($\mathcal{L}_1 + \mathcal{L}_2$) improves the performance for dataset with few positive labels. On the other hand, the lower performance of $\alpha = 0$ compared to $\alpha = 0.1, 1$ suggests that information of higher-arity facts introduced from $\mathcal{L}_n$ is benefitial for n-ary relation extraction.

5 Conclusion and Future Works

We proposed a new method for cross-sentence n-ary relation extraction that decomposes sparse n-ary facts into dense unary and binary facts. Experiments on two datasets with multiple ternary relations show that our proposed method can statistically significantly improve over previous works, which suggests the effectiveness of using unary and binary interaction among entities in surface patterns.

However, as Fatemi et al. (2019) suggests, there exists cases in which reconstructing n-ary facts from decomposed binary facts induces false positives. Tackling this issue is one important future research direction.

[12] For the proposed method, we set $\alpha = 10$.

[13] In this experiment, we conducted four experiments per each setting and set $K = 10$.

Setting	average	weighted
U	0.363	0.404
B	0.411	0.452
N	0.646	0.685
U+B	0.521	0.552
U+B+N	0.646	0.682
U+B+N ($K = 10$)	**0.650**	**0.689**
U+B+N ($K = 5$)	0.592	0.640
U+B+N (fix $w_r = 1$)	0.645	0.679

Default hyperparameter: $K = 20$

Abstract

Current region-based NER models only rely on fully-annotated training data to learn effective region encoder, which often face the training data bottleneck. To alleviate this problem, this paper proposes *Gazetteer-Enhanced Attentive Neural Networks*, which can enhance region-based NER by learning name knowledge of entity mentions from easily-obtainable gazetteers, rather than only from fully-annotated data. Specially, we first propose an *attentive neural network (ANN)*, which explicitly models the mention-context association and therefore is convenient for integrating externally-learned knowledge. Then we design an auxiliary *gazetteer network*, which can effectively encode name regularity of mentions only using gazetteers. Finally, the learned gazetteer network is incorporated into ANN for better NER. Experiments show that our ANN can achieve the state-of-the-art performance on ACE2005 named entity recognition benchmark. Besides, incorporating gazetteer network can further improve the performance and significantly reduce the requirement of training data.

1 Introduction

Named entity recognition (NER), aiming to identify text mentions of specific entity types, is a fundamental NLP task. Recently, region-based NER approaches (Finkel and Manning, 2009; Xu et al., 2017; Sohrab and Miwa, 2018) have attracted significant attention, which first encode all candidate regions (commonly all subsequences of a sentence) using a *region encoder*, then identify whether each subsequence is an entity mention of target types using a classifier. For example, in Figure 1 all subsequences of the sentence, such as "George Washington", will first be encoded, and then be classified into entity types. Compared to sequential labeling models, region-based models can naturally detect nested or overlapping mentions by considering all subsequences, and therefore are of great value to NER.

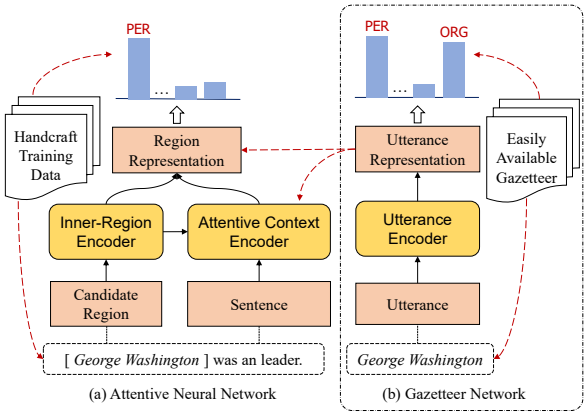

Figure 1: The overall architecture of GEANN. The candidate region is "George Washington", which literally could be a person or an organization (university).

Generally, an effective region encoder should capture two kinds of knowledge for NER. One is *name knowledge*, which encodes the inner compositional regularity of entity mentions, i.e., how likely a subsequence itself will be an entity mention. For example, a region encoder should know "George Washington" is a valid *PER* name because "George" is a common first name and "Washington" is a common last name. Another is *context knowledge*, which identifies whether the subsequence in the context indeed refers to an entity. For example, a region encoder should know "X said" is a suitable context for *PER* mention and "study at X" is a suitable context for *Org* mention.

Currently, most region-based NER models learn these two kinds of knowledge only from expensive, fully-annotated training data, and therefore often face the training data bottleneck, i.e., the lack of training data will significantly undermine

*Xianpei Han is the corresponding author.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6232–6237,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the performance. To address this problem, we find that name knowledge can be effectively captured by leveraging easily-obtainable gazetteer resources. For example, it is easy to learn the company name patterns "the...company" and "...Inc." from a company name gazetteer containing "the Walt Disney company" and "Apple Inc.". By capturing mention regularity entailing gazetteers, the region-based models can be enhanced with more accurate name knowledge, and thereby the need of fully-annotated training data can be reduced.

To this end, this paper proposes ***G**azetteer-**E**nhanced **A**ttentive **N**eural **N**etworks (GEANN)*, whose architecture is shown in Figure 1. Specifically, to better decouple name and context knowledge for incorporating gazetteer information, we first design a new region-based ***attentive neural network (ANN)***, which introduces attention mechanism (Bahdanau et al., 2014; Vaswani et al., 2017; Su et al., 2018) to explicitly model the association between mentions and contexts. Starting from ANN, we further introduce an auxiliary ***gazetteer network***, which can effectively learn name knowledge only using gazetteers, i.e., it can encode each utterance in a context-free way, and identifies whether it matches regular patterns of mentions. Finally, the learned gazetteer network is incorporated into ANN to capture better name and context knowledge. Experiments show that ANN can achieve the state-of-the-art NER performance, and incorporating name knowledge from gazetteers can significantly reduce the training data requirement. To the best of our knowledge, this is the first work trying to explicitly exploit mention-context association with attention mechanism in region-based NER, as well as the first work which enhances NER model with name knowledge captured from gazetteers using neural networks.

2 Attentive Neural Network for NER

This section describes our attentive neural network, which directly classifies over all subsequences of a sentence to recognize whether each subsequence corresponds to an entity mention. Figure 1 (a) shows the architecture of ANN.

Given a sentence, ANN first maps all words into word representations $\{\boldsymbol{x_1}, \boldsymbol{x_2}, ..., \boldsymbol{x_n}\}$ following Lample et al. (2016). Then a BiLSTM layer is used to obtain context-aware word representation $\boldsymbol{h_t^A}$. After that, for each candidate region s_{ij}, we follow Sohrab and Miwa (2018) to use an inner-region encoder to obtain its representation $\boldsymbol{s_{ij}}$, which captures name knowledge considering both its boundary and inside information:

$$\boldsymbol{s}_{ij} = \text{MLP}([\boldsymbol{h}_i^A; \frac{1}{j-i+1}\sum_{k=i}^{j}\boldsymbol{h}_k^A; \boldsymbol{h}_j^A]), \quad (1)$$

where MLP is a multi-layer perceptron. To explicitly model the association between a region and its context, we design an attentive context encoder, which outputs a contextual vector $\boldsymbol{c}_{ij}$ entailing the context knowledge of s_{ij} by:

$$\begin{aligned} \boldsymbol{c}_{ij} &= \sum_{k=1}^{i-1}\alpha_{ijk}\boldsymbol{h}_k^A + \sum_{k=j+1}^{n}\alpha_{ijk}\boldsymbol{h}_k^A \\ \alpha_{ijk} &= \frac{\exp(e_{ijk})}{\sum_{t=1}^{i-1}\exp(e_{ijt}) + \sum_{t=j+1}^{n}\exp(e_{ijt})} \end{aligned} \quad (2)$$

where

$$e_{ijk} = \tanh(\boldsymbol{s_{ij}}^T\boldsymbol{\Lambda}\boldsymbol{h}_k^A + \boldsymbol{W}\boldsymbol{h}_k^A + b) \quad (3)$$

is an attentive model which scores how important the word x_k is for recognizing the entity type of s_{ij}. After obtaining $\boldsymbol{c}_{ij}$, we concatenate it with $\boldsymbol{s}_{ij}$, and feed it into a MLP classifier to obtain the probabilities of s_{ij} corresponding to an entity type (or NIL if s_{ij} is not a mention). Similar to previous methods, ANN is learned by minimizing the cross-entropy loss on the fully-annotated training data.

By decoupling and explicitly modeling the mention-context association, ANN not only can better identify entity mentions, but also is very easy to incorporate external name knowledge. This enables convenient integration of gazetteer knowledge, as we will illustrate next.

3 Gazetteer-Enhanced ANN

One main drawback of ANN and other region-based models is that they only rely on fully-annotated data to learn both name knowledge and context knowledge. Unfortunately, such training data is very expensive to construct, which limits the applications of these model to more entity types. To tackle this problem, we proposes to learn name knowledge from easily-obtainable, large-scale gazetteers. In this way, the name knowledge can be captured more accurately, and the requirement of fully-annotated data can be reduced.

To this end, we propose to incorporate an auxiliary *gazetteer network* into ANN, which can learn and exploit name knowledge only using gazetteers. Given an utterance, gazetteer network predicts

whether it should be included in the gazetteer of specific entity types, i.e., whether it is a valid entity name. Gazetteer network is context-free, which only considers whether the input follows the compositional regularity of mentions, and therefore can be trained only using gazetteers.

Formally, given an input utterance $u = \{u_i, ..., u_j\}$, an utterance encoder first learns its representation $\boldsymbol{u}$, which has similar structure with the inner-region encoder of ANN. After that, $\boldsymbol{u}$ is used to compute the probabilities of it being a valid name for each type:

$$\boldsymbol{O}_u^G = s(\boldsymbol{W}\boldsymbol{u} + \boldsymbol{b}). \quad (4)$$

where s is the sigmoid function and k^{th} dimension of $\boldsymbol{O}_u^G$ indicates the probability of u being a valid mention of type y_k. As an utterance can possibly be a valid mention of various types, we use a multi-label, multi-class cross-entropy loss to train our gazetteer network:

$$\mathcal{L}^G(\theta) = \sum_{u \in G} [\boldsymbol{g}'_u \log \boldsymbol{O}_u^G + (1 - \boldsymbol{g}'_u) \log(1 - \boldsymbol{O}_u^G)] \quad (5)$$

where G is the gazetteers, $\boldsymbol{g}'_u$ is an one-hot vector whose k^{th} will be set to 1 if utterance u is in the gazetteer of type y_k, elsewise 0.

In this way, a well-trained gazetteer network can learn an effective utterance representation $\boldsymbol{u}$, which is used to identify whether the utterance is a valid mention. This means $\boldsymbol{u}$ should capture enough name knowledge of specific entity types. To incorporate such knowledge into ANN, we simply concatenate the representation learned by gazetteer network and the representation learned by the original inner-region encoder. Then this new representation is fed to the following modules of ANN. In this way, name knowledge learned from gazetteers is incorporated to enhance the region encoder, and the requirement of fully-annotated data can be reduced.

4 Experiments

4.1 Experimental Settings

Data Preparation. We conducted experiments on ACE2005 named entity recognition task[1]. We used the same dataset splits as Wang and Lu (2018); Katiyar and Cardie (2018). For each entity type in ACE2005, we collect a gazetteer from Wikipedia anchor texts, i.e., anchor texts linking to an entity whose type are the same will be included in a gazetteer. The same as previous studies, models are evaluated using micro-F1. To balance time complexity and recall, we follow Wang and Lu (2018) to restrict mention length up to 6, which covers more than 93% mentions.

[1]Conventional NER datasets, such as CoNLL2003, removed nested entity mentions and therefore are not suitable for evaluating region-based NER models.

	P	R	F1
LSTM-CRF	73.2	61.3	66.7
Neural Transition	75.2	65.5	70.0
Segmental Hypergraph	75.7	68.3	71.8
Exhaustive	**81.2**	66.9	73.4
ANN	78.9	69.8	74.1
GEANN	77.1	**73.3**	**75.2**

Table 1: Experiment results on ACE2005 named entity mention recognition.

Baselines. Following methods were compared:

1) **LSTM-CRF** (Lample et al., 2016), which is the most widely used NER baseline, but it cannot handle nested or overlapping mentions.

2) **Neural Transition** (Wang et al., 2018), a transition model which achieved very competitive performance on ACE2005.

3) **Segmental Hypergraph** (Wang and Lu, 2018), a hypergraph-based model which introduces a new tagging schema and achieved the state-of-the-art performance on ACE2005.

4) **Exhaustive Model** (Sohrab and Miwa, 2018), a region-based model using a region encoder to capture both inner and boundary features of a candidate region, which is similar to ANN without attentive contextual encoder.

4.2 Overall Results

Table 1 shows the overall results of our methods compared with baselines. We can see that:

1) By explicitly modeling both name and context knowledge, the proposed attentive neural network is an effective region-based NER model, and achieves the state-of-the-art performance. Compared with other baselines, ANN achieves significant F1-score improvements.

2) Incorporating name knowledge from gazetteers can significantly improve the performance. GEANN further achieves 1.1 F1-score improvement over ANN. This indicates that name knowledge learned from gazetteers can significant enhance the region encoder, and therefore improves the NER performance.

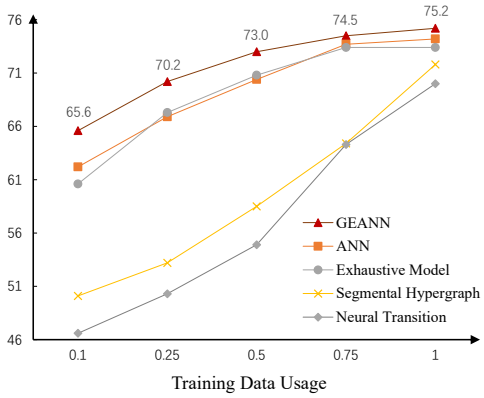

Figure 2: F1-scores on ACE2005 when training data size varies.

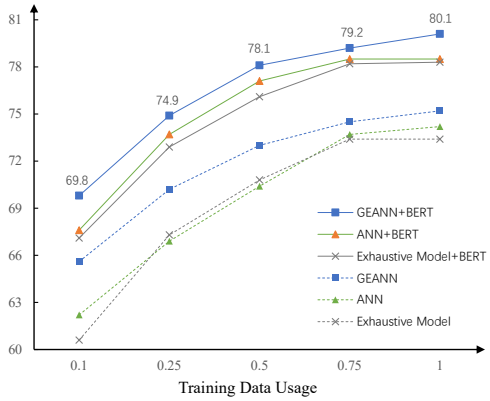

Figure 3: F1-scores of models with BERT on ACE2005 when training data size varies.

3) Our attentive context encoder provides an effective way to exploit context knowledge for NER. Compared with *Exhaustive* baseline, ANN achieves significant improvement by explicitly modeling the association between entity mentions and their contexts.

4.3 Effects of Gazetteer Network

To further investigate the effect of introducing gazetteers, Table 2 shows the results when training data size varies. We can see that:

1) For *Transition* and *SH*, their performance significantly decreased when reducing training data. We believe this because these approaches need to model complex label structure, so large scale training data are critical, and reducing training data will have huge impact on them.

2) Region-based models are less sensitive to the reduction of training data. We believe this is because their output structure is simple, and therefore can be trained using less training data.

3) GEANN can achieve significant improvements over ANN regardless of training data size. By leveraging name knowledge from gazetteers, GEANN with only 50% training data can achieve comparable performance with ANN trained with the entire dataset.

4.4 GEANN with BERT

Pretrained context-aware representation, such as ELMOs (Peters et al., 2018) and BERT (Devlin et al., 2018), have shown significant progress in many NLP tasks, especially in low-resource cases. To verify the adaptivity of the proposed GEANN, we further introduce BERT into models by replacing the word embedding with BERT representations. Figure 3 shows the results. We can see that even BERT can enhance NER, GEANN can still further achieve significant improvement over BERT regardless of the training data size. This verified GEANN can further capture task-specific name knowledge, which complement well with universal pretrained language knowledge.

5 Related Work

Sequential labeling approaches (Zhou and Su, 2002; Chieu and Ng, 2002; Bender et al., 2003; Settles, 2004; Lample et al., 2016) are widely used in NER. But this paradigm cannot handle nested mentions without specially designed tagging schema (Lu and Roth, 2015; Katiyar and Cardie, 2018; Wang and Lu, 2018; Lin et al., 2019). Recently, region-based models provide a natural solution for this issue. Finkel and Manning (2009) first proposed to classify over regions corresponding to parsing tree nodes. Xu et al. (2017) proposed to directly classify over all subsequences with a neural network model. Sohrab and Miwa (2018) extended their method by introducing a new region encoder. Generally, these methods have achieved promising results but heavily rely on fully-annotated data.

Gazetteers or dictionaries have long been regarded as a useful and easily-obtainable resource for NER. Previous methods commonly incorporated gazetteers by either using them to as handcraft features (Bender et al., 2003; Tsuruoka and Tsujii, 2003; Ciaramita and Altun, 2005; Minkov et al., 2005; Ritter et al., 2011; Seyler et al., 2018; Yu et al., 2018), or using them to generate data by distant supervision (Cohen, 2005; Ren et al., 2015; Giannakopoulos et al., 2017; Shang et al., 2018). However, the first kind of methods can not fully

leverage the inner mention structure knowledge entailing in gazetteers, while the second approaches will result in remarkable noise.

6 Conclusions

This paper first proposes *attentive neural networks*, an effective region-based model which explicitly models mention-context association. Then we propose to incorporate an auxiliary *gazetteer network* to enhance ANN. The gazetteer network can effectively learn name knowledge only using easily-available gazetteers, and therefore can significantly improve model performance and reduce data requirement. Experiments show that GEANN achieves the state-of-the-art performance on ACE2005 with much lower data requirement.

Abstract

Attributing a particular property to a person by naming another person, who is typically well-known for the respective property, is called a *Vossian Antonomasia* (VA). This subtpye of metonymy, which overlaps with metaphor, has a specific syntax and is especially frequent in journalistic texts. While identifying Vossian Antonomasia is of particular interest in the study of stylistics, it is also a source of errors in relation and fact extraction as an explicitly mentioned entity occurs only metaphorically and should not be associated with respective contexts. Despite rather simple syntactic variations, the automatic extraction of VA was never addressed as yet since it requires a deeper semantic understanding of mentioned entities and underlying relations. In this paper, we propose a first method for the extraction of VAs that works completely automatically. Our approaches use named entity recognition, distant supervision based on Wikidata, and a bi-directional LSTM for postprocessing. The evaluation on 1.8 million articles of the New York Times corpus shows that our approach significantly outperforms the only existing semi-automatic approach for VA identification by more than 30 percentage points in precision.

1 Introduction

Background. Vossian Antonomasia (VA) is a stylistic device which attributes a certain property to a person by naming another (more well-known, more popular) person as a reference point. For instance, when Jim Koch is described as "the Steve Jobs of Beer" (Fallows, 2014), certain qualities of Steve Jobs, be it entrepreneurship or persuasiveness, are assigned to Jim Koch, co-founder and chairman of the Boston Beer Company.

VA is named after Gerardus Vossius (1577–1649), the Dutch classical scholar and author of rhetorical textbooks. Although the phenomenon is traceable back to antiquity (as shows the example of Crassus, who used to be ironically referred to as "the Palatine Venus"), it was first distinguished and described as a separate phenomenon by Vossius.

It constitutes a sub-phenomenon of the classic antonomasia. In the classification of Holmqvist and Płuciennik (2010) it is called *metaphorical antonomasia* or *antonomasia*$_2$ and is described as a comparison "with paragons from other spheres". VAs are particularly popular in journalistic texts.

Definition. VAs consist of three parts: a *source* (in our example "Steve Jobs") serves as paragon to elevate the *target* ("Jim Koch") by applying a *modifier* ("of beer") that provides the corresponding context (see Bergien, 2013). Although in most cases both the source and the target are persons, one or both of them could be almost anything as long as they bear a proper name, for instance, software, as shows this example: "Word [...] was dubbed the Marquis de Sade of word processors, which was not altogether unfair." (NYT 1993/09/26/0636952)[1] The target is not necessarily part of the sentence (in particular when a VA is used in a headline – like in the title of this paper[2]) and it can be hypothetical, as in "Who is the Tolstoy of the Zulus?" (NYT 1988/01/03/0106769)

Challenges. Despite some interest in VAs in the humanities (e.g., Holmqvist and Płuciennik, 2010; Bergien, 2013), works on their automatic extraction are scarce. One reason could be that "antonomasia is essentially humanistic and anti-computational" (Holmqvist and Płuciennik, 2010) and thus identifying and understanding it in its entirety is often difficult even for humans and requires deep cultural

[1]To avoid an excessively long reference list, all examples taken from the New York Times corpus (Sandhaus, 2008) are cited using the pattern "NYT year/month/day/article-id".

[2]To resolve this example: "a Buster Keaton of linguistics" refers to the performance artist Stuart Sherman (NYT 1987/07/19/0057747).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6238–6243,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

background knowledge. For example, understanding the phrase "It's the Dolly Parton of cakes" (NYT 2007/02/14/1826062) requires specific knowledge about Dolly Parton, her skills or peculiarities. Only in rare cases like this, an explanation of the intended meaning ("a little bit tacky, but you love her") is provided. It is usually left to the reader to make sense of a VA.

Importance. From a humanities perspective, a VA constitutes an interesting phenomenon of enculturation (Holmqvist and Płuciennik, 2010) that deserves to be studied more in-depth, based on larger corpora.

However, we expect that the large-scale identification of VAs and other such stylistic devices is not only important in the humanities and for cultural reasons, but also in natural language processing to avoid mistakes in tasks such as machine translation and fact extraction. For instance, given the sentence "Today, the German Ronaldo quit his career.", we do not want to extract a fact that Ronaldo quit his career, but we need to detect that "the German Ronaldo" is a VA referring to a German soccer player.

In addition, entity disambiguation and coreference resolution could be improved. Consider the example "Jimmy Johnson is the Madonna of college football ..." (NYT 1987/01/02/0000431). We would like to refer "the Madonna of college football" to Jimmy Johnson, and, in particular, we want to avoid that Madonna is part of any coreference chain.

It could also help in new interesting question answering tasks, for example, "Who is the Bill Gates of Japan?", where the sentence "... Mr. Horie has made headline news with a success story that has turned him into the Bill Gates of Japan." (NYT 2006/01/19/1733197) could be one answer to this question.

Generally speaking, successful detection and resolution of VAs could be a further step towards full natural language understanding.

Contribution. We propose the first effective fully automated approaches for extracting VAs from texts. In our evaluation, we compare them against a baseline and assess the difficulty of identifying VAs using crowdsourcing. In addition, we extend the only existing larger data set (Fischer and Jäschke, 2019) with VAs of eight additional patterns. We have also double-checked and corrected existing and new annotations. Our code and data are freely[3] available[4] and easily extensible towards other patterns and entity types.

2 Related Work

Very similar to metaphor detection (Tsvetkov et al., 2014; Gao et al., 2018; Mao et al., 2018), identifying VAs is a difficult task. So far, we are dealing with manually curated collections like the Wall Street Journal's collection of occurrences of "Michael Jordans of ..." (Cohen et al., 2015). The only attempt automating the extraction has been presented by Fischer and Jäschke (2019). Their semi-automatic approach for English texts extracts VA candidates for only one single pattern, *the ENTITY of*. Using a regular expression to identify candidates, names and aliases of Wikidata entities whose 'instance-of' property is 'human' as a first filter, and a manually created blacklist as second filter, they extract about 3,700 VA candidates. 70% of them have been confirmed as VAs by a domain expert.

Since the phenomenon is a kind of metonymy, its detection is closely related to approaches to metonymy resolution. This has been covered extensively, specifically by Markert and Nissim, for example, in (Nissim and Markert, 2003). They compare this task to word-sense disambiguation and propose a thesaurus-based classification approach. Figures of speech that have been covered include, for instance, metaphors (Tsvetkov et al., 2014; Gao et al., 2018; Mao et al., 2018) and irony (Akhtyrska, 2014). The supervised approach of Tsvetkov et al. (2014), for instance, can quite reliably "discriminate whether a syntactic construction is meant literally or metaphorically" but is very specific, focused on subject–verb–object and adjective–noun phrases.

3 Corpus Creation and Baseline

To create a corpus of candidate phrases and manually confirmed VAs, we use the dataset of Fischer and Jäschke (2019) as starting point and their method as baseline. However, instead of relying only on one individual syntactic pattern, *the ENTITY of*, we extended the candidate generation process with the patterns *the ENTITY among*, *the ENTITY for*, and six variations thereof where *the* is

Table 1: Number of VA candidates after each step and manually confirmed VAs for all used patterns.

replaced by *a* or *an*, respectively. We identified these patterns to be the most prevalent patterns in a preliminary analysis of a manually maintained collection of VAs.

Using the New York Times corpus (Sandhaus, 2008) of 1,854,726 articles published between 1987 and 2007, the regular expression based pattern matching resulted in almost 25 million candidate phrases vs. less than 13 million candidate phrases in Fischer and Jäschke (2019)'s work.

Using Wikidata for distant supervision, we keep only candidates whose string matches the exact name or alias of Wikidata entities, respecting the case of letters, with 'instance-of' property 'human', and exclude candidates using the manually curated blacklist[5] provided by Fischer and Jäschke (2019).[6] We consider this procedure of "regex – Wikidata – blacklist" as baseline. In Table 1, we show the number of VA candidate phrases after each step.

In addition, all remaining candidates were manually annotated by a domain expert with 10 years of experience in the research of VAs and samples were double-checked by a trained student. The resulting corpus contains 6,072 VA candidates, 3,023 of them were classified to be true VAs by the human annotators. That is, the baseline approach has a precision of 49.8% (see Table 1). Note that due to the sparseness of the phenomenon, we did not try to estimate the recall of the baseline approach.

[5]words that are also common nouns or otherwise unlikely to be the source of a VA

[6]Like Fischer and Jäschke (2019), we focus on humans as source as they are the most frequent type; other types like 'team' or 'company' are left for future work.

4 VA Extraction Approaches

We aim at a fully automated extraction of VAs from texts. For this, we develop two approaches to replace the need of a manually curated blacklist of the baseline approach using named entity recognition as well as Wikidata and a link-based popularity measure. In addition, as a further approach, we extend the baseline by classifying VA candidates using a bi-directional LSTM.

4.1 Wikidata (WD)

This is a modification of the baseline approach to avoid the manual curation of a blacklist. Thus, after the regex step and linking the source candidates with the Wikidata list of humans as in the baseline approach, we assess their popularity within Wikidata.

The rationale is that a prerequisite for being a source of a VA expression is to be famous or popular or notorious for something. Otherwise, the VA is less likely to be understood by a reader. This arguably goes along with being present on several of the almost 300 international Wikipedia versions. Therefore, we remove source candidates whose name also matches the label or alias of a non-human Wikidata entity that has more sitelinks[7] (i.e., is more popular according to our measure) than the linked human. For instance, the candidate 'the House of', that matched the American botanist Homer Doliver House[8] in the first step, will be removed since in the second step the entity 'house'[9] (the building, not the botanist) has more sitelinks ($178 > 9$). The popularity measure could easily be changed to any other measure like statements or using Wikipedia clickstream data.

In addition, we remove all candidates where the source (e.g., 'Prince') together with multiple words following it (e.g., 'of Wales') match the name or alias of another Wikidata entity (https://www.wikidata.org/wiki/Q43274). This allows us to remove frequent false positives like 'Prince of Wales'.

4.2 Named Entity Recognition (NER)

This approach is built on the regex step from the baseline approach as well, but we replace the way of identifying 'persons': instead of restricting the extraction to VAs with Wikidata entities, we per-

[7]https://wikidata.org/wiki/Help:Sitelinks

[8]https://www.wikidata.org/wiki/Q3139666

[9]https://www.wikidata.org/wiki/Q3947

form Named Entity Recognition on the sentence candidates using the Stanford three-class named entity tagger (Finkel et al., 2005).

When all words of the candidate source (i.e., the words between the first and the last word of the regular expression match) are tagged as 'PERSON', we consider the candidate a positive match. However, to avoid false positives, we apply the last step from the WD approach (Sec. 4.1) and remove again all candidates whose source together with following words match another Wikidata entity.

4.3 Bi-directional Long Short-Term Memory Neural Network (BLSTM)

We use the baseline data of 6,072 VA candidates with 3,023 confirmed VAs to train and test a BLSTM on whole sentences (Schuster and Paliwal, 1997; Graves and Schmidhuber, 2005) using 5-fold cross validation. The BLSTM classifies sentences on whether they contain a VA expression or not. We represent each word from a sentence candidate with a pre-trained word embedding. We use word embeddings from GloVe which consist of 300-dimensional vectors that were trained on a Google News corpus (Pennington et al., 2014). We implement the BLSTM in Keras (Chollet et al., 2015) with Tensorflow backend, using Adam Optimizer and default hyperparameters (epochs=80, batch size=128, hidden units=300, dropout=0.25). We expect that further improvements may be possible if a fine-grained hyperparameter search was to be conducted.

5 Evaluation and Results

Determining an overall *recall* of our approaches on the New York Times corpus is unfeasible as it contains 1.8 million articles. Thus, we used a random sample of 105 articles (for each year 5). However, we found only one VA: "If Nike is the Chicago Bulls of the athletic shoe market, retailers are holding their breath for a strong underdog player to emerge." (NYT 1997/06/07/0935205). Due to our focus on individuals, it is no VA that should be part of our data set. Thus, we can only determine *precision* and *recall* of our new approaches based on the baseline data set described in Section 3.

5.1 Difficulty of the Task

Identifying VAs is a non-trivial task even for humans. Thus, we used *expert knowledge* to evaluate candidates for the ground truth data (see Section 3).

approach	prec	rec	f1
baseline	49.8%	—	—
WD	67.3%	93.0%	78.1%
NER	71.8%	81.3%	76.2%
BLSTM	86.9%	85.3%	86.1%

Table 2: Performance of the three proposed approaches in comparison with the baseline.

In addition, we leveraged *crowdsourcing* to check whether we could use (untrained) people to evaluate VA candidates. Therefore, workers on the crowdsourcing platform Figure Eight had to check whether a sentence contained a VA.[10]

Crowdsourcing resulted in 600 judgments for 200 randomly selected candidates of our baseline data set with an inter-annotator agreement calculated by Cohen's Kappa of 0.72 between expert and workers. Re-checking the 28 disagreements showed that the expert judged all correctly, which results in a crowdsourcing accuracy of 86%. This shows how difficult it is to identify VAs.

5.2 Baseline VA Candidates

We cannot determine recall for our approaches, instead we compute precision, recall and f-score based on the baseline data set (see Section 3), which is shown in Table 2 as well as precision of the baseline data set. The automated approaches using Wikidata and named entity recognition can boost the precision significantly with a moderate loss in recall. The BLSTM approach performs best. Although the loss in recall is higher than with the WD approach, the precision reaches almost 87% and is thus raised to a new level.

5.3 Non-Baseline VA Candidates

The results of our approaches are not limited to the baseline data set. The WD approach generated 955 new VA candidates, the NER approach 4,399. The human annotators evaluated 100 randomly selected VA candidates of each set, which resulted in a precision of 17% (WD) and 30% (NER). We also predicted the labels of these random samples with the trained BLSTM which resulted in 83% and

[10] https://www.figure-eight.com/. We highlighted the source candidate and included its Wikidata link. To maintain quality, we set test questions where workers had to pass a threshold (70%). We asked for three judgments per sentence and used majority voting. We paid 2 US Cents per judgment, only allowing workers with experience level 2 or higher.

75% precision on the WD approach and the NER approach, respectively. This shows that the BLSTM does not only have potential to improve the results of the baseline approach but also of the WD and NER approaches.

5.4 Error Analysis

About 13% of the WD approach errors (based on baseline) were false negatives, for example, "an Edison of magic". Here, "Thomas Edison" would have been the right source, but as the entity "Thomas Edison" has no alias "Edison", the most popular entity having 'Edison' as name or alias is a town in the United States.[11] 87% were false positives like "the Michelangelo of the Sistine Chapel" where the person name was not used as a VA source but stands for a specific work period of the artist. In the sample set that we selected randomly from the WD approach candidates which did not appear in the baseline (see Section 5.3), we detected false positives like "an Air of Mystery" as "Air" is an alias of Michael Jordan, who has more sitelinks than the word "air" (116 to 113).

The errors from the NER approach (based on baseline) had around 36% false negatives like "the Marco Polo of baseball" where the source was not detected as a person by the named entity tagger. 64% were false positives like "the Dave Brown of old". The NER approach sample set from Section 5.3 contained new false positive candidates because awards ("the Harriet H. Jonas Award of"), institutions ("the O. K. Harris Gallery of"), or titles ("the Episcopal Bishop of") were falsely tagged as persons.

5.5 Discussion

Since we presented the first approaches for the extraction of VAs that work completely automatically, our work has some limitations that we discuss in the following. The restriction to one type of source can be solved easily, for instance, by choosing not only 'humans' but proper nouns in general, as well as allowing further syntactic variations of the source phrase, for example, 'the ADJECTIVE ENTITY' ("the new Michael Jordan") or 'the ADJECTIVE/NOUN sort/version/equivalent of' ("the Georgian equivalent of") but (probably) at the expense of precision.

Beyond extending recall by tackling further syntactic variations and allowing non-human sources, we currently aim to extract the modifier and target of VAs.

Another goal is to train a neural network with a larger and better balanced training set to use the model to study a larger corpus. Alternatively, a pre-trained model could be used and fine-tuned with our labeled data to improve results.

Besides above-mentioned limitations which we plan to address in future work, we also want to report on approaches that have not lead to any improvements. For example, we tested measuring the similarity between source and modifier using word embeddings (with the assumption that a low similarity should indicate a VA). Unfortunately, there are too many neutral modifiers like "his time" or subgenres of the source like "the Tiger Woods of micro golf" where this idea does not work. Furthermore, removing candidates whose source was contained in WordNet (Fellbaum, 1998) and not labeled as 'person' did not work, since "wife", "chancellor", and so forth were labeled as persons in WordNet.

6 Conclusions

In this paper, we presented approaches for the first fully automated extraction of the stylistic device *Vossian Antonomasia*.

In addition, we were able to create the largest known collection of VAs by looking into 21 years of the New York Times. The data set contains the annotated list of 6,072 VA candidates, each with article id, date, URL, marked source and modifier, Wikidata id, and class.

The best approach, using a BLSTM, reached a precision of 86.9% and a recall of 85.3%.

Abstract

We propose a method to improve named entity recognition (NER) for chemical compounds using multi-task learning by jointly training a chemical NER model and a chemical compound paraphrase model. Our method enables the long short-term memory (LSTM) of the NER model to capture chemical compound paraphrases by sharing the parameters of the LSTM and character embeddings between the two models. The experimental results on the BioCreative IV's CHEMDNER task show that our method improves chemical NER and achieves state-of-the-art performance (+1.43 F-score).

1 Introduction

Named Entity Recognition (NER) is one of the important basic technologies for Natural Language Processing (NLP) such as Information Extraction and Entity Linking. LSTM-CRF NER models, which combine a conditional random field (CRF) and a long short-term memory (LSTM), have achieved high performance (Lample et al., 2016; Ma and Hovy, 2016). The LSTM-CRF models that use a neural language model (NLM) pre-trained from a large-scale unlabeled corpus (Akbik et al., 2018; Peters et al., 2018) have shown state-of-the-art performances on the CoNLL 2003 shared task (Sang et al., 2003).

Chemical compound databases are widely used for investigating properties of chemical compounds or for developing new chemical products. However, updating the databases by hand is hard because new findings on chemical compounds are mainly reported in scientific papers and patents every day. Hence, chemical NER has been studied to recognize chemical compounds from chemical documents (Leaman et al., 2015; Lu et al., 2015; Lin et al., 2018).

One of the problems in chemical NER is notation variants of chemical compounds. For example, *Phenylalanine* has different notations such as *L-β-phenylalanine* and *(S)-2-Benzylglycine*. The average number of notations of each compound in PubChem[1] is approximately 3.88.[2]

If these expressions are dealt with differently, the statistics of the same compound can be dispersed, especially for low frequency compounds. In other words, the more distinct these representations are, the more difficult identifying chemical compound entities becomes. However, existing chemical NER methods do not deal with notation variants of chemical compounds, derived from the partial structures or the notation fluctuation peculiar to these chemical compounds.

We propose *HanPaNE*, which *Han*dles *Pa*raphrase in *NE*R by utilizing chemical compound paraphrase pairs as multi-task learning.

To train expression identity of different notations, *HanPaNE* learns shared parameters between paraphrases using multi-task learning on NER and paraphrase generation. This contrasts with widely used approaches that automatically augment training data by replacing NEs with other NEs (Yi et al., 2004). To train paraphrase generation, we use an attention-based neural machine translation (ANMT) model (Luong et al., 2015; Bahdanau et al., 2015) that shares parameters with the NER model in the translation encoder. The experimental results on the BioCreative IV's CHEMDNER task (Krallinger et al., 2015) show that our method achieves the best accuracy (+1.43 F-score).

*Taiki Watanabe belonged to Ehime University when this work was done.

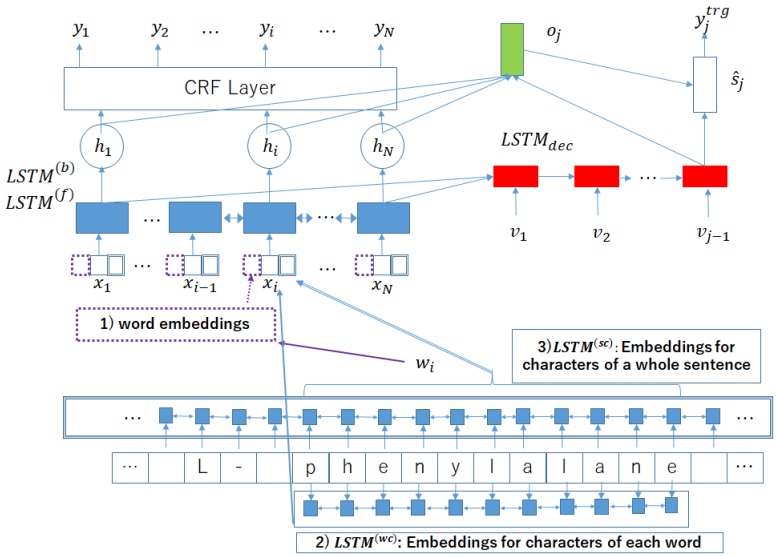

Figure 1: An overview of the method *HanPaNE*. The parameters of $LSTM^{(f)}$, $LSTM^{(b)}$, $LSTM^{(wc)}$ and $LSTM^{(sc)}$ are shared in NER and paraphrase generation.

2 Proposed Method

Figure 1 shows an overview of the method *HanPaNE*. We first describe our NER and chemical compound paraphrase model, and then describe our multi-task learning of the NER and the paraphrase model.

2.1 NER using Character-level NLM

This section describes the NER model using a character-level NLM (Akbik et al., 2018), which is our baseline comparison with our approach. This model showed state-of-the-art performance on the CoNLL 2003 shared task.

For this NER model, given an input sentence $\mathbf{w} = w_1, w_2, \cdots, w_N$, each word w_i is converted into a vector $\mathbf{x}_i$ represented as the concatenation of the following three types of embeddings.

- 1) word embeddings obtained by looking up a parameter matrix.
- 2) CWSE is the hidden state of a BiLSTM ($LSTM^{(wc)}$) on the character sequence consisting of a word (Lample et al., 2016).
- 3) CSE is the hidden state of a BiLSTM ($LSTM^{(sc)}$) on the character sequence consisting of a whole sentence (Akbik et al., 2018).

CWSE for a word is the concatenation of the last hidden states of the forward LSTM and the backward LSTM of $LSTM^{(wc)}$. CSE for a word is the concatenation of the hidden state of the last character of the word for the forward LSTM of $LSTM^{(sc)}$, and the hidden state of the first character of the word for the backward LSTM of $LSTM^{(sc)}$. We note that $LSTM^{(sc)}$ is pretrained as character-level NLMs with log-likelihood. For example, a forward LSTM is trained with the following:

$$P(\mathbf{c}_{1:T}) = \prod_{t=1}^{T} p(c_t|\mathbf{c}_{1:t-1}), \quad (1)$$

where c_t is the t-th character in a sentence.

After obtaining the vector representations of the input words $\mathbf{X} = \mathbf{x}_1, \cdots, \mathbf{x}_N$, the hidden state $\mathbf{h}_i$ of BiLSTM and the scores of NE tags $\mathbf{e}_i$ for each word w_i are computed as:

$$\overrightarrow{\mathbf{h}_i} = LSTM^{(f)}(\mathbf{x}_i, \overrightarrow{\mathbf{h}_{i-1}}), \quad (2)$$
$$\overleftarrow{\mathbf{h}_i} = LSTM^{(b)}(\mathbf{x}_i, \overleftarrow{\mathbf{h}_{i+1}}), \quad (3)$$
$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i}], \quad (4)$$
$$\mathbf{e}_i = W_e \mathbf{h}_i, \quad (5)$$

where the dimension of $\mathbf{h}_i$ is d, $W_e \in \mathcal{R}^{k \times d}$ is a weight matrix, and k is the number of NE types to be identified.

The BiLSTM-CRF+CSE model predicts a tag sequence with the score matrix $\mathbf{P} = (\mathbf{e}_1, \cdots, \mathbf{e}_N)^T \in \mathcal{R}^{N \times k}$ using CRF. Note that $P_{i,j}$ is the score of the j-th tag for the i-th word. In particular, the probability of the output tag sequence

$\mathbf{y} = y_1, \cdots, y_N$ is calculated as follows:

$$p(\mathbf{y}|\mathbf{w}) = \frac{e^{s(\mathbf{w},\mathbf{y})}}{\sum_{\tilde{\mathbf{y}} \in \mathbf{Y_w}} e^{s(\mathbf{w},\tilde{\mathbf{y}})}}, \quad (6)$$

$$s(\mathbf{w}, \mathbf{y}) = \sum_{i=-1}^{N} A_{y_i, y_{i+1}} + \sum_{i=1}^{N} P_{i, y_i}, \quad (7)$$

where $\mathbf{Y_w}$ is the set of all possible tag sequences, $\mathbf{A}$ is a matrix of transition scores, $A_{i,j}$ represents a score that transits from the i-th tag to the j-th tag, and y_{-1} and y_{N+1} are the special tag for the start of the sentence and the end of sentence, respectively.

During training, the model maximizes the following equation using the correct tag sequences:

$$\log(p(\mathbf{y}|\mathbf{w})) = s(\mathbf{w}, \mathbf{y}) - \log(\sum_{\tilde{\mathbf{y}} \in \mathbf{Y_w}} e^{s(\mathbf{w},\tilde{\mathbf{y}})}), \quad (8)$$

where $\mathbf{y}$ is the correct tag sequence of $\mathbf{w}$. When recognizing NEs, the model outputs a tag sequence that maximizes the score calculated by the following equation: $\mathbf{y}^* = \arg\max_{\tilde{\mathbf{y}} \in \mathbf{Y_w}} s(\mathbf{w}, \tilde{\mathbf{y}})$.

2.2 Paraphrase Model

We used the ANMT model (Luong et al., 2015; Bahdanau et al., 2015), which is a standard in machine translation, as a chemical compound paraphrase model. The ANMT model converts an input sequence $\mathbf{w}$ into another sequence $\mathbf{y}^{trg} = y_1^{trg}, y_2^{trg}, \cdots, y_T^{trg}$, which is a paraphrase of the input in our model, using an RNN encoder and an RNN decoder. The RNN encoder converts an input sequence to a multiset of fixed-length vectors, and then the RNN decoder generates an output sequence from the converted fixed length vector. We use a bidirectional LSTM defined by Eq. (2) and Eq. (3) as the encoder, and the vector representations $\mathbf{x}_i$ as the word embedding vectors of input sentences. The concatenation of the final hidden states of the bidirectional LSTM encoder, $\overrightarrow{\mathbf{h}}_N$ of Eq. (2) and $\overleftarrow{\mathbf{h}}_1$ of Eq. (3), was used as the initial state of the LSTM decoder: $\mathbf{s}_1 = [\overrightarrow{\mathbf{h}}_N; \overleftarrow{\mathbf{h}}_1]$.

The decoder calculates the j-th hidden state $\mathbf{s}_j$ as follows: $\mathbf{s}_j = LSTM_{dec}([\mathbf{v}_{j-1}; \hat{\mathbf{s}}_{j-1}], \mathbf{s}_{j-1})$, where $\mathbf{v}_{j-1}$ is the word embedding vector of y_{j-1}^{trg}, and $\hat{\mathbf{s}}_{j-1}$ is the $(j-1)$-th attention vector. Then, the model calculates the j-th attention vector $\hat{\mathbf{s}}_j$ using the context vector $\mathbf{o}_j$: $\hat{\mathbf{s}}_j = \tanh(W_e[\mathbf{s}_j : \mathbf{o}_j])$. where W_e is a weight matrix and tanh is the hyperbolic tangent function. The context vector $\mathbf{o}_j$ is a weighted average of the encoder's hidden states:

$$\mathbf{o}_j = \sum_{i=1}^{N} \alpha_j(i)\mathbf{h}_i, \quad (9)$$

$$\alpha_j(i) = \frac{\exp(\mathbf{h}_i \cdot \mathbf{s}_j)}{\sum_{k=1}^{N} \exp(\mathbf{h}_k \cdot \mathbf{s}_j)}, \quad (10)$$

where exp is the natural exponential function. The decoder generates an output based on the probability distribution of the j-th token: $p(y_j^{trg}|\mathbf{y}_{<j}^{trg}, \mathbf{w}) = \mathrm{softmax}(W_s\hat{\mathbf{s}}_j)$, where W_s is a weight matrix. The objective function is defined as follows:

$$J(\theta) = -\sum_{(\mathbf{w},\mathbf{y^{trg}}) \in \mathbf{D}} \log p(\mathbf{y}^{trg}|\mathbf{w}), \quad (11)$$

where D is the training data and θ is the set of model parameters.

2.3 Handling Paraphrases in NER

Our method, *HanPaNE*, learns the NER model described in Section 2.1 and the chemical compound paraphrase model described in Section 2.2 at the same time through multi-task learning. In the multi-task learning, the character embedding weight matrix and the LSTM parameters in Eq. (2), Eq. (3) and the parameters of $LSTM^{(wc)}$ are shared between the two models. By the parameter sharing, the LSTM part of the NER model is expected to convert the same compound with different notations into a similar vector expression. The objective functions of the two models are Eq. (8) and Eq. (11), respectively.

3 Experiments

3.1 Experimental Settings

We used the BioCreative IV CHEMDNER data set, which was preprocessed by Luo et al (2018)[3]. The word embedding layer with Word2vec and the character-based NLM were independently pretrained from the MEDLINE abstracts from the PubMed website (PubMedAbs)[4]. We created PubChemDic, a set of paraphrases of chemical compounds compiled from PubChem. The number of dimensions of the word embedding layer, the character embedding layer, the character LSTM, the LSTM of the NER model (the LSTM encoder of the paraphrase model), the LSTM decoder of the paraphrase model, and the LSTM of the character

Model	Precision	Recall	F-score
Baseline	92.75	92.15	92.45
VE-P	93.11	91.40	92.25
HanPaNE-P	92.71	91.94	92.32
VE+P	**93.15**	91.79	92.47
HanPaNE+P (Proposed)	92.81	**92.33**	**92.57**

Table 1: Experimental results. +P indicates consideration of paraphrases and -P does not.

NLM are set to 100, 25, 50, 200, 400, and 2048, respectively.

We compared the following methods. "+P" indicates with consideration of paraphrases in PubChemDic and "-P" indicates without consideration of paraphrases.

- A BiLSTM-CRF+CSE of (Akbik et al., 2018) described in Section 2.1 was used as our Baseline.
- VE-P is a baseline trained with virtual examples (VEs) created by randomly replacing NEs of training data with chemical compounds in the PubChemDic similar to (Yi et al., 2004).
- VE+P is a baseline trained with VEs created by replacing NEs of training data with their corresponding paraphrases in the PubChemDic.
- *HanPaNE*-P is a multi-task for NER and paraphrasing trained with randomly generated sentence pairs with PubChemDic.
- *HanPaNE*+P is the proposed method trained with generated sentence pairs by replacing NEs in sentences with their corresponding paraphrases in the PubChemDic.

The baseline was trained with 55,458 sentences of CHEMDNER training data. VE-P was trained with 110,916 sentences in total consisting of the original CHEMDNER training data and 55,458 sentences automatically generated from the CHEMDNER training data. VE+P was trained with 59,033 sentences consisting of 3,575 sentences automatically generated from the original CHEMDNER training data with paraphrases of chemical compounds and the original CHEMDNER training data.[5] For *HanPaNE*-P and *HanPaNE*+P, we used randomly selected 100,000 sentences from PubMedAbs for training paraphrasing and the original CHEMDNER training data for NER.

For example, for +P, "... *Phenylalanine* is ..." are converted into "... *L-β-phenylalanine* is ..." and ".. *(S)-2-Benzylglycine* is ...", where *L-β-phenylalanine* and *(S)-2-Benzylglycine* are paraphrases of *Phenylalanine*. As for -P, "... *Phenylalanine* is ..." is converted into like "... *ethylene* is ...." where *ethylene* is randomly sampled from chemical compounds.

3.2 Experimental Results

Table 1 shows the experimental results. We can see that *HanPaNE*+P showed the highest accuracy and *HanPaNE*+P and VE+P, with consideration of paraphrases, showed a higher accuracy than Baseline. In contrast, *HanPaNE*-P and VE-P, without consideration of paraphrases, did not. The results indicate that the use of paraphrases contributed to improved accuracy.

We also conducted the following two types of hypothesis testing. The first one is a McNemar paired test on the labeling disagreements of words assigned by *HanPaNE* and the others as in (Sha and Pereira, 2003). All the results except for Baseline were significantly different ($p < 0.01$). The second one is a bi-nominal test used in (Sasano and Kurohashi, 2008). For this test, the number of the entities correctly recognized by only *HanPaNE* and the number of entities correctly recognized by only the other method are counted. Then, based on the assumption that outputs have the binomial distribution, we apply a binomial test. All the results were significantly different for this test ($p < 0.05$). These results showed that *HanPaNE* works better than augmented training data.

We also evaluated the accuracy on NEs not covered by training data and PubChemDic. From Table 2, we can see that our method also showed the best performance for both of the NEs not covered by the training data, PubChemDic and the covered NEs. The results indicate that our method contributed to recognizing NEs not covered by existing large data sets. The training data includes 8,508 types of chemical terms and covers 60.76% of chemical terms in the test data. PubChemDic includes 337,289,536 types of chemical compound names and covers 10.02% of the chem-

[5] VE+P had a smaller number of training data than VE-P because we only replaced NEs with their paraphrases included in PubChemDic.

Model	Acc.NC	Acc.C
Baseline	0.8475	0.9672
VE+P	0.8463	0.9623
HanPaNE+P (Proposed)	**0.8510**	**0.9680**

ical terms in the test data. The joint coverage of both is 61.79%. This means almost 1/3 of the NEs in the test data are not covered by the training data and PubChemDic even if these data include over 337 million names of chemical compounds and terms.

4 Related Works

BioCreative IV's CHEMDNER task

Table 3 shows a comparison with the previous best results. (Leaman et al., 2015) and (Lu et al., 2015) proposed a feature-based approach to improve the chemical NER performance. (Lin et al., 2018) proposed a neural network approach that treats document level information to maintain tagging consistency across sentences. By learning paraphrasing, our method showed the best accuracy on the CHEMDNER task.

Multi-task learning

Multi-task learning is often utilized to leverage the performance of NLP systems (Liu et al., 2015; Luong et al., 2016; Dong et al., 2015; Hashimoto et al., 2017), including NER. Liu et al. (2018) and Rei (2017) studied multi-task learning of sequence labeling with language models. Aguilar et al. (2018) and Cao et al. (2018) proposed multi-task learning of NER with word segmentation. Peng and Dredze (2017)'s method of multi-task learning leverages the performance of domain adaptation. Clark et al. (2018)'s method utilizes multi-task learning of NER with several NLP tasks such as POS tagging and parsing. Crichton et al. (2017) and Wang et al. (2018) leverage the performance of NER by multi-task learning of several tasks of biomedical NLP.

5 Conclusions

We proposed a multi-task learning method on an NER model and a paraphrase model to utilize paraphrase pairs efficiently. The evaluations on the BioCreative IV's CHEMDNER task showed that our method achieved the best performance.

Abstract

We present FewRel 2.0, a more challenging task to investigate two aspects of few-shot relation classification models: (1) Can they adapt to a new domain with only a handful of instances? (2) Can they detect none-of-the-above (NOTA) relations? To construct FewRel 2.0, we build upon the FewRel dataset (Han et al., 2018) by adding a new test set in a quite different domain, and a NOTA relation choice. With the new dataset and extensive experimental analysis, we found (1) that the state-of-the-art few-shot relation classification models struggle on these two aspects, and (2) that the commonly-used techniques for domain adaptation and NOTA detection still cannot handle the two challenges well. Our research calls for more attention and further efforts to these two real-world issues. All details and resources about the dataset and baselines are released at https://github.com/thunlp/fewrel.

1 Introduction

Few-shot learning, which requires models to handle new classification tasks with only a handful of training instances, has drawn much attention in recent years (Ravi and Larochelle, 2017; Vinyals et al., 2016; Munkhdalai and Yu, 2017; Snell et al., 2017). To advance this field in NLP, Han et al. (2018) propose FewRel, a large-scale dataset to explore few-shot learning in relation classification. Many efforts (Gao et al., 2019; Soares et al., 2019) have been devoted to the new task and some of the methods even exceed human performance[1] on FewRel. Based on the dataset FewRel, we propose FewRel 2.0, a new task containing two real-world issues that FewRel ignores: (1) few-shot domain adaptation, and (2) few-shot none-of-the-above detection.

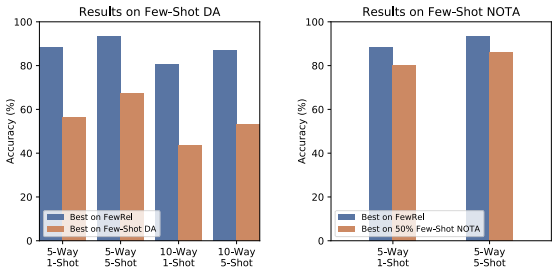

Figure 1: The comparison between the best results of the current models on FewRel, few-shot DA and few-shot NOTA. From the figures we can see that even the state-of-the-art models struggle on the new tasks.

Few-shot domain adaptation (few-shot DA) aims to evaluate the abilities of few-shot models to transfer across domains, which is crucial for real-world applications, since the test domains usually lack of annotations and could differ vastly from the training domains. To this end, we construct a new test set sharing great disparities with the original FewRel dataset, and carry out extensive experiments on the state-of-the-art few-shot models and commonly-used domain adaptation methods. Some prior experimental results in Figure 1 show that even the performance of the most effective methods on FewRel drops drastically on the new test set, proving that few-shot DA is challenging and requires further investigations.

Few-shot none-of-the-above detection (few-shot NOTA) is an advanced version of the existing N-way K-shot setting in few-shot learning. The original N-way K-shot setting samples N classes, as well as K supporting instances and several queries from each class for each test batch, assuming that all queries belong to the sampled N classes. However, in few-shot NOTA, queries could also be none-of-the-above (NOTA), which brings one more option in classification and challenges existing few-shot methods. Consider-

Query	**(A)** or (B) or NOTA	*Thiabendazole* was effective in eradicating the *strongyloides infection*.

Table 1: An example for a 2-way 1-shot scenario, including both few-shot DA and few-shot NOTA. Different colors indicate different entities, blue for head entities, and red for tail entities. For few-shot DA, instances in the training phase and test phase come from different domains. For few-shot NOTA, it requires models to detect the none-of-the-above (NOTA) relation.

ing few-shot NOTA has not yet been widely explored, we propose several solutions based on the state-of-the-art few-shot models and evaluate them with few-shot NOTA setting. Figure 1 shows that though achieving promising results, there is still a room of improvements for few-shot NOTA.

In the following sections, we first describe the two newly-added challenges in FewRel 2.0, then introduce possible directions for addressing these two issues, and finally present results and observations from our experiments.

2 FewRel 2.0

Formulation for N-Way K-Shot Setting

The original FewRel task adopts the N-way K-shot setting. The whole dataset is divided into training, validation and test subsets, which have no intersection in relation types. Models are evaluated with batches sampled from the test set, each of which consists of $(\mathcal{R}, \mathcal{S}, x, r)$, where $\mathcal{R} = \{r_1, r_2, ..., r_N\}$ is the sampled relation set, $r \in \mathcal{R}$ is the correct relation label for the query x, and $\mathcal{S}$ is the supporting set containing K instances for each relation,

$$\mathcal{S} = \{(x^j_{r_i}, r_i)\}, 1 \leq i \leq N, 1 \leq j \leq K. \quad (1)$$

Models should predict the relation label $y \in \mathcal{R}$ for the query instance x based on the given $\mathcal{S}$ and $\mathcal{R}$. Both of the following two challenges are based on this N-way K-shot setting.

Few-Shot Domain Adaptation

Both the training and test sets of the original FewRel dataset are constructed by manually annotating the distantly supervised (Bunescu and Mooney, 2007; Mintz et al., 2009) results on Wikipedia corpus and Wikidata (Vrandečić and Krötzsch, 2014) knowledge bases. In other words, they are from the same domain, yet in a real-world scenario, we might train models on one domain and perform few-shot learning on a different one. For example, we may train models on Wikipedia, which has large amounts of data and adequate annotations, and then perform few-shot learning on some domains suffering data sparsity, like literature, finance and medicine. Note that, not only do these corpora differ vastly from each other in morphology and syntax, but there are wide disparities between the relation sets defined on these domains as well, which makes transferring knowledge across different domains more challenging.

To explore few-shot DA, we construct a new test set by aligning PubMed [2], a database containing large amounts of biomedical literature, with UMLS [3], a large-scale knowledge base in the biomedical sciences. Then we let the annotators classify whether each instance we get from the distant supervision is correct. Every sentence is assigned to at least two annotators, and if their annotation results do not agree with each other, the third annotator is assigned. In the end, we gather a valid dataset with 25 relations and 100 instances for each relation.

For few-shot DA, we adopt the original FewRel training set for training, and the newly-annotated dataset for test, as shown in Table 1. Besides, we use SemEval-2010 task 8 dataset (Hendrickx et al., 2009) as the validation set, since both the corpora and the schema of SemEval-2010 task 8 are in different domains from the original FewRel dataset and the newly-annotated test set.

Few-Shot None-of-the-Above Detection

In a N-way K-shot, all queries are assumed to be in the given relation set, yet sentences expressing no specific relations or relations not in the given set should also be taken into consideration, for they make up the vast majority of text. This calls for the none-of-the-above (NOTA) relation, which

[2] https://www.ncbi.nlm.nih.gov/pubmed/

[3] UMLS represents the Unified Medical Language System®, which is the trademark of U.S. National Library of Medicine.

indicates that the query instance does not express any of the given relations. Though it is common in some conventional classification tasks, where NOTA is usually regarded as an extra class, detecting NOTA could be hard in few-shot learning, because the given relation sets are not fixed so that the NOTA relation requires to cover a different semantic space each time. An example of NOTA is given in Table 1.

We formalize few-shot NOTA based on the N-way K-shot setting. For the query instance x, the correct relation label becomes $r \in \{r_1, r_2, ..., r_N, \texttt{NOTA}\}$ rather than $r \in \{r_1, r_2, ..., r_N\}$. We use the parameter NOTA rate to describe the proportion of NOTA queries during the whole test phase. For example, 0% NOTA rate means no queries are NOTA and 50% NOTA rate means half of the queries have the label NOTA.

The NOTA queries are sampled from those relations outside the given N relations. To be more specific, denoting the whole test set as $\mathcal{D}_{\texttt{test}}$, the set containing all instances in the relation set $\mathcal{R}$ as $\mathcal{D}_{\mathcal{R}}$ and the NOTA rate as α, α of the query instances (NOTA queries) are from $\mathcal{D}_{\texttt{test}} \setminus \mathcal{D}_{\mathcal{R}}$ and $1-\alpha$ of the instances are from $\mathcal{D}_{\mathcal{R}}$.

Note that during the test phase, all the queries are from the test set, though models can sample instances from the training set as supporting instances for NOTA relation (this method is described explicitly in Section 4). Also note that to better demonstrate the effects of the NOTA relation, we use the original FewRel dataset for few-shot NOTA, instead of the new test set, which can get rid of the influence of domain adaptation.

3 Approaches for Few-Shot DA

Many efforts have been devoted for domain adaptation, like subspace mapping (Pan et al., 2010; Fernando et al., 2013), finding domain-invariant spaces (Baktashmotlagh et al., 2013; Ganin et al., 2016), feature augmentation (Blitzer et al., 2006) and minimax estimators (Provost and Fawcett, 2001). Among them, adversarial training (Goodfellow et al., 2015; Ganin et al., 2016; Wang et al., 2018) has been proved to be efficient in finding domain-invariant features. It is a game process between an encoder and a discriminator, where the encoder tries to generate domain-invariant features while the discriminator tries to tell which domain the features are from.

Here we follow the adversarial training setting in Wang et al. (2018), where a two-layer perceptron network is used as the discriminator. While training the few-shot learning task, we feed the sentence encoder $\boldsymbol{E}$ and the discriminator $\boldsymbol{D}$ with the corpora from the training domain and the test domain, and optimize the min-max game,

$$\min_{\theta_{\boldsymbol{E}}} \max_{\theta_{\boldsymbol{D}}} \sum_{x \in \mathcal{C}_0} \log[\boldsymbol{D}(\boldsymbol{E}(x))]_0 + \sum_{x \in \mathcal{C}_1} \log[\boldsymbol{D}(\boldsymbol{E}(x))]_1, \tag{2}$$

where $[\cdot]_i$ is the i-th element of the vector, $\mathcal{C}_0$ is the training corpus and $\mathcal{C}_1$ is the test corpus.

4 Approaches for Few-Shot NOTA

A simple way to handle NOTA is to regard it as an extra class in the N-way K-shot setting. To be more specific, we can sample instances outside the N relations as the supporting data of NOTA, and perform the $(N+1)$-way K-shot learning. As compared to the current methods ignoring NOTA, this approach does not bring much improvements, since the supporting data for NOTA actually belong to several different relations and are scattered in the feature space, making it hard to perform classification.

To better address few-shot NOTA, we propose a model named **BERT-PAIR** based on the sequence classification model in BERT (Devlin et al., 2019). We pair each query instance with all the supporting instances, concatenate each pair as one sequence, and send the concatenated sequence to the BERT sequence classification model to get the score of the two instances expressing the same relation. Denote the BERT model as $\boldsymbol{B}$, the query instance as x and the paired supporting instance as x_r^j (the j-th supporting instance for the relation r), $\boldsymbol{B}(x, x_r^j)$ outputs a two-element vector corresponding to scores of the pair sharing the same relation and not sharing the same relation. The probability over each relation in the few-shot scenario, including NOTA, is addressed as follows,

$$p(y = r|x) = \frac{\exp(o_r)}{\sum_{r' \in \mathcal{R}} \exp(o_{r'})}, r \in \mathcal{R} \tag{3}$$

where y is the predicted label and $\mathcal{R} = \{r_1, ..., r_N, \texttt{NOTA}\}$ is the relation set including NOTA. For $r \in \{r_1, ..., r_N\}$, o_r is calculated by averaging,

$$o_r = \frac{1}{K} \sum_{j=1}^{K} [\boldsymbol{B}(x, x_r^j)]_1. \tag{4}$$

Model	5-Way 1-Shot		5-Way 5-Shot	
	On 1.0	On 2.0	On 1.0	On 2.0
GNN (CNN)	66.23 ± 0.75	27.94 ± 0.03	81.28 ± 0.62	29.33 ± 0.11
Proto (CNN)	74.52 ± 0.07	35.09 ± 0.10	88.40 ± 0.06	49.37 ± 0.10
Proto-ADV (CNN)	70.28 ± 0.15	42.21 ± 0.09	84.63 ± 0.07	58.71 ± 0.06
Proto (BERT)	80.68 ± 0.28	40.12 ± 0.19	89.60 ± 0.09	51.50 ± 0.29
Proto-ADV (BERT)	73.35 ± 0.95	41.90 ± 0.44	82.30 ± 0.53	54.74 ± 0.22
BERT-PAIR	88.32 ± 0.64	56.25 ± 0.40	93.22 ± 0.13	67.44 ± 0.54
Model	**10-Way 1-Shot**		**10-Way 5-Shot**	
	On 1.0	**On 2.0**	**On 1.0**	**On 2.0**
GNN (CNN)	46.27 ± 0.80	16.44 ± 0.04	64.02 ± 0.77	18.26 ± 0.03
Proto (CNN)	62.38 ± 0.06	22.98 ± 0.05	80.45 ± 0.08	35.22 ± 0.06
Proto-ADV (CNN)	56.34 ± 0.08	28.91 ± 0.10	74.67 ± 0.12	44.35 ± 0.09
Proto (BERT)	71.48 ± 0.15	26.45 ± 0.10	82.89 ± 0.11	36.93 ± 0.01
Proto-ADV (BERT)	61.49 ± 0.69	27.36 ± 0.50	72.60 ± 0.38	37.40 ± 0.36
BERT-PAIR	80.63 ± 0.17	43.64 ± 0.46	87.02 ± 0.12	53.17 ± 0.09

Table 2: Accuracies (%) on few-shot DA. "On 1.0" represents the results on the original FewRel dataset and "On 2.0" represents the results on the new test set. The models with "-ADV" use adversarial training described in Section 3.

The score for NOTA o_{NOTA} is calculated by the equation,

$$o_{\text{NOTA}} = \min_{r \in \{r_1, \ldots, r_N\}} \frac{1}{K} \sum_{j=1}^{K} [\boldsymbol{B}(x, x_r^j)]_0. \quad (5)$$

Then we can treat NOTA the same as other relations and optimize the model with the cross entropy loss, which is commonly-used in few-shot learning and other classification tasks.

5 Experiments

5.1 Baseline Models for Few-Shot Learning

We pick the two best models from the results in Han et al. (2018), **GNN** (Satorras and Estrach, 2018) and **Prototypical Networks** (Snell et al., 2017), as our baseline models. As for the encoders, besides the CNN encoder used in Han et al. (2018), we also adopt BERT since it achieves the state-of-the-arts in multiple tasks (Devlin et al., 2019). For all models and encoders, we follow the parameter settings from Han et al. (2018) and Devlin et al. (2019).

5.2 Evaluation Results on Few-Shot DA

Table 2 demonstrates the evaluation results of few-shot DA on the existing FewRel test set and the new test set. Besides the baselines, we also evaluate Prototypical Networks with adversarial training described in Section 3 and our proposed BERT-PAIR model in Section 4. We get three observations from the results:

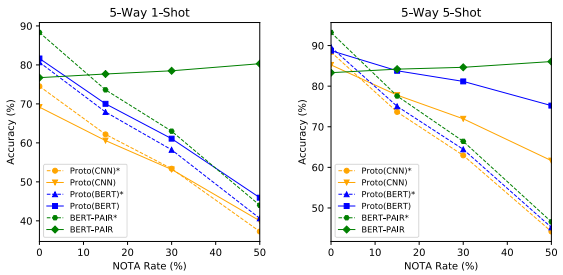

Figure 2: 5-way K-shot results under different NOTA rates. Models with * simply ignore the NOTA setting and assume all queries can be classified as one of the N relations.

(1) All few-shot models suffer dramatic performance falls when tested on a different domain.

(2) Adversarial training does improve the results on the new test domain, yet still has large space for growth.

(3) BERT-PAIR outperforms all other few-shot models on both 1.0 and 2.0 test set.

Besides, to see where the growth boundary is, we split 10 relations, $1,000$ instances out of the 2.0 test set and add them to the training set, then train and evaluate BERT-PAIR on the new data. We get 72.30% for 5-way 1-shot and 80.50% for 5-way 5-shot, 16 and 13 points higher than the current best results. Note that only $1,000$ training instances can lead to such an enormous gap, indicating that

Model	5-Way-1-Shot			
	0% NOTA	15% NOTA	30% NOTA	50% NOTA
Proto (CNN)*	74.52 ± 0.07	62.18 ± 0.22	53.38 ± 0.14	37.26 ± 0.04

BERT-PAIR*	93.22 ± 0.13	77.58 ± 0.42	66.41 ± 0.24	46.58 ± 0.09
BERT-PAIR	83.32 ± 0.38	84.19 ± 0.46	84.64 ± 0.13	86.06 ± 0.43

Table 3: Accuracies (%) on few-shot NOTA. Models with * simply ignore the NOTA setting and assume all queries can be classified as one of the given relations.

there is still a huge room for improvements.

5.3 Evaluation Results on Few-Shot NOTA

We evaluate Prototypical Networks with the naive NOTA solution described in Section 4 and BERT-PAIR under the NOTA setting. All models are trained given 50% NOTA queries and tested under four different NOTA rates: 0%, 15%, 30%, 50%. To show how accuracy falls if ignoring the NOTA relation, we also demonstrate the results of models without considering NOTA (marked with * in Figure 2). We demonstrate the evaluation results in Figure 2. For detailed numbers of results on few-shot NOTA, please refer to Table 3. From Figure 2 we can conclude that:

(1) Treating NOTA as the $N+1$ relation is beneficial for handling Few-Shot NOTA, though the results still fall fast when the NOTA rate increases.

(2) BERT-PAIR works better under the NOTA setting for its binary-classification style model, and stays stable with rising NOTA rate.

(3) Though BERT-PAIR achieves promising results, huge gaps still exist between the conventional (0% NOTA rate) and NOTA settings (gaps of 8 points for 5-way 1-shot and 7 points for 5-way 5-shot with 50% NOTA rate), which calls for further research to address the challenge.

6 Conclusion

In this paper, we propose FewRel 2.0, a more challenging few-shot relation classification task with a new test set from the biomedical domain and the none-of-the-above setting. The purpose of the new task is to explore two aspects which are ignored in the previous work: few-shot domain adaptation (few-shot DA) and few-shot none-of-the-above detection (few-shot NOTA). Extensive experiments demonstrate that the existing state-of-the-art few-shot models struggle on the new task. We also point out some possible directions to handle these two issues, implement several new models and evaluate them with the new task. Though achieving promising improvements, these commonly-used techniques are still not the satisfactory solutions for few-shot DA and few-shot NOTA, which requires further explorations in these two real-world challenges.

ner and pos when nothing is capitalized

Stephen Mayhew, Tatiana Tsygankova, Dan Roth
University of Pennsylvania
Philadelphia, PA, 19104
{mayhew, ttasya, danroth}@seas.upenn.edu

Abstract

For those languages which use it, capitalization is an important signal for the fundamental NLP tasks of Named Entity Recognition (NER) and Part of Speech (POS) tagging. In fact, it is such a strong signal that model performance on these tasks drops sharply in common lowercased scenarios, such as noisy web text or machine translation outputs. In this work, we perform a systematic analysis of solutions to this problem in English, modifying only the casing of the train or test data using lowercasing and truecasing methods. While prior work and first impressions might suggest training a caseless model, or using a truecaser at test time, we show that the most effective strategy is a concatenation of cased and lowercased training data, producing a single model with high performance on both cased and uncased text. As shown in our experiments, this result holds across tasks and input representations. Finally, we show that our proposed solution gives an 8% F1 improvement in mention detection on noisy out-of-domain Twitter data.

1 Introduction

Many languages use capitalization in text, often to indicate named entities. For tasks that are concerned with named entities, such as *named entity recognition* (NER) and *part of speech tagging* (POS), this is an important signal, and models for these tasks nearly always retain it in training.[1]

But capitalization is not always available. For example, informal user-generated texts can have inconsistent capitalization, and similarly the outputs of speech recognition or machine translation are traditionally without case. Ideally we would like a model to perform equally well on both cased and uncased text, in contrast with current models.

[1]For POS tagging, this happens in tagsets that explicitly mark proper nouns, such as the Penn Treebank tagset.

		Test	
Tool	Task	Cased	Uncased
BiLSTM-CRF w/ ELMo	NER	92.45	34.46
BiLSTM-CRF w/ ELMo	POS	97.85	88.66

Table 1: Modern tools trained on cased data perform well on cased test data, but poorly on uncased (lowercased) test data. For NER, we evaluate on the testb set of CoNLL 2003, and the scores are reported as F1. For POS, we evaluate on PTB sections 22-24, and the scores represent accuracy. ELMo refers to contextual representations from Peters et al. (2018).

Table 1 demonstrates how popular modern systems trained on cased data perform well on cased data, but suffer dramatic performance drops when evaluated on lowercased text.

Prior solutions have included models trained on lowercase text, or models that automatically recover capitalization from lowercase text, known as *truecasing*. There has a been a substantial body of literature on the effect of truecasing applied after speech recognition (Gravano et al., 2009), machine translation (Wang et al., 2006), or social media (Nebhi et al., 2015). A few works that evaluate on downstream tasks (including NER and POS) show that truecasing improves performance, but they do not demonstrate that truecasing is *the best way* to improve performance.

In this paper, we evaluate two foundational NLP tasks, NER and POS, on cased text and lowercased text, with the goal of maximizing the average score regardless of casing. To achieve this goal, we explore a number of simple options that consist of modifying the casing of the train or test data. Ultimately we propose a simple preprocessing method for training data that results in a single model with high performance on both cased and uncased datasets.

2 Related Work

This problem of robustness in casing has been studied in the context of NER and truecasing.

Robustness in NER A practical, common solution to this problem is summarized by the Stanford CoreNLP system (Manning et al., 2014): train on uncased text, or use a truecaser on test data.[2] We include these suggested solutions in our analysis below.

In one of the few works that address this problem directly, Chieu and Ng (2002) describe a method similar to co-training for training an upper case NER, in which the predictions of a cased system are used to adjudicate and improve those of an uncased system. One difference from ours is that we are interested in having a single model that works on upper or lowercased text. When tagging text in the wild, one cannot know *a priori* if it is consistently cased or not.

Truecasing Truecasing presents a natural solution for situations with noisy or uncertain text capitalization. It has been studied in the context of many fields, including speech recognition (Brown and Coden, 2001; Gravano et al., 2009), and machine translation (Wang et al., 2006), as the outputs of these tasks are traditionally lowercased.

Lita et al. (2003) proposed a statistical, word-level, language-modeling based method for truecasing, and experimented on several downstream tasks, including NER. Nebhi et al. (2015) examine truecasing in tweets using a language model method and evaluate on both NER and POS.

More recently, a neural model for truecasing has been proposed by Susanto et al. (2016), in which each character is associated with a label *U* or *L*, for upper and lower case respectively. This neural character-based method outperforms word-level language model-based prior work.

3 Truecasing Experiments

We use our own implementation of the neural method described in Susanto et al. (2016) as the truecaser used in our experiments.[3] Briefly, each sentence is split into characters (including spaces) and modeled with a 2-layer bidirectional LSTM, with a linear binary classification layer on top.

We train the truecaser on a dataset from Wikipedia, originally created for text simplification (Coster and Kauchak, 2011), but commonly used for evaluation in truecasing papers (Susanto et al., 2016). This task has the convenient property that if the data is well-formed, then supervision is free. We evaluate this truecaser on several data sets, measuring F1 on the word level (see Table 2). At test time, all text is lowercased, and case labels are predicted.

System	Test set	F1
(Susanto et al., 2016)	Wikipedia	93.19
BiLSTM	Wikipedia	93.01
	CoNLL Train	78.85
	CoNLL Test	77.35
	PTB 01-18	86.91
	PTB 22-24	86.22

Table 2: Truecaser word-level performance on English data. This truecaser is trained on the Wikipedia corpus. *Wikipedia* refers to the test set from Coster and Kauchak (2011). *CoNLL Test* refers to *testb*. *PTB* is the Penn Treebank.

First, we evaluate the truecaser on the same test set as Susanto et al. (2016) in order to show that our implementation is near to the original. Next, we measure truecasing performance on plain text extracted from the CoNLL 2003 English (Tjong Kim Sang and De Meulder, 2003) and Penn Treebank (Marcus et al., 1993) train and test sets. These results contain two types of errors: idiosyncratic casing in the gold data and failures of the truecaser. However, from the high scores in the Wikipedia experiment, we suppose that much of the score drop comes from idiosyncratic casing. This point is important: if a dataset contains idiosyncratic casing, then it is likely that NER or POS models have fit to that casing (especially with these two wildly popular datasets). As a result, truecasing, since it can't recover these idiosyncrasies, is not likely to be the best plan.

Notably, the scores on CoNLL are especially low, likely because of elements such as titles, bylines, and documents that contain league standings and other sports results written in uppercase.

The higher scores on Penn Treebank corpus suggest that the capitalization standards are more traditional. Many errors are where the truecaser fails to correctly capitalize such words as "Federal" or "Central". In addition, there are many

[2] https://stanfordnlp.github.io/CoreNLP/caseless.html

[3] cogcomp.org/page/publication_view/881

occasions where the truecaser fails to capitalize named entities, for example "Mr. susulu".

4 Methods

In this section, we introduce our proposed solutions. In all experiments, we constrain ourselves to only change the casing of the training or testing data with no changes to the architectures of the models in question. This isolates the importance of dealing with casing, and makes our observations applicable to situations where modifying the model is not feasible, but retraining is possible.

Our experiments aim to answer the extremely common situation in which capitalization is noisy or inconsistent (as with inputs from the internet). In light of this goal, we evaluate each experiment on both cased and lowercased test data, reporting individual scores as well as the average. Our experiments on lowercase text can also give insight on best practices for when test data is known to be all lowercased (as with the outputs of some upstream system).

We experiment on five different data casing scenarios described below.

1. **Train on cased** Simply apply a model trained on cased data to unmodified test data, as in Table 1.

2. **Train on uncased** Lowercase the training data and retrain. At test time, we lowercase all test data. If we did not do this, then scores on the cased test set would suffer because of casing mismatch between train and test. Since lowercasing costs nothing, we can improve average scores this way. As such, cased and uncased test data will have the same score.

3. **Train on cased+uncased** Concatenate original cased and lowercased training data and retrain a model. Test data is unmodified.

   Since this concatenation results in twice the number of training examples than other methods, we also experimented with randomly lowercasing 50% of the sentences in the original training corpus. We refer to this experiment as *3.5 Half Mixed*. We also tried ratios of 40% and 60%, but these were slightly worse than 50% in our evaluations.

4. **Train on cased, test on truecased** Do nothing to the train data, but truecase the test data. Since we lowercase text before truecasing it, the cased and uncased test data will have the same score.

5. **Truecase train and test** Truecase the train data and retrain. Truecase the test data also. As in experiment 4, cased and uncased test data will have the same score.

One way to look at these experiments is as dropout for capitalization, where a sentence is lowercased with respect to the original with probability $p \in [0, 1]$. In experiment 1, $p = 0$. In experiment 2, $p = 1$. In experiment 3, $p = 0.5$. Our implementation is somewhat different from standard dropout in that our method is a preprocessing step, not done randomly at each epoch.

5 Experiments

Before we show results, we will describe our experimental setup. We emphasize that our goal is to experiment with strong models in noisy settings, not to obtain state-of-the-art scores on any dataset.

5.1 NER

We use the standard BiLSTM-CRF architecture for NER (Ma and Hovy, 2016), using an AllenNLP implementation (Gardner et al., 2018).

We experiment with pre-trained contextual embeddings, ELMo (Peters et al., 2018), which are generated for each word in a sentence, and concatenated with GloVe word vectors (lowercased) (Pennington et al., 2014), and character embeddings. ELMo embeddings are trained with cased inputs, meaning that there will be some mismatch when generating embeddings for uncased text.

In all experiments, we train on English CoNLL 2003 Train data (Tjong Kim Sang and De Meulder, 2003) and evaluate on the CoNLL 2003 Test data (testb). We always evaluate on two different versions: the original version, and a version with all casing removed (e.g. everything lowercase).

5.2 POS Tagging

We use a neural POS tagging model built with a BiLSTM-CRF (Ma and Hovy, 2016), and GloVe embeddings (Pennington et al., 2014), character embeddings, and ELMo pre-trained contextual embeddings (Peters et al., 2018).

As our experimental data, we use the Penn Treebank (Marcus et al., 1993), and follow the training splits of (Ling et al., 2015), namely 01-18 for train,

Exp.	Test (C)	Test (U)	Avg
1. Cased	**92.45**	34.46	63.46
2. Uncased	89.32	89.32	89.32
3. C+U	91.67	89.31	**90.49**
3.5. Half Mixed	91.68	89.05	90.37
4. Truecase Test	82.93	82.93	82.93
5. Truecase All	90.25	**90.25**	90.25

Table 3: Results from NER+ELMo experiments, tested on CoNLL 2003 English test set. *C* and *U* are Cased and Uncased respectively. All scores are F1.

Exp.	Test (C)	Test (U)	Avg
1. Cased	**97.85**	88.66	93.26
2. Uncased	97.45	**97.45**	97.45
3. C+U	97.79	97.35	97.57
3.5. Half Mixed	**97.85**	97.36	**97.61**
4. Truecase Test	95.21	95.21	95.21
5. Truecase All	97.38	97.38	97.38

Table 4: Results from POS+ELMo experiments, tested on WSJ 22-24, from PTB. *C* and *U* are Cased and Uncased respectively. All scores are accuracies.

19-21 for validation, 22-24 for testing. As with NER, we evaluate on both original and lowercased versions of test.

6 Results

Results for NER are shown in Table 3, and results for POS are shown in Table 4. There are several interesting observations to be made.

Primarily, our experiments show that the approach with the most promising results was experiment 3: training on the concatenation of original and lowercased data. Lest one might think this is because of the double-size training corpus, results from experiment 3.5 are either in second place (for NER) or slightly ahead (for POS).

Conversely, we show that the folk-wisdom approach of truecasing the test data (experiment 4) does not perform well. The underwhelming performance can be explained by the mismatch in casing standards as seen in Section 3. However, experiment 5 shows that if the training data is also truecased, then the performance is good, especially in situations where the test data is known to contain no case information.

Training only on uncased data gives good performance in both NER and POS – in fact the highest performance on uncased text in POS – but never reaches the overall average scores from experiment 3 or 3.5.

We have repeated these experiments for NER in several different settings, including using only static embeddings, using a non-neural truecaser, and using BERT uncased embeddings (Devlin et al., 2019). While the relative performance of the experiments varied, the conclusion was the same: training on cased and uncased data produces the best results.

When using uncased BERT embeddings, we found that performance on the uncased test set (U) was typically higher than that of ElMo, while the maximum performance on the cased test set (C) was typically lower. This again exemplifies the challenge of using capitalization as a signal while being robust to its absence.

7 Application: Improving NER Performance on Twitter

To further test our results, we look at the Broad Twitter Corpus[4] (Derczynski et al., 2016), a dataset comprised of tweets gathered from a broad variety of genres, and including many noisy and informal examples. Since we are testing the robustness of our approach, we use a model trained on CoNLL 2003 data. Naturally, in any cross-domain experiment, one will obtain higher scores by training on in-domain data. However, our goal is to show that our methods produce a more robust model on out-of-domain data, not to maximize performance on this test set. We use the recommended test split of section F, containing 3580 tweets of varying length and capitalization quality.

Since the train and test corpora are from different domains, we evaluate on the level of mention detection, in which all entity types are collapsed into one. The Broad Twitter Corpus has no annotations for MISC types, so before converting to a single generic type, we remove all MISC predictions from our model.

Results are shown in Table 5, and a familiar pattern emerges. Experiment 3 outperforms experiment 1 by 8 points F1, followed by experiment 3.5 and experiment 5, showing that our approach holds when evaluated on a real-world data set.

Exp.	Mention Detection F1
1. Cased	58.63
2. Uncased	53.13
3. C+U	**66.14**
3.5. Half Mixed	64.69
4. Truecase Test	58.22
5. Truecase All	62.66

Table 5: Results on NER+ELMo on the Broad Twitter Corpus, set F, measured as mention detection F1.

8 Conclusion

We have performed a systematic analysis of the problem of unknown casing in test data for NER and POS models. We show that commonly-held suggestions (namely, lowercase train and test data, or truecase test data) are rarely the best. Rather, the most effective strategy is a concatenation of cased and lowercased training data. We have demonstrated this with experiments in both NER and POS, and have further shown that the results play out in real-world noisy data.

Abstract

Open Information Extraction (Open IE) systems have been traditionally evaluated via manual annotation. Recently, an automated evaluator with a benchmark dataset (OIE2016) was released – it scores Open IE systems automatically by matching system predictions with predictions in the benchmark dataset (Stanovsky and Dagan, 2016). Unfortunately, our analysis reveals that its data is rather noisy, and the tuple matching in the evaluator has issues, making the results of automated comparisons less trustworthy.

We contribute CaRB, an improved dataset and framework for testing Open IE systems. To the best of our knowledge, CaRB is the first *crowdsourced* Open IE dataset and it also makes substantive changes in the matching code and metrics. NLP experts annotate CaRB's dataset to be more accurate than OIE2016. Moreover, we find that on one pair of Open IE systems, CaRB framework provides contradictory results to OIE2016. Human assessment verifies that CaRB's ranking of the two systems is the accurate ranking. We release the CaRB framework along with its crowdsourced dataset.

1 Introduction

Open Information Extraction (Open IE) refers to the task of forming relational tuples from sentences, without a fixed relation vocabulary (Banko et al., 2007). Open IE has numerous downstream applications such as knowledge base construction, relation extraction, summarisation and learning word embeddings (Stanovsky et al., 2015; Mausam, 2016). There have been many Open IE systems till date such as TextRunner (Banko et al., 2007), ReVerb (Fader et al., 2011; Etzioni et al., 2011), OLLIE (Mausam et al., 2012), ClausIE (Del Corro and Gemulla, 2013), OpenIE 4 (Christensen et al., 2011; Pal and Mausam, 2016), OpenIE 5 (Saha et al., 2017; Saha and Mausam, 2018), PropS (Stanovsky et al., 2016), NST (Jia et al., 2018), Neural Open IE (Cui et al., 2018), and more. With the advent of so many systems, it is imperative to have a standardized mechanism for automatic evaluation so that they can be compared.

Traditionally, these systems have been evaluated over small manually curated gold datasets (e.g., (Fader et al., 2011; Mausam et al., 2012)). There are two problems with this approach. One, it is not reliable due to the small size of annotation. Second, it lacks standardization, since there is no single gold dataset over which all systems are evaluated. Moreover, the guidelines to annotate may vary across datasets and annotators. Recently, some standard benchmarks datasets and evaluators have been proposed: OIE2016 (Stanovsky and Dagan, 2016), RelVis (Schneider et al., 2017), and Wire57 (Léchelle et al., 2018). Unfortunately, these datasets are either too small or too noisy to meaningfully compare Open IE systems.

For instance, since its release in 2016, OIE2016 has been considered the de facto standard for Open IE evaluation (e.g., OIE2016 is used by the recent NST and Neural Open IE systems). However, upon close analysis, we find several issues with this benchmark. Its gold dataset makes significant errors and misses a large number of important tuples. This can be attributed to the fact that this dataset was not manually curated for Open IE, rather QA-SRL data was adapted for this task. There are also issues with its evaluation rules, which we detail later.

In response, we propose a new benchmark system CaRB: **C**rowdsourced **a**utomatic open **R**elation extraction **B**enchmark, which has a good sized and high quality dataset, along with better

Table 1: Sample gold annotations for OIE2016 vs. CaRB

evaluation metrics. In order to create this gold dataset, we crowdsource human annotation of extractions using Amazon Mechanical Turk (MTurk) using the same original sentences as OIE2016. Our MTurk task has an automated system for training and qualifying workers, which makes crowdsourcing this annotation feasible.

Two Open IE experts (authors of this paper) manually annotate 50 random sentences, which are then used as expert ground truth to evaluate the respective tuples in OIE2016's and CaRB's gold datasets (Tables 4,5). We find that CaRB outperforms OIE2016 by 21 points in precision and 16 points in recall in token level match. This demonstrates that CaRB's gold dataset is significantly more accurate than OIE2016's. Additionally, when evaluating all systems using our benchmark, we notice that CaRB reverses OIE2016's ranking of PropS and ClausIE. Human verification, again through crowdsourcing, verifies that two systems are ranked more accurately by CaRB. We release CaRB's dataset, along with its evaluator as a novel benchmark for further use by research community.[1]

2 Related Work

To the best of our knowledge, there are three benchmarks systems available for comparing Open IE systems. Of them, the first and the most prominent is OIE2016 (Stanovsky and Dagan, 2016). This has been widely adopted as the standard evaluation framework to test new systems on. In OIE2016, gold tuples are generated using an automated rule-based system built on top of a QA-SRL dataset (He et al., 2015). In early analysis we find this dataset to be rather noisy. Table 1 illustrates some sample sentences from this gold dateset. These tuples look obviously wrong, and unfit to be in the gold set.

In addition to the dataset, Stanovsky and Dagan (2016) release a scorer that compares a set of gold tuples with a set of system tuples to estimate word-level precision and recall. This scorer has been identified to not penalize long extractions. It also does not penalise extractions for misidentifying parts of a relation in an argument slot (or vice versa), leading to trivial systems that score much better than genuine Open IE systems (Léchelle et al., 2018). We also observe that the scorer compares words all-to-all allowing multiple same words in an extraction to match a corresponding one in the gold. Thus, simply repeating a word in the extraction will give it a high precision score. Finally, the scorer loops over gold tuples in an arbitrary order, and matches them to predicted extractions in a sequential manner. Once a gold matches to a predicted extraction, it is rendered unavailable for any subsequent, potentially better-matched, extraction.

Another dataset is RelVis (Schneider et al., 2017), a benchmark that borrows its data from four different datasets including OIE2016. Since OIE2016 forms a major part of this dataset, it has similar issues with noise. Its scorer makes some

[1] https://github.com/dair-iitd/CaRB

modifications to OIE2016. However, it does not reward partial coverage of gold tuples, and forces one system prediction to match just one gold. It also does not penalize overlong extractions.

Finally, Wire57 (Léchelle et al., 2018) makes further improvements in the scorer. It penalises overlong extractions and assigns a token-level precision and recall score to all gold-prediction pairs for a sentence. Moreover, it considers all pairs of extractions in its matching phase. However, it still forces one prediction to match just one gold. It also reports just one score for a system, ignoring the confidence values of the individual predictions that make the precision-recall curve of OIE2016 possible. Our scorer is inspired by theirs, with some changes. More importantly, the dataset used in Wire57 is manually curated, but with only 57 sentences, which is too small to suffice as a comprehensive test dataset.

3 Crowdsourcing CaRB Dataset

To overcome the shortcomings of dataset noise and size, we crowdsource a high-quality gold dataset for Open IE. We ask workers over Amazon Mechanical Turk (MTurk) to annotate extractions for the 1,282 sentences in dev and test splits of OIE2016. The workers annotate tuples in the form (arg1, rel, arg2), and also annotate location and time attributes for each tuple, when possible.

Open IE annotations are not easy to obtain from non-expert workers. To get acceptable quality, we train workers using a tutorial[2] that doubles up as a qualification test. Their performance in the test is automatically graded. Only workers that pass this are allowed to move on to the main task. The qualification is integrated with the task so that a new worker is served the tutorial and test first, but a qualified worker is directly taken to the main task. This makes the crowdsourcing process scalable.

We divide the task of annotating a sentence into three steps: (1) identifying the relation, (2) identifying the arguments for that relation, and (3) optionally identifying the location and time attributes for the tuple. The training process for the annotators is split into four steps, each of which focuses on a different guideline for Open IE. These are:

1. **Completeness:** The worker must attempt to extract *all* assertions from the sentence.
2. **Assertedness:** Each tuple must be implied by the original sentence.

[2]Screenshots in supplementary material

Sentence	*I ate an apple and an orange.*	(prec,rec)	
Gold	(I; ate; an apple) (I; ate; an orange)	OIE2016	CaRB
System 1	(I; ate; an apple and an orange)	(1,0.5)	(0.57,1)
System 2	(I; ate; an apple)	(1,0.5)	(1,0.87)

Table 2: One-to-One Match vs. Multi Match

Sentence	*I ate an apple.*	(prec,rec)	
Gold	(I; ate; an apple)	OIE2016	CaRB
System 1	(I; ate; an apple)	(1,1)	(1,1)
System 2	(ate; an apple; I)	(1,1)	(0,0)

Table 3: Tuple Match vs. Lexical Match

3. **Informativeness:** The worker must include the maximum amount of relevant information in an argument.
4. **Atomicity:** Each tuple must be an indivisible unit. Whenever possible, the worker must extract multiple atomic tuples from a sentence that has conjunctions.

We also develop a user-friendly interface for annotating the sentences, which almost eliminates the need for workers to type anything. However, we note that several workers got frustrated in our qualification test, could not understand the task and left the job. However, several good workers completed the task successfully, and annotated significant high-quality data for us.

For sentences involving reporting verbs like *said, told, asked,* etc., some systems annotate additional attributional context for every utterance (Mausam et al., 2012). For this, we create a separate task, so as to prevent workers from being bombarded with all the rules at the same time.

We post-process the data to remove obvious incorrect annotations, like ones with a missing arg1 or rel. We also follow the convention of ending a relation with a preposition instead of beginning arg2 with one, so all prepositions are shifted to rel.

4 The CaRB Scorer

We now describe CaRB's approach for scoring system predictions against the gold. Instead of greedily matching gold tuples to system tuples in arbitrary order, CaRB creates an all-pair matching table, with each column as system tuple and each row as gold tuple. It computes precision and recall scores between each pair of tuples. Then, for computing overall recall, the maximum recall score is taken in each row, and averaged. By taking the maximum, recall computation matches a

gold tuple with the closest system extraction. For computing precision, the system predictions are matched one to one with gold tuples, in the order of best match score to worst. The match precision scores are then averaged to compute precision. To compute precision-recall curve this computation is done at different confidence thresholds of system extractions.

In this way, CaRB's recall computation uses the notion of *multi-match*, wherein a gold tuple can match multiple system extractions. This is helpful in avoiding penalizing a system very heavily if it stuffs information from multiple gold tuples in a single extraction. Table 2 displays an example wherein system 1 combines information from two gold tuples in a single extraction, and system 2 only extracts one of the gold tuples. One-to-one match (OIE2016) is indifferent between the two which means that for OIE2016, adding more information in the same extraction has no value at all. However, multi match (CaRB) assigns higher recall to system 1, since it contains strictly more information, and higher precision to system 2, since its prediction exactly matched a gold extraction.

On the other hand, CaRB uses *single match* for precision. This is because CaRBs gold tuples are atomic, and cannot be further divided into more tuples. By single matching for precision, CaRB penalizes Open IE systems that produce several very similar and redundant extractions.

Another significant change from OIE2016 scorer is in the use of *tuple match* instead of *lexical match*. CaRB matches relation with relation, and arguments with arguments, however OIE2016 serialized the tuples into a sentence and just computed lexical matches. Table 3 illustrates an example when the arguments are shuffled, lexical match (OIE2016) shows no effect but tuple match (CaRB) rightfully decreases the scores. To avoid spurious matches, CaRB considers only matches with atleast one common word in the relation field.

Finally, some Open IE systems extract n-ary tuples and others do not. To treat all systems on equal footing, we follow previous work and append all higher numbered arguments into arg2.

5 Evaluation

5.1 Dataset Quality

We first estimate the overall quality of the crowdsourced dataset. To this end, two authors of this paper annotate 50 dev sentences from OIE2016 to create an expert dataset. They first independently annotate tuples from these sentences, achieving an agreement F1 score of 83. They then resolve the differences and merge these independent sets. This is taken as an expert gold against which both OIE2016 and CaRB datasets are assessed.

Dataset	Precision	Recall	F1
OIE2016	0.65	0.55	0.60
CaRB	0.87	0.71	0.78

Table 4: Data quality using token-level match

	Precision	Recall	F1
OIE2016	0.67	0.51	0.57
CaRB	0.74	0.73	0.73

Table 5: Data quality using lexical match

System	Precision	Recall	F1	AUC
Ollie	0.505	0.346	0.411	0.224
PropS	0.340	0.300	0.319	0.126
OpenIE 4	**0.553**	0.437	**0.488**	**0.272**
OpenIE 5	0.521	0.424	0.467	0.245
ClausIE	0.411	**0.496**	0.450	0.224

Table 6: Performance of Open IE systems on CaRB

Tables 4 and 5 estimate dataset quality of OIE2016 and CaRB. We find that CaRB has enormously high precision and recall values, suggesting that it is a much cleaner dataset. Table 1 compares the crowd sourced annotations and OIE2016 gold annotations for some sample sentences. While there is still scope for improvement, CaRB dataset appears much better than the OIE2016's gold.

Stanovsky and Dagan (2016) remark that their gold dataset reaches an F1 of 95.8 on their expert annotation, whereas our assessment suggest values around 60. We surmise that this discrepancy is due to the different gold-prediction scoring schemes used. In original OIE2016 paper, the authors "match an automated extraction with a gold proposition if both agree on the grammatical head of all of their elements (predicate and arguments)".[3] The head match criterion is a much laxer scheme than ours and can explain the very high F1 score against their expert annotation.

[3]This scheme is later changed in their github repository to a lexical match, where if the fraction of words in the prediction also present in the gold is above a threshold, the pair is declared a match.

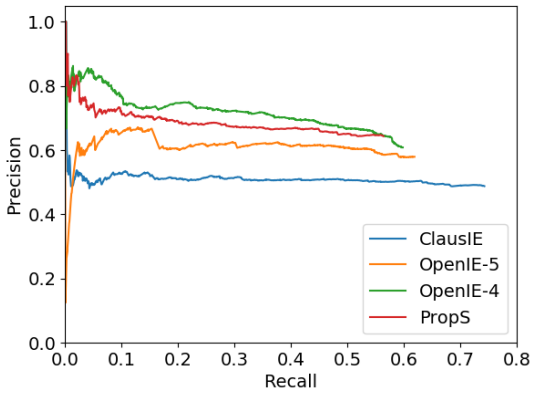

Figure 1: Comparison of Open IE systems using OIE2016

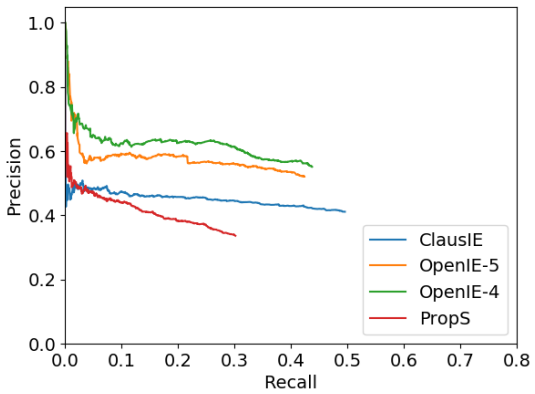

Figure 2: Evaluation of Open IE systems using CaRB

5.2 Comparison of Open IE Systems

We test the different Open IE systems depicted in Stanovsky and Dagan (2016), using the CaRB dataset and scorer. The p-r curves obtained using OIE2016 and CaRB are outlined in figures 1 (reproduced from Stanovsky et al. (2018)) and 2. Precision, recall and F1 scores (at max F1 point) and area under precision-recall curve are reported in Table 6. It can be seen that the curve for PropS lies above ClausIE at all times in OIE2016, but PropS performs the worse of all systems in CaRB. To verify that CaRB indeed gives the correct ranking, we turn back to human verification.

5.3 Human Verification

Through human verification, our goal is to learn the accurate ranking for ClausIE and PropS. We randomly select 100 test sentences and evaluate both system extractions on this subset.

We assess the correct ranking between PropS and ClausIE using MTurk. Four workers are shown the extractions from both systems in random order and asked to either choose one of the systems as the better one or indicate that both are equal. The majority opinion of these four is considered as the correct ranking for that sentence, an equal split leading to a tie. In this experiment, we only allow MTurk workers who have been trained for Open IE for the crowdsourcing task to participate.

Of these 100 sentences, PropS is chosen to have performed better for 15, ClausIE for 69 whereas 16 ended up in a tie. ClausIE is indeed considered the better system in human evaluation, and we verify that CaRB gives an accurate ranking of these two systems compared to OIE2016.

6 Conclusion

We contribute CaRB, a crowdsourced dataset for evaluation and comparison of Open IE systems. We assess this dataset against an expert-annotated dataset and find that it is dramatically more accurate than the existing OIE2016 benchmark dataset.

We also implement a scorer that computes precision, recall and area under p-r curve for a given system output by matching it with the CaRB dataset. In designing our scorer, we make several design choices that deviate from prior work in both match scores and also in finding the best match for a tuple. We believe our scheme treats various systems fairly. And in one case where CaRB and OIE2016 give different rankings to two Open IE systems, we demonstrate via human evaluation that the ranking given by CaRB is the accurate one. We release the dataset and scorer for further use by research community.

We expect that crowdsourced annotation will also be able to help the training of Open IE systems as it has helped their evaluation – we leave the creation of a suitably large crowdsourced training set for Open IE to future work.

Weakly Supervised Attention Networks for Entity Recognition

Barun Patra*, **Joel Ruben Antony Moniz***
{barunpatra95, jramoniz}@gmail.com

Abstract

The task of entity recognition has traditionally been modelled as a sequence labelling task. However, this usually requires a large amount of fine-grained data annotated at the token level, which in turn can be expensive and cumbersome to obtain. In this work, we aim to circumvent this requirement of word-level annotated data. To achieve this, we propose a novel architecture for entity recognition from a corpus containing weak binary presence/absence labels, which are relatively easier to obtain. We show that our proposed weakly supervised model, trained solely on a multi-label classification task, performs reasonably well on the task of entity recognition, despite not having access to any token-level ground truth data.

1 Introduction

Entity Recognition frequently finds use as a first step in numerous downstream NLP tasks (Wang and Xue, 2017; Lee et al., 2018; Liang et al., 2018). Traditionally, it has been posed as a sequence labeling task (Lample et al., 2016; Ma and Hovy, 2016), which in turn requires corpora with token-based annotations. A key drawback of this formulation, however, lies in its dependence on corpora annotated at the token-level, which can often be tedious to obtain and expensive to annotate.

One potential way of overcoming this limitation is to move towards a method that utilizes a weaker form of supervision that is easier to obtain. In this work, we focus on one such form of weak supervision: binary labels that indicate the presence of an entity type. The cognitive load of selecting whether an entity type is present or not is usually less than that of actually highlighting and annotating spans with their correct entity types. It also stands to reason that providing these binary labels might be faster. Both these properties are particularly advantageous for a human-in-the-loop setup in a user facing task, since a user is more likely to answer a yes/no question than to provide the annotated entity spans. This, in turn, facilitates cheaper and faster data collection; be it explicitly in the form of feedback questions, or implicitly from mined user logs (for example, clicked search engine results for queries related to "movies" are likely to contain the entity in question (Xu et al., 2009)).

In this work, we make first steps towards moving away from span-based corpora, relying solely on binary presence/absence classification labels for extracting entities. We propose a novel attention-based model that, though trained on a multi-label classification task, can be used for entity recognition. We show the efficacy of our proposed model on the widely used 2003 CoNLL dataset. Our model achieves reasonable performance without having access to token-level annotations. We thus show that it is possible to extract entities using a weak classification signal. [1]

2 Related Work

Commonly used methods for entity extraction rely on token-level annotated corpora. Conventionally, these supervised methods learn a CRF (Lafferty et al., 2001) or a Seq2Seq (Sutskever et al., 2014) model over either hand-crafter or neural features. More recently, pre-trained embeddings from language models trained on large corpora (Peters et al., 2018; Devlin et al., 2018), when augmented with previous methods, have shown marked improvements.

A contrasting line of work has been to explore unsupervised entity extraction without using

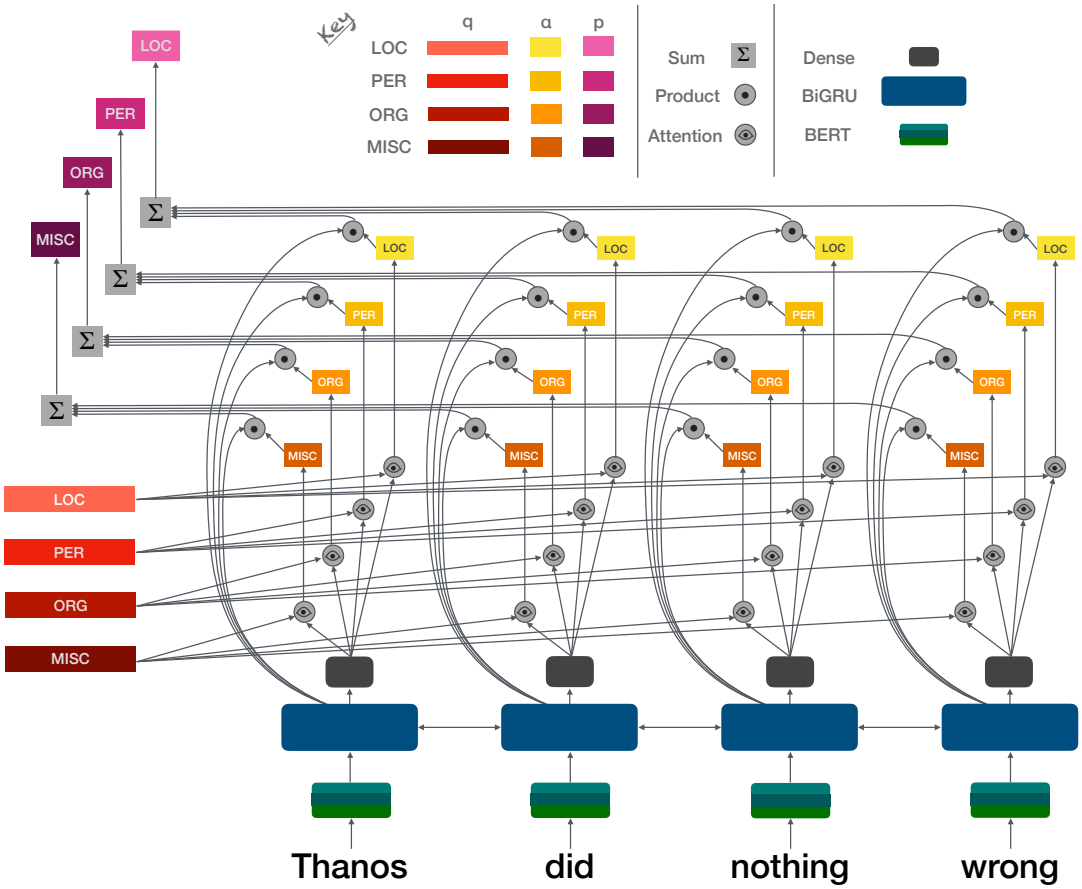

Figure 1: Model Architecture: Sentence-level Classifier. **q** represents the learned query vector per tag, α denotes the attention weights computed per token and **p** denotes the probability of predicting each tag at the sentence level.

ground-truth token or sentence level annotations. For example, a common paradigm for unsupervised Named Entity Recognition involves relying on a seed gazetteer, as in the case of Zhang and Elhadad (2013) and Ghiasvand and Kate (2015) both in the medical domain. In a more general setting, Carlson et al. (2009) use gazetteers to bootstrap training by labelling sequences that can be confidently annotated, and then use this partly labelled data to train their proposed Partial Perceptron algorithm; although they make use of a gazetteer, being the closest in setting to our proposed approach, we use Carlson et al. (2009) as our primary baseline. Another common technique involves bootstrapping the system with a set of rule templates, such as in (Etzioni et al., 2005) and (Collins and Singer, 1999). However, these methods often rely on an initial seed rule-base or on the availability of gazetteers (or the effective generation of these gazetteers using an online source such as Wikipedia).

Aside from directly improving performance on various tasks, attention (Bahdanau et al., 2014; Luong et al., 2015) has proven to be extremely useful when used indirectly in a wide variety of other ways (for example, for segmentation (Tang and Yang, 2018) and unsupervised speech-to-text alignment (Boito et al., 2017; Godard et al., 2018)). In addition, using attention-based models for object segmentation in a weakly supervised setting has been well explored in the vision domain (Teh et al., 2016; Zhang et al., 2018). Inspired by this, we leverage the attention weights of the model to identify entity spans.

3 Method

Figures 1 and 2 describe the different components of our model. Our model comprises of 4 modules: a sentence representation module, an attention module, a token-level tagger and a sentence-level classifier. Concretely, given a sentence $(x_1, \cdots x_l)$, the model predicts whether a tag $t \in \mathcal{T}$ is present in the sentence, as well as an attention distribution over the words for each tag $(\alpha_{1,t} \cdots \alpha_{l,t}) \forall t \in \mathcal{T}$ (where $\mathcal{T}$ is the set of entity tags), as described below:

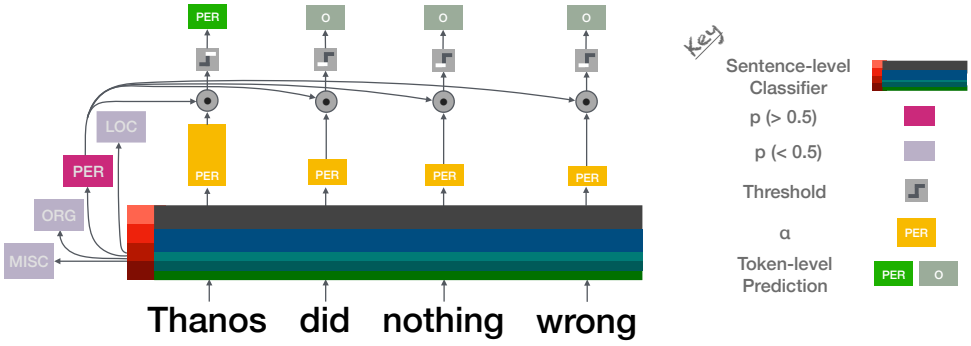

Figure 2: Model Architecture: Token Tagger. The Token Tagger performs tagging using the attention weights. α denotes the attention weights of the predicted tag(s).

Token Representation Module: generates an embedding for each token, representing the word's meaning and its left and right context. We use BERT embeddings (Devlin et al., 2018) for generating a word-level representation. We further use a Bidirectional GRU (Cho et al., 2014) layer to better adapt BERT embeddings to the task to obtain token representations $(e_1 \cdots e_l)$.

Attention Module: consists of an attention mechanism for each tag type. Given the token embeddings, a softmax distribution pertaining to the corresponding tag is generated, modelling the conditional probability of a word in a sentence being of that tag, given that the entire sentence contains the tag. We compute attention as in Bahdanau et al. (2014), using one learned query vector q_t per tag $t \in \mathcal{T}$. The token embeddings $(e_1 \cdots e_l)$ are passed through a dense layer to generate keys $(k_1 \cdots k_l)$ in the query space, which together with query q_t, yield a set of attention weights $(\alpha_{1,t} \cdots \alpha_{l,t})$.

Sentence-level Classifier: generates the probability of the presence of a tag in the sentence. For each tag, the token-level representations $(e_1 \cdots e_l)$ are weighed by the attention distribution $(\alpha_{1,t} \cdots \alpha_{l,t})$ corresponding to the tag. The weighted sum generates a sentence representation s_t per tag, which is passed through a sigmoid layer to generate the probability of the tag being present (p_t), with $p_t > 0.5$ denoting the presence of a tag.

Token Tagger Module: combines the probabilities from the Sentence-level Classifier with the attention weights obtained from the Attention Module to generate BIO tags for each token. Only the attention weights pertaining to the predicted labels $\mathcal{T}'$ are considered (i.e., if no tag is predicted, the entire sentence is marked "O"), with the attention weights being scaled by the probability of the predicted label (i.e $p_t * (\alpha_{1,t} \cdots \alpha_{l,t})$). A word x_i is assigned the label $y_i = \text{argmax}_{t \in \mathcal{T}'}(p_t * \alpha_{i,t})$ if $p_t * \alpha_{i,y_i}$ is greater than a small threshold ϵ and it is neither a punctuation symbol nor a stop-word (Figure 2).

4 Experiments

Dataset: To demonstrate the feasibility of our model, we adapt the commonly used CoNLL 2003 dataset (Ratinov and Roth, 2009). The dataset contains token-level annotations of the Reuter's Corpus (Lewis et al., 2004) for 4 entity types: person (PER), location (LOC), organization (ORG) and miscellaneous (MISC), with each token being tagged in the IOB format (Ramshaw and Marcus, 1999). For training and validation, we strip out the token-level annotations, instead annotating sentences to merely indicate the presence of entity-types. In order to quantify the quality of the extracted entities, we then measure the span level f-score on the test set using the gold entity spans.

Modelling Choices and Hyperparameters: We use the BERT-Base Multilingual Cased model for the Token Representation Module, similar to the NER tagging setup in Devlin et al. (2018). We experiment both with using the embeddings as is, and fine-tuning the top layers of the attention encoder (we only try fine-tuning the top, top-two and top-three layers due to computational constraints). For the Token Tagger module, we find that the attention probabilities usually demarcate the tagged words quite clearly, and that an ϵ value of 0.01 performs reasonably well. We use early stopping based on the (averaged) validation accuracy of the sentence-level predictions. We also observe that fine-tuning the BERT model requires learning rates comparable in order of magnitude to those used in Devlin et al. (2018), and hence use

a learning rate of 2e-7 for fine-tuning the transformer layers, and 1e-3 for the rest of the network. More details related to the hyperparameters used are presented in Appendix A. All our models have been implemented using the AllenNLP framework (Gardner et al., 2017).

5 Results and Analysis

Type	Model	F-score	Acc
S	(Lample et al., 2016)	90.9	-
	(Peters et al., 2018)	92.2	-
	(Devlin et al., 2018)	92.8	-
US	(Carlson et al., 2009)	55.3	-
WS	BERT + PS	65.8	95.5
	BERT(FT) + PS	68.4	95.5
	BERT + GRU + PS	79.2	95.5
	BERT(FT) + GRU	80.7	95.6
	BERT(FT) + GRU + PS	81.1	95.6

Table 1: Different model performances on the 2003 CoNLL test set. FT denotes fine-tuning, PS denotes probability scaling. S is supervised, US is unsupervised and WS is weakly supervised

Table 1 shows the performance of our model. We observe that our proposed approach significantly outperforms the baseline, and performs reasonably well when compared to various state-of-the-art supervised approaches that use significantly more ground-truth annotation information.

To further investigate the impact of the different components of the model, we ablate our model components (Table 1). We observe that having a contextual GRU layer for adapting to the task has a significant impact on the performance, with the final model performing much better than BERT + PS. Further, fine-tuning and probability scaling also help improve model performance.

5.1 Impact of Stop-Word Removal

We find that the model learns to focus on indicator words that frequently occur in sentences where a particular tag is present, and tends to use them to identify the presence of entities at the sentence level. For example, the word "at" is often indicative of the existence of a location in a sentence, the name of the location itself aside, and the model tends to focus on both. This behaviour is unsurprising, given that the model is trained purely using a signal of whether or not a sentence contains an entity of that type, with no idea about the entity boundaries themselves. Based on what we commonly observe, a few of these indicator words include: prepositions such as "at" and "in" when a LOC entity is present; common titles preceding PER names (such as "President" X or "Miss" Y); conjunctions that might separate two or more entities (such as X "and" Y).

This results in the model picking out spurious words alongside the actual entity, which necessitates the use of stop-word and symbol removal. However, this removal also results in the model not being able to pick out words when they occur within an entity span (for example, "Republic of Iceland"). This is particularly problematic for ORG (4.85% spans have stop-words) and MISC (3.15% spans have stop-words), compared to LOC(0.6%) and PER(0.76%). This issue can potentially be mitigated with either a more sophisticated tagger module or a better stop-word/symbol removal mechanism, which we leave to future work.

5.2 Errors due to Incorrect Entity Boundaries

Model	Text	Type	Micro
(Peters et al., 2018)	95.9	93.8	94.8
BERT(FT) + GRU + PS	84.0	89.0	86.5

Table 2: MUC f-scores for the model

Since our model does not have access to annotated training data, it has no direct supervision for learning entity boundaries. This particularly hurts the model in the CoNLL task, since precision, recall and f-score are measured based on an exact string match. In order to investigate this, we use the metric used in MUC events (Grishman and Sundheim, 1996; Chinchor, 1998), wherein a system is scored on two axes: finding the correct text and the correct type. A text is correct if the entity boundaries are correct, regardless of their type, while a type is correct if an entity is tagged with a correct type, regardless of the boundaries, as long as there is an overlap with the gold type. The final score is a micro average f-measure (see Nadeau and Sekine (2007) for more details).

Table 2 shows the performance of the model along the two axes, as well as the MUC score. We also report the same metrics for the supervised model proposed in Peters et al. (2018). We

Idx	Sentence	Predictions	Gold
0	@0@ Neal Lancaster , Dave Barr (Canada) , Mike Sullivan , Willie	LOC PER	LOC PER
1	@0@. Fatima Yusuf (Nigeria) @0@.@0@	LOC PER	LOC PER

3	" The world community should not be indifferent to the fact that President Lukashenko , who leads this European state of @0@ million people , is trying to establish a dictatorship with his new constitution , " Sharetsky said .	MISC PER	MISC PER
4	" I would like to thank the Eagles organisation and the wonderful fans of Philadelphia for supporting me throughout my career , " Cunningham said .	LOC ORG PER	ORG PER
5	June @0@-@0@ v Hampshire (three days)	LOC	ORG

Figure 3: Qualitative Analysis (Best viewed in color) PER, LOC, MISC, ORG. The Gold column shows the gold tags contained in the sentence while the Predictions column contains the tags predicted by the model. Tags in green are correctly predicted, while those in red are incorrect.

see that the model primarily loses out on the text based measure, and performs quite well on the type based one. This is in accordance with our hypothesis that the model identifies the correct entities, but fails at finding the exact entity boundaries. A better boundary detection method can consequently be used alongside our model to improve the entity retrievals in a downstream task.

5.3 Qualitative Analysis

Fig 3 shows examples of where our proposed model performs well, and where it fails. Examples 0, 1 and 2 show when the model is correctly able to identify the entity classes persons, locations and miscellaneous. Examples 3, 4 and 5 show some of the shortcomings. As described in 5.1, indicator tokens like President (Example 3) are usually marked as the PER entity type, which gets penalized when compared to the gold labels. Another common failure case we observe is when outside domain knowledge is necessary to disambiguate the entity type. For example, in Example 4, the model predicts Philadelphia as LOC, while the correct tag is ORG (referring to the Philadelphia Eagles). Similarly, in Example 5, the model classifies Hampshire as LOC, while the correct tag is ORG (the cricket club).

6 Conclusion

We present a novel method for entity recognition using a relatively weak supervision signal. Our proposed model, trained on a multi-label classification task, achieves reasonable entity recognition performance.

While our proposed method is simple, we demonstrate that it works surprisingly well. Various other formulations for this task are possible: for example, one might involve marginalizing over the tags and using this for predicting a label; another could perform attention over spans instead of tokens. We plan on investigating these alternate approaches in future work.

Acknowledgments

We would like to thank the anonymous reviewers for their invaluable feedback, which helped shaped the paper into its current form. We would also like to thank Matthew R. Gormley for the helpful discussions on the topic.

Revealing and Predicting Online Persuasion Strategy with Elementary Units

Gaku Morio and **Ryo Egawa** and **Katsuhide Fujita**

katfuji@cc.tuat.ac.jp

Abstract

In online arguments, identifying how users construct their arguments to persuade others is important in order to understand a persuasive strategy directly. However, existing research lacks empirical investigations on highly semantic aspects of elementary units (EUs), such as propositions for a persuasive online argument. Therefore, this paper focuses on a pilot study, revealing a persuasion strategy using EUs. Our contributions are as follows: (1) annotating five types of EUs in a persuasive forum, the so-called *ChangeMyView*, (2) revealing both intuitive and non-intuitive strategic insights for the persuasion by analyzing 4612 annotated EUs, and (3) proposing baseline neural models that identify the EU boundary and type. Our observations imply that EUs definitively characterize online persuasion strategies.

The annotated dataset, annotation guideline, and implementation of the neural model are available in public.[1]

1 Introduction

Persuasive discourses are common in social media. Recently, the automatic identification of such persuasive discourse is receiving attention in the field of computational linguistics (Habernal and Gurevych, 2016b; Tan et al., 2016; Habernal and Gurevych, 2016a; Persing and Ng, 2017; Musi et al., 2018; Hidey and McKeown, 2018; Ji et al., 2018; Durmus and Cardie, 2019; Gleize et al., 2019). Existing studies have examined persuasive arguments with regard to dynamics or lexical features (Tan et al., 2016), claim and premise analysis (Musi and Aakhus, 2018), and concessions (Musi et al., 2018). However, to the best of our knowledge, fine-grained analyses with an **elementary unit (EU)** semantic, such as propositions, are still in their infancy, although we estimate that EUs are important in obtaining the persuasion strategy. Also, existing studies do not extract token-level EUs via machine learning, which would be a basic step for an automatic understanding of the strategy.

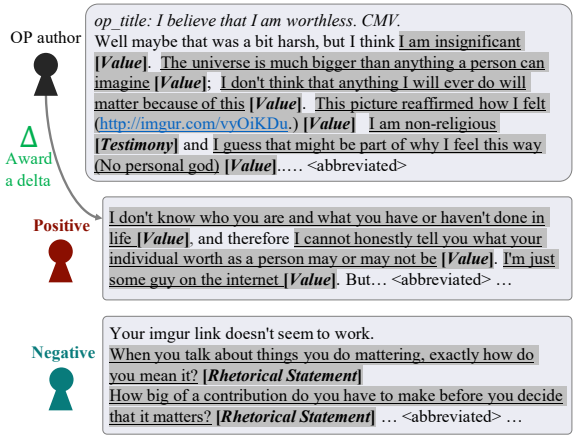

Figure 1: Overview of our EU annotation in *ChangeMyView*. We observed that Testimonies tend to appear in an original post (OP) (see Section 4.)

Therefore, this paper shows the fundamental role of EUs in a persuasive forum by annotating five types of token-level EUs (i.e., Testimony, Fact, Value, Policy, and Rhetorical Statement) in a persuasive forum and also provides a baseline neural model to identify the EUs automatically.[2]

In this study, we use the effective dataset of *ChangeMyView* (Tan et al., 2016), which is a subreddit where original post (OP) users provide a controversial view in the title to change their

[1]Dataset and annotation guideline: http://katfuji.lab.tuat.ac.jp/nlp_datasets/. Implementation: https://github.com/EdoFrank/emnlp2019_morio_egawa

[2]Although we use the partial data of the previous study (Egawa et al., 2019), this work is distinct from the previous one because we focus on the novel analysis of EUs and a novel task to predict EUs. See Section 4 and 5.

perspective through opponent users' arguments. OP users award a delta (Δ) point when their view is changed. Figure 1 presents an overview of *ChangeMyView* where the positive post is an awarded post and the negative post is a non-awarded one.

Our analyses to find out the role of EUs in *ChangeMyView* show both intuitive and non-intuitive phenomena (Section 4.) We also inject a structural feature into the neural model to improve the performance; the results show that EUs have characteristic positional roles (Section 5.)

2 Related Work

EUs have been considered in investigating the characteristics of argumentation in an argument mining discipline. Park et al. (2015); Park and Cardie (2018) deemed Testimony to be a type of objective evidence using personal state or experience. Al Khatib et al. (2016) proposed the argument model for analyzing the strategy of a news editorial. The model considers token-level discourse units of six different types. The study that is most closely related to our research is (Hidey et al., 2017) because it annotated semantic types of claims and premises in *ChangeMyView*; however, the authors did not take objective propositions such as facts into consideration.

Table 1 summarizes the comparison in terms of size, annotation granularity level, and inter-annotator agreement (IAA) of the related corpora. The table shows that our corpus is middle sized but has sufficient granularity and the reasonable IAA reliability.

3 Annotating EUs

Typology of EUs

This study considers five types of EUs. For the introduction of the scheme, the motivation is derived from our expectation that we can feature persuasive arguments by considering personal experience, facts (Park and Cardie, 2018) and rhetoric (Blankenship and Craig, 2006). The five types of EUs are defined as follows:

Ⓣ: **Testimony** is an objective proposition related to the author's personal state or experience such as the following: *I do not have children.*

Ⓕ: **Fact** is a proposition describing objective facts that can be verified using objective evidence and therefore captures the evidential facts in persuasions: *Empire Theatres in Canada has a "Reel Babies" showing for certain movies.*

Ⓥ: **Value** is a proposition that refers to subjective value judgments without providing a statement on what should be done: *it is absolutely terrifying.*

Ⓟ: **Policy** offers a specific course of action to be taken or what should be done: *intelligent students should be able to see that.*

Ⓡ: **Rhetorical Statement** implicitly states the subjective value judgment by expressing figurative phrases, emotions, or rhetorical questions: *does it physically hurt men to be raped by women (as in PIV sex)?*

Annotation Process

We extracted 115 *ChangeMyView* threads from the train set of Tan et al. (Tan et al., 2016) through a simple random sampling.[3] Each thread contains a triple of OP, positive, and negative. Therefore, we use 345 posts for the annotation.

EUs are annotated by 19 non-native annotators who are proficient in English, excluding the authors. Three annotators independently annotated 87 threads; the remaining 28 threads were annotated by 8 experts who were selected from the 19 annotators. Each annotator was asked to read the annotation guideline prior to the actual annotation. We also held several meetings to train the annotators and re-annotated the erroneous annotations when required. Given that the annotators are non-native speakers, the posts are translated into their language, and the translated documents are only used as a reference for the annotators. For the 83 threads, a gold standard is established by merging three posts using a majority vote.

We consider the token-level annotation (Stab and Gurevych, 2017), rather than the clause level one, to extract accurate minimal EU boundary and to remove irrelevant boundaries such as *for example* and *therefore*.

[3]More precisely, 419 threads were randomly extracted from the train data range 2013/01/01–2015/05/07, and the older threads were actually used due to time constraints.

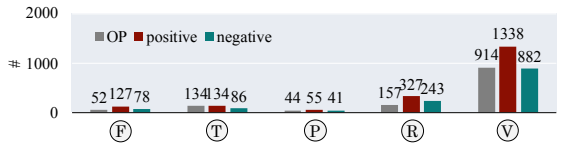

Figure 2: Distribution of the number of EUs. Most of the propositions in *ChangeMyView* are subjective.

	Ⓕ	Ⓣ	Ⓟ	Ⓡ	Ⓥ
OP vs. reply		**		**	
positive vs. negative					

Table 2: Significance of the proportion of EU frequency of *OP vs. reply* and *positive vs. negative*. Significant at $p < 0.01$ if **.

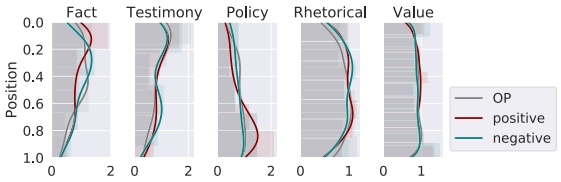

Figure 3: Kernel density estimate plots showing the distribution of EU positions in a post. Fact and Testimony tend to appear in the beginning of the post.

position	MannWhitneyU	KS
0.00 - 0.50	**Ⓕ	*Ⓕ
0.25 - 0.75		
0.50 - 1.00		

Table 3: Significance of the EU position between a positive and negative post. Significant at $p < 0.05$ if *.

Annotation Results

As a result, 4612 EUs are annotated. Figure 2 shows the distribution of the number of EUs. We see that Value dominates in *ChangeMyView*, indicating most of the propositions are subjective.

At the end of the annotation, the IAA of Krippendorff's α_U (Krippendorff, 2004) was .677. Since sentence- or clause-level annotations (Park and Cardie, 2018) cannot accurately distinguish an inference step, we assume that the reasonable agreement is due to the token-level annotation.

4 Strategy Analysis of Persuasion: Revealing the Role of EUs

Frequency of EUs Characterizes OP vs. Reply but Insignificant for Positive vs. Negative

Table 2 shows the significance of the proportion of each EU type for the post types, namely, *OP vs. reply (positive and negative)* and *positive vs. negative*. Given that the proportion is a real value, the Mann–Whitney U test is employed. A significant difference exists in Testimony in OP vs. reply and Rhetorical Statements in OP vs. reply. Therefore, OP authors are likely to assert their view with experiences, i.e., OP: *For many years, I've regularly skipped breakfast.* It is also intuitive that Rhetorical Statement exists to a high degree in persuasion (reply) posts because its strategy is for the persuasion.

In contrast, no significance is observed in a positive vs. negative case in Table 2. Although Habernal and Gurevych (2016b) stated that facts appear in persuasive comments, our result of Facts is insignificant as well as non-intuitive. We assume that this is because users are persuaded by effective indications of EUs, rather than simply presenting objective statements.

Positional Role of EUs is Characteristic

To examine the positional role of EUs as a persuasion strategy, we investigate the position with a one-dimensional axis, that is, a normalized position wherein the beginning of a post is 0.0 and the end is 1.0. Figure 3 shows the resulting histogram of the positions for each EU type. It presents the characteristic distributions: Fact and Testimony are possibly located at the beginning of the post, e.g., positive: *Eating first thing in the morning stabilizes blood sugar levels, which regulates appetite and energy*, indicating the persuasion strategy to state solid facts prior to claiming assertion. Moreover, a Policy appeared at the bottom, indicating that what should be done is regarded as a conclusion, e.g., negative: *Just keep in mind that eating breakfast may increase your ability to concentrate, even if you think you are doing ok right now*. Value is the type that dominates in most posts, and it appears in uniform distribution.

The statistical tests were performed to determine the existence of a difference between a positive and negative in terms of the position. In general, given that addressing the entire positions simultaneously could simplify the property, we set the window size to 0.5 and investigated three ranges as follows: beginning $(0.00 - 0.50)$, middle $(0.25 - 0.75)$, and end $(0.50 - 1.00)$. For each window, we employed the Mann–Whitney U test and Kolmogorov-Smirnov (KS) significance for the average positions in threads which have at least five propositions, as described in Table 3.

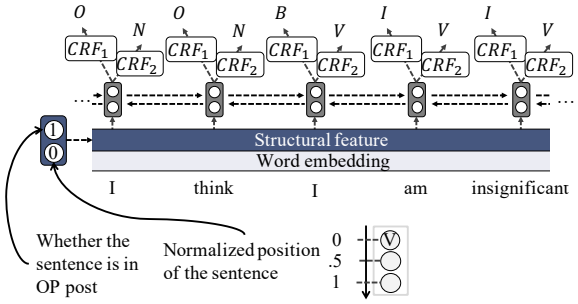

Figure 4: BiLSTM-CRF with structural features.

The table shows that the average position at the beginning of the post has significant differences in Fact.

5 Neural EU Extraction to Automatically Obtain the Strategy

In practice, we have to extract EUs computationally to obtain the strategy automatically. We consider the EU extraction problem as a sequence tagging problem in analogy using a related argument mining work (Eger et al., 2017; Habernal and Gurevych, 2017). The sequence tagging problem involves labeling each token in an input document. In each time step i, the label $y_i \in \mathcal{Y}$, where each token is associated with this label, is predicted as follows: $\mathcal{Y} = \{(b,t) \mid b \in \{B,I,O\}, t \in \{F,T,P,R,V,N\}\}$, where b denotes the unit identification whether the current token is non-EU (O), begins (B), or continues (I) an EU. In addition, t is the unit classification, i.e., Non-EU (N), Fact (F), Testimony (T), Policy (P), Rhetorical Statement (R), and Value (V).

The Multi-task Learning Approach

We employed neural multi-task learning (MTL) models for the sequence tagging problem because several existing argument mining studies achieved advanced performance when the MTL models were used (Schulz et al., 2018). Figure 4 shows the overview of the proposed model . This model comprises two modules. *(i)* The bi-directional LSTM (BiLSTM) module encodes the input tokens in a given document. *(ii)* The module for conditional random fields (CRFs) for each subtask (unit identification and classification) is applied to execute label classification, denoted by the layers toward the top of Figure 4. We call our model BiLSTM-CRF (BLC).

(i) Module of the BiLSTM

In our model, LSTMs were used to encode the input tokens. We employed the BiLSTM that uses two LSTMs to represent the forward and backward contexts in a sentence. Given an input token representation x_i (i.e., a word embedding vector) at time i, we obtained the context-aware hidden state $h_i = LSTM_F(x_{1:i}) \circ LSTM_B(x_{n:i})$, where n denotes the length of the input tokens.

(ii) Module of the CRFs

This output module discriminates the BIO tag and EU type using the hidden representations generated by the BiLSTM. When a CRF layer was utilized, the past and future tags to predict the present tag are used efficiently. Therefore, the CRF layer is effective for solving a non-independent sequence tagging problem, including BIO tagging, i.e., the label after "B" is obviously "I." Note that we provided an MTL model that shares all the trainable parameters of the BiLSTM module but does not share any parameter of the CRF module for each task.

Experimental Setting

The train and test threads were randomly divided per a ratio of $8:2$, where 30% of the train set is considered to be a development set. Herein, we set up two cases: *post-level*, a case in which an entire post is provided for the input and *sentence-level*, a case in which each sentence is given. The motivation is that the EUs cannot cross over a sentence. However, the sentence-level case would loss structural information. To remedy this problem, we focus on two structural features: whether or not the sentence is in OP post and the normalized position of the sentence in a post.

Each system was trained for 50 iterations with random seeds and the model that exhibited the optimal performance using the development set was selected (Schulz et al., 2018). The hyperparameters of our network are 100-dim GloVe embeddings (Pennington et al., 2014), the hidden layer size 200 for the BiLSTMs, the dropout rate of 0.5, and the optimizer is Adam (Kingma and Ba, 2014).

Results: Overall Performance

Table 4 shows that our proposed sentence-level BLC with structural information performs best regarding macro F1 in either boundary identification or unit classification tasks. The presence of

BLC variant	unit identification				unit classification					
	B	I	O	macro	Ⓥ	Ⓡ	Ⓟ	Ⓣ	Ⓕ	macro
sentence-level + structural	75.4	92.8	62.1	***76.8**	***80.7**	**61.5**	***16.0**	**43.1**	**33.2**	***49.2**
sentence-level	**75.6**	92.8	61.0	76.5	80.2	60.9	13.0	41.3	31.3	47.7
post-level	67.8	**92.9**	***64.7**	75.1	79.9	49.4	2.1	35.3	32.2	43.8

Table 4: Performance of the average F1. Max score if **bold** and significant differences with $p < 0.05$ if *.

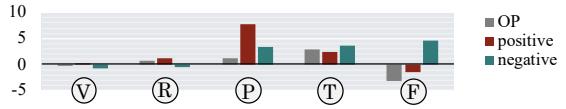

Figure 5: Performance improvement (F1 of a unit classification) by adding the structural features.

structural features provides an excellent boost in classifying unit types. For the post-level BLC, the model yields a better score in predicting non-EU parts because post-level discrimination can capture the entire post and thus identify irrelevant boundaries, such as supplementary notes, in posts.

Results: Analysis of Structural Features

Figure 5 shows the performance improvement by structural features in a distinct experiment from Table 4. In general, we see our structural features perform better for EUs that have characteristic positional distributions such as Policy and Testimony as shown in Figure 3. Interestingly, the structural features did not perform well in Fact classification for OPs and positive posts. The result implies Facts in the OPs and positive posts would be solid and can be predicted without structural information.

6 Conclusion

This paper demonstrated empirical work on the five types of elementary units (EUs) in online arguments. To find out the role of EUs, we annotated 4612 EUs and showed both intuitive and non-intuitive results. We also proposed baseline neural models to discriminate EUs. Experimental results showed that positional roles of some EUs are essential in detecting EUs. The annotated corpus and neural models will be applicable for future persuasion reasoning or evaluation of persuasiveness.

Abstract

Aspect-based sentiment analysis (ABSA) has attracted increasing attention recently due to its broad applications. In existing ABSA datasets, most sentences contain only one aspect or multiple aspects with the same sentiment polarity, which makes ABSA task degenerate to sentence-level sentiment analysis. In this paper, we present a new large-scale Multi-Aspect Multi-Sentiment (MAMS) dataset, in which each sentence contains at least two different aspects with different sentiment polarities. The release of this dataset would push forward the research in this field. In addition, we propose simple yet effective CapsNet and CapsNet-BERT models which combine the strengths of recent NLP advances. Experiments on our new dataset show that the proposed model significantly outperforms the state-of-the-art baseline methods[1].

1 Introduction

Aspect-based sentiment analysis (ABSA) aims at identifying the sentiment polarity towards the specific aspect in a sentence. An target aspect refers to a word or a phrase describing an aspect of an entity. For example, in the sentence "*The decor is not special at all but their amazing food makes up for it*", there are two aspect terms "*decor*" and "*food*", and they are associated with *negative* and *positive* sentiment respectively.

Recently, neural network methods have dominated the study of ABSA since these methods can be trained end-to-end and automatically learn important features. (Wang et al., 2016) proposed to learn an embedding vector for each aspect, and these aspect embeddings were used to calculate the attention weights to capture important information with regard to the given aspects. (Tang et al., 2016b) developed the deep memory network to compute the importance degree and text representation of each context word with multiple attention layers. (Ma et al., 2017) introduced the interactive attention networks (IAN) to interactively learn attentions in contexts and targets, and generated the representations for target and context words separately. (Xue and Li, 2018) proposed to extract sentiment features with convolutional neural networks and selectively output aspect related features for classification with gating mechanisms. Subsequently, Transformer (Vaswani et al., 2017) and BERT based methods (Devlin et al., 2018) have shown high potentials on ABSA task. There are also several studies attempting to simulate the process of human reading cognition to further improve the performance of ABSA (Lei et al., 2019; Yang et al., 2019).

So far, several ABSA datasets have been constructed, including SemEval-2014 Restaurant Review dataset, Laptop Review dataset (Pontiki et al., 2014) and Twitter dataset (Dong et al., 2014). Although these three datasets have since become the benchmark datasets for the ABSA task, most sentences in these datasets consist of only one aspect or multiple aspects with the same sentiment polarity (see Table 1)[2], which makes aspect-based sentiment analysis degenerate to sentence-level sentiment analysis. Based on our empirical observation, the sentence-level sentiment classifiers without considering aspects can still achieve competitive results with many recent ABSA methods (see TextCNN and LSTM in Table 3). On the other hand, even advanced ABSA methods trained on these datasets can hardly distinguish the sentiment polarities towards different aspects in the sentences that contain multiple aspects and multiple sentiments.

Dataset	Type	Categ.	Size	MM_size
Restaurant	ATSA	4	4827	1283
Restaurant	ACSA	4	4738	454
Laptop	ATSA	4	3012	604
Twitter	ATSA	3	6940	6

Table 1: Statistics of existing datasets for ABSA. Size and MM_size represent the total number of instances and multi-apsect multi-sentiment instances in the dataset. Each multi-apsect multi-sentiment instance contains multiple aspects with different sentiment polarities.

With the goal of advancing and facilitating research in the field of aspect-based sentiment analysis, in this paper, we present a new Multi-Aspect Multi-Sentiment (MAMS) dataset. In MAMS dataset, each sentence consists of at least two aspects with different sentiment polarities, making the proposed dataset more challenging compared with existing ABSA datasets. Considering merely the sentence-level sentiment of the sentence will fail to achieve good performance on MAMS dataset. We empirically evaluate the state-of-the-art ABSA methods on MAMS dataset, the poor results demonstrate that the proposed MAMS dataset is more challenging than the SemEval-2014 Restaurant Review dataset.

We analyze the properties of recent ABSA methods, and propose new capsule networks (denoted as CapsNet and CapsNet-BERT) to model the complicated relationship between aspects and contexts, which combine the strengths of recent NLP advances. Experimental results show that the proposed methods achieve significantly better results than the state-of-the-art baseline methods on MAMS and SemEval-14 Restaurant datasets.

Our main contributions are summarized as follows: (1) We manually annotate a large-scale multi-aspect multi-sentiment dataset, preventing ABSA degenerating to sentence-level sentiment analysis. The release of it would push forward the research of ABSA. (2) We propose a novel capsule network based model to learn the complicated relationship between aspects and contexts. (3) Experimental results show that the proposed method achieves significantly better results than the state-of-the-art baseline methods.

2 Dataset Construction

Data Collection Similar to SemEval-2014 Restaurant Review dataset (Pontiki et al., 2014), we annotate sentences from the Citysearch New York dataset collected by (Ganu et al., 2009). We split each document in the corpus into a few sentences, and remove the sentences consisting more than 70 words.

Dataset		Pos.	Neg.	Neu.	Total.
ATSA	Train	3380	2764	5042	11186
	Train (small)	1089	892	1627	3608
	Validation	403	325	604	1332
	Test	400	329	607	1336
ACSA	Train.	1929	2084	3077	7090
	Train (small)	1000	1100	1613	3713
	Validation	241	259	388	888
	Test	245	263	393	901

Table 2: Statistics of MAMS dataset.

Data Annotation We create two versions of MAMS dataset for two subtasks of aspect-based sentiment analysis: aspect-term sentiment analysis (ATSA) and aspect-category sentiment analysis (ACSA).

For ATSA, we invited three experienced researchers who work on natural language processing (NLP) to extract aspect terms in the sentences and label the sentiment polarities with respect to the aspect terms. The sentences that consist of only one aspect term or multiple aspects with the same sentiment polarities are deleted. We also provide the start and end positions in a sentence for each aspect term.

For ACSA, we pre-defined eight coarse aspect categories: *food*, *service*, *staff*, *price*, *ambience*, *menu*, *place* and *miscellaneous*. Five aspect categories are adopted in SemEval-2014 Restaurant Review Dataset. We add three more aspect categories to deal with some confusing situations. Three experienced NLP researchers were asked to identify the aspect categories described in given sentences and determine the sentiment polarities towards these aspect categories. We only keep the sentences which consist of at least two unique aspect categories with different sentiment polarities.

Dataset Analysis The statistics of MAMS dataset for ATSA and ACSA are reported in Table 2. MAMS consists of 13,854 instances for ATSA and 8,879 instances for ACSA, which is 2.87 and 1.87 times of SemEval-2014 Restaurant Review dataset respectively. In MAMS, the sentences contain 2.62 aspect terms and 2.25 aspect categories in average. All sentences in MAMS contains multiple aspects with different sentiment polarities. On the contrary, the ra-

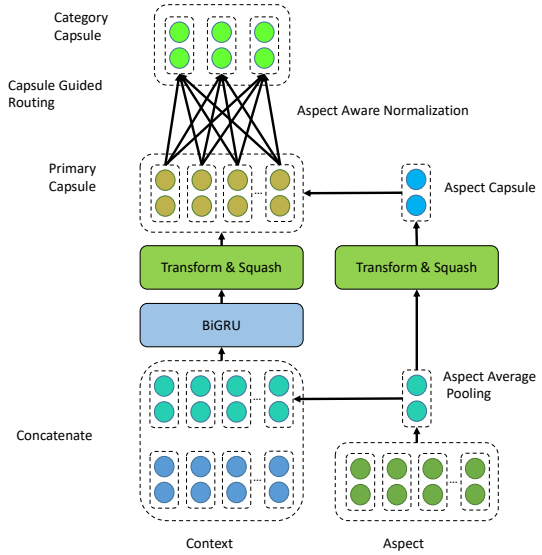

Figure 1: Model overview.

tio of multi-aspect multi-sentiment instances in Restaurant-ATSA, Restaurant-ACSA, Laptop and Twitter datasets are 26.58%, 9.58%, 20.05%, and 0.09% respectively, making the existing datasets less challenging since non-MAMS instances could be classified correctly without effectively modeling the relationships between contexts and aspects. For fair comparison with SemEval-14 Restaurant dataset, we also provide a small version of MAMS dataset (called MAMS-small) by sampling training instances from the MAMS training set, which has the same number of training instances with the SemEval-14 Restaurant dataset.

3 Methodology

We use D to denote the collection of sentences in the training data. Given a sentence $S = \{w_1^s, ..., w_n^s\}$, an aspect term $A^t = \{w_1^a, ..., w_m^a\}$ or an aspect category A^c, aspect-level sentiment classification aims to predict the sentiment polarity $y \in \{1, ..., C\}$ of sentence S with respect to A^t or A^c. Here, w denotes a specific word, n and m are the lengths of the sentence and aspect term, C represents the number of sentiment categories.

As illustrated in Figure 1, the proposed model consists of an embedding layer, an encoding layer, a primary capsule layer and a category capsule layer.

3.1 Embedding Layer

In the embedding layer, we convert the sentence S into word embeddings $\mathbf{E}$. For ACSA task, aspect category embedding $\mathbf{a}$ are randomly initialized and learned during training, while for ATSA task, aspect embedding $\mathbf{a}$ are computed as average pooling over aspect word embeddings. We get the aspect-aware sentence embedding $\mathbf{E}^{sa}$ by concatenating the aspect embedding $\mathbf{a}$ with each word embedding in S: $\mathbf{E}_i^{sa} = [\mathbf{E}_i; \mathbf{a}]$

3.2 Encoding Layer

We convert aspect-aware sentence representation $\mathbf{E}^{sa}$ into contextualized representation $\mathbf{H} = [\mathbf{h}_1, ..., \mathbf{h}_n]$ through bidirectional gated recurrent unit (BiGRU) (Cho et al., 2014) and residual connection (He et al., 2016).

$$\mathbf{H} = \text{BiGRU}(\mathbf{E}^{sa}) + \mathbf{E}^{sa} \quad (1)$$

3.3 Primary Capsule Layer

In the primary capsule layer, we get primary capsules $\mathbf{P} = [\mathbf{p}_i, ...\mathbf{p}_n]$ and aspect capsule $\mathbf{c}$ through linear transformation and squashing activation.

$$\mathbf{p}_i = \text{squash}(\mathbf{W}^p \mathbf{h}_i + \mathbf{b}^p) \quad (2)$$

$$\mathbf{c} = \text{squash}(\mathbf{W}^a \mathbf{a} + \mathbf{b}^a) \quad (3)$$

where $\mathbf{W}^p$, $\mathbf{b}^p$, $\mathbf{W}^a$ and $\mathbf{b}^a$ are learnable parameters. The squash function is defined as:

$$\text{squash}(\mathbf{s}) = \frac{\|\mathbf{s}\|^2}{1 + \|\mathbf{s}\|^2} \frac{\mathbf{s}}{\|\mathbf{s}\|} \quad (4)$$

Aspect Aware Normalization Due to the variable lengths of sentences, the number of primary capsules sent to upper layer capsules varies from sentence to sentence, leading to unstable training procedure. Extremely long sentences make the squash activation saturate and result in high confidence for all categories; while very short sentences in contrast will lead to low confidence for all categories. To alleviate this problem, we propose the aspect aware normalization that utilizes aspect capsule to select important primary capsules, and normalize primary capsule weights $\mathbf{u}$ by:

$$u_i = \frac{\exp(\mathbf{p}_i \mathbf{W}^n \mathbf{c})}{\sum_{j=1}^{n} \exp(\mathbf{p}_j \mathbf{W}^n \mathbf{c})} \quad (5)$$

where $\mathbf{W}^n$ is a learnable parameter.

Capsule Guided Routing Original dynamic routing mechanism (Sabour et al., 2017) suffer from inefficient training due to the iteration procedure of routing. And there is no upper layer information used to guide the routing process, which

makes dynamic routing work like a self-directed process.

Instead of computing coupling coefficients between primary capsules and category capsules during routing process, we design a capsule-guided routing mechanism, which leverages prior knowledge about the sentiment categories to guide the routing process effectively and efficiently. Specifically, we use a set of sentiment capsules to store prior knowledge about the sentiment categories. Let $\mathbf{G} \in R^{C \times d}$ be the sentiment matrix, which is initialized with the averaged embeddings of sentiment words. C is the number of sentiment categories, and d is the dimension of the sentiment embedding. We can get the sentiment capsules $\mathbf{Z} = [\mathbf{z}_1, ..., \mathbf{z}_C]$ by applying squash activation over sentiment matrix and compute the routing weights $\mathbf{w}$ by calculating the similarity between primary capsules and sentiment capsules:

$$\mathbf{z}_i = \text{squash}(\mathbf{G}_i) \tag{6}$$

$$w_{ij} = \frac{\exp(\mathbf{p}_i \mathbf{W}^r \mathbf{z}_j)}{\sum_{k=1}^{n} \exp(\mathbf{p}_i \mathbf{W}^r \mathbf{z}_k)} \tag{7}$$

3.4 Category Capsule Layer

Based on the normalization weights and routing weights, the final category capsules $\mathbf{V} = [\mathbf{v}_1, ..., \mathbf{v}_C]$ can be calculated as:

$$\mathbf{v}_j = \text{squash}(s \sum_{i=1}^{n} w_{ij} u_i \mathbf{p}_i) \tag{8}$$

where s is a learnable scale parameter to scale the connection weights to a suitable level.

Following (Sabour et al., 2017), we use the margin loss as loss function for aspect-based sentiment classification:

$$L = \sum_{k=1}^{C} T_k \max(0, m^+ - \|\mathbf{v}_k\|)^2 + \lambda(1 - T_k) \max(0, \|\mathbf{v}_k\| - m^-)^2 \tag{9}$$

where $T_k = 1$ if and only if a category k is present. m^+ and m^- are the margin hyper-parameters. λ control the loss for absent categories. In our experiments, m^+, m^- and λ is set to 0.9, 0.1, 0.6, respectively.

3.5 CapsNet-BERT

To utilize the features learned from large-scale corpus, we design the CapsNet-BERT model which combines the strength of BERT and capsule networks. We replace the embedding layer and encoding layer of CapsNet with pre-trained BERT. The CapsNet-BERT model takes "[CLS] sentence [SEP] aspect [SEP]" as input, which computes the deep representations of sentences and aspects with pre-trained BERT. We then feed the sentence and aspect representations into capsule layers and predict the corresponding sentiment polarities.

4 Experiments

4.1 Experimental Setup

Experimental Data In order to evaluate the effectiveness of our model, we conduct experiments on the two MAMS datasets and SemEval-14 Restaurant Review (Pontiki et al., 2014) dataset. All models share the same data pre-processing procedure, and use the same pre-trained word embeddings.

Baseline Methods We compare CapsNet with various baselines. (1) LSTM based models: TD_LSTM (Tang et al., 2016a), AT_LSTM (Wang et al., 2016), ATAE_LSTM (Wang et al., 2016), BiLSTM enhanced with attention mechanism, IAN (Ma et al., 2017) and AOA_LSTM (Huang et al., 2018); (2) CNN based model: GCAE (Xue and Li, 2018); (3) Attention based models: MemNet (Tang et al., 2016b) and AEN (Song et al., 2019). To verify the effectiveness of combining capsule networks and BERT, we also compare the performance of CapsNet-BERT with vanilla BERT model. Vanilla BERT model adopts "[CLS] sentence [SEP] aspect [SEP]" as input and predicts the sentiment polarity of the sentence towards the given aspect.

Implementation Details In all experiments, we use 300-dimentional word vectors pre-trained by GloVe (Pennington et al., 2014) to initialize the word embedding vectors for non-BERT models. The capsule size is set to 300. The batch sizes are set to 64 and 32 for CapsNet and CapsNet-BERT respectively. We use Adam optimizer (Kingma and Ba, 2015) to train our models. The learning rates are set to 0.0003 and 0.00003 for CapsNet and CapsNet-BERT respectively. We run all models for 5 times and report the average results on the test datasets. We fine-tune the hyper-parameters for all baselines on the validation set.

Method	ATSA			ACSA

Table 3: Experimental results on two MAMS datasets and SemEval-2014 Restaurant Review dataset for both ATSA and ACSA subtasks.

4.2 Experimental Results and Analysis

Experimental results are reported in Table 3. From Table 3 we draw the following conclusions. First, sentence-level sentiment classifiers (TextCNN and LSTM) achieve competitive results on SemEval-14 Restaurant Review dataset but perform poorly on MAMS datasets. This verifies that MAMS datasets can alleviate the task degeneration problem encountered in Restaurant dataset for ABSA. Second, most advanced and complex ABAS methods, which achieve impressive results on Restaurant dataset, perform poorly on the MAMS-small dataset. This verifies that MAMS (small) is more challenging than SemEval-14 Restaurant Review dataset. Third, attention based models without effectively modeling word order (e.g., MemNet and AEN) perform worst on MAMS since they lose word order information and cannot identify which part of context describes the given aspect. Fourth, CapsNet outperforms non-BERT baselines on 4 of 6 datasets, showing the potential of applying capsule networks to aspect-based sentiment analysis task. In addition, CapsNet-BERT performs significantly better than other models including BERT, indicating that combining capsule network and BERT can obtain additional improvement compared to vanilla BERT.

4.3 Ablation Study

To analyze the effectiveness of the proposed capsule-guided routing mechanism, we conduct ablation study that replace capsule-guided routing by dynamic routing in both CapsNet and CapsNet-BERT, resulting in CapsNet-DR and CapsNet-BERT-DR. From Table 3 (last two rows) we can see that capsule-guided routing boosts the performance of CapsNet and CapsNet-BERT on all the datasets.

5 Conclusion

In this paper, we present MAMS, a challenge dataset for aspect-based sentiment analysis, in which each sentence contains multiple aspects with different sentiment polarities. The proposed MAMS dataset could prevent aspect-level sentiment classification degenerating to sentence-level sentiment classification, which might push forward the researches on aspect-based sentiment analysis. In addition, we propose a simple yet effective capsule networks that significantly outperforms compared methods.

Abstract

Deep neural networks (DNNs) can fit (or even over-fit) the training data very well. If a DNN model is trained using data with noisy labels and tested on data with clean labels, the model may perform poorly. This paper studies the problem of learning with noisy labels for sentence-level sentiment classification. We propose a novel DNN model called NETAB (as shorthand for convolutional neural **NET**works with **AB**-networks) to handle noisy labels during training. NETAB consists of two convolutional neural networks, one with a noise transition layer for dealing with the input noisy labels and the other for predicting 'clean' labels. We train the two networks using their respective loss functions in a mutual reinforcement manner. Experimental results demonstrate the effectiveness of the proposed model.

1 Introduction

It is well known that sentiment annotation or labeling is subjective (Liu, 2012). Annotators often have many disagreements. This is especially so for crowd-workers who are not well trained. That is why one always feels that there are many errors in an annotated dataset. In this paper, we study whether it is possible to build accurate sentiment classifiers even with noisy-labeled training data. Sentiment classification aims to classify a piece of text according to the polarity of the sentiment expressed in the text, e.g., *positive* or *negative* (Pang and Lee, 2008; Liu, 2012; Zhang et al., 2018). In this work, we focus on sentence-level sentiment classification (SSC) with labeling errors.

As we will see in the experiment section, noisy labels in the training data can be highly damaging, especially for DNNs because they easily fit the training data and memorize their labels even when training data are corrupted with noisy labels (Zhang et al., 2017). Collecting datasets annotated with clean labels is costly and time-consuming as DNN based models usually require a large number of training examples. Researchers and practitioners typically have to resort to crowdsourcing. However, as mentioned above, the crowdsourced annotations can be quite noisy.

Research on learning with noisy labels dates back to 1980s (Angluin and Laird, 1988). It is still vibrant today (Mnih and Hinton, 2012; Natarajan et al., 2013, 2018; Menon et al., 2015; Gao et al., 2016; Liu and Tao, 2016; Khetan et al., 2018; Zhan et al., 2019) as it is highly challenging. We will discuss the related work in the next section.

This paper studies the problem of learning with noisy labels for SSC. Formally, we study the following problem.

Problem Definition: Given noisy labeled training sentences $S = \{(x_1, y_1), ..., (x_n, y_n)\}$, where $x_i|_{i=1}^n$ is the i-th sentence and $y_i \in \{1, ..., c\}$ is the sentiment label of this sentence, the noisy labeled sentences are used to train a DNN model for a SSC task. The trained model is then used to classify sentences with clean labels to one of the c sentiment labels.

In this paper, we propose a convolutional neural **NET**work with **AB**-networks (NETAB) to deal with noisy labels during training, as shown in Figure 1. We will introduce the details in the subsequent sections. Basically, NETAB consists of two convolutional neural networks (CNNs) (see Figure 1), one for learning sentiment scores to predict 'clean' [1] labels and the other for learning a noise transition matrix to handle input noisy labels. We call the two CNNs A-network and AB-network, respectively. The fundamental here is that (1) DNNs memorize easy instances first and gradu-

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ally adapt to hard instances as training epochs increase (Zhang et al., 2017; Arpit et al., 2017); and (2) noisy labels are theoretically flipped from the clean/true labels by a noise transition matrix (Sukhbaatar et al., 2015; Goldberger and Ben-Reuven, 2017; Han et al., 2018a,b). We motivate and propose a CNN model with a transition layer to estimate the noise transition matrix for the input noisy labels, while exploiting another CNN to predict 'clean' labels for the input training (and test) sentences. In training, we pre-train A-network in early epochs and then train AB-network and A-network with their own loss functions in an alternating manner. To our knowledge, this is the first work that addresses the noisy label problem in sentence-level sentiment analysis. Our experimental results show that the proposed model outperforms the state-of-the-art methods.

2 Related Work

Our work is related to sentence sentiment classification (SSC). SSC has been studied extensively (Hu and Liu, 2004; Pang and Lee, 2005; Zhao et al., 2008; Narayanan et al., 2009; Täckström and McDonald, 2011; Wang and Manning, 2012; Yang and Cardie, 2014; Kim, 2014; Tang et al., 2015; Wu et al., 2017; Wang et al., 2018). None of them can handle noisy labels. Since many social media datasets are noisy, researchers have tried to build robust models (Gamon, 2004; Barbosa and Feng, 2010; Liu et al., 2012). However, they treat noisy data as additional information and don't specifically handle noisy labels. A noise-aware classification model in (Zhan et al., 2019) trains using data annotated with multiple labels. Wang et al. (2016) exploited the connection of users and noisy labels of sentiments in social networks. Since the two works use multiple-labeled data or users' information (we only use single-labeled data, and we do not use any additional information), they have different settings than ours.

Our work is closely related to DNNs based approaches to learning with noisy labels. DNNs based approaches explored three main directions: (1) training DNNs on selected samples (Malach and Shalev-Shwartz, 2017; Jiang et al., 2018; Ren et al., 2018; Han et al., 2018b), (2) modifying the loss function of DNNs with regularization biases (Mnih and Hinton, 2012; Jindal et al., 2016; Patrini et al., 2017; Ghosh et al., 2017; Ma et al., 2018; Zhang and Sabuncu, 2018), and (3) plugging an extra layer into DNNs (Sukhbaatar et al., 2015; Bekker and Goldberger, 2016; Goldberger and Ben-Reuven, 2017; Han et al., 2018a). All these approaches were proposed for image classification where training images were corrupted with noisy labels. Some of them require noise rate to be known a priori in order to tune their models during training (Patrini et al., 2017; Han et al., 2018b). Our approach combines direction (1) and direction (3), and trains two networks jointly without knowing the noise rate. We have used five latest existing methods in our experiments for SSC. The experimental results show that they are inferior to our proposed method.

In addition, Xiao et al. (2015), Reed et al. (2015), Guan et al. (2016), Li et al. (2017), Veit et al. (2017), and Vahdat (2017) studied weakly-supervised DNNs or semi-supervised DNNs. But they still need some clean-labeled training data. We use no clean-labeled data.

3 Proposed Model

Our model builds on CNN (Kim, 2014). The key idea is to train two CNNs alternately, one for addressing the input noisy labels and the other for predicting 'clean' labels. The overall architecture of the proposed model is given in Figure 1. Before going further, we first introduce a proposition, a property, and an assumption below.

Proposition 1 *Noisy labels are flipped from clean labels by an unknown noise transition matrix.*

Proposition 1 is reformulated from (Han et al., 2018a) and has been investigated in (Sukhbaatar et al., 2015; Goldberger and Ben-Reuven, 2017; Bekker and Goldberger, 2016). This proposition shows that if we know the noise transition matrix, we can use it to recover the clean labels. In other words, we can put noise transition matrix on clean labels to deal with noisy labels. Given these, we ask the following question: *How to estimate such an unknown noise transition matrix*?

Below we give a solution to this question based on the following property of DNNs.

Property 1 *DNNs tend to prioritize memorization of simple instances first and then gradually memorize hard instances (Zhang et al., 2017).*

Arpit et al. (2017) further investigated this property of DNNs. Our setting is that simple instances are sentences of clean labels and hard instances are those with noisy labels. We also have the following assumption.

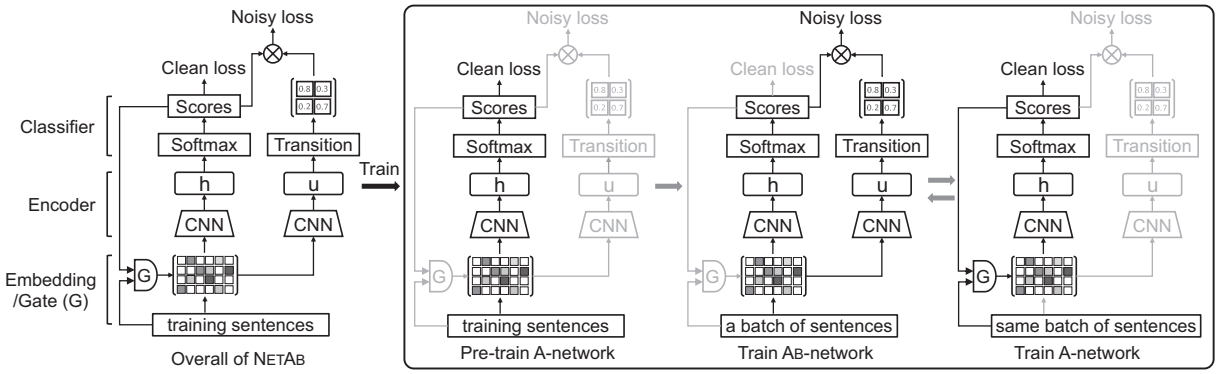

Figure 1: The proposed NETAB model (left) and its training method (right). Components in light gray color denote that these components are deactivated during training in that stage. (Color online)

Assumption 1 *The noise rate of the training data is less than* 50%.

This assumption is usually satisfied in practice because without it, it is hard to tackle the input noisy labels during training.

Based on the above preliminaries, we need to estimate the noisy transition matrix $Q \in \mathbb{R}^{c\times c}$ ($c = 2$ in our case, i.e., *positive* and *negative*), and train two classifiers $\ddot{y} \sim P(\ddot{y}|x,\theta)$ and $\widehat{y} \sim P(\widehat{y}|x,\vartheta)$, where x is an input sentence, $\ddot{y}$ is its noisy label, $\widehat{y}$ is its 'clean' label, θ and ϑ are the parameters of two classifiers. Note that both $\ddot{y}$ and $\widehat{y}$ here are the prediction results from our model, not the input labels. We propose to formulate the probability of the sentence x labeled as j with

$$P(\ddot{y}=j|x,\theta)=\sum_i P(\ddot{y}=j|\widehat{y}=i)P(\widehat{y}=i|x,\vartheta) \tag{1}$$

where $P(\ddot{y}=j|\widehat{y}=i)$ is an item (the ji-th item) in the noisy transition matrix Q. We can see that the noisy transition matrix Q is exploited on the 'clean' scores $P(\widehat{y}|x,\vartheta)$ to tackle noisy labels.

We now present our model NETAB and introduce how NETAB performs Eq. (1). As shown in Figure 1, NETAB consists of two CNNs. The intuition here is that we use one CNN to perform $P(\widehat{y}=i|x,\vartheta)$ and use another CNN to perform $P(\ddot{y}=j|x,\theta)$. Meanwhile, the CNN performing $P(\ddot{y}=j|x,\theta)$ estimates the noise transition matrix Q to deal with noisy labels. Thus we add a transition layer into this CNN.

More precisely, in Figure 1, the CNN with a clean loss performs $P(\widehat{y}=i|x,\vartheta)$. We call this CNN the A-network. The other CNN with a noisy loss performs $P(\ddot{y}=j|x,\theta)$. We call this CNN the AB-network. AB-network shares all the parameters of A-network except the parameters from the Gate unit and the clean loss. In addition, AB-network has a transition layer to estimate the noisy transition matrix Q. In such a way, A-network predict 'clean' labels, and AB-network handles the input noisy labels.

We use cross-entropy with the predicted labels $\ddot{y}$ and the input labels y (given in the dataset) to compute the noisy loss, formulated as below

$$\mathcal{L}_{noisy}=-\frac{1}{|\ddot{S}|}\sum_{x\in\ddot{S}}\sum_i \mathbb{I}(y=i|x)\log P(\ddot{y}=i|x) \tag{2}$$

where $\mathbb{I}$ is the indicator function (if $y==i$, $\mathbb{I}=1$; otherwise, $\mathbb{I}=0$), and $|\ddot{S}|$ is the number of sentences to train AB-network in each batch.

Similarly, we use cross-entropy with the predicted labels $\widehat{y}$ and the input labels y to compute the clean loss, formulated as

$$\mathcal{L}_{clean}=-\frac{1}{|\widehat{S}|}\sum_{x\in\widehat{S}}\sum_i \mathbb{I}(y=i|x)\log P(\widehat{y}=i|x) \tag{3}$$

where $|\widehat{S}|$ is the number of sentences to train A-network in each batch.

Next we introduce how our model learns the parameters (ϑ, θ and Q). An embedding matrix v is produced for each sentence x by looking up a pre-trained word embedding database (e.g., GloVe.840B (Pennington et al., 2014)). Then an encoding vector $h=CNN(v)$ (and $u=CNN(v)$) is produced for each embedding matrix v in A-network (and AB-network). A sofmax classifier gives us $P(\hat{y}=i|x,\vartheta)$ (i.e., 'clean' sentiment scores) on the learned encoding vector h. As the noise transition matrix Q indicates the transition values from clean labels to noisy labels, we com-

	#Noisy Training Data	#Clean Training Data	#Validation Data	#Test Data
Movie	13539P, 13350N	4265P, 4265N	105P, 106N	960P, 957N
Laptop	9702P, 7876N	1064P, 490N	33P, 20N	298P, 175N
Restaurant	8094P, 10299N	1087P, 823N	39P, 14N	339P, 116N

Table 1: Summary statistics of the datasets. Number of positive (P) and negative (N) sentences in (noisy and clean) training data, validation data, and test data. The second column shows the statistics of sentences extracted from the 2,000 reviews of each dataset. The last three columns show the statistics of the sentences in three clean-labeled datasets, see "Clean-labeled Datasets".

pute Q as follows

$$Q = [q_1; q_2] \quad (4)$$

$$q_i = softmax(g_i f_i),\ i = 1, 2 \quad (5)$$

$$g_i = tanh(W_i u + b_i) \quad (6)$$

where W_i is a trainable parameter matrix, b_i and f_i are two trainable parameter vectors. They are trained in the AB-network. Finally, $P(\ddot{y} = j|x, \theta)$ is computed by Eq. (1).

In training, NETAB is trained end-to-end. Based on Proposition 1 and Property 1, we pre-train A-network in early epochs (e.g., 5 epochs). Then we train AB-network and A-network in an alternating manner. The two networks are trained using their respective cross-entropy loss. Given a batch of sentences, we first train AB-network. Then we use the scores predicted from A-network to select some possibly clean sentences from this batch and train A-network on the selected sentences. Specifically speaking, we use the predicted scores to compute sentiment labels by $\arg\max_i\{\ddot{y} = i|\ddot{y} \sim P(\ddot{y}|x, \theta)\}$. Then we select the sentences whose resulting sentiment label equals to the input label. The selection process is marked by a Gate unit in Figure 1. When testing a sentence, we use A-network to produce the final classification result.

4 Experiments

In this section, we evaluate the performance of the proposed NETAB model. we conduct two types of experiments. (1) We corrupt clean-labeled datasets to produce noisy-labeled datasets to show the impact of noises on sentiment classification accuracy. (2) We collect some real noisy data and use them to train models to evaluate the performance of NETAB.

Clean-labeled Datasets. We use three clean labeled datasets. The first one is the movie sentence polarity dataset from (Pang and Lee, 2005). The other two datasets are laptop and restaurant datasets collected from SemEval-2016 [2]. The former consists of laptop review sentences and the latter consists of restaurant review sentences. The original datasets (i.e., Laptop and Restaurant) were annotated with aspect polarity in each sentence. We used all sentences with only one polarity (*positive* or *negative*) for their aspects. That is, we only used sentences with aspects having the same sentiment label in each sentence. Thus, the sentiment of each aspect gives the ground-truth as the sentiments of all aspects are the same.

For each clean-labeled dataset, the sentences are randomly partitioned into training set and test set with 80% and 20%, respectively. Following (Kim, 2014), We also randomly select 10% of the test data for validation to check the model during training. Summary statistics of the training, validation, and test data are shown in Table 1.

Noisy-labeled Training Datasets. For the above three domains (movie, laptop, and restaurant), we collected 2,000 reviews for each domain from the same review source. We extracted sentences from each review and assigned review's label to its sentences. Like previous work, we treat 4 or 5 stars as positive and 1 or 2 stars as negative. The data is noisy because a positive (negative) review can contain negative (positive) sentences, and there are also neutral sentences. This gives us three noisy-labeled training datasets. We still use the same test sets as those for the clean-labeled datasets. Summary statistics of all the datasets are shown in Table 1.

Experiment 1: Here we use the clean-labeled data (i.e., the last three columns in Table 1). We corrupt the clean training data by switching the labels of some random instances based on a noise rate parameter. Then we use the corrupted data to train NETAB and CNN (Kim, 2014).

The test accuracy curves with the noise rates [0, 0.1, 0.2, 0.3, 0.4, 0.5] are shown in Figure 2.

Table 2: Accuracy (ACC) of both classes, F1 (F1_pos) of positive class and F1 (F1_neg) of negative class on clean test data/sentences. Training data are real noisy-labeled sentences.

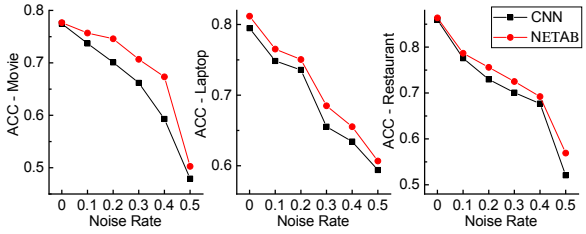

Figure 2: Accuracy (ACC) on clean test data. For training, the labels of clean data are flipped with the noise rates [0, 0.1, 0.2, 0.3, 0.4, 0.5]. For example, 0.1 means that 10% of the labels are flipped. (Color online)

From the figure, we can see that the test accuracy drops from around 0.8 to 0.5 when the noise rate increases from 0 to 0.5, but our NETAB outperforms CNN. The results clearly show that the performance of the CNN drops quite a lot with the noise rate increasing.

Experiment 2: Here we use the real noisy-labeled training data to train our model and the baselines, and then test on the test data in Table 1. Our goal is two fold. First, we want to evaluate NETAB using real noisy data. Second, we want to see whether sentences with review level labels can be used to build effective SSC models.

Baselines. We use one strong non-DNN baseline, NBSVM (with unigrams or bigrams features) (Wang and Manning, 2012) and six DNN baselines. The first DNN baseline is CNN (Kim, 2014), which does not handle noisy labels. The other five were designed to handle noisy labels.

The comparison results are shown in Table 2. From the results, we can make the following observations. (1) Our NETAB model achieves the best ACC and F1 on all datasets except for F1 of negative class on Laptop. The results demonstrate the superiority of NETAB. (2) NETAB outperforms the baselines designed for learning with noisy labels. These baselines are inferior to ours as they were tailored for image classification. Note that we found no existing method to deal with noisy labels for SSC.

Training Details. We use the publicly available pre-trained embedding GloVe.840B (Pennington et al., 2014) to initialize the word vectors and the embedding dimension is 300.

For each baseline, we obtain the system from its author and use its default parameters. As the DNN baselines (except CNN) were proposed for image classification, we change the input channels from 3 to 1. For our NETAB, we follow Kim (2014) to use window sizes of 3, 4 and 5 words with 100 feature maps per window size, resulting in 300-dimensional encoding vectors. The input length of sentence is set to 40. The network parameters are updated using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001. The learning rate is clipped gradually using a norm of 0.96 in performing the Adam optimization. The dropout rate is 0.5 in the input layer. The number of epochs is 200 and batch size is 50.

5 Conclusions

This paper proposed a novel CNN based model for sentence-level sentiment classification learning for data with noisy labels. The proposed model learns to handle noisy labels during training by training two networks alternately. The learned noisy transition matrices are used to tackle noisy labels. Experimental results showed that the proposed model outperforms a wide range of baselines markedly. We believe that learning with noisy labels is a promising direction as it is often easy to collect noisy-labeled training data.

DENS: A Dataset for Multi-class Emotion Analysis

Chen Liu and **Muhammad Osama** and **Anderson de Andrade**
Wattpad
Toronto, ON, Canada
cecilia, muhammad.osama, anderson@wattpad.com

Abstract

We introduce a new dataset for multi-class emotion analysis from long-form narratives in English. The Dataset for Emotions of Narrative Sequences (DENS) was collected from both classic literature available on Project Gutenberg and modern online narratives available on Wattpad, annotated using Amazon Mechanical Turk. A number of statistics and baseline benchmarks are provided for the dataset. Of the tested techniques, we find that the fine-tuning of a pre-trained BERT model achieves the best results, with an average micro-F1 score of 60.4%. Our results show that the dataset provides a novel opportunity in emotion analysis that requires moving beyond existing sentence-level techniques.

1 Introduction

Humans experience a variety of complex emotions in daily life. These emotions are heavily reflected in our language, in both spoken and written forms.

Many recent advances in natural language processing on emotions have focused on product reviews (McAuley et al., 2015) and tweets (Mohammad et al., 2018; Kant et al., 2018). These datasets are often limited in length (e.g. by the number of words in tweets), purpose (e.g. product reviews), or emotional spectrum (e.g. binary classification).

Character dialogues and narratives in storytelling usually carry strong emotions. A memorable story is often one in which the emotional journey of the characters resonates with the reader. Indeed, emotion is one of the most important aspects of narratives. In order to characterize narrative emotions properly, we must move beyond binary constraints (e.g. good or bad, happy or sad).

In this paper, we introduce the Dataset for Emotions of Narrative Sequences (DENS) for emotion analysis, consisting of passages from long-form fictional narratives from both classic literature and modern stories in English. The data samples consist of self-contained passages that span several sentences and a variety of subjects. Each sample is annotated by using one of 9 classes and an indicator for annotator agreement.

2 Background

Using the categorical basic emotion model (Plutchik, 1979), (Mohammad and Kiritchenko, 2015; Mohammad, 2012) studied creating lexicons from tweets for use in emotion analysis. Recently, (Mohammad et al., 2018), (Klinger et al., 2018) and (Kant et al., 2018) proposed shared-tasks for multi-class emotion analysis based on tweets.

Fewer works have been reported on understanding emotions in narratives. Emotional Arc (Reagan et al., 2016) is one recent advance in this direction. The work used lexicons and unsupervised learning methods based on unlabelled passages from titles in Project Gutenberg[1].

For labelled datasets on narratives, (Alm et al., 2005) provided a sentence-level annotated corpus of childrens' stories and (Kim and Klinger, 2018) provided phrase-level annotations on selected Project Gutenberg titles.

To the best of our knowledge, the dataset in this work is the first to provide multi-class emotion labels on passages, selected from both Project Gutenberg and modern narratives. The dataset is available upon request for non-commercial, research only purposes[2].

3 Dataset

In this section, we describe the process used to collect and annotate the dataset.

3.1 Plutchik's Wheel of Emotions

The dataset is annotated based on a modified Plutchik's wheel of emotions.

The original Plutchik's wheel consists of 8 primary emotions: *Joy, Sadness, Anger, Fear, Anticipation, Surprise, Trust, Disgust*. In addition, more complex emotions can be formed by combing two basic emotions. For example, *Love* is defined as a combination of *Joy* and *Trust* (Fig. 1).

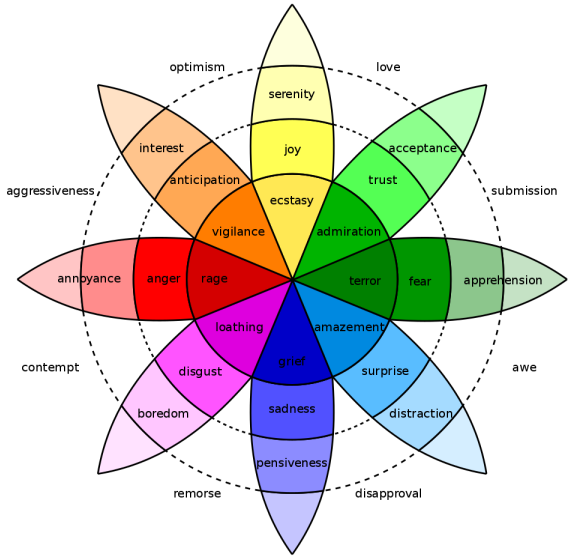

Figure 1: Plutchik's wheel of emotions (Wikimedia, 2011)

The intensity of an emotion is also captured in Plutchik's wheel. For example, the primary emotion of *Anger* can vary between *Annoyance* (mild) and *Rage* (intense).

We conducted an initial survey based on 100 stories with a significant fraction sampled from the romance genre. We asked readers to identify the major emotion exhibited in each story from a choice of the original 8 primary emotions.

We found that readers have significant difficulty in identifying *Trust* as an emotion associated with romantic stories. Hence, we modified our annotation scheme by removing *Trust* and adding *Love*. We also added the *Neutral* category to denote passages that do not exhibit any emotional content.

The final annotation categories for the dataset are: *Joy, Sadness, Anger, Fear, Anticipation, Surprise, Love, Disgust, Neutral*.

3.2 Passage Selection

We selected both classic and modern narratives in English for this dataset. The modern narratives were sampled based on popularity from Wattpad. We parsed selected narratives into passages, where a passage is considered to be eligible for annotation if it contained between 40 and 200 tokens.

In long-form narratives, many non-conversational passages are intended for transition or scene introduction, and may not carry any emotion. We divided the eligible passages into two parts, and one part was pruned using selected emotion-rich but ambiguous lexicons such as *cry, punch, kiss, etc.*. Then we mixed this pruned part with the unpruned part for annotation in order to reduce the number of neutral passages. See Appendix A.1 for the lexicons used.

3.3 Mechanical Turk (MTurk)

MTurk was set up using the standard sentiment template and instructed the crowd annotators to 'pick the best/major emotion embodied in the passage'.

We further provided instructions to clarify the intensity of an emotion, such as: "*Rage/Annoyance* is a form of *Anger*", "*Serenity/Ecstasy* is a form of *Joy*", and "*Love* includes *Romantic/Family/Friendship*", along with sample passages.

We required all annotators have a 'master' MTurk qualification. Each passage was labelled by 3 unique annotators. Only passages with a majority agreement between annotators were accepted as valid. This is equivalent to a Fleiss's κ score of greater than 0.4.

For passages without majority agreement between annotators, we consolidated their labels using in-house data annotators who are experts in narrative content. A passage is accepted as valid if the in-house annotator's label matched any one of the MTurk annotators' labels. The remaining passages are discarded. We provide the fraction of annotator agreement for each label in the dataset.

Though passages may lose some emotional context when read independently of the complete narrative, we believe annotator agreement on our dataset supports the assertion that small excerpts can still convey coherent emotions.

During the annotation process, several annotators had suggested for us to include additional emotions such as confused, pain, and jealousy,

Genre	Distribution (%)
Mystery/Thriller	19.7
Paranormal	16.6
Fantasy	13.2
Horror	11.3
Romance	8.7
Action/Adventure	5.3
Other	9.3

Table 1: Genre distribution of the modern narratives

which are common to narratives. As they were not part of the original Plutchik's wheel, we decided to not include them. An interesting future direction is to study the relationship between emotions such as 'pain versus sadness' or 'confused versus surprise' and improve the emotion model for narratives.

3.4 Dataset Statistics

The dataset contains a total of 9710 passages, with an average of 6.24 sentences per passage, 16.16 words per sentence, and an average length of 86 words.

The vocabulary size is 28K (when lowercased). It contains over 1600 unique titles across multiple categories, including 88 titles (1520 passages) from Project Gutenberg. All of the modern narratives were written after the year 2000, with notable amount of themes in *coming-of-age*, *strong-female-lead*, and *LGBTQ+*. The genre distribution is listed in Table 1.

In the final dataset, 21.0% of the data has consensus between all annotators, 73.5% has majority agreement, and 5.48% has labels assigned after consultation with in-house annotators.

The distribution of data points over labels with top lexicons (lower-cased, normalized) is shown in Table 2. Note that the *Disgust* category is very small and should be discarded. Furthermore, we suspect that the data labelled as *Surprise* may be noisier than other categories and should be discarded as well.

Table 3 shows a few examples labelled data from classic titles. More examples can be found in Table 6 in the Appendix A.2.

4 Benchmarks

We performed benchmark experiments on the dataset using several different algorithms. In all experiments, we have discarded the data labelled with *Surprise* and *Disgust*.

We pre-processed the data by using the SpaCy[3] pipeline. We masked out named entities with entity-type specific placeholders to reduce the chance of benchmark models utilizing named entities as a basis for classification.

Benchmark results are shown in Table 4. The dataset is approximately balanced after discarding the *Surprise* and *Disgust* classes. We report the average micro-F1 scores, with 5-fold cross validation for each technique.

We provide a brief overview of each benchmark experiment below. Among all of the benchmarks, Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) achieved the best performance with a 0.604 micro-F1 score.

Overall, we observed that deep-learning based techniques performed better than lexical based methods. This suggests that a method which attends to context and themes could do well on the dataset.

4.1 Bag-of-Words-based Benchmarks

We computed bag-of-words-based benchmarks using the following methods:

- Classification with TF-IDF + Linear SVM (TF-IDF + SVM)
- Classification with Depeche++ Emotion lexicons (Araque et al., 2018) + Linear SVM (Depeche + SVM)
- Classification with NRC Emotion lexicons (Mohammad and Turney, 2010, 2013) + Linear SVM (NRC + SVM)
- Combination of TF-IDF and NRC Emotion lexicons (TF-NRC + SVM)

4.2 Doc2Vec + SVM

We also used simple classification models with learned embeddings. We trained a Doc2Vec model (Le and Mikolov, 2014) using the dataset and used the embedding document vectors as features for a linear SVM classifier.

4.3 Hierarchical RNN

For this benchmark, we considered a Hierarchical RNN, following (Sordoni et al., 2015). We used two BiLSTMs (Graves et al., 2005) with 256 units

Table 2: Dataset label distribution

Text	Label
I found this was a little too close upon him, but I made it up in what follows. He stood stock-still for a while and said nothing, and I went on thus: "You cannot," says I, "without the highest injustice, believe that I yielded upon all these persuasions without a love not to be questioned, not to be shaken again by anything that could happen afterward. If you have such dishonourable thoughts of me, I must ask you what foundation in any of my behaviour have I given for such a suggestion?"	Angry
She stretched hers eagerly and gratefully towards him. What had happened? Through all the numbness of her blood, there sprang a strange new warmth from his strong palm, and a pulse, which she had almost forgotten as a dream of the past, began to beat through her frame. She turned around all a-tremble, and saw his face in the glow of the coming day.	Anticipation
Ah! That moving procession that has left me by the road-side! Its fantastic colors are more brilliant and beautiful than the sun on the undulating waters. What matter if souls and bodies are failing beneath the feet of the ever-pressing multitude! It moves with the majestic rhythm of the spheres. Its discordant clashes sweep upward in one harmonious tone that blends with the music of other worlds–to complete God's orchestra.	Joy

each to model sentences and documents. The tokens of a sentence were processed independently of other sentence tokens. For each direction in the token-level BiLSTM, the last outputs were concatenated and fed into the sentence-level BiLSTM as inputs.

The outputs of the BiLSTM were connected to 2 dense layers with 256 ReLU units and a Softmax layer. We initialized tokens with publicly available embeddings trained with GloVe (Pennington et al., 2014). Sentence boundaries were provided by SpaCy. Dropout was applied to the dense hidden layers during training.

4.4 Bi-directional RNN and Self-Attention (BiRNN + Self-Attention)

One challenge with RNN-based solutions for text classification is finding the best way to combine word-level representations into higher-level representations.

Self-attention (Yang et al., 2016; Lin et al., 2017; Sinha et al., 2018) has been adapted to text classification, providing improved interpretability and performance. We used (Lin et al., 2017) as the basis of this benchmark.

The benchmark used a layered Bi-directional RNN (60 units) with GRU cells and a dense layer. Both self-attention layers were 60 units in size and cross-entropy was used as the cost function.

Note that we have omitted the orthogonal regularizer term, since this dataset is relatively small compared to the traditional datasets used for training such a model. We did not observe any significant performance gain while using the regularizer term in our experiments.

4.5 ELMo embedding and Bi-directional RNN (ELMo + BiRNN)

Deep Contextualized Word Representations (ELMo) (Peters et al., 2018) have shown recent success in a number of NLP tasks. The unsupervised nature of the language model allows it to utilize a large amount of available unlabelled data in order to learn better representations of words.

We used the pre-trained ELMo model (v2) available on *Tensorhub*[4] for this benchmark. We fed the word embeddings of ELMo as input into a one layer Bi-directional RNN (16 units) with GRU cells (with dropout) and a dense layer. Cross-entropy was used as the cost function.

4.6 Fine-tuned BERT

Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) has achieved state-of-the-art results on several NLP tasks, including sentence classification.

We used the fine-tuning procedure outlined in the original work to adapt the pre-trained uncased $\text{BERT}_{\text{LARGE}}$[5] to a multi-class passage classification task. This technique achieved the best result among our benchmarks, with an average micro-F1 score of 60.4%.

5 Conclusion

We introduce DENS, a dataset for multi-class emotion analysis from long-form narratives in English. We provide a number of benchmark results based on models ranging from bag-of-word models to methods based on pre-trained language models (ELMo and BERT).

Our benchmark results demonstrate that this dataset provides a novel challenge in emotion analysis. The results also demonstrate that attention-based models could significantly improve performance on classification tasks such as emotion analysis.

Interesting future directions for this work include: 1. incorporating common-sense knowledge into emotion analysis to capture semantic context and 2. using few-shot learning to bootstrap and improve performance of underrepresented emotions.

Finally, as narrative passages often involve interactions between multiple emotions, one avenue for future datasets could be to focus on the multi-emotion complexities of human language and their contextual interactions.

Abstract

Stance detection aims to detect whether the opinion holder is in support of or against a given target. Recent works show improvements in stance detection by using either the attention mechanism or sentiment information. In this paper, we propose a multi-task framework that incorporates target-specific attention mechanism and at the same time takes sentiment classification as an auxiliary task. Moreover, we used a sentiment lexicon and constructed a stance lexicon to provide guidance for the attention layer. Experimental results show that the proposed model significantly outperforms state-of-the-art deep learning methods on the SemEval-2016 dataset.

1 Introduction

With the rapid growth of social media, user opinions towards various targets, e.g., politicians and religion, are abundant. These opinions can help optimize management systems and can gain insight into important events, e.g., presidential elections. The stance detection task aims to determine whether people are in favor of, against, or neutral towards a specific target. This task is similar to the three-way aspect-level sentiment analysis that determines sentiment polarity towards aspect terms. However, different from aspect-level sentiment analysis, the target in stance detection might not be explicitly mentioned in a given sentence. Consider the following example tweet: *@realDonaldTrump is the only honest voice of the @GOP and that should scare the shit out of everyone! #SemST.* Target: *Hillary Clinton*; Stance: *Against*; Sentiment: *Positive*. Observe that even though target Hillary Clinton does not appear in this tweet, we can still infer that opinion holder is less likely to be in favor of Hillary Clinton. Therefore, identifying target related information is of vital importance to stance detection.

Previous studies to stance detection used feature engineering (Mohammad et al., 2016b), Convolutional Neural Networks (CNNs) (Vijayaraghavan et al., 2016; Wei et al., 2016) and Recurrent Neural Networks (RNNs) (Zarrella and Marsh, 2016). However, they failed to take target information into considerations. In order to address this issue, several target-specific attention mechanisms (Du et al., 2017; Zhou et al., 2017; Sun et al., 2018) have been proposed to embed target information into sentence representations.

Sentiment information has also been proven to be beneficial to stance detection. For example, Sobhani et al. (2016) found that sentiment lexicon features are useful for stance detection when combined with other features. Instead of directly integrating sentiment features into vector representations, Sun et al. (2018) proposed a hierarchical attention network that learns the importance of sentiment information automatically. Later, Sun et al. (2019) proposed a joint model that determines stance and sentiment simultaneously. However, the attention mechanism is not considered in this model.

Motivated by recent advances in multi-task learning (Liu et al., 2016, 2017; Balikas et al., 2017; Yu et al., 2018; Cohan et al., 2019) and the effectiveness of sentiment information in stance detection (Sobhani et al., 2016; Sun et al., 2018, 2019), we propose an attention-based multi-task framework that takes sentiment classification as an auxiliary task for stance detection. Specifically, we first encode words of input sentences in fixed-length dense vectors (Mikolov et al., 2013; Bojanowski et al., 2017) and then feed them as input to Bidirectional Long Short-Term Memory networks (BiLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997). After that, the attention mechanism (Bahdanau et al., 2015) is used to extract important words for sentiment

representation. Besides, a target-specific attention layer is designed to identify important words related to a given target. The main task incorporates sentiment information by concatenating the outputs of the two attention layers. Moreover, in order to provide guidance to the attention mechanism, sentiment and stance lexicon features are integrated into the final loss. We show that the proposed model, called AT-JSS-Lex, achieves competitive results on the SemEval-2016 dataset (Mohammad et al., 2016a,b, 2017).

Our contributions are summarized as follows: First, we propose a joint sentiment and stance model (AT-JSS-Lex) based on multi-task learning that improves stance detection with the help of sentiment information and integrates both sentiment attention and target-specific attention. Second, we propose a novel formulation of the loss function that uses an existing sentiment lexicon and a stance lexicon, that we specifically constructed for this task, to guide the attention mechanism. As part of our contributions, we will make the stance lexicon publicly available. Finally, we show that the proposed AT-JSS-Lex model achieves remarkable improvements in performance over strong baselines and prior works on the SemEval-2016 stance detection dataset.

2 Model

2.1 Multi-Task Learning Architecture

The overall architecture of the proposed model is shown in Figure 1. For sentiment classification (the auxiliary task), the input sentence ($S = s_1, s_2, ..., s_n$) is first sent to an embedding layer and each word is represented by a dense vector ($X = x_1^{d_1}, x_2^{d_1}, ..., x_n^{d_1}$), where n is the sentence length and d_1 is the dimension of the word embedding. Then, a BiLSTM is used for feature extraction. At time step i, the hidden vector of forward LSTM is calculated based on previous hidden vector h_{i-1} and current input vector x_i, $\overrightarrow{h_i} = LSTM(x_i, \overrightarrow{h_{i-1}})$. The hidden vector $\overleftarrow{h_i}$ of backward LSTM is defined in a similar way. After concatenating the two hidden vectors, we obtain $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$.

We adopt the attention mechanism (Bahdanau et al., 2015) to improve the three-class sentiment classification. Attention weight α_i^1 is computed as:

$$\alpha_i^1 = \frac{exp(e_i)}{\sum_{j=1}^{n} exp(e_j)} \quad (1)$$

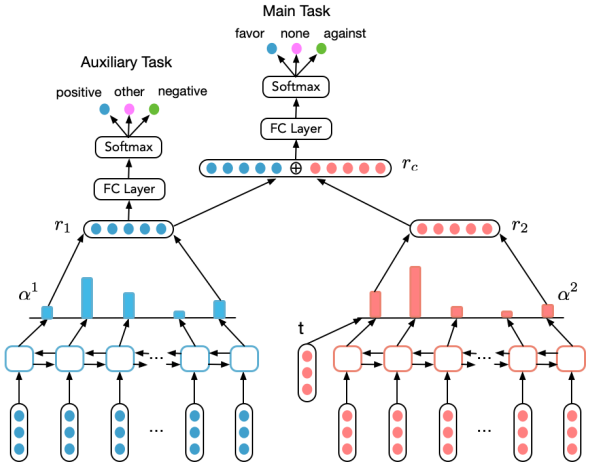

Figure 1: Our multi-task model for stance detection.

where e_i is calculated based on sentence summary vector s, the final hidden vector of BiLSTM, and hidden vector h_i:

$$e_i = v_s^T tanh(W_s s + W_i h_i + b_s) \quad (2)$$

where W_s, $W_i \in \mathbb{R}^{2d_2 \times 2d_2}$ and v_s, $b_s \in \mathbb{R}^{2d_2}$. d_2 is the dimension of hidden units of LSTM. The final vector representation is the weighted sum of hidden vectors:

$$r_1 = \sum_{i=1}^{n} \alpha_i^1 h_i \quad (3)$$

At last, a fully-connected layer and a softmax layer are applied to get label distribution.

Different from the attention layer of auxiliary task, the attention layer of main task integrates target embedding t, similar to (Zhou et al., 2017). The target embedding t is the word embedding of the target word. For example, for target "Abortion," t is the word vector of the word "Abortion." For multi-word targets (e.g., Hillary Clinton), we use the average of the constituent word vectors (e.g., the average of the vectors corresponding to "Hillary" and "Clinton"). Then $e_i^{'}$ can be written as:

$$e_i^{'} = v_t^T tanh(W_t t + W_i^{'} h_i + b_t) \quad (4)$$

where $W_t \in \mathbb{R}^{2d_2 \times d_1}$, $W_i^{'} \in \mathbb{R}^{2d_2 \times 2d_2}$, $t \in \mathbb{R}^{d_1}$, v_t and $b_t \in \mathbb{R}^{2d_2}$. Then, α^2 and r_2 are computed in the same way as Eq. (1) and Eq. (3), respectively. The final vector representation of main task is the concatenation of r_1 and r_2.

In the training stage, cross-entropy loss is used to train the model and the loss function L is defined as follows:

$$L = \lambda L_{main} + (1 - \lambda) L_{aux} \quad (5)$$

Target	#Train	%Favor	%Against	%None	#Test	%Favor	%Against	%None
Atheism	513	17.9	59.3	22.8	220	14.5	72.7	12.7
Climate	395	53.7	3.8	42.5	169	72.8	6.5	20.7
Feminism	664	31.6	49.4	19.0	285	20.4	64.2	15.4
Hillary	689	17.1	57.0	25.8	295	15.3	58.3	26.4
Abortion	653	18.5	54.4	27.1	280	16.4	67.5	16.1
Total	2914	25.8	47.9	26.3	1249	23.1	51.8	25.1

Table 1: Data distribution of SemEval-2016 dataset.

where λ is a hyper-parameter to be tuned, determining the weight of stance detection task. L_{main} and L_{aux} are loss functions of main task and auxiliary task, respectively.

2.2 Lexicon Loss

Previous works showed that the attention mechanism is beneficial for stance detection. However, the attention mechanism does not always work well due to the size of training data and inability to identify target information. In order to address these issues, we propose a reformulation of the loss in Eq. (5) that employs both sentiment and stance lexicons to improve stance detection. Our full model is called AT-JSS-Lex.

We use the sentiment lexicon[1] by Hu and Liu (2004) and construct a stance lexicon[2] (of almost 2,000 words) with words related to the five targets in the SemEval-2016 dataset. Specifically, we construct a stance lexicon for each target from the training data available from the SemEval 2016 dataset and from an extra 1,000 tweets for each target that we collected from Twitter using specific hashtags. For example, for the target "Hillary Clinton," hashtags such as "#Crooked-Hillary," "#hillaryforprison," and "#Hillary2016" are used to collect more tweets. After data collection, we manually extracted the directly related words (e.g., Killary, Shillary, and Hilly) and indirectly related words (e.g., Trump, Benghazi, and abortion) from each tweet. We ended up with around 400 lexicon words for each target.

The intuition of using sentiment and stance lexicons is to provide guidance to the attention layer. Specifically, given an input sentence, we mark sentiment and stance lexicon words as 1 and mark as 0 the remaining words that are not present in any of the two lexicons in order to obtain a lexicon vector lex. For example, the lexicon vector for "Celebrity atheism is beginning to irk me #initforthemoney #SemST" is [0 1 0 0 0 1 0 0 0]. Note that the words "atheism" and "irk" are from the stance and sentiment lexicons, respectively. The final loss from Eq. (5) is then defined as:

$$\begin{aligned} L =& \lambda L_{main} + (1-\lambda) L_{aux} \\ &+ \beta(\alpha_{norm} - lex)^2 \end{aligned} \tag{6}$$

where β is a hyperparameter that determines the importance of lexicon loss and α_{norm} is the normalization of α_{sum}. α_{sum} is the summation of attention weights α^1 and α^2. We normalize the α_{sum} by dividing with the maximum value. Through the minimization of the loss function, ideally, α_{norm} gets closer to lex, i.e., the vector components of α_{norm} get closer to 1 when the corresponding components in lex are 1 (and closer to 0 otherwise), which enforces the model to learn higher attention weights for important words.

3 Experiments and Analysis

3.1 Datasets and Experimental Settings

We use SemEval-2016 Task 6.A to test the performance of our proposed model. This dataset contains five different targets: "Atheism," "Climate Change is a Real Concern" ("Climate"), "Feminist Movement" ("Feminism"), "Hillary Clinton" ("Hillary") and "Legalization of Abortion" ("Abortion"). Table 1 shows the distribution of these targets in the dataset. Each tweet has a stance label ("Favor," "Against" or "None") and a sentiment label ("Positive," "Negative" or "Other").

We sampled about 15% of the training data as validation data to tune the parameters. Word vectors are initialized using fastText word embeddings[3] (Bojanowski et al., 2017) with dimension 300. The size of hidden units in LSTM is set to 200. The dropout rate is 0.5 for dense layer and 0.2 for LSTM layer. The learning rate of Adam optimizer (Kingma and Ba, 2015) is 0.001. The size of the dense layer for the auxiliary task and

Table 2: Performance comparison of stance detection on the SemEval-2016 dataset. The numbers are percentages.

main task is 50 and 100, respectively. λ is 0.7 and β is 0.025 for all targets. L2 regularization is applied to the loss function and the regularization parameter is set to 0.01.

3.2 Evaluation Metrics

F_{avg}, macro-average of F1 score ($MacF_{avg}$) and micro-average of F1 score ($MicF_{avg}$) are adopted to evaluate the performance of proposed model. Firstly, the F1 score of label "Favor" and "Against" is calculated as follows:

$$F_{favor} = \frac{2P_{favor}R_{favor}}{P_{favor} + R_{favor}} \quad (7)$$

$$F_{against} = \frac{2P_{against}R_{against}}{P_{against} + R_{against}} \quad (8)$$

where P and R are precision and recall respectively. Then the F1 average is calculated as:

$$F_{avg} = \frac{F_{favor} + F_{against}}{2} \quad (9)$$

Note that the label "None" is not discarded during training. However, the label "None" is not considered in the evaluation because we are only interested in labels "Favor" and "Against" in this task.

We average the F_{avg} on each target to get $MacF_{avg}$. Moreover, we get $MicF_{avg}$ by calculating F_{favor} and $F_{against}$ across all targets.

3.3 Results

First, an ablation experiment is used to determine the importance of each component of our proposed model for stance detection:

- AT-JSS-Lex is a lexicon integrated multi-task model with attention mechanisms.
- AT-JSS is a model that shares the same architecture with AT-JSS-Lex, but has no lexicon loss.
- JSS is a joint sentiment and stance model similar to AT-JSS, but without the attention mechanisms.
- AT-BiLSTM is a BiLSTM model with stance attention.
- BiLSTM is a single task model that only exploits BiLSTM to detect stance.

Table 2 (top) shows the results of this ablation study. As we can see from the table, AT-JSS-Lex performs best on "Climate," "Feminism," "Hillary," and "Abortion." Moreover, AT-JSS-Lex has the best $MacF_{avg}$ and $MicF_{avg}$ scores when compared with the other models. Experimental results show that $MacF_{avg}$ and $MicF_{avg}$ drop by 0.75% and 0.27% when we remove the lexicon component, indicating that lexicon information contributes to stance detection (except on "Atheism"). Note that AT-JSS-Lex also outperforms AT-BiLSTM model, which shows that the proposed multi-task framework has better performance than single task with attention mechanism.

Second, we compare the proposed model with the following baseline methods (all experimental results of baseline methods are retrieved from original papers):

- SVM-ngram (Mohammad et al., 2016b) is trained by using word n-grams and character n-grams features, surpassing the best model in SemEval-2016 competition.
- JOINT (Sun et al., 2019) is a joint model that exploits sentiment information to improve stance detection task without attention mechanism.
- TAN (Du et al., 2017) is an attention-based LSTM model that extracts important part of given text.

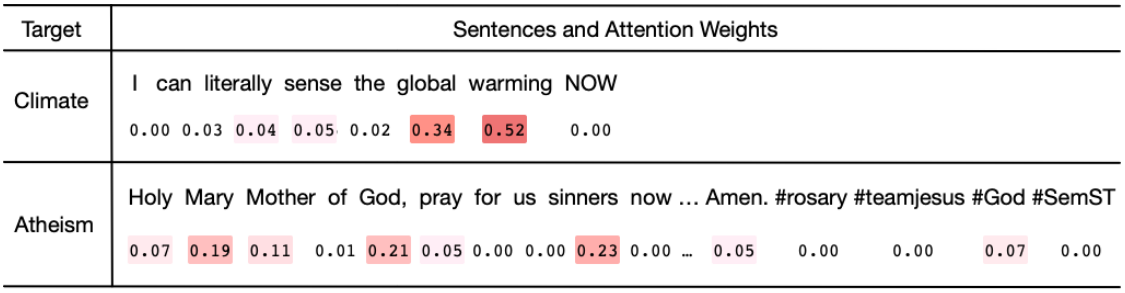

Figure 2: Visualization of learned attention weights.

- AS-biGRU-CNN (Zhou et al., 2017) is another attention-based model that adds CNN layer after attention-based LSTM model to extract target specific features.
- HAN (Sun et al., 2018) is a hierarchical attention model leveraging various linguistic features.
- TGMN-CR (Wei et al., 2018) uses attention and memory modules to extract important information for detecting stance.

Table 2 (bottom) shows the results of this comparison as well. We can observe that AT-JSS-Lex model outperforms all baseline models except on "Atheism." Specifically, the proposed model outperforms JOINT model by 5.17% and 3.11% in $MacF_{avg}$ and $MicF_{avg}$, demonstrating the effectiveness of attention mechanism and lexicon information. In addition, our AT-JSS-Lex model also performs better than attention-based models (TAN, HAN, AS-biGRU-CNN and TGMN-CR), showing that multi-task learning can benefit the stance detection task.

3.4 Attention Visualizations

In Figure 2, we list two input sentences and visualize the attention weights learned during the training process. The color indicates the importance of a word in given sentences, the darker the more important. We can observe that the words "global" and "warming" that are closely related to the target "Climate," have high attention weights in the first sentence. Likewise, in the second sentence, the words "Mary," "Mother," "God," and "sinners," are highlighted and show that the proposed model can pay attention to target-related words.

3.5 Error Analysis

Mislabeled data and compound hashtags are two challenging factors that increase the difficulty of further improving the stance classification. For example, consider the following tweet: *Watch @Dame_Lillard bring the Blazers to the playoff #Beast #SemST.* Target: *Atheism*; Stance: *Against*; Sentiment: *Positive*. Even though the stance label of this tweet is "Against," however, we can observe that the content of this sentence is nothing related to the target.

For SemEval 2016 dataset, sometimes it is hard to predict the stance without considering the compound hashtags. Here is an example: *@Reince This is very credible! Good work! America is desperately in need of good leadership. #VoteGOP #NoHillary #SemST.* Target: *Hillary Clinton*; Stance: *Against*; Sentiment: *Positive*. It would be very difficult to infer the correct stance label if we do not consider the hashtags "#NoHillary" and "#VoteGOP." Therefore, inability to separate compound hashtags results in the loss of important target information.

4 Conclusion and Future Work

In this paper, we propose an attention-based multi-task learning framework and integrate lexicon information to achieve better performance. Experimental results show that our model outperforms state-of-the-art deep learning methods for this task. Moreover, visualization results indicate the capability of our model to capture essential information. Future work includes exploiting unsupervised learning to generate target-related lexicon and incorporating more labels (e.g., emotion classification) for multi-task learning.

Acknowledgments

We thank our reviewers for their valuable comments and feedback that helped improve the quality of our paper. This research is supported by NSF awards 1541155, 1741353 and 1526542 to Cornelia Caragea. The computation for this project was performed on Amazon Web Services.

Abstract

Based on massive amounts of data, recent pretrained contextual representation models have made significant strides in advancing a number of different English NLP tasks. However, for other languages, relevant training data may be lacking, while state-of-the-art deep learning methods are known to be data-hungry. In this paper, we present an elegantly simple robust self-learning framework to include unlabeled non-English samples in the fine-tuning process of pretrained multilingual representation models. We leverage a multilingual model's own predictions on unlabeled non-English data in order to obtain additional information that can be used during further fine-tuning. Compared with original multilingual models and other cross-lingual classification models, we observe significant gains in effectiveness on document and sentiment classification for a range of diverse languages.

1 Introduction

Owing to notable advances in deep learning and representation learning, important progress has been achieved on text classification, reading comprehension, and other NLP tasks. Recently, pretrained language representations with self-supervised objectives (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018) have further pushed forward the state-of-the-art on many English tasks. While these sorts of deep models can be trained on different languages, deep models typically require substantial amounts of labeled data for the specific domain of data.

Unfortunately, the cost of acquiring new custom-built resources for each combination of language and domain is very high, as it typically requires human annotation. Available resources for domain-specific tasks are often imbalanced between different languages. The scarcity of non-English annotated corpora may preclude our ability to train language-specific machine learning models. In contrast, English-language annotations are often readily available to train deep models. Although translation can be an option, human translation is very costly and for many language pairs, any available domain-specific parallel corpora are too small to train high-quality machine translation systems.

Cross-lingual systems rely on training data from one language to train a model that can be applied to other languages (de Melo and Siersdorfer, 2007), alleviating the training bottleneck issues for low-resource languages. This is facilitated by recent advances in learning joint multilingual representations (Lample and Conneau, 2019; Artetxe and Schwenk, 2018; Devlin et al., 2018).

In our work, we propose a self-learning framework to incorporate the predictions of the multilingual BERT model (Devlin et al., 2018) on non-English data into an English training procedure. The initial multilingual BERT model was simultaneously pretrained on 104 languages, and has shown to perform well for cross-lingual transfer of natural language tasks (Wu and Dredze, 2019). Our model begins by learning just from available English samples, but then makes predictions on unlabeled non-English samples and a part of those samples with high confidence prediction scores are repurposed to serve as labeled examples for a next iteration of fine-tuning until the model converges.

Based on this multilingual self-learning technique, we demonstrate the superiority of our framework on Multilingual Document Classification (MLDoc) (Schwenk and Li, 2018) in comparison with several strong baselines. Our study then proceeds to show that our method is better on Chinese sentiment classification than other cross-lingual methods that also consider unla-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6306–6310,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

beled non-English data. This shows that our method is more effective at cross-lingual transfer for domain-specific tasks, using a mix of labeled and unlabeled data via a multilingual BERT sentence model.

2 Method

Our proposed framework consists of three parts as shown in Figure 1. The first part is the pretrained multilingual encoder, denoted as $f_n(\cdot;\theta_n)$. The encoder is assumed to have been pretrained across different languages with appropriate strategies, such as WordPiece, Byte Pair Encoding modeling, and Cross-lingual Word Alignment, to allow the model to share representations across languages to a certain degree. Hence, we obtain a universal sentence representation $\mathbf{h} \in \mathbb{R}^d$ from this encoder, where d is the dimensionality of the sentence representation. Subsequently, a task-specific classification module $f_{\text{cl}}(\cdot;\theta_{\text{cl}})$ is applied for fine-tuning on top of the pretrained model $f_n(\cdot;\theta_n)$. This module consists of a linear function mapping $\mathbf{h} \in \mathbb{R}^d$ into $\mathbb{R}^{|\mathcal{Y}|}$ and a softmax function, where $\mathcal{Y}$ is the set of target classes.

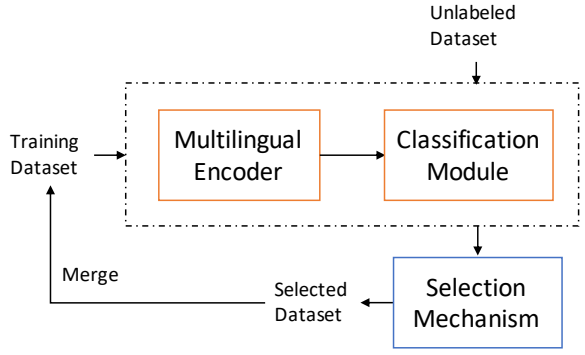

Figure 1: Illustration of self-learning process for cross-lingual classification.

For the overall process, we first train the whole network $f(\cdot;\theta)$ in K epochs using a set of the labeled data $L = \{(x_i, y_i) \mid i = 1, ..., n\}$, where n is the number of labeled instances, $x_i \in \mathcal{X}$ are instances, and $y_i \in \mathcal{Y}$ are the corresponding ground truth labels. The next step is to make predictions for the unlabeled instances in $U = \{x_u \mid u = 1, ..., m\}$. We assume that $f(\cdot;\theta)$ yields a class label as well as a confidence score.

To better take advantage of the pretrained multilingual model, a selection mechanism is invoked to repurpose unlabeled data with high confidence scores for incorporation into the training data. There are several variations of such selection mechanisms (Abney, 2007), and we rely on a *balancing* approach that considers the same number of instances for each class. Thus, we select a subset $\{x_s \mid s = 1, ..., K_t\}$ of the unlabeled data for each class, containing the top K_t highest confidence items based on the current trained model. The union set U_{s} of selected items is merged into the training set L and then we retrain the model and repeat this process iteratively. The detailed process is described in Algorithm 1, where for each class $y \in \mathcal{Y}$, $\mathcal{D}_y$ denotes the set of tuples pairing unlabeled data with corresponding confidence scores c.

Algorithm 1 Self-learning on cross-lingual tasks

repeat
  Fine-tune $f(\cdot;\theta)$ for K epochs using L

    $(y, c) \leftarrow f(x_u;\theta)$
    $\mathcal{D}_y \leftarrow \mathcal{D}_y \cup \{(x_{\text{u}}, c)\}$
  for $y \in \mathcal{Y}$ **do**
    $S_y \leftarrow \underset{S \subseteq \mathcal{D}_y,\ |S| \leq K_t}{\text{argmax}} \sum_{(x_{\text{u}}, c) \in S} c$
    $U \leftarrow U \setminus S_y$
    $U_{\text{s}} \leftarrow U_{\text{s}} \cup S_y$
  $L \leftarrow L \cup U_{\text{s}}$
until stopping criterion is true

3 Experiments

We evaluate our self-learning framework on two cross-lingual document and sentiment classification tasks to show the effectiveness of self-learning for multilingual BERT-based cross-lingual transfer.

3.1 Experimental Setup

Datasets. For evaluation, we first rely on MLDoc (Schwenk and Li, 2018), a balanced subset of the Reuters corpus covering 8 languages for document classification, with 1,000 training and validation documents and 4,000 test documents for each language. The 4-way topic classification scheme consists of CCAT (Corporate/Industrial), ECAT (Economics), GCAT (Government/Social), and MCAT (Markets) as targets. For cross-lingual classification, 1,000 target language training documents are used as unlabeled data for self-learning.

Table 1: Accuracy (in %) on MLDoc experiments. Bold denotes the best on cross-lingual transfer.

Approach	*en*	*de*	*zh*	*es*	*fr*	*it*	*ja*	*ru*

Cross-lingual transfer	
BERT	40.73
Our Approach	**43.88**

We further evaluate our method on cross-lingual sentiment classification from English to Chinese. For English, we use a balanced dataset of 700k Yelp reviews from Zhang et al. (2015) with their ratings as labels (scale 1–5) and adopting their training–validation split: 650k reviews for training and 50k as a validation set. For Chinese, we use the same dataset configuration as Chen et al. (2018), consisting of 150k unlabeled Chinese hotel reviews and 10k balanced Chinese hotel reviews as a validation set. The results are reported on a separate test set of another 10k hotel reviews. The data are also annotated with 5 labels (1–5). Both classification tasks are evaluated in terms of classification accuracy (ACC).

Model Details. We tune the hyper-parameters for our neural network architecture based on each non-English validation set. For the encoder, we invoke the multilingual BERT model (Devlin et al., 2018), which supports 104 languages[1]. It relies on a shared 110k WordPiece vocabulary across all languages and yields sentence representations in a common multilingual space. Most model hyper-parameters are the same as in pretraining, with the exception of the batch size, max. sequence length, and number of training epochs. The batch size, max. sequence length and number of training epochs used for the MLDoc task are 128, 32, and 4, respectively, while they are 128, 96, and 3 for sentiment classification. Another hyper-parameter involved in self-learning is K_t, which is 40 for MLDoc and 100 for sentiment classification. We rely on early stopping as a termination criterion.

[1]2018-11-23 version from https://github.com/google-research/bert/blob/master/multilingual.md

3.2 Results and Analysis

Cross-lingual Document Classification. Three recent strong baselines are included in our MLDoc experiments. Schwenk and Li (2018) use MultiCCA, multilingual word embeddings trained with a bilingual dictionary and convolution neural networks. Artetxe and Schwenk (2018) pretrain a multilingual sentence representation with a massively multilingual sequence-to-sequence NMT model, where the encoder is used for fine-tuning downstream tasks. We also considered multilingual BERT without self-learning as one of our baselines. As shown in Table 1, our framework significantly outperforms all baselines in 7 languages on cross-lingual document classification, including for phylogenetically unrelated languages. We also show the respective percentages of instances added into the training set that are correct for the MLDoc data based on our method in Table 3. The high percentages of correctly labeled incorporated instances in 7 languages further show the effectiveness of self-learning in our framework.

Table 3: Percentages of instances added into the training set that are correct for the MLDoc data using our method.

de	*zh*	*es*	*fr*	*it*	*ja*	*ru*
93%	92 %	89 %	92%	80%	84%	89%

Cross-lingual Sentiment Classification. To evaluate the robustness of our framework on cross-lingual sentiment classification, we consider several diverse baselines as listed in Table 2. mSDA (Chen et al., 2012) is a very effective method for cross-domain sentiment classification on Amazon reviews, which can also be used in cross-lingual tasks, but it has the worst performance. Deep Averaging Networks (DANs) by Iyyer et al. (2015) consider an arithmetic mean of word vectors as a sentence representation and pass it to a classification module, while Chen et al. (2018) translate the Chinese test text into English as a machine translation baseline. The third category of baselines includes Xu and Yang (2017), who propose a cross-lingual distillation (CLD) method that makes use of soft source predictions on a parallel corpus to train a target model (CLD-KCNN). They further propose an improved variant (CLDFA-KCNN) that utilizes adversarial training for domain adaptation within a single language. Adversarial DAN (ADAN) by Chen et al. (2018) is another state of the art baseline that improves cross-lingual generalization by means of adversarial training. We also run experiments on multilingual BERT and observe that it does not outperform CLD-based CLTC and ADAN, while our approach achieves the new state-of-the-art result, indicating that our self-learning method for cross-lingual transfer can be more effective than a diverse range of other approaches. In addition, we evaluate the proximity between incorrect prediction and the corresponding correct label in our sentiment task by means of mean squared error. The error of our method is 1.37, while for regular multilingual BERT it is 1.42, which also shows the superiority of our method.

Comparison of Selection Mechanisms. We ran experiments on two selection mechanisms. One is *balancing*, as described in Section 2. An alternative is *throttling* by selecting the top n unlabeled examples without considering specific classes (Abney, 2007). Our experiments on MLDoc show that the results suffer from a rapid decline during self-learning with *throttling*. This is because selecting from all samples leads to an imbalance between different classes and due to repeated error amplification this means that samples are increasingly likely to be assigned to the majority class in each self-learning iteration.

4 Related Work

Semi-supervised Learning. There is a long history of research on semi-supervised Learning to exploit unlabeled data. Self-learning (also known as self-training) was successfully applied to NLP tasks in early work such as on word sense disambiguation (Yarowsky, 1995) and parsing (McClosky et al., 2006). In recent work, Artetxe et al. (2018) show that self-learning can iteratively improve unsupervised cross-lingual word embeddings. Clark et al. (2018) presents Cross-View Training, a new self-training algorithm that works well for neural sequence modeling. Other semi-supervised methods, such as co-training (Blum and Mitchell, 1998) and tri-training (Zhou and Li, 2005), have as well been used for sentiment analysis. Ruder and Plank (2018) propose a novel multi-task tri-training method that reduces the time and space complexity of classic tri-training for sentiment analysis. For cross-lingual sentiment analysis, Wan (2009) uses machine translation to directly convert English training data to Chinese, which provides two views for co-training. Xu and Yang (2017) propose to use soft probabilistic predictions for the documents in a label-rich language as the (induced) supervisory labels in a parallel corpus of documents, while there is no need to use parallel corpora in our work. Chen et al. (2018) propose an Adversarial Deep Averaging Network to learn invariance across languages, which is another baseline considered in our experiments.

Cross-lingual Representation Learning. With models such as ELMo (Peters et al., 2018), GPT-2 (Radford et al., 2018), and BERT (Devlin et al., 2018), important progress has been made in learning improved sentence representations with context-specific encodings of words via a language modeling objective. The latter two approaches both rely on Transformer encoders, but BERT is trained using masked language modeling instead of right-to-left or left-to-right language modeling. Additionally, BERT also optimizes a next sentence classification objective. Recent work has also investigated cross-lingual extensions. Devlin et al. (2018) themselves published a multilingual version of BERT, following the same model architecture and training procedure, except that the union of 104 different language editions of Wikipedia serves as the training input. Lample and Conneau (2019) incorporate parallel text into BERT's architecture by

training on a new supervised learning objective. Artetxe and Schwenk (2018) also show that the encoder from a pretrained sequence-to-sequence model can be used to produce cross-lingual sentence embeddings. All these methods are compatible with our self-learning framework, since they provide a shared sentence meaning representation across languages as needed by our approach.

5 Conclusion

In this work, we propose a self-learning framework for cross-lingual text classification. Based on the cross-lingual prediction ability of pretrained multilingual model, this elegantly simple framework makes the most of unlabeled text to improve cross-lingual transfer for text classification. We achieve new state-of-the-art results on cross-lingual document and sentiment classification and demonstrate that self-learning is an effective method for improved classification accuracy without target language training data.

Learning to Flip the Sentiment of Reviews from Non-Parallel Corpora

Canasai Kruengkrai
Yahoo Japan Corporation
ckruengk@yahoo-corp.jp

Abstract

Flipping sentiment while preserving sentence meaning is challenging because parallel sentences with the same content but different sentiment polarities are not always available for model learning. We introduce a method for acquiring imperfectly aligned sentences from non-parallel corpora and propose a model that learns to minimize the sentiment and content losses in a fully end-to-end manner. Our model is simple and offers well-balanced results across two domains: Yelp restaurant and Amazon product reviews.[1]

1 Introduction

Text style transfer is the process of editing a sentence to modify specific attributes (e.g., style, sentiment, and tense) while preserving its attribute-independent content (Shen et al., 2017; Fu et al., 2018; Li et al., 2018). In this work, we are particularly interested in sentiment modification. This task is challenging because parallel data (i.e., aligned sentences with the same content but different sentiment polarities) are not always available and they are costly to annotate. Major existing solutions that exploit non-parallel data include training discriminators to guide sentence generation (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018), retrieving similar sentences from another corpus and then editing them (Guu et al., 2018; Li et al., 2018), and applying back-translation (Prabhumoye et al., 2018; Zhang et al., 2018b; Lample et al., 2019).

Achieving both accurate sentiment modification and high content preservation can be difficult. Recently, Li et al. (2018)'s framework has shown promising results. They delete sentiment-specific phrases (e.g., *"works great"*) from a given sentence, retrieve new phrases associated with the target sentiment (e.g, *"barely used"*), and recombine them to generate an output. However, their framework relies on separate modules and assumes that clear boundaries exist between the sentiment-specific phrases and the content, which is not always the case.

(a) the service was great too → the service was n't too great
(b) this one is by far the worst → this one is the best by far

Figure 1: The retrieved sentences (right) from the opposite corpora given the query sentences (left).

In this work, our objective is to develop a model that can be trained end-to-end from sentence pairs acquired from non-parallel corpora. Our approach is based on the observation that *shared* tokens between similar sentences in unaligned corpora convey the content we wish to preserve, while *non-shared* tokens more or less reflect sentiment change. Figure 1 shows the examples of the retrieved sentences from the opposite corpora given the query sentences. Although these sentence pairs are not perfectly aligned, they provide a useful signal of sentiment change and are easy to obtain. By considering the retrieved sentences as the *noisy source* sentences and the query sentences as the *target* sentences, we can extend an encoder-decoder model to learn sentiment modification using auxiliary loss functions.

Our contributions are as follows: We introduce a search-and-corrupt method for creating training data from non-parallel corpora (§3.1). We propose a model that learns to minimize the sentiment and content losses with an alignment constraint in a fully end-to-end manner (§3.2). We empirically show that our model produces more balanced results in terms of sentiment modification and content preservation than more complex models on Yelp restaurant and Amazon product reviews (§4).

2 Related wok

Following a seminal work by Hu et al. (2017), researchers have developed a variety of methods for learning the structured/unstructured parts (i.e., style/content) of latent representations. Hu et al. (2017)'s method is based on the combination of semi-supervised variational autoencoders (Kingma et al., 2014) and the wake-sleep algorithm (Hinton et al., 1995). Shen et al. (2017) utilized an adversarial training method that uses a style discriminator to align the populations of transferred and real target sentences. Other approaches related to disentangled representations include learning multi-decoder/style-embedding models (Fu et al., 2018) and using a language model as the style discriminator (Yang et al., 2018). Our model only has an objective component to align sentence representations. We do not force our model to learn the disentangled representations of style and content. Our work is closely related to classical approaches for discovering parallel sentences in non-parallel corpora (Fung and Cheung, 2004; Munteanu and Marcu, 2005) and prototype-then-edit approaches (Guu et al., 2018). Li et al. (2018) introduced the notion of attribute markers, which are style-specific words/phrases for disentangling style and content in a sentence at the word level. There is also a line of work that studies other aspects of words based on emotional information (Xu et al., 2018; Zhang et al., 2018a). Here, we make no assumption on phrase boundaries between style and content. We simply exploit the local properties of two imperfectly aligned sentences.

3 Proposed method

3.1 Data preprocessing

We derive Yelp restaurant and Amazon product reviews from Li et al. (2018).[2] The original training and validation sets consist of unaligned corpora of positive and negative sentences. Given a sentence in one corpus, we retrieve a similar sentence from another corpus. We use a nearest neighbor search based on MinHash (Broder, 2000) and LSH Forest (Bawa et al., 2005), which are implemented in datasketch.[3] Unlike Li et al. (2018), we do not use pre-computed corpus statistics to delete sentiment-specific words/phrases. We simply filter out punctuation when doing indexing and querying. We do sentence retrieval only in the training/validation data preparation steps.

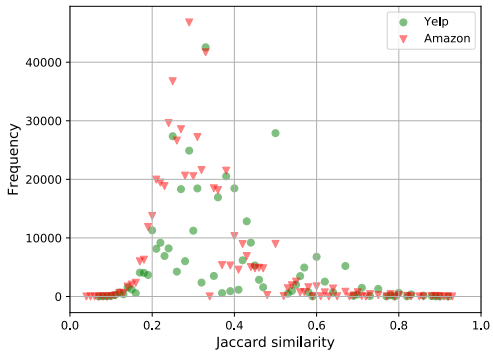

Figure 2: Distribution of Jaccard similarities between the query and retrieved sentences on the Yelp and Amazon training sets.

In the following, we use the sentence pair in Figure 1(a) as a running example. The shared tokens between the two sentences include {*"the"*, *"service"*, *"was"*, *"great"*, *"too"*}, while the token appearing only in the retrieved sentence is *"n't"*. We then consider the retrieved sentence as our noisy source sentence and the query sentence as our target sentence. Transforming the noisy source sentence to the target sentence in this example involves deleting *"n't"* and reordering *"too great"*. The sentiment flipping is obtained as a by-product of this transformation.

A practical issue is that not all the retrieved sentences are as clean as the running example. Figure 2 shows the distribution of Jaccard similarities between the query and retrieved sentences on the Yelp and Amazon training sets. Both domains have a similar characteristic in that the majority of Jaccard similarities is around 0.3. We observe that the sentence pairs with Jaccard similarities below 0.3 typically have different sentence meanings, so we filter them out. On Amazon, we also observe that the sentence pairs with high Jaccard similarities tend to have neutral sentiment. For example, given the query sentence *"my husband bought this for me as a christmas present ."* from the positive corpus, we retrieve the sentence *"i bought this as a christmas present for my husband ."* from the negative corpus with Jaccard similarity 0.82. Both sentences are neutral, which is not useful for learning sentiment flipping. Thus, on Amazon, we further filter out the sentence pairs that have Jaccard similarities exceeding 0.8.

[2] https://github.com/lijuncen/Sentiment-and-Style-Transfer

[3] https://github.com/ekzhu/datasketch

Another issue is that not all the non-shared tokens reflect sentiment change. For example, given the sentence *"very pleasant atmosphere ."*, we retrieve the sentence *"waitress was n't very pleasant ."* having Jaccard similarity 0.33. The non-shared tokens in the retrieved sentence include {*"waitress"*, *"was"*, *"n't"*}. If we directly use this retrieved sentence as the source sentence, our model must learn to delete/add many tokens to minimize the loss. Unfortunately, the tokens like *"waitress"* and *"was"* convey the content that we wish to preserve at test time, while only one token, *"n't"*, is useful for sentiment flipping. To deal with this undesired behavior, we randomly replace 20% of the non-shared tokens in the retrieved sentences having Jaccard similarities less than 0.5 with the $\langle$`mask`$\rangle$ token on both domains. In the example, random replacement of the non-shared tokens yields *"*$\langle$`mask`$\rangle$ *was n't very pleasant ."*. The sentence corruption process should alleviate overchanging the content words at test time. We also apply this technique to learn a sentence reconstructor (detailed in §3.2).

To this end, we can obtain imperfectly aligned sentences with similar content but different sentiment polarities by using our search-and-corrupt method. Assume we have the original training sets $\mathcal{X}=\{\boldsymbol{x}^{(1)},\ldots,\boldsymbol{x}^{(M)}\}$ and $\mathcal{Y}=\{\boldsymbol{y}^{(1)},\ldots,\boldsymbol{y}^{(N)}\}$. Each training set belongs to a different sentiment polarity. Let $\boldsymbol{y}'$ and $\boldsymbol{x}'$ be retrieved, corrupted versions of $\boldsymbol{y}$ and $\boldsymbol{x}$, respectively. Our unified training set becomes $\mathcal{D}=\{(\boldsymbol{y}'^{(i)},\boldsymbol{x}^{(i)})\}_{i=1}^{M}\cup\{(\boldsymbol{x}'^{(i)},\boldsymbol{y}^{(i)})\}_{i=1}^{N}$.

3.2 Model

Having the training set $\mathcal{D}$ in the form of noisy source and target sentences allows us to extend the attention-based encoder-decoder model (Bahdanau et al., 2015) for learning sentiment flipping. Let enc and dec be an encoder and a decoder parameterized by $\boldsymbol{\theta}_{\text{enc}}$ and $\boldsymbol{\theta}_{\text{dec}}$, respectively. Our model first contains the sentiment loss:

$$\mathcal{L}_{\text{sentiment}}(\boldsymbol{\theta}_{\text{enc}},\boldsymbol{\theta}_{\text{dec}}) = \frac{1}{M}\sum_{i=1}^{M} -\log p_{\text{dec}}(\boldsymbol{x}^{(i)}|\text{enc}(\boldsymbol{y}'^{(i)}),\boldsymbol{s}_x) + \frac{1}{N}\sum_{i=1}^{N} -\log p_{\text{dec}}(\boldsymbol{y}^{(i)}|\text{enc}(\boldsymbol{x}'^{(i)}),\boldsymbol{s}_y)]. \quad (1)$$

This loss is the combination of the standard negative log-likelihood losses. The only new components here are the two sentiment embeddings $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$. In practice, we represent them with two randomly initialized vectors. We add each of them to the affine transformation of the hidden layer before applying the softmax in the decoder. These sentiment embeddings should help in shifting the probability distribution over the target tokens.

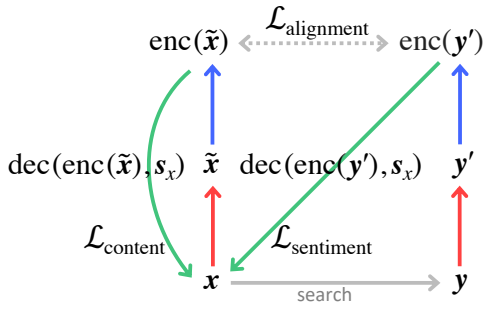

Figure 3: Workflow of the proposed method. Red arrows denote sentence corruption; blue arrows denote encoding; green arrows denote decoding.

We then randomly replace 20% of the tokens in the target sentence with the $\langle$`mask`$\rangle$ token and use the corrupted target sentence as its own source sentence. This process should guide the model to learn to reconstruct itself from its corrupted version (denoted by $\tilde{\boldsymbol{x}}$ and $\tilde{\boldsymbol{y}}$) and hopefully to retain the content. We design our content loss as follows:

$$\mathcal{L}_{\text{content}}(\boldsymbol{\theta}_{\text{enc}},\boldsymbol{\theta}_{\text{dec}}) = \frac{1}{M}\sum_{i=1}^{M} -\log p_{\text{dec}}(\boldsymbol{x}^{(i)}|\text{enc}(\tilde{\boldsymbol{x}}^{(i)}),\boldsymbol{s}_x) + \frac{1}{N}\sum_{i=1}^{N} -\log p_{\text{dec}}(\boldsymbol{y}^{(i)}|\text{enc}(\tilde{\boldsymbol{y}}^{(i)}),\boldsymbol{s}_y)]. \quad (2)$$

This loss is in the same form as Eq. (1) except that here we change the encoder input from the retrieved, corrupted sentence to the corrupted target sentence. Our idea is somewhat analogous to that of denoising autoencoders (Vincent et al., 2010; Bengio et al., 2013), in which a Gaussian noise is added to a continuous-valued input and the model learns to reconstruct a clean input.

To encourage the model to make more use of the sentiment embeddings, we use the following loss as a constraint:

$$\mathcal{L}_{\text{alignment}}(\boldsymbol{\theta}_{\text{enc}}) = \frac{1}{M}\sum_{i=1}^{M}||\text{enc}(\boldsymbol{y}'^{(i)}) - \text{enc}(\tilde{\boldsymbol{x}}^{(i)})||_2^2 + \frac{1}{N}\sum_{i=1}^{N}||\text{enc}(\boldsymbol{x}'^{(i)}) - \text{enc}(\tilde{\boldsymbol{y}}^{(i)})||_2^2. \quad (3)$$

This loss consists of the standard mean squared error (MSE) losses. Here, we want the decoder to use more information from the sentiment embeddings $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$ to generate the target sentence,

if the representations of the two noisy source sentences produced by the same encoder are not considerably different from each other. Our unified objective becomes:

$$\min_{\boldsymbol{\theta}_{\text{enc}},\boldsymbol{\theta}_{\text{dec}}} \mathcal{L}_{\text{sentiment}} + \mathcal{L}_{\text{content}} + \mathcal{L}_{\text{alignment}}. \quad (4)$$

Figure 3 shows the workflow of our method given $\boldsymbol{x}$ as the target sentence. The procedure is the same when considering $\boldsymbol{y}$ as the target sentence. The sentence retrieval and corruption are done once in preprocessing.

4 Experiments

4.1 Training details

We implement our model on top of OpenNMT-py[4] (Klein et al., 2017) based on Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). We use a single-layer bidirectional LSTM as the encoder and a single-layer unidirectional LSTM with attention (Bahdanau et al., 2015) and input-feeding (Luong et al., 2015) as the decoder. Our network configurations are identical to those of Li et al. (2018). Specifically, we use 512 hidden states and 128-dimensional word vectors.

We use Adam (Kingma and Ba, 2015) with the batch size of 256, the learning rate of 0.001, and the gradient clipping at 5. The learning rate decays by halves if the validation perplexity does not decrease. We initialize all model parameters and word embeddings by sampling from $\mathcal{U}(-0.1, 0.1)$. We train for 20 epochs or until the validation perplexity does not decrease for two epochs. At test time, we use the beam size of 5. We use the same network and parameter configurations for all experiments. We conduct all experiments on NVIDIA Tesla P40 GPUs.

4.2 Evaluation and baselines

Li et al. (2018) created 1000 human references for each of the Yelp and Amazon test sets using crowdworkers, allowing us to perform automatic evaluation. Following previous work (Shen et al., 2017; Li et al., 2018), we use two quantitative evaluation metrics: classification accuracy and BLEU. Classification accuracy indicates the percentage of system outputs correctly classified as the target sentiment by a pre-trained sentiment classifier. We train our sentiment classifier using Vowpal Wabbit[5] (Agarwal et al., 2014). We use bigram features and train for 20 epochs. BLEU indicates the content similarity between system outputs and human references. We compute a BLEU score using the `multi-bleu.perl` script shipped with OpenNMT-py.

We compare our method against three different baselines. First, Shen et al. (2017)'s cross-aligned autoencoder learns to directly align the populations of the transferred sentences from one sentiment with the actual sentences from the other. Second, Fu et al. (2018)'s multi-decoder learns the sentence representation containing only the content information and generates the output using a sentiment-specific decoder. Both Shen et al. (2017)'s and Fu et al. (2018)'s models are based on adversarial training (Goodfellow et al., 2014). Lastly, Li et al. (2018)'s delete-and-retrieve method generates the output from the content and the retrieved sentiment-specific phrases with a recurrent neural network.

[5] https://github.com/VowpalWabbit

Model	Yelp		Amazon	
	Acc	BLEU	Acc	BLEU
Shen et al. (2017)	74.5	6.79	**74.4**	1.57
Fu et al. (2018)	46.8	11.24	70.3	7.87
Li et al. (2018)	88.3	12.61	53.4	27.12
This work	**88.5**	12.13	53.8	15.95
w/o $\mathcal{L}_{\text{sentiment}}$	3.4	**24.06**	18.2	**42.65**
w/o $\mathcal{L}_{\text{content}}$	86.4	10.08	53.9	14.77
w/o $\mathcal{L}_{\text{alignment}}$	84.7	11.94	51.6	16.51
only $\mathcal{L}_{\text{sentiment}}$	85.4	10.05	53.4	14.76

Table 1: Results on the Yelp and Amazon test sets.

4.3 Results

Table 1 shows the results of various models. Our model based on the unified objective of Eq. (4) offers better balanced results compared to its variants. When removing $\mathcal{L}_{\text{sentiment}}$, our model degrades to an input copy-like method, resulting in low classification accuracies but the highest BLEU scores. When removing $\mathcal{L}_{\text{content}}$, the BLEU scores drop, indicating that the model cannot maintain a sufficient number of content words. Without $\mathcal{L}_{\text{alignment}}$, we observe a reduction in both accuracy and BLEU on Yelp. However, this tendency is inconsistent on Amazon (i.e., −2.2 accuracy and +0.56 BLEU). When using only $\mathcal{L}_{\text{sentiment}}$, our model falls back to the vanilla encoder-decoder model with a single loss, yielding poorer results on both datasets.

	Yelp	Amazon
Source	we sit down and we got some really slow and lazy service .	this is the worst game i have come across in a long time .

4.4 Discussion

Li et al. (2018) have made the outputs of their methods and those of Shen et al. (2017) and Fu et al. (2018) publicly available, which allows us to perform a comparison without much effort. On Yelp, our unified objective model achieves the best accuracy and a competitive BLEU score. On Amazon, the adversarial training models of Shen et al. (2017) and Fu et al. (2018) have high accuracies but relatively low BLEU scores. These results indicate that the adversarial training models can modify the sentence to the target sentiment but fail to preserve the content.

Compared with Li et al. (2018)'s delete-and-retrieve method, which seems to reconcile both accuracy and BLEU, our method yields reasonable results given that it does not retrieve new sentences at test time and does not explicitly delete/extract sentiment-specific phrases. Li et al. (2018) also use a separately trained neural language model to select the best output (described in the last paragraph of Sec. 4.4 in their paper), while we only use a single-trained model. Table 2 shows the example outputs of our model and others.

We further examine whether flipping between $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$ has any effect at test time. LSTM is commonly known to be powerful and could generate the output sentence with the target sentiment without using the information from the sentiment embeddings $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$. If our model fails to learn $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$, flipping them at test time should have less or no effect. In other words, given the same input sentence, changing $\boldsymbol{s}_x$ to $\boldsymbol{s}_y$ and vice versa would result in nearly the same outputs. To test this, we compose simple, neutral sentences and feed them to our unified objective model trained on Yelp with different sentiment embeddings. Table 3 shows the generated outputs, confirming that our model indeed makes use of $\boldsymbol{s}_x$ and $\boldsymbol{s}_y$.

Source	i have been there .
$\boldsymbol{s}_x$	i have *enjoyed eating* there .
$\boldsymbol{s}_y$	i have *n't* been there .
Source	i had experience .
$\boldsymbol{s}_x$	i had *great* experience .
$\boldsymbol{s}_y$	*worst* experience i *ever* had .

Table 3: Outputs of the proposed model given the same source sentences with different sentiment embeddings ($\boldsymbol{s}_x$ = positive; $\boldsymbol{s}_y$ = negative).

5 Conclusion

We have shown that our unified objective model successfully learns from the noisy training sentence pairs acquired from non-parallel corpora using our search-and-corrupt method. Even though our model is conceptually simpler, it produces competitive results against the strong baselines across two domains.

Label Embedding using Hierarchical Structure of Labels for Twitter Classification

Abstract

Twitter is used for various applications such as disaster monitoring and news material gathering. In these applications, each Tweet is classified into pre-defined classes. These classes have a semantic relationship with each other and can be classified into a hierarchical structure, which is regarded as important information. Label texts of pre-defined classes themselves also include important clues for classification. Therefore, we propose a method that can consider the hierarchical structure of labels and label texts themselves. We conducted evaluation over the Text REtrieval Conference (TREC) 2018 Incident Streams (IS) track dataset, and we found that our method outperformed the methods of the conference participants.

1 Introduction

Twitter is used for various applications such as disaster monitoring (Ashktorab et al., 2014; Mizuno et al., 2016) and news material gathering (Vosecky et al., 2013; Hayashi et al., 2015). In these applications, each Tweet is classified into pre-defined classes. These classes have a semantic relationship with each other and can be classified into a hierarchical structure. Consider a news material gathering system that has classes such as "Tornado," "Flood," and "Riot." These can be classified into two upper classes, "*Natural disaster*" ("Tornado" and "Flood" as lower classes) and "*Incident*" ("Riot" as a lower class). These relationships can be an important clue for classification. Needless to say, label texts of pre-defined classes themselves include important clues. People can understand what the criterion of the classification is by reading labels. Therefore, we propose a method that can consider the hierarchical structure of labels and the labels themselves.

Our method is based on the Label Embedding (LE) method (Zhang et al., 2018). The typical LE method embeds input text and label text, and then the embedded vectors are fed into "Matcher," which outputs the score between the input text and label. We use a two-step attention mechanism for LE to consider the hierarchical structure of labels. We confirm the effectiveness of our method through evaluation over the Text REtrieval Conference (TREC) 2018 Incident Streams (IS) track dataset.

Our contributions are as follows: (1) we propose label embedding using the hierarchical structure of labels, and (2) our method outperformed others on the TREC 2018 IS track dataset for several metrics, including the Any-type Micro F1 score, which is the target metric of the track.

2 TREC 2018 IS track

The TREC 2018 IS track is a shared-task that aims to mature social media-based emergency response technology (McCreadie et al., 2019). The task of the track is classifying Tweets by information type, which consists of 24 classes. The list of information types and the description for each information type are given as ontology as shown in Table 1. The dataset contains approximately 1,300 Tweets for training and more than 20,000 for testing. The numbers of samples for each class are also given in the table[1]. As shown in the table, a training dataset does not include much data and is unbalanced for classes.

The track uses two evaluation methods — Multi-type and Any-type — as follows[2].

Multi-type: Calculating categorization performance per information type in a 1-vs-All manner.

[1] Note that, each sample has just one information type for training data, but more than one for testing data.

[2] See http://trecis.org/2018/Evaluation.html for details.

Table 1: Ontology information type.

Intent type	Information type	Description	# (train)	# (test)
REQUEST	REQUEST-GOODSSERVICES	The user is asking for a particular service or physical good	0	126
	REQUEST-SEARCHANDRESCUE	The user is requesting a rescue (for themselves or others)	0	286
	REQUEST-INFORMATIONWANTED	The user is requesting information	10	172
REPORT	REPORT-WEATHER	The user is providing a weather report (current or forecast)	41	1,325
	REPORT-FIRSTPARTYOBSERVATION	The user is giving an eye-witness account	28	3,807
	REPORT-THIRDPARTYOBSERVATION	The user is reporting a information that they received from someone else	15	4,160
	REPORT-EMERGINGTHREATS	The user is reporting a potential problem that may cause future loss of life or damage	36	686
	REPORT-SIGNIFICANTEVENTCHANGE	The user is reporting a new occurrence that public safety officers need to respond to	34	415
	REPORT-MULTIMEDIASHARE	The user is sharing images or video	127	3,974
	REPORT-SERVICEAVAILABLE	The user is reporting that they or someone else is providing a service	15	1,076
	REPORT-FACTOID	The user is relating some facts, typically numerical	140	2,383
	REPORT-OFFICIAL	An official report by a government or public safety representative	52	403
	REPORT-CLEANUP	A report of the clean up after the event	2	62
	REPORT-HASHTAGS	Reporting which hashtags correspond to each event	4	3,363
CALLTOACTION	CALLTOACTION-VOLUNTEER	The user is asking people to volunteer to help the response effort	2	116
	CALLTOACTION-DONATIONS	The user is asking people to donate goods/money	15	804
	CALLTOACTION-MOVEPEOPLE	The user is asking people to leave an area or go to another area	26	27
OTHER	OTHER-PASTNEWS	The post is generic news, e.g. reporting that the event occurred	12	1,351
	OTHER-CONTINUINGNEWS	The post providing/linking to continuous coverage of the event	250	4,871
	OTHER-ADVICE	The author is providing some advice to the public	39	1,209
	OTHER-SENTIMENT	The post is expressing some sentiment about the event	39	6,952
	OTHER-DISCUSSION	Users are discussing the event	51	2,060
	OTHER-IRRELEVANT	The post is irrelevant, contains no information	163	2,605
	OTHER-UNKNOWN	Does not fit into any other category	26	77
	OTHER-KNOWNALREADY	The responder already knows this information	112	1101

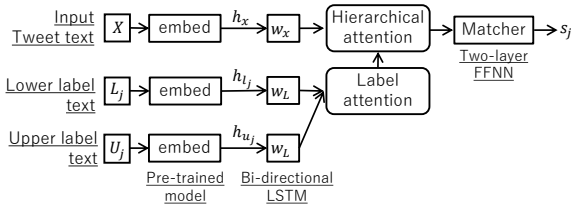

Figure 1: Overview of our proposed method.

Methods are evaluated using four metrics: Precision, Recall, F1 (positive class), and Accuracy (overall).

Any-type: A system receives a full score for a Tweet if the system assigned any of the categories that the human assessor selected for that Tweet. Methods are evaluated using four metrics: Precision, Recall, F1 (micro average: the target metric of the track), and Accuracy (micro average).

3 Our Method

As shown in Table 1, each information type has a rather rich description, so we think that using the description can improve the performance. Also, the information types can be regarded as a hierarchical-structure label, which consists of four upper classes (equal to intent type, such as REQUEST and REPORT) and 24 lower classes (equal to information type, such as REQUEST-GOODSSERVICES and REPORT-WEATHER). To use these useful features, we propose a label embedding using the hierarchical structure of labels.

The overview of our method is given in Figure 1. Our method is similar to the one Zhang et al. (2018) used, but it differs in that our method considers the hierarchical structure of labels, which is our key feature.

X, L_j, and U_j are the input text, label text of the j-th lower class, and label text of the upper class corresponding to the j-th lower class, respectively. We use "description" and "intent type" in Table 1 for the label text of the lower and upper classes, respectively. "Embed" in the figure is a pre-trained model such as BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018) of $V \times m$, where V and m denote the vocabulary size and embedding size, respectively. $\mathbf{w}_X$ and $\mathbf{w}_L$ means Bi-directional Long Short-Term Memory (Bi-LSTM), and both have a d dimension of hidden layer.

First, X, L_j, and U_j are embedded using the pre-trained model, and then the embedded vectors are fed into $\mathbf{w}_X$ for X and $\mathbf{w}_L$ for L_j and U_j, respectively. We gather the hidden states of Bi-LSTM for each input token and stack them, and then we get three matrices:

$$\text{Text representing matrix: } \mathbf{h}_x \in \mathbb{R}^{|X| \times 2d},$$
$$\text{Lower label representing matrix: } \mathbf{h}_{l_j} \in \mathbb{R}^{|L_j| \times 2d},$$
$$\text{Upper label representing matrix: } \mathbf{h}_{u_j} \in \mathbb{R}^{|U_j| \times 2d},$$

where $|X|$, $|L_j|$ and $|U_j|$ represent the number of tokens in X, L_j and U_j, respectively. Note that we have a $2d$ dimension for the row of each matrix because of concatenating forward and backward states.

Next, we calculate "label attention" and "hierarchical attention." The label attention weight $\mathbf{w}_{\text{label}} \in \mathbb{1}^{|L_j|}$ and label attention vector $\mathbf{a}_{\text{label}} \in$

$\mathbb{1}^{2d}$ are calculated as follows:

$$\mathbf{w}_{\text{label}} = \text{softmax}\left(\mathbf{h} \cdot \mathbf{h}_{l_j}^T / \sqrt{2d}\right),$$
$$\mathbf{a}_{\text{label}} = \mathbf{w}_{\text{label}} \cdot \mathbf{h}_{l_j},$$

where $\mathbf{h} \in \mathbb{1}^{2d}$ is the concatenation of hidden states of the final step of both directions of $\mathbf{h}_{u_j}$. We use scaled-dot product attention for label attention (Vaswani et al., 2017).

By using $\mathbf{a}_{\text{label}}$, the hierarchical attention weight $\mathbf{w}_{\text{hier}} \in \mathbb{1}^{|X|}$ and hierarchical attention vector $\mathbf{a}_{\text{hier}} \in \mathbb{1}^{2d}$ are obtained as follows:

$$\mathbf{w}_{\text{hier}} = \mathbf{a}_{\text{label}} \cdot \mathbf{h}_x^T,$$
$$\mathbf{a}_{\text{hier}} = \mathbf{w}_{\text{hier}} \cdot \mathbf{h}_x.$$

Note that we use normalization for label attention but not for hierarchical attention. We confirm that this condition is best by an experiment, which is detailed in the Discussion section.

Then, $\mathbf{a}_{\text{hier}}$ is fed to "Matcher," which consists of a two-layer Feed-Forward Neural Network (FFNN):

$$\mathbf{v}_{\text{mid}} = \mathbf{W}_{\text{mid}} \cdot \text{ReLU}\left(\mathbf{a}_{\text{hier}}\right) + \mathbf{b}_{\text{mid}},$$
$$s_j = \mathbf{W}_{\text{matcher}} \cdot \text{ReLU}\left(\mathbf{v}_{\text{mid}}\right) + \mathbf{b}_{\text{matcher}},$$

where $\mathbf{W}_{\text{mid}} \in \mathbb{R}^{d \times 2d}$ and $\mathbf{W}_{\text{matcher}} \in \mathbb{R}^{1 \times d}$ are weight matrices, and $\mathbf{b}_{\text{mid}} \in \mathbb{1}^d$ and $\mathbf{b}_{\text{matcher}} \in \mathbb{1}^1$ are bias. s_j is a score between input Tweet X and information type j.

We gather s_j for all $j \in C$, where C denotes the set of the information type. Finally, we obtain the estimation result o for input Tweet X as follows:

$$o = \text{argmax}\left(s_1, s_2, \ldots, s_{|C|}\right).$$

4 Experiments

4.1 Experimental Settings

Our experiments were based on TREC 2018 IS track in terms of the dataset and evaluation. The dataset consists of original json data of Tweets. We excluded @-mentions and URLs. We conducted 10-fold cross validation to find the best setting, and all models were used as ensemble models to predict the information type for testing data.

The models were implemented in Chainer (Tokui et al., 2015) and learned with the Adam optimizer (Kingma and Ba, 2014), on the basis of categorical cross-entropy loss with class weights $W_c = \frac{|c_{max}|}{|c|}$, where $|c|$ is the number of samples of information type c appearing in the training data, and $|c_{max}|$ is that of the most-frequent information type. We used BERT-base, Uncased[3] as the pre-trained model, which has a 12-layer, 768-hidden states transformer model with 12-heads attention. The BERT model was used as a frozen model without fine-tuning.

[3] https://github.com/google-research/bert

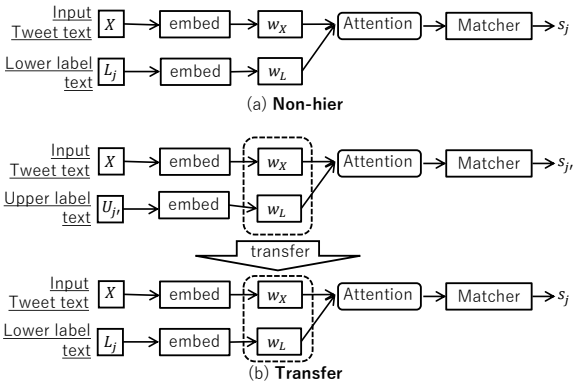

Figure 2: Baseline methods based on label embedding.

The hyperparameters used were: a minibatch size of 32; hidden layer size of 200; L_2 regularization coefficient of 10^{-5}; dropout rate of 0.5; and 100 training iterations, with early stopping on the basis of the Macro F1 score of the development data.

4.2 Baseline Methods

We prepared three baseline methods. All baseline methods used the same hyperparameters as the proposed method.

Non-LE: This method is not based on LE. We use the BERT model as token embedding. The embedded vectors are fed into Bi-LSTM, and then the concatenation of hidden states of the final step of both directions is fed into the two-layer FFNN for classification into the information type.

Non-hier: This method is almost the same as our proposed method but does not use hierarchical attention. The vector fed into Matcher is calculated as attention between embedding vectors of the input text and label text of the lower class (Figure 2-(a)).

Transfer: This method uses the same structure as Non-hier, but we use transfer learning to consider the hierarchical structure of labels. This is inspired by Shimura et al. (2018). First, the model is learned as classifying upper class labels, and then the model is transferred to be learned as classifying lower class labels (Figure 2-(b)). We tried several settings and found that transferring only the Bi-LSTM layer is better in this task.

Table 2: Experimental results. *italics* denote the best results in TREC 2018, and **bold** denotes the overall best results. For some metrics, the best results are for other TREC 2018 participants' methods not shown in the table, so no results are in *italics* or **bold** for these metrics.

Method	Multi-type, Macro Avg.				Any-type, Micro Avg.

4.3 Results

Table 2 presents the results for our methods and part of the TREC 2018 participants' results. At TREC 2018, cbunS2, KDEIS4_DM, and umdhcilfasttext had the top three results for the Any-type Micro F1 score, which is the target metric of the track. DLR_Augmented had the best Multi-type Macro F1 score.

Our proposed method outperformed others in terms of the Any-type Micro F1 score and both types of accuracy, while the best for the Multi-type F1 score is DLR_Augmented.

4.4 Discussion

Comparison with other methods

Our proposed method performs the best for several metrics including the target metric (Any-type Micro F1 score). Our hierarchical attention can give less weight for verbose phrases such as "The user is asking" in label text. These phrases include only a little information useful for classifying, so giving them less weight is reasonable and effective. This is one of the advantages of our method, which distinguishes it from LE-based baseline methods. Our method outperforms not only LE-based methods, but also the simple but strong baseline (Non-LE) and the TREC 2018 participants' methods. Therefore, we confirmed the effectiveness of our proposed method.

On the other hand, our method did not perform the best for the Multi-type Macro F1 score. DLR_Augmented, which performed the best for this metric, uses augmented data. This is effective in the learning process especially for classes that have small training data. Our method does not use augmented data, so it has lower accuracy for these classes than DLR_Augmented. Comparing our proposed method with the baseline methods, differences in the Multi-type Macro F1 score were small, and the proposed method achieved the best score for Multi-type accuracy. We think that the differences come from labels that have a small number of samples in test set because the F1 scores for these classes are sensitive to the output, which greatly affects the Macro F1 score.

Table 3: Comparing normalization methods.

label attention	hierarchical attention	Macro F1 score
normalized	normalized	0.2676
normalized	**none**	**0.3539**
none	normalized	0.0303
none	none	0.0329

Insight of our proposed method

To determine which combination of normalization is effective for our task, we conducted a small experiment using development data. Results are shown in Table 3. We used the Macro F1 score as the metric[4]. We can see that using normalization for label attention but not for hierarchical attention is best. One reason is that the norm of the output vector of hierarchical attention directly affects the score s_j. Hierarchical attention without normalization can make distinctions for the output vector of each class in the norm, so it works well. On the other hand, using normalization is better in label attention. We observed that not using normalization for label attention makes the model diverge, so normalization needs to be used for label attention.

Table 4 shows the macro F1 scores summarized for each upper class of the proposed method and Non-hier. Δ in the table means the difference between two methods. Interestingly, our method works best for the upper class OTHER, which contains the fewest meanings in the upper class label

[4] Each sample has just one information type for development data and more than one for testing data, so the Macro F1 score between Table 2 and 3 cannot be compared directly.

Table 4: Comparing macro F1 score for each upper class between proposed and Non-hier.

Upper class	Proposed	Non-hier	Δ
REQUEST	0.030	0.037	-0.007
REPORT	0.124	0.125	-0.001
CALLTOACTION	0.180	0.170	+0.010
OTHER	0.228	0.216	+0.012

text. The lower class label text for the upper class OTHER includes less verbose phrases such as "The user requesting," so label attention can give higher weight for important parts of the label text more precisely.

On the other hand, the F1 score of the proposed method for the upper class REPORT is worse than that of Non-hier. This is caused by the lower class REPORT-SIGNIFICANTEVENTCHANGE (the Δ is -0.05, which is the worst in all lower classes). The label text of the lower class includes a misspelling ("occurence" instead of "occurrence"[5]). This confuses our model when calculating label attention weight, so the F1 score is lower.

We found that the number of tokens in the lower class label text affects the effectiveness of the proposed method. The proposed method has a better F1 score than Non-hier for nine lower classes with a mean number of tokens in the lower class labels of 11.2. On the other hand, the proposed method has a lower F1 score than Non-hier for seven lower classes with a mean number of tokens of 8.0. This shows that the more tokens the lower class label text has, the more effective the proposed method becomes. Of course, this does not mean that our method works for only classes that have rich label text. For example, our method improves the F1 score for some classes that have short label text such as OTHER-DISCUSSION, which has only five tokens in the label text.

Overall, using hierarchical structure of labels is effective in many cases, but it is sensitive to the quality and quantity of label texts of the lower classes.

5 Related Work

Label embedding has attracted attention, especially for few- and zero-shot learning tasks (Socher et al., 2013; Akata et al., 2013; Kodirov et al., 2017). Now, many methods applied to natural language processing are proposed. Zhang et al. (2018) used multi-task learning, and Xia et al. (2018) used capsule networks for LE and obtained good results. Our method differs in that it considers the hierarchical structure of labels.

There are many studies using a pre-defined hierarchical structure of labels (Wu et al., 2014; Li et al., 2015; Bilal et al., 2018), and some methods are used with LE (Bengio et al., 2010; Ren et al., 2016). These approaches are effective but large-scale hierarchical data from a thesaurus need to be prepared. Our method does not need large-scale data, so it is advantageous when it comes to calculating cost and flexibility. Shimura et al. (2018) used transfer learning to consider the hierarchical structure of labels, which is the basis of our baseline method (Transfer).

6 Conclusion and Future Work

In this paper, we proposed a method of label embedding using the hierarchical structure of labels and confirmed its effectiveness through evaluation over the Text REtrieval Conference (TREC) 2018 Incident Streams (IS) track dataset. Our method outperformed other methods and obtained the best results on the dataset for several metrics including the Any-type Micro F1 score, which was the target metric of TREC 2018 IS track.

We used rather long sentences for lower label text. Typical applications use shorter labels such as "*Tornado*" and "*Riot*." Confirming whether our method works well for other datasets including ones that have only shorter label texts is left for our future work.

Acknowledgements

We would like to thank Prof. Timothy Baldwin and Dr. Ichiro Yamada for valuable discussions, and the TREC 2018 IS track organizers for providing the dataset. We also thank the anonymous reviewers for their helpful comments.

Abstract

Word embeddings have demonstrated strong performance on NLP tasks. However, lack of interpretability and the unsupervised nature of word embeddings have limited their use within computational social science and digital humanities. We propose the use of informative priors to create interpretable and domain-informed dimensions for probabilistic word embeddings. Experimental results show that sensible priors can capture latent semantic concepts better than or on-par with the current state of the art, while retaining the simplicity and generalizability of using priors.

1 Introduction

Increased availability of large digitized corpora and significant developments in natural language processing (NLP) have sparked a growing interest within computational social science and digital humanities (CSSDH) to use computational methods for textual data (Laver et al., 2003; Grimmer, 2010; DiMaggio et al., 2013; Jockers and Mimno, 2013; Tsur et al., 2015). Word embeddings, a family of unsupervised methods for representing words as dense vectors (Mikolov et al., 2013b; Pennington et al., 2014), are one such development. Although word embeddings have demonstrated strong performance on NLP tasks (Mikolov et al., 2013a,c), they have yet to gain widespread attention within CSSDH.

We believe two key limitations can help explain the lack of applications within CSSDH. First, since the dimensions of the word embeddings are largely uninterpretable, it is not clear how to disentangle why words are similar. Substantive interpretability is key for CSSDH research, and thus, the lack thereof is a major limitation. Second, off-the-shelf word embedding models generally lack a channel through which substantive research questions can be incorporated.

To improve interpretability, previous research suggests using sparsity constraints (Murphy et al., 2012; Sun et al., 2016; Faruqui et al., 2015) and rotation techniques (Park et al., 2017; Rothe and Schütze, 2016; Dufter and Schütze, 2019). Other work considers dimension-specific constraints to remove gender-bias, and, as a by-product, improve interpretability (Zhao et al., 2018). Within CSSDH, previous work derives interpretable dimensions via post-processing in the form of antonym-pair vector algebra (Kozlowski et al., 2018; Garg et al., 2018) and ideal-point anchoring of antonym word-pairs (Lauretig, 2019). Recent formulations of word embeddings as probabilistic models (Vilnis and McCallum, 2015; Rudolph et al., 2016; Barkan, 2017; Havrylov et al., 2018) enable the incorporation of domain knowledge through priors. In this paper, we add to the literature on interpretable word embeddings, proposing a novel use of *informative priors* to create predefined interpretable dimensions – thus leveraging the expressiveness and generalizeability of the probabilistic framework.

2 Informative Priors in Word Embeddings

The central idea of this paper is to use informative priors to restrict the degree to which different words can inhabit different dimensions, such that one or more dimensions become interpretable and connected to one's research interest. Specifically, we place informative priors on word types that we expect to discriminate on a particular dimension, e.g. *man-woman* for a gender dimension.

Let $\mathcal{V}_+$ and $\mathcal{V}_-$ be the set of *anchor word types* that informative priors is placed on, e.g. $\mathcal{V}_+ = \{man\}$ and $\mathcal{V}_- = \{woman\}$. Also, let $\mathcal{V}_\pm = \mathcal{V}_+ \cup \mathcal{V}_-$, and let $\overline{\mathcal{V}}_\pm$ be the word types without any informative priors, i.e. the complement set.

Given a corpora with vocabulary size V, we represent each token $x_i \in \{0, 1\}^V$ as a one-hot vector

[*] Equal contribution

with a single nonzero entry at v. Here, $v \in \mathcal{V}$ represents the word type at position i in the text. Following Rudolph et al. (2016), we model each individual entry $x_{iv} \in \{0, 1\}$ of the one-hot vectors conditional on its context $\mathbf{x}_{c_i}$, i.e the tokens surrounding x_i, where c_i denotes the positions belonging to the context.

Each word type is associated with an *embedding vector*, $\rho_v \in \mathbb{R}^K$, which governs the distribution of x_i, and a *context vector*, $\alpha_v \in \mathbb{R}^K$, governing the distributions of the tokens for which x_i is part of $\mathbf{x}_{c_i}$. The conditional probability of x_{iv} is modelled as a linear combination of the embedding and context vectors, i.e.

$$p(x_{iv}|\mathbf{x}_{c_i}) \sim \text{Bernoulli}(\eta_{iv}), \quad (1)$$

where

$$\eta_{iv} = \text{logit}^{-1}[\rho_v^\intercal(\textstyle\sum_{j \in c_i} \sum_{v'} \alpha_{jv'} x_{jv'})],$$

with logit serving as the link function. Rudolph et al. (2016) place a zero-centered Gaussian prior with variance σ on the embedding and context vectors. Letting $\theta_v = \{\rho_v, \alpha_v\}$, this translates to

$$\theta_v \sim \mathcal{N}(0, \sigma). \quad (2)$$

In addition, since evolution of semantic concepts are of special interest in CSSDH (Tahmasebi et al., 2015), we also consider a dynamic word embedding model to capture temporal dynamics in the dimension of interest. We follow the specification in Rudolph and Blei (2017) which extends Eq. (1) by associating each token with a time slice t, and fit separate $\rho_v^{(t)} \in \mathbb{R}^K$ for each t. Thus, $\theta_v^{(t)} = \{\rho_v^{(t)}, \alpha_v\}$. To share statistical strength between time-points, a Gaussian random walk prior is placed on $\rho_v^{(t)}$, i.e.

$$\rho_v^{(t)} \sim \mathcal{N}(\rho_v^{(t-1)}, \sigma_d I). \quad (3)$$

Where $\sigma_d = \frac{\sigma}{100}$, as in Rudolph and Blei (2017), determines the smoothness of the trajectories. This shows how, in contrast to the state of the art (Kozlowski et al., 2018; Garg et al., 2018; Lauretig, 2019; Zhao et al., 2018), informative priors allow easy integration with other, more complex, probabilistic models.

2.1 The Standard Basis Prior

In the following sections, we introduce a number of prior specifications that differ in how they restrict the degree to which words can occupy different dimensions. Letting K represent the dimension that we want to make interpretable, and dimensions $1 : K-1$ be standard word embedding dimensions not subject to interpretation, we define our first prior specification, the *Standard Basis Prior*, as

$$\begin{aligned} \theta_{\mathcal{V}_\pm}^{1:K} &\sim \mathcal{N}(0, \sigma) & \theta_{\mathcal{V}_+}^{K} &\sim \mathcal{N}(1, \gamma) \\ \theta_{\mathcal{V}_\pm}^{1:K-1} &\sim \mathcal{N}(0, \omega) & \theta_{\mathcal{V}_-}^{K} &\sim \mathcal{N}(-1, \gamma), \end{aligned} \quad (4)$$

where $\theta_{\mathcal{V}_+}^K$ and $\theta_{\mathcal{V}_-}^K$ are priors on the dimension of interest (K) of ρ_v and α_v for word types in $\mathcal{V}_+$ and $\mathcal{V}_-$ respectively, and where $\theta_{\mathcal{V}_\pm}^{1:K-1}$ is the shared prior for all anchor word types on dimensions $1 : K-1$. Finally, $\theta_{\mathcal{V}_\pm}^{1:K}$ is the standard prior from Eq. (2), placed on all dimensions for all non-anchor word types. Hyperparameters ω and γ are shared for $v \in \mathcal{V}_\pm$, controlling the strength of the prior. As $\gamma, \omega \to 0$, we force $v \in \mathcal{V}_\pm$ to essentially become a standard basis, defined by the word types in the prior. Consequently, the dot product for these vectors will be 0 for all dimensions except K, and thus the effect of the anchored word types on the rest of the vocabulary will exclusively depend on K.

However, this implies that, as $\gamma, \omega \to 0$, word types within $\mathcal{V}_-$ and $\mathcal{V}_+$ obtain exactly the same word embedding. For example, with $\mathcal{V}_+ = \{brother, king\}$, *brother* is treated as semantically identical to *king*. To address this issue, we consider increasing ω, allowing the anchor word types to exist more freely in the first $K-1$ dimensions while remaining close to -1 and 1 in the K^{th} dimension. This permits the use of both $brother$ and $king$ as prior anchors without assuming that they are exactly the same word. We henceforth refer to a standard basis prior with $\omega = 10^{-6}$ as *strict* and $\omega = 1$ as *weak*.

2.2 The Truncated Prior

A limitation of the prior specifications introduced thus far is the implicit assumptions that (i) anchor word types discriminate equally on the dimension of interest, and (ii) that we know their exact location in this dimension. To address this, we consider the *Truncated Prior* that does not assume a basis for the anchored word types, but only that they live on the positive and negative real line as

$$\begin{aligned} \theta_{\mathcal{V}_\pm}^{1:K} &\sim \mathcal{N}(0, \sigma) & \theta_{\mathcal{V}_+}^{K} &\sim \mathcal{N}^+(0, \gamma) \\ \theta_{\mathcal{V}_\pm}^{1:K-1} &\sim \mathcal{N}(0, \omega) & \theta_{\mathcal{V}_-}^{K} &\sim \mathcal{N}^-(0, \gamma). \end{aligned} \quad (5)$$

Where $\mathcal{N}^+(0, 1)$ and $\mathcal{N}^-(0, 1)$ is the positive and negative truncated normal distribution, truncated at 0, respectively.

2.3 Using Neutral Words

So far, we have only considered word types known to discriminate on the dimension of interest as prior anchors. However, domain knowledge might also inform us about *neutral* words in this dimension (e.g. stop words). We thus consider placing informative priors on a third set of prior anchors $\mathcal{V}_*$ containing neutral word types as

$$\begin{aligned} \theta_{\mathcal{V}_*}^{1:K-1} &\sim \mathcal{N}(0, \sigma) \\ \theta_{\mathcal{V}_*}^{K} &\sim \mathcal{N}(0, \psi)\,, \end{aligned} \tag{6}$$

where ψ is the variance for dimension K. By guiding neutral words close to 0 in the dimension of interest, explanatory power that otherwise might have been attributed to word types in $\mathcal{V}_*$ will instead be allocated to other words in $\mathbf{x}_{c_i}$.

3 Experiments

Our main empirical concern is how well the proposed priors can capture meaningful latent dimensions. We summarize our empirical questions as follows:

1. Which prior specification can best capture predefined dimensions?

2. How does the best prior specification compare with the state of the art in CSSDH (Garg et al., 2018; Kozlowski et al., 2018) (henceforth referred to as SOTA)?

We consider two semantic dimensions, *gender*, which is explored in SOTA, and *sentiment*, a dimension proven difficult to capture in standard word embedding models (Tang et al., 2014). We follow SOTA when choosing prior anchors for gender, while using the AFINN dictionary (Nielsen, 2011) to find prior anchors for sentiment. To evaluate the effect of "few" vs. "many" prior anchors, we run experiments using between 2 and 276 words depending on the dimension of interest and the dataset at hand. All prior word types used in the experiments can be found in Sec. B in the supplementary material. We follow Rudolph et al. (2016), obtaining maximum a posteriori estimates of the parameters using TensorFlow (Abadi et al., 2015) with the Adam optimizer (Kingma and Ba, 2015) and negative sampling [1]. We set the size of the embeddings $K = 100$, use a context window size of 8 and $\sigma = 1$ throughout all experiments.

[1]Code is available at: https://github.com/martinarvidsson/InterpretableWordEmbeddings

We examine the proposed priors using three commonly sized English corpora for textual analysis within CSSDH: the top 100 list of books in Project Gutenberg (2019), a sample from Twitter (Go et al., 2009) and the U.S. Congress Speeches 1981-2016 (Gentzkow et al., 2018). The number of tokens ranges from 1.8M to 40M after preprocessing (see Sec. A in the supplementary material for details). The various origins, sizes and contents of these datasets work as a check of the effect of the priors in different types of corpora.

To measure the extent to which the inferred dimension reflects the semantic concept of interest, we consider how well-placed a number of prespecified hold-out word types (not a part of $\mathcal{V}_\pm$) are in this particular dimension. Specifically, accuracy is computed as the fraction of hold-out words that are placed on the correct side of 0 on the dimension of interest in the embedding and context vectors. For the gender dimension, hold-out word types include the 200 most common names of the last century (Social Security Administration, 2019) and gendered words, while for sentiment, a sample of the AFINN dictionary is used (see Sec. C in the supplementary material). The number of hold-out word types ranges between 213 and 275, since not all exist in each corpus.

The experimental configurations are compared to SOTA, which we implement by (i) fitting the probabilistic word embedding model in Eq. (1) and (2) without informative priors, and (ii) deriving the interpretable dimension post-hoc by subtracting normalized embedding vectors of antonym-pairs, e.g. $\rho_{gender} = (\rho_{man} - \rho_{woman}) + (\rho_{he} - \rho_{she})$. Comparing the sign of the cosine similarity between hold-out words and the created vector allows us to contrast the accuracy of our method with that of SOTA. To get a measure of uncertainty we calculate binomial confidence intervals using the normal approximation.

4 Results

We begin by comparing the strict and weak *Standard Basis Priors*, with $\gamma = 10^{-6}$, varying the number of anchor words used to inform the dimension of interest. The general pattern in Fig. 1 shows how (i) increasing the number of anchor words improves the accuracy, and that (ii) this improvement is much greater for the weak than for the strict *Standard Basis Prior*. We explain this

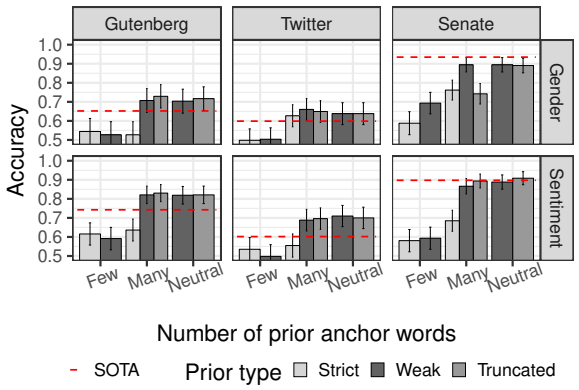

Figure 1: Comparison of prior specifications per dataset and dimension

difference by the nature of the strict prior; it forces all anchor words to have exactly the same meaning – which clearly is untrue. These results speak against methods that transform the vector space based on strict standard basis vectors, as in Lauretig (2019). Further noticeable is that the average accuracy is greater for the Senate corpus, which, using subsampling, we find is driven by corpora size.

Relaxing the location assumptions with the *Truncated Prior* ($\gamma = 1000$) and placing informative priors on neutral words ($\psi = 0.01$) show varying degrees of improvements. However, due to the limited number of hold-out test words, large improvements are required for significant differences – which only is observed for the sentiment dimension in the Senate corpus.

Fig. 1 further shows how our proposed approach generally performs better or on-par with SOTA. The one exception is the gender dimension in the Senate corpus. Follow-up analysis show that this difference is driven by misclassification of a cluster of ambiguous names, e.g. *Madison* (founding father) and *Jordan* (country). These names become correctly classified when using the full vectors, suggesting that gender has not been completely isolated in the Senate corpus (see Gonen and Goldberg (2019) for an in-depth discussion on issues of concept-isolation in word embeddings).

4.1 Case Study of Semantic Change

Using the *Truncated Prior* with neutral words, we leverage the dynamic embedding model described in Eq. (3) to explore temporal patterns in the Senate corpus. We set $\sigma_d = 0.05$ to allow for the identification of abrupt temporal changes.

The left panel of Fig. 2 displays sentiment-trajectories for two words experiencing drastic three-year consecutive changes in the sentiment dimension; *September* between 1999 and 2001 and *Oklahoma* between 1993 and 1995, capturing two terror events: the attacks on the World Trade Center on September 11th 2001, and the Oklahoma City bombing in 1995. The change precedes the event due to the smoothness of the prior. In the years that follow, the words gradually regain their previous sentiment – reflecting a decline in their association with terror.

Second, we test and find support for the gender-occupation results in Kozlowski et al. (2018), i.e. that occupations' temporal positioning in the gender dimension correlates well with the proportion of men and women within those fields. The right panel of Fig. 2 displays the gender-dimension trajectories for the words *Nurse* and *Laywer*, occupations with high shares of women and men, respectively (Kozlowski et al., 2018).

In sum, these examples showcase how interpretability can be gained using informative priors. By isolating prespecified concepts, e.g. sentiment, into one dimension (K), one can infer word type-concept associations such as *September-sentiment* – for all non-anchor word types – allowing for more meaningful within and between word type comparisons.

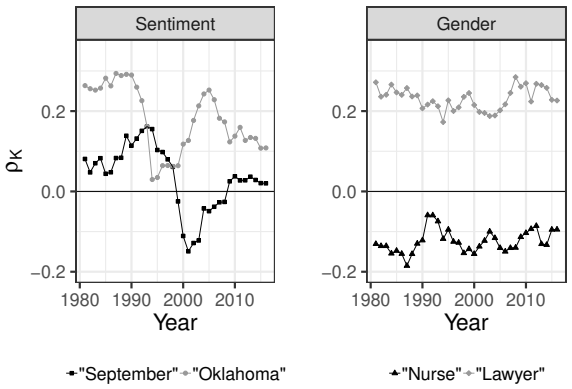

Figure 2: Gender and sentiment trajectories in the Senate corpus.

5 Conclusion

In this paper, we show how informative priors provide a simple and straightforward alternative for constructing interpretable dimensions for probabilistic word embeddings – allowing CSSDH researchers to explore how words relate to each

other in prespecified dimensions of interest, e.g. gender and sentiment.

Our results demonstrate that the biggest gains in interpretability are obtained by (i) using many prior words and (ii) increasing the degree to which they can live outside the predefined dimension. The weak *Standard Basis Prior* and the *Truncated Prior* overall capture the predefined dimensions with similar accuracy. Aligned with previous research, the experimental results indicate some issues with incomplete isolation of concepts which we believe could be addressed in future work by placing informative priors on multiple dimension to capture more complex concepts, and move away from simplistic antonym-driven dimension definitions.

Finally, while being flexible and easily extended to other probabilistic word embedding models, our approach performs better or on par with SOTA.

Adversarial Removal of Demographic Attributes Revisited

Abstract

Elazar and Goldberg (2018) showed that protected attributes can be extracted from the representations of a *debiased* neural network for mention detection at above-chance levels, by evaluating a diagnostic classifier on a held-out subsample of the data it was trained on. We revisit their experiments and conduct a series of follow-up experiments showing that, in fact, the diagnostic classifier generalizes poorly to both new in-domain samples and new domains, indicating that it relies on correlations specific to their particular data sample. We further show that a diagnostic classifier trained on the *biased* baseline neural network also does not generalize to new samples. In other words, the biases detected in Elazar and Goldberg (2018) seem restricted to their particular data sample, and would therefore not bias the decisions of the model on new samples, whether in-domain or out-of-domain. In light of this, we discuss better methodologies for detecting bias in our models.

1 Introduction

Several approaches have been proposed to learn classifiers that are invariant (unbiased with respect) to protected attributes: cost-sensitive (Agarwal et al., 2018), regularization-based (Bechavod and Ligett, 2017), and adversarial (Ganin and Lempitsky, 2015). In the adversarial approach, a model learns representations x that should be predictive for a main task y and oblivious to a protected attribute z.

Adversarial training has been used to learn data representations that are invariant to demographic attributes (Raff and Sylvester, 2018; Beutel et al., 2017; Li et al., 2018), as well as representations invariant to domain differences (Ganin and Lempitsky, 2015), clean or noisy speech (Sriram et al., 2018), and invariant to differences between source languages in multi-lingual machine translation (Xie et al., 2017). Elazar and Goldberg (2018) argue, however, that adversarial learning does not fully remove sensitive demographic traits from the data representations. This conclusion is based on the observation that a diagnostic classifier trained over the supposedly debiased data representations could still predict gender, age and race above chance level in their experimental setup.

In general, diagnostic classifiers are trained on data representations to predict the protected demographic attributes in question as well as possible, i.e., the classifier picks up on any correlations, strong or weak, between data representations and the demographic classes. Correlations come in different flavours: PREVALENT: Certain features are indicative of gender in most contexts, e.g., the distribution of phrases like 'as a mother' or 'as a guy'. SAMPLE-SPECIFIC: Some features are indicative of gender within a particular domain/sample, e.g. *bling* may correlate with a particular range of ages in a sample of reviews of accessories, and yet another range in reviews of movies. ACCIDENTAL: Yet, other features may show a correlation with the protected attribute in a given dataset, while in fact being completely unrelated to it. The correlation is unexpected and particular to a finite data sample.

This paper presents a follow-up to the experiments in Elazar and Goldberg (2018) and examines what kind of correlation the data representations in their models exhibit with demographic attributes: PREVALENT, SAMPLE-SPECIFIC or ACCIDENTAL correlations. We do this by *not only* evaluating the diagnostic classifiers on in-sample data, but also on new samples, as well as across textual domains. We also explore what the models learn in a more qualitative manner.

Table 1: Dataset sizes (in 1000 sentences).

Contributions Our contributions are methodological. We show that the diagnostic classifiers used to establish gender and age bias in Elazar and Goldberg (2018) (a) rely only on sample-specific patterns to predict gender and age, and (b) do therefore not generalize to new samples or domains. Surprisingly, we also show that this also holds for the biased baseline model in their experiments, suggesting that the particular representations induced for the mention detection task in Elazar and Goldberg (2018) were not biased with respect to protected demographic attributes. This does not show whether the data *is* biased, or whether adversarial training is a good or poor debiasing technique; merely that Elazar and Goldberg (2018) did not properly establish any of these things. Our contributions are, as said, methodological, and we believe this case study highlights the key difficulties establishing bias in model representations.

2 Adversarial Attribute Removal with Diagnostic Classifiers

In adversarial attribute removal, a model is trained with a two-fold objective: learning to solve a main task and *un*learning to predict a protected attribute (+Adv). A model trained without the second objective is referred to as a *non-adversarial* model (-Adv). The architecture of Elazar and Goldberg (2018) consists of a single-layer LSTM encoder, and two multi-layer perceptrons – one for each task. The main task $p(y|x)$ is learned as usual, with loss being backpropagated through the relevant perceptron and the encoder. The attribute unlearning is achieved by training the relevant perceptron to predict $p(z|x)$, where z is the protected attribute, while also punishing the encoder for letting any signal through that could allow the perceptron to do so (Ganin and Lempitsky, 2015). After training, a diagnostic classifier, an *attacker*, is used to evaluate the effectiveness of the adversarial training. The language encoder is used to obtain representations of the input data, and the diagnostic classifier is trained to predict the protected attributes from these representations, without access to the encoder or to the original inputs. Since the dataset is balanced and the targets are binary, *leakage* is defined in Elazar and Goldberg (2018) as any demographic attribute prediction accuracy over 50.0% by the diagnostic classifier.

Preprocessing Table 1 shows sizes for all used datasets. Our main dataset, Pan16 Twit (Rangel et al., 2016), is split into train and development, following Elazar and Goldberg (2018). We further remove 10,000 sentences from their train data to use as a held-out test split, making sure there is no author overlap between training and test data. This means that we have 12,000 fewer sentences in our train split than Elazar and Goldberg (2018), but we report results on exactly the same development split as well as on the new held-out test split. Pan16 Twit is balanced using undersampling with respect to main task and demographic attribute (gender and age respectively) which is why there are separate datasets for Gender and Age. Our main observation here is that training, development and test splits and random subsamples of one sample of data. Using random subsamples this way is common in machine learning, including bias detection studies (Elazar and Goldberg, 2018; Zhao et al., 2019) and probing studies (Ravfogel et al., 2018; Lin et al., 2019), but is known to overestimate performance (Globerson and Roweis, 2016), in particular for high-dimensional problems.

Replication We start by replicating the experiment of Elazar and Goldberg (2018) using their code on Pan16 Twit with their data splits. The main task is predicting the mentions of other Twitter users after removing all user names in the tweets. The protected demographic attributes are age and gender, both with binary targets. Our development results (main and diagnostic classifier) which are comparable to Elazar and Goldberg (2018) are reported in Table 6 in the Appendix; test set results are also in Table 4. Our results remain comparable to those obtained in Elazar and Goldberg (2018), albeit the diagnostic classifier is able to achieve 3.92 percentage points less leakage for gender and 2.59 percentage points for age, possibly due to the reduction in training data. Adver-

	AGE		GENDER	
	Mean	RStD	Mean	RStD
-ADV	14.48	0.34	5.40	0.16
+ADV	5.3	0.45	3.68	0.22

Table 2: Mean and relative standard deviation of the *leakage* of 10 attackers trained on different subsamples of the training data (PAN16 TWIT). Evaluated on the test set.

sarial training reduces the leakage of demographic attributes, but the diagnostic classifier is still able to predict the sensitive demographic attribute from the data representations significantly better than chance (line 1 of Table 4). Significance test is obtained by checking subsampled test set accuracies against the 95% confidence interval of a random distribution.

3 In-Sample Analysis

In §4, we use out-of-sample and cross-domain evaluation to show that the model trained above relies on spurious or ACCIDENTAL correlations. In this section, as a supplement, we train 10 attackers on different random subsamples of 50% of the training data to explore the robustness of the observed leakage. Each attacker is evaluated on the same PAN16 TWIT test data. Furthermore, we present a qualitative analysis of what the above model has learned.

Table 2 shows the mean and relative standard deviation (RStD) of the leakage of the 10 diagnostic classifiers in each setting. The leakage, unsurprisingly, is larger for the non-adversarial condition than the adversarial condition.

Extracting leaked samples We further analyse the tweets that were correctly labelled by the different attackers. Given that these are binary classification tasks, we consider labels predicted with a high probability to be leaked, and labels predicted with a probability close to 0.5 to be randomly chosen. We sort all of the correctly labelled test examples by the probability assigned to the label by the attacker. We denote the top n samples as the leaked samples, where n is the amount of leakage observed for a model[1].

[1]e.g., with a subsampled test accuracy of 54.4%, we take the 4.4% most confidently predicted tweets for each subsampled model and only use the intersection from all models.

	GENDER			AGE		
	M	F	n	Y	O	n
-ADV	52.1	47.9	142	69.1	30.9	553
+ADV	100.	0.	37	57.9	42.1	145

Table 3: Class distribution for the confidently predicted tweets and $n$umber of tweets per model condition for M(ale), F(emale) and Y(oung), O(ld)

We use the intersection of leaked samples across the attackers, under the assumption that samples that were correctly labelled by all ten models (and with high probability) are most likely to exhibit protected attribute leakage. After deduplicating, we have 179 sentences correctly labelled for Gender, and 698 sentences for age, as reported in Table 3. We call these the LEAKED sentences. (There are no female-authored sentences that are confidently predicted after adversarial training).

Exploring leaked samples Out of the LEAKED gender sentences, the top 10 sentences which received the highest confident scores are presented in Table 7 in the Appendix. 28 subjects rated how confident they were about the gender of the author on a 9-point scale. Subjects were recruited via the authors' professional and private networks and were not compensated for the time they spent. All subjects were unaware of the origin of the tweets, and the sentences were presented in a random order. The scale was calibrated such that the extremes represented *Very certain* about the author being a man (1) or a woman (9), with 5 a neutral middle value. The mean for sentences by male authors selected without adversarial training is 4.68 and for females 5.69. With adversarial training, this mean is 4.83. The mean of sentences extracted from the model trained with adversarial training is closest to the neutral value 5, but independent t-tests show that the differences between all classes are insignificant ($p > 0.05$). Therefore, the results show that humans had difficulties determining the gender of the author. This is contrary to the findings of Flekova et al. (2016), but is similar by the unaveraged results of Burger et al. (2011). This indicates that the data did not exhibit (m)any obvious predictors of gender or age.

In addition to this study, we also use this data to visualize what our diagnostic classifiers focus on. For this purpose, we use the models from Section 2, trained on the full PAN16 TWIT dataset, and perform feature analysis using uptraining: Us-

(a) GENDER −ADV (b) GENDER +ADV

(c) AGE −ADV (d) AGE +ADV

Figure 1: Biased n-grams in a linear simulation of the attacker model in Elazar and Goldberg (2018). Red=female, blue=male, green=young, brown=old. The size corresponds to the size of the coefficient.

ing a transparent, linear model to approximate our deep model (Bastani et al., 2017), we train a logistic regression model with L1 regularization on the train set representations, relabeled by the predictions of our diagnostic classifier. We then study the coefficients of this linear model. The data is represented using the 10,000 most frequent n-grams.[2] We also use the confidence of the diagnostic classifier for importance weighting during training; note that the predicted classes are not balanced.[3] For gender and age, and for our baseline and our adversarially trained system, we uptrain 10 models on random 50% subsets of the training data and average coefficients to filter out noise. Figure 1 shows word clouds for the n-grams in the LEAKED sentences, with word size reflecting the size of the avg. coefficients in the uptrained linear models. We observe that for models with no adversarial training, a few n-grams dominate the coefficients. In the models where adversarial training was used, there are no large coefficients dominating the space, suggesting that the model succeeded in removing strong correlates; we note that these correlates do not intuitively relate strongly to gender or age.

[2] n-gram representations are less expressive than LSTM encodings, but given the short length of tweets, we assume up to 5-gram representation capture most relevant patterns.

[3] Table 5 in the Appendix provides an overview of the class distribution.

4 Out-of-Sample and Cross-Domain Evaluation

In our main set of experiments, we now evaluate the adversarial and non-adversarial diagnostic classifiers across different samples and different domains. We use the following datasets for these experiments: PAN14 (Rangel et al., 2014)[4] - we include the English data from PAN14 for the following domains: BLOGS, hotel REVIEWS, and Social Media (SOME). The PAN14 data are not annotated for the mention task, but this is not necessary to evaluate the diagnostic classifier on the protected, demographic attribute. We also use data from Crowdflower's Gender Classifier data (CF TWIT), manually annotated for gender[5]. We also made a new Twitter dataset with manually annotated gender for 100 authors (100 AUTH TWIT) for the purpose of evaluating on a different Twitter sample, following the approach used to create PAN16 TWIT – detailed in Appendix A. The datasets are balanced with respect to demographic attributes, and the Twitter datasets are balanced with respect to mentions. We also construct an artificial dataset from PAN16 TWIT where the main task labels are preserved but the demographic label is randomly shuffled (PAN16 RAND), allowing us to run experiments with no PREVALENT or SAMPLE-SPECIFIC gender correlations, only ACCIDENTAL. This experiment supplements our in-sample analysis in §3 and shows that our models are not overly expressive, indicating that the sample-specific correlations detected

[4] We do not include PAN14-Twitter, since the PAN16 TWIT training data subsumes the data from PAN14.

[5] Downloaded from https://d1p17r2m4rzlbo.cloudfront.net/wp-content/uploads/2016/03/gender-classifier-DFE-791531.csv

in Elazar and Goldberg (2018) are relatively simple associations.

The results in Table 4 show, however, that the performance and leakage of the adversarial models do *not* generalize well across domains, but for the most part the performance of the non-adversarial models doesn't either. This is the main result presented here: The leakage shown in Elazar and Goldberg (2018) does not transfer across domains, but also does not even generalize to a new sample within the same domain. This suggests that the leakage is merely spurious correlations in a small, finite sample of data. Accuracies are, as expected, mostly lower when adversarial training is employed, but for the 100 AUTH TWIT sample, the non-adversarial accuracy is close to random, while the adversarial accuracy is two points higher: it appears that the adversarial component has merely served as a regularizer during training.

5 Conclusion and Discussion

We examined the methodology used in Elazar and Goldberg (2018) to establish bias in the representations of adversarial machine learning architectures designed to protect demographic attributes.[6] Our results suggest that when measuring demographic parity using a diagnostic classifier, one needs to be careful in controlling for spurious correlations that are limited to just one specific sample of data. In-sample correlations are not necessarily meaningful in high-dimensional problems, and while they can be lead to worse performance on test time (Globerson and Roweis, 2016), they do not lead to demographic bias in practice, when our models are deployed on new samples of data. In order to get more realistic assessments of representation bias with respect to protected attributes, we therefore need to test the out-of-sample generalization of detected bias/leakage, *and*, perhaps, to qualitatively inspect the observed leakage patterns.

We repeat here that none of our results say anything about whether the datasets used in Elazar and Goldberg (2018) are biased or not, or whether other models induced from this data are likely to exhibit biases. Our contribution is mainly methodological: What we have shown is that the methodology in Elazar and Goldberg (2018), i.e., in-sample evaluation of diagnostic classifiers, is not sufficient to establish bias/leakage beyond the current data sample. Instead we propose out-of-sample and cross-domain evaluation, as well as more qualitative investigation of the induced diagnostic classifiers. Our results are also orthogonal to the main contribution of Elazar and Goldberg (2018), which is to show that adversarial debiasing is not always able to remove bias.

[6]The methodology is not only found in Elazar and Goldberg (2018). The same methodology can be found in other papers on detecting bias in machine learning models, for example, Zhao et al. (2019), as well as in several papers probing neural network representations for linguistic knowledge, for example, Lin et al. (2019).

Abstract

In this paper we propose a deep learning framework for sarcasm target detection in predefined sarcastic texts. Identification of sarcasm targets can help in many core natural language processing tasks such as aspect based sentiment analysis, opinion mining etc. To begin with, we perform an empirical study of the socio-linguistic features and identify those that are statistically significant in indicating sarcasm targets (p-values in the range $(0.05, 0.001)$). Finally, we present a deep-learning framework augmented with socio-linguistic features to detect sarcasm targets in sarcastic book-snippets and tweets. We achieve a huge improvement in the performance in terms of exact match and dice score as compared to the current state-of-the-art baseline.

1 Introduction

Computational sarcasm is a very well studied research area in computational linguistics (Joshi et al., 2017). Sentiment analysis and opinion mining of sarcastic texts are known to be difficult problems (Pang et al., 2008). For instance, in aspect based sentiment analysis, which deals with the identification of sentiment expressed toward different aspects or dimensions of the entities present in the text, it is very important to identify the sarcasm targets and sentiments toward them in the texts. Thus, if a user expresses a sarcastic utterance such as *"My laptop has an awesome battery life that lasts for 15 minutes"*, the tool should recognize that the speaker is expressing a negative sentiment toward the battery life of the laptop, even though, it has a positive sentiment word 'awesome' in it. Similarly the opinion mining tool should identify the negative opinion of the user expressed toward the entity "battery". Sarcasm target identification can also benefit natural language generation; for example, after detection of entity toward which a negative sentiment is expressed in a sarcastic text, a natural language generation system will have more context to generate a response. Similarly, a sentiment analysis tool will flag the sentiment in a sarcastic text toward the correct aspect of a product or the entity which can help to build a more accurate product review. In this paper we present a novel method for sarcasm target identification with the help of deep learning techniques in addition to a set of socio-linguistic features.

There is a lot of literature that deal with the sarcasm detection in text (Joshi et al., 2017), but only Joshi et al. (2018) have addressed the problem of sarcasm target identification. The sarcasm target is defined as the entity or situation that is being mocked or ridiculed at in the sarcastic text. Formally, the sarcasm target identification is defined as the task of building a system that takes a sarcastic text (book snippets, tweets etc.) as input, and either identifies a subset of words as sarcasm targets or outputs a fall-back label 'outside' if the target is not present in the text. For example in the sarcastic text *"I love to be ignored"*, the target is *"I"*. We consider two assumptions in this work as the same has been done in the baseline, – (a) every sarcastic text has at least one sarcasm target as this holds true by the definition of sarcasm, and, (b) the notion of sarcasm target is applicable for sarcastic texts only.

Sarcasm target identification is a difficult task, the primary reasons being,

- **Multiple candidate phrases**: There can be multiple target candidate phrases present in the sarcastic text. For example, in the sarcastic text, "The laptop heats up so much that I strongly recommend chefs to use it as a cook-top", the target candidates could be 'chefs', 'cook-top' and 'laptop'; however, only 'laptop' is ridiculed in this sentence.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6336–6342,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- **Multiple sarcasm targets**: There can be multiple sarcasm target phrases present in the sentence. For example, in the sarcastic text, "I used to be a middle-of-the-road kid, but now with my freaky looks I'm definitely an outsider. Hooray.", have two sarcasm targets, i.e., 'my freaky looks' and 'I'.
- **Absence of any target**: It is also possible that no sarcasm target is present at all in the sarcastic text. For example in the sarcastic text "Oh, and I suppose the apples ate the cheese." the sarcasm target has to be labelled as 'outside'.

The main contributions and results of this paper can be summarized as,

- An empirical study of the socio-linguistic features that are highly significant in identifying sarcasm targets.
- A novel deep learning framework augmented with socio-linguistic features to detect sarcasm targets in sarcastic texts. We achieve a huge improvement over Joshi et al. (2018) in sarcasm target detection in terms of the evaluation metrics – exact match and dice score.

In this paper our main motive was to establish that deep neural machinery can be effectively married with socio-linguistic features to detect sarcasm targets. This exercise was a proof of concept to show that this marriage is indeed useful. The code we developed for this work is made freely available[1].

2 Related works

Most of the papers in the area of computational sarcasm address the problem of sarcasm detection, i.e., classification of a text as sarcastic or non-sarcastic. Joshi et al. (2017) present a compilation of past works including the datasets, approaches, issues and trends in automatic sarcasm detection. They observe mainly three approaches to the sarcasm detection problem – semi-supervised extraction of sarcastic patterns (Tsur et al., 2010; Ptáček et al., 2014; Bouazizi and Ohtsuki, 2015; Riloff et al., 2013; Joshi et al., 2015), use of hashtag based supervision (Davidov et al., 2010; Abercrombie and Hovy, 2016), and use of contextual information for sarcasm detection (Hazarika et al., 2018; Wallace et al., 2014; Rajadesingan et al., 2015). Recently, Tay et al. (2018) presented an attention-based neural model to explicitly model contrast and incongruity. Kolchinski and Potts (2018) presented two methods for representing authors in the context of textual sarcasm detection; they show that augmenting a bidirectional RNN with these representations improves performance in sarcasm detection. Ghosh and Muresan (2018) did a thorough analysis of sarcasm markers in social media platforms like Twitter and Reddit; in their study they found that in Twitter while emoticons or emojies are the most discriminative markers to recognize sarcastic/ironic utterances, for Reddit the morphological markers (e.g., interjections, tag questions) are the most discriminative. In socio-linguistic literature even though there are many studies that observe propagation of hate speech (Ribeiro et al., 2018; Salminen et al., 2018) and abusive behaviour (Founta et al., 2018; Maity et al., 2018; Mathew et al., 2019a,b) in social media an in-depth analysis of how sarcastic message travels in social networks and how tweets around the targets behave is an area which social scientists need to investigate. To the best of our knowledge, only Joshi et al. (2018) addresses the problem of sarcasm target identification. This problem attempts to identify the entity toward which sentiment is expressed in a sentence which in turn can have a lot of applications. Our objective here is to leverage recent deep learning methods to escalate the overall performance on this task.

3 Dataset

We consider the dataset released by Joshi et al. (2018) for our experiments. The dataset has two types of sarcastic text - - book snippets and tweets. There are 224 book snippets and 506 tweets present in the data. The sarcasm targets present in these book snippets and tweets are manually annotated by three well experienced linguists who have at least five years of linguistic annotation experience for tasks such as sentiment analysis, word sense disambiguation and other related works. For the book snippets the average length of the sarcasm target is 1.6 words while it is 2.08 words for the tweets. The average length of the whole snippets is 27.74 words whereas for the tweets this is 12.97 words. For annotation, the annotators are given a bunch of sarcastic texts and asked to identify which words represent the target that the author is mocking? In case the annotators do not find specific words in the text that corre-

[1]Code:https://github.com/Srijanb97/Sarcasm_Target_Detection-EMNLP-

spond to a target, they label it as 'outside'.

4 Socio-linguistic features

In this section, we present various socio-linguistic features that show statistically significant differences between the words corresponding to the sarcasm targets and the rest of the words in the sarcastic text. The results are shown in Table 1. Some of the observations are,

- The distribution of location (LOC) and organisation (ORG) named entities are significantly different for the sarcasm target words compared to the other words ($p < 0.001$).
- The distribution of some of the POS tags (nouns, verbs, adjectives and modifiers) are significantly different for the target words compared to the other words.
- We calculate the LIWC[2] and Empath (Fast et al., 2016) category fractional distributions across the target and the other words in the snippets and tweets. Certain categories as noted in the table are significantly different. The LIWC and Empath dictionary has many pre-defined categories (e.g., 'social', 'family' etc.). Analysis using these dictionaries has been done on different collection of tweets in many past research (Fink et al., 2012; Schwartz et al., 2013; Maity et al., 2016) which forms our primary motivation for this study.

5 Methodology

The architecture of our proposed system is shown in Figure 1. The input to our system is a sarcastic text concatenated with a dummy word at the end of the sentence. We proceed with the hypothesis that each word is a potential candidate to be a sarcasm target. Thus for each word in the sentence we create three components, (i) left context, (ii) right context, and (iii) a word representation for itself. Suppose the input sarcastic sentence is represented by a sequence of words $w_1, w_2 ... w_N$, w_{N+1}, where w_{N+1} is a dummy word. We append a start token and an end token respectively at the beginning and the end of this sentence. These two tokens are never be considered as center word, but act as the left context for the first (w_1) word and the right context for last dummy word (w_{N+1}) respectively. Thus, for a word w_K, where $1 <= K <= N + 1$, the left context is defined as $[< start > w_1 : w_{K-1}]$ while the right context is defined as $[w_{K+1} : w_{N+1} < end >]$. Each word in the left context, right context and the central word are passed through an embedding layer to initialize them through pre-trained embeddings. We experiment with various pre-trained word embeddings like Glove, fast-text, elmo, BERT etc. The word representations are then passed to a LSTM or bidirectional LSTM (Bi-LSTM) layer or a target dependent LSTM (TD-LSTM) layer. In case of unidirectional LSTM (simple LSTM) layer, we keep the flow of hidden vectors in left context and right context as toward the center. Next we concatenate the hidden vectors of rightmost LSTM cell in left context, the central word LSTM cell hidden vector and the hidden vector of leftmost LSTM cell in right context, and pass them to a dense layer. In case of Bi-LSTM we concatenate both the forward and backward hidden vectors at each component before concatenating them again across the components. The dense representation is then concatenated with socio-linguistic features as we have obtained for the word w_k, and passed to a linear layer with sigmoid activation function, for the classification of the center word as sarcasm target or not.

6 Experiments and results

6.1 Evaluation metrics

We consider two evaluation metrics – (i) exact match accuracy, and (ii) dice score, as has been also used in the baseline method (see (Joshi et al., 2018) for definitions).

6.2 Baselines

The baseline as described in Joshi et al. (2018) consists of two extractors joined by an integrator. The two extractors are (i) rule based, and (ii) statistics based. While the rule based extractor extracts candidate words for sarcasm target based on nine syntactic rules, the statistical extractor takes features such as lexical, POS tag, polarity, pragmatic features etc., and passes them to a classifier for the candidate word selection. The selected candidate words are then given as input to the integrator module, which is a hybrid 'AND' or 'OR' module, to select the final set of words as sarcasm targets.

6.3 Model setup and results

The setup: All the results reported are on 3-fold cross validation. Models were trained with Adam Optimizer having a learning rate $1e-5$ and a batch

Table 1: Features that are significantly different for the target words compared to the other words. Features for which $p < 0.05$ ($p < 0.01$ and $p < 0.001$) is represented by (*) {(**), (***)} respectively.

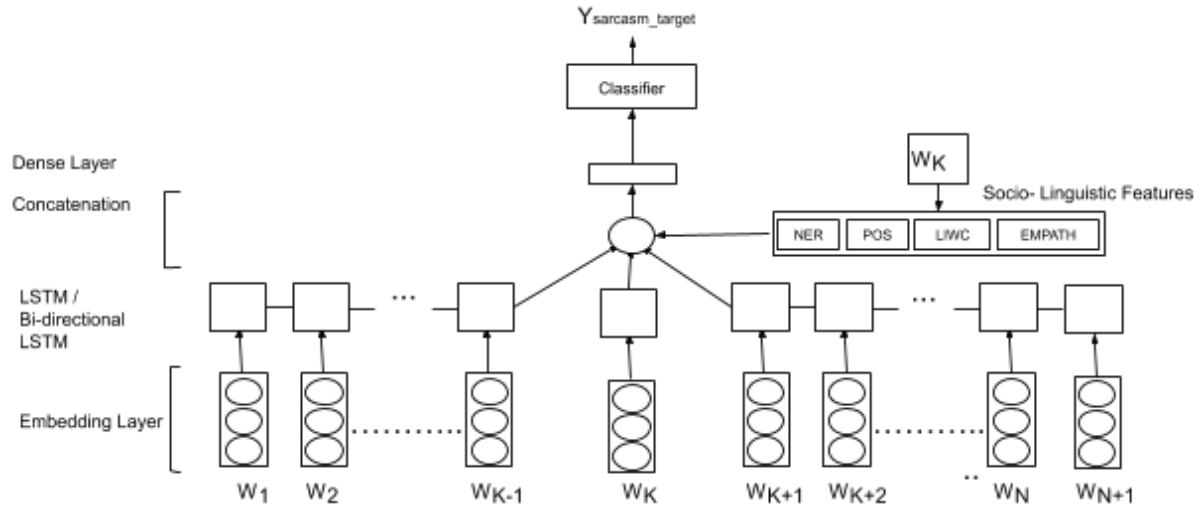

Figure 1: Architecture of the proposed system. w_K is the center word to be classified as target or not, $[< start > w_1 : w_{K-1}]$ is the left context and $[w_{K+1} : w_{N+1} < end >]$ is the right context.

size of 64. Best results were obtained with the Elmo embedding as initialization.

Results: We report the exact match and the dice score obtained from different variants of our model and compare them with the baseline in Table 2. We note that all the variants of our model outperforms the baseline approach by a large margin. Among non-augmented models, the variant with Bi-LSTM layer performs the best in most of the metrics. The dice score for the book snippets data is best when TD-LSTM is used. The augmentation of socio-linguistic features (BiLSTM layer + slf) the performance further leading to the establishment of new state-of-the-art in sarcasm target detection. In addition, for our model variants we also report the macro and micro F1-scores in Table 3. Once again the Bi-LSTM is indicative of the best performance in majority of cases. The macro-F1 and micro-F1 increases further for book snippets when augmented with socio-linguistic features.

Model	EM_T	DS_T	EM_S	DS_S
Baseline: AND	13.45	20.82	16.51	21.28
Baseline: OR	9.09	39.63	7.01	32.68

Table 3: Macro (M) and micro (μ) F1 scores for the different models.

7 Conclusion

In this work, we have presented a deep learning model for sarcasm target identification. We outperform the only available baseline by a large margin. We identify various socio-linguistic features that differentiate the target text from the rest of the snippet/tweet. When these additional socio-linguistic features are fused into our deep learning framework they seem to improve performance for both snippets and tweets establishing new state-of-the-art for this problem.

Abstract

The increasing prevalence of political bias in news media calls for greater public awareness of it, as well as robust methods for its detection. While prior work in NLP has primarily focused on the *lexical bias* captured by linguistic attributes such as word choice and syntax, other types of bias stem from the actual content selected for inclusion in the text. In this work, we investigate the effects of *informational bias*: factual content that can nevertheless be deployed to sway reader opinion. We first produce a new dataset, BASIL, of 300 news articles annotated with 1,727 bias spans[1] and find evidence that informational bias appears in news articles more frequently than lexical bias. We further study our annotations to observe how informational bias surfaces in news articles by different media outlets. Lastly, a baseline model for informational bias prediction is presented by fine-tuning BERT on our labeled data, indicating the challenges of the task and future directions.

1 Introduction

News media exercises the vast power of swaying public opinion through the way it selects and crafts information (De Vreese, 2004; DellaVigna and Gentzkow, 2010; McCombs and Reynolds, 2009; Perse, 2001; Reynolds and McCombs, 2002). Multiple studies have identified the correlation between the increasing polarization of media and the general population's political stance (Gentzkow and Shapiro, 2010, 2011; Prior, 2013), underscoring the imperative to understand the nature of news bias and how to accurately detect it.

In the natural language processing community, the study of bias has centered around what we term

Main event: Democratic presidential candidates ask to see full Mueller report
Main targets: Donald Trump, Democratic candidates

HPO: Democrats want access to special counsel Robert Mueller's investigation into Russian interference in the 2016 presidential election [*before President Donald Trump has a chance to interfere.*]$_{\text{Trump}}$ ... Sen. Mark Warner said in a statement: [*"Any attempt by the Trump Administration to cover up the results of this investigation into Russia's attack on our democracy would be unacceptable."*]$_{\text{Trump}}$

FOX: Democratic presidential candidates [**wasted no time**]$_{\text{Dems}}$ Friday evening demanding the immediate public release of the long-awaited report from Robert S. Mueller III. ... Several candidates, in calling for the swift release of the report, also [*sought to gather new supporters and their email addresses*]$_{\text{Dems}}$ by putting out [**"petitions"**]$_{\text{Dems}}$ calling for complete transparency from the Justice Department.

NYT: And on Saturday, one day before Attorney General William Barr released a short summary of Mueller's findings, former Texas Rep. Beto O'Rourke charged on the campaign trail in South Carolina that you [*"have a president, who in my opinion beyond the shadow of a doubt, sought to, however* [***ham-handedly,***]$_{\text{Trump}}$ *collude with the Russian government—a foreign power—to undermine and influence our elections."*]$_{\text{Trump}}$

Figure 1: Examples of negative bias from Huffington Post (HPO), Fox News (FOX), and New York Times (NYT) discussing the same event. *Informational bias* and **lexical bias** are highlighted. The target of the bias is noted at the end of each span. Intermediary targets of indirect bias spans are underlined.

lexical bias: bias stemming from content realization, or how things are said (Greene and Resnik, 2009; Hube and Fetahu, 2019; Iyyer et al., 2014; Recasens et al., 2013; Yano et al., 2010). Such forms of bias typically do not depend on context outside of the sentence and can be alleviated while maintaining its semantics: polarized words can be removed or replaced, and clauses written in active voice can be rewritten in passive voice.

However, political science researchers find that news bias can also be characterized by decisions

*Equal contribution. Lisa Fan focused on annotation schema design and writing, Marshall White focused on data collection and statistical analysis.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6343–6349, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

made regarding content selection and organization within articles (Gentzkow et al., 2015; Prat and Strömberg, 2013). As shown in Figure 1, though all three articles report on the same event, Huffington Post (HPO) and Fox News (FOX) each frame entities of opposing stances negatively: HPO states an assumed future action of *Donald Trump* as a fact, and FOX implies *Democrats* are taking advantage of political turmoil. Such bias can only be revealed by gathering information from a variety of sources or by analyzing how an entity is covered throughout the article.

We define these types of bias as **informational bias:** sentences or clauses that convey information tangential, speculative, or as background to the main event in order to sway readers' opinions towards entities in the news. Informational bias often depends on the broader context of an article, such as in the second FOX annotation in Figure 1: gathering new supporters would be benign in an article describing political campaign efforts. The subtlety of informational bias can more easily affect an unsuspecting reader, which presents the necessity of developing novel detection methods.

In order to study the differences between these two types of bias, we first collect and label a dataset, **BASIL** (Bias Annotation Spans on the Informational Level), of 300 news articles with lexical and informational bias spans. To examine how media sources encode bias differently, the dataset uses 100 triplets of articles, each reporting the same event from three outlets of different ideology. Based on our annotations, we find that all three sources use more informational bias than lexical bias, and informational bias is embedded uniformly across the entire article, while lexical bias is frequently observed at the beginning.

We further explore the challenges in bias detection and benchmark BASIL using rule-based classifiers and the BERT model (Devlin et al., 2019) fine-tuned on our data. Results show that identifying informational bias poses additional difficulty and suggest future directions of encoding contextual knowledge from the full articles as well as reporting by other media.

2 Related Work

Prior work on automatic bias detection based on natural language processing methods primarily deals with finding sentence-level bias and considers linguistic attributes like word polarity (Recasens et al., 2013), partisan phrases (Yano et al., 2010), and verb transitivity (Greene and Resnik, 2009). However, such studies fail to take into consideration biases that depend on a larger context, which is what we try to address in this work.

Our work is also in line with *framing analysis* in social science theory, or the concept of selecting and signifying specific aspects of an event to promote a particular interpretation (Entman, 1993). In fact, informational bias can be considered a specific form of framing where the author intends to influence the reader's opinion of an entity. The relationship between framing and news is investigated by Card et al. (2015), in which news articles are annotated with framing dimensions like "legality" and "public opinion." BASIL contains richer information that allows us to study the purpose of "frames," i.e., how biased content is invoked to support or oppose the issue at hand.

Research in political science has also studied bias induced by the inclusion or omission of certain facts (Entman, 2007; Gentzkow and Shapiro, 2006, 2010; Prat and Strömberg, 2013). However, their definition of bias is typically grounded in how a reader perceives the ideological leaning of the article and news outlet, whereas our informational bias centers around the media's sentiment towards individual entities. Furthermore, while previous work mostly uses all articles published by a news outlet to estimate their ideology (Budak et al., 2016), we focus on stories of the same events reported by different outlets.

3 BASIL Dataset Annotation

Using a combination of algorithmic alignment and manual inspection, we select 100 sets of articles, each set discussing the *same event* from three different news outlets. 10 sets are selected for each year from 2010 to 2019. We use, in order from most conservative to most liberal, Fox News (FOX), New York Times (NYT), and Huffington Post (HPO). **Main events** and **main entities** are manually identified for each article prior to annotation. The political leanings of the main entities (*liberal*, *conservative*, or *neutral*) are also manually annotated. See the Supplementary for details.

Annotation Process. To compare how the three media sources discuss a story, annotators treat each article triplet as a single unit without knowing media information. Annotations are conducted on both *document-level* and *sentence-level*. On

		NYT	FOX	HPO	All
# Articles		100	100	100	300
# Sentences		3,049	2,639	2,296	7,984
# Words		91,818	70,024	62,321	224,163
# Annotations		636	573	518	1,727
Sentences / Article		30.5 ± 13.8	26.4 ± 10.2	23.0 ± 11.0	26.6 ± 12.2
Words / Sentence		30.1 ± 14.0	26.5 ± 12.4	27.1 ± 12.5	28.1 ± 13.2
Annotations / Article		6.4 ± 4.1	5.7 ± 3.8	5.2 ± 3.5	5.8 ± 3.8
Bias Type	*Informational*	468 (73.6%)	421 (73.5%)	360 (69.5%)	1,249 (72.3%)
	Lexical	168 (26.4%)	152 (26.5%)	158 (30.5%)	478 (27.7%)
Aim	*Direct*	574 (90.2%)	485 (84.6%)	462 (89.2%)	1,521 (88.1%)
	Indirect	62 (9.8%)	88 (15.4%)	56 (10.8%)	206 (11.9%)
Polarity	*Positive*	112 (17.6%)	89 (15.5%)	110 (21.2%)	311 (18.0%)
	Negative	524 (82.4%)	484 (84.5%)	408 (78.8%)	1,416 (82.0%)
Annotations in quotes		205 (32.2%)	299 (52.2%)	217 (41.9%)	721 (41.8%)

Table 1: Descriptive statistics of the BASIL dataset. Mean and standard deviation shown where applicable. Annotation dimensions show raw counts and their percentage within the dimension in parentheses.

the document-level, annotators estimate the overall polarities of how the main event and main entities are covered, and rank the triplet's articles on the ideological spectrum with respect to one another. Before reading the articles, annotators specify their sentiment towards each main entity on a 5 point Likert scale.[2]

On the sentence-level, annotators identify spans of lexical and informational bias by analyzing whether the text tends to affect a reader's feeling towards one of the main entities. In addition to the main dimension of **bias type** (*lexical* or *informational*), each span is labeled with the **target** of the bias (a *main entity*), the bias **polarity** (*positive* or *negative* towards the target), the bias **aim** towards the main target (*direct* or *indirect*), and whether the bias is part of a **quote**. Bias aim investigates the case where the main entity is indirectly targeted through an intermediary figure (see the HPO example in Figure 1, where the sentiment towards the intermediary entity "Trump Administration" is transferred to the main target, "Donald Trump"). Statistics are presented in Table 1.

Inter-annotator Agreement (IAA). Two annotators individually annotate each article triplet before discussing their annotations together to resolve conflicts and agree on "gold-standard" labels. We measure span-level agreement according to Toprak et al. (2010), where we calculate the F1 score of span overlaps between two sets of annotations (details are in the Supplementary). Although the F1 scores of IAA are unsurprisingly low for this highly variable task, the score dramatically increases when agreement is calculated between individual annotations and the gold standard—from 0.34 to 0.70 for informational bias spans and from 0.14 to 0.56 for the sparser lexical spans, demonstrating the effectiveness of resolution discussions.

During the discussions, we noticed several trends that improved the quality of the gold standard annotations. First, the difficulty of being continually vigilant of one's own implicit bias would sometimes cause annotators to mark policies they disagreed with as negative bias (e.g., a liberal annotator might consider the detail that a politician supports an anti-abortion law as negative bias). Discussions allowed annotators to re-examine the articles from a more neutral perspective. Annotators also disagreed on whether a detail was relevant background or biasing peripheral information. During discussions, they performed comparisons to other articles of the triplet to make a final decision—if another article includes the same information, it is likely relevant to the main event. This strategy reiterates the importance of leveraging different media sources.

For overlapping spans, we find high agreement on the other annotation dimensions, with an average Cohen's κ of 0.84 for polarity and 0.92 for target main entity.

4 Media Bias Analysis

4.1 Contrasting the Bias Types

Informational bias outnumbers lexical bias. As shown in Table 1, the large majority of annotations in BASIL are classified as informational bias. One explanation for its prevalence is that journalists typically make a conscious effort to avoid

[2]The likely effect of annotators' prior beliefs on their perception of bias will be investigated in future work.

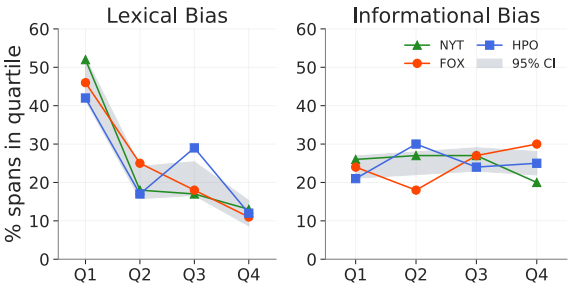

Figure 2: Distribution of lexical and informational bias spans found in each quartile of an article. The shaded area represents the 95% confidence interval for the three outlets combined.

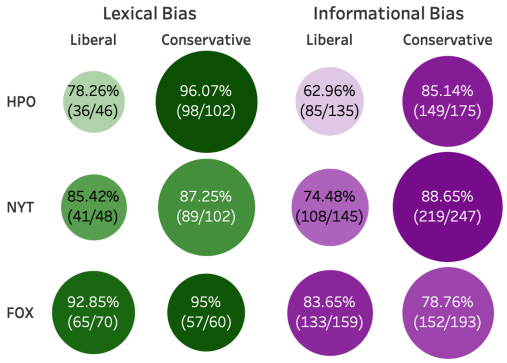

Figure 3: Percentage of bias spans with negative polarity toward targets of known ideology, grouped by media source, bias type, and target's ideology. For example, in all HPO articles, there are 46 lexical bias spans targeting liberals, 78.26% of which are negative. Larger circle means greater number of spans. Darker color corresponds to higher ratio of negative spans.

biased language, but can still introduce informational bias, either intentionally or through negligence.

For both bias types though, negative bias spans are much more pervasive than positive spans, mirroring the well-established paradigm that news media in general focuses on negative events (Niven, 2001; Patterson, 1996).

Lexical bias appears early in an article. We further study differences in characteristics between lexical and informational annotation spans and find that the two bias types diverge in positional distributions. Figure 2 shows that a disproportionate amount of lexical bias is located in the first quartile of articles. A visual inspection indicates that this may be attributed in part to media sources' attempts to hook readers with inflammatory speech early on (e.g., FOX: "Paul Ryan stood his ground against a barrage of Biden *grins, guffaws, snickers and interruptions*.").

In contrast, informational bias is often embedded in context, and therefore can appear at any position in the article. This points to a future direction of bias detection using discourse analysis.

Quotations introduce informational bias. We also find that almost half of the informational bias comes from within quotes (48.7%), highlighting a bias strategy where media sources select opinionated quotes as a subtle proxy for their own opinions (see the second HPO and first NYT annotations in Figure 1).

4.2 Portrayal of Political Entities

On the document-level, only 17 out of 100 article sets had reversed orderings (i.e. FOX marked as "more liberal" or HPO marked as "more conservative" within a triplet), confirming the ideological leanings identified in previous studies. Here, we utilize BASIL's span-level annotations to gain a more granular picture of how sources covering the same events control the perception of entities.

Concretely, we examine the polarity of bias spans with target entities of known ideology. As shown in Figure 3, for both bias types, the percentage and volume of negative coverage for liberal entities strongly correspond to the ideological leaning of the news outlet. Note that though NYT appears to have significantly more informational bias spans against conservatives than HPO, this is because NYT tends to have longer articles than the other two sources (see Table 1), and thus naturally results in more annotation spans by raw count.[3]

Moreover, the breakdown of lexical bias distinguishes FOX from the other two outlets: it comparatively has more negative bias spans towards liberals and fewer towards conservatives, even though all three outlets have more conservative entities than liberal ones across the 100 triplets (average of 99.0 conservatives, 72.7 liberals).

5 Experiments on Bias Detection

We study the bias prediction problem on BASIL as a binary classification task (i.e., whether or not a sentence contains bias) and as a BIO sequence tagging task (i.e., tagging the bias spans in one sentence at the token-level). We benchmark the performance with rule-based classifiers and the popular BERT model (Devlin et al., 2019) fine-tuned

[3]The proportion of annotations to article length are similar for all news outlets: one annotation for every 4.1 (for HPO), 4.5 (for FOX), or 4.6 (for NYT) sentences.

Sentence-level	Precision	Recall	F1
Lexical Bias			
BERT fine-tuning	29.13	38.57	31.49
Informational Bias			
TF-IDF	25.81	26.23	26.02
BERT fine-tuning	43.87	42.91	43.27

Token-level	Precision	Recall	F1
Lexical Bias			
Polarity lexicon	8.00	0.17	0.33
Subjectivity lexicon	28.00	0.65	1.28
BERT fine-tuning	25.60	29.32	25.98
Informational Bias			
BERT fine-tuning	25.56	14.78	18.71
Sentence-to-Token pipeline			
Lexical bias	12.00	13.64	12.77
Informational bias	9.52	5.08	6.63

Table 2: Sentence classification (top) and sequence tagging (bottom) results on lexical and informational bias prediction. For the BERT fine-tuning models, the mean from 10-fold cross validation is shown. The minimum standard deviation from cross validation for all BERT models is 3.36, the maximum is 12.44.

on informational and lexical bias spans separately.

Training Details. We utilize the pre-trained BERT-Base model and use the "Cased" version to account for named entities, which are important for bias detection. We run BERT on individual sentences[4] and perform stratified 10-fold cross validation. The validation set is used to determine when to stop training and a held out test set is used for the final evaluation of each fold. For the sentence-level classifiers, both our informational and lexical models use 6,819 sentences for training, 758 for validation, and 400 for testing.

Due to the sparsity of our data, we train and test our token-level models only on sentences containing bias spans of the relevant bias type. Our informational and lexical bias sequence taggers use a train/val/test split of 1,043/116/62 sentences and 383/42/23 sentences respectively. Results are shown in Table 2.

Sentence-level Classifier. The fine-tuned BERT is better at predicting informational bias than lexical bias, likely because informational bias is better captured by sentence-level context. As a baseline, we select the 4 sentences[5] in each article with the lowest average TF-IDF token scores as containing informational bias. The intuition is that sentences with different content than the rest of the article are more likely to contain extraneous information that the author chose to include to frame the story in a certain way. We find that this simple baseline performs relatively well considering the difficulty of the task, indicating the importance of explicitly modeling context. Future work may consider leveraging context in the entire article or articles on the same story by other media.

Token-level Classifier. From Table 2, we see that the BERT lexical sequence tagger produces better recall and F1 than the informational tagger, highlighting the additional difficulty of accurately identifying spans of informational bias. We also use the polarity and subjectivity lexicons from the MPQA website (Wilson et al., 2005; Choi and Wiebe, 2014) as a simple baseline for lexical bias tagging and find that these word-level cues, though widely used in prior sentiment analysis studies, are insufficient to fully capture lexical bias.

In order to evaluate token-level prediction on the larger original test set, we conduct a pipeline experiment with the fine-tuned BERT models where sentences predicted as containing bias by the best sentence-level classifier from cross validation are tagged by the best token-level model. The results reaffirm our hypothesis that while both tasks are extremely difficult, informational bias is more challenging to detect.

6 Conclusion

We presented a novel study on the effects of informational bias in news reporting from three major media outlets of different political ideology. Analysis of our annotated dataset, BASIL, showed the prevalence of informational bias in news articles when compared to lexical bias, and demonstrated BASIL's utility as a fine-grained indicator of how media outlets cover political figures. An experiment on bias prediction illustrated the importance of context when detecting informational bias and revealed future research directions.

Acknowledgements

This research is supported in part by National Science Foundation through Grant IIS-1813341. We thank Philip Resnik, Nick Beauchamp, and Donghee Jo for their valuable suggestions on various aspects of this work. We are also grateful to the anonymous reviewers for their comments.

[4]BERT's maximum input length is 512 tokens, which is shorter than most articles in BASIL. We thus treat sentences as passages, rather than using text of fixed length.

[5]BASIL averages 4.1 informational bias spans per article.

Incorporating Label Dependencies in Multilabel Stance Detection

Abstract

Stance detection in social media is a well-studied task in a variety of domains. Nevertheless, previous work has mostly focused on multiclass versions of the problem, where the labels are mutually exclusive, and typically positive, negative or neutral. In this paper, we address versions of the task in which an utterance can have multiple labels, thus corresponding to multilabel classification. We propose a method that explicitly incorporates label dependencies in the training objective and compare it against a variety of baselines, as well as a reduction of multilabel to multiclass learning. In experiments with three datasets, we find that our proposed method improves upon all baselines on two out of three datasets. We also show that the reduction of multilabel to multiclass classification can be very competitive, especially in cases where the output consists of a small number of labels and one can enumerate over all label combinations.

1 Introduction

Stance detection is an established task in the computational linguistics community, and is typically concerned with whether an utterance (e.g. a tweet) expresses an attitude (often *positive*, *negative* or *neutral*) against a target such as an entity e.g. a politician (Hasan and Ng, 2013; Mohammad et al., 2016), or another utterance, e.g. a previous tweet in a thread (Zubiaga et al., 2016). Thus stance detection is an important task for analyzing discourse in online forums and social media platforms and is a component in assessing the veracity of claims (Kochkina et al., 2018).

When the stances are mutually exclusive as in the aforementioned cases, multiclass classification is an appropriate formulation for the task. Often, however, a text may express multiple stances simultaneously. Such cases need to be formulated as multilabel classification (Sorower, 2010), where an instance can receive multiple, non-mutually exclusive labels. The most commonly used approaches to multiclass classification treat the task by learning models for each label. However, such approaches do not model dependencies between the labels explicitly, i.e. that the presence of one label results in another becoming more or less likely.

Utterance: blatant racism in #colorado, #blacklivesmatter http://fb.me/1ibyxmswm
Stances: cheating, harm

Figure 1: Examples from each of the datasets.

In this paper, we investigate multilabel stance detection in the context of three datasets: the Brexit Blog Corpus (BBC) (Simaki et al., 2018), the US Election Tweets Corpus (ETC) (Sobhani et al., 2019), and the Moral Foundations Twitter Corpus (MFTC) (Dehghani et al., 2019). Figure 1 shows examples from each dataset where the utterances have been annotated with multiple stances. In BBC and MFTC, each utterance is annotated with a variable number of stances, encoded as binary presence/absence of each possible stance. In ETC, each utterance has a three-way stance *FAVOR* (positive), *AGAINST* (negative), or *NONE* (neutral) for each of the candidates.

We show that it is possible to improve over baseline results that employ binary relevance and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6350–6354,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

multitask learning, by incorporating label dependencies explicitly with the *cross-label dependency loss* (Yeh et al., 2017), originally introduced by Zhang and Zhou (2006). We also show that a reduction of multilabel to multiclass classification by considering all label combinations, also known as label powerset, can be very competitive, especially when the output consists of a small number of labels and one can enumerate all combinations, and verify our results with statistical significance testing. Finally, we improve on the best reported results on the ETC dataset.

2 Multilabel classification

The most commonly used approach to multilabel classification encodes the labels so that a single multilabel classification task is reduced to many sub-tasks learned independently. E.g. for BBC and MFTC binary models are learnt for each of the labels that predict the presence or absence of each label, hence the name *Binary Relevance* (BR), which has also been used in image classification (Boutell et al., 2004). It is straightforward to extend BR to handle tasks such as ETC where each position in the output can have more options than presence/absence, by using multiclass classifiers instead of binary ones. While it is possible to learn the models for the subtasks jointly using multitask learning (Ruder, 2017), this does not capture label dependencies in the output directly; instead it encourages layers of the model before the output to be learned to benefit all tasks simultaneously.

An alternative encoding method, *Label Powerset* (LP), captures dependencies explicitly: each label combination appearing in the training data is encoded as a new, unique label, reducing the task once again to a multiclass classification. However, LP can introduce an exponentially large number of new labels, potentially with few training instances, thus exacerbating class imbalance. Moreover, only those label combinations seen in the data will be available during training; this can be a particular issue when there is a shortage of representative training data.

BR encoding methods ignore label dependencies, and the LP method relies on encoding each label combination appearing in the training set as an explicit new label, both methods reducing the task to binary/multiclass classification. In what follows, we adopt a middle-ground between BR and LP methods by incorporating a notion of dependence between the labels in the targets.

3 Cross-label dependency loss

To capture the dependencies among labels in the output, we follow Yeh et al. (2017) and employ the cross-label dependency (XLD) loss between vectors $\mathbf{y}$ and $\hat{\mathbf{y}}$:

$$\text{XLD}(\mathbf{y}, \hat{\mathbf{y}}) := \frac{1}{|\mathbf{y}^0||\mathbf{y}^1|} \sum_{(p,q)\in\mathbf{y}^0\times\mathbf{y}^1} \exp(\hat{\mathbf{y}}_p - \hat{\mathbf{y}}_q)$$

where $\mathbf{y}$ denotes a vector of true (binary) labels of dimension n, $\hat{\mathbf{y}}$ a vector of predicted label probabilities, $\mathbf{y}^1$ are the indices of the 1-labelled elements of $\mathbf{y}$, $\mathbf{y}^0$ are the indices of the 0-labelled elements, and $\hat{\mathbf{y}}_p$ denotes the pth element of vector $\hat{\mathbf{y}}$. Minimising the cross-label dependency loss is equivalent to maximising the distance between 0- and 1-labelled targets, by penalising the model when it predicts label pairs that shouldn't co-exist for the instance. The intuition is similar to that of Bayesian Personalized Ranking in collaborative filtering (Rendle et al., 2009). We add XLD to cross-entropy loss to define an overall loss function $\text{L}(\mathbf{Y}, \hat{\mathbf{Y}})$:

$$\text{L}(\mathbf{Y}, \hat{\mathbf{Y}}) := \text{XEnt}(\mathbf{Y}, \hat{\mathbf{Y}}) + \alpha \sum_{i\in 1\ldots m} \text{XLD}(\mathbf{Y}_i, \hat{\mathbf{Y}}_i)$$

where XEnt is cross-entropy loss, $\mathbf{Y}_i$ denotes a row vector of dimension n, and $\alpha \geq 0$ is a hyperparameter controlling the contribution of cross-label dependency loss to the overall loss.

Extending XLD to the ETC dataset is slightly complicated by the fact that the labels have three possible values, so we cannot represent a set of target labels as a binary vector. Firstly, we encode the labels using a *one-hot encoding* binary representation, so for example, $AGAINST = 100$, $NONE = 010$ and $FOR = 001$. We then apply XLD between the two encoded target labels, $\mathbf{y}$ and $\mathbf{z}$, of each tweet, and their predicted label probabilities $\hat{\mathbf{y}}$ and $\hat{\mathbf{z}}$ respectively, as follows:

$$\text{XLD}(\mathbf{y}, \mathbf{z}, \hat{\mathbf{y}}, \hat{\mathbf{z}}) = \sum_{(p,q)\in\mathbf{y}^0\times\mathbf{z}^1} \exp(\hat{\mathbf{y}}_p - \hat{\mathbf{z}}_q)$$

The above definition is not symmetric since it compares the 0-labelled positions of the first target label with the 1-labelled positions of the second target label. We re-introduce the symmetry by defining the overall loss function as:

$$\text{L}(\mathbf{Y}, \mathbf{Z}, \hat{\mathbf{Y}}, \hat{\mathbf{Z}}) := \text{XEnt}(\mathbf{Y}, \hat{\mathbf{Y}}) + \text{XEnt}(\mathbf{Z}, \hat{\mathbf{Z}})$$

$$+ \alpha_L \sum_{i \in 1...m} \text{XLD}(\mathbf{Y}_i, \mathbf{Z}_i, \hat{\mathbf{Y}}_i, \hat{\mathbf{Z}}_i)$$
$$+ \alpha_R \sum_{i \in 1...m} \text{XLD}(\mathbf{Z}_i, \mathbf{Y}_i, \hat{\mathbf{Z}}_i, \hat{\mathbf{Y}}_i)$$

where $\alpha_L \geq 0$ and $\alpha_R \geq 0$ are hyper-parameters controlling the contribution of the left and right XLD loss across the targets, respectively.

4 Experimental setup

In our experiments, we use the following multilabel stance detection datasets. The BBC dataset (Simaki et al., 2018) contains 1,239[1] utterances from social media blogs. Each utterance is assigned multiple stances by expert annotators from a set of ten stances. The ETC dataset (Sobhani et al., 2019) consists of 3 sets of tweets, each associated with a pair of election candidates in the US 2016 Election: Donald Trump-Hillary Clinton (DT-HC), Donald Trump-Ted Cruz (DT-TC), and Hillary Clinton-Bernie Sanders (HC-BS), containing 1,722, 1,317 and 1,366 tweets respectively. The MFTC dataset consists of 35,108 tweets curated from six[2] distinct discourse domains, e.g. natural disasters, politics, etc. Each tweet is annotated with up to 10 labels of moral sentiment.

Hyper-parameter selection is done using 5-fold cross-validation (CV) on the training set of each dataset. For the BBC dataset, we split the data 80% into a training set, and 20% holdout test set. For the ETC dataset, we combine the training and validation sets already provided to perform CV, and report on the original test set. For the MFTC data set, we split the data 80% into a training set, and 20% holdout test set.

In BBC and MFTC we use the *Jaccard Similarity Score* (JSS) (Jaccard, 1902) as our scoring metric:

$$J(X, Y) = \frac{\mathbf{y^1} \cap \hat{\mathbf{y}}^\mathbf{1}}{\mathbf{y^1} \cup \hat{\mathbf{y}}^\mathbf{1}} \quad (1)$$

JSS gives credit for partial matches, but does not reward predicting the absence of labels, which is desirable as most labels for each instance are absent (e.g. 90% of the instances in BBC and MFTC have at most two labels). It is less harsh than accuracy (*Exact Match Ratio*) (Sorower, 2010), which requires the entire label combination to be predicted correctly. For the ETC dataset, where each tweet is tagged with exactly two stances (i.e. no absent labels), following Sobhani et al. (2019), we use the macro-averaged F1-score for FAVOR and AGAINST, as the scoring metric.

5 Results

In our experiments, we consider models that capture label dependencies explicitly as well as baselines that do not capture these. As our baselines, we consider binary relevance using FastText (FT) classifiers (Joulin et al., 2017) for each stance label in BBC/MFTC and politician in ETC, as well as a multi-task learning (MTL) approach (Ruder, 2017) where each of the classifiers becomes a task and they all operate on a shared hidden layer (hard parameter sharing). As models capturing dependencies, we considered three options: the combination of the cross label dependency loss with MTL (MTL-XLD), and the combinations of label powerset with FT and MTL (FT-LP and MTL-LP respectively). For the latter, each label combination becomes a task learned jointly with the rest. Further details on all models and parameter tuning are in the supplementary material[3].

In Table 1 we report the test set results for all models. The results for the MFTC dataset are averaged across the six discourse domains. Overall, MTL-LP is the best performing multilabel classification method across all the datasets. MTL-LP is also better than the best performing model Seq2Seq reported in Sobhani et al. (2019) for the ETC dataset. MTL-XLD improves on the baseline models for the BBC and MFTC datasets, but performs slightly worse than MTL on the ETC dataset. We note that our results for the BBC and MFTC datasets are not directly comparable with previous work on BBC (Simaki et al., 2017) and MFTC (Dehghani et al., 2019), since we consider the full set of labels, whereas previous work removed those that were sparser. Our reimplementation of the logistic regression model of Simaki et al. (2017), as an additional baseline, resulted in poor performance in the BBC dataset (20 in JSS) and we did not consider it further.

5.1 Bootstrap training experiments

Reporting results on a held out test set is standard practice, but we also examine the results of

[1]The original dataset contained 1,682 utterances, but we removed duplicates occurring in the training and test sets.

[2]Originally seven but we dropped one domain after consultation with the authors.

[3]Code to reproduce our experiments is available here https://github.com/willferreira/multilabel-stance-detection

	BBC	ETC	MFTC
FT-BR	39.72	52.24	51.19
MTL	48.57	53.32	53.97

the classifiers for the BBC and MFTC datasets via bootstrapping (Gorman and Bedrick, 2019). We bootstrap 30 sample training sets from each dataset, by random sampling without replacement 80% of the data, retaining the 20% as a test set. For each sample, we train the MTL, MTL-LP, and best MTL-XLD model on each bootstrapped training set, and report the score on the test set. Summary statistics are shown in Tables 2 and 3. Using Welch's t-test[4], we cannot reject the null hypothesis (p=0.094) that the mean scores for the MTL-LP and MTL-XLD models on BBC are the same, but we can reject the null hypothesis that either of them are the same as the MTL baseline. For the MFTC Baltimore discourse domain, we cannot reject the null hypothesis (p=0.84) that the mean scores for the MTL-LP and MTL-XLD are the same, but we can reject the null that either of them are the same as the MTL baseline. For the remaining domains, we can reject the null hypothesis that the MTL-LP and MTL-XLD means are the same for ALM (p=6.74e-15), BLM (p=2.3e-13), Davidson (p=1.8e-24), Election (p=1.6e-17) and MeToo (p=0.0021). We can also reject the null, for each domain, that either MLT-XLD or MLT-LP have the same means as the MTL baseline.

	MTL	MTL-XLD	MTL-LP
mean	45.27	51.58	52.51
std	2.01	1.92	2.28

Table 2: Summary statistics for bootstrap results on BBC dataset.

5.2 Learning curve experiments

For the BBC and MFTC datasets, we construct the learning curve for the MTL-LP model against the MTL-XLD model. We sample increasingly larger fractions of the training sets, train the models on these fractions, and record the scoring metric on the original holdout test set. The learning curve for BBC is shown in Figure 2, from which we can see that the MTL-XLD model is superior to MTL-LP until the training dataset size is approximately 70% of the original, after which MTL-LP scores higher than MTL-XLD. The remaining learning curves for MFTC are given in the supplementary material, and show that for discourse domains ALM, BLM, Davidson, Election and MeToo, MTL-LP is superior to MTL-XLD at all training set sizes, however MTL-XLD is superior to MTL-LP for the Baltimore domain.

6 Conclusions

In this paper, we focused on multilabel stance detection and presented experiments on three

datasets. We demonstrated that taking label dependencies into account improves the performance of classification-based and multi-task baselines. In future work, we will explore how to integrate the textual descriptions of the labels in our our approach which has been shown to be beneficial in the case of large label sets (Mullenbach et al., 2018).

Abstract

Sports broadcasters inject drama into play-by-play commentary by building team and player narratives through subjective analyses and anecdotes. Prior studies based on small datasets and manual coding show that such theatrics evince commentator bias in sports broadcasts. To examine this phenomenon, we assemble FOOTBALL, which contains 1,455 broadcast transcripts from American football games across six decades that are automatically annotated with 250K player mentions and linked with racial metadata. We identify major confounding factors for researchers examining racial bias in FOOTBALL, and perform a computational analysis that supports conclusions from prior social science studies.

1 Introduction

Sports broadcasts are major events in contemporary popular culture: televised American football (henceforth "football") games regularly draw tens of millions of viewers (Palotta, 2019). Such broadcasts feature live sports commentators who weave the game's mechanical details into a broader, more subjective narrative. Previous work suggests that this form of storytelling exhibits racial bias: nonwhite players are less frequently praised for good plays (Rainville and McCormick, 1977), while white players are more often credited with "intelligence" (Bruce, 2004; Billings, 2004). However, such prior scholarship forms conclusions from small datasets[1] and subjective manual coding of race-specific language.

We revisit this prior work using large-scale computational analysis. From YouTube, we collect broadcast football transcripts and identify mentions of players, which we link to metadata about each player's race and position. Our resulting FOOTBALL dataset contains over 1,400 games spanning six decades, automatically annotated with ∼250K player mentions (Table 1). Analysis of FOOTBALL identifies two confounding factors for research on racial bias: (1) the racial composition of many positions is very skewed (e.g., only ∼5% of running backs are white), and (2) many mentions of players describe only their actions on the field (not player attributes). We experiment with an additive log-linear model for teasing apart these confounds. We also confirm prior social science studies on racial bias in naming patterns and sentiment. Finally, we publicly release FOOTBALL,[2] the first large-scale sports commentary corpus annotated with player race, to spur further research into characterizing racial bias in mass media.

Player	Race	Mention text
Baker Mayfield	white	"Mayfield the ultimate competitor he's tough he's scrappy"
Jesse James	white	"this is a guy ...does nothing but work brings his lunch pail"
Manny Lawson	nonwhite	"good specs for that defensive end freakish athletic ability"
B.J. Daniels	nonwhite	"that otherworldly athleticism he has saw it with Michael Vick"

Table 1: Example mentions from FOOTBALL that highlight racial bias in commentator sentiment patterns.

2 Collecting the FOOTBALL dataset

We collect transcripts of 1,455 full game broadcasts from the U.S. NFL and National Collegiate Athletic Association (NCAA) recorded between 1960 and 2019. Next, we identify and link mentions of players within these transcripts to infor-

★Authors contributed equally.

[1] Rainville and McCormick (1977), for example, study only 16 games.

[2] http://github.com/jmerullo/football

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6355–6361, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

mation about their race (white or nonwhite) and position (e.g., quarterback). In total, FOOTBALL contains 267,778 mentions of 4,668 unique players, 65.7% of whom are nonwhite.[3] We now describe each stage of our data collection process.

2.1 Processing broadcast transcripts

We collect broadcast transcripts by downloading YouTube videos posted by nonprofessional, individual users identified by querying YouTube for football archival channels.[4] YouTube automatically captions many videos, allowing us to scrape caption transcripts from 601 NFL games and 854 NCAA games. We next identify the teams playing and game's year by searching for exact string matches in the video title and manually labeling any videos with underspecified titles.

After downloading videos, we tokenize transcripts using spaCy.[5] As part-of-speech tags predicted by spaCy are unreliable on our transcript text, we tag FOOTBALL using the ARK TweetNLP POS tagger (Owoputi et al., 2013), which is more robust to noisy and fragmented text, including TV subtitles (Jørgensen et al., 2016). Additionally, we use `phrasemachine` (Handler et al., 2016) to identify all corpus noun phrases. Finally, we identify player mentions in the transcript text using exact string matches of first, last, and full names to roster information from online archives; these rosters also contain the player's position.[6] Although we initially had concerns about the reliability of transcriptions of player names, we noticed minimal errors on more common names. Qualitatively, we noticed that even uncommon names were often correctly transcribed and capitalized. We leave a more systematic study for future work.

2.2 Identifying player race

Racial identity in the United States is a creation of complex, fluid social and historical processes (Omi and Winant, 2014), rather than a reflection of innate differences between fixed groups. Nevertheless, popular *perceptions* of race in the United States and the prior scholarship on racial bias in sports broadcasts which informs our work (Rainville and McCormick, 1977; Rada, 1996; Billings, 2004; Rada and Wulfemeyer, 2005) typically assume hard distinctions between racial groups, which measurably affect commentary. In this work, we do not reify these racial categories; we use them as commonly understood within the context of the society in which they arise.

To conduct a large-scale re-examination of this prior work, we must identify whether each player in FOOTBALL is perceived as white or nonwhite.[7] Unfortunately, publicly available rosters or player pages do not contain this information, so we resort to crowdsourcing. We present crowd workers on the Figure Eight platform with 2,720 images of professional player headshots from the Associated Press paired with player names. We ask them to "read the player's name and examine their photo" to judge whether the player is white or nonwhite. We collect five judgements per player from crowd workers in the US, whose high inter-annotator agreement (all five workers agree on the race for 93% of players) suggests that their perceptions are very consistent. Because headshots were only available for a subset of players, the authors labeled the race of an additional 1,948 players by performing a Google Image search for the player's name[8] and manually examining the resulting images. Players whose race could not be determined from the search results were excluded from the dataset.

3 Analyzing FOOTBALL

We now demonstrate confounds in the data and revisit several established results from racial bias studies in sports broadcasting. For all experiments, we seek to analyze the statistics of contextual terms that describe or have an important association with a mentioned player. Thus, we preprocess the transcripts by collecting contextual terms in windows of five tokens around each player mention, following the approach of Ananya et al. (2019) for gendered mention analysis.[9]

We emphasize that different term extraction strategies are possible, corresponding to different

[3] See Appendix for more detailed statistics.

[4] We specifically query for `full NFL|NCAA|college football games 1960s|1970s|1980s|1990s|2000`, and the full list of channels is listed in in the Appendix.

[5] https://spacy.io/ (2.1.3), Honnibal and Montani (2017)

[6] Roster sources listed in Appendix. We tag first and last name mentions only if they can be disambiguated to a single player in the rosters from opposing teams.

[7] While we use the general term "nonwhite" in this paper, the majority of nonwhite football players are black: in 2013, 67.3% of the NFL was black and most of the remaining players (31%) were white (Lapchick, 2014).

[8] We appended "NFL" to every query to improve precision of results.

[9] If multiple player mentions fall within the same window, we exclude each term to avoid ambiguity.

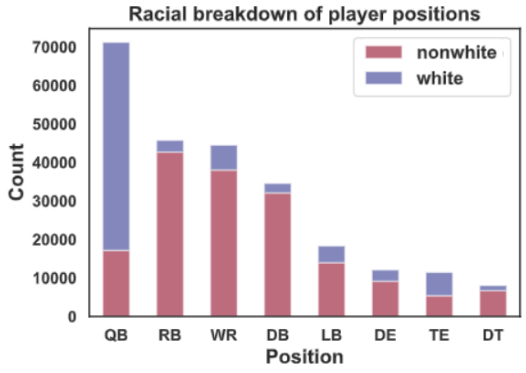

Figure 1: Almost all of the eight most frequently-mentioned positions in FOOTBALL are heavily skewed in favor of one race.

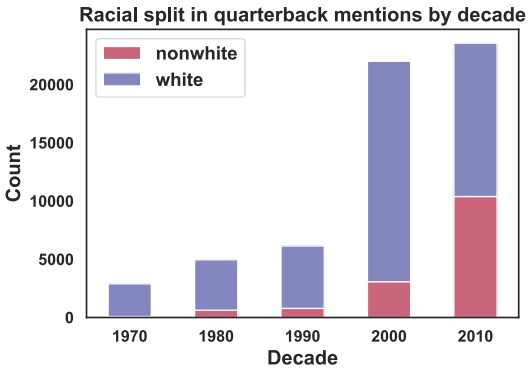

Figure 2: The percentage of nonwhite quarterbacks mentions has drastically increased over time, exemplifying the changing racial landscape in FOOTBALL across time.

precision–recall tradeoffs. For instance, instead of collecting all terms in a window (high recall) we might instead only collect terms in copular constructions with the entity mention (high precision), such as 'devoted' in "Tebow is devoted". Because mention detection strategies affect conclusions about bias in FOOTBALL, systematically defining, analyzing or even learning different possible strategies offers an exciting avenue for future work.

3.1 Statistical and linguistic confounds

Identifying racial bias in football broadcasts presents both statistical and linguistic modeling challenges. Many descriptions of players in broadcasts describe temporary player states (e.g., "Smith deep in the backfield") or discrete player actions ("Ogden with a huge block"), rather than possibly-biased descriptions of players themselves ("Cooper is one scrappy receiver"). Moreover, many players' actions ("passes the ball downfield") depend on the position they play, which is often skewed by race (Figure 1). Furthermore, the racial composition of mentions across different decades can differ dramatically—Figure 2 shows these changes for quarterback mentions—which makes the problem even more complex. Modeling biased descriptions of players thus requires disentangling attributes describing shifting, position-dependent player actions on field (e.g., "Paulsen the tight end with a *fast* catch") from attributes referring to intrinsic characteristics of individual players ("Paulsen is just so, so *fast*").

To demonstrate this challenge, we distinguish between per-position effects and racial effects using an additive, log-linear model which represents the log probability that a word or noun phrase w will describe a player entity e as the sum of two learned coefficients, corresponding to two observed covariates. One observed covariate records a player's race and the other a player's position, which allows us to use learned coefficients to represent how much a player's race or position contributes to the chance of observing an (w, e) pair.

Formally, we model such effects using a sparse MAP estimation variant of SAGE (Eisenstein et al., 2011). We define the binary vector $y_e \in \{0, 1\}^J$ to represent the observed player covariates of race (white or nonwhite) and position. For example, component $y_{e,k}$ will be set to 1 if player e is a quarterback and the component k indexes the quarterback covariate; y_e is a concatenation of two one-hot vectors. We then model $p(w \mid e) \propto \exp\left(\beta_w + (\gamma y_e)_w\right)$, with $\beta_w \in \mathbb{R}^{|\mathcal{V}|}$ as a background distribution over the vocabulary $\mathcal{V}$, set to empirical corpus-wide word and phrase log-probabilities, and $\gamma \in \mathbb{R}^{J \times |\mathcal{V}|}$ as a matrix of feature effects on those log probabilities. $\gamma_{j,w}$ denotes the *difference* in log-probability of w for the j^{th} player feature being on versus off. For example, if j indexes the quarterback covariate and w indexes the word "tough", then $\gamma_{j,w}$ represents how much more likely the word "tough" is to be applied to quarterbacks over the base distribution. We impose a uniform Laplace prior on all elements of γ to induce sparsity, and learn a MAP estimate with the LibLBFGS implementation of OWL-QN, an L1-capable quasi-Newtonian convex optimizer (Andrew and Gao, 2007; Okazaki, 2010).

Table 2 shows several highest-valued $\gamma_{j,w}$ for a subset of the J covariates. The adjective "quick"

White	*long way, long time, valuable*
DB	*strong safety, free safety, state university*
RB	*second effort,single setback,ground game*
QB	*freshman quarterback, arm strength, easier*
WR	*quick slant, end zone touchdown, punt returner*

Table 2: Top terms for the white, defensive back (DB), running back (RB), quarterback (QB), and wide receiver (WR) covariates for the log linear model.

is predictive of wide receivers, but refers to an action the players take on the field ("quick slant"), not an attribute of the receivers themselves. We also find that since "strong safety" is a kind of defensive back, the adjective "strong" is often associated with defensive backs, who are often nonwhite. In this case, "strong" does not reflect racial bias. Preliminary experiments with per-position mention-level race classifiers, as per Ananya et al. (2019), were also unable to disentangle race and position.

These results suggest that a more sophisticated approach may be necessary to isolate race effects from the confounds; it also raises sharp conceptual questions about the meaning of race-conditional statistical effects in social scientific inquiry, since race is a multifaceted construct (a "bundle of sticks," as Sen and Wasow (2016) argue). For future work, it may be useful to think of comparisons between otherwise similar players: how do broadcasters differ in their discussions of two players who are both quarterbacks, and who have similar in-game performance, but differ by race?

We now describe two experiments that sidestep some of these confounds, each motivated by prior work in social science: the first examines player naming patterns, which are less tied to action on field than player attributes. The other uses words with known sentiment polarity to identify positive and negative attributes, regardless of player position or game mechanics.

3.2 Exploring naming patterns

Naming patterns in sports broadcasting—how commentators refer to players by name (e.g., first or last name)—are influenced by player attributes, as shown by prior small-scale studies. For example, Koivula (1999) find that women are more frequently referred to by their first names than men in a variety of sports. Bruce (2004) discover a similar trend for race in basketball games: white players are more frequently referred to by their last names than nonwhite players, often because

Position	Race	First	Last	Full
QB	white	8.3%	20.0%	71.7%
QB	nonwhite	18.1%	7.5%	74.5%
WR	white	6.9%	36.5%	56.5%
WR	nonwhite	11.3%	24.1%	64.6%
RB	white	10.5%	41.2%	48.4%
RB	nonwhite	8.5%	35.4%	56.1%
TE	white	16.6%	18.7%	64.7%
TE	nonwhite	13.8%	16.6%	69.7%

Table 3: White players at the four major offensive positions are referred to by last name more often than nonwhite players at the same positions, a discrepancy that may reflect unconscious racial boundary-marking.

commentators believe their first names sound too "normal". Bruce (2004) further points out that the "practice of having fun or playing with the names of people from non-dominant racial groups" contributes to racial "othering". A per-position analysis of player mentions in FOOTBALL corroborates these findings for all offensive positions (Table 3).

3.3 Sentiment patterns

Prior studies examine the relationship between commentator sentiment and player race: Rainville and McCormick (1977) conclude that white players receive more positive coverage than black players, and Rada (1996) shows that nonwhite players are praised more for physical attributes and less for cognitive attributes than white ones.

To examine sentiment patterns within FOOTBALL, we assign a binary sentiment label to contextualized terms (i.e., a window of words around a player mention) by searching for words that match those in domain-specific sentiment lexicons from Hamilton et al. (2016).[10] This method identifies 49,787 windows containing sentiment-laden words, only 12.8% of which are of negative polarity, similar to the 8.3% figure reported by Rada (1996).[11] We compute a list of the most positive words for each race ranked by ratio of relative frequencies (Monroe et al., 2008).[12] A qualitative inspection of these lists

[10] We use a filtered intersection of lexicons from the NFL, CFB, and sports subreddits, yielding 121 positive and 125 negative words.

[11] Preliminary experiments with a state-of-the-art sentiment model trained on the Stanford Sentiment Treebank (Peters et al., 2018) produced qualitatively unreliable predictions due to the noise in FOOTBALL.

[12] We follow Monroe et al. (2008) in removing infrequent words before ranking; specifically, a word must occur at least ten times for each race to be considered.

Race	Most positive words
white (all)	*enjoying, favorite, calm, appreciate, loving, miracle, spectacular, perfect, cool, smart*
nonwhite (all)	*speed, gift, versatile, gifted, playmaker, natural, monster, wow, beast, athletic*
white (QBs)	*cool, smart, favorite, safe, spectacular, excellent, class, fantastic, good, interesting*
nonwhite (QBs)	*ability, athletic, brilliant, awareness, quiet, highest, speed, wow, excited, wonderful*

Table 4: Positive comments for nonwhite players (top two rows: all player mentions; bottom two rows: only quarterback mentions) focus on their athleticism, while white players are praised for personality and intelligence.

(Table 4) confirms that nonwhite players are much more frequently praised for physical ability than white players, who are praised for personality and intelligence (see Table 1 for more examples).

Limitations: The small lexicon results in the detection of relatively few sentiment-laden windows; furthermore, some of those are false positives (e.g., "beast mode" is the nickname of former NFL running back Marshawn Lynch). The former issue precludes a per-position analysis for all non-QB positions, as we are unable to detect enough sentiment terms to draw meaningful conclusions. The top two rows of Table 4, which were derived from all mentions regardless of position, are thus tainted by the positional confound discussed in Section 3.1. The bottom two rows of Table 4 are derived from the same analysis applied to just quarterback windows; qualitatively, the results appear similar to those in the top two rows. That said, we hope that future work on contextualized term extraction and sentiment detection in noisy domains can shed more light on the relationship between race and commentator sentiment patterns.

4 Related Work

Our work revisits specific findings from social science (§3) on racial bias in sports broadcasts. Such non-computational studies typically examine a small number of games drawn from a single season and rely on manual coding to identify differences in announcer speech (Rainville and McCormick, 1977; Billings, 2004; Rada and Wulfemeyer, 2005). For example, Rada (1996) perform a fine-grained analysis of five games from the 1992 season, coding for aspects such as players' cognitive or physical attributes. Our computational approach allows us to revisit this type of work (§3) using FOOTBALL, without relying on subjective human coding.

Within NLP, researchers have studied gender bias in word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017), racial bias in police stops (Voigt et al., 2017) and on Twitter (Hasanuzzaman et al., 2017), and biases in NLP tools like sentiment analysis systems (Kiritchenko and Mohammad, 2018). Especially related to our work is that of Ananya et al. (2019), who analyze mention-level gender bias, and Fu et al. (2019), who examine gender bias in tennis broadcasts. Other datasets in the sports domain include the event-annotated baseball commentaries of Keshet et al. (2011) and the WNBA and NBA basketball commentaries of Aull and Brown (2013), but we emphasize that FOOTBALL is the first large-scale sports commentary corpus annotated for race.

5 Conclusion

We collect and release FOOTBALL to support large-scale, longitudinal analysis of racial bias in sports commentary, a major category of mass media. Our analysis confirms the results of prior smaller-scale social science studies on commentator sentiment and naming patterns. However, we find that baseline NLP methods for quantifying mention-level genderedness (Ananya et al., 2019) and modeling covariate effects (Eisenstein et al., 2011) cannot overcome the statistical and linguistic confounds in this dataset. We hope that presenting such a technically-challenging resource, along with an analysis showing the limitations of current bias-detection techniques, will contribute to the emerging literature on bias in language. Important future directions include examining the temporal aspect of bias as well as developing more precise mention identification techniques.

Abstract

Judgment prediction for legal cases has attracted much research efforts for its practice use, of which the ultimate goal is prison term prediction. While existing work merely predicts the total prison term, in reality a defendant is often charged with multiple crimes. In this paper, we argue that charge-based prison term prediction (CPTP) not only better fits realistic needs, but also makes the total prison term prediction more accurate and interpretable. We collect the first large-scale structured data for CPTP and evaluate several competitive baselines. Based on the observation that fine-grained feature selection is the key to achieving good performance, we propose the Deep Gating Network (DGN) for charge-specific feature selection and aggregation. Experiments show that DGN achieves the state-of-the-art performance.

1 Introduction

Judgment prediction (Kort, 1957; Ulmer, 1963; Segal, 1984; Liu et al., 2004; Liu and Hsieh, 2006) aims at automatically predicting the judgment result given a textual description of a legal case (An example is given in Figure 1). Recently, there has been a resurgent interest in this task due to the availability of more data and new machine learning techniques (Luo et al., 2017; Zhong et al., 2018b; Hu et al., 2018).

Judgment prediction can be decomposed into several sub-tasks: (a) relevant law article extraction (Liu and Hsieh, 2006; Liu and Liao, 2005; Liu et al., 2015), (b) charge prediction (Liu and Hsieh, 2006; Luo et al., 2017; Hu et al., 2018), (c) and prison term prediction (Zhong et al., 2018a). The dependencies among them have also been studied by Zhong et al. (2018b). While effective methods exist for sub-task (a) and (b), (e.g In CAIL2018 competition (Zhong et al., 2018a), both the charge prediction and the article prediction have attained F_{micro} over 95%), the prison term prediction remains the performance bottleneck.

Case description: On July 7, 2017, when the defendant Cui XX was drinking in a bar, he came into conflict with Zhang XX…… After arriving at the police station, he refused to cooperate with the policeman and bited on the arm of the policeman……

Result of judgment: Cui XX was sentenced to *12* months imprisonment for *creating disturbances* and *12* months imprisonment for *obstructing public affairs*……

● Charge#1	creating disturbances	term 12 months
● Charge#2	obstructing public affairs	term 12 months

Figure 1: An example of judgment prediction.

In this paper, we improve the accuracy of prison term prediction by decomposing it into a set of *charge-based* prison term predictions (CPTPs). In this way, more subtle and sophisticated interactions between textual description and a specific charge can be captured, resulting in more precise term predictions for individual charges. Meanwhile, CPTPs also shed light on the prediction of the total prison term.

On the other hand, CPTP also poses challenges due to the following reasons: The case description can be very lengthy and not all parts are relevant to a specific charge. The charge-related descriptions are often presented in an interleaving way, making it difficult to associate a specific charge with its corresponding information.

To address the above problems, we propose the Deep Gating Network (DGN) for gradually filtering and aggregating charge-specified information at different levels of granularity. Specifically, we stack multiple blocks of an LSTM layer and a charge-specific gating layer for generating a focused charge-based representation of the case description. Finally, the whole document representa-

tion is obtained by a convolutional neural network.

To conduct the experiments, we construct a new dataset, which contains more than 200, 000 criminal cases.[1] To show the effectiveness of the proposed approach, we compare it with several strong baselines adapted from aspect-based sentiment classification (Wang et al., 2016; Tang et al., 2016; Chen et al., 2017; Li et al., 2018). Experiments show that our method achieves significantly better results than all of them. In addition, when we leverage the results of charge-based term predictions for the total prison term prediction, it also surpasses several strong baselines that are directly aimed at the total term prison prediction.

In summary, our contributions are as follows:

- We formally define the task of charge-based prison term prediction and collect the first dataset for it.
- We propose the Deep Gating Network (DGN). Experiments show our method achieves the state-of-the-art performance.
- We show that the accuracy of the total term prediction is also improved by a simple heuristic integration of individual charge-based term predictions.

2 Problem Definition & Dataset Construction

We formally define the task of charge-based prison term prediction as follows. The input are a case description $\mathbf{x} = \{x_1, x_2, \cdots, x_n\}$ and a set of corresponding charges $\mathbf{c} = \{c_1, c_2, \cdots, c_k\}$, where n and k are the length of case description and the number of charges respectively. The goal is to predict the prison terms $\mathbf{y} = \{y_1, y_2, \cdots, y_k\}$, where y_j is the prison term corresponding to charge c_j.

To the best of our knowledge, there is no existing structured dataset for the above task. We thus collect and construct a dataset based on the published records from the Supreme People's Court of China,[2] where each criminal case document includes the accusation by the procuratorate, the court view, and the result of judgment. Following Xiao et al. (2018), we take the accusation by the procuratorate as the input textual description. The charges and the corresponding prison terms are extracted from the result of judgment using regular expressions like "sentence to __ months imprisonment for __". We build 238,749 well-structured cases in total (An example is given in Fig 1). The collected cases are further split into the training set, the validation set, and the test set. The statistics of the dataset are detailed in Table 1. The range of possible prison terms is [1, 240] (in months). The dataset has a broad coverage of common charges, 157 different types of charges are involved.

	#single	#multiple	total
Train	147, 580	42, 420	190, 000
Valid	19, 350	5, 602	24, 952
Test	18, 539	5, 258	23, 797

Table 1: The statistics of the proposed dataset. #single/#multiple means single/multiple charge(s) cases.

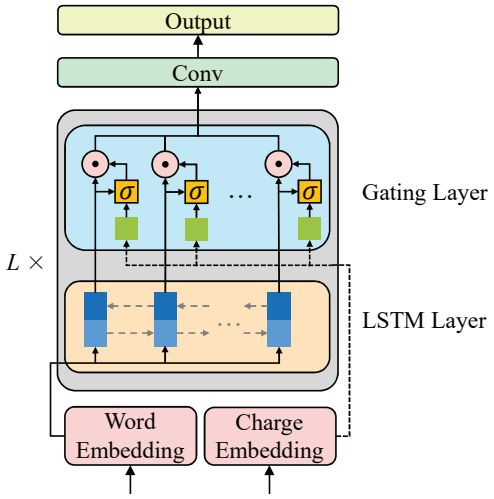

Figure 2: The architecture of DGN

3 Our Approach

Figure 2 gives an overview of our model, which consists of two components: (1) Deep Gating Network (DGN) for charge-based feature filtering and aggregation. (2) Convolutional Neural Network (CNN) for the whole document representation learning.

3.1 Deep Gating Network

At the bottom layer of DGN, each word x_i is mapped into a low dimensional vector $h_i^{(0)}$ according to a word embedding table.

DGN then starts to construct charge-specific representations gradually. L identical blocks are

[1] The dataset can be found at https://github.com/huajiechen/CPTP

[2] http://wenshu.court.gov.cn/

hierarchically stacked. The l-th block takes the output of the $(l-1)$-th layer h_i^{l-1} as input. Each block transforms its input semantic vectors into more sophisticated and focused representations based on gated feature selection and combination.

Specifically, each gating block consists of a bi-LSTM layer for context aggregation and a gating layer for charge-specific feature filtering.

$$\tilde{h}_i^{(l)} = [\overrightarrow{\text{LSTM}}(h_i^{(l-1)}); \overleftarrow{\text{LSTM}}(h_i^{(l-1)})]$$
$$h_k^{(l)} = g_i^{(l)} \odot \tilde{h}_i^{(l)}$$

where $g_i^{(l)}$ is the gate for i-th vector of the l-th gating block and $\odot$ denotes element-wise multiplication. $g_i^{(l)}$ is computed as:

$$g_i^{(l)} = \text{sigmoid}(W^{(l)}[\tilde{h}_i^{(l)}; c_j] + b^{(l)})$$

where c_j is target charge embedding. The gating layers can select the charge-specific features according to the target charge embedding.

3.2 Convolutional Neural Network

Convolutional Neural Network (CNN) has been effective in modeling sequential data (Kim, 2014; Hu et al., 2014; Pang et al., 2016). It uses convolution operations (with multiple groups of filters) for n-gram feature extraction. The sequence-level representation is then obtained through max-pooling, where the most salient n-gram features are detected and selected.

In this work, we use a CNN with filter width in $[1, 2, 3, 4, 5]$. The number of filters for each width is 256. We concatenate the outputs of different filters for the final document representation z.

3.3 Output and Training

The charge-specific document representation z is passed to a fully connected layer with ReLU activation for the final prediction.

$$\hat{y}_j = \text{ReLU}(W_o z + b_o) \quad (1)$$

where W_o and b_o are trainable parameters.

Since the Mean Squared Error (MSE) loss cannot reflect the relative deviation ratio between the prediction and the ground-truth, we take the logarithm before estimating their difference.

$$\delta_j = |\log(y_j + 1) - \log(\hat{y}_j + 1)| \quad (2)$$

To alleviate the impact of outliers and stabilize the training, we propose to use Huber Loss (Huber, 1964), a is set to 1 in experiments:

$$l(x, y_j) = \begin{cases} 0.5 \times \delta_j^2, & \text{if } \delta_j < a \\ a(\delta_j - 0.5a), & \text{otherwise} \end{cases}$$
$$\mathcal{L}(x, y) = \sum_{j=1}^{k} l(x, y_j)$$

Total Term Prediction Although our model is trained to predict the prison term for specific charge, it can be readily adapted to predict the total term by a simple heuristic integration of individual charge-based prison term predictions. There are certain regulations for combined punishment of crimes in Chinese legislation. For simplicity, we take the average of the maximum and summation of individual charge-specific term predictions. The total term prediction is also capped at 240 months.

$$\hat{y}_{total} = \min(240, \frac{\max_j(\hat{y}_j) + \sum_j(\hat{y}_j)}{2})$$

4 Experiments

4.1 Evaluation Metrics

For evaluation, we adopt the official score function (S metric) of the CAIL2018 Competition (Zhong et al., 2018a). The score function measures the log different δ between prediction value $\hat{y}$ and gold value y as in Eq 2. The final score $s(\delta)$ is a piecewise function that increases monotonically with the value of δ. For more details about the S metric, we refer interested readers to (Zhong et al., 2018a). We also report the exact match (EM) rate and error-tolerant accuracy Acc@p, where p is the maximum acceptable error rate. Formally, a prediction is considered "correct" if and only if its value is in the range $[y(1-p), y(1+p)]$.

4.2 Compared Methods

The task of charged-based prison term prediction is similar in spirit to aspect-based sentiment classification (Pang et al., 2008), where multiple classification decisions are made given one text description and different target entities. This suggests that other neural architectures proposed for aspect-based sentiment classification may also be suitable for our task. The adaption from classification to regression can be easily accomplished by replacing the original final layer with that of Eq 1. Specifically, we adapted the following models:

Model	S	EM	Acc@0.1	Acc@0.2
ATE-LSTM	66.49	7.72	16.12	33.89
MemNet	70.23	7.52	18.54	36.75
RAM	70.32	7.97	18.87	37.38
TNet	73.94	8.06	19.55	39.89
DGN	**76.48**	**8.92**	**20.66**	**42.61**

Table 2: Results on charge-based prison term prediction(%).

- ATAE-LSTM (Wang et al., 2016): it concatenates aspect embedding and the output of LSTM, and uses self-attention to obtain aspect-based representation.
- MemNet (Tang et al., 2016): it uses multi-hop attention over the word embeddings for a sentence, where aspect embedding is regarded as the initial key.
- RAM (Chen et al., 2017): it also uses multi-hop attention for aspect-specific representation learning, while the attention at different time steps are aggregated by recurrent neural network.
- TNet (Li et al., 2018): it has a similar architecture to DGN. The major difference is that it employs a Transformation Network for mixing the information in aspect embedding and token representations rather than the explicit gates in our model.

The aspect embedding in above models is replaced by charge embedding in our experiments. In addition, we also compare with the popular models for total term prediction (Zhong et al., 2018a,b):

- CNN (Kim, 2014): the case description is encoded by a CNN with multiple filter widths, followed by max-pooling.
- RNN (Hochreiter and Schmidhuber, 1997): bi-LSTM are used for case description encoding, where the final states are regarded as the document representation.
- RCNN (Lai et al., 2015): we stack a CNN on the top of LSTM states for final representation.

4.3 Main Results

The results of charge-based prison term prediction are shown in Table 2. The proposed DGN achieves the best results on all four metrics. In addition, the margins between our model and others are remarkably wide. It can be observed that aspect-based sentiment models only give moderate performance, which we attribute to that the case description is so long that more rigorous feature selection, such as the treatment of DGN, is needed. Our model selects and aggregates features in a explicit way which is more efficient and effective in dealing with charge-specific descriptions often spread out across lengthy case documents in CPTP.

Model	S	EM	Acc@0.1	Acc@0.2
CNN	67.24	8.41	16.96	35.58
RNN	67.27	8.04	16.79	35.11
RCNN	69.56	8.54	17.57	35.75
DGN	**75.74**	**8.64**	**19.32**	**40.43**

Table 3: Results on total term prediction(%).

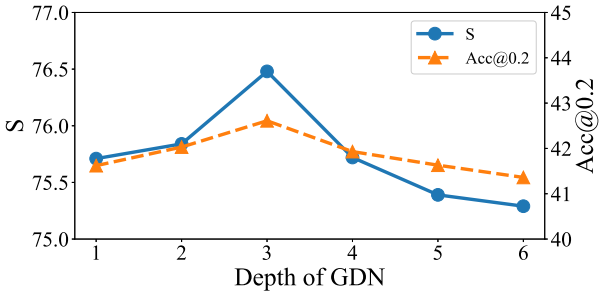

Figure 3: Performance with different depths of DGN.

Table 3 presents the results of the total term prediction. Although our method is not directly trained to make the final prediction, the performance of our model surpasses all baselines, which confirms that the breakdown charge-based analysis can indeed help the total prison term prediction.

4.4 Depth of DGN

To study the impact of the number of DGN blocks, we test our model with various depths and show the results in Fig 3.[3] As shown, the performance improves as the depth of DGN increases until it reaches 3 when the performance begins to drop likely due to overfitting.

4.5 Effects of Log Huber Loss

We compare Log Huber Loss (LHL) with Mean Square Error (MSE), Mean Absolute Error (MAE) and Huber Loss (HL). We also try Log Cosh Loss

[3]For simplicity, we only show S score and Acc@0.2.

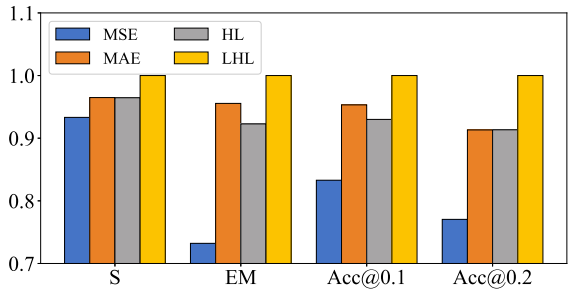

Figure 4: Compare of different loss functions. The result of LHL is regarded as unit 1.

(LCL), but it does not converge. As shown in Figure 4, Log Huber Loss performs best in all metrics for all models. The improvement is most significant in S metric. It also suggests that making the loss function consistent with the evaluation metric is beneficial.

4.6 Error Analysis

So far, our model has the best results on prison term predictions. In this section, we aim to conduct an in-depth analysis and answer the following questions: (1) In which cases, our model fails to deliver accurate predictions? (2) What are the prospects for further improvement? After carefully analyzing 100 examples, we roughly classify them into the following categories.

Lengthy Description Some cases are extremely complicated, especially for cases with gangs. These descriptions are often lengthy and involve multiple criminal suspects.

Incomplete Information In some cases, the input case description does not contain sufficient information for precise prediction. Note we only take the accusation by the procuratorate as input, which is incomplete compared to the whole materials relevant to a case. For example, if a defendant is recidivism within a shorter period, he/she shall be given a heavier punishment.

Rare Cases Some special circumstances will influence the prison term, yet rarely happen in the training set. For example, if a defendant cause injuries to others due to excessive defense, he/she shall be given a lighter punishment. This knowledge is easily understandable by humans, bu hard to be learned by machine learning models.

5 Ethical Discussions

Although the research on prison term prediction has considerable potential to improve efficiency and fairness in criminal justice, there are certain ethical concerns worth discussions.

First, does the training data provide unbiased examples and sufficient? For example, some may worry about that the model may treat people differently based on race, social class, age and so on (Tonry, 2014). Discrimination in the past may be learned in models. Also, with the development of our society, new forms of crimes will appear. A model trained on historical data may fail in these new cases.

Second, is the learned system robust enough? Some subtle details may significantly affect the result of judgment. For example, the amount of theft and the number of drugs, these numerical values are often not uniform in different case descriptions, causing it hard to learn by neural models. Some infrequent words, such as named entities, may also cause undesirable interference.

The mistake of legal judgment is serious, it is about people losing years of their lives in prison, or dangerous criminals being released to reoffend. We should pay attention to how to avoid judges' over-dependence on the system. It is necessary to consider its application scenarios. In practice, we recommend deploying our system in the "Review Phase", where other judges check the judgment result by a presiding judge. Our system can serve as one anonymous checker.

In summary, the judgment prediction is an emerging technology at its exploratory stage. We should be aware of the risks and prevent any inappropriate use of the technology.

6 Conclusion

In this paper, we formally presented the task of charge-based prison term prediction. We introduced the first large-scale dataset for this task. To tackle the problem of the noisy and entangled description of legal cases, we proposed the deep gating network for charge-specific information filter. Experiments show that our model significantly improves the accuracy of charge-based prison term prediction, as well as the total term prediction. Finally, we discussed some ethical problems of the proposed techniques that are worth cautious thinking.

Restoring ancient text using deep learning: a case study on Greek epigraphy

Yannis Assael[1,2,†], **Thea Sommerschield**[1,†], **Jonathan Prag**[1]
University of Oxford[1], DeepMind[2]

Abstract

Ancient History relies on disciplines such as Epigraphy, the study of ancient inscribed texts, for evidence of the recorded past. However, these texts, "inscriptions", are often damaged over the centuries, and illegible parts of the text must be restored by specialists, known as epigraphists. This work presents PYTHIA, the first ancient text restoration model that recovers missing characters from a damaged text input using deep neural networks. Its architecture is carefully designed to handle long-term context information, and deal efficiently with missing or corrupted character and word representations. To train it, we wrote a non-trivial pipeline to convert PHI, the largest digital corpus of ancient Greek inscriptions, to machine actionable text, which we call PHI-ML. On PHI-ML, PYTHIA's predictions achieve a 30.1% character error rate, compared to the 57.3% of human epigraphists. Moreover, in 73.5% of cases the ground-truth sequence was among the Top-20 hypotheses of PYTHIA, which effectively demonstrates the impact of this assistive method on the field of digital epigraphy, and sets the state-of-the-art in ancient text restoration.

1 Introduction

One of the key sources for Ancient History is the discipline of epigraphy, which delivers firsthand evidence for the thought, society and history of ancient civilisations. Epigraphy is the study of documents, "inscriptions", written on a durable surface (stone, ceramic, metal) by individuals, groups and institutions of the past (Davies and Wilkes, 2012). Only a small minority of surviving inscriptions are fully legible and complete, as many have been damaged in time (Figure 1). An epigraphist must then hypothesise how much text is missing, and what it might have originally been. These hypotheses are called "restorations" (Bodel, 2012). The present work offers a fully automated aid to the epigraphist's restoration task.

Restoring text is a complex and time-consuming task (Woodhead, 1967; Mattingly, 1996). Epigraphists rely on accessing vast repositories of information to find textual and contextual "parallels" (recurring expressions in similar documents). These repositories primarily consist in a researcher's mnemonic repertoire of such parallels, and in digital corpora for performing "string matching" searches (The Packard Humanities Institute, 2005; Clauss, 2012). However, minor differences in the search query can exclude or obfuscate relevant results, making it hard to estimate the true probability distribution of possible restorations. To the best of our knowledge, this is the first work to bypass the constraints of current epigraphic methods by means of a fully automated deep learning model, PYTHIA, which aids the task of ancient text restoration. It is supplemented by PHI-ML, an epigraphic dataset of a machine actionable text. PYTHIA takes as input a sequence of damaged text, and is

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6368–6375, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

trained to predict character sequences comprising the hypothesised restorations. It works both at a character- and a word-level, thereby effectively handling incomplete or missing words. PYTHIA can furthermore be used by all disciplines dealing with ancient texts (philology, papyrology, codicology) and applies to any language (ancient or modern). To aid and encourage future research, PYTHIA and PHI-ML have been open-sourced at http://tiny.cc/ancient-text-restoration.

2 Related work

Natural language processing (NLP) has dealt with tasks akin to text restoration. Indeed, standard count-based n-gram language models (LM) share with epigraphists the "parallel-finding" approach. N-gram models are outperformed by neural language models, which operate at a word-level (Mikolov et al., 2010, 2011), at a subword- or character-level (Sutskever et al., 2011; Mikolov et al., 2012; Botha and Blunsom, 2014), or a combination of both, known as character-aware language models (Miyamoto and Cho, 2016; Kim et al., 2016; Hwang and Sung, 2017). Despite our efforts to include BERT (Devlin et al., 2018) in our evaluation, we found that the excessive resources required did not allow for training on a single GPU. Text restoration also shares similarities with machine reading comprehension (Hermann et al., 2015; Kočiskỳ et al., 2018), and cloze deletion tests (Hill et al., 2016; Bajgar et al., 2017; Fedus et al., 2018; Xie et al., 2018; Zhang et al., 2018). Although word-level language modelling is capable of capturing context information more efficiently than character-level alternatives, damaged inscriptions preserve only limited parts of words, complicating the learning of representations. To overcome this issue, PYTHIA works simultaneously at both a character- and a word-level, thereby capturing long-term dependencies ("context information").

Finally, several works have used machine learning to study ancient inscriptions, focusing on assistive tools (Roued-Cunliffe, 2010), optical character recognition and visual analysis (Terras and Robertson, 2006; Garz et al., 2014; Soumya and Kumar, 2014; Shaus, 2017; Hussien et al., 2015; Amato et al., 2016; Can et al., 2016; Suganya and Murugavalli, 2017; Palaniappan and Adhikari, 2017; Avadesh and Goyal, 2018), writer identification (Tracy and Papaodysseus, 2009; Panagopoulos et al., 2009; Faigenbaum-Golovin et al., 2016), text analysis (Rao et al., 2009b,a, 2010; Yadav et al., 2010; Lee and Haug, 2010; Vatri and McGillivray, 2018), and machine translation (Pagé-Perron et al., 2017; Luo et al., 2019).

3 Generating PHI-ML

Due to availability of digitised epigraphic corpora, PYTHIA has been trained on ancient Greek (henceforth, "AG") inscriptions, written in the ancient Greek language between 7^{th} century BCE and 5^{th} century CE. We chose AG epigraphy as a case study for two reasons: a) the variability of contents and context of the AG epigraphic record makes it an excellent challenge for NLP; b) several digital AG textual corpora have been recently created, the largest ones being PHI (The Packard Humanities Institute, 2005; Gawlinski, 2017) for epigraphy; Perseus (Smith et al., 2000) and First1KGreek (Crane et al., 2014) for ancient literary texts.

When restoring damaged AG inscriptions, the epigraphists' conjectures on the total number of missing characters are guided by grammatical and syntactical considerations, as well as by the reconstructed graphical layout of the inscription. Conjectured missing characters are conventionally marked with hyphens, one hyphen equating to one missing character. Additionally, epigraphists traditionally convert edited texts to lower case and add punctuation and diacritics, which are generally absent from the original inscription. These conventions were also used in PHI.

Because human annotations in PHI were noisy and often syntactically inconsistent (Iversen, 2007), we wrote a pipeline to convert it into a machine actionable text. We first computed the character frequencies and standardised the AG alphabet to include all core characters, including all accentuation (147 characters), numbers, spaces and punctuation marks. Two additional characters were introduced: '-' representing a missing character, and '?' signifying a character to be predicted. Then we wrote regular expressions to replace all AG numerical notations appearing in the texts with 0 to avoid numerical correlations, strip the remaining punctuation marks, remove the conventional epigraphical symbols surrounding certain characters ("Leiden Conventions"), and discard notes whose content was not in Greek. We then proceeded to clear human comments, fix the spacing and cases of duplicate punctuation,

and filtered the resulting text so as to retain only the restricted alphabetical characters. The texts with fewer than 100 characters were also discarded. Lastly, we matched the number of missing characters with those conjectured by epigraphists, thereby converting the length value to an equal number of '-' symbols.

The resulting dataset is named PHI-ML, and consists of more than 3.2 million words (Table 1). The inscriptions whose PHI IDs ended in {3, 4} (every inscription in PHI was assigned a unique identifier when the original corpus was created) were held out and used respectively as test and validation sets.

Split	Inscriptions	Words	Chars
Train	34,952	2,792k	16,300k
Valid	2,826	211k	1,230k
Test	2,949	223k	1,298k

Table 1: Statistics for the PHI-ML corpus.

4 Restoring text using PYTHIA

PYTHIA's architecture is a sequence-to-sequence (Sutskever et al., 2014) based neural network architecture, consisting of a Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) encoder, an LSTM decoder, and an attention mechanism introduced by Luong et al. (2015); Bahdanau et al. (2014). The encoder takes an inscription text x as input, where the symbol '-' denotes the missing characters, and '?' the blanks to be predicted. The input characters are first passed through a lookup table with learnable embedding vectors. Next, the encoded sequence is used as input for the decoder, which is trained to predict the content of the '?' characters, as shown in Figure 2. Attention allows the decoder to "attend" to parts of the input sequence relevant to the current output, thus improving the modelling of long-term dependencies. To further improve performance, we designed PYTHIA's encoder to take an additional input stream of word embeddings, as it is difficult to model the word-level context using only character-level information. Thus, we generated a list of the 100k most frequent words appearing in PHI-ML, and using a separate lookup table we concatenated at each time-step the embedding of each character with the embedding of the word it belongs to. Words that do not appear in the list, or that contain missing characters were mapped to 'unk', an embedding for unknown words. Figure 2 illustrates PYTHIA processing the phrase μηδέν ἄγαν. Finally, to allow better modelling we used a bidirectional LSTM encoder and refer to this architecture as PYTHIA-BI-WORD. Further details are given in Appendix A.

Obtaining suggestions. To better aid the epigraphist's task, PYTHIA returns multiple predictions as well as the level of confidence for each result, rather than a single prediction per text restoration. Specifically, we provide a set of the Top 20 predictions decoded using beam search.

5 Experimental evaluation

The ground-truths for incomplete epigraphic texts were lost over millennia. Consequently, in order to generate a ground-truth sequence, we artificially removed part of the input text and treated this as the ground-truth sequence. On each training step we selected an inscription and sampled a start index and a length value $\in [100, 1000]$, and extracted the context text x, which was then used as input. Within x, we sampled a new start index and length $\in [1, 10]$ to select the target sequence y; its characters' positions were replaced with the special symbol '?', which denotes the positions to be predicted. The test and validation sets used the maximum context length. Beam search with a beam width of 100 was used to decode hypothesis. To simplify comparisons, all AG accentuation was discarded, as inputting accents was time-consuming for the human evaluations described in the following paragraph. This decision did not noticeably influence the reported scores.

5.1 Methods evaluated

ANCIENT HISTORIAN. Because text restoration is an extremely time-consuming task even for an expert epigraphist, we set out to evaluate the difficulty of the restoration task at hand - and thereby judge the impact of our work - with the help of two doctoral students with epigraphical expertise. The scholars were allowed to use the training set to search for "parallels", and made an average of 50 restorations in 2 hours, with a 57.3% character error rate (CER).

LM PHILOLOGY. To evaluate the performance of a model using "parallels", we trained a LM. Since large parts of the text are garbled, making complete words unidentifiable, and because BERT was not an option, the LM works at a character-

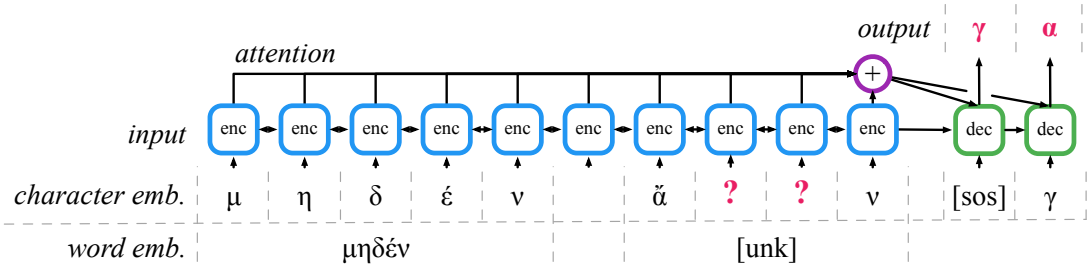

Figure 2: PYTHIA-BI-WORD processing the phrase μηδέν ἄγαν (mēdén ágan) "nothing in excess", a fabled maxim inscribed on Apollo's temple in Delphi. The letters "γα" are the characters to be predicted, and are annotated with '?'. Since ἄ??ν is not a complete word, its embedding is treated as unknown ('unk'). The decoder outputs correctly "γα".

level and is based on the setup of Zaremba et al. (2015) (Appendix B). The LM was trained on two larger digital corpora of literary AG texts ("philology"), First1KGreek and Perseus, and evaluated on PHI-ML.

LM PHILOLOGY & EPIGRAPHY. LM jointly trained on First1KGreek, Perseus and PHI-ML.

LM EPIGRAPHY. LM trained on PHI-ML.

PYTHIA-UNI. An ablation architecture, using only characters as input and unidirectional LSTM.

PYTHIA-BI. Similar to the PYTHIA-UNI ablation, but with a bidirectional LSTM.

PYTHIA-BI-WORD. This is our proposed model of choice, which uses a bidirectional LSTM and both characters and words as inputs.

5.2 Results

The aforementioned methods were evaluated using: a) the character error rate (CER) of the top prediction and the target sequence, b) the Top-20 accuracy score, where we ascertain whether the ground-truth sequence exists within the first 20 predictions. The latter evaluates the effectiveness of PYTHIA as an assistive tool providing restoration suggestions to epigraphists. As shown in Table 2, the ancient historians' restorations had a CER of 57.3%, which is telling of the difficulty of the task. The language model trained on epigraphic datasets performed slightly better, with a CER of 57.3%. Interestingly, the two attempts to use larger philological datasets performed worse. This is very likely due to a divergence in epigraphical and literary cultures. The CER of the unidirectional PYTHIA-UNI and the bidirectional PYTHIA-BI alternatives were 42.2% and 32.5% respectively. The top score was therefore achieved by the bidirectional PYTHIA-BI-WORD, which took both word and character embeddings as inputs, with a CER of 30.1%. Furthermore, the ground-truth appeared among the 20 most probable predictions of PYTHIA-BI-WORD 73.5% of the times, which indicates that it could be a uniquely effective assistive tool.

Method	CER	Top-20
Ancient Historian	57.3%	–
LM Philology	68.1%	26.0%
LM Philology & Epigraphy	65.0%	28.8%
LM Epigraphy	52.7%	47.0%
PYTHIA-UNI	42.2%	60.6%
PYTHIA-BI	32.5%	71.1%
PYTHIA-BI-WORD	**30.1%**	**73.5%**

Table 2: Predictive performance on PHI-ML.

5.3 The importance of context

The presence of context information is a determining factor in the accuracy of epigraphic restorations. We therefore evaluated the impact of different textual lengths acting as augmented context on the Top-20 accuracy measure of PYTHIA. As can be seen in Figure 3, the correlation between the "context length" and the predictive performance of our model is positive. Specifically, the performance peaks around 500 characters of context

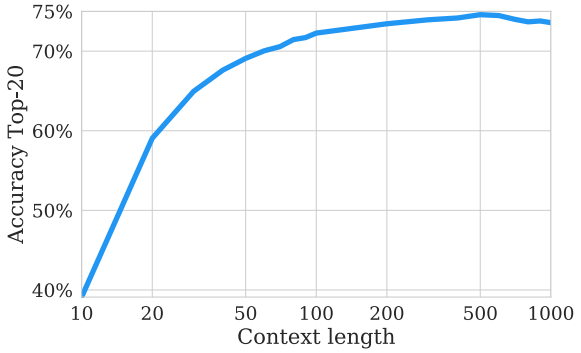

Figure 3: Predictive performance of the PYTHIA-BI-WORD model under different context lengths.

length. Furthermore, Figure 3 exemplifies the increased difficulty faced by the model when only a short context length (e.g. 20 characters) is offered. The latter scenario recalls the similar difficulties encountered by string-matching and "parallel" search approaches, where the search queries would often be short.

5.4 Visualising PYTHIA's attention

We set up an example modifying lines b.8 - c.5 of the inscription MDAI(A) 32 (1907) 428, 275 (PHI ID PH316753), to evaluate PYTHIA's receptiveness to context information and visualise the attention weights at each decoding step. In the text of Figure 4, the last word is a Greek personal name ending in -ου. We set ἀπολλοδώρου ("Apollodorou") as the personal name, and hid its first 9 characters. This name was specifically chosen because it already appears within the input text. Figure 4 illustrates the attention weights for decoding the first 4 missing characters. To aid visualisation, the weights were separately scaled between 0 and 1 within the area of the characters to be predicted ('?') in green, and of the rest of the text in blue; the magnitude is represented by the colour intensity. As can be seen, PYTHIA is attending to the contextually-relevant parts of the text: specifically, ἀπολλοδώρου. The name is correctly predicted. As a litmus test, we substituted ἀπολλοδώρου in the input text with another personal name of the same length: ἀρτεμιδώρου ("Artemidorou"). The predicted sequence alters accordingly to ἀρτεμιδώρ, thereby illustrating the importance of context in the prediction process.

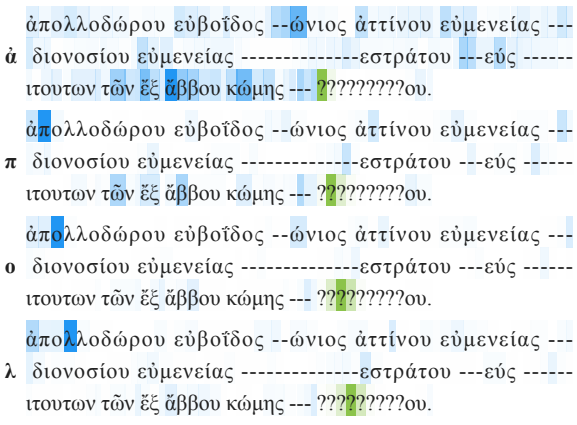

Figure 4: Visualisation of the attention weights for the decoding of the first 4 missing characters. The ground-truth text y = ἀπολλοδώρ appears in the input text, and PYTHIA attends to the relevant parts of the sequence.

5.5 Restoring full texts

We then applied PYTHIA iteratively in order to predict all the missing text of an AG inscription, comparing PYTHIA's predictions with an edition of reference (Rhodes and Osborne, 2003). In Figure 5 the correct restorations are highlighted in colour blue and erroneous ones are in purple. In a real-world scenario, PYTHIA would provide more than one hypothesis to the epigraphist. The ground-truth sequence did in fact exist within the Top-20 hypotheses in nearly all cases, illustrating the efficacy of such technologies when paired with human decision-making.

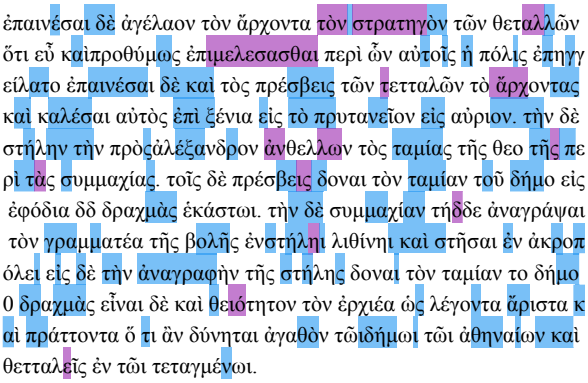

Figure 5: Sample restoration of the inscription *IG* II^2 116, lines 34 - 48. Restorations are in colour blue when correct, purple when incorrect.

6 Conclusions

PYTHIA is the first ancient text restoration model of its kind. Our experimental evaluation and ablation studies illustrate the validity of our design decisions, and illuminate the ways PYTHIA can assist, guide and advance the ancient historian's task - and digital humanities proper. The combination of machine learning and epigraphy has the potential to impact meaningfully the study of inscribed textual cultures, both ancient and modern. By open-sourcing PYTHIA, and PHI-ML's processing pipeline, we hope to aid future research and inspire further interdisciplinary work.

Abstract

We propose a novel tensor embedding method that can effectively extract lexical features for humor recognition. Specifically, we use word-word co-occurrence to encode the contextual content of documents, and then decompose the tensor to get corresponding vector representations. We show that this simple method can capture features of lexical humor effectively for continuous humor recognition. In particular, we achieve a distance of 0.887 on a global humor ranking task, comparable to the top performing systems from SemEval 2017 Task 6B (Potash et al., 2017) but without the need for any external training corpus. In addition, we further show that this approach is also beneficial for small sample humor recognition tasks through a semi-supervised label propagation procedure, which achieves about 0.7 accuracy on the *16000 One-Liners* (Mihalcea and Strapparava, 2005) and *Pun of the Day* (Yang et al., 2015) humour classification datasets using only 10% of known labels.

1 Introduction

Recognizing humor automatically is an important step for natural human-computer interaction (Shahaf et al., 2015). While early works tend to frame humor recognition as a binary classification task (Mihalcea and Strapparava, 2005; Yang et al., 2015), the last few years have seen the emergence of humor recognition as a pairwise relative ranking task (Cattle and Ma, 2016; Shahaf et al., 2015). In addition to pairwise ranking, SemEval 2017 Task 6 also includes a global ranking subtask. However, the majority of submissions build global rankings using a series of pairwise comparisons (Potash et al., 2017). Only Yan and Pedersen (2017) attempt to predict global rankings directly, ranking documents inversely to their probability according to an n-gram language model.

State-of-the-art humor recognition algorithms usually require a considerable amount of training data with labels to learn effective features (Yang et al., 2015). However, such data are difficult to obtain – especially fine-grained humor annotations. First, the humor judgments differ from individual to individual. Thus, collecting perceptually consistent human labels is expensive and time-consuming. Second, fine-grained degrees of humor add a further challenge. Therefore, methods on small sample learning or even unsupervised rule-based methods merit investigation.

In this paper, considering the importance of lexical information for humor recognition (Radev et al., 2015), we propose a tensor decomposition method to capture the contextual nuances of a corpus. This allows us to model the lexical similarity of sentences regardless of the size of the corpus. In this way, we can rank the degree of humor effectively via lexical centrality (Radev et al., 2015), namely, regarding the distance to the lexical center as an indicator of the degree of humor. Experimental results on the SemEval 2017 Task 6 dataset (Potash et al., 2017) show that *without external training data*, the tensor embedding method can achieve performance equivalent to the second place on SemEval 2017 Task 6B without the need for any external training corpus. In addition, by applying a semi-supervised label propagation procedure (Zhou et al., 2003), we can also use the tensor embedding method for small sample humor recognition, achieving about 0.7 accuracy with only 10% of known labels on the *16000 One-Liners* (Mihalcea and Strapparava, 2005) and *Pun of the Day* (Yang et al., 2015) datasets.

The contributions of this paper are: 1) we propose a tensor embedding method to model the lexical features of documents, which can capture lexical similarity effectively regardless of the size of the corpus, 2) we show that the lexical features can be used effectively for fine-grained humor ranking and small sample humor recognition. Our implementation is open-sourced, and can be found at https://github.com/zhaozj89/TensorEmbeddingNLP.

2 Related Work

2.1 Humor Feature Extraction

Modeling and learning humor features are critical for automatic humor recognition. Previous works tend to use a combination of phonological, stylistic, semantic, and content-based features. Phonological features include acoustic features extracted from sitcom audio tracks (Bertero and Fung, 2016) and "phonetic embeddings" generated using a character-to-phoneme LSTM encoder-decoder (Donahue et al., 2017). Stylistic features include alliteration, rhyming, negative sentiment, and adult slang (Mihalcea and Strapparava, 2005) as well as emotional scenarios (Reyes et al., 2012). Semantic features range from attempts to measure incongruity (Cattle and Ma, 2018; Shahaf et al., 2015; Yang et al., 2015) to the use of word embeddings as inputs to neural models (Bertero and Fung, 2016; Donahue et al., 2017). Content-based approaches include word frequency (Mihalcea and Strapparava, 2005), n-gram probability (Yan and Pedersen, 2017), and lexical centrality (Radev et al., 2015).

Centrality is based on the observation that humorous responses to common stimuli tend to cluster around a small number of core jokes (Radev et al., 2015; Shahaf et al., 2015), with more central documents benefiting from "wisdom of the crowd". While most humor features involve making population-level inferences based on document-level features, centrality is instead population-level feature directly. Radev et al. (2015) calculate their centrality feature using LexRank, a graph-based text summarization method (Erkan and Radev, 2004). Compared with more traditional lexical similarity measures like tf-idf, this method is better suited to short humor texts due to their short lengths leading to sparse vector representations (Erkan and Radev, 2004).

2.2 Small Sample Humor Recognition

Once the humor features have been extracted, the next step is training a machine learning model to make predictions. Although learning-based methods have shown significant performance improvement recently (Yang et al., 2015), one of their main bottlenecks is the lack of appropriate training corpora. While previous works have employed data crawled from websites (Mihalcea and Strapparava, 2005; Yang et al., 2015), Twitter (Cattle and Ma, 2016; Reyes et al., 2012), sitcom subtitles (Bertero and Fung, 2016; Purandare and Litman, 2006), or the New Yorker Cartoon Caption Contest (Radev et al., 2015; Shahaf et al., 2015), these datasets are generally not released publicly. Owing to the difficulty in obtaining fine-grained labeled humor data, it is critical to study how to recognize humor by a small training sample or even without labeled data.

3 Method

3.1 Tensor Embedding

Contextual patterns of words can be used to measure lexical similarity for humor recognition. State-of-the-art learning-based approaches like doc2vec (Le and Mikolov, 2014) or sent2vec (Pagliardini et al., 2018) usually require a large amount of data. This is difficult to obtain for humor recognition. We propose to use a novel tensor decomposition method to obtain lexical features of short humor texts. To capture lexical similarity for humor recognition, we propose to represent the tensor through a novel word-word co-occurrence method, which has only been explored in the context of fake news detection (Hosseinimotlagh and Papalexakis, 2018). Considering a corpus $\mathcal{D} = \{s_1, s_2, \ldots, s_D\}$ with D sentences, we first build a vocabulary for it, namely, $w_1, w_2, \ldots, w_V$, where V is the number of words. For each sentence s in $\mathcal{D}$, we count the word-word co-occurrence in a small window H, and build a frequency matrix $\mathbf{W}_s \in \mathbb{Z}^{V \times V}$, where $\mathbb{Z}$ denotes the set of integers. In particular, $\mathbf{W}_s(i, j)$ indicates the frequency that word w_i and w_j co-occur in s within the window H. In this way, we can capture the lexical patterns of s in $\mathbf{W}_s$. We then stack all $\mathbf{W}_s$ as a three-dimensional tensor $\boldsymbol{\mathcal{W}} \in \mathbb{Z}^{V \times V \times D}$. The objective of tensor decomposition is to find an approximation $\hat{\boldsymbol{\mathcal{W}}}$ of $\boldsymbol{\mathcal{W}}$ so

Table 2: The results of our label propagation system. XX% refers to XX% of the data used as training and (100-XX)% as test. Baseline results reproduced from Yang et al. (2015)

that:

$$\hat{\mathcal{W}} = \sum_{r=1}^{R} \mathbf{v}_r \otimes \mathbf{v}_r \otimes \mathbf{d}_r, \quad (1)$$

where $\mathbf{v}_r \in \mathbb{R}^V$, $\mathbf{d}_r \in \mathbb{R}^D$, R is the pre-defined rank parameter, and $\otimes$ is the outer product, namely, $\mathbf{v}_r \otimes \mathbf{v}_r \otimes \mathbf{d}_r$ being a three-dimensional tensor, and

$$\mathbf{v}_r \otimes \mathbf{v}_r \otimes \mathbf{d}_r(i,j,k) = \mathbf{v}_r(i) \cdot \mathbf{v}_r(j) \cdot \mathbf{d}_r(k). \quad (2)$$

With the tensor decomposition, we can find low-rank embeddings of sentences that capture the similarity of contextual patterns (Hosseinimotlagh and Papalexakis, 2018). In particular, $\mathbf{C} = [\mathbf{d}_1, \mathbf{d}_2, \ldots, \mathbf{d}_R] \in \mathbb{R}^{D \times R}$, where the s-row of $\mathbf{C}$ is the embedding vector of sentence s. The Euclidean distance of embeddings is used to measure the similarity of two sentences.

3.2 Lexical Centrality

We use lexical centrality to rank the degree of humor (Radev et al., 2015). While Radev et al. (2015) utilize a graph-based definition of centrality, we instead take a vector-space approach. Given the decomposed $\mathbf{C} = [\mathbf{c}_1^T, \mathbf{c}_2^T, \ldots, \mathbf{c}_D^T]^T$, we compute a centroid as the average $\mathbf{m}$ of all sentence vectors of a corpus:

$$\mathbf{m} = \frac{1}{D} \sum_{k=1}^{D} \mathbf{c}_k. \quad (3)$$

The Euclidean distance to the center is then taken as an indicator of the degree of humor. In other words, given two sentences s_1 and s_2 and their embeddings $\mathbf{x}_1$ and $\mathbf{x}_2$, $d(\mathbf{m}, \mathbf{x1}) < d(\mathbf{m}, \mathbf{x2})$ implies s_1 is funnier than s_2.

3.3 Label Propagation

With the lexical similarity captured by tensor embeddings, we can build a similarity graph, and use a label propagation algorithm (Zhou et al., 2003) for semi-supervised humor recognition. In this way, we can use only a small portion of labeled data to predict the remaining unlabeled data effectively (Zhou et al., 2003). In particular, with the tensor embeddings, we first find the K nearest neighbors of each data point, and build a similarity graph $\mathcal{G}$. We then form an affinity matrix W, where $W_{ij} = 1$ if i and j are connected, otherwise, $W_{ij} = 0$. Afterwards, we iterate:

$$F(t+1) = \alpha W F(t) + (1-\alpha) Y, \quad (4)$$

and can get the results F^* as the limit of this sequence. Equation (4) means we propagate the labels of each data point to its neighbors in a weighted average way, where α is the ratio of propagating labels each iteration. For each point x_i, its label is $y_i = \arg\max_{j \le c} F^*_{ij}$.

4 Experiment

To evaluate the effectiveness of the tensor embedding method, we conduct two experiments on global humor ranking and binary humor classification separately. The alternating least squares

method of CANDECOMP/PARAFAC tensor decomposition (Sidiropoulos et al., 2017) is used to calculate the low-rank sentence embeddings as implemented in the Matlab tensor toolbox [1].

4.1 Global Humor Ranking

To show the effectiveness of the lexical centrality of our tensor embedding method, we conduct an experiment on SemEval 2017 Task 6B (Potash et al., 2017) consisting of tweeted responses to specific thematic prompts generated as part of a TV show. For each prompt, the writing staff of the show pick a top 10 and an overall winner. These humor judgments are used as gold standard labels.

Tensor embeddings and centroids are computed on a per-prompt basis and responses are ranked according to their distance from the centroid. We run a grid search procedure to determine the optimal rank value as 100, the window size as 5. For evaluation, we adopt the same edit distance-based metric used in Potash et al. (2017).

The results of our lexical centrality system using tensor embeddings is shown in Table 1, where the official results of other state-of-the-art systems are taken from Potash et al. (2017). Our system outperforms all but the Duluth (Yan and Pedersen, 2017) system in the official results for SemEval 2017 Task 6B (Potash et al., 2017), making our performance equivalent to second place. It is notable that our system can perform well on the **Broadway** prompt, where other methods usually fail. Moreover, because our system does not have a learning procedure, the performance is more stable than others.

4.2 Binary Humor Classification

To show the effectiveness of label propagation of our tensor embedding method for small sample humor recognition, we conduct an experiment on two humor classification datasets *16000 One-Liners* (Mihalcea and Strapparava, 2005) and *Pun of the Day* (Yang et al., 2015). Similarly, we run a grid search procedure to find optimal parameters, and set the rank as 10, window size as 5, neighbor number as 50, α as 0.2. $F(0)$ is set as a zero matrix initially. For each dataset, we randomly select 5%, 10%, 30%, and 90% of the data for training. We run a 10-fold procedure, and report the average accuracy, precision, recall, and F1 score values.

The results of humor classification are shown in Table 2. Our own implementation of Yang et al. (2015) is included as a baseline. While Yang et al. (2015) uses a large portion of data for training and combine different features, we find that at similar portion of training data (90%), the results of our method are comparable to it. In addition, with only a small portion of training data, our method still achieves good results.

4.3 Discussion

4.3.1 Lexical Centrality

The most notable aspect of our tensor embedding/lexical centrality approach is how little training data our system requires. Our system's unsupervised nature means that we do not need to use the 106 training prompts included with the SemEval 2017 Task 6 dataset. Our results are obtained exclusively using the six evaluation prompts. By comparison, almost all the systems reported in Potash et al. (2017) take a supervised approach and make full use of the training set. Furthermore, since we consider prompts one-at-a-time and since each prompt only contains approximately 100 responses, we are able to achieve a state-of-the-art performance with 100 training documents. The only system reported in Potash et al. (2017) to take an unsupervised approach is Duluth (Yan and Pedersen, 2017). Like ours, their results are obtained without using the training set. However, their system uses an n-gram language model trained on a 6.2GB subset of the News Commentary Corpus and the News Crawl Corpus. Similarly, most other systems use some form of external training corpora for training word embeddings, phoneme models, semantic models, and so on.

Another advantage of our approach is the ease of interpretability, in contrast to neural-based state-of-the-art baselines. Because our lexical feature is in an Euclidean space, we can compare and rank humor level more easily. Tweets labeled as "overall winners" exhibited a smaller mean distance from their respective centroids (0.848) than those labeled as "merely in the top 10" (0.942). These tweets then in turn exhibited smaller distances than those labeled as "not in the top 10" (1.00). A one-way ANOVA test gives mild evidence that overall winners are drawn from a different distribution than tweets not in the top 10 ($p = 0.106$). This slight result is likely due to the fuzzy nature of humor and the relatively small

[1] www.tensortoolbox.org

dataset. Finally, ad hoc analysis of tweets with distances > 2 revealed these to be mostly "not in the top 10".

4.3.2 Label Propagation

Although the semi-supervised framework provides a good alternative for small sample humor recognition, our method still cannot achieve a state-of-the-art performance with the same portion of training data. There is still space to improve the method; for example, by modeling not only the lexical similarity, but also other features, such as word association (Cattle and Ma, 2016), and the like, that are important for humor recognition. In addition, label propagation cannot handle unbalanced data well. Adding prior knowledge of the ratio of labels, e.g., the unbalanced SemEval 2017 Task 6 dataset, also deserves further investigation.

5 Conclusion

In this paper, we show the importance of lexical features for small sample humor recognition. We propose a tensor embedding method to capture the lexical similarity effectively. Without training data, on SemEval 2017 Task 6B, we can achieve a relatively good result. Under a semi-supervised framework, the tensor embedding method can also achieve pretty good results for small sample humor classification. It is interesting to further investigate a unified tensor embedding model to combine not only lexical, but also other features that are important for the sense of humor.

Abstract

We present **EDA**: **e**asy **d**ata **a**ugmentation techniques for boosting performance on text classification tasks. EDA consists of four simple but powerful operations: synonym replacement, random insertion, random swap, and random deletion. On five text classification tasks, we show that EDA improves performance for both convolutional and recurrent neural networks. EDA demonstrates particularly strong results for smaller datasets; on average, across five datasets, training with EDA while using only 50% of the available training set achieved the same accuracy as normal training with all available data. We also performed extensive ablation studies and suggest parameters for practical use.

1 Introduction

Text classification is a fundamental task in natural language processing (NLP). Machine learning and deep learning have achieved high accuracy on tasks ranging from sentiment analysis (Tang et al., 2015) to topic classification (Tong and Koller, 2002), but high performance often depends on the size and quality of training data, which is often tedious to collect. Automatic data augmentation is commonly used in computer vision (Simard et al., 1998; Szegedy et al., 2014; Krizhevsky et al., 2017) and speech (Cui et al., 2015; Ko et al., 2015) and can help train more robust models, particularly when using smaller datasets. However, because it is challenging to come up with generalized rules for language transformation, universal data augmentation techniques in NLP have not been thoroughly explored.

Previous work has proposed some techniques for data augmentation in NLP. One popular study generated new data by translating sentences into French and back into English (Yu et al., 2018). Other work has used data noising as smoothing (Xie et al., 2017) and predictive language models for synonym replacement (Kobayashi, 2018). Although these techniques are valid, they are not often used in practice because they have a high cost of implementation relative to performance gain.

Operation	Sentence
None	A sad, superior human comedy played out on the back roads of life.
SR	A ***lamentable***, superior human comedy played out on the ***backward*** road of life.
RI	A sad, superior human comedy played out on ***funniness*** the back roads of life.
RS	A sad, superior human comedy played out on ***roads*** back ***the*** of life.
RD	A sad, superior human out on the roads of life.

Table 1: Sentences generated using EDA. SR: synonym replacement. RI: random insertion. RS: random swap. RD: random deletion.

In this paper, we present a simple set of universal data augmentation techniques for NLP called EDA (**e**asy **d**ata **a**ugmentation). To the best of our knowledge, we are the first to comprehensively explore text editing techniques for data augmentation. We systematically evaluate EDA on five benchmark classification tasks, showing that EDA provides substantial improvements on all five tasks and is particularly helpful for smaller datasets. Code is publicly available at `http://github.com/jasonwei20/eda_nlp`.

2 EDA

Frustrated by the measly performance of text classifiers trained on small datasets, we tested a number of augmentation operations loosely inspired by those used in computer vision and found that they helped train more robust models. Here, we present the full details of EDA. For a given sentence in the training set, we randomly choose and perform one of the following operations:

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6382–6388, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

1. **Synonym Replacement (SR):** Randomly choose n words from the sentence that are not stop words. Replace each of these words with one of its synonyms chosen at random.
2. **Random Insertion (RI):** Find a random synonym of a random word in the sentence that is not a stop word. Insert that synonym into a random position in the sentence. Do this n times.
3. **Random Swap (RS):** Randomly choose two words in the sentence and swap their positions. Do this n times.
4. **Random Deletion (RD):** Randomly remove each word in the sentence with probability p.

Since long sentences have more words than short ones, they can absorb more noise while maintaining their original class label. To compensate, we vary the number of words changed, n, for SR, RI, and RS based on the sentence length l with the formula $n=\alpha l$, where α is a parameter that indicates the percent of the words in a sentence are changed (we use $p=\alpha$ for RD). Furthermore, for each original sentence, we generate n_{aug} augmented sentences. Examples of augmented sentences are shown in Table 1. We note that synonym replacement has been used previously (Kolomiyets et al., 2011; Zhang et al., 2015; Wang and Yang, 2015), but to our knowledge, random insertions, swaps, and deletions have not been extensively studied.

3 Experimental Setup

We choose five benchmark text classification tasks and two network architectures to evaluate EDA.

3.1 Benchmark Datasets

We conduct experiments on five benchmark text classification tasks: (1) **SST-2**: Stanford Sentiment Treebank (Socher et al., 2013), (2) **CR**: customer reviews (Hu and Liu, 2004; Liu et al., 2015), (3) **SUBJ**: subjectivity/objectivity dataset (Pang and Lee, 2004), (4) **TREC**: question type dataset (Li and Roth, 2002), and (5) **PC**: Pro-Con dataset (Ganapathibhotla and Liu, 2008). Summary statistics are shown in Table 5 in Supplemental Materials. Furthermore, we hypothesize that EDA is more helpful for smaller datasets, so we delegate the following sized datasets by selecting a random subset of the full training set with N_{train}={500, 2,000, 5,000, all available data}.

3.2 Text Classification Models

We run experiments for two popular models in text classification. **(1)** Recurrent neural networks (RNNs) are suitable for sequential data. We use a LSTM-RNN (Liu et al., 2016). **(2)** Convolutional neural networks (CNNs) have also achieved high performance for text classification. We implement them as described in (Kim, 2014). Details are in Section 9.1 in Supplementary Materials.

4 Results

In this section, we test EDA on five NLP tasks with CNNs and RNNs. For all experiments, we average results from five different random seeds.

4.1 EDA Makes Gains

We run both CNN and RNN models with and without EDA across all five datasets for varying training set sizes. Average performances (%) are shown in Table 2. Of note, average improvement was 0.8% for full datasets and 3.0% for N_{train}=500.

	Training Set Size			
Model	500	2,000	5,000	full set
RNN	75.3	83.7	86.1	87.4
+EDA	79.1	84.4	87.3	88.3
CNN	78.6	85.6	87.7	88.3
+EDA	80.7	86.4	88.3	88.8
Average	76.9	84.6	86.9	87.8
+EDA	79.9	85.4	87.8	**88.6**

Table 2: Average performances (%) across five text classification tasks for models with and without EDA on different training set sizes.

4.2 Training Set Sizing

Overfitting tends to be more severe when training on smaller datasets. By conducting experiments using a restricted fraction of the available training data, we show that EDA has more significant improvements for smaller training sets. We run both normal training and EDA training for the following training set fractions (%): {1, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100}. Figure 1(a)-(e) shows performance with and without EDA for each dataset, and 1(f) shows the averaged performance across all datasets. The best average accuracy without augmentation, 88.3%, was achieved using 100% of the training data. Models trained using EDA surpassed this number by achieving an

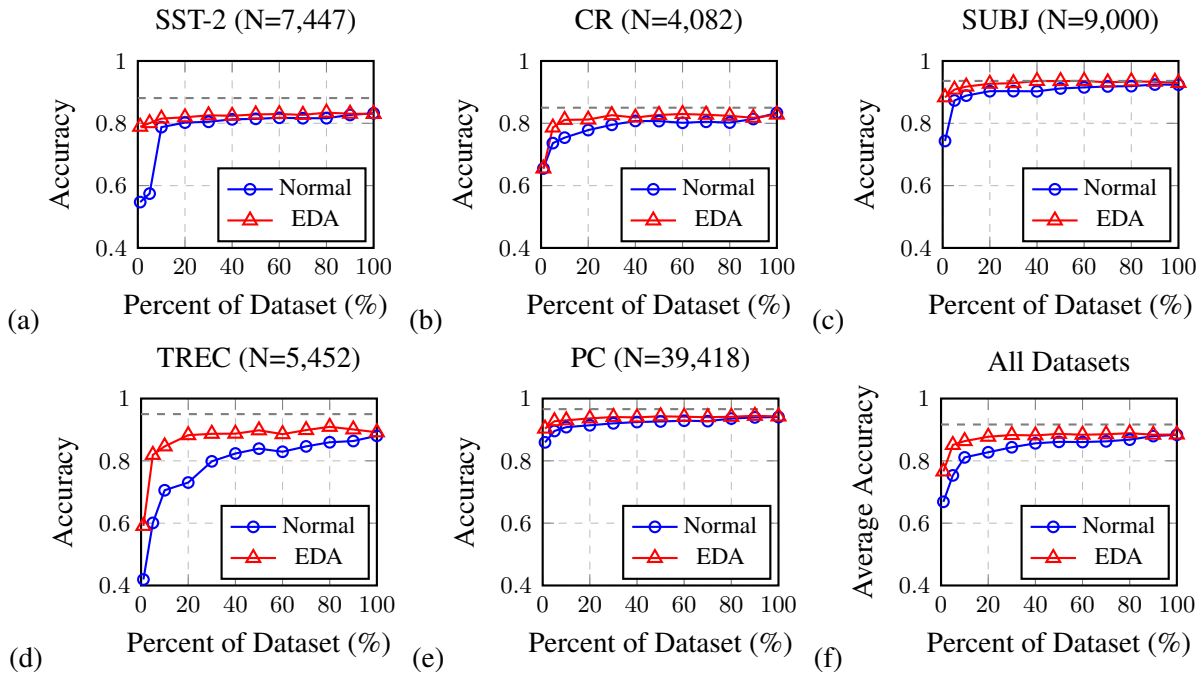

Figure 1: Performance on benchmark text classification tasks with and without EDA, for various dataset sizes used for training. For reference, the dotted grey line indicates best performances from Kim (2014) for SST-2, CR, SUBJ, and TREC, and Ganapathibhotla (2008) for PC.

average accuracy of 88.6% while only using 50% of the available training data.

4.3 Does EDA conserve true labels?

In data augmentation, input data is altered while class labels are maintained. If sentences are significantly changed, however, then original class labels may no longer be valid. We take a visualization approach to examine whether EDA operations significantly change the meanings of augmented sentences. First, we train an RNN on the pro-con classification task (PC) without augmentation. Then, we apply EDA to the test set by generating nine augmented sentences per original sentence. These are fed into the RNN along with the original sentences, and we extract the outputs from the last dense layer. We apply t-SNE (Van Der Maaten, 2014) to these vectors and plot their 2-D representations (Figure 2). We found that the resulting latent space representations for augmented sentences closely surrounded those of the original sentences, which suggests that for the most part, sentences augmented with EDA conserved the labels of their original sentences.

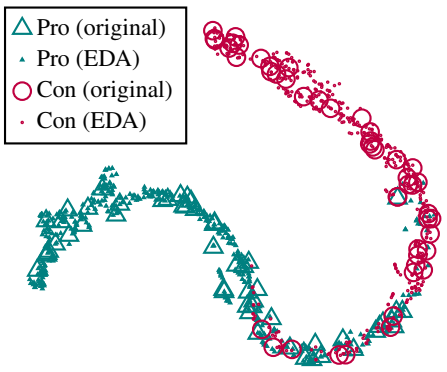

Figure 2: Latent space visualization of original and augmented sentences in the Pro-Con dataset. Augmented sentences (small triangles and circles) closely surround original sentences (big triangles and circles) of the same color, suggesting that augmented sentences maintianed their true class labels.

4.4 Ablation Study: EDA Decomposed

So far, we have seen encouraging empirical results. In this section, we perform an ablation study to explore the effects of each operation in EDA. Synonym replacement has been previously used (Kolomiyets et al., 2011; Zhang et al., 2015; Wang and Yang, 2015), but the other three EDA operations have not yet been explored. One could hypothesize that the bulk of EDA's performance gain is from synonym replacement, so we isolate each of the EDA operations to determine their individual ability to boost performance. For all four operations, we ran models using a single oper-

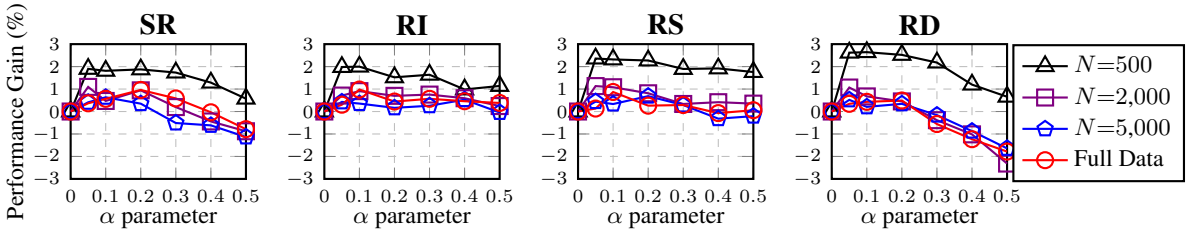

Figure 3: Average performance gain of EDA operations over five text classification tasks for different training set sizes. The α parameter roughly means "percent of words in sentence changed by each augmentation." SR: synonym replacement. RI: random insertion. RS: random swap. RD: random deletion.

ation while varying the augmentation parameter α=$\{0.05, 0.1, 0.2, 0.3, 0.4, 0.5\}$ (Figure 3).

It turns out that all four EDA operations contribute to performance gain. For SR, improvement was good for small α, but high α hurt performance, likely because replacing too many words in a sentence changed the identity of the sentence. For RI, performance gains were more stable for different α values, possibly because the original words in the sentence and their relative order were maintained in this operation. RS yielded high performance gains at $\alpha \leq 0.2$, but declined at $\alpha \geq 0.3$ since performing too many swaps is equivalent to shuffling the entire order of the sentence. RD had the highest gains for low α but severely hurt performance at high α, as sentences are likely unintelligible if up to half the words are removed. Improvements were more substantial on smaller datasets for all operations, and α=0.1 appeared to be a "sweet spot" across the board.

4.5 How much augmentation?

The natural next step is to determine how the number of generated augmented sentences per original sentence, n_{aug}, affects performance. In Figure 4, we show average performances over all datasets for n_{aug}=$\{1, 2, 4, 8, 16, 32\}$. For smaller training sets, overfitting was more likely, so generating many augmented sentences yielded large performance boosts. For larger training sets, adding more than four augmented sentences per original sentence was unhelpful since models tend to generalize properly when large quantities of real data are available. Based on these results, we recommend usage parameters in Table 3.

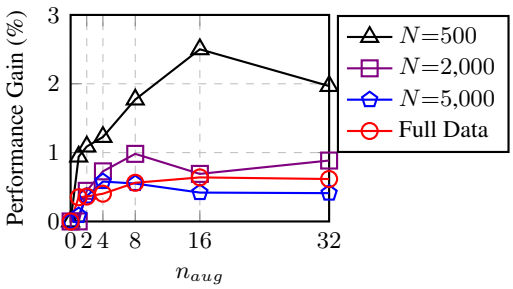

Figure 4: Average performance gain of EDA across five text classification tasks for various training set sizes. n_{aug} is the number of generated augmented sentences per original sentence.

N_{train}	α	n_{aug}
500	0.05	16
2,000	0.05	8
5,000	0.1	4
More	0.1	4

Table 3: Recommended usage parameters.

5 Comparison with Related Work

Related work is creative but often complex. Back-translation (Sennrich et al., 2016), translational data augmentation (Fadaee et al., 2017), and noising (Xie et al., 2017) have shown improvements in BLEU measure for machine translation. For other tasks, previous approaches include task-specific heuristics (Kafle et al., 2017) and back-translation (Silfverberg et al., 2017; Yu et al., 2018). Regarding synonym replacement (SR), one study showed a 1.4% F1-score boost for tweet classification by finding synonyms with k-nearest neighbors using word embeddings (Wang and Yang, 2015). Another study found no improvement in temporal analysis when replacing headwords with synonyms (Kolomiyets et al., 2011), and mixed results were reported for using SR in character-level text classification (Zhang et al., 2015); however, neither work conducted extensive ablation studies.

Most studies explore data augmentation as a complementary result for translation or in a task-specific context, so it is hard to directly compare

EDA with previous literature. But there are two studies similar to ours that evaluate augmentation techniques on multiple datasets. Hu (2017) proposed a generative model that combines a variational auto-encoder (VAE) and attribute discriminator to generate fake data, demonstrating a 3% gain in accuracy on two datasets. Kobayashi (2018) showed that replacing words with other words that were predicted from the sentence context using a bi-directional language model yielded a 0.5% gain on five datasets. However, training a variational auto-encoder or bidirectional LSTM language model is a lot of work. EDA yields results on the same order of magnitude but is much easier to use because it does not require training a language model and does not use external datasets. In Table 4, we show EDA's ease of use compared with other techniques.

Technique (#datasets)	LM	Ex Dat
Trans. data aug.[1] (1)	yes	yes
Back-translation[2] (1)	yes	yes
VAE + discrim.[3] (2)	yes	yes
Noising[4] (1)	yes	no
Back-translation[5] (2)	yes	no
LM + SR[6] (2)	yes	no
Contextual aug.[7] (5)	yes	no
SR - kNN[8] (1)	no	no
EDA (5)	**no**	**no**

Table 4: Related work in data augmentation. #datasets: number of datasets used for evaluation. Gain: reported performance gain on all evaluation datasets. LM: requires training a language model or deep learning. Ex Dat: requires an external dataset.[9]

6 Discussion and Limitations

Our paper aimed to address the lack of standardized data augmentation in NLP (compared to vision) by introducing a set of simple operations that might serve as a baseline for future investigation. With the rate that NLP research has progressed in recent years, we suspect that researchers will soon find higher-performing augmentation techniques that will also be easy to use.

Notably, much of the recent work in NLP focuses on making neural models larger or more complex. Our work, however, takes the opposite approach. We introduce simple operations, the result of asking the fundamental question, *how can we generate sentences for augmentation without changing their true labels?* We do not expect EDA to be the go-to augmentation method for NLP, either now or in the future. Rather, we hope that our line of thought might inspire new approaches for universal or task-specific data augmentation.

Now, let's note many of EDA's limitations. Foremost, performance gain can be marginal when data is sufficient; for our five classification tasks, the average performance gain for was less than 1% when training with full datasets. And while performance gains seem clear for small datasets, EDA might not yield substantial improvements when using pre-trained models. One study found that EDA's improvement was negligible when using ULMFit (Shleifer, 2019), and we expect similar results for ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018). Finally, although we evaluate on five benchmark datasets, other studies on data augmentation in NLP use different models and datasets, and so fair comparison with related work is highly non-trivial.

7 Conclusions

We have shown that simple data augmentation operations can boost performance on text classification tasks. Although improvement is at times marginal, EDA substantially boosts performance and reduces overfitting when training on smaller datasets. Continued work on this topic could explore the theoretical underpinning of the EDA operations. We hope that EDA's simplicity makes a compelling case for further thought.

Abstract

News recommendation can help users find interested news and alleviate information overload. Precisely modeling news and users is critical for news recommendation, and capturing the contexts of words and news is important to learn news and user representations. In this paper, we propose a neural news recommendation approach with multi-head self-attention (NRMS). The core of our approach is a news encoder and a user encoder. In the news encoder, we use multi-head self-attentions to learn news representations from news titles by modeling the interactions between words. In the user encoder, we learn representations of users from their browsed news and use multi-head self-attention to capture the relatedness between the news. Besides, we apply additive attention to learn more informative news and user representations by selecting important words and news. Experiments on a real-world dataset validate the effectiveness and efficiency of our approach.

1 Introduction

Online news platforms such as Google News[1] and MSN News[2] have attracted many users to read news online (Das et al., 2007). Massive news articles are generated everyday and it is impossible for users to read all news to find their interested content (Phelan et al., 2011). Thus, personalized news recommendation is very important for online news platforms to target user interests and alleviate information overload (IJntema et al., 2010).

Learning accurate representations of news and users are two core tasks in news recommendation (Okura et al., 2017). Several deep learning based methods have been proposed for these tasks (**?**Kumar et al., 2017; Khattar et al., 2018; Wu et al., 2019b,c,a; Zhu et al., 2019; An et al., 2019). For example, Okura et al. (2017) proposed to learn news representations from news bodies via auto-encoders, and learn representations of users from their browsed news via GRU. However, GRU is quite time-consuming, and their method cannot capture the contexts of words. Wang et al. (2018) proposed to learn news representations from news titles via a knowledge-aware convolutional neural network (CNN), and learn representations of users based on the similarities between candidate news and their browsed news. However, CNN cannot capture the long-distance contexts of words, and their method cannot model the relatedness between browsed news.

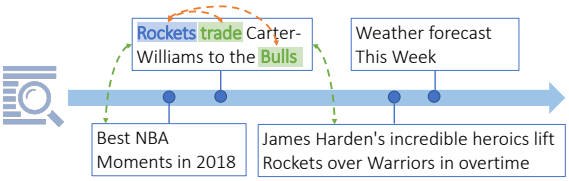

Figure 1: Several news browsed by an example user. Orange and green dashed lines represent the interactions between words and news respectively.

Our work is motivated by several observations. First, the interactions between words in news title are important for understanding the news. For example, in Fig. 1, the word "Rockets" has strong relatedness with "Bulls". Besides, a word may interact with multiple words, e.g., "Rockets" also has semantic interactions with "trade". Second, different news articles browsed by the same user may also have relatedness. For example, in Fig. 1 the second news is related to the first and the third news. Third, different words may have different importance in representing news. In Fig. 1, the word "NBA" is more informative than "2018". Besides, different news articles browsed by the same user may also have different importance in repre-

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

senting this user. For example, the first three news articles are more informative than the last one.

In this paper, we propose a neural news recommendation approach with multi-head self-attention (NRMS). The core of our approach is a news encoder and a user encoder. In the news encoder, we learn news representations from news titles by using multi-head self-attention to model the interactions between words. In the user encoder, we learn representations of users from their browsing by using multi-head self-attention to capture their relatedness. Besides, we apply additive attentions to both news and user encoders to select important words and news to learn more informative news and user representations. Extensive experiments on a real-world dataset show that our approach can effectively and efficiently improve the performance of news recommendation.

2 Our Approach

Our NRMS approach for news recommendation is shown in Fig. 2. It contains three modules, i.e., *news encoder*, *user encoder* and *click predictor*.

2.1 News Encoder

The *news encoder* module is used to learn news representations from news titles. It contains three layers. The first one is word embedding, which is used to convert a news title from a sequence of words into a sequence of low-dimensional embedding vectors. Denote a news title with M words as $[w_1, w_2, ..., w_M]$. Through this layer it is converted into a vector sequence $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M]$.

The second layer is a word-level multi-head self-attention network (Vaswani et al., 2017; Wu et al., 2018). The interactions between words are important for learning news representations. For example, in the news title "Rockets Ends 2018 with a Win", the interaction between "Rockets" and "Win" is useful for understanding this news, and such long-distance interactions usually cannot be captured by CNN. In addition, a word may interact with multiple words in the same news. For instance, in above example the word "Rockets" has interactions with both "Ends" and "Win". Thus, we propose to use multi-head self-attention to learn contextual representations of words by capturing their interactions. The representation of the i_{th} word learned by the k_{th} attention head is

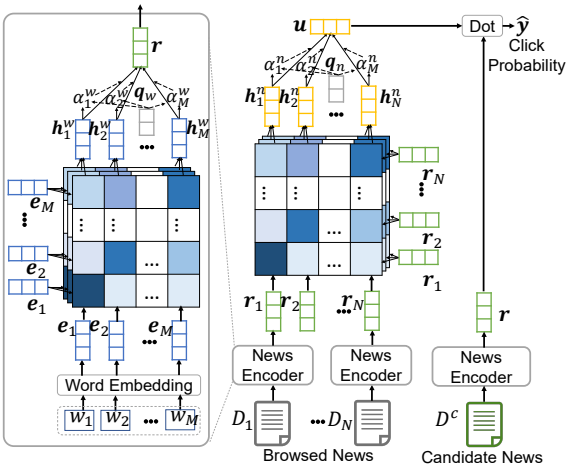

Figure 2: The framework of our *NRMS* approach.

computed as:

$$\alpha_{i,j}^k = \frac{\exp(\mathbf{e}_i^T \mathbf{Q}_k^w \mathbf{e}_j)}{\sum_{m=1}^{M} \exp(\mathbf{e}_i^T \mathbf{Q}_k^w \mathbf{e}_m)}, \quad (1)$$

$$\mathbf{h}_{i,k}^w = \mathbf{V}_k^w (\sum_{j=1}^{M} \alpha_{i,j}^k \mathbf{e}_j), \quad (2)$$

where $\mathbf{Q}_k^w$ and $\mathbf{V}_k^w$ are the projection parameters in the k_{th} self-attention head, and $\alpha_{i,j}^k$ indicates the relative importance of the interaction between the i_{th} and j_{th} words. The multi-head representation $\mathbf{h}_i^w$ of the i_{th} word is the concatenation of the representations produced by h separate self-attention heads, i.e., $\mathbf{h}_i^w = [\mathbf{h}_{i,1}^w; \mathbf{h}_{i,2}^w; ...; \mathbf{h}_{i,h}^w]$.

The third layer is an additive word attention network. Different words in the same news may have different importance in representing this news. For example, in the second news of Fig. 1, the word "NFL" is more informative than "Today" for understanding this news. Thus, we propose to use attention mechanism to select important words in news titles for learning more informative news representations. The attention weight α_i^w of the i-th word in a news title is computed as:

$$a_i^w = \mathbf{q}_w^T \tanh(\mathbf{V}_w \times \mathbf{h}_i^w + \mathbf{v}_w), \quad (3)$$

$$\alpha_i^w = \frac{\exp(a_i^w)}{\sum_{j=1}^{M} \exp(a_j^w)}, \quad (4)$$

where $\mathbf{V}_w$ and $\mathbf{v}_w$ are projection parameters, and $\mathbf{q}_w$ is the query vector. The final representation of a news is the weighted summation of the contextual word representations, formulated as:

$$\mathbf{r} = \sum_{i=1}^{M} \alpha_i^w \mathbf{h}_i^w. \quad (5)$$

2.2 User Encoder

The *user encoder* module is used to learn the representations of users from their browsed news. It contains two layers. The first one is a news-level multi-head self-attention network. Usually, news articles browsed by the same user may have some relatedness. For example, in Fig. 1, the first two news articles are related. In addition, a news article may interact with multiple news articles browsed by the same user. Thus, we propose to apply multi-head self-attention to enhance the representations of news by capturing their interactions. The representation of the i_{th} news learned by the k_{th} attention head is formulated as follows:

$$\beta_{i,j}^k = \frac{\exp(\mathbf{r}_i^T \mathbf{Q}_k^n \mathbf{r}_j)}{\sum_{m=1}^M \exp(\mathbf{r}_i^T \mathbf{Q}_k^n \mathbf{r}_m)}, \tag{6}$$

$$\mathbf{h}_{i,k}^n = \mathbf{V}_k^n (\sum_{j=1}^M \beta_{i,j}^k \mathbf{r}_j), \tag{7}$$

where $\mathbf{Q}_k^n$ and $\mathbf{V}_k^n$ are parameters of the k_{th} news self-attention head, and $\beta_{i,j}^k$ represents the relative importance of the interaction between the j_{th} and the k_{th} news. The multi-head representation of the i_{th} news is the concatenation of the representations output by h separate self-attention heads, i.e., $\mathbf{h}_i^n = [\mathbf{h}_{i,1}^n; \mathbf{h}_{i,2}^n; ...; \mathbf{h}_{i,h}^n]$.

The second layer is an additive news attention network. Different news may have different informativeness in representing users. For example, in Fig. 1 the first news is more informative than the fourth news in modeling user interest, since the latter one is usually browsed by massive users. Thus, we propose to apply the additive attention mechanism to select important news to learn more informative user representations. The attention weight of the i_{th} news is computed as:

$$a_i^n = \mathbf{q}_n^T \tanh(\mathbf{V}_n \times \mathbf{h}_i^n + \mathbf{v}_n), \tag{8}$$

$$\alpha_i^n = \frac{\exp(a_i^n)}{\sum_{j=1}^N \exp(a_j^n)}, \tag{9}$$

where $\mathbf{V}_n$, $\mathbf{v}_n$ and $\mathbf{q}_n$ are parameters in the attention network, and N is the number of the browsed news. The final user representation is the weighted summation of the representations of the news browsed by this user, which is formulated as:

$$\mathbf{u} = \sum_{i=1}^N \alpha_i^n \mathbf{h}_i^n. \tag{10}$$

2.3 Click Predictor

The *click predictor* module is used to predict the probability of a user clicking a candidate news. Denote the representation of a candidate news D^c as $\mathbf{r}^c$. Following (Okura et al., 2017), the click probability score $\hat{y}$ is computed by the inner product of the user representation vector and the news representation vector, i.e., $\hat{y} = \mathbf{u}^T \mathbf{r}^c$. We also explored other kinds of scoring methods such as perception, but dot product shows the best performance and efficiency.

2.4 Model Training

Motivated by (Huang et al., 2013), we use negative sampling techniques for model training. For each news browsed by a user (regarded as a positive sample), we randomly sample K news which are shown in the same impression but not clicked by the user (regarded as negative samples). We shuffle the orders of these news to avoid possible positional biases. Denote the click probability score of the positive and the K negative news as $\hat{y}^+$ and $[\hat{y}_1^-, \hat{y}_2^-, ..., \hat{y}_K^-]$ respectively. These scores are normalized by the softmax function to compute the posterior click probability of a positive sample as follows:

$$p_i = \frac{\exp(\hat{y}_i^+)}{\exp(\hat{y}_i^+) + \sum_{j=1}^K \exp(\hat{y}_{i,j}^-)}. \tag{11}$$

We re-formulate the news click probability prediction problem as a pseudo $(K+1)$-way classification task, and the loss function for model training is the negative log-likelihood of all positive samples $\mathcal{S}$, which is formulated as follows:

$$\mathcal{L} = -\sum_{i \in \mathcal{S}} \log(p_i). \tag{12}$$

3 Experiments

3.1 Datasets and Experimental Settings

We conducted experiments on a real-world news recommendation dataset collected from MSN News[3] logs in one month (Dec. 13, 2018 to Jan. 12, 2019). The detailed statistics are shown in Table 1. The logs in the last week were used for test, and the rest were used for training. We randomly sampled 10% of training data for validation.

[3]https://www.msn.com/en-us/news

# users	10,000	avg. # words per title	11.29
# news	42,255	# positive samples	489,644
# impressions	445,230	# negative samples	6,651,940

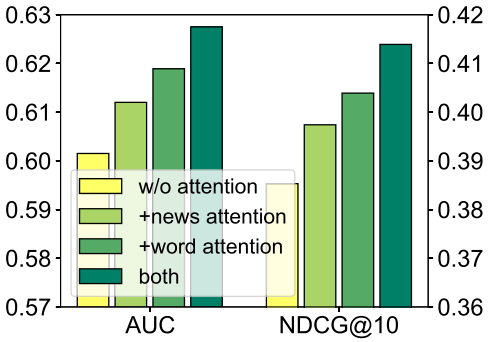
Table 1: Statistics of our dataset.

In our experiments, the word embeddings are 300-dimensional and initialized by the Glove embedding (Pennington et al., 2014). The self-attention networks have 16 heads, and the output of each head is 16-dimensional. The dimension of the additive attention query vectors is 200. Following (Wu et al., 2019b), the negative sampling ratio K is 4. Adam (Kingma and Ba, 2014) is used for model optimization. We apply 20% dropout to the word embeddings to mitigate overfitting. The batch size is 64. These hyperparameters are tuned on validation set. We conducted experiments on a machine with Xeon E5-2620 v4 CPUs and a GTX1080Ti GPU. We independently repeated each experiment 10 times and reported average results in terms of AUC, MRR, nDCG@5 and nDCG@10.

3.2 Performance Evaluation

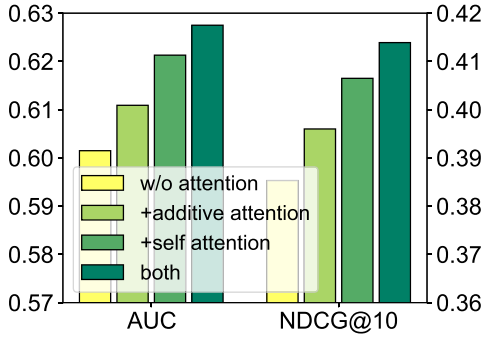
We evaluate the performance of our approach by comparing it with several baseline methods, including: (1) *LibFM* (Rendle, 2012), a matrix factorization based recommendation method; (2) *DSSM* (Huang et al., 2013), deep structured semantic model; (3) *Wide&Deep* (Cheng et al., 2016), a popular neural recommendation method; (4) *DeepFM* (Guo et al., 2017), another popular neural recommendation method; (5) *DFM* (Lian et al., 2018), deep fusion model for news recommendation; (6) *DKN* (Wang et al., 2018), deep knowledge-aware network for news recommendation; (7) *Conv3D* (Khattar et al., 2018), a neural news recommendation method with 3-D CNNs to learn user representations; (8) *GRU* (Okura et al., 2017), a neural news recommendation method using GRU to learn user representations; (9) *NRMS*, our approach. In methods (1) and (3-5), we use one-hot encoded user ID, news ID and the TF-IDF features extracted from news titles as the model input. In methods (6-9), we all use news titles for fair comparison. The results of these methods are summarized in Table 2.

We have several observations from Table 2. First, neural recommendation methods such as *DSSM* and *NRMS* outperform traditional recommendation methods such as *LibFM* on news recommendation. This may be because neural networks can learn better representations of news and users than matrix factorization methods. Thus, it may be more appropriate to learn news and user representations via neural networks rather than craft them manually. Second, among the deep learning based methods, the methods which exploit the relatedness between news (e.g., *Conv3D*, *GRU* and *NRMS*) can outperform other methods. This may be because the news browsed by the same user usually have relatedness, and capturing the news relatedness is useful for understanding these news and modeling user interests. Third, our approach performs better than all baseline methods. This is because our approach can capture the interactions between both words and news via multi-head self-attention to enhance representation learning of news and users. Besides, our approach employs additive attention to select important words and news for learning informative news and user representations. These results validate the effectiveness of our approach.



Methods	AUC	MRR	nDCG@5	nDCG@10
LibFM	0.5661	0.2414	0.2689	0.3552
DSSM	0.5949	0.2675	0.2881	0.3800
Wide&Deep	0.5812	0.2546	0.2765	0.3674
DeepFM	0.5830	0.2570	0.2802	0.3707
DFM	0.5861	0.2609	0.2844	0.3742
DKN	0.6032	0.2744	0.2967	0.3873
Conv3D	0.6051	0.2765	0.2987	0.3904
GRU	0.6102	0.2811	0.3035	0.3952
NRMS*	**0.6275**	**0.2985**	**0.3217**	**0.4139**

Table 2: The results of different methods. *The improvement is significant at $p < 0.01$.



We also conducted experiments to compare the time efficiency of our approach with several popular news recommendation methods. The results are shown in Table 3. From the results, we find our approach has a smaller parameter size and a lower time complexity in learning news and user representations than existing news recommendation methods. In addition, different from *DKN*, our approach does not need to memorize the news browsing histories of users when computing the click probability scores. In addition, since our approach can be further accelerated by computing the hidden representations of different attention heads in parallel, our approach is more suitable for being deployed in large-scale news recommendation scenarios. These results validate the efficiency of our approach.

Method	# Parameters	News Encoding Time	User Encoding Time
DKN	681 K	46.4 s	10.1 min
Conv3D	575 K	29.8 min	16.7 min
GRU	541 K	59.8 s	148.0 min
NRMS	530 K	39.7 s	6.7 min

Table 3: The number of parameters in *NRMS* and baseline methods, and their time in encoding 1 million news and 1 million users. *Word embeddings are excluded.

(a) Attention mechanisms at different levels.

(b) Attention mechanisms of different kinds.

Figure 3: Effectiveness of different attention networks.

3.3 Effectiveness of Attention Mechanism

Next we explore the effectiveness of attentions in our approach. First, we verify the word- and news-level attentions. The results are shown in Fig. 3(a). We find the word-level attention is very useful. This is because modeling the interactions between words and selecting important words can help learn informative news representations. Besides, the news-level attention is also useful. This is because capturing the relatedness of news and selecting important news can benefit the learning of user representations. Moreover, combining both word- and news-level attentions can further improve the performance of our approach.

We also study the influence of additive and self-attentions on our approach. The results are shown in Fig. 3(b). From these results, we find the self-attentions are very useful. This is because the interactions between words and news are important for understanding news and modeling users. In addition, the additive attentions are also helpful. This is because different words and news may usually have different importance in representing news and users. Thus, selecting important words and news can help learn more informative news and user representations. Combining both additive and self-attention can further improve our approach. Thus, these results validate the effectiveness of the attention mechanism in our approach.

4 Conclusion and Future Work

In this paper we propose a neural news recommendation approach with multi-head self-attention. The core of our approach is a news encoder and a user encoder. In both encoders we apply multi-head self-attentions to learn contextual word and news representations by modeling the interactions between words and news. In addition, we use additive attentions to select important words and news to learn more informative news and user representations. Extensive experiments validate the effectiveness and efficiency of our approach.

In our future work, we will try to improve our approach in the following potential directions. First, in our framework we do not consider the positional information of words and news, but they may be useful for learning more accurate news and user representations. We will explore position encoding techniques to incorporate the word position and the time-stamps of news clicks to further enhance our approach. Second, we will explore how to effectively incorporate multiple kinds of news information in our framework, especially long sequences such as news body, which may challenge the efficiency of typical self-attention networks.

Abstract

Building named entity recognition (NER) models for languages that do not have much training data is a challenging task. While recent work has shown promising results on cross-lingual transfer from high-resource languages to low-resource languages, it is unclear what knowledge is transferred. In this paper, we first propose a simple and efficient neural architecture for cross-lingual NER. Experiments show that our model achieves competitive performance with the state-of-the-art. We further analyze how transfer learning works for cross-lingual NER on two transferable factors: sequential order and multilingual embeddings, and investigate how model performance varies across entity lengths. Finally, we conduct a case-study on a non-Latin language, Bengali, which suggests that leveraging knowledge from Wikipedia will be a promising direction to further improve the model performances. Our results can shed light on future research for improving cross-lingual NER.

1 Introduction

Named Entity Recognition (NER) is an important NLP task that identifies the boundary and type of named entities (e.g., person, organization, location) in texts. However, for some languages, it is hard to obtain enough labeled data to build a fully supervised learning model. Cross-lingual transfer models, which train on high-resource languages and transfer to target languages are a promising direction for languages with little annotated data (Bharadwaj et al., 2016; Tsai et al., 2016; Pan et al., 2017; Yang et al., 2017; Mayhew et al., 2017; Wang et al., 2017; Cotterell and Duh, 2017; Feng et al., 2018; Xie et al., 2018; Zhou et al., 2019).

Cross-lingual NER models learn transferable knowledge mainly from four sources: translation (Mayhew et al., 2017; Feng et al., 2018), bilingual embeddings (Ni et al., 2017; Xie et al., 2018), phonetic alphabets (Bharadwaj et al., 2016) and multi-source learning (Mayhew et al., 2017; Lin et al., 2018; Zhou et al., 2019; Chen et al., 2019; Rahimi et al., 2019). Translation can be applied at either the sentence level via machine translation or at the word and phrase level via application of bilingual dictionaries. Bilingual embeddings are a form of bilingual dictionaries; they constitute a projection from one pre-trained language representation into the same vector space as the other such that words with the same meaning have similar representations (Conneau et al., 2018). Phonetic alphabets enable different languages to share the same pronunciation characters so that the character-level knowledge is transferable between languages that otherwise have different character sets, such as English and Bengali (Hermjakob et al., 2018). Multi-source learning is effective when multiple or similar language resources are available by learning shareable knowledge. For example, training a model on both English and Hindi can significantly improve the model performance on Bengali than only using English (Mayhew et al., 2017). However, there is little prior work with detailed analysis of how cross-lingual NER models transfer knowledge between languages on different levels.

In this paper, we focus on a single-source zero-shot transfer setting where we transfer from English to target languages that have no annotated data. In our settings, the resources are limited to annotated source language data, bilingual dictionaries, and unlabeled corpora from both source and target languages. We first propose a neural cross-lingual NER model that combines the ideas of translation, bilingual embedding, and phonetic

alphabets. Next, we conduct qualitative analyses to answer the following questions on how the model transfers knowledge under the cross-lingual settings: 1) does the source language syntax matter? 2) how do word and character embeddings affect the model transfer? We analyze how F1 scores differ across different entity lengths. Finally, we conduct a case study on Bengali.

2 Model

NER models take a sequence of tokens as input and predict a sequence of labels such as person (PER) or location (LOC). In this paper, we adopt the neural architecture NER model from Lample et al. (2016); Ma and Hovy (2016). The model first combines pre-trained word and character embeddings as token representations, then feeds the representations to one layer of a Bidirectional Long Term Short Memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997), and finally predicts the outputs via a Conditional Random Field (CRF). We show the model architecture on left of Figure 1. However, languages express the same named entity in different words and characters. To bridge the barriers, we combine three strategies: bilingual embedding, reverse translation, and transliteration.

Bilingual Embedding. Word embeddings are usually trained for each language separately and therefore in different vector spaces (Ruder et al., 2019). To map word embeddings into the same shared space, we use MUSE (Conneau et al., 2018) to build our bilingual embeddings. The bilingual embeddings enable the words with the same meaning to have similar word representations in the shared space.

Reverse Translation. We use the bilingual dictionaries provided by Rolston and Kirchhoff (2016). Language variations exist among source and target languages and training on monolingual corpus might limit learning the variations. Therefore, we translate the source language, English, to the target language for the training corpus to reconstruct source language sentences and learn source and target languages jointly. However, one English word might have multiple corresponding translations. To select the best translation, we define an empirical score function $F(w, w_{t,i})$ that calculates the cosine similarity between the translated target word ($w_{t,i}$) and the English source word (w) based on its contextual words ($w_{c,j}$).

$$F(w, w_{t,i}) = \alpha \cdot \cos(E(w), E(w_{t,i})) + (1-\alpha) \cdot \sum_{j=1}^{m} \frac{\cos(E(w_{t,i}), E(w_{c,j}))}{(d_j+1)^2} \quad (1)$$

where $E(w)$ is the bilingual embedding vector of the word, d_j is the sequential distance between the word and its contextual word j, and α is the trade-off factor that balances impacts of translation pair and contextual words. In this study, we set α to 0.5. We choose the translation pair with the highest similarity score. Note that the reverse only applies during the training step that translates English into the target language.

Target word	Source word	Uroman	Type
grünen	green	gruenen	ORG
ইউরোপের	Europe	iuropera	LOC

Table 1: Examples of Uroman that maps different languages into the same character space. We show two target languages, German (top) and Bengali (bottom). The second column is a translation of the target language. The transliterations show the phonetic similarity between the source and target languages.

Character - Uromanization. Different languages may not share the same characters, but some named entities in the multilingual corpora share phonetic similarities (Huang et al., 2004). To map multilingual corpora into the same character space and connect the phonetic similarity between entities, we employ Uroman[1] (Hermjakob et al., 2018), which transliterates any language into something roughly pronounceable English spellings, while keeps the English words unchanged. We show some examples of Uroman in Table 1.

3 Experiments

In this study, we first evaluate our proposed cross-lingual method on the CoNLL 2002 and 2003 NER datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). We then conduct ablation studies to examine how the model learns transferable knowledge under the cross-lingual settings. Finally, we conduct a case study on Bengali, a low resource language.

[1] https://www.isi.edu/~ulf/uroman.html

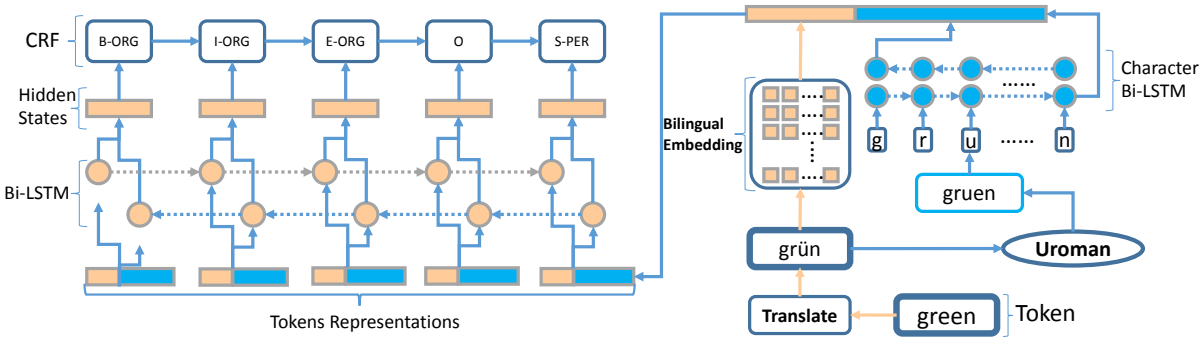

Figure 1: Architecture of our proposed model. Each word is translated from the source. Each token representation contains two concatenated parts: a bilingual word embedding (light orange) and character representations (blue). The character representation for each word is generated via the Bi-LSTM. Words are first transliterated and split into individual characters before being fed into the character Bi-LSTM.

3.1 Data

The CoNLL datasets contain four different European languages, Spanish, Dutch, English, and German. The data contains four types of named entities: person (PER), organization (ORG), location (LOC) and MISC. We use Bengali language data from LDC2015E13 (V2.1). To be consistent, we only keep the PER, ORG and LOC tags and ignore MISC tags from the Bengali corpus.

In this study, we choose the BIOSE tag schema instead of standard BIO, where the B, I, O, S, E refer to the beginning, inside, outside, single and end of an entity, respectively. Previous work shows that BIOSE can learn a more expressive model than the BIO schema does (Ratinov and Roth, 2009). We lowercase the data and replace numbers and URLs as "num" and "url" respectively. We use the training data to train our model, the development sets to select the best well-trained model, and the test sets to evaluate performance, where the training data is English and the development and test sets are from the target language.

3.2 Experimental Settings

Bilingual Embedding. We use the 300-dimensional bilingual word embeddings pre-trained by MUSE (Conneau et al., 2018) and 300-dimensional randomly initialized character embeddings. Specifically, we first collect monolingual pre-trained word embeddings from fastText (Bojanowski et al., 2017). We then align the embeddings using the MUSE supervised model. We normalize the inputs to MUSE and keep the other hyperparameters as defaults. We merge the aligned word embeddings and remove duplicates. Updating the embedding during training time will change the vector space of partial bilingual embeddings and therefore break the vector alignment. Thus, we freeze the embedding weights during the training step. For OOV (out-of-vocabulary) words, we use a randomly initialized 300 dimension vector within $[-0.1, 0.1]$.

Reverse Translation. We follow the general translation step in Section 2. Specifically, we replace English words with target language words if the translation pairs exist in the bilingual dictionaries (Rolston and Kirchhoff, 2016). If a translation pair does not exist for a word, we keep the word unchanged in the training data. We use the pre-trained bilingual embedding to help select the best choice of polysemy.

Model parameters. We use 300-dimension hidden states for both character and token level Bi-LSTMs. To prevent overfitting, we apply dropout (Srivastava et al., 2014) with a rate of 0.5 on outputs of the two Bi-LSTMs. We follow the Conditional Random Field (CRF) setup of Peng and Dredze (2015). We then randomly initialize the weights of the layers within $[-0.1, 0.1]$. We train the model for 200 epochs and optimize the parameters by Stochastic Gradient Descent (SGD) with momentum, gradient clipping, and learning rate decay. We set the learning rate (lr) and the decay rate (dr) as 0.01 and 0.05 respectively. We update the learning rate by $\frac{lr}{(1+(n+1)*dr)}$ after epoch n. We clip the gradients to the range of [-5.0, 5.0]. We measure performance by F1 score.

3.3 Baselines

In this study, we compare our proposed method with three close works under the cross-lingual settings. We compare our method with the best-reported performance from their works. We briefly

summarize the the three baselines in this section.

- WikiNER (Tsai et al., 2016) first links named entities in the multilingual Wikipedia corpora and extracts page categories as "wikifier" features, and use these features to achieve cross-lingual transfer.
- CTNER (Mayhew et al., 2017) first translates the corpora into English via bilingual dictionaries and multilingual Wikipedia entries on both word and phrase levels, and directly perform NER on the translated target language.
- NCNER (Xie et al., 2018) proposes a neural NER model with attention mechanism. The work is closest to ours. However, our model takes different approaches in obtaining multilingual embedding, translation, and transliteration as Xie et al. (2018), while the neural models share the similar architecture of Bi-LSTMs-CRF, and use multi-lingual embeddings to achieve transfer.

3.4 Results

Models	Spanish	Dutch	German
WikiNER*	60.55	61.60	48.10
CTNER*	51.82	53.94	50.96
CTNER*+	65.95	66.50	59.11
NCNER	**72.37**	71.25	57.76
Our Model	64.48	**73.44**	**62.26**

Table 2: F1 score comparisons of cross-lingual models on Spanish, Dutch and German. The "*" indicates the model uses the Wikipedia resources. The "+" means training model by multiple language resources.

As seen in Table 2, our proposed method outperforms the previous works in nearly all cross-lingual tasks. Moreover, the two neural model methods exceed the performance of the other models. These results suggest the effectiveness of neural cross-lingual transfer through multi-lingual embedding space, and show competitive results of our proposed methods.

3.5 Ablation Studies

We conduct ablation analyses to understand how the model transfers learned knowledge from one language to the other. We focus on two aspects: syntax and embeddings.

Syntax analysis. Different languages might not share the same syntax structures. The neural model learns sequential information from the source language and applies the learned knowledge on the target language. The importance of this sequential information is unknown. We shuffle the sentences of training data while keeping the internal order of named entities unchanged. We show the results in Table 3. The results show that after shuffling, the performances of our model decrease and the decreases vary among different languages. This suggests the importance of sequential information for those languages under the cross-lingual settings.

Models	Spanish	Dutch	German
Full Model	64.48	73.44	62.26
Shuffle	49.44	40.61	27.25
Word-only	53.00	59.60	52.58
Char-only	18.88	12.15	16.46

Table 3: F1 scores of different ablation analyses, compared to our full model.. "Shuffle" means the training data is shuffled. "Word-only" means our proposed model is only fed bilingual word embeddings, and "Char-only" means the model only receives character embeddings as input.

Embeddings analysis. We train our proposed models with both character and bilingual word embeddings, however, how the model values different embeddings is unknown. We feed the model with either bilingual word or character embeddings. Table 3 shows that bilingual word embeddings have better performance than character embeddings across the three languages. The results suggest that the aligned bilingual embeddings are more important than the character embeddings for the three languages.

3.6 Entity length analysis

While we can observe how models perform overall on the named entities, we can not know how models differ from short to long entities. Particularly, probing if models hold strong biases towards shorter entities can help interpret the process of cross-lingual transfer learning. To make the comparison, we first categorize entities into three levels: single token, two tokens and greater or equal to three tokens. We then calculate the F1-score of the three entity lengths in the test set and among correctly predicted entities. Finally we summarize the F1-score in Table 4.

With comparing to the overall performance across the three languages in Table 2, we can observe that the single token shows relatively closer

Language	1	2	≥3
Spanish	68.93	68.21	47.57
Dutch	69.49	82.46	60.85
German	59.50	70.76	37.22

Table 4: F1 scores of different lengths of entities across the three languages: Spanish, Dutch and German. The number 1 refers to the entities with single token, the 2 means the entities with two tokens and the ≥ 3 indicates the entities with not less than three tokens.

to the performance, the entities with two tokens achieve the higher scores, while the entities with more than 2 tokens decrease significantly ranging from 12.59 to 25.04 absolute percentages of F1 scores. The observation indicates that entities longer than two tokens are more difficult to infer. This might encourage us to balance the weight of long entities in our current evaluation method which ignores entity length when datasets have high volumes of long entities.

4 Case Study: Bengali

Models	F1 score
CTNER	30.47
CTNER+	31.70
CTNER*	46.28
CTNER*+	45.70
Our Model	34.29

Table 5: F1 score comparisons of translation-based models on Bengali. The "*" indicates the model uses Wikipedia resources. The "+" means a model is trained with multiple language resources.

The previous cross-lingual settings were only for European languages, which share similar alphabets. However, many languages use non-Latin orthography. In this work, we present a case study on Bengali, which does not use a Latin alphabet. We compare our proposed method with the translation-based method, CTNER (Mayhew et al., 2017). The results in Table 5 show that our model outperforms the previous methods without Wikipedia.

The results suggest multilingual Wikipedia is critical for future performance improvements beyond simple transfer. This is to be expected; a domain discrepancy exists between the source and target language data and therefore many named entities are missing or mismatched: partial data sources of the Bengali come from social media and online forums (Cieri et al., 2016). By contrast, the only data source of CoNLL data is from news articles (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). While transfer can help provide universal context clue information across languages there is no substitute for a resource of actual names.

Language	Type	Token
Spanish	2.5	0.8
Dutch	2.5	0.9
German	2.3	1.5
Bengali	18.2	12.2

Table 6: OOV rate (percentage) in our bilingual word embeddings across the four languages. Type indicates unique words, and token refers to counting token numbers.

The colloquium words from social media may cause the issue of out of vocabulary (*OOV*) and further impact the transferring process. We summarize the percentage of missing words in our pretrained bilingual word embeddings in Table 6. The OOV rate of Bengali is significantly higher than that of the other three languages. This suggests that the high OOV rate and the discrepancy of data sources may hurt the effectiveness of transfer.

5 Conclusion

We have presented a simple but efficient method to adapt neural NER for the cross-lingual settings. The proposed method benefits from multiple transferable knowledge and shows competitive performances with the state of the art using limited resources. We examine multiple factors that impact the transfer process and conduct an ablation study to measure their influences. Our experiment on Bengali shows that leveraging knowledge from Wikipedia will be a promising direction for future research.

Abstract

Humor plays important role in human communication, which makes it important problem for natural language processing. Prior work on the analysis of humor focuses on whether text is humorous or not, or the degree of funniness, but this is insufficient to explain why it is funny. We therefore create a dataset on humor with 9,123 manually annotated jokes in Chinese. We propose a novel annotation scheme to give scenarios of how humor arises in text. Specifically, our annotations of linguistic humor not only contain the degree of funniness, like previous work, but they also contain key words that trigger humor as well as character relationship, scene, and humor categories. We report reasonable agreement between annotators. We also conduct an analysis and exploration of the dataset. To the best of our knowledge, we are the first to approach humor annotation for exploring the underlying mechanism of the use of humor, which may contribute to a significantly deeper analysis of humor. We also contribute with a scarce and valuable dataset, which we will release publicly.

1 Introduction

Humor plays important role in human communication, which not only serves to exchange ideas or convey messages, but also involves emotion regulation such as provoking laughter, generating amusement, and reducing stress (Wooten, 1996; Morse, 2007). In particular, with the rapid growth of social media applications such as Facebook and Twitter, a significantly increasing number of individuals are using these social media public platforms to release humorous texts. Humor often arises when two incongruous concepts are applied and examined through one semantic frame (Lefcourt, 2001; Paulos, 2008). The two concepts often involve semantic disconnection in forms such as contradiction and contrast/comparison. Humor sometimes occurs due to ambiguity (Yang et al., 2015), such as unexpected homophones/homographs.

The importance and complexity of humor has thus gained attention in natural language processing (NLP), and many computational approaches to it have been proposed (Binsted et al., 2006; Yang et al., 2015; Baziotis et al., 2017; Ortega-Bueno et al., 2018; Liu et al., 2018). Corpora are fundamental in NLP for sound analysis of humor and for high-quality automatic humor detection. Scholars have been devoted to the study of the humor resources in both English and other languages. Mihalcea and Strapparava (2005) constructed a humorous witticism dataset with 16,000 text data for humor identification in English sentences. The dataset comes from one-liners, reuters titles, BNC sentences, and proverbs, and was annotated with humor and non-humor. Reyes et al. (2013) established an English irony dataset of 40,000 tweets for conducting the study of irony on tweets. The dataset contains the label of irony and other specific hashtags of non-irony (education, humor, and politics). Zhang and Liu (2014) established an English humor corpus with 3,000 tweets to recognize humor on Twitter. The dataset contains the annotation of humorous tweets, non-humorous tweets and humorous non-tweets. Potash et al. (2017) built a 12,734 tweets dataset of English for studying the comparative ranking of humor. The dataset comes from the midnight TV program called Hashtag Wars which published on Twitter. Castro et al. (2017) established a humorous text corpus containing 33,531 tweets for detecting humor in Spanish Tweets. The dataset involves humorous annotation and humor level annotation. The humor level annotation is based on a 5-point scale, 1 signifying the lowest level and 5 signifying the highest level. Castro et al. (2018) revised

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6402–6407, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the Spanish Twitter corpus with crowd notes and presented a 27,000 tweets dataset in total. Specially, the authors used 5 different emojis to represent the 5 degrees of humor instead of using the 5-point annotation.

However, while previous work focuses on textual humor annotation of humorous/non-humorous and degree of funniness, such annotations do not provide adequate knowledge and scenarios to explain how humor arises, so they may not provide a deep analysis of the underlying mechanism of humor. In addition, as the majority of data came from Twitter, the data source lacks variety. To this end, we create a dataset on humor with 9,123 manually annotated jokes in Chinese. We propose a novel scheme with annotations of key words that make text humorous as well as character relationship, scene, humor category, and degree of funniness. The annotation agreement analyses for multiple annotators are described. We also conduct analysis and exploration on the dataset. Our contributions are as follows.

• We propose a novel annotation scheme to explain how humor arises in text. Unlike previous work, we annotate not only what is humorous, but also what causes humor.

• We contribute to a new, sizeable, and scarce joke dataset, which is being released publicly and particularly valuable in languages other than English.

2 Data Collection

To make the dataset objective and comprehensive, we collected joke data involving both diachronic and synchronic relationships simultaneously from a variety of fields. Also, We selected jokes based on a four-dimensional model. On the time axis, our dataset includes jokes from books, literary journals, etc. published over the past decade, which satisfies the diachronic requirement. It also includes jokes posted on websites and microblogs, many of which are novel, which conforms to the synchronic requirement. On the spatial axis, the dataset contains both domestic and translated foreign jokes. On the subject axis, the perception of intensity of jokes also varies from person to person, due to their varying backgrounds and senses of humor. On the style axis, jokes from books have various themes, and they are relatively canonical, while online jokes seem more oral and informal. The source information is in Table 1.

Sources	Words	Sentences	Jokes
Websites	2,397,816	23,508	5,463
Micro-blogs	1,207,856	11,614	2,581
Books,Journals	504,920	4,855	1,079
Total	4,110,592	39,977	9,123

Table 1: Information on data sources.

3 Annotation Scheme

3.1 Annotation model

The annotation model is as follows:

JokeModel = (Relationship, Scene, Category, HumorLevel, Keyword, DataSource)

• Relationship: We annotated the mutual relationship between the main characters such as teacher-student, doctor-patient, lovers, superior and subordinate, etc. because accessing the relationship between people in jokes is helpful for a clearer understanding of the contextual coordinates on the joke (Popa, 2005).

• Scene: The scene refers to the place where the joke occurs. Previous studies indicate humor plays an important role in the places including campus (Morrison et al., 2012), workplace (Blumenfeld and Alpern, 1994), family (Lovorn, 2008) and public space (Thornton, 2007). We therefore selected the campus, workplace, family and public space for the annotation of scene in humor.

• Category: There is no consensus on the category of humor in the literature. Based on our investigation of a wide range of literature, we focused on eight main types of the most frequently appearing humor including homophonic, harmonic, antiphrasis, analogy, euphemism, irony, exaggeration, and reversal.

• Level: We weighed the fine-grained annotation of humor (Bressler and Balshine, 2006; Castro et al., 2018; Deckers and Devine, 1981) and presented a 5 point-scale for humor rating, 1 signifying the non-humor, 2-5 signifying the gradually increasing degree of humor. (Gan, 2015; Stein, 1998; Tsakona, 2009)

• DataSource: Table 1 presents the source of jokes.

• Keyword: We define the key words as words that trigger humor and that may have conflicting, incongruous and ambiguous meanings in jokes (Van Hee et al., 2016). Van Hee et al. (2016) proposed the annotation item based on the text spans of contrasting which contains the type of explicit

Example1:
<Humor>
<ID>H02</ID>
<Contents>妻子：每次我唱歌的时候，你为什么总要到阳台上去?
"Wife: When I sing, why do you always go to the balcony?"
丈夫：我想让大家都知道，不是我在打你
"Husband: Because I want to let everyone know that I am not hitting you."
<Contents>
<Relationship>丈夫 "husband"/妻子 "wife"</Relationship>
<Scene>家庭 "family"</Scene>
<Category>讽刺 "irony"</Category>
<HumorLevel>3</HumorLevel>
<Keywords>唱歌 "sing"/打 "hit"</Keywords>
<DataSource>N</DataSource>
</Humor>

Figure 1: An example of annotation

and implicit. The special word pair in the contrasting text spans triggers the production of humor. Specially, we annotated the keyword based on the thought of contrasting text spans in humor in the format of prototype. An annotation example shows in figure 1.

3.2 Keyword annotation

The keyword is the most challenging of the six annotating items. Following Van Hee et al. (2016), our annotation of key words is at the relation level, which involves the identification of incongruous or ambiguous vocabulary, resulting in a comic effect. To discriminate key words, the annotators followed the below guidelines:

• Read the entire text-discourse to establish a general understanding of the meaning.

• For each word in the text, establish its meaning in context.

• Determine which words have the meaning of incongruous/conflicting/ambiguous/unexpected or strong emotions that make text humorous in the given context.

• Decide whether the contextual meaning can be understood.

• If yes, mark the word as a key word.

Figure 2 shows the example of keyword annotation in humor.

The words "sing" and "hit" act as keywords, because the two phrases are the main indicators of humor: "she sings badly, and it sounds like she

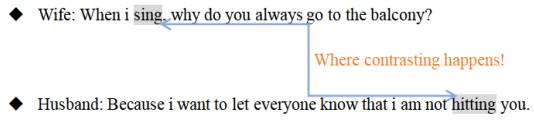

Figure 2: An example of keyword annotation

is being beaten and screaming." The comparison of "sing" and "hit" invokes the humor, so they are keywords.

3.3 Annotation process

Eight postgraduate students and one PhD student worked together to complete the annotation of the joke dataset. The participants were divided into four groups of two. Each group annotated the jokes using cross-validation. The PhD student arbitrated. During the annotation process, when two people reached agreement on the annotation result, then the marking was complete; when there was disagreement, the arbitrator attempted to resolve it. When the arbitration was inconsistent with the views of the two persons' judgment: Case 1. If the inconsistency was in the degree of humor, we used the average value of the three people. Case 2. If there was any disagreement about the generation mechanism, it was discussed by the whole group of nine people, and the mechanism receiving the largest number of votes was the final result.

3.4 Annotation agreement and challenges

To evaluate inter-annotator agreement, we let three annotators annotate the same 600 sentences to assess inter-annotator agreement. We used Fleiss' s kappa (Fleiss, 1971). The agreement on the relationship annotation was κ = 0.85; the agreement on the scene annotation was κ = 0.79; the agree-

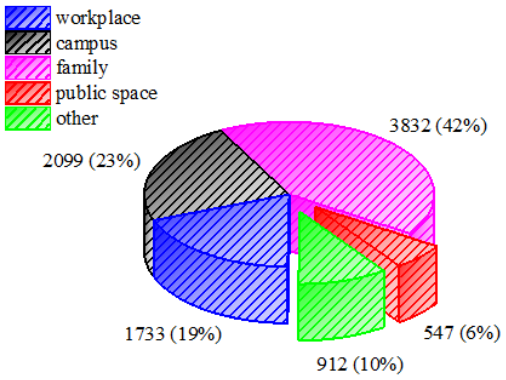

Figure 3: Quantity of joke scenes

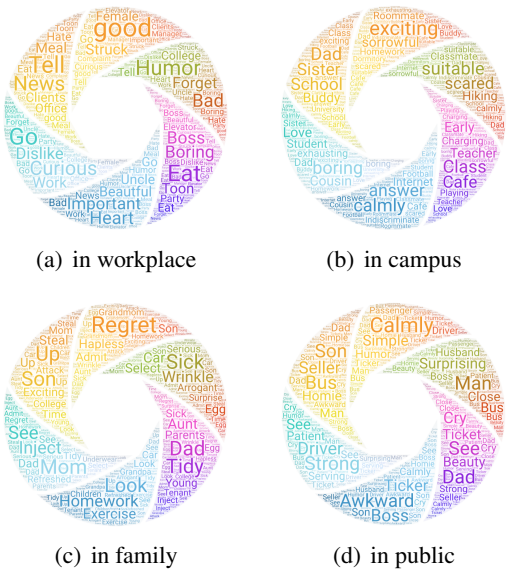
ment on the category annotation was κ = 0.71, the



agreement on the humor level annotation was κ = 0.65, and the agreement on the keywords annotation was κ = 0.59.

The keywords and humor level annotation was the most challenging part of the annotation, due to the subjective nature of cognition and the different background knowledge of people. To minimize the problems annotators faced, we held a seminar once a week to discuss the ambiguities. Then, the guide gave an authoritative explanation. Finally, ambiguity points and measures were added into the annotating guide manual to help annotators to make judgments quickly and correctly when they encountered the same problem.

4 Dataset Analysis

The dataset contains 9,123 jokes, 39,977 sentences and 4,110,592 words in total, with an average of 4.38 sentences per joke. In the dataset, there are five scenes of joke (where the joke occurs): workplace, campus, family, public space and others. Family accounts for 42% of the dataset. This is perhaps because family life accounts for the largest proportion of life as a whole. These statistical data fully confirm that the jokes originate from life, and that they are known to the general public, which shows that the audience for jokes is very wide. The specific distribution is in Figure 3.

Figure 4 shows the vocabulary that appears

(a) in workplace (b) in campus

(c) in family (d) in public

Figure 4: Word cloud in each scene (translated from Chinese)

most frequently in each scene of joke. As Figure 4 shows, the high-frequency words for each

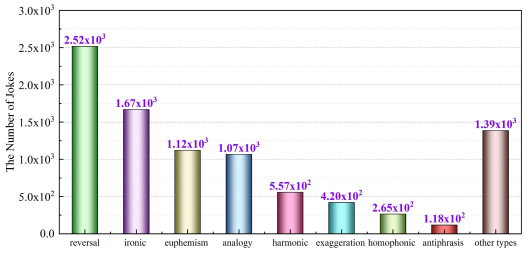


Figure 5: Humor categories

scene of jokes are various. For instance, the top five high-frequency words in campus jokes are "school, class, exciting, suitable, answer"; in family jokes are "son, mom, regret, homework, see"; in workplace jokes are "boring, boss, curious, forget, tell"; in public space jokes are "man, bus, surprising, cry, calmly". It is intriguing that some high-frequency words in certain jokes are related to certain scenes.

For instance, the high-frequency words in workplace jokes are "boss, boring, forget, which not only is in line with the bias of the work place, but also proves the validity of this classification to some extent.

We also analyzed the humor categories because they may associate with underlying mechanism of the use of humor. The quantitative statistics for humor categories are shown in Figure 5.

Our annotation not only contains the degree of funniness, but also key words that trigger humor, as well as character relationship, scene, and humor categories. Specially, we have improved on the study of Castro et al. (2018) by providing evidence of what causes humor and explaining how humor arises in text. Furthermore, our data have come from a range of sources in numerous domains rather than only from Twitter.

5 Conclusion

We propose a novel annotation scheme to explain how humor arises in text. Unlike previous work, we annotate not only what is humorous, but also what causes humor. Our dataset creation involved nine volunteer students for 8 months. We will release the dataset publicly. With 9,123 Chinese jokes and 39,977 sentences in total, and with fine-grained annotation of humor, the dataset provides a new, sizeable, and scarce joke dataset, which is particularly valuable in languages other than English for scholars in many disciplines, such as computational, linguistic, and cognitive studies.

Abstract

An anagram is a sentence or a phrase that is made by permutating the characters of an input sentence or a phrase. For example, "Trims cash" is an anagram of "Christmas". Existing automatic anagram generation methods can find possible combinations of words form an anagram. However, they do not pay much attention to the naturalness of the generated anagrams. In this paper, we show that simple depth-first search can yield natural anagrams when it is combined with modern neural language models. Human evaluation results show that the proposed method can generate significantly more natural anagrams than baseline methods.

1 Introduction

Making an *anagram* is one of the most popular wordplay games and has a long history that can be traced back to the time of the Ancient Greeks (Wheatley, 1862). An anagram is a sentence or a phrase that is made as a permutation of characters of an input sentence or phrase. For example, "Trims cash" is an anagram of "Christmas" since the former can be made by permutating the characters contained in the latter.

The automatic generation of anagrams is a challenging task since it is NP-hard[1]. Existing automatic anagram generation methods mainly focus on search efficiency in finding word combinations that can form anagrams (Jordan and Monteiro, 2003). However, they place little consideration on the word orders that seem natural to humans. Fortunately, recent progress in NLP techniques now enables natural sentences to be generated in many NLP tasks (Józefowicz et al., 2016; Gehrmann et al., 2018; Skadina and Pinnis, 2017). However, beam search, the de-facto decoding algorithm used in many language generation methods, cannot be used as-is to generate anagrams since it cannot ensure that the generated sentences are anagrams. Although beam search variants that can generate sentences that satisfy some constraints have been proposed (Anderson et al., 2017; Hokamp and Liu, 2017), applying them to anagram generation tasks soon becomes intractable. To summarize, generating natural anagrams is a challenging task that cannot be solved by simply applying existing methods.

In this paper, we propose an anagram generation algorithm. The proposed algorithm is very simple; we run depth-first search to enumerate anagrams. As to the generation procedure, we use a neural language model and character frequency to suppress unnecessary search operations. Due to the power of the currently available pre-trained neural language models, this simple approach works surprisingly well. In experiments that employ human evaluations we confirm that the proposed natural anagram generation method can generate more natural anagrams than a baseline method.

2 Related Work

Although anagram generation is NP-hard, the basic algorithm that can output a set of words as anagrams is relatively simple (Jordan and Monteiro, 2003). As a result many anagram generation software and web services exist including the Internet Anagram Server[2] and the Anagram Artist[3]. Unfortunately, these methods pay scant attention to the naturalness of the generated anagrams. In Wikipedia (Wikipedia, 2019), it is said that the

This work was conducted while the author was at NTT Communication Science Laboratories.

[1] NP-hardness of anagram generation can be proved by using the fact that it contains an exact cover problem, which has been proven to be NP-complete (Karp, 1972), as a special case.

[3] https://www.anagrammy.com/resources/anagram_artist.html

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6408–6412, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

automatic anagram generators work poorly when challenged with multi-word anagrams since they cannot take word meanings into account.

The anagram generation task can be seen as a variant of the language generation problem under some constraints. Anderson et al. (2017) proposes a constrained beam search algorithm for image captioning. Their method can generate sentences containing pre-specified words. Their method first creates a finite-state automaton (FSA) representing the constraints. Then it runs beam search over the FSA to obtain results that satisfy the constraints. It is possible to apply their method to anagram generation. However, since the number of FSA states grows exponentially with input length, it rapidly becomes intractable. Hokamp and Liu (2017) proposes the constrained decoding method called grid beam search for machine translation. It is also impractical if applied to the anagram generation task.

3 Preliminaries

We represent sentence s as a sequence of words, $s = (w_1, w_2, \ldots, w_{|s|})$, where $|s|$ is the number of words contained in s. Every word w_i is selected from vocabulary V, which consists of $|V|$ distinct words. We use $C(s)$ to represent the multiset of characters contained in s. For example, if $s =$ "Christmas", then $C(s) = \{\mathrm{a}, \mathrm{c}, \mathrm{h}, \mathrm{i}, \mathrm{m}, \mathrm{r}, \mathrm{s}, \mathrm{s}, \mathrm{t}\}$. In the following, we ignore case and we assume that every word $w \in V$ consists of the characters from a to z. We say sentence t is an *anagram* of sentence s if $C(s) = C(t)$. For example, if $t =$ "Trims cash", then $C(t) = \{\mathrm{a}, \mathrm{c}, \mathrm{h}, \mathrm{i}, \mathrm{m}, \mathrm{r}, \mathrm{s}, \mathrm{s}, \mathrm{t}\}$, which is equivalent to $C(s)$ for $s =$ "christmas". The *anagram generation problem* is the problem of finding sentence t given input sentence s, where t is an anagram of s.

We use a language model when generating anagrams. Let $p(s)$ be the probability that sentence $s = (w_1, w_2, \ldots, w_{|s|})$ appears. A language model is a stochastic model that gives conditional probability $p(w_{i+1}|w_1, \ldots, w_i)$. A language model derives probability $p(s)$ by

$$p(s) = p(w_1) \prod_{i=1}^{|s|-1} p(w_{i+1}|w_1, \ldots, w_i). \quad (1)$$

While our anagram generation algorithm can use any language model, our experiments use the neural language model of ELMo (Peters et al., 2018).

4 Anagram Generation

Our anagram generation algorithm uses simple DFS. Given input string s, we start the search with the initial string $t =$"$\langle \mathtt{S} \rangle$" and then try to append a word $w \in V$ to the tail of t for each step to search for anagrams of s. If we find that t yields no solution by appending any words to it, we pop back the last word from t and continue the search by appending a different word to the tail of t. Since there are $|V|^N$ possible sentences consisting of N words, naive DFS is intractable. Thus we need to reduce the search steps. For this we introduce the following two criteria.

The first criteria checks frequency of each character appearing in t. Partial sentence t cannot be an anagram of s by appending any words to it once the condition $C(t) \setminus C(s) \neq \emptyset$ is satisfied. For example, partial sentence $t =$"$\langle \mathtt{S} \rangle$ The" cannot form an anagram of $s =$"Christmas" since $C(t) \setminus C(s) = \{\mathrm{e}\} \neq \emptyset$.

The second criterion exploits sentence probability. Since a language model can evaluate how natural a sentence is by calculating sentence occurrence probability, we threshold this probability and remove candidates with insufficient sentence probability. We use score function $f(w)$ defined as

$$f(w) = p(w \mid t) \cdot |w|^2 \quad (2)$$

as the score yielded by adding word w to sentence t, where $|w|$ is the number of characters of w. We select word w if it makes $f(w)$ larger than threshold value η. We use the number of characters of word w in the score function since shorter words tend to have high conditional probability $p(w \mid t)$ but using them would often read to unnatural sentences that consist of only very short ($|w| \leq 2$) words.

Branch and Bound for top-K search If we need only a few solutions, then we can further reduce the number of search steps by employing a simple branch and bound technique. Here we assume that we need K anagrams with high sentence probability $p(t)$. We use the fact that the sentence probability $p(t)$ defined in (1) is monotone decreasing when we append new word w to the sentence tail. Therefore, once we have found K anagrams and their probabilities are larger than θ, we can omit unnecessary subsequent search steps if the current partial sentence t satisfies $\theta > p(t)$.

We show the final natural anagram generation

Algorithm 1 Anagram generation algorithm

4	Natural as a spoken language.
3	A few grammatical errors.
2	Meaning is guessable.
1	Meaning is unclear.

Table 1: Human evaluation criteria.

procedure in Algorithm 1. It first initializes sentence t and set of top-K anagrams A and then calls the recursive search procedure SEARCH. SEARCH first checks whether t is an anagram or not (line 8). If t is an anagram whose probability $p(t)$ is larger than $\min_{a \in A} p(a)$, then replace anagram $a^* = \text{argmin}_{a \in A} p(a)$ with t (line 10). If t is not an anagram, we proceed with the search by appending a word $w \in V$ to the tail of t. Here we use $t+w$ to represent the sentence obtained by appending w to the tail of t. We check that appending word w satisfies the conditions shown above (lines 14, 15), then we recursively call SEARCH$(t + w)$.

Implementation Details We tried to use the data structure called *dancing links* (Knuth, 2000) for managing the set of words satisfying the character frequency constraints. Dancing links is a link-based data structure that supports efficient DFS for some combinatorial search problems (Details are shown in (Knuth, 2019)). However, we found that using a simple array-based representation is sufficient since the conditional probability evaluation consumes most of the time.

5 Experiments

We conduct human evaluations to assess the performance of the proposed method. For inputs, we randomly select 100 titles of English Wikipedia articles whose length lies between 15 to 20 characters. We use the language model included in the TensorFlow (Abadi et al., 2015) implementation of ELMo[4], which is a CNN-LSTM language model trained with a 1 billion word benchmark corpus and that consists of approximately 800 million tokens[5]. It is also possible to combine the proposed method with conventional n-gram language models. However, since the superiority of neural language models over n-gram models has been reported in previous works (e.g., (Du et al., 2016; Józefowicz et al., 2016)), we conducted experiments using only ELMo. We use parameter $\eta = 0.005$ and we conduct top-K search with $K = 5$. We terminate the search after 20000 steps, which takes about 40 minutes.

Method	Average Score	
Proposed	4.11	(0.99)
Baseline	2.18	(1.17)

Table 2: Human evaluation results. The values in parentheses are standard deviations.

The baseline method used Anagram Artist, a freely available anagram generation software package. Anagram Artist can generate anagrams consisting of at most 5 words given inputs with lengths less than 25 characters. Although the algorithm used in anagram artist is not explained, it seems to use dictionary matching combining with some heuristics for deciding word order. We also tried an Internet anagram server. However, the quality of the anagrams generated by those two baseline methods are not much different. We compute the perplexities of the outputs of the baseline method and use the values to select the top-K anagrams. We run all experiments on computers with GeForce GTX 1080 Ti GPUs. The proposed method was mainly implemented in Python and the module for checking character frequency constraints was implemented in C++. We asked three native speakers to rate each anagram with scores ranging from 1 to 5 following the criteria shown in Table 1.

Table 2 shows the human evaluation results, where we compute the average score by first com-

[4] https://github.com/allenai/bilm-tf

[5] We also considered the use of pre-trained BERT (Devlin et al., 2018) since it is trained with a larger dataset. However, the pre-trained model does not contain weights of output layers and we cannot use it as-is for our task.

Table 4: Results of generating famous anagrams.

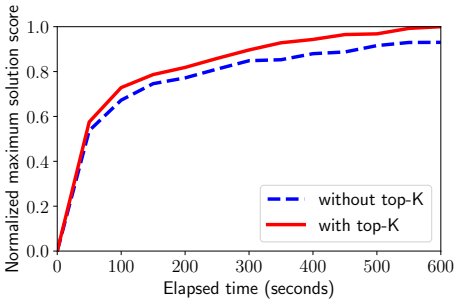

Figure 1: Running time comparison of the proposed method when applying the branch and bound method for retaining top-K solutions.

puting the average score of the three evaluators for each of the top-K outputs, then selecting the maximum of the K scores as the score of the method. The average shown in the table is the average of such maximum scores. The proposed method failed to generate any anagram for 3 instances. We therefore set the score of the proposed method to 1.0 for them. We can see that the proposed method yielded significantly higher human evaluation scores. Table 3 shows example anagrams generated by the proposed method and the baseline method. While the baseline method seems to employ some heuristics for deciding the word order, the combinations of selected words tend to form meaningless sentences. On the other hand, the proposed method tends to generate readable sentences. The anagrams shown in the table are listed in decreasing order of sentence probability. We can find that sentences with high probability are not always highly rated by the human evaluations. However, the normalized discounted cumulative gain (NDCG) score for the proposed method was 0.86. It suggests that using sentence probability works well for finding natural anagrams.

To evaluate the effectiveness of applying the branch and bound technique, we select problem instances that took longer than 600 seconds to complete and compared the maximum sentence probabilities of solutions found at a given time when top-K search is used. Figure 1 shows the comparison results, where the vertical axis plots the maximum scores of found anagrams normalized by the maximum one found within 600 seconds. This figure suggests using branch and bound accelerates the output of high score solutions. For example, with top-K, solutions with 0.8 maximum solution scores are found after 150 seconds, while it takes about 250 seconds without top-K search.

We also evaluated whether some famous anagrams appearing in Wikipedia (Wikipedia, 2019) can be generated with the proposed method. Table 4 shows the results of trying to generate fa-

mous anagrams. Unfortunately, the proposed method fails to find the famous anagram for these inputs. This is due to the fact that the famous anagrams use relatively rare words. However, the generated anagrams contain natural sentences.

6 Conclusion

We proposed an algorithm for generating natural anagrams. Surprisingly, a simple depth-first search approach is shown to be sufficient for generating natural anagrams when it is combined with modern neural language models. Since our current search procedure is relatively naive, there is room for improvement. More efficient use of GPUs in performing the DFS procedure is a promising future work.

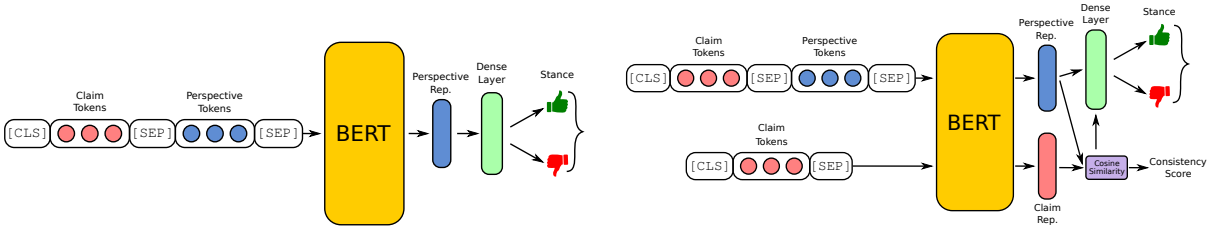
Abstract

Controversial claims are abundant in online media and discussion forums. A better understanding of such claims requires analyzing them from different perspectives. Stance classification is a necessary step for inferring these perspectives in terms of supporting or opposing the claim. In this work, we present a neural network model for stance classification leveraging BERT representations and augmenting them with a novel consistency constraint. Experiments on the *Perspectrum* dataset, consisting of claims and users' perspectives from various debate websites, demonstrate the effectiveness of our approach over state-of-the-art baselines.

1 Introduction

There is an abundance of contentious claims on the Web including controversial statements from politicians, biased news reports, rumors, etc. People express their perspectives about these controversial claims through various channels like editorials, blog posts, social media, and discussion forums. To achieve a deeper understanding of these claims, we need to understand users' perspectives and stance towards the claims. Recent research (FNC-1, 2016; Baly et al., 2018; Chen et al., 2019) has shown stance classification to be a critical step for information credibility and automated fact-checking.

Prior Work and Limitations: Prior approaches for stance classification proposed in Somasundaran and Wiebe (2010); Anand et al. (2011); Walker et al. (2012); Hasan and Ng (2013, 2014); Sridhar et al. (2015); Sun et al. (2018) rely on various linguistic features, e.g., n-grams, dependency parse tree, opinion lexicons, and sentiment to determine the stance of perspectives regarding controversial topics. Ferreira and Vlachos (2016) further incorporate natural language claims and propose a logistic regression model using the lexical and semantic features of claims and perspectives. SemEval tasks (Mohammad et al., 2016; Kochkina et al., 2017) and other approaches (Chen and Ku, 2016; Lukasik et al., 2016; Sobhani et al., 2017) have focused on determining stance only in Tweets.



Bar-Haim et al. (2017) propose classifiers based on hand-crafted lexicons to identify important phrases in perspectives and their consistency with the claim to predict the stance However, their model critically relies on manual lexicons and assumes that the important phrases in claims are already identified.

Neural-network-based approaches for stance classification learn the claim and perspective representations separately and later combine them with conditional LSTM encoding (Augenstein et al., 2016), attention mechanisms (Du et al., 2017) or memory networks (Mohtarami et al., 2018). Some neural network models also incorporate lexical features (Riedel et al., 2017; Hanselowski et al., 2018). None of these approaches leverage knowledge acquired from massive external corpora.

Approach and Contributions: To overcome the limitations of prior works, we present STANCY, a neural network model for stance classification. Given an input pair of a claim and a user's perspective, our model predicts whether the perspective is *supporting* or *opposing* the claim. For example, the claim *"You have nothing to worry about surveillance, if you have done nothing wrong"* is supported by the user perspective *"Information gathered through surveillance could be used to fight terrorism"* and opposed by another user perspective *"With surveillance, the user privacy will go away!"*.

Our model for stance classification leverages representations from the BERT (Bidirectional

(b) $\text{BERT}_{\text{CONS}}$: Enhancing BERT using the joint loss ($loss_{ce}$ for stance classification and $loss_{cos}$ for consistency).

Figure 1: BERT-based methods for determining the stance of the perspective with respect to the claim.

Encoder Representations from Transformers) neural network model (Devlin et al., 2019). BERT is trained on huge text corpora and serves as background knowledge. We fine-tune BERT for our task which also allows us to jointly model claims and perspectives. Furthermore, we enhance our model by augmenting it with a novel consistency constraint to capture agreement between the claim and perspective.

Key contributions of this paper are:

- **Model**: A neural network model for stance classification leveraging BERT representations learned over massive external corpora and a novel consistency constraint to jointly model claims and perspectives.
- **Interpretability**: A simple approach to interpret the contribution of perspective tokens in deciding their stance towards the claim.
- **Experiments**: Experiments on a recent dataset, *Perspectrum*, highlighting the effectiveness of our approach with error analysis.

2 BERT-based Approaches

In this section, first we describe the base model, $\text{BERT}_{\text{BASE}}$, that is adapted for the stance classification (Chen et al., 2019). Thereafter, we present our consistency-aware model, $\text{BERT}_{\text{CONS}}$.

2.1 Adapting BERT for Stance Classification

The goal of the stance classification task is to determine the stance of the user *Perspective (P)* with respect to the *Claim (C)*. Since this task involves a pair of sentences (C and P), we follow the approach for sentence pair classification task as proposed in Devlin et al. (2019); Chen et al. (2019).

In order to obtain the representation $X^{P|C}$ of P with respect to C, this sentence pair is fused into a single input sequence by using a special classification token (`[CLS]`) and a separator token (`[SEP]`): `[CLS]` C_{toks} `[SEP]` P_{toks} `[SEP]`. The input sequences are tokenized using WordPiece tokenization. The final hidden state representation corresponding to the `[CLS]` token is used as $X^{P|C} \in R^H$. The classification probability is given by passing this representation through the softmax layer:

$$\hat{y} = softmax(X^{P|C}W^T) \quad (1)$$

where softmax layer weights $W \in R^{H \times K}$ and K is the number of stance (classification) labels. All the parameters of BERT and W are fine-tuned jointly by minimizing the cross-entropy loss ($loss_{ce}$). The architecture of this model, $\text{BERT}_{\text{BASE}}$, is shown in Figure 1a.

2.2 Consistency-aware Stance Classification

In this setting, we want to incorporate the consistency between the claim (C) and perspective (P) representations. We hypothesize that the latent representations of claim and perspective should be *dissimilar* if the perspective *opposes* the claim, whereas their representations should be *similar* if the claim is *supported* by the perspective. We capture this with the following components.

Claim Representation: To capture the latent representation of the claim, we use only the claim text as the input sequence to BERT, i.e., `[CLS]` C `[SEP]`. The final hidden state of the first input token (`[CLS]`) is used as the claim's representation $X^C \in R^H$.

Perspective Representation: Latent representation of the perspective (with respect to the claim) is captured by fusing the two sequences as described in Section 2.1. We pack the claim and perspective pair as a single input sequence and use the final hidden state of the first input token as the perspective representation $X^{P|C} \in R^H$.

Split	Supporting Pairs	Opposing Pairs	Total Pairs
train	3603	3404	7007
dev	1051	1045	2096
test	1471	1302	2773
Total	6125	5751	11876

Table 1: Perspectrum data statistics.

Capturing Consistency: To incorporate the consistency between claim and perspective representations, we use the *cosine embedding loss*:

$$loss_{cos} = \begin{cases} 1 - \cos(X^C, X^{P|C}) & y_{sim} = 1 \\ max(0, \cos(X^C, X^{P|C})) & y_{sim} = -1 \end{cases}$$

where $\cos(.)$ is the cosine similarity function. y_{sim} is equal to 1 if the perspective is *supporting* the claim (*similar* representations), and -1 if the claim is *opposed* by the perspective (*dissimilar* representations).

Joint Loss: The classification probabilities are determined by concatenating $X^{P|C}$ and $\cos(X^C, X^{P|C})$ and passing it through a softmax layer. However, unlike the $\text{BERT}_{\text{BASE}}$ configuration, parameters of the consistency-aware model are learned by optimizing the joint loss function: $loss = loss_{ce} + loss_{cos}$. With this joint loss function, we enforce consistency between latent representations of the claim and perspective. The architecture of this consistency-aware model, $\text{BERT}_{\text{CONS}}$, is shown in Figure 1b.

3 Experimental Setup

For our experiments, we consider the base version of BERT[1] with 12 layers, 768 hidden size, and 12 attention heads. We fine-tune BERT-based models using the Adam optimizer with learning rates $\{1, 3, 5\} \times 10^{-5}$ and training batch sizes $\{24, 28, 32\}$. We choose the best parameters based on the development split of the dataset. For measuring the performance, we use per-class and macro-averaged Precision/Recall/F1.

3.1 Dataset

We evaluate our approach on the *Perspectrum* dataset (Chen et al., 2019). *Perspectrum* contains claims and users' perspectives from various online debate websites like `idebate.com`, `debatewise.org`, and `procon.org`. Each claim has different perspectives along with the stance (*supporting* or *opposing* the claim). We use the same train/dev/test split as provided in the released dataset. Statistics of the dataset is shown in Table 1.

3.2 Baselines

We use the following baselines:

LSTM: A long short-term memory (LSTM) model, in which we pass the claim and perspective word representations (using GloVE-6B word embeddings of size 300) through a bidirectional LSTM. Then we concatenate the final hidden states of the claim and perspective, and pass it through dense layers with ReLU activations.

ESIM: An enhanced sequential inference model (ESIM) for natural language inference proposed in Chen et al. (2017).

MLP: Multi-layer perceptron (MLP) based model using lexical and similarity-based features – presented as a *simple but tough-to-beat baseline* for stance detection in Riedel et al. (2017).

WordAttn: Our implementation of word-by-word attention-based model using long short-term memory networks (Rocktäschel et al., 2016).

LangFeat: A random forest classifier using linguistic lexicons like NRC lexicon (Mohammad and Turney, 2010), hedges (e.g., *possibly*, *might*, etc.), positive/negative sentiment words (Hu and Liu, 2004), MPQA subjective lexicon (Wilson et al., 2005) and bias lexicon (Recasens et al., 2013) along with sentiment scores as features.

$\text{BERT}_{\text{BASE}}$: Approach proposed in Chen et al. (2019) (as described in Section 2.1).

Human: Human performance on this task as reported in Chen et al. (2019).

4 Results and Discussion

Stance classification performance of our model and the baselines on the *test* split of the Perspectrum dataset are presented in Table 2. Our consistency-aware model $\text{BERT}_{\text{CONS}}$ outperforms all the other baselines. It achieves a performance improvement of about 2 points in F1-score over the strong baseline corresponding to the $\text{BERT}_{\text{BASE}}$ model (p-value of $4.985\text{e}{-4}$ as per the McNemar test). This highlights the value addition achieved by incorporating consistency cues. Since the BERT-based models incorporate the knowledge acquired from massive external corpora, our model, $\text{BERT}_{\text{CONS}}$, captures better semantics and outperforms the other baselines.

Table 3: Top phrases for determining stance.

4.1 Interpreting Token-level Contribution

Due to the massive structure of BERT with a complex attention mechanism, it is difficult to interpret the significance of different lexical units in the text. Therefore, we propose a simple technique to interpret the contribution of each token in the text in determining the stance.

Given the claim (C) and perspective (P) pair, we tokenize P into *phrases*. We record the change in stance classification probabilities by adding one perspective phrase at a time to the input:

$$\Delta_i = |BERT_{CONS}(C, P_i) - BERT_{CONS}(C, P_{i-1})|$$

where P_i is the prefix of P up to the i^{th} phrase. This helps us in understanding the contribution of each perspective phrase towards determining the stance – the larger the change in the classification probabilities, the larger the contribution. For this analysis, we consider unigrams and chunks from a shallow parser as phrases. The top contributing phrases for the *supporting* and *opposing* classes are shown in Table 3.

4.2 Error Analysis

In this section, we analyze why the task of stance classification is challenging and why the performance of the best model configuration is far from human performance as observed by the performance gap in Table 2.

Negations: One of the major challenges in solving this task is understanding negations and their scope. For example, given the claim *"College education is worth it"*, the perspective *"Many college graduates are employed in jobs that **do not** require college degrees"* is opposing the claim. However, our model is not able to capture that the negation phrase *'do not require'* opposes the claim. On the other hand, the presence of negation in the perspective does not necessarily imply that it is opposing the claim. Contrast this with the claim *"Chess must be at the Olympics"* and perspective *"Chess is currently **not** an Olympic sport, but it should be"* – where the negation is merely a part of the statement and the stance is given by the discourse segment following *'but'*.

Commonsense: Determining the stance may require commonsense knowledge. For example, the claim *"Chess must be at the Olympics"* is opposed by the perspective *"Olympic sports are supposed to be **physical**"*. To understand this, the model should have the background knowledge that chess is not a physical sport.

Semantics: Understanding the stance also involves a deeper understanding of semantics. For example, given the claim *"Make all museums free of charge"* is opposed by the perspective *"State funding should be used **elsewhere**"*. Here, the word *'elsewhere'* is the key cue which determines the stance. However, the presence of the word *'elsewhere'* does not necessarily imply that the perspective is opposing the claim. For instance, the perspective *"We could spend the money **elsewhere**"* is supporting the claim *"The EU should significantly reduce the amount it spends on agricultural production subsidies"*. Hence, the polarity of the word *'elsewhere'* is determined by the context and semantics of the statement.

5 Conclusion

In this work, we propose a consistency-aware neural network model for stance classification. Our model leverages representations from the BERT model trained over massive external corpora and a novel consistency constraint to jointly model claims and perspectives. Our experiments on a recent benchmark highlight the advantages of our approach. We also study the gap in human performance and the performance of the best model for stance classification.

Abstract

This paper explores different approaches to multilingual intent classification in a low resource setting. Recent advances in multilingual text representations promise cross-lingual transfer for classifiers. We investigate the potential for this transfer in an applied industrial setting and compare to multilingual classification using machine translated text. Our results show that while the recently developed methods show promise, practical application calls for a combination of techniques for useful results.

1 Introduction

Classifying the intent represented in a customer message is a core functionality of natural language understanding applications in customer service. Once the intent of the customer's message is understood and various entities are resolved, actions can be triggered, such as automatically replying to the customer, routing the message to the right customer service representative, or asking the customer for more information.

The rise of automation in customer service and the growing customer expectation of immediate answers is generating increasing demand for accurate intent detection across many languages. Recent advances in natural language processing have enabled impressive performance on text classification tasks, provided that large-scale labelled data are available. In industrial settings, this is often not the case, or at least not for all languages for which intent detection is required.

This paper studies what we believe to be a common case in industry, in which a small amount of labeled data are available for a single language, say English, but neither data nor labels are available for other languages. This setting poses an interesting constraint on the application of modern machine learning techniques, in that much fewer in-domain data are available for the task than is generally required. We believe that the findings in this paper can be generalized outside our specific industrial domain and apply in general to the challenge of enabling classification in a target language based on supervision in a source language.

This paper investigates the application of two techniques from the literature to this problem. The first technique is an out-of-domain machine translation system, as can be assumed to be generally available, applied to the source language data set in order to generate supervised data in the target language. The second technique that we investigate is transfer learning based on multi-lingual document representations. We study the results of applying these techniques, as well as the combination of both, in a number of experiments.

2 Related work

This study is broadly positioned in the application of cross-lingual transfer, with special focus on low resource applications. We study two approaches to this problem: machine translation and transfer through multilingual text representations.

One approach to NLP tasks in multilingual settings where the target language has scarce resources relies on machine translation. There are two popular methods: translating target language to English and vice versa, translating English to target language (Garca et al., 2012; He et al., 2013). While straightforward, a disadvantage of this approach is that building a reliable machine translation system with few resources in the target language is challenging (Upadhyay et al., 2018).

Enriched word embeddings are used to solve

various (monolingual) NLP tasks including intent classification (Kim et al., 2016). Multilingual representations of characters, words or documents can be used to solve multilingual NLP tasks. (Klementiev et al., 2012) present a representation for single words for a pair of languages that preserves semantic similarity. This approach relies on parallel data sets, a challenge to their scalability. To address this issue (Søgaard et al., 2015) propose an inter-lingual representation of words obtained with inverted indexing from common subsets of Wikipedia articles on a larger set of languages.

A recent approach is the construction of alignments between monolingual word representations for different languages into a single embedding space (Ammar et al., 2016; Alaux et al., 2018; Conneau et al., 2017; Schuster et al., 2019).

Recent studies evaluated shared sentence representations from multiple languages using both unsupervised learning on monolingual corpora (Lample and Conneau, 2019; Eriguchi et al., 2018) and supervised learning using parallel data (Artetxe and Schwenk, 2018). Advances in generative pretraining models like the Transformer (Vaswani et al., 2017), GPT (Radford et al., 2018), and BERT (Devlin et al., 2018) models make this approach even more promising. In (Lample and Conneau, 2019) authors successfully apply these techniques and propose methods for cross-lingual language modelling, unsupervised and supervised, outperforming previous best approaches.

In this paper, we study the capability of transfer from a source language to a target language through machine translation and pretrained multilingual document representations.

3 Data sets

The data set for the source language ("EN") consists of 48,875 English chat messages from customers to the customer service department of a large e-commerce website. The messages typically express intents from customers to get information or make changes on an existing transaction, e.g. cancelling a past transaction, modifying it in a certain way, or enquiring about information related to the transaction or the product. A test set for the target language ("FR") of 4,336 messages was similarly collected from the production system of the conversational agent. The median number of words in the source language messages is 16, the 99th percentile is at 93 words.

The messages were anonymized by replacing email addresses, transaction id's, credit card and telephone numbers and other personally identifiable information with token placeholders. After this process, The messages were manually labeled on 17 intents, covering the majority of incoming requests. Each message received one or more intent labels. The distribution of intents is shown in Figure 1 showing that the English and French sets have roughly the same label distribution, although there are some differences.

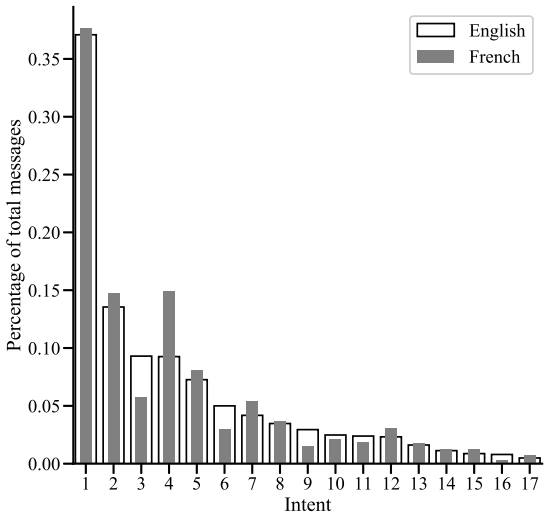

Figure 1: Intent distribution for English and French.

To support the investigation of using machine translation, an additional data set ("MT") was constructed by translating the EN data set using an in-house neural machine translation model (Levin et al., 2017). The machine translation model was trained on the open parallel corpus (Tiedemann, 2012), product descriptions, and fine-tuned for user reviews. While the product descriptions apply to the same industry as the chat messages we are investigating here, the training set for the machine translation model contains no documents from customer service interactions, so we consider it to be an out-of-domain system for the purpose of this study, as might be available to any investigator.

The EN data were split into fixed train, development, and test sets. The same splits were maintained for the translated (MT) data set. The FR data were used only for testing. Table 1 shows the volume of each of the data sets.

Language	Train	Dev	Test
EN	39,094	4,887	4,894
MT	39,094	4,887	-
FR	-	-	4,336

Table 1: Data set sizes for each approach.

4 Experiments

We study the effects of two approaches to cross-lingual transfer for intent classification; machine translation and transfer from multilingual document representations. We conduct three main experiments; one each for the two approaches and one that combines both approaches.

4.1 Machine translation

Machine translation for cross-lingual transfer is assessed by comparing a classifier trained and tested on the source language (EN) with one trained on the machine translated samples (MT) and tested on the target language (FR).

We evaluate two text classification architectures. The first architecture is a linear support vector machine (SVM) with bag-of-ngram input features and ℓ_1- and ℓ_2-regularization, a classic text classification setup (Sebastiani, 2002). A combination of unigram, bigram, and trigram features with tf-idf weighting is used.

The second text classification architecture is a convolutional neural network (CNN) similar to (Kim, 2014). The system represents input documents as sequences of word embeddings (Mikolov et al., 2018; Grave et al., 2018) that are passed through a single convolutional layer followed by a densely connected layer. The network was trained using the Adam (Kingma and Ba, 2015) optimizer and the hyperparameters of the network (size and amount of kernels, size of pre-final layer, dropout- and ℓ_1-, ℓ_2-regularization strength) were found using Bayesian optimization (Snoek et al., 2012). These text classification systems were chosen because both are commonly used in industry.

To assess machine translation for cross-lingual transfer, we compare two settings for each of the classifiers. In the first setting, both training and test data come from the source language (EN). In the second setting, training data is machine translated (MT) and test data is drawn from the target language (FR). If machine translation is a feasible strategy for transfer, then the results for the second setting should be close to those for the first.

4.2 Multilingual document embeddings

To investigate the use of multilingual document embeddings for cross-lingual transfer, we build a set of classifiers based on representations from the base multilingual BERT model (Devlin et al., 2018). We use the aggregate document representation of the input message and add a single output layer with sigmoid activations for multi-label classification, as recommended in (Devlin et al., 2018). With this system we study two setups.

In the first setup a classifier is trained on the source language (EN) only, and evaluated on both the source (EN) and the target language (FR). The hypothesis here is that if the multilingual representations from BERT allow for lossless transfer between source and target language, then the performance on the target language will be close to the performance on the source language.

In the second setup, we combine the approaches of machine translation and multilingual document representation. We train a similar classifier as above with input representations from BERT on both the source language (EN) data and the machine translated target language (MT) data. A separate classifier is trained only on the machine translated (MT) training set. We compare the performance of these two classifiers on the target (FR) test set. If the architecture facilitates task-specific transfer learning then there will be a difference in the performance between the two classifiers.

Lastly we compare the classifier that uses multilingual document representations and machine translated data with the classifiers that use only either of those approaches. If there is a cumulative effect from the combination of these approaches, then the first will outperform both of the latter.

5 Results

For the application described in this paper, false positive identifications of a class are worse than false negatives. Therefore the classifiers are calibrated on the development set to a precision close to 0.90 and maximum recall. This is a common practice in applications in which there is an asymmetry in the cost of errors. Table 2 shows the main results. Note that not all systems could achieve the required precision.

For assessing the feasibility of machine translation for cross-lingual transfer, we compare the re-

Test	Train	System	P	R	F1
EN	EN	svm	.91	.60	.72
	EN	cnn	.90	.67	.77
	EN	bert	.91	**.71**	.80
	EN+MT	bert	.91	**.71**	.80
FR	MT	svm	.86	.43	.57
	MT	cnn	.86	.47	.61
	EN	bert	.74	.51	.61
	MT	bert	.86	.62	.72
	EN+MT	bert	.86	**.63**	.73

Table 2: Test set results for the experiments.

sults of the linear SVM and the CNN. For both of these classifiers, the source (EN) to source (EN) setting outperforms the translated (MT) to target (FR) setting, by 0.17 to 0.2 recall and 0.15 to 0.16 F1-score. The latter results are, however, substantially better than chance for both classifiers. It is interesting to note that the results of the SVM do not lag far behind those of the CNN, both for EN and FR, indicating that the machine translation approach is feasible even for the SVM.

Next, the capability of multi-lingual document representations to provide cross-lingual transfer is tested by comparing the performance on EN and FR for the BERT model trained solely on EN. For the FR test case, this model could not be calibrated for a precision ≥ 0.9, so we can only compare the F1-scores. Here again, the EN setting shows better performance than the FR setting (F1 of 0.80 versus 0.61), indicating that the transfer incurs a loss in performance, but is not entirely without meaning.

Lastly, the BERT system trained on translated (MT) data shows the combination of the approaches. The evaluation on target data (FR) shows that this combination achieves higher performance than all of the above settings, outperforming MT only (0.62 recall versus 0.47 and 0.43), as well as only transfer from multilingual embeddings (0.72 F1 versus 0.61). Adding EN data to this combination model improves performance slightly (0.63 versus 0.62 recall), but these extra data do not seem to have a large effect on the performance of the system. In addition, this latter BERT model, trained on both EN and MT, when tested on the EN test set performs on par with the BERT model trained only on EN data. The implication of this is that the MT data do not introduce a degradation of the model. It is interesting to note that the results of this setting on the target language are higher than those of the SVM on the source language.

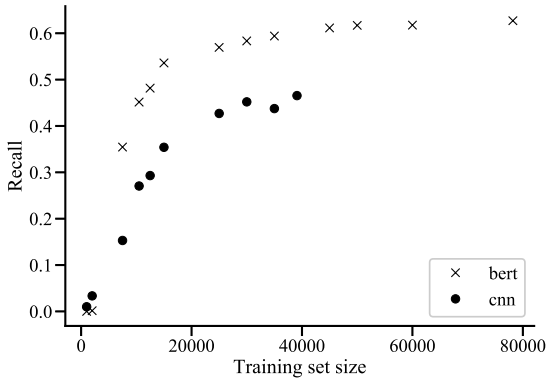

Figure 2: Recall as a function of the size of the training data. This figure shows the recall of the BERT model trained on both EN and MT and the recall of the CNN model trained on MT.

To evaluate the dependence of the BERT system with source and translated data on the amount of data available for fine-tuning the BERT model, we look at the performance as a function of the data set size and compare it in this respect to the CNN. Figure 2 shows that both the BERT model and the CNN performances converge on about 10,000 to 25,000, indicating that only a relatively small amount of labeled data is necessary.

6 Discussion

In this paper we studied two techniques for cross-lingual transfer in a typical industrial setting, with small amounts of labeled data. The results show that both machine translated data and multilingual document representations are decent strategies for cross-lingual transfer for intent detection on short chat messages. Both approaches incur a significant loss when compared to the source-to-source classification results, showing that there is still room for improvement before "zero-shot" transfer from multilingual document representations is viable as a stand-alone approach to cross-lingual transfer.

The combination of both techniques performs competitively and the observation that this setting outperforms the SVM in the source-to-source setting illustrates the advances that have been made in recent years in both machine translation and document representation.

It is an open question on whether these results generalize to other language pairs. The languages studied here are both western Indo-European languages so the results obtained here may not apply to pairs of distant languages. In addition, the label distributions between the source and target language in our experiments were fairly closely aligned, which may not apply to other use cases. In general, more investigation is needed to assess how well the current generation of multi-lingual document representations supports cross-lingual transfer and if there are differences in how well the representations between languages align.

It is promising to note though that the results in this study can be obtained with data set sizes that are generally available in industrial settings.

Abstract

We continue the study of generating semantically correct regular expressions from natural language descriptions (NL). The current state-of-the-art model, SemRegex, produces regular expressions from NLs by rewarding the reinforced learning based on the semantic (rather than syntactic) equivalence between two regular expressions. Since the regular expression equivalence problem is PSPACE-complete, we introduce the EQ_Reg model for computing the similarity of two regular expressions using deep neural networks. Our EQ_Reg model essentially softens the equivalence of two regular expressions when used as a reward function. We then propose a new regex generation model, SoftRegex, using the EQ_Reg model, and empirically demonstrate that SoftRegex substantially reduces the training time (by a factor of at least 3.6) and produces state-of-the-art results on three benchmark datasets.

1 Introduction

Regular expressions are an efficient tool to represent structured data with specific rules in a variety of fields such as natural language processing or text classification. However, it is not always an easy task to write an exact regular expression for those who do not have a deep knowledge of regular expressions or when the expression is very complicated, and incorrect or sloppy regular expressions may cause unexpected consequences in practice (Bispo et al., 2006; Zhang et al., 2018). Indeed, even a single character difference between regular expressions can cause them to represent completely different sets of strings. As such, researchers have begun working on a system than generates a regular expression from a natural language description provided by a human while reducing possible errors caused by incorrect regular expressions (Liu et al., 2019). Recently, Locascio et al. (2016) designed the DeepRegex model based on the sequence-to-sequence (Seq2Seq) model (Sutskever et al., 2014) using minimal domain knowledge during the learning phase while still accurately predicting regular expressions from NLs. Later, Zhong et al. (2018a) improved the performance by training on not only syntactic content of the expressions (i.e. the exact textual representation of the expression that was used), but also the semantic content (the regular language described by the expression). However, the reward function in the SemRegex model (Zhong et al., 2018a) that determines if the predicted regular expression is semantically equivalent to the ground truth expression is known to be PSPACE-complete and is a bottleneck in practice (Stockmeyer and Meyer, 1973). Thus, if we can solve this problem (even approximately) more quickly, then we can decrease the required learning time in the natural-language-to-regular expression (NL-RX) model. Reward shaping (Mataric, 1994; Ng et al., 1999) is a well-known mechanism to estimate the reward of an action in reinforced learning without executing the action. As a reward shaping mechanism for NL-RX, we build a new model, EQ_Reg, based on deep learning that estimates the equivalence probability of two regular expressions and use it to improve the NL-RX training speed substantially. During the NL-

RX model training phase, EQ_Reg can quickly determine the equivalence of the predicted expression and the true expression, and pass this value as a reward for reinforcement learning. Our new NL-RX model together with the EQ_Reg model as a reward function is called SoftRegex. We demonstrate that SoftRegex substantially reduces the training time and produces state-of-the-art results on three benchmark datasets.

2 Related Work

Generating Regular Expressions: Ranta (1998) studied rule-based techniques for the conversion between multi-languages and regular expressions. Kushman and Barzilay (2013) built a parsing model that translates a natural language sentence to a regular expression, and provided a dataset which is now a popular benchmark dataset for related research. Locascio et al. (2016) proposed the Deep-Regex model based on Seq2Seq for generating regular expressions from natural language descriptions together with a dataset of 10,000 NL-RX pairs. However, due to the limitations of the standard Seq2Seq model, the Deep-Regex model can only generate regular expressions similar in shape to the training data. The SemRegex model improved the Deep-Regex model by using reinforcement learning based on the deterministic finite automata (DFA) equivalence oracle (which determines if two regular expressions describe the same language) as a reward function. This model can generate correct regular expressions that may not resemble the ground truth answer.

Comparing Regular Expressions: A regular language can have several syntactically different regular expressions. We say that two regular expressions are equivalent if they both define the same language. The most basic method to deciding whether or not two regular expressions are equivalent is to convert both regular expressions to DFAs. However, the time and space complexity of converting regular expressions to DFAs are both exponential (Hopcroft and Ullman, 1979). Stockmeyer and Meyer (1973) showed that it is PSPACE-complete to decide if two regular expressions generate the same set of words. Thus, deciding equivalence for two regular expressions is a bottleneck calculation even for small inputs.

3 Methods

3.1 NL-RX Model

We apply the Seq2Seq model with an attention mechanism (Luong et al., 2015). We utilize LSTM (Hochreiter and Schmidhuber, 1997) cells in the Seq2Seq model, which consists of an encoder and decoder. The encoder generates a latent vector from the given natural language description. Concurrently, the decoder receives the latent vector from the encoder and generates an output.

Maximum Likelihood Estimation (MLE): Let θ be all parameters in the Seq2Seq model. The probability that the model outputs regular expressions R from a natural language input S is

$$p_\theta(R \mid S) = \prod_{t=1}^{T} p_\theta(r_t \mid r_{<t}, S). \quad (1)$$

Here, r_t represents a predicted token at time step t. The Deep-Regex model trains itself to find the proper r_t using MLE and optimizes through minimizing loss.

Policy Gradient: The SemRegex model additionally trains the NL-RX model via a policy gradient (Williams, 1992) by rewarding the model if it generates regular expressions that are semantically equivalent to the ground truth. The reward function returns 1 if the output regular expression is equivalent to the answer, and 0 otherwise. In short, the SemRegex model trains itself to maximize the following objective function:

$$J(\theta) = \sum_{(S,R)\in D} p(R \mid S) r(R), \quad (2)$$

where D is a training set, $p(R \mid S)$ represents the probability that the model predicts regular expression for given sentence, and $r(R)$ is the return value of the reward function that receives the predicted regular expression.

3.2 EQ_Reg Model

The reward function in the SemRegex model is based on a regular expression equivalence oracle. This test is time intensive (the regular expression equivalence problem is PSPACE-complete) and returns only a binary value (0/1) representing the equivalence. Therefore, the equivalence test is a major hurdle when training large amounts of data, which is closely related to model performance. Recently, there have been a few attempts to tackle intractable problems using deep learning (Prates

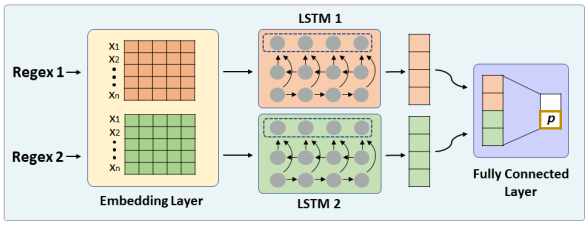

Figure 1: The configuration of the EQ_Reg model

et al., 2019; Selsam et al., 2019). This motivates us to study a different approach that can speed up the equivalence test based on deep learning and propose the EQ_Reg model that returns an equivalence probability of two regular expressions. We can then reward the NL-RX model with continuous values (the equivalence probability of two regular expressions) and significantly boost the learning speed of the NL-RX model using the EQ_Reg model.

The EQ_Reg model converts the input regular expressions to two sequences of embedding vectors. Next, we feed the embedding vector sequences into two different LSTM layers. Each LSTM layer converts the sequences to latent vectors. Since the regular expression is a grammatical expression, we present its context using a bidirectional RNN method (Graves et al., 2013) as

$$\overrightarrow{h}_t = \sigma(W_{x\overrightarrow{h}} x_t + W_{\overrightarrow{h}\overrightarrow{h}} \overrightarrow{h}_{t-1} + b_{\overrightarrow{h}}), \quad (3)$$

$$\overleftarrow{h}_t = \sigma(W_{x\overleftarrow{h}} x_t + W_{\overleftarrow{h}\overleftarrow{h}} \overleftarrow{h}_{t-1} + b_{\overleftarrow{h}}), \quad (4)$$

$$y_t = \sigma(W_{y\overrightarrow{h}} \overrightarrow{h} + W_{y\overleftarrow{h}} \overleftarrow{h}) + b_y, \quad (5)$$

where $\overrightarrow{h}$ is the forward hidden sequence and $\overleftarrow{h}$ is the backward hidden sequence. We concatenate the latent vectors from each LSTM layer into one vector and so that a single vector contains both regular expressions information. Finally, the fully connected layer predicts the equivalence of the two regular expressions from their concatenated vector.

4 Experimental Setup

We run our experiments on a computer with the following specifications: AMD Ryzen 7 1700 8-core with 64GB RAM and a GTX 1080Ti GPU on Ubuntu 16.04.1. Our source code is written using PyTorch 0.4.0 (Ketkar, 2017).

4.1 EQ_Reg Model

Datasets: Locascio et al. (2016) created a set of NL-RX pair data by arbitrarily creating and combining data in a tree form. We define the *depth* of a regular expression in this dataset as the depth of the tree that generated the NL-RX pair (see Appendix A). Similar to Locascio et al. (2016), we randomly generate regular expression pairs up to depth three and label the equivalence between each pair. We sample approximately 200,000 pairs using this method with a ratio of equivalent and non-equivalent pairs of about 2:1. We prepare three sets of data having different depths for test data. One set is made up of only regular expressions with depth at most 3, which is the same as the training data (10,000 pairs). The other two have depths 4 and 5, respectively, and each contain 1,000 pairs of regular expressions of which half are equivalent.

Model Settings: We set the two LSTMs in our model to not have shared parameters as we found this gives better performance. The embedding dimension size is set to 4, since the size of vocabulary for regular expressions is relatively small compared to natural languages. We configure two independent LSTMs with 1 layer to receive the two regular expressions. The LSTM layers use the average value of the sequence output values as their final outputs and pass them to the next layer. We set the batch size to 256 and the learning rate to 0.1 and use a stochastic gradient descent optimizer (Bottou, 2010).

4.2 SoftRegex Model

Datasets: We use three public datasets to compare SoftRegex with the-state-of-the-art model, SemRegex. The KB13 (Kushman and Barzilay, 2013) dataset was constructed by regex experts and is relatively small. On the other hand, NL-RX-Synth is data generated automatically and NL-RX-Turk is made from ordinary people by paraphrasing NL descriptions in NL-RX-Synth using Mechanical Turk (Locascio et al., 2016). Both datasets have 10,000 pairs of NL-RX data. We follow the previous work in splitting the data (train: 65%, dev: 10%, test: 25%).

Description: lines having words with lower-case letter at least 5 times or no digit.

Regular expression (Ground truth): \b(([a-z]){5,})|(~([0-9])))\b

Regular expression (Equivalent with ground truth): ((~([0-9]))|([a-z]){5,}))

Figure 2: An example NL-RX pair and another regular expression that is semantically equivalent to the ground truth.

Model settings: We arrange the SoftRegex architecture based on SemRegex. We embed the input sequence tokens with dimension size 128, stack two LSTM layers, and set the hidden state dimension size to 256. We set the batch size to 32 and learning rate to 0.05 with the ADADELTA optimizer (Zeiler, 2012). We substitute in the EQ_Reg model as the reward function which gives high reward value 1 if our model generate a regular expression that is equivalent to the ground truth (Figure 2).

5 Results and Analysis

5.1 Model Performance

EQ_Reg: We test the EQ_Reg model with the three datasets from Section 4.1. The F1-score of test set 1 (depth 3) is 0.986, test set 2 (depth 4) is 0.868, and test set 3 (depth 5) is 0.853. As expected, we can see the model is showing high performance for test data with the same range of depth with the training data. In addition, although the EQ_Reg model has a simple structure, it shows reasonable accuracy for more complex data that has not been previously seen. Here, we can notice the model does not just remember the structure of the training data but generalizes to solve the equivalence problem by understanding the semantics of regular expressions.

SoftRegex: Table 1 shows the experimental results of Deep-Regex, SemRegex, and our SoftRegex model. The average accuracy of 10 evaluations is given. The distinguishing test cases method is based on the membership test of samples for the case when an oracle is not available and is described in (Zhong et al., 2018a). The accuracy of SoftRegex is similar to or better than SemRegex (Oracle) and always better than Deep Regex and SemRegex (Distinguishing Test Cases). Figure 3 shows the average training time per epoch over 30 epochs for each of the three models (SoftRegex and both SemRegex variants) and datasets. The training time with EQ_Reg vastly outperforms the training time for SemRegex. In the worst case (the NL-RX-Synth dataset), we see that our new method is still 3.6 times faster than that of SemRegex. Though the speedup described in experimental result may appear constant, our softened equivalence approximately decides a PSPACE-complete problem in linear time to the length of regular expressions, which would otherwise take exponential time.

Methods	KB13	NL-RX-Synth	NL-RX-Turk
Deep-Regex	65.6%	89.7%	58.2%
SemRegex (Oracle)	78.2%	91.6%	62.3%
SemRegex (Distinguishing Test Cases)	77.5%	90.2%	61.3%
SoftRegex	78.2%	91.4%	62.8%

Table 1: The accuracy of NL-RX models.

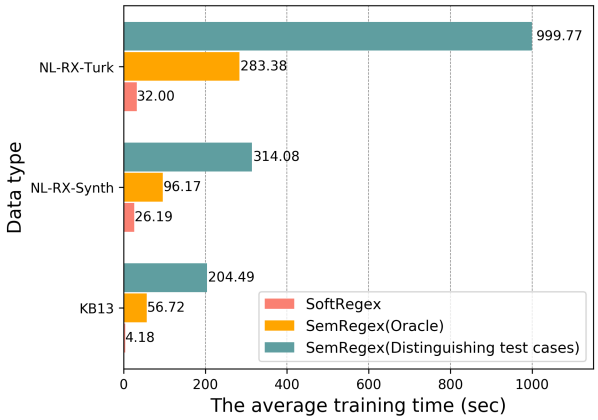

Figure 3: The average training time of NL-RX models.

5.2 Error Analysis

Zhong et al. (2018b) pointed out some problems in the NL-RX datasets. Specifically, there are some ambiguities since Locascio et al. (2016) tried to obtain data from machine-generated sentences. Thus, there are situations that even expert humans cannot accurately classify. On the other hand, the NL-RX-Turk dataset is unreliable in that it is generated by non-experts who are paraphrasing previously generated data. We investigate all 921 incorrect predictions of SoftRegex in NL-RX-Turk and categorize the resulting errors into 4 types (Table 2). The 354 type-1 errors are caused by ambiguity in the natural language description where SoftRegex prediction matches one interpretation of the natural language description but not the ground truth. The 256 type-2 errors are from incorrect regex descriptions. These errors occur when descriptions from NL-RX-Synth are misunderstood by the human annotators. The 56 type-3 errors are from incorrect user-generated data (e.g. typos in the descriptions). The remaining 296 type-4 errors are true errors that our model failed to give correct answers for. For the

NL Example	Predicted Answer	Ground Truth	Error Type
lines containing 3 or more capital letters	.*([[A-Z]]){3,}.*	(.*[A-Z].*){3,}	Description ambiguity (type-1)
lines without a capital letter or string 'dog'	∼(([A-Z])|(dog))	(∼[A-Z]))|((dog)+)	Wrong description (type-2)
lines with 5 or more words without characters	\b∼(.)\b	\b∼((.){5,})\b	Typo in description (type-3)
lines with words and 4 lower-case letters	\b.*[a-z].*\b	\b([a-z]){4,}\b	True error (type-4)

Table 2: Example of errors caused by SoftRegex for NL-RX-Turk.

type-1 errors, we need to train more NL-RX data where a single NL is paired with several equivalent regex to cope with the NL ambiguity problem. The type-2 and type-3 errors are caused from crowd-sourcing, which might be hard to detect in the current learning model. We may consider a rule-based prescreening procedure. Finally, for the type-4 errors, we plan to incorporate the copying mechanism (Gu et al., 2016) and the sequence-to-tree translation model (Dong and Lapata, 2016) to enhance the performance of our model considering the deterministic relationship between input and output sequences and hierarchical structure of output regular expressions. Although errors are mostly caused by data errors that we can handle easily, we chose to conduct our experiments under the same condition as SemRegex to provide a fair comparison with prior work.

6 Conclusions

Recently, there have been several successful attempts to generate regular expressions from natural language. The current state-of-the-art model is based on reinforced learning using the (in)equivalence of two regular expressions. The regular expression equivalence procedure is a PSPACE-complete problem and, thus, is a major bottleneck in training both in time and space. We sidestep this bottleneck by using the EQ_Reg model as reward shaping, which gives a regex equivalence probability for two regular expressions, and build a new NL-RX model called SoftRegex. Our SoftRegex model with EQ_Reg as a reward function substantially speeds up the training phase (at least 3.6 times faster than SemRegex) while having similar or better performance on a series of standard benchmarks.

A Supplemental Material

We now describe how Locascio et al. (2016) generated their synthetic regular expression data. To begin, they manually mapped primitive regular expression operations, such as union and concatenation, to natural language. They then defined a small alphabet on which the operations could be performed. In the end, their system has 15 operations and 6 types of characters in the vocabulary. From this, they were able to build up NL-RX pairs automatically by creating a parse tree of repeated applications of operations to an initial regular expression. The operations (non-terminals) and alphabet (terminals) are shown in Table 3.

Figure 4 gives an example of how a NL-RX pair is generated by creating a parse tree. It can be seen that it builds from the bottom up by starting with a series of words or characters (terminals) and applying some primitive operations (non-terminals). Simultaneously, natural language descriptions of terminals and non-terminals are composed together to create a semantically identical natural language description. In this example, the NL-RX pair has depth 2.

Non-Terminals		
x&y → x and y	x|y → x or y	∼(x) → not x
.*x.*y → x followed by y	.*x.* → contains x	x{N, } → x, N or more times
x&y&z → x and y and z	x|y|z → x or y or z	x{1, N} → at most N times
x.* → starts with x	.*x → ends with x	\bx\b → words with x
(x)+ → x, at least once	(x)* → x, zero or more times	x → only x

Terminals		
[AEIOUaeiou] → a vowel	[0-9] → a number	word → the string word
[A-Z] → an uppercase letter	[a-z] → a lowercase letter	. → a character

Table 3: The non-terminal and terminal operations with their corresponding natural language description as constructed by Locascio et al. (2016).

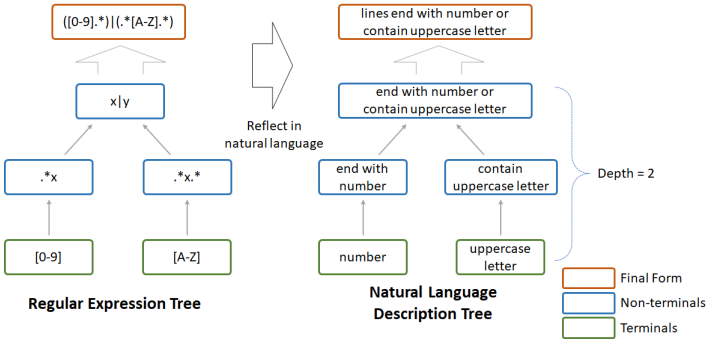

Figure 4: An example of how Locascio et al. (2016) generate the dataset of NL-RX pairs.

Using Clinical Notes with Time Series Data for ICU Management

Abstract

Monitoring patients in ICU is a challenging and high-cost task. Hence, predicting the condition of patients during their ICU stay can help provide better acute care and plan the hospital's resources. There has been continuous progress in machine learning research for ICU management, and most of this work has focused on using time series signals recorded by ICU instruments. In our work, we show that adding clinical notes as another modality improves the performance of the model for three benchmark tasks: in-hospital mortality prediction, modeling decompensation, and length of stay forecasting that play an important role in ICU management. While the time-series data is measured at regular intervals, doctor notes are charted at irregular times, making it challenging to model them together. We propose a method to model them jointly, achieving considerable improvement across benchmark tasks over baseline time-series model. Our implementation can be found at https://github.com/kaggarwal/ClinicalNotesICU.

1 Introduction

With the advancement of medical technology, patients admitted into the intensive care unit (ICU) are monitored by different instruments on their bedside, which measure different vital signals about patient's health. During their stay, doctors visit the patient intermittently for check-ups and make *clinical notes* about the patient's health and physiological progress. These notes can be perceived as *summarized expert knowledge* about the patient's state. All these data about instrument readings, procedures, lab events, and clinical notes are recorded for reference. Availability of ICU data and enormous progress in machine learning have opened up new possibilities for health care research. Monitoring patients in ICU is a challenging and high-cost task. Hence, predicting the condition of patients during their ICU stay can help plan better resource usage for patients that need it most in a cost-effective way. Prior works (Harutyunyan et al., 2019; Ghassemi et al., 2015; Suresh et al., 2018; Song et al., 2018; Caballero Barajas and Akella, 2015) have focused exclusively on modeling the problem using the time series signals from medical instruments. Expert knowledge from doctor's notes has been ignored in the literature.

In this work, we use clinical notes in addition to the time-series data for improved prediction on benchmark ICU management tasks (Harutyunyan et al., 2019). While the time-series data is measured continuously, the doctor notes are charted at intermittent times. This creates a new challenge to model continuous time series and discrete-time note events jointly. We propose such a multimodal deep neural network that comprises of recurrent units for the time-series and convolution network for the clinical notes. We demonstrate that adding clinical notes improves the performance on in-hospital mortality prediction, modeling decompensation, and length of stay forecasting tasks.

2 Related Work

We provide a review of machine learning approaches for clinical prediction tasks.

Biomedical natural language processing The recent developments in deep learning-based techniques for NLP have been adapted for clinical notes. Convolutional neural networks have been used to predict ICD codes from clinical texts (Mullenbach et al., 2018; Li et al., 2018; Gangavarapu et al., 2019). Rios and Kavuluru (2015) and Baker et al. (2016) used convolutional neural networks to classify various biomedical articles. Pre-trained word and sentence embeddings have also shown good results for sentence similarity tasks (Chen

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6432–6437,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

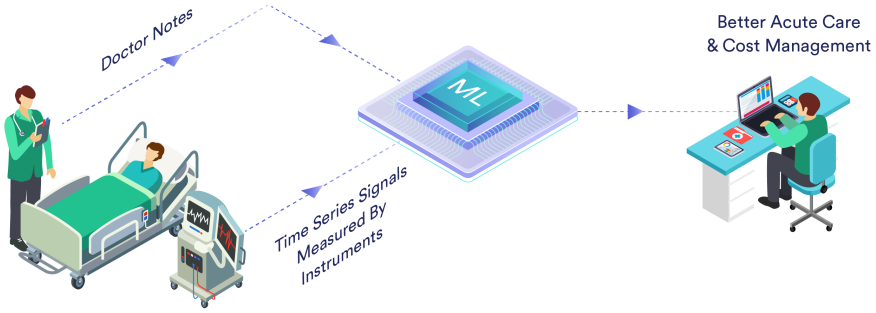

Figure 1: Doctor notes compliments measured physiological signals for better ICU management.

et al., 2018). Recently, there is an interest in the community to use clinical notes for ICU related tasks (Jin et al., 2018; Boag et al., 2018; Liu et al., 2019; Huang et al., 2019). Given the long structured nature of the clinical text, we prefer convolutional neural networks over recurrent networks, as demonstrated in previous studies (Zhang et al., 2016; Boag et al., 2018). The work closest to ours is Jin et al. (2018), who use an aggregated word embeddings of clinical notes for in-hospital mortality prediction.

ICU management related literature ICU management literature has focused exclusively on using time-series measurements for the prediction tasks Harutyunyan et al. (2019); Ghassemi et al. (2015); Suresh et al. (2018); Song et al. (2018); Caballero Barajas and Akella (2015). Recurrent neural networks have been models of choice for these recent works, with additional gains from using attention or multi-task learning (Song et al. (2018)). Xu et al. (2018) accommodated supplemental information like diagnosis, medications, and lab events to improve model performance. We use RNNs for modeling time-series in this work, utilizing the setup identical to Harutyunyan et al. (2019).

Multi-modal learning has shown success in speech, natural language, and computer vision (Ngiam et al. (2011), Mao et al. (2014)). Recently, a lot of work has been done using images/videos with natural language text (Elliott et al. (2016)). We use a similar intuition for utilizing clinical notes with time-series data for ICU management tasks. In the next section, we define the three benchmark tasks we evaluate in this work.

3 Prediction Tasks

We use the definitions of the benchmark tasks defined by Harutyunyan et al. (2019) as the following three problems:

1. **In-hospital Mortality**: This is a binary classification problem to predict whether a patient dies before being discharged from the first two days of ICU data.

2. **Decompensation**: Focus is to detect patients who are physiologically declining. Decompensation is defined as a sequential prediction task where the model has to predict at each hour after ICU admission. Target at each hour is to predict the mortality of the patient within a 24 hour time window.

3. **Length of Stay Forecasting (LOS)**: The benchmark defines LOS as a prediction of bucketed remaining ICU stay with a multi-class classification problem. Remaining ICU stay time is discretized into 10 buckets: $\{0-1, 1-2, 2-3, 3-4, 4-5, 5-6, 6-7, 7-8, 8-14, 14+\}$ days where first bucket, covers the patients staying for less than a day (24 hours) in ICU and so on. This is only done for the patients that did not die in ICU.

These tasks have been identified as key performance indicators of models that can be beneficial in ICU management in the literature. Most of the recent work has focused on using RNN to model the temporal dependency of the instrument time series signals for these tasks (Harutyunyan et al. (2019), Song et al. (2018)).

4 Methods

In this section, we describe the models used in this study. We start by introducing the notations used, then describe the baseline architecture, and finally present our proposed multimodal network.

For a patient's length of ICU stay of T hours, we have time series observations, x_t at each time step t (1 hour interval) measured by instruments along with doctor's note n_i recorded at *irregular* time stamps. Formally, for each patient's ICU

stay, we have time series data $[x_t]_{t=1}^{T}$ of length T, and K doctor notes $[N_i]_{i=1}^{K}$ charted at time $[TC(i)]_{i=1}^{K}$, where K is generally much smaller than T. For **in-hospital mortality** prediction, m is a binary label at $t = 48$ hours, which indicates whether the person dies in ICU before being discharged. For **decompensation** prediction performed hourly, $[d_t]_{t=5}^{T}$ are the binary labels at each time step t, which indicates whether the person dies in ICU within the next 24 hours. For **LOS** forecasting also performed hourly, $[l_t]_{t=5}^{T}$ are multi-class labels defined by buckets of the remaining length of stay of the patient in ICU. Finally, we denote N_T as the concatenated doctor's note during the ICU stay of the patient (*i.e.,*, from $t = 1$ to $t = T$).

4.1 Baseline: Time-Series LSTM Model

Our baseline model is similar to the models defined by Harutyunyan et al. (2019). For all the three tasks, we used a Long Short Term Memory or LSTM (Hochreiter and Schmidhuber, 1997) network to model the temporal dependencies between the time series observations, $[x_t]_{t=1}^{T}$. At each step, the LSTM composes the current input x_t with its previous hidden state h_{t-1} to generate its current hidden state h_t; that is, $h_t = \text{LSTM}(x_t, h_{t-1})$ for $t = 1$ to $t = T$. The predictions for the three tasks are then performed with the corresponding hidden states as follows:

$$\begin{aligned} \hat{m} &= \text{sigmoid}(W_m h_{48} + b_m) \\ \hat{d}_t &= \text{sigmoid}(W_d h_t + b_d) \;\; \text{for } t = 5 \ldots T \\ \hat{l}_t &= \text{softmax}(W_l h_t + b_l) \;\; \text{for } t = 5 \ldots T \end{aligned} \tag{1}$$

where $\hat{m}$, $\hat{d}_t$, and $\hat{l}_t$ are the probabilities for in-hospital mortality, decompensation, and LOS, respectively, and W_m, W_d, and W_l are the respective weights of the fully-connected (FC) layer. Notice that the in-hospital mortality is predicted at end of 48 hours, while the predictions for decompensation and LOS tasks are done at each time step after first four hours of ICU stay. We trained the models using cross entropy (CE) loss defined as below.

$$\begin{aligned} \mathcal{L}_{\text{ihm}} &= \text{CE}(m, \hat{m}) \\ \mathcal{L}_{\text{decom}} &= \frac{1}{T} \sum_t \text{CE}(d_t, \hat{d}_t) \\ \mathcal{L}_{\text{los}} &= \frac{1}{T} \sum_t \text{CE}(l_t, \hat{l}_t) \end{aligned} \tag{2}$$

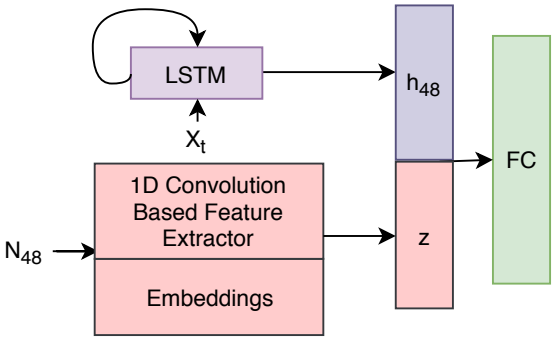

Figure 2: Block diagram from the in-hospital mortality multi-modal network.

4.2 Multi-Modal Neural Network

In our multimodal model, our goal is to improve the predictions by taking both the time series data x_t and the doctor notes n_i as input to the network.

Convolutional Feature Extractor for Doctor Notes. As shown in Fig. 2, we adopt a convolutional approach similar to Kim (2014) to extract the textual features from the doctor's notes. For a piece of clinical note N, our CNN takes the word embeddings $\mathbf{e} = (e_1, e_2, \ldots, e_n)$ as input and applies 1D convolution operations, followed by max-pooling over time to generate a p dimensional feature vector $\hat{z}$, which is fed to the fully connected layer along side the LSTM output from time series signal (described in the next paragraph) for further processing. From now onwards, we denote the 1D convolution over note N as $\hat{z} = \text{Conv1D}(N)$.

Model for In-Hospital Mortality. This model takes the time series signals $[x_t]_{t=1}^{T}$ and all notes $[N_i]_{i=1}^{K}$ to predict the mortality label m at $t = T$ ($T = 48$). For this, $[x_t]_{t=1}^{T}$ is processed through an LSTM layer just like the baseline model in Sec. 4.1, and for the notes, we concatenate ($\otimes$) all the notes N_1 to N_K charted between $t = 1$ to $t = T$ to generate a single document N_T. More formally,

$$\begin{aligned} N_T &= N_1 \otimes N_2 \otimes \cdots \otimes N_K \\ h_t &= \text{LSTM}(x_t, h_{t-1}) \;\; \text{for } t = 1 \ldots T \\ \hat{z} &= \text{Conv1D}(N_T) \\ \hat{m} &= \text{sigmoid}(W_1 h_{48} + W_2 \hat{z} + b) \end{aligned} \tag{3}$$

We use pre-trained word2vec embeddings (Mikolov et al., 2013) trained on both MIMIC-III clinical notes and PubMed articles to initialize our methods as it outperforms other embeddings as shown in (Chen et al., 2018). We also freeze the embedding layer parameters, as we did not observe any improvement by fine-tuning them.

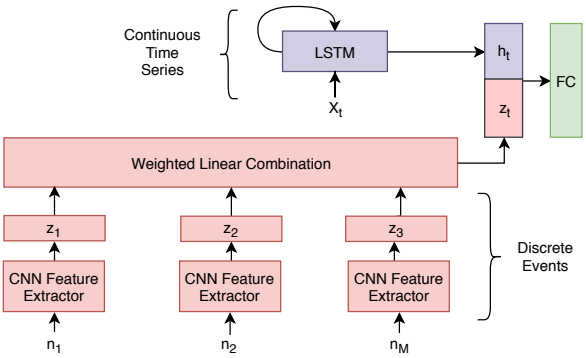

Figure 3: Block diagram from decompensation and length of stay prediction multi-modal network.

Model for Decompensation and Length of Stay. Being sequential prediction problems, modeling decompensation and length-of-stay requires special technique to align the discrete text events to continuous time series signals, measured at 1 event per hour. Unlike in-hospital mortality, here we extract feature maps z_i by processing each note N_i independently using 1D convolution operations. For each time step $t = 1, 2 \ldots T$, let z_t denote the extracted text feature map to be used for prediction at time step t. We compute z_t as follows.

$$\begin{aligned} z_i &= \text{Conv1D}(N_i) \;\text{ for } i = 1 \ldots K \\ w(t,i) &= \exp[-\lambda * (t - CT(i))] \\ z_t &= \frac{1}{M} \sum_{i=1}^{M} z_i w(t,i) \end{aligned} \tag{4}$$

where M is the number of doctor notes seen before time-step t, and λ is a decay hyperparameter tuned on a validation data. Notice that z_t is computed as a weighted sum of the feature vectors, where the weights are computed with an exponential decay function. The intuition behind using a decay is to give preference to recent notes as they better describe the current state of the patient.

The time series data x_t is modeled using an LSTM as before. We concatenate the attenuated output from the CNN with the LSTM output for the prediction tasks as follows:

$$\begin{aligned} h_t &= \text{LSTM}(x_t, h_{t-1}) \\ \hat{d}_t &= \text{sigmoid}(W_d^1 h_t + W_d^2 z_t + b) \\ \hat{l}_t &= \text{softmax}(W_l^1 h_t + W_l^2 z_t + b) \end{aligned} \tag{5}$$

Both our baselines and multimodal networks are regularized using dropout and weight decay. We used Adam Optimizer to train all our models.

5 Experiments

We used MIMIC-III (Johnson et al., 2016) dataset for all our experiments following Harutyunyan et al. (2019)'s benchmark setup for processing the time series signals from ICU instruments. We use the same test-set defined in the benchmark and 15% of remaining data as validation set. For in-hospital mortality task, only those patients are considered who were admitted in the ICU for at least 48 hours. However, we dropped all clinical notes which doesn't have any chart time associated and also dropped all the patients without any notes. Owing to this step, *our results are not directly comparable to the numbers reported by Harutyunyan et al. (2019).* Notes which have been charted before ICU admission are concatenated and treated as one note at $t = 1$. After preprocessing, the number of patients for in-hospital mortality is 11,579 and 22,353 for the other two tasks.

For in-hospital mortality task, best performing baseline and multimodal network have 256 hidden units LSTM cell. For convolution operation, we used 256 filters for each of kernel size 2, 3 and 4. For decompensation and LOS prediction, we used 64 hidden units for LSTM and 128 filters for each 2,3 and 4 size convolution filters. The best decay factor λ for text features was 0.01. We implement our methods with TensorFlow Abadi et al. (2015)[1]. All our models were regularized using 0.2 dropout and 0.01 weight decay coefficient. We run the experiments 5 times with different initialization and report the mean and standard deviations.

6 Results

We use Area Under Precision-Recall (AUCPR) metric for in-hospital mortality and decompensation tasks as they suffer from class imbalance with only 10% patients suffering mortality, following the benchmark. Davis and Goadrich (2006) suggest AUCPR for imbalanced class problems. We use Cohen's linear weighted kappa, which measures the correlation between predicted and actual multi-class buckets to evaluate LOS in accordance with with Harutyunyan et al. (2019).

We compared the multimodal network with the baseline time series LSTM models for all three tasks. Results from our experiments are documented in Table 1. Our proposed multimodal net-

Table 1: Mean metrics for all three tasks. Standard deviations: IHM (AUCROC < 0.004, AUCPR < 0.015), Decompensation (AUCROC < 0.008, AUCPR < 0.008), and LOS (Kappa < 0.003).

work outperforms the time series models for all three tasks. For in-hospital mortality prediction, we see an improvement of around 7.8% over the baseline time series LSTM model. The other two problems were more challenging itself than the first task, and modeling the notes for the sequential task was difficult. With our multimodal network, we saw an improvement of around 6% and 3.5% for decompensation and LOS, respectively.

We did not observe a change in performance with respect to results reported in benchmark (Harutyunyan et al., 2019) study despite dropping patients with no notes or chart time. In order to understand the predictive power of clinical notes, we also train text only models using CNN part from our proposed model. Additionally, we try average word embedding without CNN as another method to extract feature from the text as a baseline. Text-only-models perform poorly compared to time-series baseline. Hence, text can only provide additional predictive power on top of time-series data.

7 Conclusion

Identifying the patient's condition in advance is of critical importance for acute care and ICU management. Literature has exclusively focused on using time-series measurements from ICU instruments to this end. In this work, we demonstrate that utilizing clinical notes along with time-series data can improve the prediction performance significantly. In the future, we expect to improve more using advanced models for the clinical notes since text summarizes expert knowledge about a patient's condition.

Abstract

We present a machine foreign-language teacher that modifies text in a student's native language (L1) by replacing some word tokens with glosses in a foreign language (L2), in such a way that the student can acquire L2 vocabulary simply by reading the resulting *macaronic* text. The machine teacher uses no supervised data from human students. Instead, to guide the machine teacher's choice of which words to replace, we equip a cloze language model with a training procedure that can incrementally learn representations for novel words, and use this model as a proxy for the word guessing and learning ability of real human students. We use Mechanical Turk to evaluate two variants of the student model: (i) one that generates a representation for a novel word using only surrounding context and (ii) an extension that also uses the spelling of the novel word.

1 Introduction

Reading plays an important role in building our native language (L1) vocabulary (Nation, 2001). While some novel words might require the assistance of a dictionary, a large portion are acquired through *incidental learning* – where a reader, exposed to a novel word, tries to infer its meaning using clues from the surrounding context and spelling (Krashen, 1989). An initial "rough" understanding of a novel word might suffice for the reader to continue reading, with subsequent exposures refining their understanding of the novel word.

Our goal is to design a machine teacher that uses a human reader's incidental learning ability to teach foreign language (L2) vocabulary. The machine teacher's modus operandi is to replace L1 words with their L2 glosses, which results in a *macaronic* document that mixes two languages in an effort to ease the human reader into understanding the L2. While some of our prior work (Renduchintala et al., 2016b,a) considered incorporating other features of the L2 such as word order and fixed phrases, in this paper we only consider simple lexical substitutions.

Our hope is that such a system can augment traditional foreign language instruction. As an example, consider a native speaker of English (learning German) presented with the following sentence: **Der** Nile is a **Fluss** in **Afrika**. With a little effort, one would hope the student could infer the meaning of the German words because there is sufficient contextual information and spelling information for the cognate **Afrika**.

In our previous papers on foreign language teaching (Renduchintala et al., 2016b; Knowles et al., 2016; Renduchintala et al., 2017), we focused on fitting detailed models of students' learning when the instructional stimuli (macaronic or otherwise) were chosen by a simple random or heuristic teaching policy. In the present paper, we flip the emphasis to choosing *good* instructional stimuli—machine teaching. This still requires a model of student learning. We employ a reasonable model that is not trained on any human students at all, but only on text that a generic student is presumed to have read. Thus, our model is not personalized, although it may be specialized to the domain of L1 text that it was initially trained on.

That said, our model is reasonably sophisticated and includes new elements. It uses a neural cloze language model (in contrast to the weaker pairwise CRF model of Renduchintala et al. (2016b)) to intelligently guess the meaning of L2 words in full macaronic sentential context. Guessing actually takes the form of a learning rule that jointly improves the embeddings of all L2 words in the sentence. This is our simulation of incidental learning which accumulates over repeated exposures to the same L2 words in different contexts.

Our machine teacher tries to construct macaronic sentences that the human student ought to understand, given all the learning that our generic model predicts would have happened from the previous

Sentence	The	Nile	is	a	river	in	Africa
Gloss	**Der**	**Nil**	**ist**	**ein**	**Fluss**	**in**	**Afrika**
Macaronic Configurations	**Der**	Nile	**ist**	a	river	in	Africa
	The	Nile	is	a	**Fluss**	in	Africa
	Der	**Nil**	**ist**	**ein**	river	in	Africa

Table 1: An example English (L1) sentence with German (L2) glosses. Using the glosses, many possible macaronic configurations are possible. Note that the gloss sequence is not a fluent L2 sentence.

macaronic sentences shown to the student. Our teacher does not yet attempt to monitor the human student's *actual* learning. Still, we show that it is useful to a beginner student and far less frustrating than a random (or heuristic based) alternative.

A "pilot" version of the present paper appeared at a recent workshop (Renduchintala et al., 2019): it experimented with three variants of the generic student model, using an artificial L2 language. In this paper, we extend the best of those models to consider an L2 word's spelling (along with its context) when guessing its embeddings. We therefore conduct our experiments on real L2 languages (Spanish and German).

2 Related Work

Our motivation is similar to that of commercially available prior systems such as Swych (2015) and OneThirdStories (2018) that also incorporate incidental learning within foreign language instruction. Other prior work (Labutov and Lipson, 2014; Renduchintala et al., 2016b) relied on building a model of the student's incidental learning capabilities, using supervised data that was painfully collected by asking students to react to the actions of an initially untrained machine teacher. Our method, by contrast, constructs a generic student model from unannotated L1 text alone. This makes it possible for us to quickly create macaronic documents in any domain covered by that text corpus.

3 Method

Our machine teacher can be viewed as a search algorithm that tries to find the (approximately) best macaronic configuration for the next sentence in a given L1 document. We assume the availability of a "gold" L2 gloss for each L1 word: in our experiments, we obtained these from bilingual speakers using Mechanical Turk. Table 1 shows an example English sentence with German glosses and three possible macaronic configurations (there are exponentially many configurations). The machine teacher must assess, for example, how accurately a student would understand the meanings of **Der**, **ist**, **ein**, and **Fluss** when presented with the following candidate macaronic configuration: **Der** Nile **ist ein Fluss** in Africa.[1] Understanding may arise from inference on this sentence as well as whatever the student has learned about these words from previous sentences. The teacher makes this assessment by presenting this sentence to a generic student model (§§3.1–3.3). It uses a L2 embedding scoring scheme (§3.4) to guide a greedy search for the best macaronic configuration (§3.5).

3.1 Generic Student Model

Our model of a "generic student" (GSM) is equipped with a cloze language model that uses a bidirectional LSTM to predict L1 words in L1 context (Mousa and Schuller, 2017; Hochreiter and Schmidhuber, 1997). Given a sentence $\mathbf{x} = [x_1, \ldots, x_t, \ldots, x_T]$, the cloze model defines $p(x_t \mid \mathbf{h}^{\mathbf{f}}{}_t, \mathbf{h}^{\mathbf{b}}{}_t) \forall t \in \{1, \ldots, T\}$, where:

$$\mathbf{h}^{\mathbf{f}}{}_t = \text{LSTM}^{\mathbf{f}}([\mathbf{x}_1, \ldots, \mathbf{x}_{t-1}]; \boldsymbol{\theta}^{\mathbf{f}}) \in \mathbb{R}^D \quad (1)$$

$$\mathbf{h}^{\mathbf{b}}{}_t = \text{LSTM}^{\mathbf{b}}([\mathbf{x}_T, \ldots, \mathbf{x}_{t+1}]; \boldsymbol{\theta}^{\mathbf{b}}) \in \mathbb{R}^D \quad (2)$$

are hidden states of forward and backward LSTM encoders parameterized by $\boldsymbol{\theta}^{\mathbf{f}}$ and $\boldsymbol{\theta}^{\mathbf{b}}$ respectively. The model assumes a fixed L1 vocabulary of size V, and the vectors $\mathbf{x}_t$ above are embeddings of these word types, which correspond to the rows of an embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times D}$. The cloze distribution at each position t in the sentence is obtained using

$$p(\cdot \mid \mathbf{h}^{\mathbf{f}}, \mathbf{h}^{\mathbf{b}}) = \text{softmax}(\mathbf{E}\, h([\mathbf{h}^{\mathbf{f}}; \mathbf{h}^{\mathbf{b}}]; \boldsymbol{\theta}^{\mathbf{h}})) \quad (3)$$

where $h(\cdot; \boldsymbol{\theta}^{\mathbf{h}})$ is a projection function that reduces the dimension of the concatenated hidden states from $2D$ to D. We "tie" the input embeddings and output embeddings as in Press and Wolf (2017).

We train the parameters $\boldsymbol{\theta} = [\boldsymbol{\theta}^{\mathbf{f}}; \boldsymbol{\theta}^{\mathbf{b}}; \boldsymbol{\theta}^{\mathbf{h}}; \mathbf{E}]$ using Adam (Kingma and Ba, 2014) to maximize $\sum_{\mathbf{x}} \mathcal{L}(\mathbf{x})$, where the summation is over sentences $\mathbf{x}$ in a large L1 training corpus, and

$$\mathcal{L}(\mathbf{x}) = \sum_t \log p(x_t \mid \mathbf{h}^{\mathbf{f}}{}_t, \mathbf{h}^{\mathbf{b}}{}_t) \quad (4)$$

We set the dimensionality of word embeddings and LSTM hidden units to 300. We use the WikiText-103 corpus (Merity et al., 2016) as the L1 training corpus. We apply dropout ($p = 0.2$) between the word embeddings and LSTM layers, and between the LSTM and projection layers (Srivastava et al., 2014). We assume that the resulting model represents the entirety of the student's L1 knowledge.

[1] By "meaning" we mean the L1 token that was originally in the sentence before it was replaced by an L2 gloss.

3.2 Incremental L2 Vocabulary Learning

Our generic student model (GSM) supposes that to learn new vocabulary, the student continues to try to improve $\mathcal{L}(\mathbf{x})$ on additional sentences. Thus, if x_i is a new word, the student will try to adjust its embedding to increase all summands of (4), both the $t=i$ summand (making x_i more predictable) and the $t\neq i$ summands (making x_i more predictive of x_t).

For our purposes, we do not update $\boldsymbol{\theta}$ (which includes L1 embeddings), as we assume that the student's L1 knowledge has already converged. For the L2 words, we use another word-embedding matrix, $\mathbf{F}$, initialized to $\mathbf{0}^{V'\times D}$, and modify (3) to consider both the L1 and L2 embeddings:

$$p(\cdot \mid [\mathbf{h^f};\mathbf{h^b}]) = \text{softmax}([\mathbf{E};\mathbf{F}]\cdot h([\mathbf{h^f};\mathbf{h^b}];\boldsymbol{\theta^h}))$$

We also restrict the softmax function here to produce a distribution not over the full bilingual vocabulary of size $|V| + |V'|$, but only over the bilingual vocabulary consisting of the L1 types V together with only the L2 types $v' \subset V'$ that actually appear in the macaronic sentence. (In the above example macaronic sentence, $|v'|=4$.) This restriction prevents the model from updating the embeddings of L2 types that are not visible in the macaronic sentence, on the grounds that students are only going to update the meanings of what they are currently reading (and are not even aware of the entire L2 vocabulary).

We assume that when a student reads a macaronic sentence $\mathbf{x}$, they update (only) $\mathbf{F}$ so as to maximize

$$\mathcal{L}(\mathbf{x}) - \lambda \|\mathbf{F} - \mathbf{F^{prev}}\|^2 \tag{5}$$

As mentioned above, increasing the $\mathcal{L}$ term adjusts $\mathbf{F}$ so that the surrounding context can easily predict each L2 word, and each L2 word can, in turn, easily predict the surrounding context (both L1 and L2). However, the penalty term with coefficient $\lambda > 0$ prevents $\mathbf{F}$ from straying too far from $\mathbf{F^{prev}}$, which represents the value of $\mathbf{F}$ before this sentence was read. This limits the degree to which a *single* sentence influences the update to $\mathbf{F}$. As a result, an L2 word's embedding reflects *all* the past sentences that contained that word, not just the most recent such sentence, although with a bias toward the most recent ones, which is realistic. Given a new sentence $\mathbf{x}$, we (approximately) maximize the objective above using 10 steps of gradient ascent (with step-size of 0.1), which gave good convergence in practice. In principle, λ should be set based on human-subject experiments. In practice, in this paper, we simply took $\lambda = 1$.

3.3 Spelling-Aware Extension

So far, our generic student model ignores the fact that a novel word like **Afrika** is guessable simply by its spelling similarity to Africa. Thus, we augment the generic student model to use character n-grams. In addition to an embedding per word type, we learn embeddings for character n-gram types that appear in our L1 corpus. The row in $\mathbf{E}$ for a word w is now parameterized as:

$$\tilde{\mathbf{E}}\cdot\tilde{\mathbf{w}} + \sum_n \tilde{\mathbf{E}}^{\mathbf{n}}\cdot\tilde{\mathbf{w}}^n \frac{1}{\mathbf{1}\cdot\tilde{\mathbf{w}}^n} \tag{6}$$

where $\tilde{\mathbf{E}}$ is the full-word embedding matrix and $\tilde{\mathbf{w}}$ is a one-hot vector associated with the word type w, $\tilde{\mathbf{E}}^{\mathbf{n}}$ is a character n-gram embedding matrix and $\tilde{\mathbf{w}}^n$ is a *multi*-hot vector associated with all the character n-grams for the word type w. For each n, the summand gives the average embedding of all n-grams in w (where $\mathbf{1}\cdot\tilde{\mathbf{w}}^n$ counts these n-grams). We set n to range from 3 to 4 (see Appendix B). This formulation is similar to previous sub-word based embedding models (Wieting et al., 2016; Bojanowski et al., 2017).

Similarly, the embedding of an L2 word w is parameterized as

$$\tilde{\mathbf{F}}\cdot\tilde{\mathbf{w}} + \sum_n \tilde{\mathbf{F}}^{\mathbf{n}}\cdot\tilde{\mathbf{w}}^n \frac{1}{\mathbf{1}\cdot\tilde{\mathbf{w}}^n} \tag{7}$$

Crucially, we initialize $\tilde{\mathbf{F}}^{\mathbf{n}}$ to $\mu\tilde{\mathbf{E}}^{\mathbf{n}}$ (where $\mu > 0$) so that L2 words can inherit part of their initial embedding from similarly spelled L1 words: $\tilde{\mathbf{F}}^{\mathbf{4}}{}_{\texttt{Afri}} := \mu\tilde{\mathbf{E}}^{\mathbf{4}}{}_{\texttt{Afri}}$.[2] But we allow $\tilde{\mathbf{F}}^{\mathbf{n}}$ to diverge over time in case an n-gram functions differently in the two languages. In the same way, we initialize each row of $\tilde{\mathbf{F}}$ to the corresponding row of $\mu\cdot\tilde{\mathbf{E}}$, if any, and otherwise to $\mathbf{0}$. Our experiments set $\mu = 0.2$ (see Appendix B). We refer to this spelling-aware extension to GSM as sGSM.

3.4 Scoring L2 embeddings

Did the simulated student learn correctly and usefully? Let $\mathcal{P}$ be the "reference set" of all (L1 word, L2 gloss) pairs from *all tokens in the entire document*. We assess the machine teacher's success by how many of these pairs the simulated student has learned. (The student may even succeed on some pairs that it has never been shown, thanks to n-gram clues.) Specifically, we measure the "goodness" of

[2] We set $\mu = 0.2$ based on findings from our hyperparameter search (see Appendix B).

the updated L2 word embedding matrix $\mathbf{F}$. For each pair $p = (e, f) \in \mathcal{P}$, sort all the words in the entire L1 vocabulary according to their cosine similarity to the L2 word f, and let r_p denote the rank of e. For example, if the student had managed to learn a matrix $\mathbf{F}$ whose embedding of f exactly equalled $\mathbf{E}$'s embedding of e, then r_p would be 1. We then compute a mean reciprocal rank (MRR) score of $\mathbf{F}$:

$$\text{MRR}(\mathbf{F}) = \frac{1}{|\mathcal{P}|} \sum_{p \in \mathcal{P}} \left(\frac{1}{r_p} \textbf{ if } r_p \leq r_{\text{max}} \textbf{ else } 0 \right) \quad (8)$$

We set $r_{\text{max}} = 4$ based on our pilot study. This threshold has the effect of only giving credit to an embedding of f such that the correct e is in the simulated student's top 4 guesses. As a result, §3.5's machine teacher focuses on introducing L2 tokens whose meaning can be deduced *rather accurately* from their single context (together with any prior exposure to that L2 type). This makes the macaronic text comprehensible for a human student, rather than frustrating to read. In our pilot study we found that r_{max} substantially improved human learning.

3.5 Macaronic Configuration Search

Our current machine teacher produces the macaronic document greedily, one sentence at a time. Actual documents produced are shown in Appendix D.

Let $\mathbf{F}^{\text{prev}}$ be the student model's embedding matrix after the reading the first $n-1$ macaronic sentences. We evaluate a candidate next sentence $\mathbf{x}$ by the score $\text{MRR}(\mathbf{F})$ where $\mathbf{F}$ maximizes (5) and is thus the embedding matrix that the student would arrive at after reading $\mathbf{x}$ as the n^{th} macaronic sentence.

We use best-first search to seek a high-scoring $\mathbf{x}$. A search state is a pair $(i, \mathbf{x})$ where $\mathbf{x}$ is a macaronic configuration (Table 1) whose first i tokens may be either L1 or L2, but whose remaining tokens are still L1. The state's score is obtained by evaluating $\mathbf{x}$ as described above. In the initial state, $i = 0$ and $\mathbf{x}$ is the n^{th} sentence of the original L1 document. The state $(i, \mathbf{x})$ is a final state if $i = |\mathbf{x}|$. Otherwise its two successors are $(i+1, \mathbf{x})$ and $(i+1, \mathbf{x}')$, where $\mathbf{x}'$ is identical to $\mathbf{x}$ except that the $(i+1)^{\text{th}}$ token has been replaced by its L2 gloss. The search algorithm maintains a priority queue of states sorted by score. Initially, this contains only the initial state. A step of the algorithm consists of popping the highest-scoring state and, if it is not final, replacing it by its two successors. The queue is then pruned back to the top 8 states. When the queue becomes empty, the algorithm returns the configuration $\mathbf{x}$ from the highest-scoring final state that was ever popped.

L2	Model	Closed-class	Open-class
Es	random	0.74±0.0126(54)	0.61±0.0134(17)
	GSM	0.72±0.0061(54)	0.70±0.0084(17)
	sGSM	**0.82±0.0038**(41)	**0.80±0.0044**(21)
De	random	0.59±0.0054(34)	0.38±0.0065(13)
	GSM	0.80±0.0033(34)	0.78±0.0056(13)
	sGSM	**0.82±0.0063**(33)	**0.79±0.0062**(14)

Table 2: Average token guess quality ($\tau = 0.6$) in the comprehension experiments. The ± denotes a 95% confidence interval computed via bootstrap resampling of the set of human subjects. The % of L1 tokens replaced with L2 glosses is in parentheses. Appendix C evaluates with other choices of τ.

4 Evaluation

Does our machine teacher generate useful macaronic text? To answer this, we measure whether *human* students (i) comprehend the L2 words in context, and (ii) retain knowledge of those L2 words when they are later seen without context.

We assess (i) by displaying each successive sentence of a macaronic document to a human student and asking them to guess the L1 meaning for each L2 token f in the sentence. For a given machine teacher, all human subjects saw the same macaronic document, and each subject's comprehension score is the average quality of their guesses on all the L2 tokens presented by that teacher. A guess's quality $q \in [0,1]$ is a thresholded cosine similarity between the embeddings[3] of the guessed word $\hat{e}$ and the original L1 word e: $q = \text{cs}(e, \hat{e})$ **if** $\text{cs}(e, \hat{e}) \geq \tau$ **else** 0. Thus, $\hat{e} = e$ obtains $q = 1$ (full credit), while $q = 0$ if the guess is "too far" from the truth (as determined by τ).

To assess (ii), we administer an L2 vocabulary quiz after having human subjects *simply* read a macaronic passage (without any guessing as they are reading). They are then asked to guess the L1 translation of each L2 word type that appeared at least once in the passage. We used the same guess quality metric as in (i).[4] This tests if human subjects naturally learn the meanings of L2 words, in informative contexts, well enough to later translate them out of context. The test requires only short-term retention, since we give the vocabulary quiz immediately after a passage is read.

We compared results on macaronic documents constructed with the generic student model (GSM), its spelling-aware variant (sGSM), and a random

[3] Here we used pretrained word embeddings from Mikolov et al. (2018), in order to measure actual semantic similarity.

[4] If multiple L1 types e were glossed in the document with this L2 type, we generously use the e that maximizes $\text{cs}(e, \hat{e})$.

baseline. In the baseline, tokens to replace are randomly chosen while ensuring that each sentence replaces the same number of tokens as in the GSM document. This ignores context, spelling, and prior exposures as reasons to replace a token.

Our evaluation was aimed at native English (L1) speakers learning Spanish or German (L2). We recruited L2 "students" on Amazon Mechanical Turk (MTurk). They were absolute beginners, selected using a placement test and self-reported L2 ability.

4.1 Comprehension Experiments

We used the first chapter of Jane Austen's "Sense and Sensibility" for Spanish, and the first 60 sentences of Franz Kafka's "Metamorphosis" for German. Bilingual speakers provided the L2 glosses (see Appendix A).

For English-Spanish, 11, 8, and 7 subjects were assigned macaronic documents generated with sGSM, GSM, and the random baseline, respectively. The corresponding numbers for English-German were 12, 7 and 7. A total of 39 subjects were used in these experiments (some subjects did both languages). They were given 3 hours to complete the entire document (average completion time was ≈ 1.5 hours) and were compensated \$10.

Table 2 reports the mean comprehension score over all subjects, broken down into comprehension of function words (closed-class POS) and content words (open-class POS).[5] For Spanish, the sGSM-based teacher replaces *more* content words (but fewer function words), and furthermore the replaced words in both cases are *better understood* on average, which we hope leads to more engagement and more learning. For German, by contrast, the number of words replaced does not increase under sGSM, and comprehension only improves marginally. Both GSM and sGSM do strongly outperform the random baseline. But the sGSM-based teacher only replaces a few additional cognates (**hundert** but not **Mutter**), apparently because English-German cognates do not exhibit large *exact* character n-gram overlap. We hypothesize that character skip n-grams might be more appropriate for English-German.

4.2 Retention Experiments

For retention experiments we used the first 25 sentences of our English-Spanish dataset. New participants were recruited and compensated \$5. Each participant was assigned a macaronic document generated with the sGSM, GSM or random model (20, 18, and 22 participants respectively). As Table 3 shows, sGSM's advantage over GSM on comprehension holds up on retention. On the vocabulary quiz, students correctly translated > 30 of the 71 word types they had seen (Table 8), and more than half when near-synonyms earned partial credit (Table 3).

L2	Model	Closed-class	Open-class
Es	random	$0.47 \pm 0.0058 (60)$	$0.40 \pm 0.0041 (46)$
	GSM	$0.48 \pm 0.0084 (60)$	$0.42 \pm 0.0105 (15)$
	sGSM	$\mathbf{0.52 \pm 0.0054} (47)$	$\mathbf{0.50 \pm 0.0037} (24)$

Table 3: Average type guess quality ($\tau = 0.6$) in the retention experiment. The % of L2 gloss types that were shown in the macaronic document is in parentheses. Appendix C evaluates with other choices of τ.

5 Future Work

We would like to explore different character-based compositions such as Kim et al. (2016) that can potentially generalize better across languages. We would further like to extend our work beyond simple lexical learning to allow learning phrasal translations, word reordering, and morphology.

Beyond that, we envision machine teaching interfaces in which the student reader *interacts* with the macaronic text—advancing through the document, clicking on words for hints, and facing occasional quizzes (Renduchintala et al., 2016b)—and with other educational stimuli. As we began to explore in Renduchintala et al. (2016a, 2017), interactions provide feedback that the machine teacher could use to adjust its model of the student's lexicons (here $\mathbf{E}, \mathbf{F}$), inference (here $\boldsymbol{\theta}^{\mathbf{f}}, \boldsymbol{\theta}^{\mathbf{b}}, \boldsymbol{\theta}^{\mathbf{h}}, \mu$), and learning (here λ). In this context, we are interested in using models that are *student-specific* (to reflect individual learning styles), *stochastic* (since the student's observed behavior may be inconsistent owing to distraction or fatigue), and able to model *forgetting* as well as learning (e.g., Settles and Meeder, 2016).

6 Conclusions

We presented a method to generate macaronic (mixed-language) documents to aid foreign language learners with vocabulary acquisition. Our key idea is to derive a model of student learning from only a cloze language model, which uses both context and spelling features. We find that our model-based teacher generates comprehensible macaronic text that promotes vocabulary learning.

Abstract

Solving long-lasting problems such as food insecurity requires a comprehensive understanding of interventions applied by governments and international humanitarian assistance organizations, and their results and consequences. Towards achieving this grand goal, a crucial first step is to extract past interventions and when and where they have been applied, from hundreds of thousands of reports automatically. In this paper, we developed a corpus annotated with interventions to foster research, and developed an information extraction system for extracting interventions and their location and time from text. We demonstrate early, very encouraging results on extracting interventions.

1 Introduction

The world is a complex socio-political system: there are long lasting problems such as food insecurity, global warming and diseases affecting much of the world's population, as well as bursting, extreme events such as war, natural disasters and financial crisis. Recently, there has been growing interests in applying event extraction to provide better situation awareness ("what happened"), but rarely in terms of offering insight into providing guidance on what humanitarian assistance interventions have been applied in the past and how they influence the situation.

Furthermore, interventions may have intended outcomes and unintended consequences. An example of an unintended consequence is that free food distribution depresses prices for local produce, and creates a disincentive for farmers. It is extremely useful to automatically extract interventions, their outcome and consequences from hundreds of thousands of articles, to provide to decision makers in governments or humanitarian aid organizations a comprehensive understanding of what intervention options are available when crisis happened, and what outcomes to expect when applying each of them.

This paper is a first step in this direction, starting with developing Information Extraction (IE) techniques to automatically extract interventions from text including academic studies, program/project guidance and evaluation documents from non-profit or international organizations.

We view interventions as a (series of) event(s) [1] with time and space dimensions. For example:

S1: *WFP is scaling up its* **food assistance** *activities in Baghdad, Anbar, Dohuk and Ninewa governorates in 2018.*

The intervention "Food Assistance" is happening in the year 2018 in locations "Baghdad, Anbar, Dohuk and Ninewa governorates". Being able to extract interventions and their location and time is a first step towards enabling comprehensive understanding of their effects and consequences.

In this paper, we develop IE techniques towards reading for interventions. The basic methodology is to treat intervention extraction as an event extraction problem, and read intentional and factual statements about interventions in existing project documentation and evaluations literature. Our contributions are three fold:

- We construct a new corpus, annotated with interventions to foster research.
- We develop an IE algorithm for extracting interventions and their locations and time.
- Experiments show the effectiveness of our approach.

We discuss related work in the next section and describe our intervention extraction models in Section 3. In Section 4, we describe our ontology

[1] The main difference between an intervention and other events is that an intervention is a deliberate policy choice, whereas famine or a terrorist attack, for example, is not.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 6444–6448, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of intervention types and the intervention dataset. We present experiment results in Section 5, before concluding in Section 6. The intervention corpus and source code are available at https://github.com/BBN-E/mr-intervention.

2 Related Work

Event extraction is often formulated as a multi-stage (Ahn, 2006) classification (trigger classification then argument identification) problem. Prior works either use high-level features (Huang and Riloff, 2012; Ji and Grishman, 2008) or are Neural Network models (Chen et al., 2015). Nguyen (2016) propose joint event extraction using recurrent neural networks.

In need of labeled datasets for training models and evaluation, datasets such as MUC (Grishman and Sundheim, 1996), ACE (Doddington et al., 2004) and Situation Frames (Strassel et al., 2017) have been developed. There are also datasets created for specific domains. An example is the GENIA biomedical event annotation (Kim et al., 2008). Our work is the latest continuation along this path: creating a dataset to foster research in automatically extracting interventions from text, and demonstrating encouraging results.

3 Extraction Models

We model interventions as events. Given a sentence, we perform intervention extraction using a two-stage process:

- Trigger classification: Labeling words with their predicted intervention type (if any). For instance, in sentence S1, the extraction system should label "food **assistance**" [2] as a trigger of an intervention type *provide food*.
- Argument classification: If a sentence contains predicted triggers $\{t_i\}$, we pair each t_i with each entity and time mention $\{m_j\}$ in the sentence to generate candidate event arguments. Given a candidate argument (t_i, m_j), the system predicts its associated role (if any). For instance, given the candidate argument ("food assistance", "Baghdad"), it predicts the role $Place$.

To perform event trigger and argument classification, we developed two convolution neural network (CNN) models: one for performing trigger extraction, and one for performing argument extraction. We show the argument model in Figure 1. These models are based on the work of Chen et al. (2015), which achieve competitive performance for event extraction.

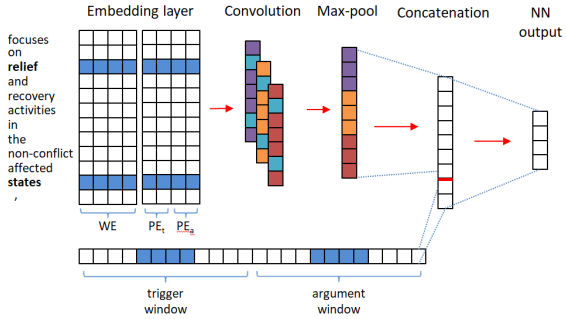

Figure 1: A CNN based model for event argument classification. WE is word embeddings. PE_t and PE_a are position embeddings, capturing a token's distance to the candidate trigger and argument respectively. These position embeddings are randomly initialized and learnt during training.

Our trigger model uses pre-trained word embeddings[3] (Baroni et al., 2014), and learns position embeddings during training (to represent relative distance of each word in the sentence to the candidate trigger). Our argument model uses these, as well as position embeddings relative to the candidate argument, and event embeddings (to represent event type of predicted candidate trigger). The position and event embeddings are randomly initialized and learnt during training.

4 Intervention Ontology and Dataset

In this section, we first present the types of interventions that we focus on, then describe a corpus annotated with intervention instances.

4.1 Intervention ontology

We focus on modeling interventions or humanitarian assistances that are meant to alleviate mass suffering, improve socioeconomic conditions, and maintain human dignity. We list our intervention ontology in Table 1. Types include promotion of *anti-retroviral* healthcare, promoting respect of *human rights*, ensuring *children friendly learning spaces*, *management of sexual violence*, *therapeutic feeding* of the severely malnourished, *vector control* of insects and pests, and *provision of various humanitarian aid* such as cash, food, etc.

[2] Our model makes predictions on single words, which we then automatically expand to phrases.

[3] EN-wform.w.5.cbow.neg10.400.subsmpl.txt.gz embeddings from the "Don't count, predict" project at http://clic.cimec.unitn.it/composes/semantic-vectors.html

Intervention Type	Example Snippet
anti-retroviral treatment	postpartum ARV *drugs* may also be given to infants
capacity building human rights	mission personnel are also engaged in building the capacity of national authorities to promote and *respect* human rights
child friendly learning spaces	promotes quality education for indigenous girls and boys through child-friendly learning *environments*
provision of goods and services	
• provide cash	cash *distributions* during emergencies
• provide delivery kit	*distributing* a home delivery kit to every pregnant woman
• provide education kit	developing and freely *distributing* education materials
• provide farming tool	the scope of the program encompasses *provision* of fertilizer
• provide fishing tool	restoration of livelihoods through *provision* of fishing boats and fishing equipment
• provide food	food *aid* is often supplied in emergency situations together with seed aid
• provide hygiene tool	respond to humanitarian emergencies always aim to *distribute* soap routinely
• provide livestock feed	where they were *provided* with fodder
• provide seed	food aid is often supplied in emergency situations together with seed *aid*
• provide veterinary service	*providing* free or subsidized animal health services
sexual violence management	health professionals expected to provide *post-rape care*
therapeutic feeding or treating	therapeutic food *provided* in supplementary feeding centers
vector control	Malathion is commonly used to *control* mosquitoes

Table 1: Types of interventions with example text snippets, where event triggers are italicized.

4.2 An intervention corpus

State-of-the-art event extraction systems adopt a supervised approach where they learn from a corpus of manually labeled examples that are specific to a predefined event ontology. For instance, the Automatic Content Extraction (ACE) (Doddington et al., 2004) corpus contains more than 500 documents manually annotated with examples for 33 event types. We similarly take a supervised learning approach by collecting and annotating examples for training extraction systems.

Humanitarian assistance programs are associated with various documentation: project proposals, guidances, progress reports, and evaluation reports on program execution. These documents are ideal for mining intervention instances. We collected several hundred documents from the following sources:

- Literature reviews, e.g., the REFANI review[4]. which reviews Cash Transfer Programmes and their impact on malnutrition in humanitarian contexts.
- Programme/project guidelines, e.g., the Sphere Handbook, which lists universal standards in core areas of humanitarian response.
- Evaluation documents, which range from thorough external evaluation of intervention operations[5], to brief presentations of results in programme documents, and post-intervention summary articles.
- Programme documents by implementers[6].
- Academic studies, such as quasi-experimental studies from ebrary.ifpri.org.

4.3 Annotating intervention instances

We provided definitions and text examples for the intervention types [7] to two annotators, and then asked them to identify and annotate intervention instances for each document. Annotators are provided with a User Interface (UI) (Chan et al., 2019) which allows them to search for examples efficiently. 30 documents are annotated by two annotators, resulting in an inter-annotator agreement of 0.83.

A total of 976 intervention instances (triggers) are found for the target intervention types. The "Count" column of Table 2 shows numbers of examples for each intervention type.

5 Experiments

In this section, we first present experiments in extracting interventions (triggers), and then describe early results on extracting locations and time for interventions.

As shown in Table 1, a large number of the intervention types (e.g. *provide cash*, *provide delivery kit*) have to do with *provision of goods and services*. Although we have kept the labeling of these interventions separate during the annotation process, so that we could optionally perform fine-grained evaluation (and indeed we will later in this section), we found that these interventions share

[7] A portion is shown in Table 1.

Intervention Type	Count	F1-score
anti-retroviral treatment	114	0.59
capacity building human rights	65	0.68
child friendly learning spaces	39	0.30
provision of goods and services	432	0.77
sexual violence management	131	0.45
therapeutic feeding or treating	49	0.52
vector control	146	0.67
Aggregate	976	0.68

Table 2: Intervention types with number of trigger examples and F1-scores based on 5-fold cross validation.

common trigger words (e.g. "provide", "provision", "distribute", etc.) and really rely on their arguments (e.g. "cash", "fertilizer", "fishing boats") for disambiguation. Hence, we perform two sets of trigger classification evaluation: coarse-grained and fine-grained.

5.1 Coarse-grained trigger classification

Our annotated trigger examples are spread across 240 documents. We perform 5-fold cross validation to evaluate trigger classification, over the 7 intervention types shown in Table 2. In each fold, we use 20% of the documents as test data and the remainder as training data. We performed minimal hyper-parameters tuning, using 30 epochs and batch size of 40. These were found to achieve good performance in preliminary experiments where we had further split the training data into training and development. We follow (Chen et al., 2015) for the values of the remaining hyper-parameters, e.g. CNN filter size of 3, position and event embeddings of length 5, etc. In our evaluation, a trigger is correctly classified if its intervention event type and offsets match those of a reference trigger. We show the coarse-grained trigger classification scores in the column "F1-score" of Table 2. We obtained a micro-averaged F1-score of 0.68 from the cross validation experiments.

Analysis on the decoding results show that examples vary greatly in terms of difficulty in extracting them. For example, for "sexual violence management", some triggers are phrases such as "post-rape care" that are straightforward for a classifier to recognize, if given sufficient training data. However, there is a long tail of examples where long range dependencies need to be resolved in order to type them correctly. For example, in "**counseling** ... sexual violence" and "clinical **management** ... sexual abuse", the trigger words are often more than 5 tokens far away from additional contextual clues that indicate the target type. We leave modeling these as future work.

5.2 Fine-grained trigger classification

As mentioned earlier in this section, we propose that the intervention type *provision of goods and services* rely on their event arguments (artifacts involved) for disambiguation into the finer-grained interventions listed in Table 1. To enable this, we first need to detect mentions of different goods/services in text. We adopt a simple list-based approach, where we manually compiled lists [8] of descriptors for each category. For instance, we use the descriptors ("livestock feed", "fodder", "hay", etc.) for the category *livestock feed*.

Then, when we note that our coarse-grained trigger model had predicted a trigger instance of *provision of goods and services* in a sentence, we check the trigger's surrounding context (5 token window) for mentions of *livestock feed*, *farming tool*, *fishing tool*, etc. We thus deterministically relabel *provision of goods and services* into the appropriate finer-grained intervention type, depending on which category of descriptor is present in the trigger's context window. As shown in Table 2, the coarse-grained F1-score of *provision of goods and services* is 0.77. After performing the deterministic re-labeling into finer-grained intervention types, we obtain an aggregate F1-score of 0.56 when evaluating against our fine-grained trigger labels. Recall misses such as those resulting from incomplete descriptor lists, and precision misses resulting from multiple descriptor categories being present within a trigger's surrounding context, contributed to the drop in F1-score.

5.3 Extracting locations and time

We leverage the ACE corpus, which contains annotations of *Place* and *Time* event arguments, to train an event type independent *Place/Time* argument classifier, based on the neural architecture described in Section 3. In our evaluation, an argument is correctly classified if its event type, event argument role, and offsets match any of the reference event arguments.

Africa countries are often the focus sites of humanitarian programs and agencies, such as the World Food Programme (WFP). Hence, to evaluate the performance of our argument model for intervention events, we randomly selected 250 documents from around 6,000 documents collected from `allafrica.com`.

[8] These lists are available at `https://github.com/BBN-E/mr-intervention`

We first apply our coarse-grained trigger classifier on these documents. We then ask annotators to evaluate trigger predictions and retain only correct ones (188 triggers), which we subsequently use to evaluate our argument classifier. We focus on using correct triggers to evaluate argument classification, to avoid error propagation (from erroneous trigger predictions) from muddling a fair assessment of the argument classifier.

Our annotators assigned a total of 15 *Time* arguments and 77 Place arguments to the 188 event triggers. Our argument classifier predicted a total of 12 Time arguments, giving a precision, recall, and F1 of 0.92, 0.73, and 0.81 respectively. Our argument classifier predicted 30 *Place* arguments, giving a precision, recall, and F1 of 0.93, 0.36, and 0.52 respectively.

6 Conclusion and Future Work

In this paper, we introduced a new corpus annotated with intervention events, and presented a system that achieves encouraging results.

Our next step is to annotate more documents and make them available to the research community to foster research in this area. We also plan to add *Location* and *Time* annotation on top of the intervention annotation.

Acknowledgements

The authors would like to thank Ben Watkins and colleagues at Kimetrica LLC for the inspiring discussions on interventions, and providing initial definitions of intervention types in Table 1. The authors also would like to thank the anonymous reviewers for their insightful comments, which helped us to improve the final version of the paper.

{tzufar,reut.tsarfaty}@gmail.com

Abstract

Following navigation instructions in natural language requires a composition of language, action, and knowledge of the environment. Knowledge of the environment may be provided via visual sensors or as a symbolic world representation referred to as a *map*. Here we introduce the *Realistic Urban Navigation* (RUN) task, aimed at interpreting navigation instructions based on a real, dense, urban map. Using Amazon Mechanical Turk, we collected a dataset of 2515 instructions aligned with actual routes over three regions of Manhattan. We propose a strong baseline for the task and empirically investigate which aspects of the neural architecture are important for the RUN success. Our results empirically show that *entity abstraction*, *attention over words and worlds*, and a constantly updating *world-state*, significantly contribute to task accuracy.

1 Introduction and Background

The task of interpreting and following natural language (NL) navigation instructions involves interleaving different signals, at the very least the linguistic utterance and the representation of the world. For example, in "turn right on the first intersection", the instruction needs to be interpreted, and a specific object in the world (the intersection) needs to be located in order to execute the instruction. In NL navigation studies, the representation of the world may be provided via visual sensors (Misra et al., 2018; Blukis et al., 2018; Nguyen et al., 2018; Yan et al., 2018; Anderson et al., 2018) or as a symbolic world representation. This work focuses on navigation based on a symbolic world representation (referred to as a *map*).

Previous datasets for NL navigation based on a symbolic world representation, HCRC (Anderson et al., 1991; Vogel and Jurafsky, 2010; Levit and Roy, 2007) and SAIL (MacMahon et al., 2006; Chen and Mooney, 2011; Kim and Mooney, 2012, 2013; Artzi and Zettlemoyer, 2013; Artzi et al., 2014; Fried et al., 2017; Andreas and Klein, 2015) present relatively simple worlds, with a small fixed set of entities known to the navigator in advance. Such representations bypass the great complexity of real urban navigation, which consists of long paths and an abundance of previously unseen entities of different types.

In this work we introduce *Realistic Urban Navigation* (RUN), where we aim to interpret navigation instructions relative to a rich symbolic representation of the world, given by a real dense urban map. To address RUN, we designed and collected a new dataset based on OpenStreetMap, in which we align NL instructions to their corresponding routes. Using Amazon Mechanical Turk, we collected 2515 instructions over 3 regions of Manhattan, all specified (and verified) by (respective) sets of humans workers. This task raises several challenges. First of all, we assume a large world, providing long routes, vulnerable to error propagation; secondly, we assume a rich environment, with entities of various different types, most of which are unseen during training and are not known in advance; finally, we evaluate on the full route intended, rather than on last-position only.

We then propose a strong neural baseline for RUN where we augment a standard encoder-decoder architecture with an entity abstraction layer, attention over words and worlds, and a constantly updating world-state. Our experimental results and ablation study show that this architecture is indeed better-equipped to treat *grounding* in realistic urban settings than standard sequence-to-sequence architectures. Given this RUN benchmark, empirical results, and evaluation procedure, we hope to encourage further investigation into the topic of interpreting NL instructions in realistic and previously unseen urban domains.

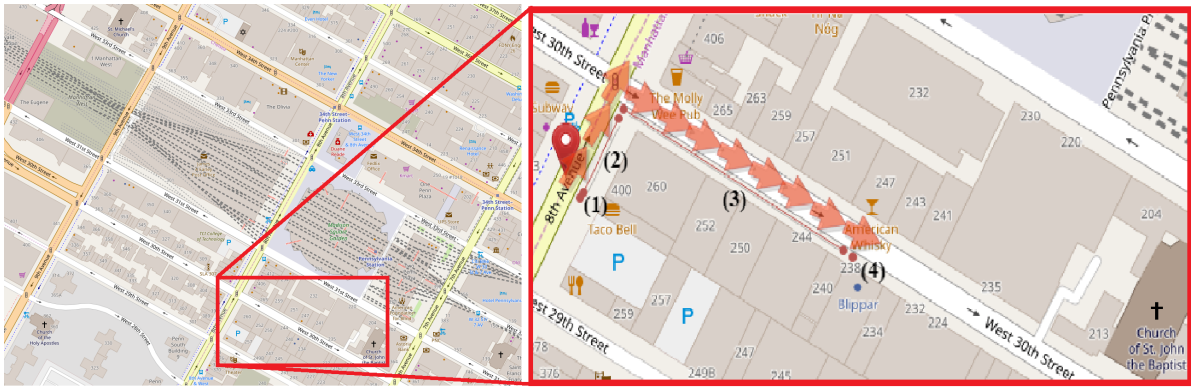
Table 3: Quantitative Comparison of the HCRC (Anderson et al., 1991), SAIL (MacMahon et al., 2006), TTW (de Vries et al., 2018), and the new RUN Dataset. *We average over three randomly chosen maps. **de Vries et al. (2018) assume perfect perception: all entities at each location are known in advance.

2 The RUN Task and Dataset

In this work we address the task of following a sequence of NL navigation instructions given in colloquial language based on a dense urban map.

The *input* to the RUN task we define is as follows: (i) a map with rich details divided into tiles, (ii) an explicit starting point, and (iii) a sequence of navigation instructions we henceforth refer to as a navigation *paragraph* . We refer to each sentence as an *instruction*, and we assume that following the individual instructions in the *paragraph* one by one will lead the agent to the intended end-point. The *output* of RUN is the entire route described by the paragraph, i.e., all coordinates up to and including its end-point, pinned on the map.



In order to address RUN we designed and collected a novel dataset, henceforth the *RUN dataset*, which is based on OpenStreetMap (OSM).[2] The map contains rich layers and an abundance of entities of different types. Each entity is complex and can contain (at least) four labels: name, type, is_building=y/n, and house number. An entity can spread over several tiles. As the maps do not overlap, only very few entities are shared among them. The RUN dataset aligns NL navigation instructions to coordinates of their corresponding route on the OSM map.

We collected the RUN dataset using Amazon Mechanical Turk (MTurk), allowing only native English speakers to perform the task. We collected instructions based on three different areas, all in urban, dense parts of Manhattan. The size of each map is $0.5\ km^2$. The dataset contains 2515 navigation instructions (equal to 389 complete paragraphs) paired with their routes. The paragraphs are crowd-sourced from 389 different instructors, of which style and language vary (Geva et al., 2019).

Our data collection protocol is as follows. First, we asked the MTurk worker to describe a route between two landmarks of their choice. After having described the complete route in NL, the same worker was instructed to pin their described route on the map. This was moderated by showing them the paragraph they narrated, sentence by sentence,

[1] The task defined by Vogel and Jurafsky (2010) is of moving between entities only.

[2] OSM is a free, editable, map of the whole world, that was built by volunteers, with millions of users constantly adding informative tags to the map.

Instructions: (1) As you walk out of Taco Bell on 8th Avenue, turn right. (2) Then turn right as you reach the intersection of West 30th Street. (3) Now head down West 30th Street for approximately a half block. (4) You have gone too far if you reach Church of St. John the Baptist.

Figure 1: An Example of a Short Navigation Paragraph: showing a navigation paragraph at the bottom and two images - full map (left image) and a small part of the map (right image). In the full map, many entities are not seen until zoom-in is applied. The navigation paragraph is divided into four sentences: (1) sentence requires a turn action; (2) requires implicit walk actions and an explicit turn; (3) requires walk actions; the last (4) sentence is a verification only and no action is required.

so that they have to pin on the map each instruction separately. A worker could only pin routes on street paths. Furthermore, on every turn the worker had to mark an explicit point on the map which marked the direction in which the worker needs to move next. An example of simple individual instructions and their respective route is given in Figure 1.

We then asked a disjoint set of workers (testers) to verify the routes by displaying the starting point of the route, and displaying the instructions in the paragraph sentence-by-sentence. The tester had to pin the final point of the sentence. Each route was tested by three different workers. Testing the routes allowed us to find incorrect routes (paragraphs that don't match an actual path) and discard them. They also provide an estimate of the human performance on the task (Reported in Section 4, Experiments).

Having collected the data, we divided the map into tiles, each tile is 11.132 m X 11.132 m. Each tile contains the labels of the entities it displays on the map, such as restaurants, traffic-lights, etc., and the walkable streets in it. Each walkable street is composed of an ordered list of tiles, including a starting tile and an end tile. Table 1 shows statistics over the dataset. Table 2 characterize linguistic phenomena in RUN, categorized according to the catalogue of Chen et al. (2018). Table 3 shows a quantitative comparison of the RUN dataset to previous datasets of map-based navigation. The table underscores some key features of RUN, relative to the previous tasks. RUN contains longer paths and many more entities that are unique, thus appearing for the first time during testing; the size of the map is on a different scale than previous tasks, thus, amplifying the grounding challenge; the number of tiles moved is accordingly larger than in previous datasets, hence increasing the vulnerability to error propagation.

Overall, RUN contains challenging linguistic phenomena, at least as in previous work, and a rich environment, with more realistic paths than in previous tasks.

3 Models for RUN

We model RUN as a sequence-to-sequence learning problem, where we map a sequence of instructions to a sequence of actions that should be performed in order to pin the actual path on the map. The execution system we provide for the task defines three types of actions: 'TURN', 'WALK', 'END'.[3] 'TURN' is one of the following: right-turn, left-turn, turn-around. The turning move is not necessarily an exact 90-degree turn; the execution system looks for the closest turn option.

[3]RUN has a variation that contains two more types of actions: 'FACE' is a change of direction to face a specific street and end of the street; 'VERIFY' gives verification to the current direction when it is explicitly mentioned in the instructions. For example, "turn right on to 8th Avenue". However, we have been unsuccessful in benefiting from "FACE" and "VERIFY". We leave them for future research.

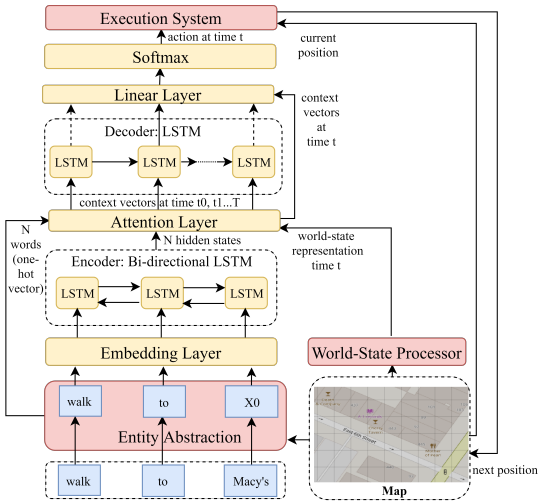


Figure 2: Our Model, Conditioned Generation with Attention over Words and World-States, an Entity Abstraction Layer and an Execution System (CGAEW). The light color (yellow) parts presents a standard Encoder-Decoder with attention, while the dark color (red) are components added on top of a standard CGA.

'WALK' is a change of position in the direction we are facing. The streets can be curved, so 'WALK' is relative to the street that the agent is on. Each street is an ordered-list of tiles, so an action of walking two steps is in fact two actions of 'WALK', in the direction the agent is facing. The 'END' action defines the end of each route. The input consists of an instruction sequence $x_{1:N}$, a map M, and a starting point p_0 on the map. The output is a sequence of actions $a^*_{1:T}$ to be executed.

$$a^*_{1:T} = arg\max_{a_{1:T}} P(a_{1:T}|x_{1:N}, M, p_0)$$

$$= \arg\max_{a_{1:T}} \prod_{t=1}^{T} P(a_t|a_{1:t-1}, x_{1:N}, M, p_0)$$

Where x_i denote sentences, a_i denotes actions, M is the map and p_0 is the starting point.

Our basic model for RUN is a sequence-to-sequence model similar to the work of Mei et al. (2015) on SAIL, and inspired by Xu et al. (2015). It is based on Conditioned Generation with Attention (CGA). To this model we added an Entity abstraction layer (CGAE) and a World-state representation (CGAEW). It thus consists of six components we describe in turn – Encoder, Decoder, Attention, Entity Abstraction, World-State Processor, Execution-System. The complete architecture is depicted in Fig. 2.

The Encoder takes the sequence of words that assembles a single sentence and encodes it as a vector using a biLSTM (Graves and Schmidhuber, 2005). **The Decoder** is an LSTM generating a sequence of actions that the execution-system can perform, according to weights defined by an Attention layer. The **Entity Abstraction** component deals with out-of-vocabulary words (OOV). We adopt a similar approach to Iyer et al. (2017); Suhr et al. (2018), replacing phrases in the sentences which refer to previously unseen entities with variables, prior to delivering the sentence to the Encoder. E.g., "Walk from Macy's to 7th street" turns into "Walk from X1 to Y1". Variables are typed (streets, restaurants, etc.) and are numbered based on their order of occurrence in the sentence. The numbering resets after every utterance, so the model remains with a handful of typed entity-variables. The **World-State Processor** maps variables to the entities on the map which are mentioned in the sentence. The world-state representation consists of two vectors, one representing the entities at the current position, and one representing the entities in the path ahead. The **Attention** layer considers the sequence of encoded words *as well as* current world-state, and provides weights on the words for each of the decoder steps. In both training and testing, the **Execution-System** executes each action separately to produce the next position.[4]

4 Experiments

We evaluate our model on RUN and assess the contribution of the particular components that we added on top of the standard CGA model.

We train the model using a negative log-likelihood loss, and used Adam (Kingma and Ba, 2014) optimization. For weights initialization we rely on Glorot and Bengio (2010). We used a grid search to validate the hyper-parameters. The model converged at around 30 epochs and produced good results with 0.9 drop-out and a beam of size 4. During inference, we seek the best candidate path using beam-search and normalize the scores of the sequences according to Wu et al. (2016).

We follow the evaluation methodology defined by Chen and Mooney (2011) for SAIL where we use three-fold validation, and in each fold, we use two maps for training (90%) and validation (10%) and test on the third one. We report a sized-

Table 4: Bounds on Accuracy for Sentences\Paragraphs, weighted averages over folds (std).

	Sentence	JUMP baseline	CGA	CGAE	CGAEW
1	Just before 9th Avenue, you will see your destination on the right, the West Side Jewish Center.	✓	✗	✗	✓
2	Turn left onto West 34th Street.	✗	✓	✓	✓
3	At the 8th Avenue and West 20th Street intersection, turn right onto West 20th Street.	✗	✗	✓	✓
4	Keep going till you get to the intersection of West 21st Street.	✗	✗	✗	✓
5	Head west on East 7th for 2 (large) blocks; Its a one-way street.	✗	✗	✗	✗

Table 5: Error analysis of all models, for different instructions, showing succeeded / failure on predicting the path.

weighted average test result. For all models we report the accuracy per single sentences and full paragraphs. Success is measured by generating an exact route, not striding away from the path. The last position on the path should be within five tile euclidean distance from the intended destination, as the position explained in the instruction might not be specific enough for one tile.[5] In single-sentences, the last position should also be facing the correct direction.

We provide three simple baselines for the RUN task: (1) NO-MOVE: the only position considered is the starting point; (2) RANDOM: As in Anderson et al. (2018), turn to a randomly selected heading, then execute a number of 'WALK' actions of an average route; (3) JUMP: at each sentence, extract entities from the map and move between them in the order they appear. If the 'WALK' action is invalid we take a random 'TURN' action.

Table 4 shows the results for the baseline models as well as the HUMAN measured performance on the task. The human performance provides an upper bound for the RUN task performance, while the simple baselines provide lower bounds. The best baseline model is NO-MOVE, reaching an accuracy of 30.3% on single sentences and 0.3 on complete paragraphs. For the HUMAN case, paragraph accuracy reaches above 80.

Table 4 shows the results of our model as an ablation study, and Table 5 shows typical errors of each variant. We see that CGAE outperforms CGA, as the swap of entities with variables lowers the complexity of the language that the model needs to learn, allowing the model to effectively cope with unseen entities at test time. We further found that, in many cases, CGAE produces the right type of action, but it does not produce enough of it to reach the intended destination. We attribute these errors to the absence of a world-state representation, resulting in an incapability to ground instructions to specific locations. CGAEW improves upon CGAE as the existence of world-state in the score of the attention layer allows the model better learn the grounding of entities in the instruction to the map. However our best model still fails on features not captured by our world-state: abstract unmarked entities such as blocks, intersections, etc, and generic entities such as traffic-lights (Tab. 5).

[5] We selected this distance as it was the average distance our successful mechanical tester-workers arrived from the intended pinned point.

5 Conclusion

We introduce RUN, a new task and dataset for NL navigation in realistic urban environments. We collected (and verified) NL navigation instructions aligned with actual paths, and propose a strong neural baseline for the task. Our ablation studies show the significant contribution of each of the components we propose. In the future we plan to extend the world-state representation, and enable the model to ground *generic* and *abstract* concepts as well. We further intend to add additional signals, for instance coming from vision (cf. Chen et al. (2018)), for more accurate localization.

Context-Aware Conversation Thread Detection in Multi-Party Chat

Abstract

In multi-party chat, it is common for multiple conversations to occur concurrently, leading to intermingled conversation threads in chat logs. In this work, we propose a novel Context-Aware Thread Detection (CATD) model that automatically disentangles these conversation threads. We evaluate our model on three real-world datasets and demonstrate an overall improvement in thread detection accuracy over state-of-the-art benchmarks.

1 Introduction

In multi-party chat conversations, such as in Slack[1], multiple topics are often discussed at the same time (Wang et al., 2019; Zhang et al., 2017). For example, in Table 1, Alice and Bob talk about work, while Bob and Chuck chat about lunch, and this results in intermingled messages. Automatic conversational thread detection could be used to disentangle and group the messages into their respective topic threads. The resulting thread information could in turn be used to improve response relevancy for conversational agents (Shamekhi et al., 2018) or improve chat summarization quality (Zhang and Cranshaw, 2018).

Unlike most of today's Email and Forum systems that use threaded structure by default. However, the Instant Messaging systems (e.g., Slack) often require users to manually organize messages in threads. A recent study (Wang et al., 2019) found that users most likely do not manually create threads. On average, only 15.3 threads were created per Slack channel with 355 messages, when they discuss group projects.

Prior work on conversation thread disentanglement is often based on pairwise message comparison. Some solutions use unsupervised clustering methods with hand-engineered features (Wang and Oard, 2009; Shen et al., 2006), while others use supervised approaches with statistical (Du et al., 2017) or linguistic features (Wang et al., 2008; Wang and Rosé, 2010; Elsner and Charniak, 2008, 2010, 2011; Mayfield et al., 2012). Recent work by (Jiang et al., 2018; Mayfield et al., 2012) adopt deep learning approaches to compute message pair similarity, using a combination of message content and simple contextual features (e.g., authorship and timestamps).

Thread	Message
T1	Alice: Bob, please send me the proposal.
T2	Bob: Where are we going for lunch?
T1	Bob: Sent.
T1	Alice: Thanks.
T2 ?	Chuck: How about the Thai place?

Table 1: Messages and threads in a chat channel. Does Chuck's message belong to T1, T2, or a new thread?

However, linguistic theories (Biber and Conrad, 2019) differentiate the following three concepts: register, genre and style, to describe the text varieties. Register refers to the linguistic features such as the choice of words in content. Genre and Style refer to the conversational structure such as the sentence sequence and distribution. All aforementioned thread disentanglement methods fail to take into account the *contextual information of the thread*, or the *conversational flow and genre*.

A *thread's contextual information* is a useful feature for thread-detection because considering the relationship between a single new input message and an existing message alone may not be enough to accurately determine thread membership. Hence, using the full thread context history during comparison can improve pre-

diction. Additionally, the *conversational flow and genre* may also be useful because (Butler et al., 2002) suggests this represents a conversation's signature. For example, we observe that users act distinctively in public Q&A (StackOverflow) and enterprise Q&A (IBM Social Q&A) online community (Wang et al., 2016), even when they are answering a similar question. Based on these hypotheses, we propose two context-aware thread detection (**CATD**) models. The first model (**CATD-MATCH**) captures contexts of existing threads and computes the distance between the context and the input message; the second model (**CATD-FLOW**) captures the conversational flow, and computes the language genre consistency while attaching the input message to a thread. We also combine them with a dynamic gate for further performance improvement, followed by an efficient beam search mechanism in the inference step. The evaluation proves our approach improves over the existing methods.

The contribution of this work is two-fold: 1) We propose context-aware deep learning models for thread detection and it advances the state-of-the-art; 2) Based on the dataset in (Jiang et al., 2018), we develop and release a more realistic multi-party multi-thread conversation dataset for future research.

2 Methodology

We model thread-detection as a topic detection and tracking task by deciding whether an incoming message starts a new thread or belongs to an existing thread (Allan, 2002). The goal is to assign each message m_i in the sequence, $M = \{m_i\}_{i=1}^{N}$, a thread label t_i, such that the complete thread label sequence $T = \{t_i\}_{i=1}^{N}$ contains multiple threads $(\mathcal{T}^1, \mathcal{T}^2, \cdots)$, where each thread $\mathcal{T}^l$ contains all messages with the same label. We denote $\mathcal{T}_{i-1}^{l} = \{m_{\delta(l,k)}\}$ as the l-th thread context already detected with $M_{i-1} = \{m_j\}_{j=1}^{i-1}$, and $\delta(l,k)$ is a function returning the index of the *last* k-th message of $\mathcal{T}_{i-1}^{l}$ in M_{i-1}. $m_{\delta(l,k)}$ is always before m_i, but may not be the last message m_{i-1}.

The training and inference steps are as follows: we train an LSTM-based thread classification model to obtain the membership of the message m_i to an existing- or a new thread, given the existing message sequence's thread tags $T_{i-1} = \{t_j\}_{j=1}^{i-1}$, which form L threads $\{\mathcal{T}_{i-1}^{l}\}_{l=1}^{L}$ (Subsection 2.1). During inference, we use this model to sequentially perform message thread labelling (Subsection 2.2).

2.1 Context-Aware Thread Detection

We first adopt the Universal Sentence Encoder[2] with deep averaging network (USE) (Cer et al., 2018) to get a static feature representation for each message in the form of sentence embeddings. We encode each message m_j as $\mathbf{enc}(m_j)$, by concatenating the USE output with two 20-dimensional embeddings: (1) **User-identity** difference between m_j and m_i. (2) **Time difference** by mapping the time difference between m_j and m_i into 11 ranges (from 1 minutes to 72 hours, details in Appendix A). These two features are also used in (Jiang et al., 2018), and another baseline model **GTM** uses only these features (Elsner and Charniak, 2008).

Given a message sequence M_{i-1}, which has been detected with L threads $\{\mathcal{T}_{i-1}^{l}\}_{l=1}^{L}$, we predict the thread tag $t_i \in \{\mathcal{T}_{i-1}^{l}\}_{l=1}^{L} \cup \{\mathcal{T}_{i-1}^{L+1}\}$ for m_i, where $\mathcal{T}_{i-1}^{L+1}$ indicates that m_i starts a new thread. As shown in Fig.1, we adopt a message-level single directional LSTM to encode each thread $\mathcal{T}_{i-1}^{l}$, whose inputs are $\mathbf{enc}(\cdot)$ of maximum K last messages (set to 20) in the thread, denoted as $\{m_{\delta(l,k)}\}_{k=1}^{K}$. The messages outside that window are viewed as irrelevant to the prediction of m_i. In Fig.1, we propose two CATD models, CATD-FLOW and CATD-MATCH, each one capturing the semantic relationship between the new message and the existing thread contexts.

CATD-FLOW (left in Fig.1): This model considers each thread as a conversation flow for a particular topic with its own genre, and the current message should belong to the thread with which it is more likely to form a fluent conversation. Therefore, we concatenate the $\mathbf{enc}(m_i)$ to each LSTM sequence of $\mathcal{T}_{i-1}^{l}$, and get the last output $\mathbf{e}_{\mathbf{flow}}^{l}$ to dot-product a trainable vector $\mathbf{w}$ and compute the probability of m_i being labeled with $\mathcal{T}_{i-1}^{l}$,

$$P(t_i = \mathcal{T}_{i-1}^{l} | M_i, T_{i-1}) = \frac{\exp(\gamma \tanh(\mathbf{w} \cdot \mathbf{e}_{\mathbf{flow}}^{l}))}{\sum_{\mathcal{T}_{i-1}^{l'}} \exp(\gamma \tanh(\mathbf{w} \cdot \mathbf{e}_{\mathbf{flow}}^{l'}))} \quad (1)$$

where γ is a scaling hyper-parameter. We differentiate $\mathcal{T}_{i-1}^{L+1}$ from other existing threads by introducing a parameter $\mathbf{u}$ as the only input for LSTM.

CATD-MATCH (right in Fig.1): An alternative view of determining the thread tag of m_i is to find

[2] https://tfhub.dev/google/universal-sentence-encoder/2

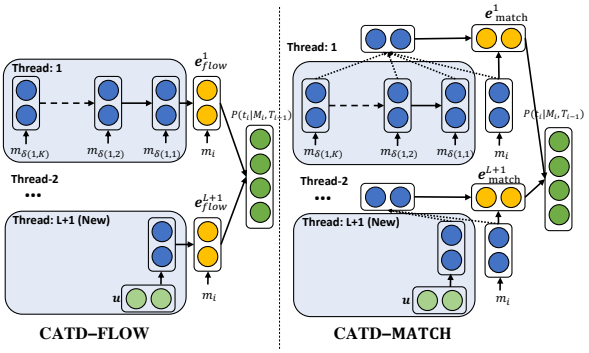

Figure 1: CATD Models: After being encoded by USE with user and time embeddings, ie. $\mathbf{enc}(\cdot)$, the last K messages for each thread $\mathcal{T}^l_{i-1}$ in history are encoded by an LSTM. **CATD-FLOW** concatenates the current message m_i as the final step of each LSTM, and gets the last output of LSTMs $\mathbf{e}^l_{\mathbf{flow}}$ to perform thread classification. **CATD-MATCH** runs LSTM on $\mathcal{T}^l_{i-1}$ and m_i separately, performs attention to obtain the context embeddings and then gets the matching vector $\mathbf{e}^l_{\mathbf{match}}$ for thread classification. For a newly-generated thread, we use a parameter $\mathbf{u}$ as the only input for its LSTM.

a thread $\mathcal{T}^l_{i-1}$ semantically closest to m_i. Thus we independently encode each thread and m_i with the parameter-shared LSTM (Only one LSTM step for m_i). In order to dynamically point to more related messages in the thread history, we use an one-way attention, which has been successfully adopted in many NLP tasks (Tan et al., 2016; Hermann et al., 2015). Specifically, given the sequence outputs of each thread's LSTM, $\{\mathbf{h}^l_{\delta(l,k)}\}^K_{k=1}$, we perform a weighted mean pooling to get a context embedding $\mathbf{e}^l_{cxt}$, attended by the one-step LSTM-encoded m_i, denoted as $\hat{\mathbf{h}}_i$.

$$\alpha^l_k = softmax(\mathbf{h}^l_{\delta(l,k)} \cdot \hat{\mathbf{h}}_i)_{k=[1,K]} \quad (2)$$

$$\mathbf{e}^l_{cxt} = \sum_k \alpha^l_k \mathbf{h}^l_{\delta(l,k)} \quad (3)$$

Next, we compute a matching vector $\mathbf{e}^l_{\mathbf{match}}$ below, which again computes dot-product $\mathbf{w}$ for classification. The function $\mathcal{N}(\mathbf{x})$ normalizes $\mathbf{x}$ by l_2 norm. $\otimes$ is element-wise multiplication.

$$\mathbf{e}^l_{\mathbf{match}} = \mathcal{N}(\mathbf{e}^l_{cxt}) \otimes \mathcal{N}(\hat{\mathbf{h}}_i) \quad (4)$$

CATD-COMBINE: Finally, we propose the dynamically-gated combination of FLOW and MATCH model, such that the $\mathbf{e}^l_{\mathbf{flow}}$ in Eq. 1 is replaced by a combination of the two models,

$$\mathbf{e}^l_{\mathbf{combine}} = (1-g^l)\mathbf{e}^l_{\mathbf{match}} + g^l \mathbf{e}^l_{\mathbf{flow}} \quad (5)$$

$$g^l = \text{sigmoid}\left(\left|\mathcal{N}(\mathbf{e}^l_{cxt}) - \mathcal{N}(\hat{\mathbf{h}}_i)\right| \cdot \mathbf{w}'\right) \quad (6)$$

where $\mathbf{w}'$ is a parameter vector. g^l is determined by the distance between $\mathcal{N}(\mathbf{e}^l_{cxt})$ and $\mathcal{N}(\hat{\mathbf{h}}_i)$. We use this dynamic gate g to linearly combine the two models. g is computed based on the difference of the MATCH vector of context and the input message. Intuitively, if they are close, both FLOW and MATCH will be considered equally for prediction. Otherwise, the model dynamically computes the weights of MATCH and FLOW.

Training Procedure: Following (Jiang et al., 2018), apart from a new thread, we consider the candidate threads (**Active Threads**) in Eq. 1 only from those appearing in one hour time-frame before m_i. During training, we treat the messages of a channel as a single sequence, and optimize Eq. 1 with training examples, containing m_i and its active threads. Though messages are sorted by time, the training examples are shuffled during training.

2.2 Thread Inference

During inference, we want to find the optimal thread labeling by maximizing:

$$\log P(T|M) = \sum_{i=1}^{N} \log P(t_i|M_i, T_{i-1}) \quad (7)$$

where t_i are selected from active threads and the new thread. However, searching the entire space of T is unfeasible. Hence, we resort to **Beam Search**, a generalized version of greedy search. It predicts sequentially from m_1 to m_N, while keeping B states in the beam. For each m_i, each state in the beam is a candidate T_{i-1}. Each new state T_i is ranked after labeling t_i for m_i:

$$\max_{\mathcal{T}^l_{i-1}} P(T_i|M_i) = \max_{\mathcal{T}^l_{i-1}} [P(t_i = \mathcal{T}^l_{i-1}|M_i, T_{i-1}) \times P(T_{i-1}|M_{i-1})] \quad (8)$$

where $\mathcal{T}^l_{i-1}$ is selected from the active threads in the previous state and a new thread tag. The new states with scores lower than top-B candidates are discarded. Similar to training, the active threads are also pruned by the "one-hour" constraint. However, they are not extracted from the ground-truth, but from previously-detected threads.

3 Experiments

Datasets: We conduct extensive experiments on three publicly available datasets from Reddit datasets. We strictly follow (Jiang et al., 2018) to construct our data. Comments under a post can be treated as messages in a single conversational thread, and we merge all comments in a

Table 2: CATD models are compared with baselines wrt. metrics of NMI, ARI and F1 for the three datasets

sub-reddit to construct a synthetic dataset of interleaved conversations. We take three sub-reddits to build three datasets, Gadgets, IPhones and Politics. [3] The data statistics and examples are shown in Appendix B.

Reddit Dataset Improvement: We use the same pre-processing method in (Jiang et al., 2018): we discard the messages which have less than 10 words or more than 100 words. Conversations less than 10 messages are also discarded. We guarantee that no more than 10 conversations happen at the same time. In their work, different message pairs of the same thread might be included in both train and test sets. Instead, we split the datasets on the thread level because in realistic settings, test threads should be completely unseen in train set. [4]

Experimental Setup: We use Adam (Kingma and Ba, 2015) to optimize the training objective (Eq. 1). During training, we fix γ in Eq. 1 as 10. In inference, this value may influence the search quality. We set it as 20.0 by the validation accuracy on Politics. We set LSTM output dimensions to 400, the batch size to 10 and the beam size to 5 by default. We train 50 epochs and select the model with the best validation-set performance.

Baseline: (1) CISIR-SHCNN (Jiang et al., 2018): A recently proposed model based on CNN and ranking message pairs. (2) CISIR-USE: We replace CNN encoder in CISIR with a USE to test the effect of different sentence encoders. (3) GTM (Elsner and Charniak, 2008): A graph-theoretical model with chat and content specific features.

[3] We did not use the IRC dataset from (Jiang et al., 2018), because of its extremely small number of data, 39 threads and 491 messages.

[4] This dataset is released in https://github.com/SLAD-ml/thread_detection_data

	Model Variations	NMI	ARI	F1
A	COMBINE (share)	.832	.420	.422
B	COMBINE (concat)	.828	.446	.448
C	SPLIT	.824	.417	.420
D	FLOW (K=5)	.813	.395	.398
E	FLOW (K=10)	.823	.414	.417
F	FLOW (K=20)	.826	.420	.423

J	MATCH (K=20, bi-LSTM)	.832	.428	.430
K	COMBINE (K=5)	.811	.378	.381
L	COMBINE (K=10)	.822	.403	.405
M	COMBINE (K=20, B=1)	.828	.452	.455
N	COMBINE (K=20, B=5)	**.834**	**.461**	**.464**
O	COMBINE (K=20, B=10)	.833	.431	.433

Table 3: Analysis on Politics dataset

Evaluation Metrics: Normalized mutual information (NMI), Adjusted rand index (ARI) and F1 score, following (Jiang et al., 2018). F1 is computed based on all message pairs in a test set. Also, following their work, we assume the candidate threads of each message for our models and baselines are obtained from the ones which have messages in the previous hour. For examples, the CISIR-SHCNN models will take pairs only within the one-hour frame.

Main Results: Table 2 compares the CATD models and baselines on NMI, ARI and F1. CISIR models are generally better than non-deep-learning GTM. There is a clear gap between CISIR-USE and our proposed models, which proves our models' improvement is not due to the usage of USE but the new model structures. CATD models are significantly superior to all baselines and CATD-COMBINE generally performs best. Specifically, all baselines failed on Politics, probably because there are more threads in Politics than the other two datasets (see Appendix B), making disentanglement more difficult. But CATD models achieve better results because they encode ac-

tive threads in parallel, while considering longer history in each thread.

Analysis : In Table 3, we analyze our models on Politics, the largest dataset. First, we examine the effect of K. For all CATD models, with K from 5 to 20 (D-F, G-I, K, L and N), and all metrics improve, showing the importance of the longer history in LSTM. Second, we adopt bidirectional LSTMs (J) for CATD-MATCH, without an obvious improvement, probably because most messages in the datasets can be fully comprehended only with previous history. This assumption is consistent with a mild improvement when we increase beam size from 1 (M) to 5 (N). We see a lower ARI with beam size as 10 (O), because of the incorrect candidates at lower ranking positions. Finally, the models are generally good when beam=1, enabling an "online" detection without knowing the future messages, which can not be directly fulfilled by most pairwise prior work.

	Model Variations	NMI	ARI	F1
A	COMBINE (share)	.699	.403	.412
B	COMBINE (concat)	.675	.366	.396
C	SPLIT	.692	.359	.382
D	FLOW (K=5)	.676	.368	.398
E	FLOW (K=10)	.690	.354	.386
F	FLOW (K=20)	.688	.374	.400
G	MATCH (K=5)	.667	.366	.396
H	MATCH (K=10)	.674	.368	.399
I	MATCH (K=20)	.703	.385	.404
J	MATCH (K=20, bi-LSTM)	**.707**	**.405**	.412
K	COMBINE (K=5)	.686	.312	.330
L	COMBINE (K=10)	.687	.369	.399
M	COMBINE (K=20, B=1)	.694	.395	.411
N	COMBINE (K=20, B=5)	.694	.395	.413
O	COMBINE (K=20, B=10)	.692	.394	**.414**

Table 4: Analysis on Gadgets dataset

Comparison with Model Variations: In Table 3, we also shared the LSTM parameters for MATCH and FLOW models (A), with 4% drop on ARI. This is because we need two independent LSTMs to capture different linguistic features. Next, we combine FLOW and MATCH (B) by concatenating $\mathbf{e}^l_{\mathbf{flow}}$ and $\mathbf{e}^l_{\mathbf{match}}$, resulting in 1.5% drop on ARI, which proves the benefit of the gate in CATD-COMBINE. Also, we break the links between LSTM nodes and perform one-step LSTM on all the history messages (C), leading to over 4% drop on ARI. This reflects the necessity of a RNN encoding inter-messages information.

In Table 4 and 5, we show the analysis for for Gadgets and Iphones datasets similar to Politics dataset in Table 3. As compared to Politics, we observe that for Gadgets and Iphones, CATD-FLOW models have some fluctuations in performance when we increase K from 5 to 20, which may be due to the limited capability of LSTMs for memorizing long-term history. This issue is more prevalent when the training data size is small.

	Model Variations	NMI	ARI	F1
A	COMBINE (share)	.748	.415	.427
B	COMBINE (concat)	.745	.419	.433
C	SPLIT	.749	.418	.433
D	FLOW (K=5)	.742	.411	.425

N	COMBINE (K=20, B=5)	.750	.434	.445
O	COMBINE (K=20, B=10)	**.750**	**.434**	**445**

Table 5: Analysis on Iphones dataset

4 Conclusion

We propose context-aware thread detection models to perform thread detection for multi-party chat conversations which take into account threads' contextual information. These are integrated into an efficient beam search for inference. Our proposed method advances the state-of-the-art.
