where the encoder-decoder model (E, D) is shared across domains. The domain vectors, $d^{\mathcal{S}}$, $d^{\mathcal{T}}$, learned from the model, implicitly guide the decoder to generate sentences with domain-specific characteristics. Note that l_i and l'_i are shared, i.e., $l^{\mathcal{T}} = l^{\mathcal{S}}$. This enables the model to learn generic style information from both domains. On the other hand, explicitly learning precise stylized information within each domain is crucial to generate domain-specific styles. Thus, two domain-specific style classifiers ensure the model to learn the corresponding styles by conditioning on $(d^{\mathcal{S}}, \widetilde{l}'_i)$ in the source domain or $(d^{\mathcal{T}}, \widetilde{l}_i)$ in the target domain:

$$\begin{aligned} L_{style}^{\mathcal{S},\mathcal{T}} = &- \mathop{\mathbb{E}}_{\widetilde{x}'_i \sim p_D(\widetilde{x}'_i | c'_i, d^{\mathcal{S}}, \widetilde{l}'_i)} \log P_{C^{\mathcal{S}}}(\widetilde{l}'_i | \widetilde{x}'_i) \\ &- \mathop{\mathbb{E}}_{\widetilde{x}_i \sim p_D(\widetilde{x}_i | c_i, d^{\mathcal{T}}, \widetilde{l}_i)} \log P_{C^{\mathcal{T}}}(\widetilde{l}_i | \widetilde{x}_i)\,, \end{aligned} \tag{8}$$

where $\widetilde{x}'_i, \widetilde{x}_i$ are the transferred sentences with pre-specific styles $\widetilde{l}'_i, \widetilde{l}_i$ in the source and target domains, respectively. The domain-specific style classifiers, $C^{\mathcal{T}}$ and $C^{\mathcal{S}}$, are trained separately on each domain. The signals from classifiers encourage the model to learn domain-specific styles combining with the domain vectors and style labels. The overall training objective of the proposed DAST model is:

$$L_{\text{DAST}} = L_{ae}^{\mathcal{S},\mathcal{T}} + L_{style}^{\mathcal{S},\mathcal{T}}\,. \tag{9}$$

The domain-specific style classifiers enforce the model to learn domain-specific style information

conditioning on $(d^{\mathcal{S}}, \widetilde{l}'_i)$ or $(d^{\mathcal{T}}, \widetilde{l}_i)$, which in turn controls the model to generate sentences with domain-specific words. The model can thus distinguish domain-specific features, and adaptively transfer the styles in a domain-aware manner.

5 Experiments

We evaluate our proposed models on two tasks: sentiment transfer (positive-to-negative and negative-to-positive), and formality transfer (informal-to-formal). In both tasks, we make comparisons with previous approaches over multiple target domains. All experiments are conducted on one Nvidia GTX 1080Ti GPU.

5.1 Dataset

A statistics for the source and target corpora used in the experiments is summarized in Table 1.

Sentiment Transfer					
Source	Train	Target	Train	Dev	Test
IMDB	344k	YELP	444k	4k	1k
		AMAZON	554k	2k	1k
		YAHOO	4k	2k	1k
Formality Transfer					
Source	Train	Target	Train	Dev	Test
GYAFC	103k	ENRON	6k	500	500

Table 1: Statistics of source and target datasets.

Sentiment Transfer. For the source domain, we use IMDB movie review corpus (Diao et al., 2014) by following the filtering and preprocessing pipelines from Shen et al. (2017). This results in $344k$ training samples with sentiment labels. For the target domain, both the Yelp restaurant review dataset and the Amazon product review dataset are from Li et al. (2018). For the test sets, we evaluate our methods by using $1k$ human-transferred sentences, annotated by Li et al. (2018), on both Yelp and Amazon datasets. In addition to the two standard sentiment datasets, we manually collected a Yahoo sentimental question dataset - $7k$ question samples with sentiments from Yahoo! Answers dataset (Zhang et al., 2015). We split the $7k$ sentimental questions into $4k$/$2k$/$1k$ for train/dev/test sets, respectively. Note that the Yahoo sentiment dataset only consists of questions, which have different domain characteristics with the IMDB dataset. In all the sentiment experiments, we consider both transfer directions (positive-to-negative and negative-to-positive).

Formality Transfer. We use Grammarly's Yahoo Answers Formality Corpus (GYAFC) (Rao and Tetreault, 2018) as the source dataset. The publicly released version of GYAFC only covers two topics (*Entertainment & Music* and *Family & Relationships*), where each topic contains $50k$ paired informal and formal sentences written by humans. For the target domain, we use Enron email conversation dataset[1], which covers several different fields like *Business, Politics, Daily Life, etc.* We manually labeled $7k$ *non-parallel* sentences written in either the formal or informal style. We split the Enron dataset into $6k, 500, 500$ samples for training, validation and testing, respectively. Both the validation and test set consist of mere informal sentences, where the corresponding formal references are annotated by us from a crowd-sourcing platform for evaluation. We only assess the informal-to-formal transfer direction in the formality transfer experiment.

5.2 Evaluation

Automatic Metrics. We evaluate the effectiveness of our DAST models based on three automatic metrics:

(i) Content Preservation. We assess the content preservation according to n-gram statistics, by measuring the BLEU scores (Papineni et al., 2002) between generated sentences and human references on the target domain, refered as *human* BLEU (*h*BLEU). When no human reference is available (e.g., Yahoo), we compute the BLEU scores with respect to the input sentences.

(ii) Style Control. We generate samples from the model and measure the style accuracy with a style classifier that is pre-trained on the target domain. We refer the style accuracy as S-acc.

(iii) Domain Control. To validate whether the generated sentences hold the characteristics of the target domain, we adopt a pre-trained domain classifier to measure the percentage of generated sentences that belong to the target domain. We refer the domain accuracy as D-acc.

All the pre-trained classifiers are implemented by TextCNN (Kim, 2014; Zhang et al., 2017). The test accuracy of all these classifiers used for evaluation are reported in Appendix A.1. Following Xu et al. (2018), we also evaluate all methods using a single unified metric called G-score, which calculates the geometric mean of style accuracy and *h*BLEU.

[1] https://www.cs.cmu.edu/~./Enron/

	Yelp				Amazon			
Model (100% target data)	D-acc	S-acc	*h*BLEU	G-score	D-acc	S-acc	*h*BLEU	G-score
CrossAlign (Shen et al., 2017)	-	85.0	3.7	8.3	-	23.0	34.1	18.0

Table 2: Automatic evaluation results on Yelp and Amazon test sets. D-acc and S-acc denote domain accuracy and style accuracy, respectively. G-score is the geometric mean of S-acc and *h*BLEU.

Human Evaluation. To assess the quality of transferred sentences, we conduct human evaluations based on the facets of *content preservation*, *style control* and *fluency*, following Mir et al. (2019). Previous works (Subramanian et al., 2018; Gong et al., 2019) ask workers to evaluate the quality via a numerical score, however, we found that this empirically leads to high-variance results. Instead, we pair transferred sentences from two different models, and ask workers to choose the sentence they prefer *when compared to the input* on each evaluation aspect. We provide a "No Preference" option to choose when the workers think the qualities of the two sentences are indistinguishable. Details of the human evaluation instruction are included in Appendix A.3. For each testing, we randomly sample 100 sentences from the corresponding test set and collect three human responses for each pair on every evaluation aspect, resulting in 2700 responses in total.

5.3 Experimental Setup

The encoder E and the decoder D are implemented by one-layer GRU (Cho et al., 2014) with hidden dimensions 500 and 700, respectively. The domain-vector dimension is set to 50. The style labels are represented by learnable vectors with 150 dimensions. The decoder is initialized by a concatenation of representations of content, style, and domain vectors. If domain vectors are not used, the dimension of style labels is set to 200; accordingly, the initialization of the decoder is a concatenation of content and style representations. TextCNN (Kim, 2014) is employed for the domain-specific style classifiers pre-trained on corresponding domains. After pre-training, the parameters of the classifiers are fixed. We use the hard-sampling trick (Logeswaran et al., 2018) to back-propagate the loss through discrete tokens from the classifier to the encoder-decoder model. During training, we assign each mini-batch the same amount of source and target data to balance the training.

We make an extensive comparison with five state-of-the-art text style transfer models: CrossAlign (Shen et al., 2017), Delete&Retrieve (Li et al., 2018), CycleRL (Xu et al., 2018), SMAE (Zhang et al., 2018c) and ControlGen (Hu et al., 2018). We also experiment a simple and effective domain adaptation baseline - Finetune, which is trained with Eqn. (4) on the source domain and then fine-tuned on the target domain.

5.4 Results

Model Comparisons. To evaluate the effectiveness of leveraging massive data from other domains, we compare our proposed DAST models with previously proposed models trained on the target domain (Table 2). We observe that by leveraging massive data from the IMDB dataset, our models achieve better performance against all

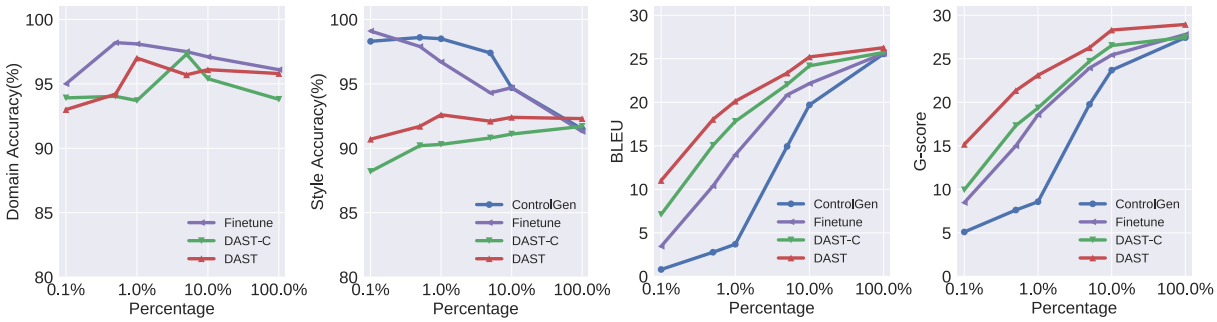

Figure 2: Results on Yelp test set in terms of different percentage of target domain data. $0.1\% \approx 400$ samples.

Style Control (Yelp 1% data)					Content Preservation (Yelp 1% data)					Fluency (Yelp 1% data)

Table 3: Results of **Human Evaluation** for style control, content preservation and fluency, showing preferences (%) for DAST model vis-a-vis baseline or other comparison systems. Evaluation results of the **overall transfer quality** are provided in Appendix A.3.

Yahoo Sentiment Transfer			
Model	D-acc	S-acc	BLEU
ControlGen	-	99.1	9.7
Finetune	**97.8**	98.8	31.4
DAST-C	90.7	98.8	35.9
DAST	90.8	**99.2**	**39.2**

Table 4: Results on Yahoo sentiment transfer task.

baselines on the sentiment transfer tasks in both the Yelp and Amazon domains.

Notably, when the target domain has limited data (1%), all baselines trained only on the target domain fail completely on content preservation. Finetune preserves better content but experiences the catastrophic forgetting problem (Goodfellow et al., 2013) to the source domain information. As a result, the overall style transfer performance is still nonoptimal. By contrast, with the help of the source domain, DAST obtains considerable content preservation performance improvement when compared with other baselines. Our model also attains favorable performance in terms of style transferring accuracy (S-acc), resulting in a good overall G-score. In general, we observe that DAST-C is able to better preserve content information, while DAST further improves both content preservation and style control abilities. Additionally, both DAST-C and DAST can adapt to the target domain, as evidenced by the high domain accuracy (D-acc). The human evaluation results (Table 3) show a strong preference of DAST over DAST-C as well as ControlGen in terms of style control, content preservation and fluency.

Finally, we evaluate our models on Yahoo sentiment transfer task. As can be seen in Table 4, both DAST and DAST-C achieve successful style transfer even if the target data is formed as questions which have a large discrepancy with the source IMDB domain. The samples of Yelp and Yahoo sentiment transfer are shown in Table 5. We also investigate the effect of different source domain data, included in Appendix A.2.

Limiting the Target Domain Data. We further test the limit of our model by using as few target domain data as possible. Figure 2 shows the quantitative results with different percentages of target domain training data. When the target domain data is insufficient, especially less than 10%, the content preservation ability of the baseline (trained with target data only) has degenerated rapidly despite a relatively high style transfer accuracy. This is less than desirable because by retrieving sentences with the target style a transferred sentence

	Yelp (positive-to-negative)	Yelp (negative-to-positive)
Input	the service was great , food delicious , and the value impeccable .	and the pizza was cold , greasy , and generally quite awful .
ControlGen	the service was horrible , service , the service and very frustrated .	and the food was delicious, delicious , and freaking tasty , delicious .
Finetune	the service was poor , food ... , and the experience were .	and the pizza was professional , friendly , and always have great .
DAST-C	the service was horrible , food horrible , and the slow sparse .	and the pizza was fresh, greasy , and generally quite cool .
DAST	the service was horrible , food bland , and the value lousy .	and the pizza was tasty , juicy , and definitely quite amazing .
Human	service was poor and the food expensive and weak tasting .	the pizza was warm , not greasy , and generally tasted great .
	Yahoo (positive-to-negative)	Yahoo (negative-to-positive)
Input	who is more romantic ? man or woman ?	why do stupid questions constantly receive intelligent answers ?
ControlGen	which is more stupid ? and or why ?	men do fantastic questions constantly receive intelligent bound !
Finetune	the is more expensive ? man or woman ?	why do great questions read more entertaining answers ?
DAST-C	who is more ugly ? man or woman ?	why do important questions constantly receive intelligent answers ?
DAST	who is more crazy ? man or woman ?	why do nice questions constantly receive intelligent answers ?
	Enron (informal-to-formal)	Enron (informal-to-formal)
Input	ya 'll need to come visit us in austin .	are n't you suppose to be teaching some kids or something ?
ControlGen	could we need to look on saturday in enpower .	are you not supposed to be disloyal some kids or something ?
Finetune	you will need to go in bed with him .	are you not to be able to be some man or something ?
DAST-C	you will need to visit town .	are not you supposed to be teaching some kids or something ?
DAST	yes , you will need to visit us in austin .	are you not supposed to be teaching some children or something ?
Human	all of you should come visit us in austin .	are you not supposed to be instructing children ?

Table 5: Transferred sentences on Yelp (1% data), Yahoo and Enron datasets, where red denotes successful style transfers, blue denotes content losses, and orange denotes grammar errors. Better looked in color.

Model	D-acc	S-acc	*h*BLEU	G-score
DAST	**97.0**	**92.6**	**20.1**	**23.1**
w/o d-spec attributes	83.9	90.9	20.0	22.7
w/o d-spec classifiers	91.4	83.8	19.0	20.8
w/o both	73.8	80.6	18.7	19.9
Setup	D-acc	S-acc	*h*BLEU	G-score

Enron Formality Transfer			
Model	D-acc	S-acc	*h*BLEU
ControlGen	-	81.2	4.74
Finetune	**91.3**	81.6	14.7
DAST-C	87.6	89.2	15.5
DAST	88.4	**91.6**	**16.4**

Table 7: Results on Enron formality transfer tasks.

can easily exhibit the correct style while retaining barely any content similar to the input. Finetune improves content preservation but still suffers the same problem with less target data. Note that DAST-C is not comparable to Finetune as the former does not use the style information in the source domain.

Both DAST models bring substantial improvements to content preservation, and can still successfully manipulate the styles, resulting in consistently higher G-scores. This is presumably because our models adapt the content information as well as the style information from the source domain to consistently sustain the style transfer on the target domain. By learning both generic and domain-specific stylized information, DAST outperforms DAST-C in terms of content preservation and style control. Even with 0.1% target domain data (400 samples), DAST was able to attain a reasonable degree of text style transfer, whereas the model trained on the target data generated entirely nonsensical sentences. Meanwhile, DAST succeeded in transferring the sentences in a domain-aware manner, achieving consistently high domain accuracy.

Ablation Study. To investigate the effect of individual components and training setup on the overall performance, we conduct an ablation study in Table 6. The domain vectors enable the model to transfer sentences in a domain-aware manner, and thus give the largest boost on domain accuracy. Without domain-specific style classifiers, the model mixes the style information on both domains, resulting in worse style control and content preservation. Additionally, simply increasing the number of training examples (i.e., the row "w/o both") improves content preserving, while introducing a data distribution discrepancy between the training (Yelp+IMDB) and test data (Yelp), as evidenced by the lower S-acc and D-acc scores.

In terms of the training setup, the source domain IMDB mostly helps content preservation, while accurate style information is mainly learned from the target domain Yelp. Finetune gives higher S-acc and D-acc and lower *h*BLEU due to catastrophic forgetting. Our proposed DAST successfully exploits the source domain data, and thus yields balanced results on style and domain control, while maintaining content preservation.

Non-parallel Style Transfer with Parallel Source Data. Finally, to verify the versatility of our proposed models in different scenarios, we investigate another domain adaptation setting, where the source domain data (GYAFC) is parallel but the target domain data (Enron) is non-parallel. Since parallel data is available in the source domain, we are able to simply add a sequence-to-sequence loss $L^{\mathcal{S}}_{s2s}$ on source domain data in Eqn. (6) and Eqn. (9) to help the target domain without parallel data. The training objectives can be written as: $L^{\mathcal{T}}_{ae}+L^{\mathcal{T}}_{style}+L^{\mathcal{S}}_{ae}+L^{\mathcal{S}}_{s2s}$ and $L^{\mathcal{S},\mathcal{T}}_{ae}+L^{\mathcal{S},\mathcal{T}}_{style}+L^{\mathcal{S}}_{s2s}$, respectively. Results are summarized in Table 7. DAST outperforms other methods on both style control and content preservation while keeping the transferred sentences with target-specific characteristics (D-acc). A strong human preference for DAST can be observed in Table 3 when compared to the baselines. Qualitative samples are provided in Table 5.

6 Conclusion

We present two simple yet effective domain adaptive text style transfer models that leverage massively available data from other domains to facilitate the transfer task in the target domain. The proposed models achieve better content preservation with the generic information learned from the source domain and simultaneously distinguish the domain-specific information, which enables the models to transfer text in a domain-adaptive manner. Extensive experiments demonstrate the robustness and applicability on various scenarios where the target data is limited.

Acknowledgments

We would like to thank the reviewers for their constructive comments. We thank NVIDIA Corporation for the donation of the GPU used for this research. We also thank Hao Peng and Tianyi Zhou for their helpful discussions.

Abstract

In this work, we focus on the task of Automatic Question Generation (AQG) where given a passage and an answer the task is to generate the corresponding question. It is desired that the generated question should be (i) grammatically correct (ii) answerable from the passage and (iii) specific to the given answer. An analysis of existing AQG models shows that they produce questions which do not adhere to one or more of the above-mentioned qualities. In particular, the generated questions look like an incomplete draft of the desired question with a clear scope for refinement. To alleviate this shortcoming, we propose a method which tries to mimic the human process of generating questions by first creating an initial draft and then refining it. More specifically, we propose Refine Network (RefNet) which contains two decoders. The second decoder uses a dual attention network which pays attention to both (i) the original passage and (ii) the question (initial draft) generated by the first decoder. In effect, it refines the question generated by the first decoder, thereby making it more correct and complete. We evaluate RefNet on three datasets, *viz.*, SQuAD, HOTPOT-QA, and DROP, and show that it outperforms existing state-of-the-art methods by 7-16% on all of these datasets. Lastly, we show that we can improve the quality of the second decoder on specific metrics, such as, fluency and answerability by explicitly rewarding revisions that improve on the corresponding metric during training. The code has been made publicly available [1].

1 Introduction

Over the past few years, there has been a growing interest in Automatic Question Generation (AQG) from text - the task of generating a question from a passage and optionally an answer. AQG is used in curating Question Answering datasets, enhancing user experience in conversational AI systems (Shum et al., 2018) and for creating educational materials (Heilman and Smith, 2010). For the above applications, it is essential that the questions are (i) grammatically correct (ii) answerable from the passage and (iii) specific to the answer. Existing approaches focus on encoding the passage, the answer and the relationship between them using complex functions and then generate the question in *one* single pass. However, by carefully analysing the generated questions, we observe that these approaches tend to miss one or more of the important aspects of the question. For instance, in Table 1, the question generated by the single-pass baseline model for the first passage is grammatically correct but is not specific to the answer. In the second example, the generated question is both syntactically incorrect and incomplete.

Passage 1: Liberated by Napoleon's army in 1806, Warsaw was made the capital of the newly created Duchy of Warsaw.	
Generated Questions	
Baseline	What was the capital of the newly duchy of Warsaw?
RefNet	Who liberated Warsaw in 1806?
Reward-RefNet	Whose army liberated Warsaw in 1806?
Passage 2: To fix carbon dioxide into sugar molecules in the process of photosynthesis, chloroplasts use an enzyme called rubisco	
Generated Questions	
Baseline	What does chloroplasts use?
RefNet	What does chloroplasts use to fix carbon dioxide into sugar molecules?
Reward-RefNet	What do chloroplasts use to fix carbon dioxide into sugar molecules?

Table 1: Samples of generated questions from Baseline, RefNet and Reward-RefNet model on the SQuAD dataset. Answers are shown in blue

The above examples indicate that there is clear scope of improving the general quality of the questions. Additionally, the quality can be specifically improved in terms of aspects like: fluency (Example 2) and answerability (Example 1). One way to approach this is by re-visiting the passage and answer with the aim to *refine* the initial draft by generating a better question in the second pass and then improving it with respect to a certain aspect. We can draw a comparison between this process and how humans tend to write a rough initial draft first and then refine it over multiple passes, where the later revisions focus on improving the draft aiming at certain aspects like fluency or completeness. With this motivation, we propose **Refine Network (RefNet)**, which examines the initially generated question and performs a second pass to generate a *revised* question. Furthermore, we propose **Reward-RefNet** which uses explicit reward signals to achieve refinement focused on specific properties of the question such as fluency and answerability.

Our RefNet is a seq2seq based model that comprises of two decoders: *Preliminary* and *Refinement Decoder*. The Refinement Decoder takes the initial draft of the question generated by the Preliminary decoder as an input along with passage and answer, and generates the refined question by attending onto both the passage and the initial draft using a Dual Attention Network. The proposed dual attention aids RefNet to generate the final question by revisiting the appropriate parts of the input passage and initial draft. From Table 1, we can infer that our RefNet model is able to generate better questions in the second pass by fixing the errors in the initial draft. Our Reward-RefNet model uses REINFORCE with a baseline algorithm to explicitly reward the Refinement Decoder for generating a better question as compared to the Preliminary Decoder based on certain desired parameters like fluency and answerability. This leads to more answerable (see Reward-RefNet example for passage 1 in Table 1) and fluent (see Reward-RefNet example for passage 2 in Table 1) questions as compared to vanilla RefNet model.

Our experiments show that the proposed RefNet model outperforms existing state-of-the-art models on the SQuAD dataset by 12.3% and 3.7% (on BLEU) given the relevant sentence and passage respectively. We also achieve state-of-the-art results on HOTPOT-QA and DROP datasets with an improvement of 7.57% and 15.25% respectively over the single-decoder baseline (on BLEU). Our human evaluations further validate these results. We further analyze and explain the impact of including the Refinement Decoder by examining the interaction between both the decoders. Interestingly, we observe that the inclusion of the Refinement Decoder boosts the quality of the questions generated by the initial decoder also. Lastly, our human evaluation of the questions generated by Reward-RefNet corroborate empirical results, *i.e.*, it improves the question *w.r.t.* to fluency and answerability as compared to RefNet questions.

2 Refine Networks (RefNet) Model

In this section, we discuss various components of our proposed model as shown in Figure 1. For a given passage $\mathbf{P} = \{w_1^p, \ldots, w_m^p\}$ of length m and answer $\mathbf{A} = \{w_1^a, \ldots, w_n^a\}$ of length n, we first obtain *answer-aware* latent representation, $\mathbf{U} = \{\tilde{\mathbf{h}}_1^p, \ldots, \tilde{\mathbf{h}}_m^p\}$, for every word of the passage and an answer representation $\mathbf{h}^a$ (as described in Section 2.1). We then generate an initial draft $\tilde{\mathbf{Q}} = \{\tilde{q}_1, \ldots, \tilde{q}_T\}$ by computing $\tilde{q}_t$ as

$$\tilde{q}_t = \arg\max_{\tilde{q}} \prod_{t=1}^{l} \tilde{p}(\tilde{\mathrm{q}}_t | \tilde{\mathrm{q}}_{t-1}, \ldots, \tilde{\mathrm{q}}_1, \mathbf{U}, \mathbf{h}^a)$$

Here $\tilde{p}(.)$ is a probability distribution modeled using the Preliminary Decoder. We then refine the initial draft $\tilde{\mathbf{Q}}$ using the Refinement Decoder to obtain the refined draft $\mathbf{Q} = \{q_1, \ldots q_T\}$:

$$q_t = \arg\max_{q} \prod_{t=1}^{l} p(\mathrm{q}_t | \mathrm{q}_{t-1}, \ldots, \mathrm{q}_1, \tilde{\mathbf{Q}}, \mathbf{U}, \mathbf{h}^a)$$

We then use explicit rewards to enforce refinement on a desired metric, such as, fluency or answerability through our Reward-RefNet model. In the following sub-sections, we describe the passage encoder, preliminary and refinement decoders and our reward mechanism.

2.1 Passage and Answer Encoder

We use a 3 layered encoder consisting of: (i) Embedding, (ii) Contextual and (iii) Passage-Answer Fusion layers as described below. To capture interaction between passage and answer, we ensure that the passage and answer representations are fused together at every layer.

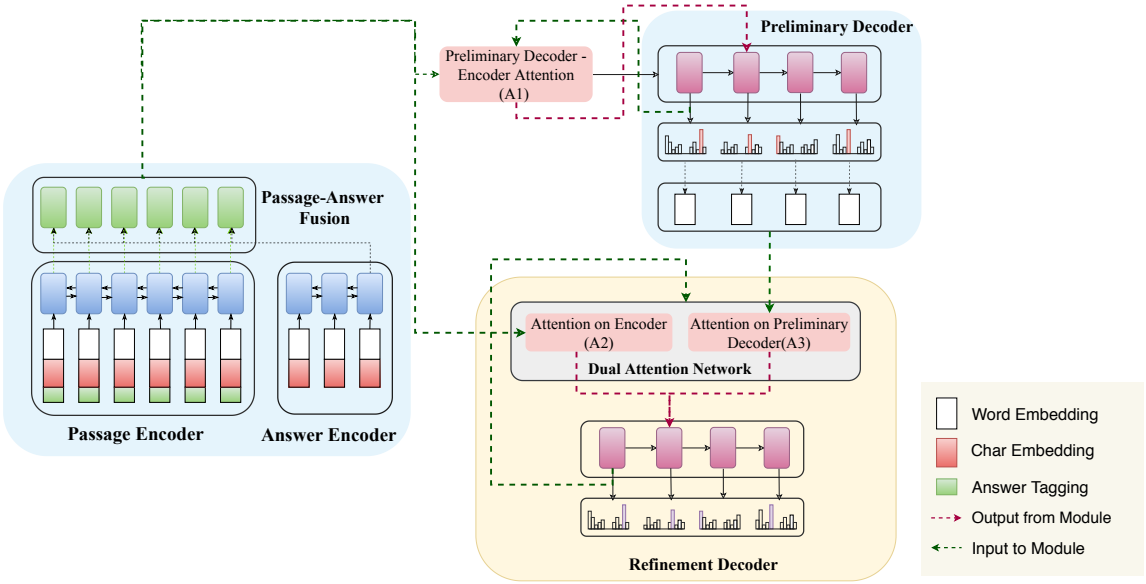

Figure 1: Our RefNet model with Preliminary and Refinement Decoder.

Embedding Layer: In this layer, we compute a d-dimensional embedding for every word in the passage and the answer. This embedding is obtained by concatenating the word's Glove embedding (Pennington et al., 2014) with its character based embedding as discussed in (Seo et al., 2016). Additionally, for passage words, we also compute a positional embedding based on the relative position of the word *w.r.t.* the answer span as described in (Zhao et al., 2018). For every passage word, this positional embedding is also concatenated to the word and character based embeddings. We discuss the impact of character embeddings and answer tagging in Appendix A. In the subsequent sections, we will refer to embedding of the i-th passage word w_i^p as $\mathbf{e}(\mathbf{w_i^p})$ and the j-th answer word w_j^a as $\mathbf{e}(\mathbf{w_j^a})$.

Contextual Layer: In this layer, we compute a contextualized representation for every word in the passage by passing the word embeddings (as computed above) through a bidirectional-LSTM (Hochreiter and Schmidhuber, 1997):

$$\overrightarrow{\mathbf{h}_t^p} = \text{LSTM}(\mathbf{e}(\mathbf{w_t^p}), \overrightarrow{\mathbf{h}^p}_{t-1}) \;\; \forall t \in [1, m]$$

where $\overrightarrow{\mathbf{h}_t^p}$ is the hidden state of the forward LSTM at time t. We then concatenate the forward and backward hidden states as $\mathbf{h}_t^p = [\overrightarrow{\mathbf{h}_t^p}; \overleftarrow{\mathbf{h}_t^p}]$.

The answer could correspond to a span in the passage. Let $j+1$ and $j+n$ be the start and end indices of the answer span in the passage respectively. We can thus refer to $\{\mathbf{h}_{j+1}^p, \ldots, \mathbf{h}_{j+n}^p\}$ as the representation of the answer words in the context of the passage. We then obtain contextualized representations for the n answer words by passing them through LSTM as follows:

$$\overrightarrow{\mathbf{h}_t^a} = \text{LSTM}([\mathbf{e}(\mathbf{w_t^a}), \mathbf{h}_{j+t}^p], \overrightarrow{\mathbf{h}^a}_{t-1}) \;\; \forall t \in [1, n]$$

The final state $\mathbf{h}^a = [\overrightarrow{\mathbf{h}_n^a}; \overleftarrow{\mathbf{h}_n^a}]$ of this Bi-LSTM is used as the answer representation in the subsequent stages. When the answer is not present in the passage, only $\mathbf{e}(\mathbf{w_t^a})$ is passed to the LSTM.

Passage-Answer Fusion Layer: In this layer, we refine the representations of the passage words based on the answer representation as follows:

$$\tilde{\mathbf{h}}_i^p = \tanh\left(\mathbf{W}_u\left[\mathbf{h}_i^p; \mathbf{h}^a; \mathbf{h}_i^p \odot \mathbf{h}^a\right]\right) \;\; \forall i \in [1, m]$$

Here $\mathbf{W}_u \in \mathbb{R}^{l \times 3l}$. l is the hidden size of LSTM. This is similar to how (Seo et al., 2016) capture interactions between passage and question for QA. We use $\mathbf{U} = \{\tilde{\mathbf{h}}_1^p, \ldots, \tilde{\mathbf{h}}_m^p\}$ as the fused passage-answer representation which is then used by our decoder(s) to generate the question $\mathbf{Q}$.

2.2 Preliminary and Refinement Decoders

As discussed earlier, RefNet has two decoders, *viz.*, Preliminary Decoder and Refinement Decoder, as described below:

Preliminary Decoder: This decoder generates an initial draft of the question, one word at a time,

using an LSTM as follows:

$$\tilde{\mathbf{h}}_t^d = \text{LSTM}([\mathbf{e_w}(\tilde{\mathbf{q}}_{\mathbf{t-1}}); \tilde{\mathbf{c}}_{t-1}; \mathbf{h}^a], \tilde{\mathbf{h}}_{t-1}^d)$$
$$\tilde{\mathbf{c}}_t = \sum_{i=1}^{m} \alpha_t^i \tilde{\mathbf{h}}_i^p \quad (1)$$

Here $\tilde{\mathbf{h}}_t^d$ is the hidden state at time t, $\mathbf{h}^a$ is the answer representation as computed above, $\tilde{\mathbf{c}}_{t-1}$ is an attention weighted sum of the contextualized passage word representations, α_t^i are parameterized and normalized attention weights (Bahdanau et al., 2014). Let's call this attention network as $\mathbf{A}_1$. $\mathbf{e_w}(\tilde{\mathbf{q}}_\mathbf{t})$ is the embedding of the word $\tilde{q}_t$. We obtain $\tilde{q}_t$ as:

$$\tilde{q}_t = \arg\max_{\tilde{q}} \left(\text{softmax}(\mathbf{W}_o[\mathbf{W}_c[\tilde{\mathbf{h}}_t^d; \tilde{\mathbf{c}}_t])\right), \quad (2)$$

where $\mathbf{W}_c$ is a $\mathbb{R}^{l \times 2l}$ matrix and $\mathbf{W}_o$ is the output matrix which projects the final representation to $\mathbb{R}^V$ where V is the vocabulary size.

Refinement Decoder: Once the preliminary decoder generates the entire question, the refinement decoder uses it to generate an updated version of the question using a **Dual Attention Network**. It first computes an attention weighted sum of the embeddings of the words generated by the first decoder as:

$$g_t = \sum_{i=1}^{T} \beta_i^t \mathbf{e_w}(\tilde{\mathbf{q}}_\mathbf{i})$$

where β_i^t are parameterized and normalized attention weights computed by attention network $\mathbf{A}_3$. Since the initial draft could be erroneous or incomplete, we obtain additional information from the passage instead of only relying on the output of the first decoder. We do so by computing a context vector $\mathbf{c}_t$ as

$$\mathbf{c}_t = \sum_{i=1}^{m} \gamma_i^t \tilde{\mathbf{h}}_i^p$$

where γ_i^t are parameterized and normalized attention weights computed by attention network $\mathbf{A}_3$. The hidden state of the refinement decoder at time t is computed as follows:

$$\mathbf{h}_t^d = \text{LSTM}([\mathbf{e}(\mathbf{q_{t-1}}); \mathbf{c}_{t-1}; \mathbf{g}_{t-1}; \mathbf{h^a}], \mathbf{h}_{t-1}^d)$$

Finally, q_t is predicted using

$$q_t = \arg\max_{q}(\text{softmax}(\mathbf{W}_o[\mathbf{W'}_c[\mathbf{h}_t^d; \mathbf{c}_{t-1}; \mathbf{g}_{t-1}]))$$

where $\mathbf{W}'_c$ is a weight matrix and $\mathbf{W}_o$ is the output matrix which is shared with the Preliminary decoder (Equation 2). Note that RefNet generates two variants of the question : initial draft $\tilde{\mathbf{Q}}$ and final draft $\mathbf{Q}$. We compare these two versions of the generated questions in Section 4.

2.3 Reward-RefNet

Next, we address the following question: *Can the refinement decoder be explicitly rewarded for generating a question which is better than that generated by the preliminary decoder on certain desired parameters?* For example, (Nema and Khapra, 2018) define fluency and answerability as desired qualities in the generated question. They evaluate fluency using BLEU score and answerability using a score which captures whether the question contains the required {named entities, important words, function words, question types} (and is thus answerable). We use these fluency and answerability scores proposed by (Nema and Khapra, 2018) as reward signals. We first compute the reward $r(\tilde{\mathbf{Q}})$ and $r(\mathbf{Q})$ for the question generated by the preliminary and refinement decoder respectively. We then use "REINFORCE with a baseline" algorithm (Williams, 1992) to reward Refinement Decoder using the Preliminary Decoder's reward $r(\tilde{\mathbf{Q}})$ as the baseline. More specifically, given the Preliminary Decoder's generated word sequence $\tilde{\mathbf{Q}} = \{\tilde{q}_1, \tilde{q}_2, \ldots, \tilde{q}_T\}$ and the Refinement Decoder's generated word sequence $\mathbf{Q} = \{q_1, q_2, \ldots, q_T\}$ obtained from the distribution $p(\mathrm{q}_t|\mathrm{q}_{t-1}, \ldots, \mathrm{q}_1, \tilde{\mathbf{Q}}, \mathbf{U}, \mathbf{h}^a)$, the training loss is defined as follows

$$L(\mathbf{Q}) = (r(\mathbf{Q}) - r(\tilde{\mathbf{Q}})) \cdot \sum_{t=1}^{T} \log p(q_t|\, q_{t-1}, \ldots, q_1, \tilde{\mathbf{Q}}, \mathbf{U}, \mathbf{h}^a)$$

where $r(\mathbf{Q})$ and $r(\tilde{\mathbf{Q}})$ are the rewards obtained by comparing with the reference question $\mathbf{Q}^*$. As mentioned, this reward $r(.)$ can be the fluency score or answerability score as defined by (Nema and Khapra, 2018).

2.4 Copy Module

Along with the above-mentioned three modules, we adopt the pointer-network and coverage mechanism from (See et al., 2017). We use it to (i) handle Out-of-Vocabulary words and (ii) avoid repeating phrases in the generated questions.

Dataset	Model	n-gram

Table 2: Comparsion of RefNet model with existing approaches and EAD model. Here * denotes our implementation of the corresponding work.

3 Experimental Details

In this section, we discuss (i) the datasets for which we tested our proposed model, (ii) implementation details and (iii) evaluation metrics used to compare our model with the baseline and existing works.

3.1 Datasets

SQuAD (Rajpurkar et al., 2016): It contains 100K (question, answer) pairs obtained from 536 Wikipedia articles, where the answers are a span in the passage. For SQuAD, AQG has been tried from both sentences and passages. In the former case, only the sentence which contains the answer span is used as input, whereas in the latter case the entire passage is used. We use the same train-validation-test splits as used in (Zhao et al., 2018).

Hotpot QA (Yang et al., 2018) : Hotpot-QA is a multi-document and multi-hop QA dataset. Along with the triplet (P, A, Q), the authors also provide supporting facts that potentially lead to the answer. The answers here are either yes/no or answer span in P. We concatenate these supporting facts to form the passage. We use 10% of the training data for validation and use the original dev set as test set.

DROP (Dua et al., 2019): The DROP dataset is a reading comprehension benchmark which requires discrete reasoning over passage. It contains 96K questions which require discrete operations such as addition, counting, or sorting to obtain the answer. We use 10% of the original training data for validation and use the original dev set as test set.

3.2 Implementation Details

We use 300 dimensional pre-trained Glove word embeddings, which are fixed during training. For character-level embeddings, we initially use a 20 dimensional embedding for the characters which is then projected to 100 dimensions. For answer-tagging, we use embedding size of 3. The hidden size for all the LSTMs is fixed to 512. We use 2-layer, 1-layer and 2-layer stacked BiLSTM for the passage encoder, answer encoder and the decoders (both) respectively. We take the top $30,000$ frequent words as the vocabulary. We use Adam optimizer with a learning rate of 0.0004 and train our models for 10 epochs using cross entropy loss. For the Reward-RefNet model, we fine-tune the pre-trained model with the loss function mentioned in Section 2.3 for 3 epochs. The best model is chosen based on the BLEU (Papineni et al., 2002) score on the validation split. For all the results we use beam search decoding with a beam size of 5.

3.3 Evaluation

We evaluate our models, based on n-gram similarity metrics BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), and METEOR (Lavie and Denkowski, 2009) using the package released in (Sharma et al., 2017)[2]. We also quantify the answerability of our models using QBLEU-4[3](Nema and Khapra, 2018).

4 Results and Discussions

In this section, we present the results and analysis of our proposed model RefNet. Throughout this section, we refer to our models as follows:

Encode-Attend-Decode (EAD) model is our single decoder model containing the encoder and the Preliminary Decoder described earlier. Note that the performance of this model is comparable to our implementation of the model proposed in (Zhao et al., 2018).

Refine Network (RefNet) model includes the encoder, the Preliminary Decoder and the Refinement Decoder.

We will (i) compare RefNet's performance with EAD and existing models across all the mentioned datasets (ii) report human evaluations to compare RefNet and EAD (iii) analyze Refinement and Preliminary Decoders iv) present the performance of Reward RefNet with two different reward signal (fluency and answerability).

4.1 RefNet's performance across datasets

In Table 2, we compare the performance of RefNet with existing single decoder architectures across different datasets. On BLEU-4 metric, RefNet beats the existing state-of-the-art model by 12.30%, 9.74%, 17.48%, and 3.71% respectively on SQuAD (sentence), HOTPOT-QA, DROP and SQuAD (passage) dataset. Also it outperforms EAD by 7.83%, 7.57%, 15.25% and 3.85% respectively on SQuAD (sentence), HOTPOT-QA, DROP and SQuAD (passage). In general, RefNet is consistently better than existing models across all n-gram scores (BLEU, ROUGE-L and METEOR). Along with n-gram scores, we also observe improvements on Q-BLEU4 as well, which as described earlier, gives a measure of both answerability and fluency.

4.2 Human Evaluations

We conducted human evaluations to analyze the quality of the questions produced by EAD and RefNet. We randomly sampled 500 questions generated from the SQuAD (sentence level) dataset and asked the annotators to compare the quality of the generated questions. The annotators were shown a pair of questions, one generated by EAD and one by RefNet from the same sentence, and were asked to decide which one was better in terms of Fluency, Completeness, and Answerability. They were allowed to skip the question pairs where they could not make a clear choice. Three annotators rated each question and the final label was calculated based on majority voting. We observed that the RefNet model outperforms the EAD model across all three metrics. Over 68.6%, 66.7% and 64.2% of the generated questions from RefNet were respectively more fluent, complete and answerable when compared to the EAD model. However, there are some cases where EAD does better than RefNet. For example, in Table 3, we show that while trying to generate a more elaborate question, RefNet introduces an additional phrase *"in the united"* which is not required. Due to such instances, annotators preferred the EAD model in around 30% of the instances.

Passage: Before the freeze ended in 1952, there were only 108 existing television stations in the United States; a few major cities (such as Boston) had only two television stations, ...
Questions *EAD*: how many television stations existed in boston ? *RefNet*: how many television stations did boston have in the united ?

Model	**Decoder**	**BLEU-4**	**QBLEU-4**
without $\mathbf{A_3}$	*RefNet*	17.16	25.80
	Initial Draft	17.59	26.00
with $\mathbf{A_3}$	*RefNet*	18.37	27.40
	Initial Draft	17.89	26.00

Table 4: Comparison between Preliminary Decoder and Refinement Decoder in RefNet Model for SQuAD Sentence Level QG.

4.3 Analysis of Refinement Decoder and Preliminary Decoder

The two decoders impact each other through two paths: (i) indirect path, where they share the encoder and the output projection to the vocabulary V, (ii) direct path, via the dual attention network, where the initial draft of the question is attended by the Refinement Decoder. When RefNet has only indirect path, we can infer from row 1 of Table 4 that the performance of Preliminary Decoder improves when compared to the EAD model (16.84 v/s 17.59 BLEU). This suggests that generating two variants of the question improves the performance of the first decoder pass as well. This is perhaps due to the additional feedback that the

Sample:	**Sentence:** For instance , the language { xx — x is any binary string } can be solved in linear time on a multi-tape Turing machine , but necessarily requires quadratic time in the model of single-tape Turing machines . **Reference Question:** A multi-tape Turing machine requires what type of time for a solution ?
with A_3	**Refinement Decoder**: in what time can the language be solved on a multi-tape turing machine ? **Preliminary Decoder:** in what time can the language be solved ?
without A_3	**Refinement Decoder:** in what time can the language { xx — x x x x is any binary string ? **Preliminary Decoder:** in what time can the language — x x x x is solved ?

Model	BLEU Reward Signal		Answerability Reward Signal	
	BLEU4	%preference	Ans.	%preference
RefNet	18.37	32.9%	36.9	30%
Reward-RefNet	18.52	67.1%	37.5	70%

Table 6: Impact of Reward-RefNet on fluency and answerability. %preference denotes the percentage of times annotators prefer the generated output from the model for fluency in case of BLEU Reward signal and answerability in case of Answerability Reward signal.

Passage: Cost engineers and estimators apply expertise to relate the work and materials involved to a proper valuation
Questions *Generated*: Who apply expertise to relate the work and materials involved to a proper valuation ? *True*: Who applies expertise to relate the work and materials involved to a proper valuation ?

Table 7: An example of question with significant overlap with the passage. The answer is shown in blue.

shared encoder and output layer get from the Refinement Decoder. When we add the direct path (attention network) between the two decoders, the performance of the Refinement Decoder improves as compared to the Preliminary Decoder as shown in rows 3 and 4 of the Table 4

Comparison on Answerability: We also evaluate both the initial and refined draft using QBLEU4. As discussed earlier, Q-Metric measures Answerability using four components, *viz.*, Named Entities, Important Words, Function Words, and Question Type. We observe that the increase in Q-Metric for refined questions is because the RefNet model can correct/add the relevant Named Entities in the question. In particular, we observe that the Named Entity component score in Q-Metric increases from 32.42 for the first draft to 37.81 for the refined draft.

Qualitative Analysis: Figure 2 shows that the RefNet model indeed generates more elaborate questions when compared to the Preliminary Decoder. As shown in Table 5, the quality of the refined question is better than the initial draft of the questions. Here RefNet adds the phrase "multi-tape Turing Machine," (row 2) which removes any ambiguity in the question.

4.4 Analysis of Reward-RefNet

In this section, we analyze the impact of employing different reward signals in Reward-RefNet. As discussed earlier in section 2.3, we use fluency and answerability scores as reward signals. As shown in Table 6, when BLEU-4 (fluency) is used as a reward signal, there is improvement in BLEU-4 scores of Reward-RefNet as compared to RefNet model. We validated these results through human evaluations across 200 samples. Annotators prefer the Reward-RefNet model in 67% of the cases for fluency. Similarly when we use Answerability score as a reward signal, answerability improves for the model and annotators prefer the Reward-RefNet in 70% of the cases for answerability. The performance of Reward-RefNet on fluency and answerability is similar for other datasets (see Appendix B).

Case Study: Originality of the Questions

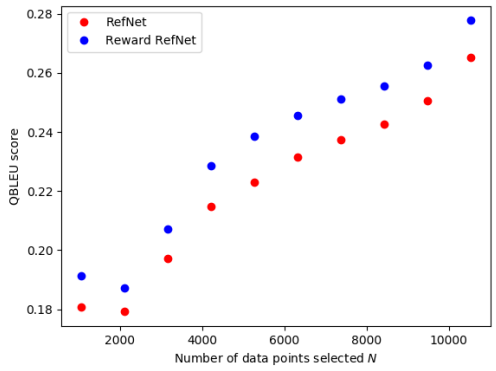

Figure 3: Originality Analysis: Plot of Q-BLEU score vs N - the number points selected.

We observe that current state-of-the-art models perform very well in terms of BLEU/QBLEU scores when the actual question has significant overlap with the passage. For example, consider a passage from the SQuAD dataset in Table 7, where except the question word *who*, the model sequentially copies everything from the passage and achieves a QBLEU score of 92.4. However, the model performs poorly in situations where the true question is novel and does not contain a large sequence of words from the passage itself. In order to quantify this, we first sort the true questions based on its BLEU-2 overlap with the passage in ascending order. We then select the first N true questions and compute the QBLEU score with the generated questions. The results are shown in red in Figure 3. Towards the left, where there are true questions with low overlap with the passage, the performance is poor, but it gradually improves as the overlap increases.

The task of generating questions with high *originality* (where the model phrases the question in its own words) is a challenging aspect of AQG since it requires complete understating of the semantics and syntax of the language. In order to improve questions generated on *originality*, we explicitly reward our model for having low n-gram score with the passage as compared to the initial draft. As a result we observe that with Reward-RefNet(Originality), there is an improvement in the performance where the overlap with the passage was less (as shown in blue in Figure 3).As shown in Table 8, although both questions are answerable given the passage, the question generated from Reward-RefNet(Originality) is better.

Passage: McLetchie was elected on the Lothian regional list and the Conservatives suffered a net loss of five seats , with leader Annabel Goldie claiming that their support had held firm, nevertheless, she too announced she would step down as leader of the party.
Questions
True: Who announced she would step down as leader of the Conservatives ?
RefNet: who claiming that their support had held firm ?
Reward-RefNet: who was the leader of the conservatives?

Table 8: An example where Reward-RefNet(Originality) is better than RefNet.

5 Related Work

Early works on Question Generation were essentially rule based systems (Heilman and Smith, 2010; Mostow and Chen, 2009; Lindberg et al., 2013; Labutov et al., 2015). Current models for AQG are based on the encode-attend-decode paradigm and they either generate questions from the passage alone (Du and Cardie, 2017; Du et al., 2017; Yao et al., 2018) or from the passage and a given answer (in which case the generated question must result in the given answer). Over the past couple of years, several variants of the encode-attend-decode model have been proposed. For example, (Zhou et al., 2018) proposed a sequential copying mechanism to explicitly select a sub-span from the passage. Similarly, (Zhao et al., 2018) mainly focuses on efficiently incorporating paragraph level content by using Gated Self Attention and Maxout pointer networks. Some works (Yuan et al., 2017) even use Question Answering as a metric to evaluate the generated questions. There has also been some work on generating questions from images (Jain et al., 2017; Li et al., 2017) and from knowledge bases (Serban et al., 2016; Reddy et al., 2017). The idea of multi pass decoding which is central to our work has been used by (Xia et al., 2017) for machine translation and text summarization albeit with a different objective. Some works have also augmented seq2seq models (Rennie et al., 2017; Paulus et al., 2018; Song et al., 2017) with external reward signals using REINFORCE with baseline algorithm (Williams, 1992). The typical rewards used in these works are BLEU and ROUGE scores. Our REINFORCE loss is different from the previous ones as it uses the first decoder's reward as the baseline instead of reward of the greedy policy.

6 Conclusion and Future Work

In this work, we proposed **Refine Networks (RefNet)** for Question Generation to focus on refining and improving the initial version of the generated question. Our proposed RefNet model consisting of a Preliminary Decoder and a Refinement Decoder with Dual Attention Network outperforms the existing state-of-the-art models on the SQuAD, HOTPOT-QA and DROP datasets. Along with automated evaluations, we also conducted human evaluations to validate our findings. We further showed that using Reward-RefNet improves the initial draft on specific aspects like fluency, answerability and originality. As a future work, we would like to extend RefNet to have the ability to decide whether a refinement is needed on the generated initial draft.

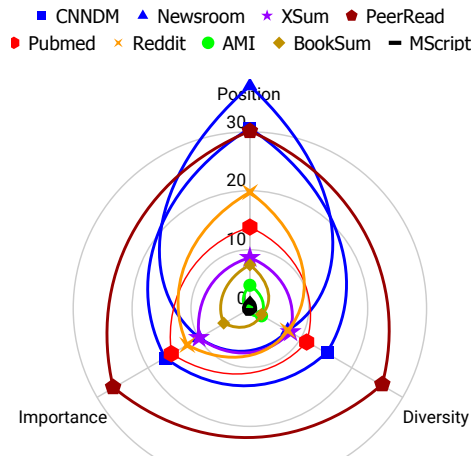
Abstract

Despite the recent developments on neural summarization systems, the underlying logic behind the improvements from the systems and its corpus-dependency remains largely unexplored. Position of sentences in the original text, for example, is a well known bias for news summarization. Following in the spirit of the claim that summarization is a combination of sub-functions, we define three sub-aspects of summarization: `position`, `importance`, and `diversity` and conduct an extensive analysis of the biases of each sub-aspect with respect to the domain of nine different summarization corpora (e.g., news, academic papers, meeting minutes, movie script, books, posts). We find that while `position` exhibits substantial bias in news articles, this is not the case, for example, with academic papers and meeting minutes. Furthermore, our empirical study shows that different types of summarization systems (e.g., neural-based) are composed of different degrees of the sub-aspects. Our study provides useful lessons regarding consideration of underlying sub-aspects when collecting a new summarization dataset or developing a new system.

1 Introduction

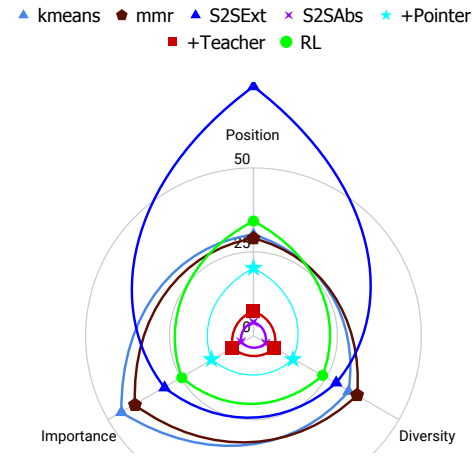
Despite numerous recent developments in neural summarization systems (Narayan et al., 2018b; Nallapati et al., 2016; See et al., 2017; Kedzie et al., 2018; Gehrmann et al., 2018; Paulus et al., 2017) the underlying rationales behind the improvements and their dependence on the training corpus remain largely unexplored. Edmundson (1969) put forth the position hypothesis: important sentences appear in preferred positions in the document. Lin and Hovy (1997) provide a method to empirically identify such positions. Later, Hong and Nenkova (2014) showed an intentional lead bias in news writing, suggesting that sentences appearing early in news articles are more important for summarization tasks. More generally, it is well known that recent state-of-the-art models (Nallapati et al., 2016; See et al., 2017) are often marginally better than the first-k baseline on single-document news summarization.

In order to address the position bias of news articles, Narayan et al. (2018a) collected a new dataset called XSum to create single sentence summaries that include material from multiple positions in the source document. Kedzie et al. (2018) showed that the position bias in news articles is not the same across other domains such as meeting minutes (Carletta et al., 2005).



In addition to `position`, Lin and Bilmes (2012) defined other sub-aspect functions of summarization including `coverage`, `diversity`, and `information`. Lin and Bilmes (2011) claim that many existing summarization systems are instances of mixtures of such sub-aspect functions; for example, maximum marginal relevance (MMR) (Carbonell and Goldstein, 1998) can be seen as an combination of diversity and importance functions.

Following the sub-aspect theory, we explore three important aspects of summarization (§3): POSITION for choosing sentences by their position, IMPORTANCE for choosing relevant contents, and DIVERSITY for ensuring minimal redundancy between summary sentences.



We then conduct an in-depth analysis of these aspects over nine different domains of summarization corpora (§5) including news articles, meeting minutes, books, movie scripts, academic papers, and personal posts. For each corpus, we investigate which aspects are most important and develop a notion of **corpus bias** (§6). We provide an empirical result showing how current summarization systems are compounded of which sub-aspect

[*] Equal contribution, name order decided by coin flip.

(a) Corpus bias

(b) System bias

Figure 1: Corpus and system biases with the three sub-aspects, showing what portion of aspect is used for each corpus and each system. The portion is measured by calculating ROUGE score between (a) summaries obtained from each aspect and target summaries or (b) summaries obtained from each aspect and each system.

factors called **system bias** (§7). At last, we summarize our actionable messages for future summarization researches (§8). We summarize some notable findings as follows:

- Summarization of personal post and news articles except for XSum (Narayan et al., 2018a) are biased to the position aspect, while academic papers are well balanced among the three aspects (see Figure 1 (a)). Summarizing long documents (e.g. books and movie scripts) and conversations (e.g. meeting minutes) are extremely difficult tasks that require multiples aspects together.
- Biases do exist in current summarization systems (Figure 1 (b)). Simple ensembling of multiple aspects of systems show comparable performance with simple single-aspect systems.
- Reference summaries in current corpora include less than 15% of new words that do not appear in the source document, except for abstract text of academic papers.
- Semantic volume (Yogatama et al., 2015) overlap between the reference and model summaries is not correlated with the hard evaluation metrics such as ROUGE (Lin, 2004).

2 Related Work

We provide here a brief review of prior work on summarization biases. Lin and Hovy (1997) studied the position hypothesis, especially in the news article writing (Hong and Nenkova, 2014; Narayan et al., 2018a) but not in other domains such as conversations (Kedzie et al., 2018). Narayan et al. (2018a) collected a new corpus to address the bias by compressing multiple contents of source document in the single target summary. In the bias analysis of systems, Lin and Bilmes (2012, 2011) studied the sub-aspect hypothesis of summarization systems. Our study extends the hypothesis to various corpora as well as systems. With a specific focus on `importance` aspect, a recent work (Peyrard, 2019a) divided it into three subcategories; redundancy, relevance, and informativeness, and provided quantities of each to measure. Compared to this, ours provide broader scale of sub-aspect analysis across various corpora and systems.

We analyze the sub-aspects on different domains of summarization corpora: news articles (Nallapati et al., 2016; Grusky et al., 2018; Narayan et al., 2018a), academic papers or journals (Kang et al., 2018; Kedzie et al., 2018), movie scripts (Gorinski and Lapata, 2015), books (Mihalcea and Ceylan, 2007), personal posts (Ouyang et al., 2017), and meeting minutes (Carletta et al., 2005) as described further in §5.

Beyond the corpora themselves, a variety of summarization systems have been developed: Mihalcea and Tarau (2004); Erkan and Radev (2004) used graph-based keyword ranking algorithms. Lin and Bilmes (2010); Carbonell and Goldstein (1998) found summary sentences which are highly relevant but less redundant. Yogatama et al. (2015) used semantic volumes of bigram features for extractive summarization. Internal structures of documents have been used in summarization: syntactic parse trees (Woodsend and Lapata, 2011; Cohn

and Lapata, 2008), topics (Zajic et al., 2004; Lin and Hovy, 2000), semantic word graphs (Mehdad et al., 2014; Gerani et al., 2014; Ganesan et al., 2010; Filippova, 2010; Boudin and Morin, 2013), and abstract meaning representation (Liu et al., 2015). Concept-based Integer-Linear Programming (ILP) solver (McDonald, 2007) is used for optimizing the summarization problem (Gillick and Favre, 2009; Banerjee et al., 2015; Boudin et al., 2015; Berg-Kirkpatrick et al., 2011). Durrett et al. (2016) optimized the problem with grammatical and anarphorcity constraints.

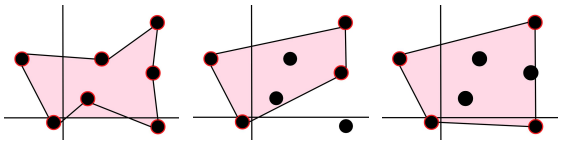
With a large scale of corpora for training, neural network based systems have recently been developed. In abstractive systems, Rush et al. (2015) proposed a local attention-based sequence-to-sequence model. On top of the seq2seq framework, many other variants have been studied using convolutional networks (Cheng and Lapata, 2016; Allamanis et al., 2016), pointer networks (See et al., 2017), scheduled sampling (Bengio et al., 2015), and reinforcement learning (Paulus et al., 2017). In extractive systems, different types of encoders (Cheng and Lapata, 2016; Nallapati et al., 2017; Kedzie et al., 2018) and optimization techniques (Narayan et al., 2018b) have been developed. Our goal is to explore which types of systems learns which sub-aspect of summarization.

3 Sub-aspects of Summarization

We focus on three crucial aspects : Position, Diversity, and Importance. For each aspect, we use different extractive algorithms to **capture how much of the aspect is used in the oracle extractive summaries**[1]. For each algorithm, the goal is to select k extractive summary sentences (equal to the number of sentences in the target summaries for each sample) out of N sentences appearing in the original source. The chosen sentences or their indices will be used to calculate the various evaluation metrics described in §4

For some algorithms below, we use vector representation of sentences. We parse a document x into a sequence of sentences $x = x_1..x_N$ where each sentence consists of a sequence of words $x_i = w_1..w_s$. Each sentence is then encoded:

$$\mathrm{E}(x_i) = \texttt{BERT}(w_{i,1}..w_{i,s}) \quad (1)$$



where BERT (Devlin et al., 2018) is a pre-trained bidirectional encoder from transformers (Vaswani et al., 2017)[2]. We use the last layer from BERT as a representation of each token, and then average them to get final representation of a sentence. All tokens are lower cased.

3.1 Position

Position of sentences in the source has been suggested as a good indicator for choosing summary sentences, especially in news articles (Lin and Hovy, 1997; Hong and Nenkova, 2014; See et al., 2017). We compare three position-based algorithms: **First**, **Last**, and **Middle**, by simply choosing k number of sentences in the source document from these positions.

3.2 Diversity

Yogatama et al. (2015) assume that extractive summary sentences which maximize the semantic volume in a distributed semantic space are the most diverse but least redundant sentences. Motivated by this notion, our goal is to find a set of k sentences that maximizes the volume size of them in a continuous embedding space like the BERT representations in Eq 1. Our objective is to find the optimal search function $\mathcal{S}$ that maximizes the volume size $\mathcal{V}$ of searched sentences: $\arg\max_{1..k} \mathcal{V}(\mathcal{S}_{1..c}(\mathrm{E}(x_1), \ldots, \mathrm{E}(x_N)))$.

(a) Default (b) Heuristic (c) ConvexFall

Figure 2: Volume maximization functions. Black dots are sentences in source document, and red dots are chosen summary sentences. The red-shaded polygons are volume space of the summary sentences.

If k=N, we use every sentence from the source document. (Figure 2 (a)). However, its volume space does not guarantee to maximize the volume size because of the non-convex polygonality. In order to find a convex maximum volume, we consider two different algorithms described below.

Heuristic. Yogatama et al. (2015) heuristically choose a set of summary sentences using a greedy algorithm: It first chooses a sentence which has the farthest vector representation from the centroid of whole source sentences, and then repeatedly finds sentences whose representation is farthest from

[1] See §4 for our oracle set construction.

[2] The other encoders such as averaging word embeddings (Pennington et al., 2014) show comparable performance.

the centroid of vector representations of the chosen sentences. Unlike the original algorithm in (Yogatama et al., 2015) restricting the number of words, we constrain the total number of selected sentences to k. This heuristic algorithm can fail to find the maximum volume depending on its starting point and/or the farther distance between two points detected (Figure 2 (b)).

ConvexFall. Here we first find the convex-hull[3] using Quickhull (Barber et al., 1996), implemented by Qhull library[4]. It guarantees the maximum volume size of selected points with minimum number of points (Figure 2 (c)). However, it does not reduce a redundancy between the points over the convex-hull, and usually choose larger number of sentences than k. Marcu (1999) shows an interesting study regarding an importance of sentences: given a document, if one deletes the least central sentence from the source text, then at some point the similarity with the reference text rapidly drops at sudden called the *waterfall* phenomena. Motivated by his study, we similarly prune redundant sentences from the set chosen by convex-hull search. For each turn, the sentence with the lowest volume reduction ratio is pruned until the number of remaining sentences is equivalent to k.

3.3 Importance

We assume that contents that repeatedly occur in one document contain *important* information. We find sentences that are nearest to the neighbour sentences using two distance measures: **N-Nearest** calculates an averaged Pearson correlation between one and the rest for all source sentence vector representations. k sentences having the highest averaged correlation are selected as final extractive summaries. On the other hand, **K-Nearest** chooses the K nearest sentences per each sentence, and then averages distances between each nearest sentence and the selected one. The one has the lowest averaged distance is chosen. This calculation is repeated k times and the selected sentences are removed from the remaining pool.

4 Metrics

In order to determine the aspects most crucial to the summarization task, we use three evaluation metrics:

ROUGE is Recall-Oriented Understudy for Gisting Evaluation (Lin and Hovy, 2000) for evaluating summarization systems. We use ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) F-measure scores which corresponds to uni-gram, bigrams and longest common subsequences, respectively, and their averaged score (R).

Volume Overlap (VO) ratio. Hard metrics like ROUGE often ignore semantic similarities between sentences. Based on the volume assumption in (Yogatama et al., 2015), we measure overlap ratio of two semantic volumes calculated by the model and target summaries. We obtain a set of vector representations of the reference summary sentences $\hat{Y}$ and the model summary sentences Y predicted by any algorithm *algo* in §3 for the i-th document:

$$\hat{Y}_i = (\hat{y}_{i,1} .. \hat{y}_{i,k}), \quad Y_i^{algo} = (y_{i,1}^{algo} .. y_{i,k}^{algo}) \tag{2}$$

Each volume $\mathtt{V}$ is then calculated using the convex-hull algorithm and their overlap ($\sqcap$) is calculated using a shapely package[5][6]. The final VO is then:

$$\mathrm{VO}_{algo} = \sum_{i=1}^{N} \frac{\mathtt{V}(E(Y_i^{algo})) \sqcap \mathtt{V}(E(\hat{Y}_i))}{\mathtt{V}(E(\hat{Y}_i))} \tag{3}$$

where N is the total number of input documents, E is the BERT sentence encoder in Eq 1, and $E(\hat{Y}_i)$ and $E(Y_i^{algo})$ are a set of vector representations of the reference and model summary sentences, respectively. The volume overlap indicates how two summaries are semantically overlapped in a continuous embedding space.

Sentence Overlap (SO) ratio. Even though ROUGE provides a recall-oriented lexical overlap, we don't know the upper-bound on performance (called `oracle`) of the extractive summarization. We extract the oracle extractive sentences (i.e. a set of input sentences) which maximizes ROUGE-L F-measure score with the reference summary. We then measure sentence overlap (SO) which determines how many extractive sentences from our algorithms are in the oracle summary. The SO is:

$$\mathrm{SO}_{algo} = \sum_{i=1}^{n} \frac{\mathtt{C}(Y_i^{algo} \cap \hat{Y}_i)}{\mathtt{C}(\hat{Y}_i)} \tag{4}$$

where $\mathtt{C}$ is a function for counting the number of elements in a set. The sentence overlap indicates

[3] Definition: a set of points is defined as the smallest convex set that includes the points.

[4] http://www.qhull.org/

[5] https://pypi.org/project/Shapely/

[6] Due to the lack of overlap calculation between two polygons of high dimensions, we reduce it to 2D PCA space.

how well the algorithm finds the oracle summaries for extractive summarization.

5 Summarization Corpora

We use various domains of summarization datasets to conduct the bias analysis across corpora and systems. Each dataset has source documents and corresponding abstractive target summaries. We provide a list of datasets used along with a brief description and our pre-processing scheme:

- `CNNDM` (Nallapati et al., 2016): contains 300K number of online news articles. It has multiple sentences (4.0 on average) as a summary.
- `Newsroom` (Grusky et al., 2018): contains 1.3M news articles and written summaries by authors and editors from 1998 to 2017. It has both extractive and abstractive summaries.
- `XSum` (Narayan et al., 2018a): has news articles and their single but abstractive sentence summaries mostly written by the original author.
- `PeerRead` (Kang et al., 2018): consists of scientific paper drafts in top-tier computer science venues as well as `arxiv.org`. We use full text of introduction section as source document and of abstract section as target summaries.
- `PubMed` (Kedzie et al., 2018): is 25,000 medical journal papers from the PubMed Open Access Subset.[7] Unlike `PeerRead`, full paper except for abstract is used as source documents.
- `MScript` (Gorinski and Lapata, 2015): is a collection of movie scripts from ScriptBase corpus and their corresponding user summaries of the movies.
- `BookSum` (Mihalcea and Ceylan, 2007): is a dataset of classic books paired to summaries from Grade Saver[8] and Cliffs Notes[9]. Due to a large number of sentences, we only choose the first 1K sentences for source document and the first 50 sentences for target summaries.
- `Reddit` (Ouyang et al., 2017): is a collection of personal posts from `reddit.com`. We use a single abstractive summary per post. The same data split from Kedzie et al. (2018) is used.
- `AMI` (Carletta et al., 2005): is documented meeting minutes from a hundred hours of recordings and their abstractive summaries.

Table 1 summarizes the characteristics of each dataset. We note that the Gigaword (Graff et al., 2003), New York Times[10], and Document Understanding Conference (DUC)[11] are also popular datasets commonly used in summarization analyses, though here we exclude them as they represent only additional collections of news articles, showing similar tendencies to the other news datasets such as `CNNDM`.

6 Analysis on Corpus Bias

We conduct different analyses of how each corpus is biased with respect to the sub-aspects. We highlight some key findings for each sub-section.

6.1 Multi-aspect analysis

Table 2 shows a comparison of the three aspects for each corpus where we include random selection and the oracle set. For each dataset metrics are calculated on a test set except for `BookSum` and `AMI` where we use train+test due to the smaller sample size.

Earlier isn't always better. Sentences selected early in the source show high `ROUGE` and `SO` on `CNNDM`, `Newsroom`, `Reddit`, and `BookSum`, but not in other domains such as medial journals and meeting minutes, and the condensed news summaries (`XSum`). For summarization of movie scripts in particular, the last sentences seem to provide more important summaries.

`XSum` requires much IMPORTANCE than other corpora. Interestingly, the most powerful algorithm for `XSum` is `N-Nearest`. This shows that summaries in `XSum` are indeed collected by abstracting multiple important contents into single sentence, avoiding the position bias.

First, ConvexFall, and N-Nearest tend to work better than the other algorithms for each aspect. `First` is better than `Last` or `Middle` in new articles except for `XSum` and personal posts, while not in academic papers (i.e., `PeerRead`, `PubMed`) and meeting minutes. `ConvexFall` finds the set of sentences that maximize the semantic volume overlap with the target sentences better than the heuristic one.

`ROUGE` and `SO` show similar behavior, while `VO` does not. In most evaluations, ROUGE scores are linear to SO ratios as expected. However, VO has high variance across algorithms and aspects.

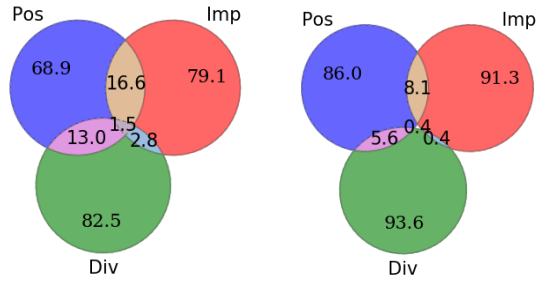
Table 2: Comparison of different corpora w.r.t the three sub-aspects: POSITION, DIVERSITY, and IMPORTANCE. We averaged R1, R2, and RL as R (See Appendix for full scores). Note that volume overlap (VO) doesn't exist when target summary has a single sentence. (i.e., XSum, Reddit)

This is mainly because the semantic volume assumption maximizes the semantic diversity, but sacrifices other aspects like importance by choosing the outlier sentences over the convex hull.

Social posts and news articles are biased to the position aspect while the other two aspects appear less relevant. (Figure 1 (a)) However, XSum requires all aspects equally but with relatively less relevant to any of aspects than the other news corpora.

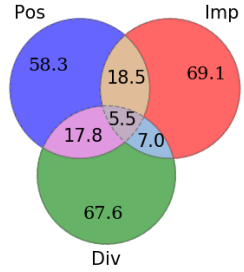
Paper summarization is a well-balanced task. The variance of SO across the three aspects in PeerRead and PubMed is relatively smaller than other corpora. This indicates that abstract summary of the input paper requires the three aspects at the same time. PeerRead has relatively higher SO then PubMed because it only summarize text in Introduction section, while PubMed summarize whole paper text, which is much difficult (almost random performance).



Conversation, movie script and book summarization are very challenging. Conversation of spoken meeting minutes includes a lot of witty replies repeatedly (e.g., 'okay.' , 'mm -hmm.' , 'yeah.'), causing importance and diversity measures to suffer. MScript and BookSum which include very long input document seem to be extremely difficult task, showing almost random performance.

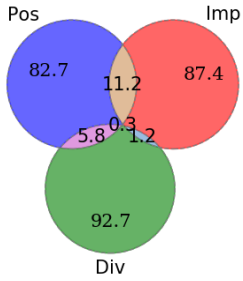
6.2 Intersection between the sub-aspects

Averaged ratios across the sub-aspects do not capture how the actual summaries overlap with each other. Figure 3 shows Venn diagrams of how sets of summary sentences chosen by different sub-aspects are overlapped each other on average.

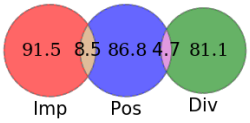


XSum, BookSum, and AMI have high Oracle Recall. If we develop a mixture model of the three aspects, the Oracle Recall means its upper bound, meaning that another sub-aspect should be considered regardless of the mixture model. This indicates that existing procedures are not enough to cover the Oracle sentences. For example, AMI and BookSum have a lot of repeated noisy sentences, some of which could likely be removed without a significant loss of pertinent information.

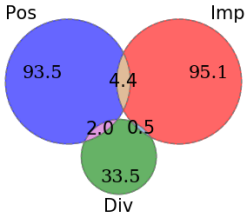
IMPORTANCE and DIVERSITY are less overlapped with each other. This means that important sentences are not always diverse sentences, indicating that they should be considered together.



(a) CNNDM (49.4%)



(b) XSum (76.8%)



(c) PeerRead (37.6%)

(d) Reddit (68.1%)

(e) AMI (94.1%)

(f) BookSum (87.1%)

Figure 3: Intersection of averaged summary sentence overlaps across the sub-aspects. We use First for Position, ConvexFall for Diversity, and N-Nearest for Importance. The number in the parenthesis called *Oracle Recall* is the averaged ratio of how many the oracle sentences are **NOT** chosen by union set of the three sub-aspect algorithms. Other corpora are in Appendix with their Oracle Recalls: Newsroom(54.4%), PubMed (64.0%) and MScript (99.1%).

6.3 Summaries in a embedding space

Figure 4 shows two dimensional PCA projections of a document in CNNDM on the embedding space.

Source sentences are clustered on the convexhull border, not in the middle. We conjecture that sentences are not uniformly distributed in the embedding space but their positions gradually move over the convexhull. Target summaries reflect different sub-aspects according to the sample and corpora. For example, many target sentences in CNNDM are near by First-k sentences.

6.4 Single-aspect analysis

We calculate the frequency of source sentences overlapped with the oracle summary where the

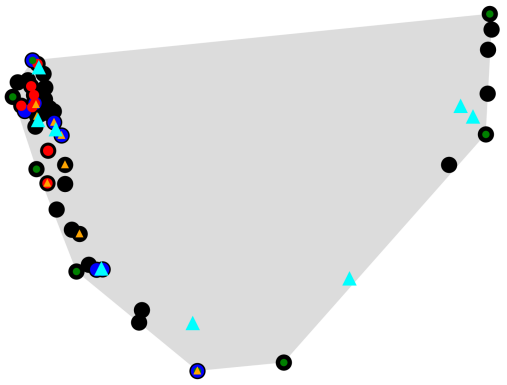


Figure 4: PCA projection of extractive summaries chosen by multiple aspects of algorithms (CNNDM). Source and target sentences are black circles (●) and cyan triangles, respectively. The blue, green, red circles are summary sentences chosen by First, ConvexFall, NN, respectively. The yellow triangles are the oracle sentences. Shaded polygon represents a ConvexHull volume of sample source document. Best viewed in color. Please find more examples in Appendix.

source sentences are ranked differently according to the algorithm of each aspect (See Figure 5). Heavily skewed histograms indicate that oracle sentences are positively (right-skewed) or negatively (left-skewed) related to the sub-aspect.

In most cases, some oracle sentences are overlapped to the first part of the source sentences. Even though their degrees are different, oracle summaries from many corpora (i.e, CNNDM, NewsRoom, PeerRead, BookSum, MScript) are highly related to the Position. Compared to the other corpora, PubMed and AMI contain more top-ranked important sentences in their oracle summaries. News articles and papers tend to find oracle sentences without Diversity (i.e., right-skewed), meaning that non-diverse sentences are frequently selected as part of the oracle.

We also measure how many *new* words occur in abstractive target summaries, by comparing overlap between oracle summaries and document sentences (Table 3). One thing to note is that XSum and AMI have less *new* words in their target summaries. On the other hand, paper datasets (i.e., PeerRead and PubMed) include a lot, indicating that abstract text in academic paper is indeed "abstract".

7 Analysis on System Bias

We study how current summarization systems are biased with respect to three sub-aspects. In addition, we show that a simple ensemble of sys-

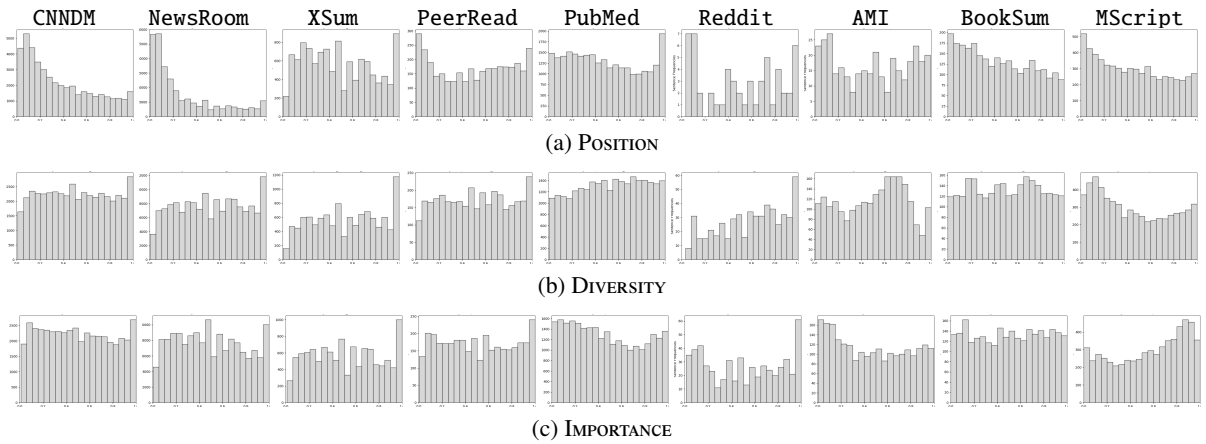

Figure 5: Sentence overlap proportion of each sub-aspect (row) with the oracle summary across corpora (column). y-axis is the frequency of overlapped sentences with the oracle summary. X-axis is the normalized RANK of individual sentences in the input document where size of bin is 0.05. E.g., the first / the most diverse / the most important sentence is in the first bin. If earlier bars are frequent, the aspect is positively relevant to the corpus.

	R(O,T)	O∩T		T\S	
		Unigram	Bigram	Unigram	Bigram
CNNDM	42.8	66.0	36.4	14.7	5.7

MScript	38.9	13.9	4.0	0.3	0.1

Table 3: ROUGE of oracle summaries and averaged N-gram overlap ratios. O, T and S are a set of N-grams from Oracle, Target and Source document, respectively. **R(O,T)** is the averaged ROUGE between oracle and target summaries, showing how similar they are. **O∩T** shows N-gram overlap between oracle and target summaries. The higher the more overlapped words in between. **T\S** is a proportion of N-grams in target summaries not occurred in source document. The lower the more abstractive (i.e., new words) target summaries.

tems shows comparable performance to the single-aspect systems.

Existing systems. We compare various extractive and abstractive systems: For extractive systems, we use *K-Means* (Lin and Bilmes, 2010), Maximal Marginal Relevance (*MMR*) (Carbonell and Goldstein, 1998), *cILP* (Gillick and Favre, 2009; Boudin et al., 2015), *TexRank* (Mihalcea and Tarau, 2004), *LexRank* (Erkan and Radev, 2004) and three recent neural systems; *CL* (Cheng and Lapata, 2016), *SumRun* (Nallapati et al., 2017), and *S2SExt* (Kedzie et al., 2018). For abstractive systems, we use *WordILP* (Banerjee et al., 2015) and four neural systems; *S2SAbs* (Rush et al., 2015), *Pointer* (See et al., 2017), *Teacher* (Bengio et al., 2015), and *RL* (Paulus et al., 2017). The detailed description and experimental setup for each algorithm are in Appendix.

Proposed ensemble systems. Motivated by the sub-aspect theory (Lin and Bilmes, 2012, 2011), we combine different types of systems together from two different pools of extractive systems: asp from the three best algorithm from each aspect and ext from all extractive systems. For each combination, we choose the sumary sentences randomly among the union set of the predicted sentences (rand) or the most frequent unique sentences (topk).

Results. Table 4 shows a comparison of existing and proposed summarization systems on the set of corpora in §5 except for Newsroom[12]. Neural extractive systems such as *CL*, *SumRun* and *S2SExt* outperform the others in general. *LexRank* is highly biased toward the position aspect. On the other hand, *MMR* is extremely biased to the importance aspect on XSum and Reddit. Interestingly, neural extractive systems are somewhat balanced compared to the others. Ensemble systems seem to have the three sub-aspects in balance, compared to the neural extractive systems. They also outperform the others (either ROUGE or SO) on five out of eight datasets.

[12]We exclude it because of its similar behavior as CNNDM.

Table 4: Comparison of different systems using the averaged ROUGE scores (1/2/L) with target summaries (R) and averaged oracle overlap ratios (SO, only for extractive systems). We calculate R between systems and selected summary sentences from each sub-aspect (R(P/D/I)) where each aspect uses the best algorithm: First, ConvexFall and NNearest. R(P/D/I) is rounded by the decimal point. - indicates the system has too few samples to train the neural systems. x indicates SO is not applicable because abstractive systems have no sentence indices. The best score for each corpora is shown in bold with different colors.

8 Conclusion and Future Directions

We define three sub-aspects of text summarization: position, diversity, and importance. We analyze how different domains of summarization dataset are biased to these aspects. We observe that news articles strongly reflect the position aspect, while the others do not. In addition, we investigate how current summarization systems reflect these three sub-aspects in balance. Each type of approach has its own bias, while neural systems rarely do. Simple ensembling of the systems shows more balanced and comparable performance than single ones.

We summarize actionable messages for future summarization research:

- Different domains of datasets except for news articles pose new challenges to the appropriate design of summarization systems. For example, summarization of conversations (e.g., `AMI`) or dialogues (`MSCript`) need to filter out repeated, rhetorical utterances. Book summarization (e.g., `BookSum`) is very challenging due to its extremely large document size. Here current neural encoders suffer from computation limits.
- Summarization systems to be developed should clearly state their computational limits as well as effectiveness in each aspect and in each corpus domain. A good summarization system should reflect different kinds of the sub-aspects harmoniously, regardless of corpus bias. Developing such bias-free or robust models can be very important for future directions.
- Nobody has clearly defined the deeper nature of meaning abstraction yet. A more theoretical study of summarization, and the various aspects, is required. A recent notable example is Peyrard (2019a)'s attempt to theoretically define different quantities of `importance` aspect, and demonstrate the potential of the framework on an existing summarization system. Similar studies can be applied to other aspects and their combinations in various systems and different domains of corpora.
- One can repeat our bias study on evaluation metrics. Peyrard (2019b) showed that widely used evaluation metrics (e.g., ROUGE, Jensen-Shannon divergence) are strongly mismatched in scoring summary results. One can compare different measures (e.g., n-gram recall, sentence overlaps, embedding similarities, word connectedness, centrality, importance reflected by discourse structures), and study bias of each with respect to systems and corpora.

Acknowledgements

This work would not have been possible without the efforts of the authors who kindly share the summarization datasets publicly. We thank Rada Mihalcea for sharing the book summarization dataset. We also thank Diane J. Litman, Taylor Berg-Kirkpatrick, Hiroaki Hayashi, and anonymous reviewers for their helpful comments.

Abstract

The task of bilingual dictionary induction (BDI) is commonly used for intrinsic evaluation of cross-lingual word embeddings. The largest dataset for BDI was generated automatically, so its quality is dubious. We study the composition and quality of the test sets for five diverse languages from this dataset, with concerning findings: (1) a quarter of the data consists of proper nouns, which can be hardly indicative of BDI performance, and (2) there are pervasive gaps in the gold-standard targets. These issues appear to affect the ranking between cross-lingual embedding systems on individual languages, and the overall degree to which the systems differ in performance. With proper nouns removed from the data, the margin between the top two systems included in the study grows from 3.4% to 17.2%. Manual verification of the predictions, on the other hand, reveals that gaps in the gold standard targets artificially inflate the margin between the two systems on English to Bulgarian BDI from 0.1% to 6.7%. We thus suggest that future research either avoids drawing conclusions from quantitative results on this BDI dataset, or accompanies such evaluation with rigorous error analysis.

1 Introduction

Bilingual dictionary induction (BDI) refers to retrieving translations of individual words. The task has been widely used for intrinsic evaluation of cross-lingual embedding algorithms, which aim to map two languages into the same embedding space, for transfer learning purposes (Klementiev et al., 2012). Recently, Glavas et al. (2019) reported limited evidence in support of this practice—they found that cross-lingual embeddings optimized for a BDI evaluation metric were not necessarily better on downstream tasks. Here, we study BDI evaluation in itself, as has been done for other evaluation methods in the past (cf. Faruqui et al., 2016's work on word similarity), with concerning findings about its reliability.

A massive dataset of 110 bilingual dictionaries, known as the MUSE dataset, was introduced in early 2018 along with a strong baseline (Conneau et al., 2018). Subsets of the MUSE dictionaries have been used for model comparison in the evaluation of numerous cross-lingual embedding systems developed since (cf. Grave et al., 2018; Jawanpuria et al., 2018; Hoshen and Wolf, 2018a,b; Wada and Iwata, 2018; Joulin et al., 2018). Even though the field has been very active, progress has been incremental for most language pairs. Moreover, there have been very few attempts at a linguistically-informed error analysis of BDI performance as measured on MUSE (cf. Kementchedjhieva et al., 2018). This is problematic for two reasons: on one hand, most systems greatly vary in their approach and architecture, so it is difficult to identify the source of the reported performance gains; on the other hand, the MUSE dataset was compiled automatically, with no manual post-processing to clean up noise, so the real impact of the performance gains is unclear.

In this work, we study the composition and quality of the MUSE data for five diverse languages: German, Danish, Bulgarian, Arabic and Hindi. A manual part-of-speech annotation of the test sets for these languages reveals a strikingly high number of proper nouns. We refer to linguistic literature to argue that proper nouns, having no lexical meaning but rather just a referential function, cannot reliably be used in the evaluation of word-level translation systems. We find that excluding proper noun pairs from the test dictionaries for the aforementioned languages affects the ranking and degree of performance gaps between five of the most influential recent systems for BDI.

With a new, more reliable ranking at hand, we

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3336–3341,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

perform qualitative analysis on the performance gap between the best and second best systems for Bulgarian. This reveals another major issue with the data: limited coverage of morphological variants for the target words. Through manual verification of the models' predictions, we find that the gap in performance between the two systems is far smaller than previously perceived.

The uncovered issues of high noise levels (proper nouns) and limited coverage (missing gold standard targets) clearly have a crucial impact on BDI results obtained on the MUSE dataset, and need to be addressed. Filtering out proper nouns could be achieved automatically, by checking against gazetteers of named entities. We find that an automatic procedure for the filling of missing targets, however, yields only minor improvements. Until an alternative solution to the latter problem is found, we urge researchers to be cautious when reporting quantitative results on MUSE, and to account for the problems presented here through manual verification and analysis of the results. We share our part-of-speech annotations, such that future work can use this resource for analysis purposes. [1]

2 Bilingual Dictionary Induction

Improvements on BDI mostly stem from developments in the space of cross-lingual embeddings, which use BDI for intrinsic evaluation.

Systems Five influential recent systems for cross-lingual embeddings are MUSE (Conneau et al., 2018), which can be supervised (**MUSE-S**) or unsupervised (**MUSE-U**); VecMap, which also can be supervised (**VM-S**) (Artetxe et al., 2018a) or unsupervised (**VM-U**) (Artetxe et al., 2018b); and RCSLS (Joulin et al., 2018), a supervised system (**RCSLS**), which scores best on BDI out of the five. We refer the reader to the respective publications for a general description of the systems.

Metrics Performance on BDI in these works is evaluated by verifying the system-retrieved translations for a source word against a set of gold-standard targets. The metric used is Precision at k (P@k), which measures how often the set of k top predictions contains one of the gold-standard targets, i.e. what is the ratio of True Positives to the sum of True Positives and False Positives.

[1] Available at https://github.com/coastalcph/MUSE_dicos

Data All systems listed above report results on one or both of two test sets: the MUSE test sets Conneau et al. (2018) and/or the Dinu test sets (Dinu et al., 2015; Artetxe et al., 2017). Similarly to MUSE, the Dinu dataset was compiled automatically (from Europarl word-alignments), but it only covers four languages. Due to the bigger size of MUSE (110 language pairs), we deem its impact larger and focus our study entirely on it.

3 Annotation-based observations

In order to gain insights into the linguistic composition of the MUSE dictionaries, we employ annotators fluent in German, Danish, Bulgarian, Arabic and Hindi (hereafter, DE, DA, BG, AR, HI) to annotate the entire dictionaries from English to one of these languages (hereafter, from-EN) and the entire dictionaries from these languages to English (hereafter, to-EN) with part-of-speech (POS) tags. Details on the annotation procedure can be found in Appendix A. Below, we discuss our findings on the POS composition of the data, and we evaluate the performance of RCSLS per POS tag.[2]

3.1 Analysis of POS composition

The average percentage of common nouns, proper nouns, verbs, and adjectives/adverbs in the dictionaries to-EN was respectively 49.6, 24.9, 12.5, and 12.9.[3] Nouns constitute half of the dictionaries' volume, while verbs and adjectives/adverbs collectively make up only about a fourth of the average dictionary. A skewed ratio between these three categories is not surprising: in the EWT dependency treebank, for example, which contain gold-standard POS tags, the proportion of noun, verb and adjective/adverb types is 34, 17 and 14 percent, respectively. Notice, however, that in the case of the MUSE data, the ratio is even more skewed in favour of nouns over the other two categories.

The large number of proper nouns in the dictionaries seems even more problematic. Proper nouns are considered to have no lexical meaning, but rather just a referential function (Pierini, 2008). Personal names usually refer to a specific referent in a given context, but they can, in general, be attributed to different referents across different contexts, and they are almost univer-

[2] For all experiments, we use the pretrained embeddings of Bojanowski et al. (2017), trained on Wikipedia.

[3] The numbers were similar across from-EN dictionaries.

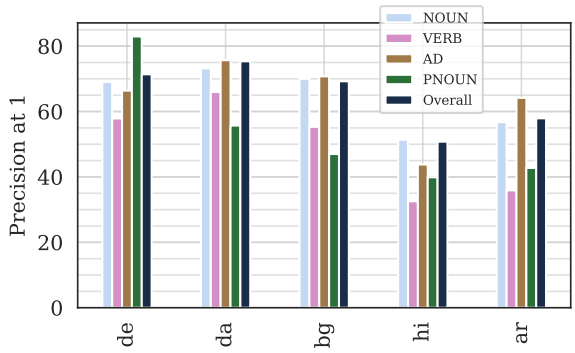

Figure 1: Precision of RCSLS by POS tag on to-EN data.

sally interchangeable in any given context. Some personal names and most place and organization names may have a unique referent, e.g. *Barack Obama, Wisconsin, Skype*, but these names still do not carry a *sense*, their referent is resolved through access to encyclopedic knowledge (Pierini, 2008). Considering that the pretrained embeddings which we use were trained on Wikipedia, we can expect that such encyclopedic information would indeed appear in the context of certain unique names, but importantly, the alignability of the embeddings for such entities would depend on the level of parallelism between the contents of Wikipedia articles in the different languages.

With these considerations in mind, one should wonder how stable the representation of names can be in an embedding space. This question has previously been raised by Artetxe et al. (2017). We address it empirically below.

3.2 Evaluation by POS

Figure 1 shows the precision of the RCSLS embedding alignment method on different POS segments of the test data in mapping to-EN (results from-EN were similar and are shown in Appendix B). Verbs pose a greater challenge to BDI systems than nouns and adjectives do. Generally, we can attribute this observation to the higher abstraction of concepts described by verbs. This is a known problem for word embedding methods in general (Gerz et al., 2016), which BDI systems naturally inherit.

With respect to proper nouns, we observe that they indeed introduce a level of instability in the evaluation of BDI systems. Notice that while the other parts of speech follow a similar pattern across languages, with higher precision obtained for nouns and adjectives/adverbs than for verbs,

Corpora	NOUN	VERB	AD	PNOUN
Wikipedia	69.0	57.9	66.4	83.0
Mixed*	64.0	55.5	59.4	37.6

Table 1: Comparison in performance by POS category with two different embedding sets. * The out-of-vocabulary rate for items in the dictionaries is negligible: 2, 0, and 1 for NOUN, VERB , and AD , respectively.

relative precision on proper nouns is highly variable. For DE, proper nouns are easier to translate than other parts of speech by a margin of 15%, for HI and AR they are easier than nouns and adjectives/adverbs, but harder than verbs, and for DA and BG they are hardest out of all four categories. We looked into the individual word pairs marked as proper nouns in the DE and DA data, as these languages are related and RCSLS performs comparably on them otherwise, and did not find any patterns that could explain the large differences. In fact, between the 384 proper noun pairs in the EN-DE dictionary and the 330 proper noun pairs in the EN-DA dictionary, there was an overlap of 279 pairs, retrieved with precision of 89.21% in the EN-DE setting and 51.30% in the EN-DA setting. We conjecture that this result relates to the level of parallel content between the Wikipedia dumps for the different language pairs, which is likely higher for EN-DE , since the dumps for these languages are also closer in size: 5.8M articles in EN, 2.3M in DE (and only 0.2M in DA).[4]

We evaluate this hypothesis through an experiment where we train an RCSLS alignment for DE-EN using the DE embeddings of Artetxe et al. (2017), trained on SdeWaC (Baroni et al., 2009) and the EN embeddings of Dinu et al. (2015), trained on ukWaC (Baroni et al., 2009), Wikipedia and the BNC [5] corpora. The level of parallel content between the data used to train the two sets of embeddings is thus far more limited in this case, and the DE embeddings are not explicitly trained on Wikipedia data. Table 1 summarizes the results: while with the new embeddings performance is somewhat reduced for nouns, verbs and adjectives/adverbs, precision at 1 for proper nouns, in particular, drops by over 50%, indicating that this category of test word pairs is indeed highly sensitive to the nature of the training data.

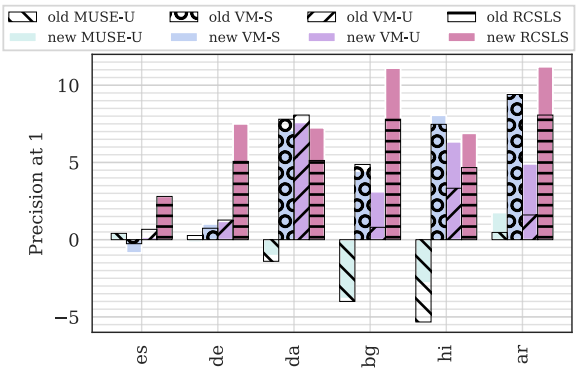

Figure 2: Absolute difference in performance on from-EN BDI, relative to MUSE-S. Pattern-filled bars show results as estimated on the original data (*old*), while colored bars show results as estimated on the cleaned data (*new*).

3.3 Re-ranking on clean data

Based on the analysis presented above, we removed all pairs that were annotated as proper nouns and all pairs that were marked as invalid during the annotation process.[6] This clean-up resulted in a drop in the size of the test dictionaries of about 25% on average. A detailed size comparison between the old test dictionaries and their new cleaned versions is presented in the top rows of Table 4 in Appendix B. Figure 2 visualizes a re-evaluation of the five systems for BDI listed in Section 2, on the original test data and on the new clean versions of the test dictionaries from-EN.[7] The results are reported in terms of change in performance relative to MUSE-S (chosen as a baseline) as estimated on the original MUSE data (pattern-filled bars) and on the cleaned version of the data (colored bars). The absolute system performances before and after the clean-up can be found in Table 4 in Appendix B.

We see that the ranking between the models changes most notably for AR, where RCSLS appears inferior to VM-S on the original test data, but on the clean data it emerges as best. For BG, the evaluation on the clean test data reveals that RCSLS outperforms the next best system, VM-S, by a larger factor than it appeared on the original test data. Lastly, for DA, evaluation on the original test data makes RCSLS seem far inferior to VM-S and VM-U, but on the clean test data we see that it outperforms VM-S and matches the performance of VM-U. These observations show that the noise coming from proper nouns has a large impact on the perceived ranking and difference in performance between systems.

4 *False* False Positives

With a more reliable estimate of the models' performance at hand, we next manually study the remaining performance gap between RCSLS, the best-performing model overall, and VM-S, the second best model overall, for EN–BG.[8] We present some examples in Table 2 and more can be found in Table 5, Appendix C.

We find that there are 125 source words that RCSLS translated correctly and VM-S did not. Upon closer inspection, we find that for 54% of these words, both RCSLS and VM-S predicted a valid translation, but RCSLS predicted a more *canonical* translation, which was listed among the gold-standard targets, while VM-S predicted another word form that was missing from the list of gold-standard targets. By more canonical we mean, for example, indefinite instead of definite forms of nouns and adjectives (see Ex. A, Table 2, masculine instead of feminine or neuter forms of adjectives (see Ex. B), singular instead of plural forms. To the extent that a more canonical translation should be considered better, RCSLS is definitely showing superiority over VM-S. It is not clear, however, if that should be the case, since for some words, the test dictionary exhibits higher coverage than for others, i.e. the less canonical translations are not omitted by design, but appear to be accidental gaps.

Another 19% of the instances where RCSLS outperformed VM-S, we find to be clear cases of a missing translation in the test dictionary, i.e. not a missing form of a listed target, but a missing synonym or a missing sense altogether (see Ex. C and D).

The two types of errors in precision at 1 discussed above can be considered cases of *false* False Positives, because they really should have been True Positives. The remaining 27% of the gap between the two models' performance indeed illustrate that RCSLS provides better translations in some cases (see Ex. E).

Notice, however, that it is not the case that RCSLS outperformed VM-S in all cases–for 50 test words, VM-S predicted a correct translation and RCSLS did not. Among these, there are cases of missing translations from the dictionary as well

[6] The latter constitute less than 1% of the removed data.

[7] The to-EN results were similar, see Appendix B.

[8] We also analyzed EN–DE, with very similar results.

Ex.	SRC	TGT	RCSLS	VM-S	Description
A	joke	шега лаф виц	шега [INDEF]	шегата [DEF]	definite form missing from targets
B	remembered	запомнен	запомнен[MASC]	запомнена[FEM]	feminine form missing from targets
C	hide	скриване	скриване [NOUN]	скрива̀т[VERB]	*hide* as a verb vs. *hide* as a noun
D	bench	пейка пейката	пейка	скамейка	synonym missing from targets
E	depot	депо	депо	гара	VM-S predicted 'train station'
F	crowned	коронован	коронована[FEM]	коронован[MASC]	feminine form missing from targets
G	pond	езерце	къщичка	езерце	RCSLS predicted 'cottage'
H	grants	субсидии	стипендии	стипендии	synonym missing from targets
I	armies	армии	армиите	армиите	definite form missing from targets

Table 2: Example translations from EN to BG. Underlined forms are more canonical. Grey forms are incorrect.

(see Ex. F), but they can explain less of the lack in performance of RCSLS, i.e. 50% of the translations of RCSLS are indeed erroneous (see Ex. G).

To summarize, originally the performance gap between the two models appeared to be $(125 - 50)/1125 * 100 = 6.67\%$, while after the manual verification, it is $(27\% * 125 - 50\% * 50)/1125 * 100 = 0.1\%$.[9] Such a substantial narrowing in the gap between the two models clearly indicates that conclusions drawn on the original result, i.e. that RCSLS is far superior that VM-S for this language pair, is hardly supported by the updated result.

A surface analysis of the subset of words for which neither RCSLS nor VM-S retrieved correct translations revealed similar patterns of extensive false False Positives, due to gaps in the coverage of the dictionary (see Ex. H and I). Our takeaway from these observations is two-fold. Firstly, when RCSLS retrieves a correct target form, it also usually retrieves its most *canonical* form. More importantly, the evaluation of BDI systems on even the cleaned test dictionaries still does not represent accurately the differences in quality between them, due to major gaps in the coverage of the test dictionaries.

5 Concluding remarks

Our study of the MUSE dataset revealed two striking problems: a high level of noise coming from proper nouns, and an issue of *false* False Positives, due to gaps in the gold-standard targets. The former problem, we conjecture, can be solved by filtering names out with gazetteers. The quality of this solution would depend on the coverage of the gazetteers. The more challenging problem, however, is filling in the gaps, especially in terms of inflectional forms. We carried out preliminary experiments aiming to enrich the EN–BG and EN-DE dictionaries. We extracted additional word forms of verbal and nominal targets from the UniMorph inflectional tables (Kirov et al., 2018), according to a manually designed morphosyntactic correspondence map.[10] Unfortunately, due to limited coverage of the UniMorph data, and, in the case of BG, limited vocabulary of the pretrained embeddings, the impact of this procedure was almost negligible. Alternative approaches for enrichment exists, of course, but we wonder how worthwhile further efforts would be. That is, especially in light of Glavas et al. 2019's findings that BDI performance is not necessarily indicative of cross-lingual embedding quality. We therefore hope that our work adds weight to the call of Glavas et al. (2019) for more reliable evaluation methods in cross-lingual embedding research. When BDI performance is used for evaluation purposes, it should be accompanied by manual verification, of the type presented here.

Towards Realistic Practices In Low-Resource Natural Language Processing: The Development Set

Katharina Kann, Kyunghyun Cho and Samuel R. Bowman
New York University, USA
{kann, kyunghyun.cho, bowman}@nyu.edu

Abstract

Development sets are impractical to obtain for real low-resource languages, since using all available data for training is often more effective. However, development sets are widely used in research papers that purport to deal with low-resource natural language processing (NLP). Here, we aim to answer the following questions: Does using a development set for early stopping in the low-resource setting influence results as compared to a more realistic alternative, where the number of training epochs is tuned on development *languages*? And does it lead to overestimation or underestimation of performance? We repeat multiple experiments from recent work on neural models for low-resource NLP and compare results for models obtained by training with and without development sets. On average over languages, absolute accuracy differs by up to 1.4%. However, for some languages and tasks, differences are as big as 18.0% accuracy. Our results highlight the importance of realistic experimental setups in the publication of low-resource NLP research results.

1 Introduction

Parametric machine learning models are frequently trained by minimizing the loss on the training set $\mathcal{T}$,

$$\mathcal{L}_{\mathcal{T}}(\boldsymbol{\theta}) = \sum_{x \in \mathcal{T}} l\left(\theta, x\right), \qquad (1)$$

for model parameters θ and a predefined loss function l. Gradient-based optimizers minimize this loss $\mathcal{L}(\boldsymbol{\theta})$ by updating θ in the direction of the gradient $\nabla\mathcal{L}(\boldsymbol{\theta})$. A low loss characterizes a model which makes accurate predictions for examples in $\mathcal{T}$. However, since $\mathcal{T}$ is finite, overfitting the training set might lead to poor generalization performance. One way to avoid fitting Equation 1 too closely is *early stopping*: a separate *development* or *validation* set is used to end training as soon as the loss on the development set $\mathcal{L}_{\mathcal{D}}(\boldsymbol{\theta})$ starts increasing or model performance on the development set $\mathcal{D}$ starts decreasing. The best set of parameters $\boldsymbol{\theta}$ is used in the final model.

Table 1: Number of examples used for training and development in recent low-resource NLP experiments; *ES*=early stopping on the development set. Experiments from papers in bold will be revisited here.

This works well when large amounts of data are available to create training, development and test splits. Recently, however, with the success of pre-training (Peters et al., 2018; Devlin et al., 2019) and multi-task learning (Caruana, 1997; Ruder, 2017; Wang et al., 2019) approaches, neural models are showing promising results on various natural language processing (NLP) tasks also in *low-resource* or *few-shot* settings (Johnson et al., 2017; Kann et al., 2017; Yu et al., 2018). Often, the high-resource experimental setup and training procedure are kept unchanged, and the size of the original training set is reduced to simulate limited data. This leads to settings where validation examples may outnumber training examples. Table 1 shows such cases for the tasks of historical text normalization (Bollmann et al., 2018), morphological segmentation (Kann et al., 2018), morphological inflection (Makarov and Clematide, 2018; Sharma et al., 2018), argument component identification (Schulz et al., 2018), and transliteration (Upadhyay et al., 2018).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3342–3349, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

However, in a real-world setting with limited resources, it is unlikely that such a development set would be available for early stopping, since it would be more effective to use at least part of it for training instead. Here, we investigate how previous results relate to those obtained in a setting that does *not* assume a development set. Instead of early stopping, we use data from the same task in other languages, the *development languages*, to decide on the number of training epochs. We are interested in two questions: Does recent work in low-resource NLP overestimate model performance by using an unrealistically precise performance signal to stop training? Or, inversely, is model performance underestimated by overfitting the finite development set?

Our experiments on historical text normalization, morphological inflection, and transliteration, featuring a variety of languages, show that performance does differ between runs with and without early stopping on the development set; if using the development set leads to better or worse results depends on the task and language. Differences of up to 18% absolute accuracy highlight that a realistic evaluation of models for low-resource NLP is crucial for estimating real-world performance.

2 Related Work

Realistic evaluation of machine learning. Oliver et al. (2018) investigate how to evaluate semi-supervised training algorithms in a realistic way; they differ from us in that they focus exclusively on semi-supervised learning (SSL) algorithms, and do not consider NLP explicitly. However, in line with our conclusion, they report that recent practices for evaluating SSL techniques do not address the question of the algorithms' real-word applicability in a satisfying way. In NLP, several earlier works have explicitly investigated real-world low-resource settings as opposed to artificial proxy settings, e.g., for part-of-speech tagging (Garrette et al., 2013) or machine translation (Irvine and Callison-Burch, 2013). While those mostly focus on real data-poor languages, we explicitly investigate the effect of the common practice to assume a relatively large development set for early stopping in the low-resource setting.

Low-resource settings in NLP. Research in the area of neural methods for low-resource NLP has gained popularity in recent years, with a dedicated workshop on the topic appearing in 2018 (Haffari et al., 2018). High-level key words under which other work on neural networks for data-poor scenarios in NLP can be found are domain adaptation (Daume III, 2007), multi-task learning (Caruana, 1997; Ruder, 2017), few-shot/zero-shot/one-shot learning (Johnson et al., 2017; Finn et al., 2017), transfer learning (Yarowsky et al., 2001), semi-supervised training (Zhu, 2005), or pretraining (Erhan et al., 2010).

While options for early stopping without a development set exist (Mahsereci et al., 2017), they require hyperparameter tuning, which might not be feasible without a development set, and, most importantly, they are not commonly used in low-resource NLP research. Here, we investigate if *current practices* might lead to unrealistic results.

3 Experimental Design

We compare early stopping using development set accuracy (*DevSet*) with an alternative strategy where the amount of training epochs is a hyperparameter tuned on development languages (*DevLang*). We perform two rounds of training:

- **Stopping point selection phase.** Models for the development languages are trained with the original early stopping strategy from previous work. The number of training epochs for the target languages is then calculated as the average over the best epochs for all development languages.[1] All development languages also function as target languages. To make this possible, for development languages, we compute the average over *other* development languages only.

- **Main training phase.** We train models for all languages keeping both the model resulting from the original early stopping strategy (DevSet) and that from the epoch computed in the stopping point selection phase (DevLang).[2]

The stopping point selection phase exclusively serves the purpose of tuning the number of epochs for the DevLang training setup. Models obtained

[1] We round this number to an integer. It is important for our experiments that the training sets for all languages are of the same size, cf. Table 1. Otherwise we would need to account for the number of training examples per epoch.

[2] This requires training for at least the number of target epochs, even if early stopping would end training earlier.

in this phase are discarded. The development sets we use in our experiments are those from the original papers without alterations.

Since both final models obtained in the main training phase result from the same training run, our experimental design enables a direct comparison between the models from both setups.

Example. Assume that, in the stopping point selection phase, we obtain the best development set results for a given task in development languages L1 and L2 after epochs 14 and 18, respectively. In the main training phase, we then train a model for the same task in target language L3 with the original early stopping strategy, but keeping additionally the model from epoch 16. If the best development result for language L3 is obtained after epoch 19, we compare the model from epoch 19 (DevSet) to that from epoch 16 (DevLang).

4 Tasks, Data, Models

For our study, we select previously published experiments which fulfill the following criteria: (1) datasets exist for at least four languages, and all training sets are of equal size; (2) the original authors use early stopping with a development set; (3) the authors explicitly investigate low-resource settings; and (4) the original code is publically available, or a standard model is used. Since our main goal is to confirm the effect of the development set and not to compare between tasks, we further limit this study to sequence-to-sequence tasks.

4.1 Historical Text Normalization (NORM)

Task. The goal of historical text normalization is to convert old texts into a form that conforms with contemporary spelling conventions. Historical text normalization is a specific case of the general task of text normalization, which additionally encompasses, e.g., correction of spelling mistakes or normalization of social media text.

Data. We experiment on the ten datasets from Bollmann et al. (2018), which represent eight different languages: German (two datasets; Bollmann et al., 2017; Odebrecht et al., 2017); English, Hungarian, Icelandic, and Swedish (Pettersson, 2016); Slovene (two datasets; Ljubešic et al., 2016); and Spanish and Portuguese (Vaamonde, 2015). We treat the two datasets for German and Slovene as different languages. All languages serve both as development languages for all *other* languages and as target languages.

Model. Our model for this task is an LSTM (Hochreiter and Schmidhuber, 1997) encoder-decoder model with attention (Bahdanau et al., 2015). Both encoder and decoder have a single hidden layer. We use the default model in OpenNMT (Klein et al., 2017)[3] as our implementation and employ the hyperparameters from Bollmann et al. (2018). In the original paper, *early stopping* is done by training for 50 epochs, and the best model regarding development accuracy is applied to the test set.

4.2 Morphological Inflection (MORPH)

Task. Morphological inflection consists of mapping the canonical form of a word, the lemma, to an indicated inflected form. This task gets very complex for morphologically rich languages, where a single lemma can have hundreds or thousand of inflected forms. Recently, morphological inflection has frequently been cast as a sequence-to-sequence task, mapping the characters of the input word together with the morphological features specifying the target to the characters of the corresponding inflected form (Cotterell et al., 2018).

Data. We experiment on the datasets released for a 2018 shared task (Cotterell et al., 2018), which cover 103 languages and feature an explicit low-resource setting. We randomly choose ten development languages: Armenian, Basque, Galician, Georgian, Greenlandic, Icelandic, Karbadian, Kannada, Latin, and Lithuanian.

Model. For MORPH, we experiment with a pointer-generator network architecture (Gu et al., 2016; See et al., 2017). This is a sequence-to-sequence model similar to that for NORM, but employs separate encoders for characters and features. It is further equipped with a copy mechanism: using attention to decide on what element from the input sequence to copy, the model computes a probability for either copying or generation while producing an output. The final probability distribution over the target vocabulary is a combination of both. Hyperparameters are taken from Sharma et al. (2018).[4] For *early stopping*, we also follow Sharma et al. (2018): all models are trained

[3] github.com/OpenNMT/OpenNMT-py

[4] github.com/abhishek0318/conll-sigmorphon-2018

for at least 300 epochs, and training is continued for another 100 epochs each time there has been improvement on the development set within the last 100 epochs.

4.3 Transliteration (TRANSL)

Task. Transliteration is the task of converting names from one script into another, while staying as close to the original pronunciation as possible. Unlike for *translation*, focus lies on the sound; the target language meaning is usually ignored.

Data. For our transliteration experiments, we follow Upadhyay et al. (2018). We experiment on datasets from the Named Entities Workshop 2015 (Duan et al., 2015) in Hindi, Kannada, Bengali, Tamil, and Hebrew. For this task, all languages are both development and target languages.

Model. The last featured model is an LSTM sequence-to-sequence model similar to that by Bahdanau et al. (2015), except for using hard monotonic attention (Aharoni and Goldberg, 2017). It attends to a *single* character at a time, and attention moves monotonically over the input. We take hyperparameters and code from Upadhyay et al. (2018).[5] *Early stopping* is done by training for 20 epochs and applying the best model regarding development accuracy to the test data.

4.4 Experimental Setup

We run all experiments using the implementations from previous work or OpenNMT as described above. Existing code is only modified where necessary. Most importantly, we add storing of the DevLang model during the main training phase.

5 Results

Development sets vs. development languages. We are asking if the use of a development set for early stopping leads to over- or underestimation of realistic model performance. Thus, we show in Table 2 how often we obtain higher accuracy for each of DevLang and DevSet. Additionally, averaged performance over all languages as well as the maximum difference in absolute accuracy are listed in Table 3. For NORM and TRANSL, results for individual languages are shown in Tables 4 and 5, respectively; for detailed results for MORPH see Appendix A. We see in Table 2 that, for MORPH and NORM, the use of unrealistically large development sets leads to better results than DevLang for 72 and 8 languages, respectively. For 8 and, respectively, 2 languages there is no difference, and a look at the detailed results in Appendix A and Table 4 reveals that, for those cases, we end up training for the same number of epochs for DevLang and DevSet. Only in 23 cases for MORPH, and none for NORM, we obtain *better* results for DevLang. This suggests that, for these two tasks, we frequently overestimate realistic model performance by early stopping on the development set. Indeed, Table 3 confirms this finding and shows that, on average across languages, DevSet models outperform DevLang models. The maximum difference is 18% absolute accuracy for the language Azeri and MORPH: for DevSet, we reach 64% accuracy after epoch 217, while, for DevLang, we only obtain 46% accuracy after the predefined epoch 324.

We obtain a different picture for TRANSL: results are equal for 3 languages, and better for DevLang for the remaining 2. Equal performance might be explained by the overall smaller number of training epochs in the original regime: stopping at the same epoch for both strategies is more likely. Overall, for TRANSL, performance on the development set seems to be less predictive for the final test performance than for the other tasks.

Influence of the final epoch. Since without a development set performance decreases on MORPH for most languages, we investigate if this can be explained by training often being too short. Therefore, we plot the difference of training du-

	MORPH	NORM	TRANSL
DevLang>DevSet	23	0	2
DevLang=DevSet	8	2	3
DevLang<DevSet	72	8	0

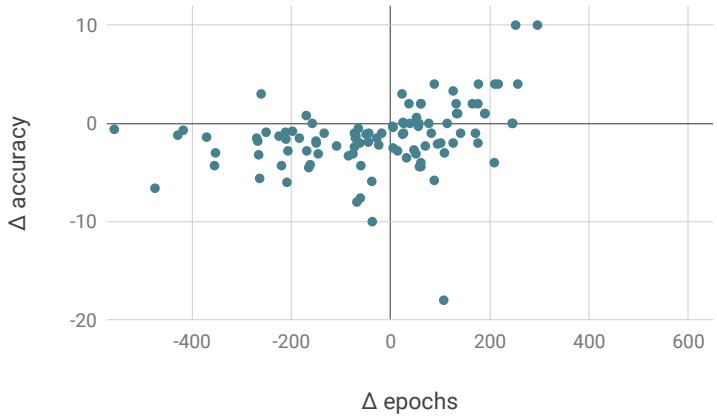

Figure 1: Difference in accuracy (DevLang-DevSet) depending on the difference in training epochs (DevLang-DevSet) for MORPH.

Language	DevSet	DevLang
English	0.7705 (26)	0.7682 (43.44)
German (1)	0.6749 (44)	0.6749 (44.44)
German (2)	0.7075 (43)	0.6837 (41.78)
Hungarian	0.4897 (44)	0.4773 (41.67)
Icelandic	0.7017 (27)	0.6952 (43.56)
Portuguese	0.7944 (43)	0.7860 (42.44)
Slovene (1)	0.8206 (38)	0.8202 (41.67)
Slovene (2)	0.8952 (46)	0.8873 (42.00)
Spanish	0.8352 (42)	0.8352 (41.89)
Swedish	0.7985 (43)	0.7913 (42.11)

Table 4: Detailed results per language for NORM; corresponding epochs in parenthesis.

Language	DevSet	DevLang
Bengali	0.374 (9)	0.387 (10.50)
Hebrew	0.135 (10)	0.135 (10.00)
Hindi	0.248 (10)	0.248 (10.25)
Kannada	0.216 (11)	0.229 (10.00)
Tamil	0.116 (10)	0.116 (10.25)

Table 5: Detailed results per language for TRANSL; corresponding epochs in parenthesis.

ration in epochs between DevLang and DevSet against the resulting difference in accuracy in Figure 1. While we indeed find that shorter training duration for a pointer-generator network for this task mostly results in worse performance, longer training can lead to either lower or higher accuracy. Thus, while longer training seems better for MORPH, not all performance loss can be explained by aborting training too early.

6 Discussion And Conclusion

Limitations. We investigate the effect of early stopping on the validation set as compared to a realistic setting without target language development examples. However, we would like to point out that, in certain situations, standard practices might be sufficient, e.g., for comparing different methods in equal settings, if absolute performance is not the main focus.

Further, we do not claim to show that using a validation set always *over-* or *under*estimates real-world performance, since this depends on how representative the validation set is of the target distribution. Our main result is that using a development set gives a poor estimate of real-world performance and that it is important to be aware of potential performance differences.

Practical take-aways. We replicate experiments from recent low-resource NLP research, once with the original experimental design and once without assuming development sets for early stopping. Since differences in absolute accuracy are up to 18.0%, we conclude that low-resource NLP research should move away from using large development sets for early stopping whenever real-world settings are being considered.

Acknowledgments

We would like to thank Nikita Nangia and Jason Phang for their feedback on this work. This work has benefited from the support of Samsung Research under the project *Improving Deep Learning using Latent Structure* and from the donation of a Titan V GPU by NVIDIA Corporation.

Abstract

In this paper, we introduce a novel interactive approach to translate a source language into two different languages simultaneously and interactively. Specifically, the generation of one language relies on not only previously generated outputs by itself, but also the outputs predicted in the other language. Experimental results on IWSLT and WMT datasets demonstrate that our method can obtain significant improvements over both conventional Neural Machine Translation (NMT) model and multilingual NMT model.

1 Introduction

Neural Machine Translation (NMT) based on the encoder-decoder framework has significantly improved translation quality due to its powerful end-to-end modeling (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017; Gehring et al., 2017; Hassan et al., 2018; Zhang and Zong, 2015). This paradigm facilitates the development of multilingual NMT (Dong et al., 2015; Luong et al., 2016; Johnson et al., 2017; Ha et al., 2016; Firat et al., 2016; Lakew et al., 2017; Tan et al., 2019; Wang et al., 2019), which handles multiple language pairs in one model, with the benefit of simplifying offline model training and easing online maintenance cost.

Although multilingual NMT attempts to utilize the complementary information of different languages (Lu et al., 2018; Neubig and Hu, 2018; Platanios et al., 2018; Wang et al., 2018), all of the models handle one language pair at each moment for both training and testing. However, we find that the generation process of different target languages can help each other. For example in Figure 1, when decoding the Chinese word "书" meaning "*book*" at step $t = 5$, the predicted Japanese word "本" with same meaning can provide the context at step $t = 4$. The reason is that the sentence structure between the two languages is different. It is *subject-verb-object* in Chinese while it is *subject-object-verb* in Japanese. Moreover, we find that two languages are complementary, and if decoders belonging to two different languages can interact with each other, the quality of translation will be improved.

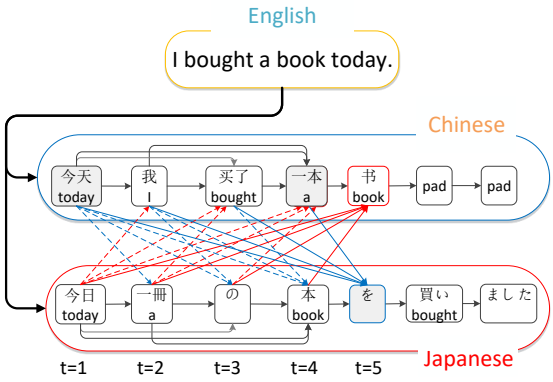

Figure 1: An example of an English sentence translated into Chinese and Japaneses sentences, in which two targets can interact with each other.

In this work, we present a novel interactive decoding algorithm to generate two target languages simultaneously and interactively. To this end, we propose a synchronous attention model, in which the generation of one language can attend to already generated outputs of another language. As shown in Figure 1, the two decoders predict their outputs at the same time. At each moment, word prediction of each language does not only rely on previously generated targets itself but also depends on outputs of the other language.

We conduct extensive experiments to verify the effectiveness of our proposed approaches on English-to-German/French and English-to-Chinese/Japanese translation tasks.

Our contributions in this work are two-fold:

(1) We propose a novel synchronous translation model that can predict outputs of two different languages simultaneously and interactively, which can enhance the translation quality of both languages.

(2) Extensive experiments show the superiority of our proposed method. Specifically, this synchronous approach can significantly outperform both the conventional NMT model and the multilingual NMT model.

2 Background

Owing to powerful modeling ability, our synchronous method relies on Transformer architecture (Vaswani et al., 2017), which is entirely based on the attention mechanism detailed below.

Scaled Dot-Product Attention: The inputs of attention mechanism contain queries Q, keys K, and values V. This function can be described as mapping a query and a set of key-value pairs to an output, and the output is calculated as a weighted sum of the values.

$$\text{Attention}\,(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V \quad (1)$$

where d_k is dimension of keys, Q, K, V are obtained by linearly transforming input hidden states with projection matrices.

3 Synchronous Translation Method

As discussed in Sec. 1, outputs in different languages can be complementary and can help with each other. Thus, it is reasonable to improve translation quality with interactions of two decoders. In this section, we propose an interactive decoding algorithm and then describe how to implement it by a new attention mechanism, named as synchronous attention model.

3.1 Interactive Decoding Algorithm

Interactive decoding algorithm can generate translations of different languages in the same beam. At each step, each half of the beam produces translations in one target language conditioning on source sentence and the predicted tokens in both target languages. Here, we use two decoders with separated embeddings and softmax layers to operate two languages. The two decoders predict each token in parallel and keep interaction with each other, which can be formalized as follows:

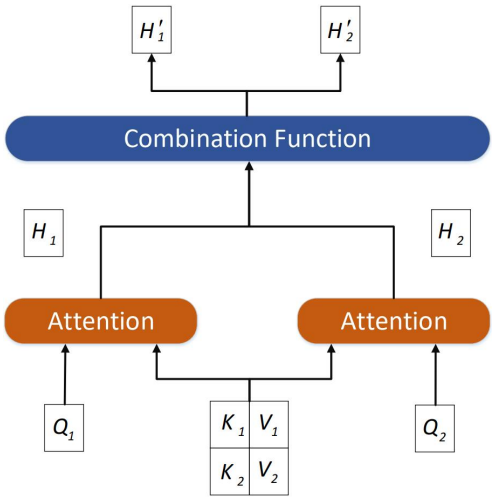

Figure 2: The synchronous self-attention framework, which simultaneously operates on the keys, queries and values of two different decoders.

$$\log P(\boldsymbol{y}^1|\boldsymbol{x}) = \log \prod_{i=0}^{n-1} p(y_i^1|\boldsymbol{x}, y_0^1, \ldots, y_{i-1}^1, y_0^2, \ldots, y_{i-1}^2)$$
$$\log P(\boldsymbol{y}^2|\boldsymbol{x}) = \log \prod_{i=0}^{n-1} p(y_i^2|\boldsymbol{x}, y_0^2, \ldots, y_{i-1}^2, y_0^1, \ldots, y_{i-1}^1) \quad (2)$$

where $\boldsymbol{x}$ is source sentence, $\boldsymbol{y}^1, \boldsymbol{y}^2$ are target sentences corresponding to two different languages. At time-step i, we have generated the first $i-1$ tokens of language-1 $\boldsymbol{y}^1$ and the first $i-1$ tokens of language-2 $\boldsymbol{y}^2$. Then both languages predictions can be utilized together with source sentence to generate tokens y_i^1 and y_i^2. This interaction between two languages is realized by synchronous attention model, which will be detailed in the following subsection.

It should be noted that the two language sentences can be generated in different directions (Liu et al., 2016; Zhang et al., 2018; Zhou et al., 2019), which means language-1 can be produced in left-to-right (L2R) manner while language-2 in right-to-left (R2L) manner. We will analyze the effect of different decoding manners in Sec. 5.2.

3.2 Synchronous Attention Model

Synchronous attention model (SyncAtt) is shown in Figure 2, in which inputs of two decoders contain queries (Q_1, Q_2), keys (K_1, K_2), and values (V_1, V_2) separately. The new hidden states (H_i') can be computed by our proposed synchronous atten-

tion as follows:

$$\begin{aligned} H_1^{'} &= \text{SyncAtt}\,(Q_1, [K_1; K_2], [V_1; V_2]) \\ H_2^{'} &= \text{SyncAtt}\,(Q_2, [K_1; K_2], [V_1; V_2]) \end{aligned} \tag{3}$$

where synchronous attention model (SyncAtt) can be described in detail:

$$\begin{aligned} H_1 &= \text{Attention}\,(Q_1, K_1, V_1) \\ \widetilde{H}_1 &= \text{Attention}\,(Q_1, K_2, V_2) \\ H_2 &= \text{Attention}\,(Q_2, K_2, V_2) \\ \widetilde{H}_2 &= \text{Attention}\,(Q_2, K_1, V_1) \\ H_1^{'} &= f(H_1; \widetilde{H}_1) = H_1 + \lambda \times \tanh(\widetilde{H}_1) \\ H_2^{'} &= f(H_2; \widetilde{H}_2) = H_2 + \lambda \times \tanh(\widetilde{H}_2) \end{aligned} \tag{4}$$

where λ is a balance weight of hidden states between two decoders decided by development set.

We apply our synchronous attention model to replace self-attention sub-layer in Transformer decoder, and it also utilizes the residual connections (He et al., 2016) around each sub-layer, followed by layer normalization (Ba et al., 2016).

3.3 Training

Since our synchronous method decodes two languages at the same time, the different decoders can be optimized simultaneously.

Supposing we have the trilingual datasets $\boldsymbol{D} = \{(\boldsymbol{x}, \boldsymbol{y}^1, \boldsymbol{y}^2)\}$, the objective function is to maximize the log-likelihood over the two target sentences:

$$L(\boldsymbol{\theta}) = \sum_{(\boldsymbol{x},\boldsymbol{y}^1,\boldsymbol{y}^2)\in D} \Big(\sum_{i=1}^{|y_i^1|} \log P(y_i^1|\boldsymbol{x}) + \sum_{i=1}^{|y_i^2|} \log P(y_i^2|\boldsymbol{x})\Big) \tag{5}$$

When calculating $P(y_i^1|\boldsymbol{x})$, except for the context from source side $\boldsymbol{x}$, our synchronous method employs not only previous reference $y_{<i}^1$ as condition, but the previous context of the other decoder reference $y_{<i}^2$. The calculation process of $P(y_i^2|\boldsymbol{x})$ is similar.

However, the practical situation is that the triple data is limited and hard to be collected. In this work, we construct the trilingual training corpus by data augmenting method (Sennrich et al., 2016a; Zhang and Zong, 2016). To achieve this, we first learn two independent translation models **Model-1** and **Model-2** on the bilingual training data $(\boldsymbol{x}^1, \boldsymbol{y}^1)$ and $(\boldsymbol{x}^2, \boldsymbol{y}^2)$ separately. Then, **Model-1** and **Model-2** are employed to decode the input sentences $\boldsymbol{x}^2$ and $\boldsymbol{x}^1$, resulting in pseudo training data $(\boldsymbol{x}^2, \boldsymbol{y}^{1\star})$ and $(\boldsymbol{x}^1, \boldsymbol{y}^{2\star})$, respectively. Thus, we can obtain the triple parallel training data $\boldsymbol{D} = \{(\boldsymbol{x}^1, \boldsymbol{y}^1, \boldsymbol{y}^{2\star})\} \cup \{(\boldsymbol{x}^2, \boldsymbol{y}^{1\star}, \boldsymbol{y}^2)\}$, which can be used to train our synchronous translation model mentioned above.

4 Experimental Settings

4.1 Data

We evaluate our proposed synchronous method on two translation tasks, which include English→Chinese/Japanese (briefly, En→Zh/Ja) and English→German/French (briefly, En→De/Fr) on IWSLT[1] datasets. The *IWSLT.TED.tst2013* and *IWSLT.TED.tst2014* are employed as devlopment set and test set respectively. Besides, we also perform En→De/Fr translation in large scale WMT14[2] datasets. We use *newstest2014* as test set.

En→Zh/Ja: For this translation task, the training sets of En→Zh and En→Ja consist of 231K, 223K sentence pairs. We tokenize the English sentences using a script from Moses (Koehn et al., 2007), and we segment Chinese and Japanese data by *jieba*[3] and *mecab*[4]. We use BPE method (Sennrich et al., 2016b) to encode the source side sentences and the combination of target side sentences respectively and limit the vocabularies of both sides to the most frequent 10k tokens.

En→De/Fr: We conduct this translation task on two different settings. One setting is using training set of IWSLT datasets which contains 206K sentence pairs for En→De and 233K sentence pairs for En→Fr. We follow the common practice to tokenize and lowercase all words. Sentences are encoded using BPE, which has a shared vocabulary of 10K tokens. At last, we construct pseudo triple data by the method described in Sec. 3.3. For the other setting, we extract the trilingual subset in WMT14 inspired by Zoph and Knight (2016), which includes about 2.43M sentence triples. We use 37K shared BPE tokens as vocabulary.

4.2 Training Details

We implement our synchronous translation based on the tensor2tensor[5] library. We train our models using the configuration *transformer_base* adopted

by Vaswani et al. (2017), which contains a 6-layer encoder and a 6-layer decoder with 512-dimensional hidden representations. During training, each mini-batch contains roughly 4,096 tokens for both source and target sides. We use Adam optimizer (Kingma and Ba, 2014) with β_1=0.9, β_2=0.98, and ϵ=10^{-9}. For decoding, we set beam size to be $k = 4$ and length penalty $\alpha = 0.6$. All our methods are trained and tested on single Nvidia P40 GPU.

We investigate the impact of different λs in our synchronous attention model. As shown in Table 1, when λ=0.1, the translation results perform best on development set for both En→Zh/Ja and En→De/Fr tasks, and we will use this setting in the subsequent experiments.

5 Results and Analysis

The translation performance of IWSLT datasets is evaluated by case-insensitive BLEU4 (Papineni et al., 2002) for En→De/Fr task and character-level BLEU5 for En→Zh/Ja task. For WMT14 datasets, we calculate the case-sensitive BLEU4 the same as previous work. In our experiments, the NMT models trained on individual language pair are denoted by *Indiv*.

5.1 Results on IWSLT

Table 2 shows the main translation results of En→Zh/Ja and En→De/Fr on IWSLT datasets. We also conduct a typical one-to-many translation adopting Johnson et al. (2017) method on Transformer as our another baseline model, referred to *Multi*. Compared with *Indiv*, we can see that *Multi* achieves better results on all cases, which can be attributed to that the encoder can be enhanced by extra training data from the other language pair.

As for our proposed method, the synchronous translation method performs significantly better than both *Indiv* and *Multi* baseline methods, and it can achieve the improvements up to 2.75 BLEU points (19.31 vs. 16.56) on En→Ja.

To perform synchronous translation, the triple parallel corpus contains pseudo training data we construct. For a fair comparison, we also conduct our baseline methods on the training sentences augmented by the pseudo corpus. From row 2 and row 4 in Table 2, our method achieves better performance than both *Multi + pseudo* method and *Indiv + pseudo* method with gains of 0.82 BLEU and 1.09 points on average, which demonstrates the effectiveness of our method.

5.2 L2R or R2L Manner

As described in Sec. 3.1, two target languages can be generated in L2R or R2L manner, which can provide the future contexts for each other. We further conduct an experiment to investigate different decoding manners in this work.

Figure 3 reports the results. We observe that when performing En→De/Fr translation, one language generated from R2L manner is helpful for the other language but do harm to itself. However, for En→Zh/Ja translation, Japanese can achieve improvements on both L2R and R2L decoding settings. The reason is that Japanese is suited for translating from right-to-left manner, and it can take advantage of future outputs from Chinese.

5.3 Results on WMT

We also employ our method on the real triple training datasets, which can be collected from WMT14 En→De/Fr datasets as described in Sec. 4.1. From Table 3, we observe that our method consistently outperforms baseline models. Note that in contrast to results on IWSLT datasets, *Multi* can not perform on par with *Indiv*, because the source side data for two language pairs are the same, and encoder network can not be enhanced as *Multi* method in Sec. 5.1.

Moreover, we construct a large scale pseudo

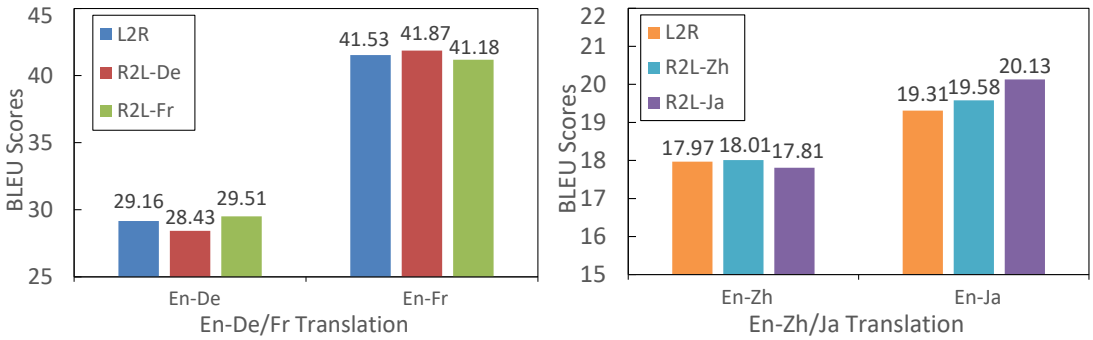

Figure 3: The comparison of L2R and R2L decoding manners, in which one of target languages generated from R2L manner.

Method	WMT14 (2.43M)		WMT14 (4.50M)
	En-De	En-Fr	En-De
Indiv	24.33	37.12	26.53
Multi	23.46	36.33	25.81
SyncTrans	**24.84**$^{\dagger *}$	**37.66**$^{\dagger *}$	**27.01**$^{\dagger *}$

Table 3: Translation quality of En-De/Fr on WMT14 datasets. The significance values with respect to the baseline method *Indiv* and *Multi* method are denoted by "$*$" and "†" respectively, indicating our proposed *SyncTrans* significantly better than both *Indiv* ($p < 0.05$) and *Multi* ($p < 0.01$) methods.

triple data about 4.5M[6]. The result is demonstrated in the last column of Table 3, in which our synchronous method performs better than the baseline methods as well.

6 Conclusion

In this paper, we propose an interactive decoding algorithm to generate two target languages simultaneously and interactively. The empirical experiments on four language pairs demonstrate that our approach can obtain significant improvements over both the NMT model trained on individual language pair and multilingual NMT model. For the future work, we plan to extend our method on more than two target languages and explore other effective interactive approaches to improve the translation quality further.

On NMT Search Errors and Model Errors: Cat Got Your Tongue?

Abstract

We report on search errors and model errors in neural machine translation (NMT). We present an exact inference procedure for neural sequence models based on a combination of beam search and depth-first search. We use our exact search to find the global best model scores under a Transformer base model for the entire WMT15 English-German test set. Surprisingly, beam search fails to find these global best model scores in most cases, even with a very large beam size of 100. For more than 50% of the sentences, the model in fact assigns its global best score to the empty translation, revealing a massive failure of neural models in properly accounting for adequacy. We show by constraining search with a minimum translation length that at the root of the problem of empty translations lies an inherent bias towards shorter translations. We conclude that vanilla NMT in its current form requires just the right amount of beam search errors, which, from a modelling perspective, is a highly unsatisfactory conclusion indeed, as the model often prefers an empty translation.

1 Introduction

Neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015, NMT) assigns the probability $P(\mathbf{y}|\mathbf{x})$ of a translation $\mathbf{y} = y_1^J \in \mathcal{T}^J$ of length J over the target language vocabulary $\mathcal{T}$ for a source sentence $\mathbf{x} \in \mathcal{S}^I$ of length I over the source language vocabulary $\mathcal{S}$ via a left-to-right factorization using the chain rule:

$$\log P(\mathbf{y}|\mathbf{x}) = \sum_{j=1}^{J} \log P(y_j|y_1^{j-1}, \mathbf{x}). \quad (1)$$

The task of finding the most likely translation $\hat{\mathbf{y}} \in \mathcal{T}^*$ for a given source sentence $\mathbf{x}$ is known as the *decoding* or *inference* problem:

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y} \in \mathcal{T}^*} P(\mathbf{y}|\mathbf{x}). \quad (2)$$

The NMT search space is vast as it grows exponentially with the sequence length. For example, for a common vocabulary size of $|\mathcal{T}| = 32,000$, there are already more possible translations with 20 words or less than atoms in the observable universe ($32,000^{20} \gg 10^{82}$). Thus, complete enumeration of the search space is impossible. The size of the NMT search space is perhaps the main reason why – besides some preliminary studies (Niehues et al., 2017; Stahlberg et al., 2018b; Ott et al., 2018) – analyzing search errors in NMT has received only limited attention. To the best of our knowledge, none of the previous studies were able to quantify the number of search errors in unconstrained NMT due to the lack of an exact inference scheme that – although too slow for practical MT – guarantees to find the global best model score for analysis purposes.

In this work we propose such an exact decoding algorithm for NMT that exploits the monotonicity of NMT scores: Since the conditional log-probabilities in Eq. 1 are always negative, partial hypotheses can be safely discarded once their score drops below the log-probability of any *complete* hypothesis. Using our exact inference scheme we show that beam search does not find the global best model score for more than half of the sentences. However, these *search* errors, paradoxically, often prevent the decoder from suffering from a frequent but very serious *model* error in NMT, namely that the empty hypothesis often gets the global best model score. Our findings suggest a reassessment of the amount of model and search errors in NMT, and we hope that they will spark new efforts in improving NMT modeling capabilities, especially in terms of adequacy.

*Now at Google.

Algorithm 1 BeamSearch($\mathbf{x}, n \in \mathbb{N}_+$)

Input: $\mathbf{x}$: Source sentence, n: Beam size

1: $\mathcal{H}_{cur} \leftarrow \{(\epsilon, 0.0)\}$ {Initialize with empty translation prefix and zero score}
2: **repeat**
3: $\quad\mathcal{H}_{next} \leftarrow \emptyset$
4: $\quad$**for all** $(\mathbf{y}, p) \in \mathcal{H}_{cur}$ **do**
5: $\quad\quad$**if** $y_{|\mathbf{y}|} = < /\mathtt{s} >$ **then**
6: $\quad\quad\quad\mathcal{H}_{next} \leftarrow \mathcal{H}_{next} \cup \{(\mathbf{y}, p)\}$ {Hypotheses ending with $< /\mathtt{s} >$ are not expanded}
7: $\quad\quad$**else**
8: $\quad\quad\quad\mathcal{H}_{next} \leftarrow \mathcal{H}_{next} \cup \bigcup_{w \in \mathcal{T}} (\mathbf{y} \cdot w, p + \log P(w|\mathbf{x}, \mathbf{y}))$ {Add all possible continuations}
9: $\quad\quad$**end if**
10: $\quad$**end for**
11: $\quad\mathcal{H}_{cur} \leftarrow \{(\mathbf{y}, p) \in \mathcal{H}_{next} : |\{(\mathbf{y}', p') \in \mathcal{H}_{next} : p' > p\}| < n\}$ {Select n-best}
12: $\quad(\tilde{\mathbf{y}}, \tilde{p}) \leftarrow \arg\max_{(\mathbf{y}, p) \in \mathcal{H}_{cur}} p$
13: **until** $\tilde{y}_{|\tilde{\mathbf{y}}|} = < /\mathtt{s} >$
14: **return** $\tilde{\mathbf{y}}$

Algorithm 2 DFS($\mathbf{x}, \mathbf{y}, p \in \mathbb{R}, \gamma \in \mathbb{R}$)

Input: $\mathbf{x}$: Source sentence
$\mathbf{y}$: Translation prefix (default: ϵ)
p: $\log P(\mathbf{y}|\mathbf{x})$ (default: 0.0)
γ: Lower bound

1: **if** $y_{|\mathbf{y}|} = < /\mathtt{s} >$ **then**
2: $\quad$**return** $(\mathbf{y}, p)$ {Trigger γ update}
3: **end if**
4: $\tilde{\mathbf{y}} \leftarrow \perp$ {Initialize $\tilde{\mathbf{y}}$ with dummy value}
5: **for all** $w \in \mathcal{T}$ **do**
6: $\quad p' \leftarrow p + \log P(w|\mathbf{x}, \mathbf{y})$
7: $\quad$**if** $p' \geq \gamma$ **then**
8: $\quad\quad(\mathbf{y}', \gamma') \leftarrow \text{DFS}(\mathbf{x}, \mathbf{y} \cdot w, p', \gamma)$
9: $\quad\quad$**if** $\gamma' > \gamma$ **then**
10: $\quad\quad\quad(\tilde{\mathbf{y}}, \gamma) \leftarrow (\mathbf{y}', \gamma')$
11: $\quad\quad$**end if**
12: $\quad$**end if**
13: **end for**
14: **return** $(\tilde{\mathbf{y}}, \gamma)$

2 Exact Inference for Neural Models

Decoding in NMT (Eq. 2) is usually tackled with beam search, which is a time-synchronous approximate search algorithm that builds up hypotheses from left to right. A formal algorithm description is given in Alg. 1. Beam search maintains a set of active hypotheses $\mathcal{H}_{cur}$. In each iteration, all hypotheses in $\mathcal{H}_{cur}$ that do not end with the end-of-sentence symbol $< /\mathtt{s} >$ are expanded and collected in $\mathcal{H}_{next}$. The best n items in $\mathcal{H}_{next}$ constitute the set of active hypotheses $\mathcal{H}_{cur}$ in the next iteration (line 11 in Alg. 1), where n is the beam size. The algorithm terminates when the best hypothesis in $\mathcal{H}_{cur}$ ends with the end-of-sentence symbol $< /\mathtt{s} >$. Hypotheses are called *complete* if they end with $< /\mathtt{s} >$ and *partial* if they do not.

Beam search is the ubiquitous decoding algorithm for NMT, but it is prone to search errors as the number of active hypotheses is limited by n. In particular, beam search never compares partial hypotheses of different lengths with each other. As we will see in later sections, this is one of the main sources of search errors. However, in many cases, the model score found by beam search is a reasonable approximation to the global best model score. Let γ be the model score found by beam search ($\tilde{p}$ in line 12, Alg. 1), which is a lower bound on the global best model score: $\gamma \leq \log P(\hat{\mathbf{y}}|\mathbf{x})$. Furthermore, since the conditionals $\log P(y_j|y_1^{j-1}, \mathbf{x})$ in Eq. 1 are log-probabilities and thus non-positive, expanding a partial hypothesis is guaranteed to result in a lower model score, i.e.:[1]

$$\forall j \in [2, J] : \log P(y_1^{j-1}|\mathbf{x}) > \log P(y_1^j|\mathbf{x}). \quad (3)$$

Consequently, when we are interested in the global best hypothesis $\hat{\mathbf{y}}$, we only need to consider partial hypotheses with scores greater than γ. In our exact decoding scheme we traverse the NMT search space in a depth-first order, but cut off branches along which the accumulated model score falls below γ. During depth-first search (DFS), we update γ when we find a better complete hypothesis.

[1] Equality in Eq. 3 is impossible since probabilities are modeled by the neural model via a softmax function which never predicts a probability of *exactly* 1.

Alg. 2 specifies the DFS algorithm formally. An important detail is that elements in $\mathcal{T}$ are ordered such that the loop in line 5 considers the $< /\mathtt{s} >$ token first. This often updates γ early on and leads to better pruning in subsequent recursive calls.[2]

Exact inference under length constraints Our admissible pruning criterion based on γ relies on the fact that the model score of a (partial) hypothesis is always lower than the score of any of its translation prefixes. While this monotonicity condition is true for vanilla NMT (Eq. 3), it does not hold for methods like length normalization (Jean et al., 2015; Boulanger-Lewandowski et al., 2013; Wu et al., 2016) or word rewards (He et al., 2016): Length normalization gives an advantage to longer hypotheses by dividing the score by the sentence length, while a word reward directly violates monotonicity as it rewards each word with a positive value. In Sec. 4 we show how our exact search can be extended to handle arbitrary length models (Murray and Chiang, 2018; Huang et al., 2017; Yang et al., 2018) by introducing length dependent lower bounds γ_k and report initial findings on exact search under length normalization. However, despite being of practical use, methods like length normalization and word penalties are rather heuristic as they do not have any justification from a probabilistic perspective. They also do not generalize well as (without retuning) they often work only for a specific beam size. It would be much more desirable to fix the length bias in the NMT model itself.

3 Results without Length Constraints

We conduct all our experiments in this section on the entire English-German WMT `news-test2015` test set (2,169 sentences) with a Transformer base (Vaswani et al., 2017) model trained with Tensor2Tensor (Vaswani et al., 2018) on parallel WMT18 data excluding ParaCrawl. Our pre-processing is as described by Stahlberg et al. (2018a) and includes joint subword segmentation using byte pair encoding (Sennrich et al., 2016) with 32K merges. We report cased BLEU scores.[3] An open-source implementation of our exact inference scheme is available in the SGNMT decoder (Stahlberg et al., 2017, 2018b).[4]

Search	BLEU	Ratio	#Search errors	#Empty
Greedy	29.3	1.02	73.6%	0.0%
Beam-10	30.3	1.00	57.7%	0.0%
Exact	2.1	0.06	0.0%	51.8%

Table 1: NMT with exact inference. In the absence of search errors, NMT often prefers the empty translation, causing a dramatic drop in length ratio and BLEU.

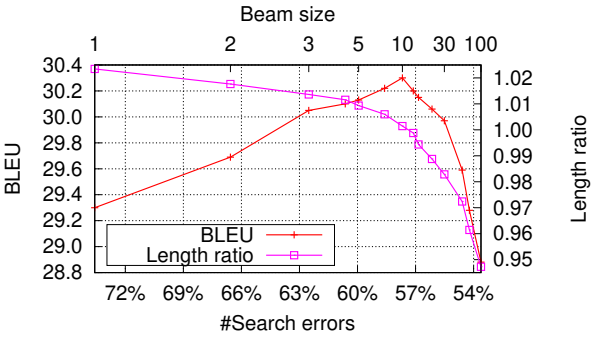

Figure 1: BLEU over the percentage of search errors. Large beam sizes yield fewer search errors but the BLEU score suffers from a length ratio below 1.

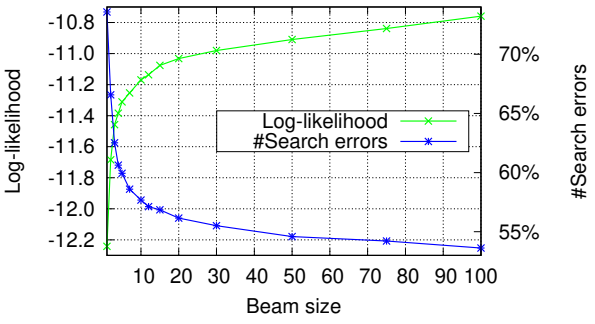

Figure 2: Even large beam sizes produce a large number of search errors.

Our main result is shown in Tab. 1. Greedy and beam search both achieve reasonable BLEU scores but rely on a high number of search errors[5] to not be affected by a serious NMT model error: For 51.8% of the sentences, NMT assigns the global best model score to the empty translation, i.e. a single $< /\mathtt{s} >$ token. Fig. 1 visualizes the relationship between BLEU and the number of search errors. Large beam sizes reduce the number of search errors, but the BLEU score drops because translations are too short. Even a large beam size of 100 produces 53.62% search errors. Fig. 2 shows that beam search effectively reduces search

[2]Note that the order in which the for-loop in line 5 of Alg. 2 iterates over $\mathcal{T}$ may be important for efficiency but does not affect the correctness of the algorithm.

[3]Comparable with `http://matrix.statmt.org/`

[4]`http://ucam-smt.github.io/sgnmt/html/`, `simpledfs` decoding strategy.

[5]A sentence is classified as search error if the decoder does not find the global best model score.

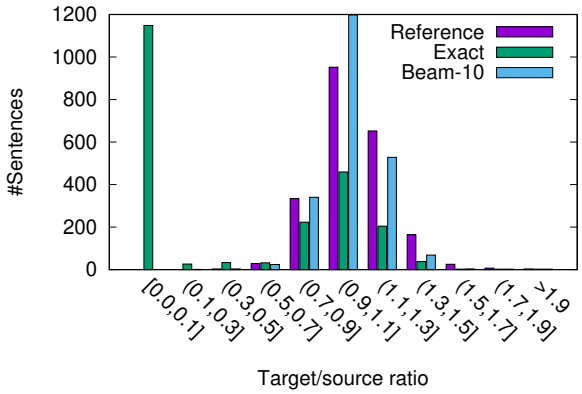

Figure 3: Histogram over target/source length ratios.

Model	Beam-10 BLEU	Beam-10 #Search err.	Exact #Empty
LSTM*	28.6	58.4%	47.7%
SliceNet*	28.8	46.0%	41.2%
Transformer-Base	30.3	57.7%	51.8%
Transformer-Big*	31.7	32.1%	25.8%

Table 2: *: The recurrent LSTM, the convolutional SliceNet (Kaiser et al., 2017), and the Transformer-Big systems are strong baselines from a WMT'18 shared task submission (Stahlberg et al., 2018a).

errors with respect to greedy decoding to some degree, but is ineffective in reducing search errors even further. For example, Beam-10 yields 15.9% fewer search errors (absolute) than greedy decoding (57.68% vs. 73.58%), but Beam-100 improves search only slightly (53.62% search errors) despite being 10 times slower than beam-10.

The problem of empty translations is also visible in the histogram over length ratios (Fig. 3). Beam search – although still slightly too short – roughly follows the reference distribution, but exact search has an isolated peak in $[0.0, 0.1]$ from the empty translations.

Tab. 2 demonstrates that the problems of search errors and empty translations are not specific to the

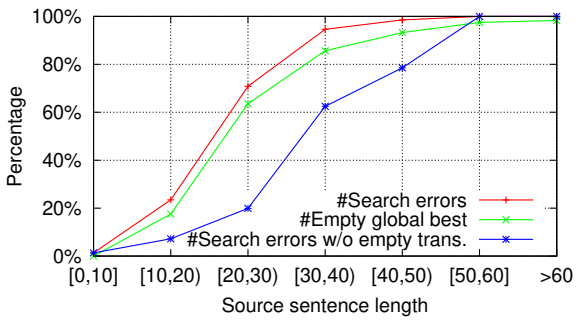

Figure 4: Number of search errors under Beam-10 and empty global bests over the source sentence length.

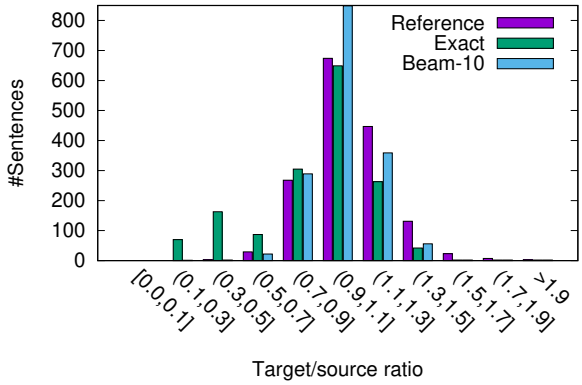

Figure 5: Histogram over length ratios with minimum translation length constraint of 0.25 times the source sentence length. Experiment conducted on 73.0% of the test set.

Transformer base model and also occur with other architectures. Even a highly optimized Transformer Big model from our WMT18 shared task submission (Stahlberg et al., 2018a) has 25.8% empty translations.

Fig. 4 shows that long source sentences are more affected by both beam search errors and the problem of empty translations. The global best translation is empty for almost all sentences longer than 40 tokens (green curve). Even without sentences where the model prefers the empty translation, a large amount of search errors remain (blue curve).

4 Results with Length Constraints

To find out more about the length deficiency we constrained exact search to certain translation lengths. Constraining search that way increases the run time as the γ-bounds are lower. Therefore, all results in this section are conducted on only a subset of the test set to keep the runtime under control.[6] We first constrained search to translations longer than 0.25 times the source sentence length and thus excluded the empty translation from the search space. Although this mitigates the problem slightly (Fig. 5), it still results in a peak in the $(0.3, 0.5]$ cluster. This suggests that the problem of empty translations is the consequence of an inherent model bias towards shorter hypotheses and cannot be fixed with a length constraint.

We then constrained exact search to either the

[6]We stopped decoding if the decoder took longer than a day for a single sentence on a single CPU. Exact search *without* length constraints is much faster and does not need maximum execution time limits.

Search	BLEU	Ratio
Beam-10	37.0	1.00
Exact for Beam-10 length	37.0	1.00
Exact for reference length	37.9	1.01

Table 3: Exact search under length constraints. Experiment conducted on 48.3% of the test set.

Search	W/o length norm.		With length norm.	
	BLEU	Ratio	BLEU	Ratio
Beam-10	37.0	1.00	36.3	1.03
Beam-30	36.7	0.98	36.3	1.04
Exact	27.2	0.74	36.4	1.03

Table 4: Length normalization fixes translation lengths, but prevents exact search from matching the BLEU score of Beam-10. Experiment conducted on 48.3% of the test set.

length of the best Beam-10 hypothesis or the reference length. Tab. 3 shows that exact search constrained to the Beam-10 hypothesis length does not improve over beam search, suggesting that any search errors between beam search score and global best score for that length are insignificant enough so as not to affect the BLEU score. The oracle experiment in which we constrained exact search to the correct reference length (last row in Tab. 3) improved the BLEU score by 0.9 points.

A popular method to counter the length bias in NMT is *length normalization* (Jean et al., 2015; Boulanger-Lewandowski et al., 2013) which simply divides the sentence score by the sentence length. We can find the global best translations under length normalization by generalizing our exact inference scheme to *length dependent* lower bounds γ_k. The generalized scheme[7] finds the best model scores for each translation length k in a certain range (e.g. zero to 1.2 times the source sentence length). The initial lower bounds are derived from the Beam-10 hypothesis $\mathbf{y}_{\text{beam}}$ as follows:[8]

$$\gamma_k = (k+1)\frac{\log P(\mathbf{y}_{\text{beam}}|\mathbf{x})}{|\mathbf{y}_{\text{beam}}|+1}. \quad (4)$$

Exact search under length normalization does not suffer from the length deficiency anymore (last row in Tab. 4), but it is not able to match our best BLEU score under Beam-10 search. This suggests that while length normalization biases search towards translations of roughly the correct length, it does not fix the fundamental modelling problem.

[7] Available in our SGNMT decoder (Stahlberg et al., 2017, 2018b) as `simplelendfs` strategy.

[8] We add 1 to the lengths to avoid division by zero errors.

5 Related Work

Other researchers have also noted that large beam sizes yield shorter translations (Koehn and Knowles, 2017). Sountsov and Sarawagi (2016) argue that this model error is due to the locally normalized maximum likelihood training objective in NMT that underestimates the margin between the correct translation and shorter ones if trained with regularization and finite data. A similar argument was made by Murray and Chiang (2018) who pointed out the difficulty for a locally normalized model to estimate the "budget" for all remaining (longer) translations. Kumar and Sarawagi (2019) demonstrated that NMT models are often poorly calibrated, and that that can cause the length deficiency. Ott et al. (2018) argued that uncertainty caused by noisy training data may play a role. Chen et al. (2018) showed that the consistent best string problem for RNNs is decidable. We provide an alternative DFS algorithm that relies on the monotonic nature of model scores rather than consistency, and that often converges in practice.

To the best of our knowledge, this is the first work that reports the exact number of search errors in NMT as prior work often relied on approximations, e.g. via n-best lists (Niehues et al., 2017) or constraints (Stahlberg et al., 2018b).

6 Conclusion

We have presented an exact inference scheme for NMT. Exact search may not be practical, but it allowed us to discover deficiencies in widely used NMT models. We linked deteriorating BLEU scores of large beams with the reduction of search errors and showed that the model often prefers the empty translation – an evidence of NMT's failure to properly model adequacy. Our investigations into length constrained exact search suggested that simple heuristics like length normalization are unlikely to remedy the problem satisfactorily.

"Going on a vacation" takes longer than *"Going for a walk"*: A Study of Temporal Commonsense Understanding

Abstract

Understanding time is crucial for understanding events expressed in natural language. Because people rarely say the obvious, it is often necessary to have commonsense knowledge about various temporal aspects of events, such as duration, frequency, and temporal order. However, this important problem has so far received limited attention. This paper systematically studies this *temporal commonsense* problem. Specifically, we define five classes of temporal commonsense, and use crowdsourcing to develop a new dataset, MCTACO 🌮, that serves as a test set for this task. We find that the best current methods used on MCTACO are still far behind human performance, by about 20%, and discuss several directions for improvement. We hope that the new dataset and our study here can foster more future research on this topic.[1]

1 Introduction

Natural language understanding requires the ability to reason with *commonsense* knowledge (Schubert, 2002; Davis, 2014), and the last few years have seen significant amount of work in this direction (e.g., Zhang et al. (2017); Bauer et al. (2018); Tandon et al. (2018)). This work studies a specific type of commonsense: *temporal commonsense*. For instance, given two events *"going on a vacation"* and *"going for a walk,"* most humans would know that a vacation is typically longer and occurs less often than a walk, but it is still challenging for computers to understand and reason about temporal commonsense.

[ ] every day [ ] every month
[x] every 4 years [ ] every 100 years
Reasoning type: *event frequency*

Figure 1: Five types of temporal commonsense in MCTACO. Note that a question may have *multiple* correct answers.

Temporal commonsense has received limited attention so far. **Our first contribution** is that, to the best of our knowledge, we are the first to systematically study and quantify performance on a range of temporal commonsense phenomena. Specifically, we consider five temporal properties: *duration* (how long an event takes), *temporal ordering* (typical order of events), *typical time* (when an event happens), *frequency* (how often an event occurs), and *stationarity* (whether a state holds for a very long time or indefinitely). Previous work has investigated some of these aspects, either explicitly or implicitly (e.g., duration (Gusev et al., 2011; Williams, 2012) and ordering (Chklovski and Pantel, 2004; Ning et al., 2018b)), but none of them have defined or studied

[1] The dataset, annotation interfaces, guidelines, and qualification tests are available at: https://cogcomp.seas.upenn.edu/page/publication_view/882.

all aspects of temporal commonsense in a unified framework. Kozareva and Hovy (2011) defined a few temporal aspects to be investigated, but failed to quantify performances on these phenomena.

Given the lack of evaluation standards and datasets for temporal commonsense, **our second contribution** is the development of a new dataset dedicated for it, MCTACO (short for **m**ultiple **c**hoice **t**empor**a**l **co**mmon-sense). MCTACO is constructed via crowdsourcing with guidelines designed meticulously to guarantee its quality. When evaluated on MCTACO, a system receives a *sentence* providing context information, a *question* designed to require temporal commonsense knowledge, and multiple *candidate answers* (see Fig. 1; note that in our setup, more than one candidate answer can be plausible). We design the task as a binary classification: determining whether a candidate answer is *plausible* according to human commonsense, since there is no *absolute* truth here. This is aligned with other efforts that have posed commonsense as the choice of plausible alternatives (Roemmele et al., 2011). The high quality of the resulting dataset (shown in §4) also makes us believe that the notion of plausibility here is robust.

Our third contribution is that, using MCTACO as a testbed, we study the temporal commonsense understanding of the best existing NLP techniques, including *ESIM* (Chen et al., 2017), *BERT* (Devlin et al., 2019) and their variants. Results in §4 show that, despite a significant improvement over random-guess baselines, the best existing techniques are still far behind human performance on temporal commonsense understanding, indicating the need for further research in order to improve the currently limited capability to capture temporal semantics.

Measure		Value
# of unique questions		1893
# of unique question-answer pairs		13,225
avg. sentence length		17.8
avg. question length		8.2
avg. answer length		3.3
Category	# questions	avg # of candidate
event frequency	433	8.5
event duration	440	9.4
event stationarity	279	3.1
event ordering	370	5.4
event typical time	371	6.8

Table 1: Statistics of MCTACO.

2 Related Work

Commonsense has been a very popular topic in recent years and existing NLP works have mainly investigated the acquisition and evaluation of commonsense in the physical world, including but not limited to, size, weight, and strength (Forbes and Choi, 2017), roundness and deliciousness (Yang et al., 2018), and intensity (Cocos et al., 2018). In terms of "events" commonsense, Rashkin et al. (2018) investigated the intent and reaction of participants of an event, and Zellers et al. (2018) tried to select the most likely subsequent event. To the best of our knowledge, no earlier work has focused on *temporal* commonsense, although it is critical for event understanding. For instance, Ning et al. (2018c) argues that resolving ambiguous and implicit mentions of event durations in text (a specific kind of temporal commonsense) is necessary to construct the timeline of a story.

There have also been many works trying to understand time in natural language but not necessarily the commonsense understanding of time. Most recent works include the extraction and normalization of temporal expressions (Strötgen and Gertz, 2010; Lee et al., 2014), temporal relation extraction (Ning et al., 2017, 2018d), and timeline construction (Leeuwenberg and Moens, 2018). Among these, some works are implicitly on temporal commonsense, such as event durations (Williams, 2012; Vempala et al., 2018), typical temporal ordering (Chklovski and Pantel, 2004; Ning et al., 2018a,b), and script learning (i.e., what happens next after certain events) (Granroth-Wilding and Clark, 2016; Li et al., 2018). However, existing works have not studied all five types of temporal commonsense in a unified framework as we do here, nor have they developed datasets for it.

Instead of working on each individual aspect of temporal commonsense, we formulate the problem as a machine reading comprehension task in the format of selecting plausible responses with respect to natural language queries. This relates our work to a large body of work on question-answering, an area that has seen significant progress in the past few years (Clark et al., 2018; Ostermann et al., 2018; Merkhofer et al., 2018). This area, however, has mainly focused on *general* natural language comprehension tasks, while we tailor it to test a *specific* reasoning capability, which is temporal commonsense.

3 Construction of MCTACO

MCTACO is comprised of $13k$ tuples, in the form of *(sentence, question, candidate answer)*; please see examples in Fig. 1 for the five phenomena studied here and Table 1 for basic statistics of it. The sentences in those tuples are randomly selected from MultiRC (Khashabi et al., 2018) (from each of its 9 domains). For each sentence, we use crowdsourcing on Amazon Mechanical Turk to collect questions and candidate answers (both correct and wrong ones). To ensure the quality of the results, we limit the annotations to native speakers and use qualification tryouts.

Step 1: Question generation. We first ask crowdsourcers to generate questions, given a sentence. To produce questions that need temporal commonsense to answer, we require that a valid question: (a) should ask about one of the five temporal phenomena we defined earlier, and (b) should not be solved simply by a word or phrase from the original sentence. We also require crowdsourcers to provide a correct answer for each of their questions, which on one hand gives us a positive candidate answer, and on the other hand ensures that the questions are answerable at least by themselves.

Step 2: Question verification. We further ask another two crowdsourcers to check the questions generated in Step 1, i.e., (a) whether the two requirements are satisfied and (b) whether the question is grammatically and logically correct. We retain only the questions where the two annotators unanimously agree with each other and the decision generated in Step 1. For valid questions, we continue to ask crowdsourcers to give one correct answer and one incorrect answer, which we treat as a seed set to automatically generate new candidate answers in the next step.

Step 3: Candidate answer expansion. Until this stage, we have collected a small set of candidate answers (3 positive and 2 negative) for each question.[2] We automatically expand this set in three ways. First, we use a set of rules to extract numbers and quantities ("2", "once") and temporal terms (e.g. "a.m.", "1990", "afternoon", "day"), and then randomly perturb them based on a list of temporal units ("second"), adjectives ("early"), points ("a.m.") and adverbs ("always"). Examples are "2 a.m." → "3 p.m.", "1 day" → "10 days", "once a week"→ "twice a month" (more details in the appendix).

Second, we mask each individual token in a candidate answer (one at a time) and use *BERT* (Devlin et al., 2019) to predict replacements for each missing term; we rank those predictions by the confidence level of *BERT* and keep the top three.

Third, for those candidates that represent events, the previously-mentioned token-level perturbations rarely lead to interesting and diverse set of candidate answers. Furthermore, it may lead to invalid phrases (e.g., "he left the house" → "he walked the house".) Therefore, to perturb such candidates, we create a pool of $60k$ event phrases using PropBank (Kingsbury and Palmer, 2002), and perturb the candidate answers to be the most similar ones extracted by an information retrieval (*IR*) system.[3] This not only guarantees that all candidates are properly phrased, it also leads to more diverse perturbations.

We apply the above three techniques on non-"event" candidates sequentially, in the order they were explained, to expand the candidate answer set to 20 candidates per question. A perturbation technique is used, as long as the pool of candidates is still less than 20. Note there are both correct and incorrect answers in those candidates.

Step 4: Answer labeling. In this step, each (*sentence, question, answer*) tuple produced earlier is labeled by 4 crowdsourcers, with three options: "likely", "unlikely", or "invalid" (sanity check for valid tuples).[4] Different annotators may have different interpretations, yet we ensure label validity through high agreement. A tuple is kept only if all 4 annotators agree on "likely" or "unlikely". The final statistics of MCTACO is in Table 1.

4 Experiments

We assess the quality of our dataset through human annotation, and evaluate a couple of baseline systems. We create a uniform split of 30%/70% of the data to dev/test. The rationale behind this split is that, a successful system has to bring in a

[2] One positive answer from Step 1; one positive and one negative answer from each of the two annotators in Step 2.

[3] www.elastic.co

[4] We use the name "(un)likely" because commonsense decisions can be naturally ambiguous and subjective.

huge amount of world knowledge and derive commonsense understandings *prior* to the current task evaluation. We therefore believe that it is not reasonable to expect a system to be *trained* solely on this data, and we think of the development data as only providing a *definition* of the task. Indeed, the gains from our development data are marginal after a certain number of training instances. This intuition is studied and verified in Appendix A.2.

Evaluation metrics. Two question-level metrics are adopted in this work: exact match (*EM*) and *F1*. For a given candidate answer a that belongs to a question q, let $f(a;q) \in \{0,1\}$ denote the correctness of the prediction made by a fixed system (1 for correct; 0 otherwise). Additionally, let D denote the collection of questions in our evaluation set.

$$EM \triangleq \frac{\sum_{q \in D} \prod_{a \in q} f(a;q)}{|\{q \in D\}|}$$

The recall for each question q is:

$$R(q) = \frac{\sum_{a \in q} [f(a;q) = 1] \wedge [a \text{ is "likely" }]}{|\{a \text{ is "likely" } \wedge a \in q\}|}$$

Similarly, $P(q)$ and $F1(q)$ are defined. The aggregate $F1$ (across the dataset D) is the macro average of question-level $F1$'s:

$$F1 \triangleq \frac{\sum_{q \in D} F1(q)}{|\{q \in D\}|}$$

EM measures how many questions a system is able to correctly label all candidate answers, while *F1* is more relaxed and measures the average overlap between one's predictions and the ground truth.

Human performance. An expert annotator also worked on MCTACO to gain a better understanding of the human performance on it. The expert answered 100 questions (about 700 (*sentence, question, answer*) tuples) randomly sampled from the test set, and could only see a single answer at a time, with its corresponding question and sentence.

Systems. We use two state-of-the-art systems in machine reading comprehension for this task: *ESIM* (Chen et al., 2017) and *BERT* (Devlin et al., 2019). *ESIM* is an effective neural model on natural language inference. We initialize the word embeddings in *ESIM* via either *GloVe* (Pennington et al., 2014) or *ELMo* (Peters et al., 2018) to demonstrate the effect of pre-training. *BERT* is a state-of-the-art contextualized representation used for a broad range of tasks . We also add unit normalization to *BERT*, which extracts and converts temporal expressions in candidate answers to their most proper units. For example, "30 months" will be converted to "2.5 years". To the best of our knowledge, there are no other available systems for the "stationarity", "typical time", and "frequency" phenomena studied here. As for "duration" and "temporal order", there are existing systems (e.g., Vempala et al. (2018); Ning et al. (2018b)), but they cannot be directly applied to the setting in MCTACO where the inputs are natural languages.

System	*F1*	*EM*
Random	36.2	8.1
Always Positive	49.8	12.1
Always Negative	17.4	17.4
ESIM + GloVe	50.3	20.9
ESIM + ELMo	54.9	26.4
BERT	66.1	39.6
BERT + unit normalization	**69.9**	**42.7**
Human	87.1	75.8

Table 2: Summary of the performances for different baselines. All numbers are in percentages.

Experimental setting. In both *ESIM* baselines, we model the process as a sentence-pair classification task, following the *SNLI* setting in AllenNLP.[5] In both versions of *BERT*, we use the same sequence pair classification model and the same parameters as in *BERT*'s *GLUE* experiments.[6] A system receives two elements at a time: (a) the concatenation of the sentence and question, and (b) the answer. The system makes a binary prediction on each instance, "likely" or "unlikely".

Results and discussion. Table 2 compares native baselines, *ESIM*, *BERT* and their variants on the entire test set of MCTACO; it also shows human performance on the subset of 100 questions.[7] The system performances reported are based on default random seeds, and we observe a maximum

[5] https://github.com/allenai/allennlp

[6] https://github.com/huggingface/pytorch-pretrained-BERT

[7] *BERT + unit normalization* scored $F1 = 72, EM = 45$ on this subset, which is only slightly different from the corresponding number on the entire test set.

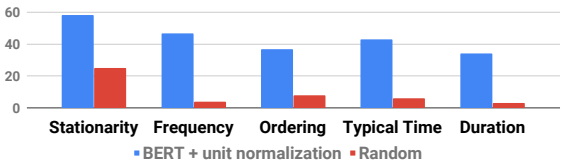

Figure 2: *EM* scores of *BERT + unit normalization* per temporal reasoning category comparing to the random-guess baseline.

standard error [8] of 0.8 from 3 runs on different seeds across all entries. We can confirm the good quality of this dataset based on the high performance of human annotators. *ELMo* and *BERT* improve naive baselines by a large margin, indicating that a notable amount of commonsense knowledge has been acquired via pre-training. However, even *BERT* still falls far behind human performance, indicating the need of further research. [9]

We know that *BERT*, as a language model, is good at associating surface forms (e.g. associating "sunrise" with "morning" since they often co-occur), but may be brittle with respect to variability of temporal mentions.

Consider the following example (the correct answers are indicated with ✓and *BERT* selections are underlined.) This is an example of *BERT* correctly associating a given event with "minute" or"hour"; however, it fails to distinguish between "1 hour" (a "likely" candidate) and "9 hours" (an "unlikely" candidate).

P: *Ratners's chairman, Gerald Ratner, said the deal remains of "substantial benefit to Ratners."*
Q: *How long did the chairman speak?*
✓(a) 30 minutes ✓(b) 1 hour
✗(c) 9 hours ✗(d) twenty seconds

This shows that *BERT* does not infer a range of true answers; it instead associates discrete terms and decides individual options, which may not be the best way to handle temporal units that involve numerical values.

BERT+unit normalization is used to address this issue, but results show that it is still poor compared to human. This indicates that the information acquired by *BERT* is still far from solving temporal commonsense.

Since exact match (EM) is a stricter metric, it is consistently lower than $F1$ in Table 2. For an ideal system, the gap between EM and $F1$ should be small (humans only drop 11.3%.) However, all other systems drop by almost 30% from $F1$ to EM, possibly another piece of evidence that they only associate surface forms instead of using one representation for temporal commonsense to classify all candidates.

A curious reader might ask why the human performance on this task as shown in Table 2 is not 100%. This is expected because commonsense is what *most* people agree on, so any *single* human could disagree with the gold labels in MCTACO. Therefore, we think the human performance in Table 2 from a single evaluator actually indicates the good quality of MCTACO.

The performance of *BERT+unit normalization* is not uniform across different categories (Fig. 2), which could be due to the different nature or quality of data for those temporal phenomena. For example, as shown in Table 1, "stationarity" questions have much fewer candidates and a higher random baseline.

5 Conclusion

This work has focused on temporal commonsense. We define five categories of questions that require temporal commonsense and develop a novel crowdsourcing scheme to generate MCTACO, a high-quality dataset for this task. We use MCTACO to probe the capability of systems on temporal commonsense understanding. We find that systems equipped with state-of-the-art language models such as *ELMo* and *BERT* are still far behind humans, thus motivating future research in this area. Our analysis sheds light on the capabilities as well as limitations of current models. We hope that this study will inspire further research on temporal commonsense.

QAInfomax: Learning Robust Question Answering System by Mutual Information Maximization

Yi-Ting Yeh Yun-Nung Chen

Abstract

Standard accuracy metrics indicate that modern reading comprehension systems have achieved strong performance in many question answering datasets. However, the extent these systems truly understand language remains unknown, and existing systems are not good at distinguishing distractor sentences, which look related but do not actually answer the question. To address this problem, we propose QAInfomax as a regularizer in reading comprehension systems by maximizing mutual information among passages, a question, and its answer. QAInfomax helps regularize the model to not simply learn the superficial correlation for answering questions. The experiments show that our proposed QAInfomax achieves the state-of-the-art performance on the benchmark Adversarial-SQuAD dataset[1].

1 Introduction

Question answering tasks are widely used for training and testing machine comprehension and reasoning (Rajpurkar et al., 2016; Joshi et al., 2017). However, high performance in standard automatic metrics has been achieved with only superficial understanding, as models exploit simple correlations in the data that happen to be predictive on most test examples. Jia and Liang (2017) addressed this problem and proposed an adversarial version of the SQuAD dataset, which was created by adding a distractor sentence to each paragraph. The distractor sentences challenge the model robustness, and the created Adversarial-SQuAD data shows the inability of a model about distinguishing a sentence that actually answers the question from one that merely has words in common with it, where almost all state-of-the-art machine comprehension systems are significantly degraded on adversarial examples.

Lewis and Fan (2018) argued that over-fitting to superficial biases is partially caused by discriminative loss functions, which saturate when simple correlations allow the question to be answered confidently, leaving no incentive for further learning on the example. Therefore, they designed generative QA models, which use a generative loss function in question answering instead, and showed the improvement on Adversarial-SQuAD.

Instead of regularizing models by generative loss functions, we propose an alternative approach named "QAInfomax" by maximizing mutual information (MI) among passages, questions, and answers, aiming at helping models be not stuck with superficial biases in the data during learning. To efficiently estimate MI, QAInfomax incorporates the recently proposed deep infomax (DIM) in the model (Hjelm et al., 2018), which was proved effective in learning representations for image, audio (Ravanelli and Bengio, 2018), and graph domains (Veličković et al., 2018). In this work, the proposed QAInfomax further extends DIM to the text domain, and encourages the question answering model to generate answers carrying information that can explain not only questions but also itself, and thus be more sensitive to distractor sentences. Our contributions are summarized:

- This paper first attempts at applying DIM-based MI estimation as a regularizer for representation learning in the NLP domain.
- The proposed QAInfomax achieves the state-of-the-art performance on the Adversarial-SQuAD dataset without additional training data, demonstrating its better robustness.

2 Mutual Information (MI) Estimation

In this section, we introduce how scalable estimation of mutual information is performed in terms

[1]The source code is publicly available at https://github.com/MiuLab/QAInfomax.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3370–3375,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of practical scenarios via mutual information neural estimation (MINE) (Belghazi et al., 2018) and the deep infomax (DIM) (Hjelm et al., 2018) described below.

The mutual information between two random variable X and Y is defined as:

$$\text{MI}(X, Y) = D_{\text{KL}}(p(X, Y) \parallel p(X)p(Y)),$$

where D_{KL} is the Kullback-Leibler (KL) divergence between the joint distribution $p(X, Y)$ and the product of marginals $p(X)p(Y)$.

MINE estimates mutual information by training a classifier to distinguish between positive samples (x, y) from the joint distribution and negative samples $(x, \bar{y})$ from the product of marginals. Mutual information neural estimation (MINE) uses Donsker-Varadhan representation (DV) (Donsker and Varadhan, 1983) as a lower-bound to estimate MI.

$$\text{MI}(X, Y) \geq \mathbb{E}_{\mathbb{P}}[g(x, y)] - \log(\mathbb{E}_{\mathbb{N}}[e^{g(x,\bar{y})}]),$$

where $\mathbb{E}_{\mathbb{P}}$ and $\mathbb{E}_{\mathbb{N}}$ denote the expectation over positive and negative samples respectively, and g is the discriminator function that outputs a real number modeled by a neural network.

While the DV representation is the strong bound of mutual information shown in MINE, we are primarily interested in maximizing MI but not focusing on its precise value. Thus DIM proposes an alternative estimation using Jensen-Shannon divergence (JS), which can be efficiently implemented using the cross-entropy (BCE) loss:

$$\begin{aligned} \text{MI}(X, Y) \quad &\geq \quad \mathbb{E}_{\mathbb{P}}[\log(g(x, y))] \\ &+ \quad \mathbb{E}_{\mathbb{N}}[\log(1 - g(x, \bar{y}))]. \end{aligned} \tag{1}$$

While two representations should behave similarly, considering that both act like classifiers with objectives maximizing the expected log-ratio of the joint over the product of marginals, it is found that the BCE loss empirically works better than the DV-based objective (Hjelm et al., 2018; Ravanelli and Bengio, 2018; Veličković et al., 2018). The reason may be that the BCE loss is bounded (i.e., its maximum is zero), making the convergence of the network more numerically stable. In our experiments, we primarily use the JS representation to estimate mutual information.

Recently, Tian et al. (2019) showed strong empirical performance through the improved multiview CPC training (Oord et al., 2018), which shares many common ideas as mutual information maximization. Inspired by their work, we modify (1) by first switching the role of x and y and summing them up:

$$\begin{aligned} \text{MI}(X, Y) \quad &\geq \quad \mathbb{E}_{\mathbb{P}}[\log(g(x, y))] \\ &+ \quad \frac{1}{2}\mathbb{E}_{\mathbb{N}}[\log(1 - g(x, \bar{y}))] \\ &+ \quad \frac{1}{2}\mathbb{E}_{\mathbb{N}}[\log(1 - g(\bar{x}, y))], \end{aligned} \tag{2}$$

where $(\bar{x}, y)$ is also the negative sample sampled from the product of marginals.

We empirically find that (2) gives the best performance, and more exploration about parameterization of MI is left as our future work.

3 Methodology

In the extractive question answering dataset like SQuAD, the answer $A = \{a_1, \ldots, a_M\}$ to the question $Q = \{q_1, \ldots, q_K\}$ is guaranteed to be the span $\{p_m, \ldots, p_{m+M}\}$ in the paragraph $P = \{p_1, \ldots, p_N\}$. Given Q and P, the encoded representations from the QA system M can be formulated as:

$$\{r^q, r^p\} = \{r^q_1, \ldots, r^q_K, r^p_1, \ldots, r^p_N\} = M(Q, P),$$

where r^q and r^p are representations of the question and the passage respectively after the reasoning process in the QA system M.

Most models then feed the passage representation r^p to a single-layer neural network, obtain the span start and end probabilities for each passage word, and compute the loss L_{span}, which is the negative sum of log probabilities of the predicted distributions indexed by true start and end indices.

Our QAInfomax aims at regularizing the QA system M to not simply exploit the superficial biases in the dataset for answering questions. Therefore, two constraints are introduced in order to guide the model learning.

1. **Local Constraint (LC)**: each answer word representation r^p_i in the answer representation $r^a = \{r^p_m, \ldots, r^p_{m+M}\}$ should contain information about what the remaining answer words and its surrounding context are.

2. **Global Constraint (GC)**: the summarized answer representation $s = S(r^a)$ should maximize the averaged mutual information to all other question representations in r^q and passage representations in r^p, where S is a summarization function described below.

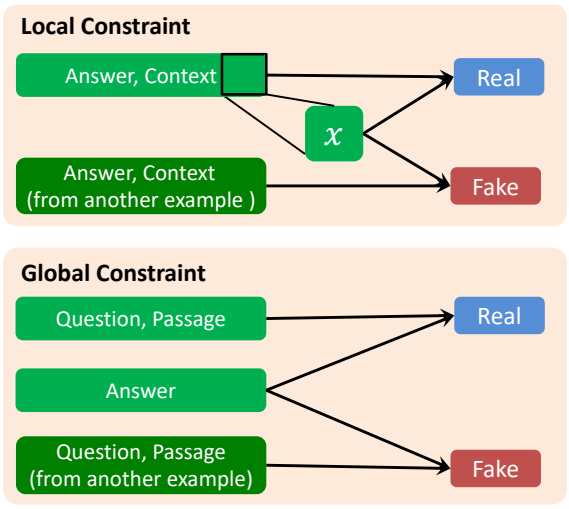

Figure 1: Illustration of the LC and GC.

Intuitively, the model is expected to *choose the answer span after fully considering the entire question and paragraph*. However, traditional QA models suffered the overstability problem, and tended to be fooled by distractor answers, such as the one containing an unrelated human name. As Lewis and Fan (2018) argued, we also believe that the main reason is that QA models are only trained to predict start and end positions of answer spans. Correlation in the dataset allows QA models to find shortcuts and ignore what the answer span looks like. A learned behavior of traditional QA models can be viewed as a simple pattern matching, such as choosing the 5-length span after the word "river" if a question is about a river and the context talks about countries in European.

Following the intuition, two constraints LC and GC are introduced to guide models to learn the desired behaviors. To prevent the model from only learning to match some specific word patterns to find the answer, LC forces the model to generate answer span representations while maximizing mutual information among words in the span and the context words surrounding the span. By maximizing the mutual information between an answer word and *all* of its context words, models need to incorporate the entire context into its decision process while choosing answers, and thus can be more robust to the adversarial sentences. Then we further require models to maximize mutual information among answer words, so models can no longer ignore any word in the chosen answer span.

On the other hand, different from LC , which only focuses on the answer span and its context, GC pushes the model to prefer answer representations carrying information that is globally shared across the whole input conditions Q and P, because shortcuts do not necessarily appear near to the answer. If the model only learns to leverage the correlation specific to the partial input, the MI of any input word without such relationship would *not* increased.

The overview about two proposed constraints is illustrated in Figure 1. The detail of two constraints and our QAInfomax regularizer is described below.

3.1 Local Constraint

As shown in Section 2, the maximization of MI needs positive samples and negative samples drawn from joint distribution and the product of marginal distribution respectively.

In LC , because all answer word representations are expected to carry the information of each other and their contexts, we choose to maximize averaged MI between the sampled answer word representations and the whole answer sequence with its context words. Specifically, a positive sample is obtained by pairing the sampled answer word representation $x \in r^a = \{r^p_m, \ldots, r^p_{m+M}\}$ to all other answer and context words $r^c = \{r^p_{m-C}, \ldots r^p_{m+M+C}\} \setminus \{x\}$, where C is the hyperparameter defining how many context words for consideration. Negative samples, on the other hand, are obtained by randomly sampling answer representation $\bar{r}^a = \{\bar{r}^p_l, \ldots, \bar{r}^p_{l+L}\}$ and the corresponding $\bar{r}^c$ from other training examples. Following (2), the objective for sampled x, r^c, $\bar{x} \in \bar{r}^a$ and $\bar{r}^c$ is formulated.

$$\begin{aligned} \mathrm{LC}(x, r^c, \bar{x}, \bar{r}^c) &= \frac{1}{|r^c|} \sum_{r^c_i \in r^c} \log(g(x, r^c_i)) \\ &+ \frac{1}{2|\bar{r}^c|} \sum_{\bar{r}^c_j \in \bar{r}^c} \log(1 - g(x, \bar{r}^c_j)) \\ &+ \frac{1}{2|r^c|} \sum_{r^c_i \in r^c} \log(1 - g(\bar{x}, r^c_i)). \end{aligned} \quad (3)$$

3.2 Global Constraint

Different from LC described above, GC forces the learned answer representations r^a to have information shared with all other question and passage representations. Here, we maximize the mutual information between the summarized answer vector $s = S(r^a)$ and $r_l \in r = \{r^q, r^p\} \setminus \{r^a\}$ pairs. In

Model	Original	ADDSENT	ADDONESENT
BiDAF-S (Seo et al., 2016)	75.5	34.3	45.7
ReasoNet-S (Shen et al., 2017)	78.2	39.4	50.3

QANet-S (Yu et al., 2018)	83.8	45.2	55.7
GQA-S (Lewis and Fan, 2018)	83.7	47.3	57.8
FusionNet-E (Huang et al., 2017)	83.6	51.4	60.7
BERT-S (Devlin et al., 2018)	88.5	51.0	63.4
BERT-S + QAInfomax	**88.6**	**54.5** †	**64.9** †

Table 1: F-measure on ADVERSARIALSQUAD (S: single, E: ensemble). † indicates the significant improvement over baselines with p-value < 0.05.

the experiments, we use $S(r^a) = \sigma(\frac{1}{M}\sum r_i^a)$ as our summarization function, where σ is the logistic sigmoid nonlinearity.

Specifically, a positive sample here is the pair of a answer summary vector $s = S(r^a)$ and all other word representations in r. Negative samples are provided by sampling question, passage and answer representations $\{\bar{r}^q, \bar{r}^p, \bar{r}^a\}$ from an alternative training example. Then we pair the summary s with $\bar{r} = \{\bar{r}^q, \bar{r}^p\} \setminus \{\bar{r}^a\}$, and $\bar{s} = S(\bar{r}^a)$ with r.

Similar to (3), the objective for the sampled s, r, $\bar{s}$ and $\bar{r}$ is:

$$\begin{aligned} \mathrm{GC}(s, r, \bar{s}, \bar{r}) &= \frac{1}{|r|}\sum_{r_i \in r} \log(g(s, r_i)) \\ &+ \frac{1}{2|\bar{r}|}\sum_{\bar{r}_j \in \bar{r}} \log((1 - g(s, \bar{r}_j))) \\ &+ \frac{1}{2|r|}\sum_{r_i \in r} \log((1 - g(\bar{s}, r_i))). \end{aligned} \tag{4}$$

3.3 QAInfomax

In our proposed model, we combine two objectives and formulate the model as the complete QAInfomax regularizer. For each training batch consisting of training examples $\{\{Q_1, P_1, A_1\}, \ldots \{Q_B, P_B, A_B\}\}$, we pass the batch into the model M and obtain representations $\{\{r_1^q, r_1^p, r_1^a\}, \ldots, \{r_B^q, r_B^p, r_B^a\}\}$. Note that we abuse the subscripts to denote the example index in the batch for simplicity.

Then we shuffle the whole batch to obtain negative examples $\{\{\bar{r}_1^q, \bar{r}_1^p, \bar{r}_1^a\}, \ldots, \{\bar{r}_B^q, \bar{r}_B^p, \bar{r}_B^a\}\}$. The complete objective L_{info} for QAInfomax becomes:

$$-\frac{1}{B}\sum_{i=1}^{B}(\alpha LC(x_i, r_i^c, \bar{x}_i, \bar{r}_i^c) + \beta GC(s_i, r_i, \bar{r}_i)),$$

where x_i and $\bar{x}_i$ are the representation sampled from r_i^a and $\bar{r}_i^a$, r_i^c and $\bar{r}_i^c$ are r_i^a and $\bar{r}_i^a$ expanded with its context words respectively, s_i and $\bar{s}_i$ are the summary vectors of r_i^a and $\bar{r}_i^a$, and α and β are hyperparameters.

Combined with QAInfomax as a regularizer, the final objective of the model becomes

$$L = L_{span} + \gamma L_{info}, \tag{5}$$

where L_{span} is the answer span prediction loss and γ is the regularize strength. The objective can be optimized through the simple gradient descent.

4 Experiments

To evaluate the effectiveness of the proposed QAInfomax, we conduct the experiments on a challenging dataset, Adversarial-SQuAD.

4.1 Setup

BERT-base (Devlin et al., 2018) is employed as our QA system M in the experiments, where we set the same hyperparameters as one released in SQuAD training[2].

We set C, α, β and γ to be 5, 1, 0.5, 0.3 respectively in all experiments, and add the proposed QAInfomax into the BERT model as described above. The discriminator function g is the bilinear function similar to the scoring used by Oord et al. (2018):

$$g(x, y) = x^T W y, \tag{6}$$

where W is a learnable scoring matrix.

We train the BERT model with the proposed QAInfomax on the orignal SQuAD dataset, and

[2]We use PyTorch (Paszke et al., 2017) reimplementation for experiments: https://github.com/huggingface/pytorch-pretrained-BERT.

Model	Adversary F1	Speed (iter/s)
BERT	51.0 / 63.4	3.80
+ LC	53.6 / 64.2	3.51
+ GC	52.2 / 63.7	2.75
+ LC + GC	**54.5 / 64.9**	2.72

Table 2: Ablation study with F1 scores on ADDSENT / ADDONESENT. The speed is measured on RTX 2080Ti.

use Adversarial-SQuAD to test the robustness of the augmented model. Only ADDSENT and ADDONESENT metrics are reported for the comparison with previous models, because most previous models did not report their ADDANY and ADDCOMMON scores. Briefly, for each example, ADDSENT runs the model M on every human-approved adversarial sentence, picks the one that makes the model give the worst answer and returns that score. ADDONESENT, on the other hand, only picks a random human-approved adversarial sentence. The numbers reported in all experiments are the best number across at least three runs.

4.2 Results

Table 1 reports model performance on Adversarial-SQuAD. It can be found that QAInfomax yields substantial improvement over the vanilla BERT model, and achieves the state-of-the-art performance on both ADDSENT and ADDONESENT metrics.[3] QAInfomax obtains larger improvement on the ADDSENT, which picks the worst scores of the model. It shows the effectiveness of our QAInfomax in terms of forcing the model to ignore simple correlation in the data and learn the more human-like reasoning processes. It is worth to note that while QAInfomax mitigates the overstability problem and improves the robustness to adversarial examples, it does not hurt the original performance of the QA system, demonstrating the benefit for the practical usage. Some example results from the Adversarial-SQuAD dataset can be found in the Appendix, where adversarial distracting sentences are shown in italic blue fonts.

Table 2 shows the ablation study of our proposed QAInfomax, where two proposed constraints are both important for achieving such results. We also show the training speed of the proposed method and its limitation, where the GC objective degrades the training speed by 28%. The reason is that GC measures the averaged MI over the *whole* question and passage representations, which may include a long sequence of vectors.

[3]Note that Wang and Bansal modified distractor paragraphs and added them into training data, so we do not compare with them, because we only use the original SQuAD training data.

Function	ADDSENT	ADDONESENT
Mean	**52.2**	**63.7**
Max	52.0	63.3
Sample	**52.2**	63.0

Table 3: Different summarization functions for GC .

Considering that the summarization function S plays an important role in GC, we explore its different variants in Table 3:

- Mean: $\sigma(\frac{1}{M}\sum r_i^a)$
- Max: $\sigma(maxpool(r^a))$
- Sample: randomly sample one $r_i^a \in r^a$

According to the experimental results, Mean performs the best while Max and Sample has the competitive performance, showing the great robustness of the proposed methods to different architecture choices.

5 Conclusion

This paper presents a novel regularizer based on MI maximization for question answering systems named QAInfomax, which helps models be not stuck with superficial correlation in the data and improves its robustness. The proposed QAInfomax is flexible to apply to different machine comprehension models. The experiments on Adversirial-SQuAD demonstrate the effectiveness of our model, and the augmented model achieves the state-of-the-art results. In the future, we will investigate more methods for reducing the limitations of QAInfomax and improving the capability of generalization in QA systems.

Abstract

Multi-hop knowledge graph (KG) reasoning is an effective and explainable method for predicting the target entity via reasoning paths in query answering (QA) task. Most previous methods assume that every relation in KGs has enough training triples, regardless of those few-shot relations which cannot provide sufficient triples for training robust reasoning models. In fact, the performance of existing multi-hop reasoning methods drops significantly on few-shot relations. In this paper, we propose a meta-based multi-hop reasoning method (Meta-KGR), which adopts meta-learning to learn effective meta parameters from high-frequency relations that could quickly adapt to few-shot relations. We evaluate Meta-KGR on two public datasets sampled from Freebase and NELL, and the experimental results show that Meta-KGR outperforms the current state-of-the-art methods in few-shot scenarios. Our code and datasets can be obtained from https://github.com/THU-KEG/MetaKGR.

1 Introduction

Recently, large-scale knowledge graphs (KGs) have been demonstrated to be beneficial for many NLP tasks like query answering (QA). A triple query for QA is generally formalized as $(e_s, r_q, ?)$, where e_s is the source entity and r_q is the query relation. For example, given a language query "*What is the nationality of Mark Twain?*", we can transform it into $(\textit{Mark Twain}, \textit{nationality}, ?)$ and then search the target entity *America* from KGs as the answer. However, as many KGs are constructed automatically and face serious incompleteness problems (Bordes et al., 2013), it is often hard to directly get target entities for queries.

To alleviate this issue, some knowledge graph embedding methods (Bordes et al., 2013; Dettmers et al., 2018) have been proposed to embed entities and relations into semantic spaces to capture inner connections, and then use the learned embeddings for final predictions. Although these embedding-based methods have shown strong abilities in predicting target entities for queries, they only give answers and lack interpretability for their decisions (Lin et al., 2018). In order to make models more intuitive, Das et al. (2018) and Lin et al. (2018) propose multi-hop reasoning methods, which leverage the symbolic compositionality of relations in KGs to achieve explainable reasoning results. For example, when queried with $(\textit{Mark Twain}, \textit{nationality}, ?)$, multi-hop reasoning models can give not only the target entity *America* but also multi-hop explainable paths $(\textit{Mark Twain}, \textit{bornIn}, \textit{Florida}) \wedge (\textit{Florida}, \textit{locatedIn}, \textit{America})$ as well.

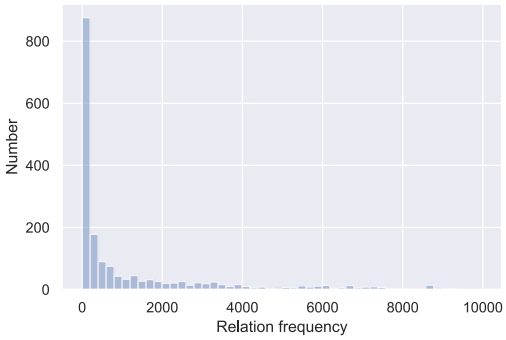

Figure 1: The histogram of relation frequency in the real-world knowledge graph Wikidata.

Most previous work assumes that there are enough triples to train an effective and robust reasoning models for each relation in KGs. However, as shown in Figure 1, a large portion of KG relations are actually long-tail (Xiong et al., 2018; Han et al., 2018) and only contain few triples, which can be called few-shot relations. Some pilot experiments show that the performance of

previous multi-hop reasoning models, e.g., MINERVA (Das et al., 2018) and MultiHop (Lin et al., 2018), on these few-shot relations will drop significantly. Note that, there are some knowledge graph embedding models (Xiong et al., 2018; Shi and Weninger, 2018; Xie et al., 2016) that can deal with zero-shot or one-shot relations, but they still have two main drawbacks: (1) they are embedding-based models and lack interpretability; (2) they focus on zero-shot or one-shot relations, which is a little far away from real-world scenes. In fact, even for people, it is hard to grasp new knowledge with almost no examples. Therefore, few-shot multi-hop reasoning is a quite important and practical problem that has not yet been fully resolved.

In this paper, we propose a meta-based algorithm for multi-hop reasoning (Meta-KGR) to address the above problems, which is explainable and effective for few-shot relations. Specifically, in Meta-KGR, we regard triple queries with the same relation r in KGs as a task. For each task, we adopt reinforcement learning (RL) to train an agent to search target entities and reasoning paths. Similar to previous meta-learning method MAML (Finn et al., 2017), we use tasks of high-frequency relations to capture meta information, which includes common features among different tasks. Then, the meta information can be rapidly adapted to the tasks of few-shot relations, by providing a good starting point to train their specific reasoning agents. In experiments, we evaluate Meta-KGR on two datasets sampled from Freebase and NELL, and the experimental results show that Meta-KGR outperforms the current state-of-the-art multi-hop reasoning methods in few-shot scenarios.

2 Problem Formulation

We formally define a KG $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{F}\}$, where $\mathcal{E}$ and $\mathcal{R}$ denote the entity and relation sets respectively. $\mathcal{F} = \{(e_s, r, e_o)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is the triple set, where $e_s, e_o \in \mathcal{E}$ are entities and $r \in \mathcal{R}$ is a relation between them. In this paper, if the number of triples mentioning a relation r is smaller than the specific threshold K, r is considered as a few-shot relation, otherwise, it is a normal relation.

Given a query $(e_s, r_q, ?)$, where e_s is the source entity and r_q is the few-shot relation, the goal of few-shot multi-hop reasoning is to predict the right entity e_o for this query. Different from the previous knowledge graph embedding work, multi-hop reasoning also gives a reasoning path from e_s to e_o over $\mathcal{G}$ to illustrate the whole reasoning process.

3 Related Work

Knowledge Graph Embedding (Bordes et al., 2013; Yang et al., 2015; Dettmers et al., 2018) aims to embed entities and relations into low-dimensional spaces, and then uses embeddings to define a score function $f(e_s, r, e_o)$ to evaluate the probability that a triple is true. Recently, several models (Xie et al., 2016; Shi and Weninger, 2018) incorporate additional entity descriptions to learn embeddings for unseen entities, which can be seen as zero-shot scenarios. Xiong et al. (2018) predict new facts under a challenging setting where only one training triple for a given relation r is available, which can be seen as a one-shot scenario. Although these models are effective, they lack interpretability for their decisions.

Multi-Hop Reasoning over KGs aims to learn symbolic inference rules from relational paths in $\mathcal{G}$ and has been formulated as sequential decision problems in recent years. DeepPath (Xiong et al., 2017) first applies RL to search reasoning paths in KGs for a given query, which inspires much later work (e.g., MINERVA (Das et al., 2018) and DIVA (Chen et al., 2018)). Because it is hard to train an RL model, ReinforceWalk (Shen et al., 2018) proposes to solve the reward sparsity problem using off-policy learning. MultiHop (Lin et al., 2018) further extends MINERVA with reward shaping and action dropout, achieveing the state-of-the-art performance. These reasoning methods are intuitive and explainable. However, all of them have a weak performance in few-shot scenarios. In addition to multi-hop reasoning over KGs, there are also some multi-hop QA methods in recent years. Yang et al. (2018) proposes a high quality dataset, which greatly promotes the development of this field. After that, many methods like CogQA (Ding et al., 2019) and DFGN (Xiao et al., 2019) are also proposed.

Meta-Learning tries to solve the problem of "fast adaptation on a new training task". It has been proved to be very successful on few-shot task (Lake et al., 2015; Gu et al., 2018). Previous meta-learning models mainly focus on computer vision and imitation learning domains. In this paper, we propose a new model (Meta-KGR) using the meta-learning algorithm MAML (Finn et al., 2017) for

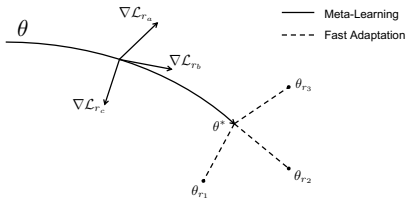

Figure 2: Meta-learning.

few-shot multi-hop reasoning. To the best of our knowledge, this work is the first research on few-shot learning for multi-hop reasoning.

4 Model

The main idea of MAML is to use a set of tasks to learn well-initialized parameters θ^* for a new task with few training examples. When applied to few-shot multi-hop reasoning, triple queries with the same relation r are considered as a task $\mathcal{T}_r$. We use triples with normal relations to find well-initialized parameters θ^* and train new models on triples with few-shot relations from the found initial parameters. As shown in Figure 2, we can easily fast adapt to new models with parameters θ_{r_1}, θ_{r_2} or θ_{r_3} for few-shot relation r_1, r_2 or r_3.

The learning framework of Meta-KGR can be divided into two parts: (1) relation-specific learning; (2) meta-learning. Relation-specific learning aims to learn a REINFORCE model with parameters θ_r for a specific relation r (task) to search target entities and reasoning paths. Meta-learning is based on relation-specific learning and is used to learn a meta-model with parameters θ^*. We will introduce these two parts in the following sections.

4.1 Relation-Specific Learning

For each query relation $r_q \in \mathcal{R}$, we learn a relation-specific multi-hop reasoning agent to search for reasoning paths and target entities over $\mathcal{G}$, which is based on the on-policy RL approach proposed by Lin et al. (2018).

4.1.1 Reinforcement Learning Formulation

The search process over $\mathcal{G}$ can be seen as a Markov Decision Process (MDP): We express $\mathcal{G}$ as a directed graph, with entities and relations as nodes and edges respectively. When given a query and its answer (e_s, r_q, e_o), we expect the agent for r_q can start from the source entity e_s and walk through several edges to reach the target entity e_o. More specifically, the MDP is defined as follows.

States The state of the t-th time step is defined as a tuple $s_t = (r_q, e_s, \hat{e}_t)$, where r_q is the query relation, e_s is the source entity and $\hat{e}_t$ is the current entity over $\mathcal{G}$.

Actions The action space $\mathcal{A}_t$ for a given state s_t includes all outgoing edges and next entities of $\hat{e}_t$. Formally, $\mathcal{A}_t = \{(r_{t+1}, \hat{e}_{t+1}) | (\hat{e}_t, r_{t+1}, \hat{e}_{t+1}) \in \mathcal{G}\}$. We add a self-loop edge to every $\mathcal{A}_t$, which is similar to a "STOP" action.

Transition For the state s_t, if the agent selects an action $(r_{t+1}, \hat{e}_{t+1}) \in \mathcal{A}_t$, the state will be changed to $s_{t+1} = (r_q, e_s, \hat{e}_{t+1})$. The transition function is defined as $\delta(s_t, \mathcal{A}_t) = (r_q, e_s, \hat{e}_{t+1})$. In this paper, we unroll the search over $\mathcal{G}$ up to a fixed number of time steps T, and finally achieve the state $s_T = (r_q, e_s, \hat{e}_T)$.

Rewards The reward $R(s_T | r_q, e_s)$ will be 1 if the agent finally stops at the right entity, i.e., $\hat{e}_T = e_o$, otherwise it will get an embedding-based reward $f(e_s, r_q, \hat{e}_T)$, where f is a score function from knowledge graph embedding methods to measure the probability over $(e_s, r_q, \hat{e}_t)$.

Algorithm 1 Meta-Learning for multi-hop reasoning over knowledge graphs

Require: $p(\mathcal{R})$: distribution over relations
Require: α, β: learning rate hyperparameters
Randomly initialize θ for meta policy network
while not stop training **do**
  Sample batch of relations $r \sim p(\mathcal{R})$
  for all relation r **do**
    Sample supporting set $\mathcal{D}_S$ and query set $\mathcal{D}_Q$ for task $\mathcal{T}_r$
    Evaluate $\nabla_\theta L_r^{\mathcal{D}_S}(\theta)$ in Eq. (3)
    Compute adapted parameters: $\theta'_r = \theta - \alpha \nabla_\theta L_r^{\mathcal{D}_S}(\theta)$
  end for
  Update $\theta \leftarrow \theta - \beta \nabla_\theta \sum_{\mathcal{T}_r} L_r^{\mathcal{D}_Q}(\theta'_r)$
end while

4.1.2 Policy Network

To solve the above MDP problem, we need a model which has policy to choose actions at each state. Specifically, different from normal RL problems, we apply a policy network considering the search history over $\mathcal{G}$. Formally, after embedding all entities and relations in $\mathcal{G}$ as $\mathbf{e} \in \mathbb{R}^d$ and $\mathbf{r} \in \mathbb{R}^d$ respectively, each action $a_t = (r_{t+1}, \hat{e}_{t+1}) \in \mathcal{A}_t$ is represented as $\mathbf{a}_t = [\mathbf{r}_{t+1}; \hat{\mathbf{e}}_{t+1}]$. We use an LSTM to encode the search path,

$$\mathbf{h}_t = \text{LSTM}(\mathbf{h}_{t-1}, \mathbf{a}_{t-1}). \quad (1)$$

Then, we represent the action space by stacking all actions in $\mathcal{A}_t$ as $\mathbf{A}_t \in \mathbb{R}^{|\mathcal{A}_t| \times 2d}$. The parameterized policy network is defined as,

$$\pi_\theta(a_t | s_t) = \text{softmax}(\mathbf{A}_t(\mathbf{W}_2 \text{ReLU}(\mathbf{W}_1[\hat{\mathbf{e}}_t; \mathbf{h}_t; \mathbf{r}_q]))), \quad (2)$$

Table 1: Experimental results for link prediction. The MRR, Hits@1 and Hits@10 metrics are multiplied by 100.

where $\pi_\theta(a_t|s_t)$ is the probability distribution over all actions in $\mathcal{A}_t$.

4.1.3 Loss Function

Given a query relation r and a batch of triples set $\mathcal{D}$ with relation r, the overall loss for this relation-specific policy network is defined as:

$$\mathcal{L}_r^{\mathcal{D}}(\theta) = -\mathbb{E}_{(e_s,r,e_o)\in\mathcal{D}}\mathbb{E}_{a_1,\ldots,a_{T-1}\in\pi_\theta}[R(s_T|e_s,r)]. \tag{3}$$

4.2 Meta-Learning

In meta-learning, we aim to learn well-initialized parameters θ^*, such that small changes in the parameters will produce significant improvements on the loss function of any task (Finn et al., 2017).

Formally, we consider a meta policy network with parameters θ. When adapting to a new task $\mathcal{T}_r$, the parameters of the model become θ'_r. Following MAML, the updated parameter θ'_r is computed using one or more gradient descent updates on task $\mathcal{T}_r$. For example, assuming a single gradient step is taken with the learning rate α

$$\theta'_r = \theta - \alpha\nabla_\theta L_r^{\mathcal{D}_S}(\theta), \tag{4}$$

where $\mathcal{D}_S$ is a supporting set randomly sampled from the triples belonging to $\mathcal{T}_r$. After the relation-specific parameters θ'_r is learned, we evaluate θ'_r on the query set $\mathcal{D}_Q$ belonging to $\mathcal{T}_r$, which is sampled like $\mathcal{D}_S$. The gradient computed from this evaluation can be used to update the meta policy network with parameters θ. Usually, we will go over many tasks in a batch and update θ as follows:

$$\theta = \theta - \beta\nabla_\theta \sum_{\mathcal{T}_r} L_r^{\mathcal{D}_Q}(\theta'_r), \tag{5}$$

where β is the meta-learning rate. We detail the meta-learning algorithm in Algorithm 1.

After previous meta-learning steps, Meta-KGR can fast adapt to a relation-specific policy network for every few-shot relation by using θ as well-initialized parameters θ^*.

Dataset	#Ent	#Rel	#Triples
FB15k-237 (normal)	14,448	200	268,039
FB15k-237 (few-shot)	3,078	37	4,076
NELL-995 (normal)	63,524	170	115,454
NELL-995 (few-shot)	2,951	30	2,680

Table 2: Statistics of datasets.

5 Experiments

5.1 Datasets

We use two typical datasets FB15K-237 (Toutanova et al., 2015) and NELL-995 (Xiong et al., 2017) for training and evaluation. Specifically, we set $K = 137$ and $K = 114$ to select few-shot relations from FB15K-237 and NELL-995 respectively. Besides, we rebuild NELL-995 to generate few-shot relations in valid and test set. Statistics are given separately for normal relations and few-shot relations in Table 2.

5.2 Baselines

We compare with four multi-hop reasoning models in experiments: (1) Neural Logical Programming (NerualLP) (Yang et al., 2017); (2) NTP-λ (Rocktäschel and Riedel, 2017); (3) MINERVA (Das et al., 2018) and (4) MultiHop (Lin et al., 2018). For MultiHop and our model, we use both DistMult (Yang et al., 2015) and ConvE (Dettmers et al., 2018) as the reward function to create two different model variations, which are labeled in parentheses in Table 1.

5.3 Link Prediction

Given a query $(e_s, r_q, ?)$, link prediction for QA aims to give a ranking list of candidate entities from the KG. Following previous work (Dettmers et al., 2018; Lin et al., 2018), we use two evaluation metrics in this task: (1) the mean reciprocal rank of all correct entities (MRR) and (2) the proportion of correct entities that rank no larger than N (Hits@N).

Threshold	MultiHop		Meta-KGR	
	MRR	Hits@1	MRR	Hits@1
$K = 1$	20.8	16.9	**22.3**	**19.3**
$K = 5$	25.7	20.8	**29.6**	**26.6**
$K = 10$	29.1	25.0	**31.3**	**27.2**
$K = \text{max}$	42.7	36.7	**46.9**	**41.2**

Table 3: Experimental results for robustness analysis.

Evaluation results on two datasets are shown in Table 1. From the table, we can conclude that: (1) Our models outperform previous work in most cases, which means meta parameters learned from high-frequency relations can adapt to few-shot relations well. (2) ConvE is better than DistMult when used as the reward function in our models. This indicates that more effective knowledge graph embedding methods may provide fine-grained rewards for training multi-hop reasoning models. (3) Compared with NELL-995, FB15K-237 is denser. Our models perform well on both datasets, which demonstrates Meta-KGR can accommodate different types of KGs.

5.4 Robustness Analysis

We can use different frequency thresholds K to select few-shot relations. In this section, we will study the impact of K on the performance of our model. In our experiments, some triples will be removed until every few-shot relation has only K triples. We do link prediction experiments on FB15K-237 and use ConvE as our reward function. The final results are shown in Table 3. $K = \text{max}$ means we use the whole datasets in Table 2 and do not remove any triples. From Table 3 we can see our model is robust to K and outperforms MultiHop in every case.

6 Conclusion

In this paper, we propose a meta-learning based model named Meta-KGR for multi-hop reasoning over few-shot relations of knowledge graphs. Meta-KGR uses training triples with high-frequency relations to find well-initialized parameters and fast adapt to few-shot relations. The meta information learned from high-frequency relations is helpful for few-shot relations. In experiments, our models achieve good performance on few-shot relations and outperform previous work in most cases. Some empirical analysis also demonstrates that our models are robust and generalized to different types of knowledge graphs.

Abstract

Recent studies have significantly improved the state-of-the-art on common-sense reasoning (CSR) benchmarks like the Winograd Schema Challenge (WSC) and SWAG. The question we ask in this paper is whether improved performance on these benchmarks represents genuine progress towards common-sense-enabled systems. We make case studies of both benchmarks and design protocols that clarify and qualify the results of previous work by analyzing threats to the validity of previous experimental designs. Our protocols account for several properties prevalent in common-sense benchmarks including size limitations, structural regularities, and variable instance difficulty.

1 Introduction

The proliferation of artificial-intelligence technologies that interact with human users (e.g., dialogue systems, recommendation systems, information retrieval tools) has led to renewed interest in common-sense reasoning (CSR). The progress of these technologies and the general societal reaction toward them greatly depend on advances in CSR, since systems can seem glaringly *un*intelligent when they lack common sense. Common sense is vital for resolving ambiguity that arises from implicit knowledge and underspecification. Consider the following sentence:

(1) The delivery truck zoomed by the school bus because it was going so **fast**.

Humans resolve the pronoun *it* to *the delivery truck* with no difficulty, whereas a system without common sense might be unable to distinguish the truck from the otherwise viable candidate, *the school bus*. The above sentence is an example from a popular binary-choice pronoun co-reference problem called the Winograd Schema Challenge (WSC) (Levesque et al., 2011), designed to directly test a machine's grasp of common sense. What makes sentences like (1) especially challenging for machine learning approaches is that they are formulated such that simple word co-occurrence statistics cannot resolve them at a rate above chance (i.e., *the delivery truck* is unlikely to co-occur with *going so fast* much more frequently than *the school bus* does in large text corpora). In the same vein, a recently proposed common-sense inference task called SWAG (Zellers et al., 2018) further challenges co-occurrence-based approaches. SWAG's problem instances comprise a partial description, along with four candidate succeeding sentences designed to be distributionally similar. Among these, one successor is the most plausible. An example SWAG instance follows.

(2) Someone is lifting the pinata. The pinata
a) drops from the swings.
b) bounces bigger than a third.
c) slumps across his shoulder back.
d) falls on the ground.

Recently, a number of systems have attained new state-of-the-art results on WSC and SWAG by querying a language model trained on a very large corpus (Trinh and Le, 2018; Radford et al., 2019; Devlin et al., 2018). The primary goal of this paper is to examine whether one can conclude from these systems' high performance on these CSR benchmarks that they actually possess common sense. We do so by systematically examining threats to the validity of experiments involving recent CSR models.

In particular, any study aiming to show a conclusion (e.g., that a particular model can perform CSR) is subject to threats to its internal and exter-

*Equal contribution.

Table 1: Examples and distribution of associative vs. non-associative WSC instances.

nal validity (Campbell and Stanley, 1963). Internal validity refers to whether the study is carried out correctly without any alternative explanations for its results, such as confounds or procedural errors. External validity refers to whether the results of the study can be generalized to other settings.

We find that most of the performance gains of recent approaches can be explained by issues with the experimental setup that concern validity threats of both types, but a small portion of those gains can be attributed to genuine progress.

On WSC, the small size of the dataset and the predictable structure of its questions represent threats to external validity. We demonstrate this by applying perturbations to the dataset, whereby we switch the locations of the entities on a subset of data points. We find that the tested models' performances drop substantially in this new setting. We also analyze the portion of the performance gain not attributable to issues with the experimental setup in WSC, and find that current systems are very good at the subset of questions that require associative knowledge about semantic relatedness between words. Meanwhile, large parts of common-sense reasoning that require higher-level social, situational, or spatio-temporal awareness remain intractable.

In the case of SWAG, a possible confound is that the incorrect endings are generated semi-automatically by a language model, whereas the correct endings are generated by humans (threat to internal validity). We evaluate a representation model, BERT (Devlin et al., 2018) on a modified version of the task that strips away the context sentence, such that models predict solely on the endings. We find that most (but not all) of the performance gain above chance level can be achieved by this deficient model.

2 Related Work

Our work presents new findings that reinforce realizations made in the community concerning the validity of a variety of different CSR tasks, most of which are in Natural Language Inference (NLI); some of these include that state-of-the-art models often do very well while being either agnostic to the premises in the task instance (which should be crucial for resolution) or by using linguistic cues that have little or nothing to do with world-knowledge or common-sense reasoning (Gururangan et al., 2018). In similar spirit, Glockner et al. (2018) create an NLI test set specifically to show the deficiencies of state-of-the-art models in inferences that require lexical and world knowledge. Alternatively, validity checks through manual investigation as in (Kalouli et al., 2017) have revealed another NLI corpus to be vulnerable to errors and model exploitation. To the best of our knowledge, our work is the first analysis performed on two very popular CSR tasks, the WSC and SWAG, that have recently garnered considerable attention in the community and on which we are beginning to see models perform relatively well (Trinh and Le, 2018; Zellers et al., 2018).

3 Validity of CSR Experiments

We now discuss the possible threats to the validity of CSR task setups in more detail.

Predictable Structure. In general, instances from both WSC and SWAG exhibit distinctive regularities. In SWAG, the counterfactual successor sentences are generated using an LSTM language model (LM), while the true successor comes from naturally occurring text. Despite recent advances in text generation, LSTM-generated responses feature stylistic patterns, such as repeated tokens, and display an overall lack of diversity (Xie, 2017). The approach SWAG introduces to minimize stylistic artifacts, *adversarial filtering*, is based on fooling a discriminator that classifies successors as human- or LM-generated. Nevertheless, upon inspecting the data, we found that LM-generated successors still contain repeated tokens and other signatures. A model that exploits these patterns could perform well without using

any common sense.

An example regularity found in the WSC is that instances are often composed of two clauses connected by a causal discourse connective, like *because* (as in (1)). This allows for simplifying assumptions (Liu et al., 2016) or schematizations (Emami et al., 2018). The issue with exploiting these structural regularities is that systems become brittle to perturbations that would not affect the judgment of a human.

Limited Size. Comprising only 273 test instances, the main drawback of the Winograd Schema Challenge is its limited size and the absence of training and validation sets for hyperparameter tuning. As a result, achieving above random accuracy on the WSC does not necessarily correspond to capturing common sense; it could be the result of a lucky draw.[1]

Associativity. The WSC task definition specifies that instances should not be resolvable via statistics that associate a candidate antecedent to other components of the sentence (Levesque et al., 2011). For example, in "The lions ate the zebras because they are predators" (Rahman and Ng, 2012), the pronoun *they* can be resolved to *lions* on the basis of a much stronger association of lions with predators than of zebras with predators. We will call this (flawed) type of instance *associative* (or non-*Google-proof* in (Levesque et al., 2011)). Although the WSC should contain no associative sentences, there was no rigorous enforcement of this constraint. We therefore sought to quantify the associative proportion. We only consider sentences to be associative if there is a clear argument for one antecedent being statistically preferred. Table 1 outlines some examples and gives the associative proportions of the WSC.[2]

4 New Evaluation Protocols

To probe the limitations discussed above, we propose evaluation protocols for the WSC and SWAG and apply them to several state-of-the-art methods.

WSC. First, we augment the existing dataset by switching candidates in sentences whenever possible (i.e., whenever switching the candidates does not obscure the sentence or affect the rationale to make the resolution decision). For example:

(3) **Original:** *Emma* did not pass the ball to *Janie* although she saw that she was open.

(4) **Switched:** *Janie* did not pass the ball to *Emma* although she saw that she was open.

When switching the candidates *Emma* and *Janie*, the correct answer changes as well (from *Emma* to *Janie*). A system that relies on the entity itself to make a prediction produces the same answer when the candidates are switched, even though it should not. Thus, a system that correctly resolves both the original and the switched sentence can more confidently claim to reason about the full sentence, instead of exploiting a statistical quirk of the participant entities. We introduce two new metrics based on this observation: **accuracy on the switchable subset** before and after switching the candidates, and a **consistency score**. The consistency score is the percentage of predictions that change (as would be expected) after candidates in the switchable subset are switched. In total, we counted 131 switchable instances in the WSC, which accounts for 47% of the original problem set.[2]

Taking special account of both the switchable and associative instances suggests the following evaluation protocol for a given model. First, we compute the accuracy on the original WSC and the accuracy on the *switchable* subset of the WSC before and after switching the candidates, and compute the corresponding consistency score. Next, we compute the accuracy on the *associative* subset. A model can be tailored to use statistical information about the entities but perform poorly when this cannot be exploited.

SWAG. When evaluating on SWAG, it is important to determine whether the prediction relies on an understanding of the context or on shallow patterns in the LM-generated counterfactuals. To isolate this effect, we remove the context from the problem instances, keeping only the four successors. Three of these are machine generated. Predicting the correct label thus amounts to discriminating the human-written successor from the machine-generated ones. By comparing the performance difference between a model that has access to the context versus one that does not, we can determine the extent to which the model actually relies on contextual reasoning.

[1] The justification for this is included in the extra material.

[2] The details of the study can be found in the appendix. The related datasets are available at https://github.com/ptrichel/How-Reasonable-are-Common-Sense-Reasoning-Tasks

Model	Full WSC Acc.	Unswitched Acc.	Switched Acc.	Consistency
Single LM	54.58%	54.96%	54.20%	56.49%
Ensemble 10 LMs	61.54%	58.78%	49.62%	43.51%
Ensemble 14 LMs	63.74%	63.36%	53.43%	44.27%
GPT-2 117M Full	55.68%	54.20%	54.20%	26.72%

Table 2: Evaluation of state-of-the-art methods on WSC using the proposed switchability metrics. The last three columns give numbers on the switchable subset only.

5 Experiments

We test several recently proposed systems using our proposed protocols: specially-trained, ensembled language models (LMs) (Trinh and Le, 2018), a large language model GPT-2 (Radford et al., 2019) a knowledge hunting method (Emami et al., 2018); and a fine-tuned representation model, BERT (Devlin et al., 2018) for SWAG.[3]

In both Trinh and Le (2018) and Radford et al. (2019), the language model scores the two sentences obtained when replacing the pronoun by the two candidates. The sentence that is assigned a higher probability designates the chosen candidate. Probability is calculated via the chain rule, as the product of the probabilities of each word in the sentence. The knowledge hunting method, from Emami et al. (2018), is a rule-based system that uses search engines to gather evidence for the candidate resolutions without relying on the entities themselves. BERT, a pre-trained deep bidirectional representation, is fine-tuned for SWAG using a softmax over the four possible endings.

6 Results

WSC. Performance of the state-of-the-art methods with respect to our proposed switchability metrics is shown in Table 2. We observe that accuracy is stable across the different subsets for the single LM and GPT-2 117M with full scoring. However, the performance of the ensembled LMs and GPT-2 117M with partial scoring falls back to near random on the switched subset. This correlates with a lower consistency score and suggests that the two models overfit to the dataset.

[3]We include implementation details in the appendix.

Model	Assoc.	Non-Assoc.
Single LM	73.0%	51.7%
Ensemble 10 LMs	91.9%	56.8%
Ensemble 14 LMs	83.8%	60.6%
GPT-2 117M Full	73.0%	53.0%
GPT-2 117M Partial	78.4%	58.9%
GPT-2 774M Full	81.1%	61.9%
GPT-2 774M Partial	91.9%	65.7%
Knowledge Hunter	50.0%[4]	58.3%[4]

Table 3: Accuracy of state-of-the-art methods on associative and non-associative WSC instances.

Discriminator Model	Accuracy
Successor-only	70.0%
Full model	80.9%

Table 4: Evaluation of BERT on SWAG using the proposed metrics.

The GPT-2 774M language models, the largest available ones, show the highest accuracy on the WSC, despite a significant drop in accuracy on the switched subset. In addition, they show the highest consistency scores on the WSC. As for the knowledge hunting method, it performed relatively well on the entire WSC, and is 100% consistent by definition, since it does not utilize the entities themselves during resolution.

In Table 3, we present model performance on the associative and non-associative subsets of the

[4]This is the expected accuracy and consistency. For those instances that the knowledge hunter did not acquire evidence, we expect half to be correct by chance.

WSC. These demonstrate that LM-based methods perform very well on the associative sentences, as expected. However, their performance drops significantly on the non-associative subset, when information related to the candidates themselves does not give away the answer.

SWAG. The performance of the state-of-the-art model is shown in Table 4. We observe that the model can distinguish human and LM-generated endings with an accuracy of 70.0%. This suggests that a strong performance on SWAG can be obtained without any consideration of the context, and that the task may not be well-suited to evaluate CSR. Nevertheless, BERT performs at 10.9% above this score when it uses the full context, indicating that the model does possess some "understanding" of the described situation.

7 Conclusion

The function of common sense in AI systems is both important and difficult to address. This paper is an attempt to make experiments, namely those performed on the WSC and SWAG, more rigorous by examining threats to the validity of these experimental designs. Based on the protocols we introduce, we show that performing at state-of-the-art on these datasets does not necessarily imply strong common-sense reasoning capability. We are happy to see a rising interest in the WSC in the community, including very recent work by Ruan et al. (2019) and Sap et al. (2019), which reinforces the need for proper evaluation protocols. With the release of an increasing number of fine-grained inference tasks aimed at these abilities (Roemmele et al., 2011; Morgenstern et al., 2016; Wang et al., 2018; Rashkin et al., 2018; McCann et al., 2018), the issue of experimental validity in CSR will also become even more important.

Abstract

In this paper, we focus on the task of generating a pun sentence given a pair of word senses. A major challenge for pun generation is the lack of large-scale pun corpus to guide the supervised learning. To remedy this, we propose an adversarial generative network for pun generation (Pun-GAN), which does not require any pun corpus. It consists of a generator to produce pun sentences, and a discriminator to distinguish between the generated pun sentences and the real sentences with specific word senses. The output of the discriminator is then used as a reward to train the generator via reinforcement learning, encouraging it to produce pun sentences which can support two word senses simultaneously. Experiments show that the proposed Pun-GAN can generate sentences that are more ambiguous and diverse in both automatic and human evaluation.[1]

1 Introduction

Generating creative and interesting text is a key step towards building an intelligent natural language generation system. A pun is a clever and amusing use of a word with two meanings (word senses), or of words with the same sound but different meanings (Miller and Gurevych, 2015). In this paper, we focus on the former type of pun, i.e., homographic pun. For example, "I used to be a banker but I lost *interest*" is a pun sentence because the pun word "*interest*" can be interpreted as either *curiosity* or *profits*.

An intractable problem for pun generation is the lack of a large-scale pun corpus in which each pun sentence is labeled with two word senses. Early researches (Hong and Ong, 2009; Valitutti et al., 2013; Petrovic and Matthews, 2013) are mainly based on templates and rules, thus lacking creativity and flexibility. Yu et al. (2018) is the first endeavor to apply neural network to this task, which adopts a constrained neural language model (Mou et al., 2015) to guarantee that a pre-given word sense to appear in the generated sequence. However, Yu et al. (2018) only integrates the generation probabilities of two word senses during the *inference* decoding process, without ***detecting*** whether the generated sentences can support the two senses indeed during *training*. Promisingly, Word Sense Disambiguate (WSD) (Pal and Saha, 2015) which aims at identifying the correct meaning of the word in a sentence via a multi-class classifier, can help the detection of pun sentences to some extent.

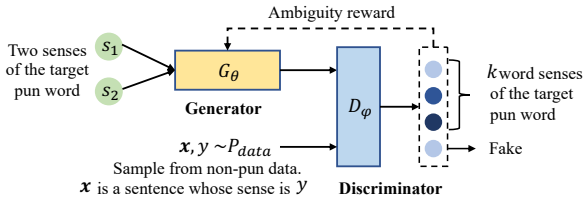

Figure 1: The proposed Pun-GAN framework.

Based on the above motivations, we introduce Generative Adversarial Net (Goodfellow et al., 2014) into pun generation task. Specifically, the generator can be any model that is able to generate a pun sentence containing a given word with two specific senses. The discriminator is a word sense classifier to classify the real sentence to its correct word sense label and classify a generated pun sentence to a fake label. With such a framework, the discriminator can provide a well-designed ambiguity reward to the generator, thus encouraging the ambiguity of the generated sentence via reinforcement learning (RL) to achieve the goal of punning, without using any pun corpus.

*Equal Contribution.

Evaluation of the pun generation is also challenging. We conduct both automatic and human evaluations. The results show that the proposed Pun-GAN can generate a higher quality of pun sentence, especially in ambiguity and diversity.

2 Model

The sketch of the proposed Pun-GAN is depicted in Figure 1. It consists of a pun generator G_θ and a word sense discriminator D_ϕ. The following sections will elaborate on the architecture of Pun-GAN and its training algorithm.

2.1 Model Structure

2.1.1 Generator

Given two senses (s_1, s_2) of a target word w, the generator G_θ aims to output a sentence $\boldsymbol{x}$ which not only contains the target word w but also express the two corresponding meanings. Considering the simplicity of the model and the ease of training, we adopt the neural constrained language model of Yu et al. (2018) as the generator. Due to space constraints, we strongly recommend that readers refer to the original paper for details. Compared with traditional neural language model, the main difference is that the generated words at each timestep should have the maximum sum of two probabilities which are calculated with s_1 and s_2 as input, *respectively*. Formally, the generation probability over the entire vocabulary at t-th timestep is calculated as

$$G_\theta(x_t|\boldsymbol{x}_{<t}) = f(Wh_t^1 + b) + f(Wh_t^2 + b) \quad (1)$$

where h_t^1 (h_t^2) is the hidden state of t-th step when taking s_1 (s_2) as input, f is the softmax function, and $\boldsymbol{x}_{<t}$ is the preceding $t-1$ words.

Therefore, the generation probability of the whole sentence $\boldsymbol{x}$ is formulated as

$$G_\theta(\boldsymbol{x}|s_1, s_2) = \prod_t G_\theta(x_t|\boldsymbol{x}_{<t}) \quad (2)$$

To give a warm start to the generator, we pretrain it using the same general training corpus in the original paper.

2.1.2 Discriminator

The discriminator is extended from the word sense disambiguation models (Kågebäck and Salomonsson, 2016; Luo et al., 2018a,b). Assuming the pun word w in sentence $\boldsymbol{x}$ has k word senses, we add a new "generated" class. Then, the discriminator is designed to produce a probability distribution over $k+1$ classes, which is computed as

$$D_\phi(y|\boldsymbol{x}) = \text{softmax}(U_w c + b') \quad (3)$$

where c is the context vector from a bi-directional LSTM when taking $\boldsymbol{x}$ as input, U_w is a word-specific parameter and y is the target label.

Therefore, $D_\phi\big(y = i|x, i \in \{1, ..., k\}\big)$ denotes the probability that it belongs to the real i-th word sense, while $D_\phi(y = k+1|x)$ denotes the probability that it is produced by a pun generator.

2.2 Training

We follow the training techniques of Salimans et al. (2016) which applys GAN to semi-supervised learning. For real sentence $\boldsymbol{x}$, if it is sense labeled, D_ϕ should classify $\boldsymbol{x}$ to its correct word sense label y, otherwise D_ϕ should classify $\boldsymbol{x}$ to anyone of the k labels. For generated sentence $\boldsymbol{x}$, D_ϕ should classify $\boldsymbol{x}$ to the $(k+1)$-th generated label. Thus, the training objective of the discriminator is to minimize:

$$\begin{aligned}\mathcal{J}(\phi) = &- \mathbb{E}_{\boldsymbol{x},y\sim p_{\text{data}}(\boldsymbol{x},y)} \log p_\phi(y|\boldsymbol{x}) \\ &- \mathbb{E}_{\boldsymbol{x}\sim p_{\text{data}}(\boldsymbol{x})} \log p_\phi(y < k+1|\boldsymbol{x}) \\ &- \mathbb{E}_{\boldsymbol{x}\sim G_\theta} \log p_\phi(y = k+1|\boldsymbol{x})\end{aligned} \quad (4)$$

where p_{data} denotes the sentence which only supports one word sense.

To encourage the generator to produce pun text, the discriminator is required to assign a higher reward to the ambiguous pun text which can be interpreted as two meanings simultaneously. For pun sentence, the probability of the target two sense $D_\phi(s_1|\boldsymbol{x})$ and $D_\phi(s_2|\boldsymbol{x})$ should not only *have a small gap*, but also *account for the most*. For example, (0.1, 0.5, 0.4) and (0.1, 0.8, 0.1) are two probability distributions outputted from D_ϕ. The former is more likely to be a pun with the second (0.5) and third (0.4) meaning, while the latter is mostly a generic single sense sentence with the second meaning (0.8). Based on the above observations, the reward is designed as

$$r = \frac{D_\phi(s_1|\boldsymbol{x}) + D_\phi(s_2|\boldsymbol{x})}{|D_\phi(s_1|\boldsymbol{x}) - D_\phi(s_2|\boldsymbol{x})| + 1} \quad (5)$$

where 1 is a coefficient that avoids the denominator being zero.

Then, the goal of generator training is to minimize the negative expected reward.

$$\mathcal{L}(\theta) = -\sum_k r^{(k)} G_\theta(\boldsymbol{x}^{(k)}|s_1, s_2) \quad (6)$$

where $\boldsymbol{x}^{(k)}$ is the k-th sampled sequence, $r^{(k)}$ is the reward of $\boldsymbol{x}^{(k)}$.

By means of policy gradient method (Williams, 1992), for each pair of senses (s_1, s_2), the expected gradient of Eq. 6 can be approximated as:

$$\nabla_\theta \mathcal{L}(\theta) \simeq -\frac{1}{K}\sum_{k=1}^{K} r^{(k)} \nabla_\theta \log\big(G_\theta(\boldsymbol{x}^{(k)})\big) \quad (7)$$

where K is the sample size.

Similar to other GANs (Salimans et al., 2016; Yu et al., 2017), the generator and discriminator are trained alternatively.

3 Experiment

3.1 Dataset

Training Dataset: To keep in line with previous work (Yu et al., 2018), we use a generic corpus – English Wikipedia to train Pun-GAN. For generator, we first tag each word in the English Wikipedia corpus with *one* word sense using an unsupervised WSD tool[2]. Then we use the 2,595K tagged corpus to pre-train our generator. For discriminator, we use several types of data for training: 1) SemCor (Luo et al., 2018a,b) which is a manually annotated corpus for WSD, consisting of 226K sense annotations[3] (first part in Eq.4); 2) Wikipedia corpus as unlabeled corpus (second part in Eq.4); 3) Generated puns (third part in Eq.4).

Evaluation Dataset: We use the pun dataset from SemEval 2017 task7 (Miller et al., 2017) for evaluation. The dataset consists of 1274 human-written puns where target pun words are annotated with two word senses. During testing, we extract the word sense pair as the input of our model.

3.2 Experimental Setting

The generator is the same as Yu et al. (2018). The discriminator is a single-layer bi-directional LSTM with hidden size 128. We randomly initialize word embeddings with the dimension size of 300. The sample size K is set as 32. Batch size is 32 and learning rate is 0.001. The optimization algorithm is SGD. Before adversarial training, we pre-train the generator for 5 epochs and pre-train the discriminator for 4 epochs. In adversarial training, the generator is trained every 1 step and the discriminator is trained every 5 steps.

[2] https://github.com/alvations/pywsd

[3] The reason why we don't use SemCor to train generator is that this dataset is too small for training a language model.

Model	Unusualness	Dist-1	Dist-2
LM (Mikolov et al., 2010)	-	6.8	15.4
CLM (Mou et al., 2015)	0.45	8.3	17.9
CLM+JD (Yu et al., 2018)	0.05	8.8	19.8
Pun-GAN	**0.50**	**11.3**	**26.2**
Human	1.38	27.9	73.5

Table 1: Automatic evaluation results.

Model	Ambiguity	Fluency	Overall
LM (Mikolov et al., 2010)	1.6	3.1	2.5
CLM (Mou et al., 2015)	2.0	2.1	2.0
CLM+JD (Yu et al., 2018)	3.4	3.6	3.5
Pun-GAN	**3.9**	**3.7**	**3.8**
Human	4.3	4.6	4.5

Table 2: Human evaluation results.

3.3 Baselines

We compare with the following systems:

LM (Mikolov et al., 2010): It is a normal recurrent neural language model which takes the target pun word as input.

CLM (Mou et al., 2015): It is a constrained language model which guarantees that a pre-given word will appear in the generated sequence.

CLM+JD (Yu et al., 2018): It is a state-of-the-art model for pun generation which extends a constrained language model by jointly decoding conditioned on two word senses.

3.4 Evaluation Metrics

Automatic evaluation: We use two metrics to automatically evaluate the creativeness of the generated puns in terms of unusualness and diversity. Following Pauls and Klein (2012) and He et al. (2019)[4], the unusualness is measured by subtracting the log-probability of training sentences from the log-probability of generated pun sentences. Following Yu et al. (2018), the diversity is measured by the ratio of distinct unigrams (Dist-1) and bigrams (Dist-2) in generated sentences.

Human evaluation: Three annotators score the randomly sampled 100 outputs of different systems from 1 to 5 in terms of three criteria. Ambiguity evaluates how likely the sentence is a pun. Fluency measures whether the sentence is fluent. Overall is a comprehensive metric.

Model	Ours	No Pref.	Others
Pun-GAN vs CLM+JD	57	19	24
Pun-GAN vs Human	8	13	79

Table 3: Results from human A/B testing of different pairs of models. Each cell indicates the times that a judge preferred one of the models or no preference of them among 100 sentences.

Model	Unusualness	Dist-1	Dist-2
Full Model	**0.50**	**11.3**	**26.2**
- adversarial leaning	0.46	10.9	25.1

Table 4: Ablation study.

3.5 Results

Table 1 and Table 2 show the results of automatic evaluation and human evaluation, respectively. We find that: 1) Pun-GAN achieves the best ambiguity score. This is in line with our expectations that adversarial training can better achieve the aim of punning; 2) Compared with CLM+JD which is actually the same as our pre-trained generator, Pun-GAN has a large improvement in unusualness. We assume that it is because the discriminator can promote to generate more creative and unexpected sentences to some extent via adversarial training; 3) Pun-GAN can generate more diverse sentence with different tokens and words. This phenomenon accords with previous work of GANs (Wang and Wan, 2018).

In addition, Table 3 shows the A/B tests between two the models. It shows that Pun-GAN can generate more vivid pun sentences compared with the previous best model CLM+JD. However, there still exists a big gap between generated puns and human-written puns. To conclude, both automatic evaluation and human evaluation show the effectiveness of the proposed Pun-GAN, especially in ambiguity and diversity.

3.6 Ablation Study

In order to validate the effectiveness of adversarial learning, we fix the discriminator after pre-training. Table 4 shows the results, from which we can conclude that adversarial leaning can help improve the creativeness of generated puns.

3.7 Case Study

Figure 2 shows the randomly sampled examples of state-of-the-art model (CLM+JD) and Pun-GAN. Human-written puns are also given. It demonstrates that, compared with CLM+JD, Pun-GAN can generate puns which are closer to the funniness and creativeness of human-written puns. However, both CLM+JD and Pun-GAN may sometimes generate short sentences. Since too short sentences lack sufficient context, they always tend to ambiguous. More analysis can be found in Section 3.8.

[4] He et al. (2019) is a contemporaneous work.

Model	Example
touch	
s_1: the event of something coming in contact with the body.	
s_2: a suggestion of some quality.	
CLM+JD	It is a *touch* in the united states.
Pun-GAN	It is a *touch* with the red sox.
Human	The massage which came with the spa treatment was a nice *touch*.
state	
s_1: an organized political community forming part of a country.	
s_2: mode or condition of being.	
CLM+JD	According to the *state*, he was the first time in the united states.
Pun-GAN	In the *state*, the national assembly was established.
Human	Many people need to learn to be happy with the *state* they are in.

Figure 2: Example outputs of different models.

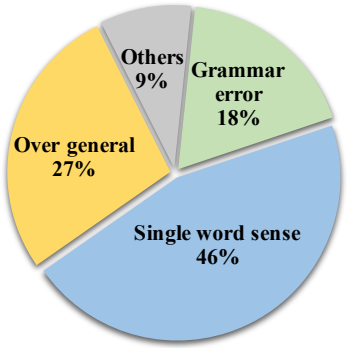

Figure 3: Pie chart of the error types.

3.8 Error Analysis

We carefully analyze the generated results of Pun-GAN with low overall scores in human evaluation. Fig 3 shows the proportion of different error types. The most common type of error is generating a sentence which only supports a single word sense. This accords with our expectations since generating a sentence which can support two word senses without any labeled corpus is very hard. Another common type of error is generating over generic

sentences. For example, "*It is a bank*". In most instances, these generic sentences are always very short and they begin with a pronoun like "*It is*" or "*He can*". The reasons are two-fold. One is that these type of sentences can get a high generation probability since the generator is actually a language model. The other is these type of sentences can even get a not bad reward since they are indeed ambiguous. Moreover, grammar error also accounts for about 1/5. We hypothesize that it is caused by the joint generation process in Eq.2.

4 Conclusion and Future Work

In this paper, we propose Pun-GAN: a generative adversarial network for pun generation. It consists of a pun generator and a word sense discriminator, which unifies the task of pun generation and word sense disambiguation. Even though Pun-GAN does not require any pun corpus, it can still enhance the ambiguity of sentence produced by the generator via the reward from the discriminator to achieve the goal of punning. Pun-GAN is generic and flexible, and may be extended to other constrained text generation tasks in future work.

Abstract

This paper explores the task of answer-aware questions generation. Based on the attention-based pointer generator model, we propose to incorporate an auxiliary task of language modeling to help question generation in a hierarchical multi-task learning structure. Our joint-learning model enables the encoder to learn a better representation of the input sequence, which will guide the decoder to generate more coherent and fluent questions. On both SQuAD and MARCO datasets, our multi-task learning model boosts the performance, achieving state-of-the-art results. Moreover, human evaluation further proves the high quality of our generated questions.

1 Introduction

Question generation (QG) receives increasing interests in recent years due to its benefits to several real applications: (1) QG can aid in the development of annotated questions to boost the question answering systems (Duan et al., 2017; Tang et al., 2017); (2) QG enables the dialogue systems to ask questions which make it more proactive (Shum et al., 2018; Colby, 1975); (3) QG can help to generate questions for reading comprehension texts in the education field. In this paper, we focus on answer-aware QG. Giving a sentence and an answer span as input, we want to generate a question whose response is the answer.

Previous work on QG was mainly tackled by two approaches: the rule-based approach and neural-based approach. The neural-based approach receives a booming development due to the release of large-scale reading comprehension datasets like SQuAD (Rajpurkar et al., 2016) and MARCO (Nguyen et al., 2016). Most of the neural approaches on QG employ the encoder-decoder framework, which incorporate attention mechanism to pay more attention to the informative part and copy mode to copy some tokens from the input text (Du et al., 2017; Zhou et al., 2017; Song et al., 2018; Subramanian et al., 2018; Zhao et al., 2018; Sun et al., 2018). To make better use of answer information, Song et al. (2018) leverage multi-perspective matching, and Sun et al. (2018) propose a position-aware model that aims at putting more emphasis on the answer-surrounded context words. Zhao et al. (2018) aggregate paragraph-level information to help QG. Another line of work is to deal with question answering and question generation as dual tasks (Tang et al., 2017; Duan et al., 2017). Some other works try to generate questions from a text without answers as input (Subramanian et al., 2018; Du and Cardie, 2017). Although some progress has been made, there is still much room for improvement for QG.

Multi-task learning is an effective way to improve model expressiveness via related tasks by introducing more data and fruitful semantic information to the model (Caruana, 1998). Many works in NLP have adopted multi-task learning and prove its effectiveness on textual entailment (Hashimoto et al., 2017), keyphrase generation (Ye and Wang, 2018) and document summarization (Guo et al., 2018). To the best of our knowledge, no work attempts to employ multi-task learning for question generation. Although language modeling has been applied to multi-task learning for classification tasks, they are different from our generation task.

In this work, we propose to incorporate language modeling as an auxiliary task to help QG via multi-task learning. We adopt the pointer-generator (See et al., 2017) reinforced with features as the baseline model, which yields state-of-the-art result (Sun et al., 2018). The language modeling task is to predict the next word and the

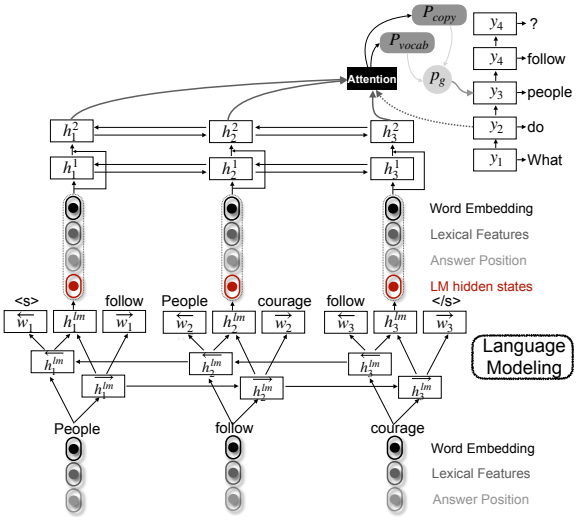

Figure 1: Overall structure of our joint-learning model.

previous word whose input is a plain text without relying on any annotation. The two tasks are then combined with a hierarchical structure, where the low-level language modeling encourages our representation to learn richer language features that will help the high-level network to generate better expressive questions.

We conduct extensive experiments on two reading comprehension datasets: SQuAD and MARCO. We experiment with different settings to prove the efficacy of our multi-task learning model: with/without language modeling and with/without features. Experimental results show that the language modeling consistently yields obvious performance gain over baselines, for all evaluation metrics, including *BLEU*, *perplexity* and *distinct*. Our full model outperforms the existing state-of-the-art results on both datasets, achieving a high BLEU-4 score of 16.23 on SQuAD and 20.88 on MARCO, respectively. We also conduct human evaluation, and our generated questions get higher scores on all three metrics, including $matching$, $fluency$ and $relevance$.

2 Model Description

The baseline model is an attention-based seq2seq pointer-generator reinforced by lexical features, like the work of Sun et al. (2018). In our proposed model, we employ multi-task learning with language modeling as an auxiliary task for QG. The whole structure of our model is shown in Figure 1.

2.1 Feature-enriched Pointer Generator

The feature-rich encoder is a bidirectional LSTM used to produce a sequence of hidden states h_t^L. The encoder takes a sequence of word-and-feature vectors as input ($(x_1, ..., x_T)$), which concatenates the word embedding e_t, answer position embedding a_t and lexical feature embedding l_t ($x_t = [e_t; a_t; l_t]$).The lexical feature is composed of POS tags, NER tags, and word case.

The attention-based decoder is another unidirectional LSTM, which is conditioned on the previous decoder state s_{i-1}, decoded word w_{i-1}, and context vector c_{i-1} which is generated via attention mechanism (Bahdanau et al., 2014):

$$s_i = LSTM([w_{i-1}; c_{i-1}], s_{i-1}) \quad (1)$$

Further, a two-layer feed-forward network is used to produce the vocabulary distribution P_{vocab}.

The pointer generator (See et al., 2017) incorporates a copy mode $P_{copy}(w)$, which allows copying words from the source text via pointing. The final probability distribution is to combine both modes with a generation probability $p_g \in [0, 1]$:

$$P(w) = p_g P_{vocab}(w) + (1 - p_g) P_{copy}(w) \quad (2)$$

The model is trained to minimize the negative log-likelihood of the target sequence. We denote this loss as E.

2.2 Language Modeling

The language model is to predict the next word and previous word in the sequence with a forward LSTM and a backward LSTM, respectively. First, we feed the input sequence into a bidirectional LSTM to get the hidden representations h_t^{lm}.

Then, these states are fed into a softmax layer to predict the next and the previous word:

$$P^{lm}(w_{t+1}|w_{<t+1}) = softmax(W_f \overrightarrow{h_t^{lm}}) \quad (3)$$

$$P^{lm}(w_{t-1}|w_{>t-1}) = softmax(W_b \overleftarrow{h_t^{lm}}) \quad (4)$$

The training objective is to minimize the loss function which is defined as the average of the negative log-likelihood of the next word and the previous word in the sequence:

$$E^{lm} = -\frac{1}{T-1}\sum_{t=1}^{T-1} log(P^{lm}(w_{t+1}|w_{<t+1})) - \frac{1}{T-1}\sum_{t=2}^{T} log(P^{lm}(w_{t-1}|w_{>t-1})) \quad (5)$$

Table 1: Experimental results of our model in different settings comparing with previous methods on two datasets.

2.3 Multi-task Learning

Instead of sharing representations between two tasks (Rei, 2017) or encoding two tasks at the same level (Liu et al., 2018; Chen et al., 2018; Kendall et al., 2018), we adopt a hierarchical structure to combine the two tasks, by treating language modeling as a low-level task and pointer generator network as high-level, because language modeling is fundamental and its semantic information will benefit question generation. In details, we first feed the input sequence into the language modeling layer to get a sequence of hidden states. Then we concatenate them with the input sequence to obtain the input of the feature-rich encoder.

Finally, the loss of LM is added to the main loss to form a combined training objective:

$$E^{total} = E + \beta E^{lm} \quad (6)$$

where β is a hyper-parameter, which is used to control the relative importance of two tasks.

3 Experiments

3.1 Dataset

We conduct experiments on two reading comprehension datasets: SQuAD and MARCO, using the data shared by Zhou et al. (2017) and Sun et al. (2018), where the lexical features are extracted with Stanford CoreNLP. In details, there are 86,635, 8,965 and 8,964 sentence-answer-question triples in the training, development and test set for SQuAD, and 74,097, 4,539 and 4,539 sentence-answer-question triples in the training, development and test set for MARCO.

3.2 Experiment Settings

Our vocabulary contains the most frequent 20,000 words in each training set. Word embeddings are initialized with the pre-trained 300-dimensional Glove vectors, and are allowed to be fine-tuned during training. The representations of answer position, POS tags, NER tags and word cases are randomly initialized as 32-dimensional vectors, respectively. The encoder of our baseline model consists of 2 BiLSTM layers, and the hidden size of both the encoder and decoder is set to 512.

In our joint model, grid search is used to determine β and results are shown in Figure 2. Consequently, we set the value of β to 0.6.

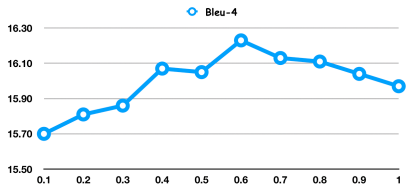

Figure 2: The impact of β on BLEU-4

We search the best-trained checkpoint base on the dev-set. In order to mitigate the fluctuation of the training procedure, we then average the nearest 5 checkpoints to obtain a single averaged model. Beam search is used with a beam size of 12.

3.3 Automatic Evaluation

Results on BLEU The experimental results on BLEU (Papineni et al., 2002) are illustrated in Table 1. Our full model (*w/ features + language modeling*) significantly outperforms previous models and achieves state-of-the-art results on both datasets, with 16.23 BLEU-4 score on SQuAD and 20.88 on MARCO respectively.

Results without Features To investigate the robustness of our model, we conduct an experiment whose input sequence only takes word embeddings and answer position, but without lexical fea-

Dataset / Model	SQuAD Matching	SQuAD Fluency	SQuAD Relevance	MARCO Matching	MARCO Fluency	MARCO Relevance
pointer generator with features (baseline)	0.983	1.573	1.540	1.133	1.667	1.593
+ language modeling	**1.147**	**1.690**	**1.600**	**1.160**	**1.720**	**1.603**
kendall correlation coefficient	0.820	0.814	0.796	0.852	0.792	0.824

Table 3: Human evaluation results on two datasets.

tures (*w/o features + language modeling*). We can see that the auxiliary task of language modeling boosts model performance on both datasets, demonstrating that our model guarantees higher stability because it does not depend on the quality of lexical features. Therefore, our model can apply to low-resource languages where there is not adequate data for training a well-performed model for lexical features extraction.

Results with a 3-layer Encoder To validate that we gain the improvement not due to a deeper network, we replace the language modeling module with one encoder layer, that is to say, we adopt a 3-layer encoder. Comparing this model (*w/ features+1-layer encoder*) with the full model (*w/ features+language modeling*), we can see that our joint-learning model performs better than simply adding an extra encoding layer. The results on MARCO also clearly show that a deeper network does not guarantee better performance.

Perplexity and Diversity Since BLEU only measures a hard matching between references and generated text, we further adopt *perplexity* and *distinct* (Li et al., 2016) to judge the quality of generated questions. The results in Table 2 indicate that the language modeling task helps the model to generate more fluent and readable questions. Besides, the generated questions have better diversity.

3.4 Human Evaluation

For a better study on the quality of generations, we perform human evaluation. Three annotators are asked to grade the generated questions in three aspects: $matching$ indicates whether a question can be answered with the given answer; $fluency$ indicates whether a question is fluent and grammatical; $relevance$ indicates whether a question can be answered according to the given context. The rating score ranges from 0 to 2. We randomly sample 100 cases from each dataset for evaluation. Results are displayed in Table 3. The coefficient between human judges is high, validating a high quality of our annotation. The results show that by incorporating language modeling, the generated questions receive higher scores across all three metrics.

Context: Prior to the early 1960s, access to the forest's interior was highly restricted, and the forest remained basically intact.
Answer: The early 1960s
Reference: Accessing the Amazon rainforest was restricted before what era?
Baseline: When did access to the forest's interior?
Joint-model: When did access to the forest's interior become restricted?

Context: This teaching by Luther was clearly expressed in his 1525 publication on the bondage of the will, which was written in response to on free will by Desiderius Erasmus (1524).
Answer: 1525
Reference: When did Luther publish on the bondage of the will?
Baseline: In what year was the bondage of the will on the bondage of the will?
Joint-model: When was the bondage of the will published?

Table 4: Examples of generated questions by different models.

3.5 Case Study

Further, Table 4 gives two examples of the generated questions on SQuAD dataset, by the base-

line model and our joint model respectively. It is obvious that questions generated by our proposed model are more complete and grammatical.

4 Conclusion

This paper proves that equipped with language modeling as an auxiliary task, the neural model for QG can learn better representations that help the decoder to generate more accurate and fluent questions. In future work, we will adopt the auxiliary language modeling task to other neural generation systems to test its generalization ability.

Abstract

Autoregressive state transitions, where predictions are conditioned on past predictions, are the predominant choice for both deterministic and stochastic sequential models. However, autoregressive feedback exposes the evolution of the hidden state trajectory to potential biases from well-known train-test discrepancies. In this paper, we combine a latent state space model with a CRF observation model. We argue that such autoregressive observation models form an interesting middle ground that expresses local correlations on the word level but keeps the state evolution non-autoregressive. On unconditional sentence generation we show performance improvements compared to RNN and GAN baselines while avoiding some prototypical failure modes of autoregressive models.[1]

1 Introduction

Sequential autoregressive models express predictions of observations based on past predictions. They are the predominant architecture for text generation in a maximum likelihood setup (Graves, 2013; Sutskever et al., 2014) and are used in machine translation (Bahdanau et al., 2015; Vaswani et al., 2017), summarization (Rush et al., 2015), and dialogue systems (Serban et al., 2016).

An immediate consequence of combining autoregressive modeling and maximum likelihood training is that past observations enter the loss functions as ground-truth, not predicted observations (Goodfellow et al., 2016). This discrepancy is often summarized as *teacher-forcing* and the bias it implies is referred to as *exposure-bias* (Ranzato et al., 2016; Goyal et al., 2016).

[1]Code and generated sentences available at https://github.com/schmiflo/crf-generation

The standard methodology to turn a sequential model into an autoregressive one is to introduce a *feedback loop*, where one provides the last predicted token as a feature to the computation of the next state (Graves, 2013). The ground-truth observations become effectively input features for the evolution of the hidden state trajectory at training time. Several attempts have been made to introduce robustness with respect to the model's predictions by leaving the maximum likelihood framework, either implicitly (Bengio et al., 2015; Bowman et al., 2016) or explicitly (Goyal et al., 2016; Leblond et al., 2018). Nevertheless, the same feedback mechanisms have been adopted in latent sequential models where they obfuscate the true stochasticity of transitions during training. Non-autoregressive sequence models have recently regained attention for unconditional (Schmidt and Hofmann, 2018; M. Ziegler and M. Rush, 2019) and conditional (Lee et al., 2018) generation.

We argue that there is an interesting intermediate regime between feedback-driven autoregressive models and completely non-autoregressive models, namely modeling temporal correlations as part of the *observation model*. We propose a neural CRF observation model that leverages word-embeddings to explain local word correlations in a global sequence score. We show how training and generation can be performed efficiently. The result is an autoregressive model that keeps the hidden state evolution less affected by observation noise while generating coherent word sequences.

Conditional Random Fields (CRF) were originally introduced by Sha and Pereira (2003) to overcome

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3400–3406, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

label bias, a shortcoming of locally normalized observation models. They have been applied and integrated into neural-network architectures (Ma and Hovy, 2016; Huang et al., 2017) in various sequence labeling tasks (Goldman and Goldberger, 2017) where the observation space exhibits small cardinality (typically tens to hundreds).

The importance of global normalization for sequence generation has only lately been emphasized, most notably by Wiseman and Rush (2016) for conditional generation in a learning-as-search-optimization framework and by (Andor et al., 2016) for parsing.

Word-embeddings have been reported as excellent dense representations of sparse co-occurrence statistics within several learning frameworks (Mikolov et al., 2013; Pennington et al., 2014). Using embeddings in pairwise potentials has been proposed by Goldman and Goldberger (2017), but they do not compute the true log-likelihood during training as we do. Similar techniques have been applied for various message passing schemata (Kim et al., 2017; Domke, 2013).

Local correlations such as our pairwise potentials have been used by (Noraset et al., 2018), yet as an auxiliary loss and not for model design.

Other approaches to tackle teacher-forcing have been proposed in an adversarial setting (Goyal et al., 2016), in search based optimization (Leblond et al., 2018) and in a reinforcement learning setting (Rennie et al., 2016).

3 Model

Latent sequential models for text generation typically consist of two parts: A mechanism for generating a latent hidden state trajectory $\mathbf{h} = \mathbf{h}_{1:T}$, and an observation model. The latter predicts the data $w = w_{1:T}$ given the latent states. The most simple dependency structure for such a model is that of an Hidden Markov Model, which breaks into transitions $p(\mathbf{h}_t|\mathbf{h}_{t-1})$ and observations $p(w_t|\mathbf{h}_t)$. In contrast, models with *autoregressive transitions* factorize as

$$p(w, \mathbf{h}) = \prod_{t=1}^{T} p(w_t|\mathbf{h}_t)p(\mathbf{h}_t|\mathbf{h}_{t-1}, w_{t-1}) \,. \quad (1)$$

The result is a next-state distribution with dependencies identical to deterministic RNN transitions $\mathbf{h}_t = F(\mathbf{h}_{t-1}, w_{t-1})$ and indeed similar neural networks can be used to parametrize a simple, e.g., Gaussian distribution (Fraccaro et al., 2016).

As a negative consequence, we inherit teacher-forcing. This comes with aforementioned biases and also conflicts with our notion of uncertainty in $p(\mathbf{h}_t|\mathbf{h}_{t-1}, w_{t-1})$ which during training solely depends on the continuous parameters (i.e. a mean and a variance), but is greatly affected by the discrete sampling noise in w_{t-1} at test time.

Autoregressive observation model We consider an alternative to autoregressive feedback mechanisms such as (1), where predictions are directly injected into states. We write

$$p(w, \mathbf{h}) = p(w|\mathbf{h}) \prod_{t=1}^{T} p(\mathbf{h}_t|\mathbf{h}_{t-1}) \quad (2)$$

assuming only Markovian transitions and focus on finding a powerful observation model instead. Crucially, since the state space model is not affected by previous outputs, word coherence may be lost when simply factorizing as in $p(w|\mathbf{h}) = \prod_t p(w_t|\mathbf{h}_t)$, i.e. with independent soft-max factors $p(w_t|\mathbf{h}_t) \propto \exp \psi(w_t, \mathbf{h}_t)$ where $\psi(w_t, \mathbf{h}_t) = \mathbf{x}(w_t)^\top \mathbf{h}_t$. However, a natural extension can be found by reformulating local normalization as a form of global normalization without correlations across time

$$p(w|\mathbf{h}) = \prod_{t=1}^{T} \frac{\exp \psi(w_t, \mathbf{h}_t)}{\sum_{w'_t} \exp \psi(w'_t, \mathbf{h}_t)} \quad (3)$$

$$= \frac{\exp S(w, \mathbf{h})}{\sum_{w'} \exp S(w', \mathbf{h})} \quad (4)$$

where $S = \sum_{t=1}^{T} \psi(w_t, \mathbf{h}_t)$ contains no dependencies between w_t and $w_{t'}$ for $t \neq t'$. As soon as we add word-correlations to S, we obtain a truly global observation model that cannot be expressed in the form of (3).

3.1 CRF Observation Model

Equation (4) describes a conditional random field (CRF) with an energy function S (Sha and Pereira, 2003). We consider up to pairwise interactions between consecutive words

$$S(w; \mathbf{h}) = \sum_{t=1}^{T} \psi(w_t; \mathbf{h}_t) + \psi(w_{t-1}, w_t; \mathbf{h}_{t-1:t}) \quad (5)$$

The potentials ψ reflect the independence assumptions among w and determine the complexity of the normalizer $Z = \sum_{w'} \exp S(w')$. Fortunately, for chain-like interactions such as (5), efficient dynamic programming routines are available.

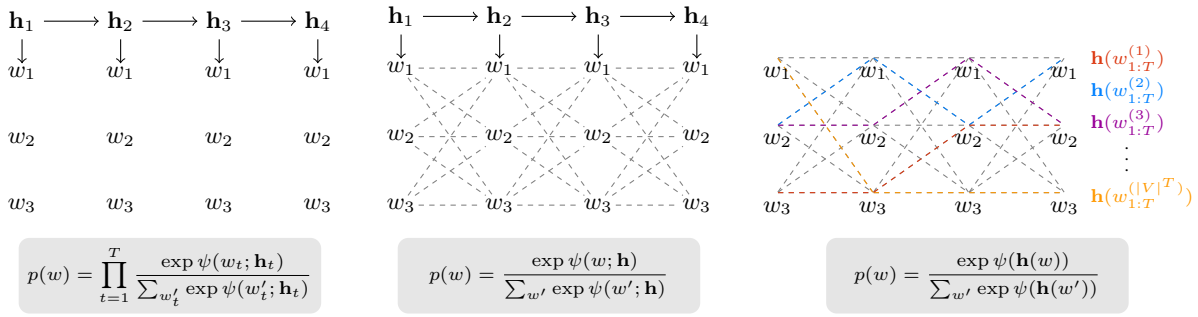

Figure 1: Schematic comparison of differently normalized architectures. We sketch trellis diagrams for $V = \{w_1, w_2, w_3\}$ and $T = 4$. Dashed lines indicate autoregressive dependencies in the log-likelihood computation. **Left**: Standard RNN with soft-max observations. Since the model is locally normalized, the trellis diagram does not unfold across time-steps. **Middle**: Our proposed CRF model. The potentials only span across pairs, but the normalization is global and can be computed exactly and efficiently. **Right**: An intractable globally normalized model in which fully-connected potentials $\psi(\mathbf{h}(w))$ are obtained from an RNN. Computing a single $p(w)$ would require running the RNN $|V|^T$ times. We highlight four runs for illustration.

Two properties set our model apart from feedback-driven autoregressive models. First, although ψ captures only pairwise interactions, a state $\mathbf{h}_t$ will not only affect future observations but also all *past* observations through the global coupling. Second, our model implicitly considers *all* possible sequences w also at training time due to the global normalizer Z.

3.2 Sampling

Given a trained model, we can perform ancestral sampling via $\mathbf{h} \sim p(\mathbf{h})$ and $w \sim p(w|\mathbf{h})$. However, CRFs are undirected graphical models not designed with generation in mind and therefore we first need to derive ancestral sampling for $p(w|\mathbf{h})$. We can always write $p(w|\mathbf{h}) = \prod_t p(w_t|w_{1:t-1}, \mathbf{h})$ and find the factors

$$p(w_t|w_{1:t-1}, \mathbf{h}) = e^{\psi(w_{t-1}, w_t) + \psi(w_t)} \frac{\beta_{t+1}(w_t)}{\beta_t(w_{t-1})} \quad (6)$$

where

$$\beta_t(w_{t-1}) = \sum_{w_t} e^{\psi(w_{t-1}, w_t) + \psi(w_t)} \beta_{t+1}(w_t) \quad (7)$$

with special cases $\beta_1(w_0) = 1$ and $\beta_{T+1}(w_T) = Z$ are the backwards probabilities we anyway need to compute for (4). Not surprisingly, multiplying (6) for $t = 1:T$ lets all β terms cancel except for $1/Z$ and we recover (4). However, this form is more amendable to sampling[2] and reveals an interesting property of globally normalized models: While the chain rule always allows to write such models autoregressively, we must expect a factor – here $\beta_{t+1}(w_t)$ – that implicitly marginalizes out future observations to assess compatibility with a specific next word w_t. Tractability of this factor is key to obtain a tractable model and is traded for expressiveness. While locally normalized models are on one end of the spectrum, a globally normalized with fully-connected potentials $\psi(\mathbf{h}(w))$ is on the other end. Such models employ an RNN in *each* potential to obtain an un-normalized score ψ from states $\mathbf{h}$ and have been investigated in conditional generation where argmax-decoding rather than sampling is requried (Wiseman and Rush, 2016). Figure 1 shows the dependencies of the two extremes with our model in the middle.

3.3 Embedding-based Local Correlations

Often pairwise potentials can be parametrized directly, i.e. as $\psi(w_i, w_j) = \mathbf{A}_{ij}$ for some parameter matrix $\mathbf{A} \in \mathbb{R}^{V \times V}$. However, in our setting this is problematic for two reasons. First, $|V|^2$ parameters are impractical in terms of model size for most vocabularies. Second, computations involving $\mathbf{A}$ are central to the complexity of computing log-likelihood during training. Namely, to compute the normalizer Z, we need to compute all β quantities in (7). Identifying $\beta_t(w_{t-1})$ as a $|V|$-dimensional vector $\boldsymbol{\beta}_t$, we can write the summation in (7) as a matrix-vector product

$$\boldsymbol{\beta}_t = \mathbf{T}(\mathbf{o}_t \odot \boldsymbol{\beta}_{t+1}) \quad (8)$$

where $\odot$ is an element-wise product, $\mathbf{o}_t$ are the unary potentials $\psi(w_t)$ written as a vector and $\mathbf{T} = \exp \mathbf{A}$ element-wise. We observe, computing Z naively requires $\mathcal{O}(|V|^2 T)$ operations.

[2] In fact, one can train on (6) instead of (4). However, in our experiments we found the latter global normalization to be much more stable numerically.

To overcome the above shortcomings, we propose to factorize $\mathbf{T}$ as

$$\mathbf{T} = \mathbf{X}^\top \mathbf{S}(\mathbf{h}_{t-1}, \mathbf{h}_t)\mathbf{Y} \tag{9}$$

into context-independent d-dimensional embeddings $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{d \times |V|}$ and a context-dependent $d \times d$ interaction matrix computed by a neural network $\mathbf{S} : \mathbb{R}^{d'} \times \mathbb{R}^{d'} \to \mathbb{R}^{d \times d}$. This reduces the memory requirement to $\mathcal{O}(d|V|)$ and compute time to $\mathcal{O}(d|V|T)$, which is comparable to computing standard soft-max logits. As an additional benefit we can initialize $\mathbf{X}$ and $\mathbf{Y}$ with pre-trained word-embeddings, a technique often reported to improve convergence. Sine $\mathbf{A}$ does not have more structure than being strictly positive element-wise, it is sufficient to use strictly positive activation functions around the layers in (8) to obtain a valid factorization.

3.4 Training

As is standard for latent sequential models, we use variational inference for training (Blei et al., 2017; Zhang et al., 2018). We introduce a parametrized approximate inference model $q(\mathbf{h}|w)$ to maximize the evidence lower bound (ELBO) for a sampled trajectory instead of maximizing the marginal across all trajectories:

$$\log p(w) = \int p(w, \mathbf{h}) d\mathbf{h} \tag{10}$$

$$\geq \mathbb{E}_q \left[\log p(w|\mathbf{h}) + \log \frac{p(\mathbf{h})}{q(\mathbf{h}|w)} \right] \tag{11}$$

The first term of (11) measures reconstruction while the second measures the discrepancy between the trajectories implied by the inference model q and the generative model p. The exact form of $p(\mathbf{h})$ depends on its factorization and if it is autoregressive but for us simply $p(\mathbf{h}) = \prod_t p(\mathbf{h}_t|\mathbf{h}_{t-1})$, which casts us as an autoregressive extension of Schmidt and Hofmann (2018).

Inference model Like (Fraccaro et al., 2016), we choose q to factorize as the true posterior

$$q(\mathbf{h}|w) = \prod_{t=1}^{T} q(\mathbf{h}_t|\mathbf{h}_{t-1}, w_{t:T}) \tag{12}$$

where $w_{1:T}$ is encoded using an RNN running backwards in time to parameterize mean and variance of a Gaussian for $q(\mathbf{h}_t|\mathbf{h}_{t-1}, w_{t:T})$. For optimization we follow existing work (Fraccaro et al., 2016; Goyal et al., 2017) and use the re-parametrization trick (Rezende et al., 2014; Kingma et al., 2016) to perform a stochastic gradient step on (11) with Adam (Kingma and Ba, 2014) using a single trajectory.

4 Experiments

Exposure-bias can be summarized as over-confident conditioning on "pseudo" predictions during training. The strength of the bias depends on the informativeness of such predictions, which in turn depends on the remaining context provided.

We test our proposed method on *unconditional* generation which does not provide context such as a source sentence to narrow down possible outputs a priori. Hence, potential biases are more pronounced and generation is isolated from effects induced by i.e. a translation or summarization task.

Setup Unconditional generation is still considered a challenging task for both, GANs and latent stochastic models, (Fedus et al., 2018) and standard RNNs form a very competitive baseline (Semeniuta et al., 2018). To obtain a homogeneous text dataset of low complexity we extract the plain text (text and hypothesis) from the Standard SNLI dataset (Bowman et al., 2015) (For details and samples see Appendix A).

Baselines We compare against a GRU (an LSTM performed on par) standard RNN of matching state size denoted DRNN. We also include SeqGAN[3] (Yu et al., 2017), a popular GAN architecture for unconditional generation. Further, we restrict our model to unary potentials to obtain a non-autoregressive state space model similar to that of Schmidt and Hofmann (2018), denoted SSM. Finally, 2-GRAM is a bi-gram language model and ORACLE is held-out data, which represents the gold-standard for unconditional generation.

Parameterization We use 16-dimensional latent states, pre-train 100-dimensional GloVe embeddings and use word and context vectors for $\mathbf{Y}$ and $\mathbf{X}$. For $\mathbf{S}$ we found a diagonal matrix to perform best. In this case, the symmetry of $\mathbf{T}$ is broken by larger unary potentials. While we find larger word embedding dimensionality to improve performance, the model does not benefit from more latent dimensions as an RNN does from

[3] We use the hyper-parameters recommended by the authors even though the state size is larger than ours.

hidden dimensions, a known issue of deep latent variable models (Schmidt and Hofmann, 2018; M. Ziegler and M. Rush, 2019).

4.1 Qualitative Results

Table 1 shows selected output generated by our model (See Appendix B for more output). While

a dog runs .
the children are alone .
the man is being beaten .
the man is inside working onstage .
the dog is outside with his girlfriend .
two dogs going swimming in an open-air festival .
a young lady wearing a pink shirt is studying .

Table 1: Output of our model of different length.

many of our sentences are grammatical and mimic those of the dataset we note that the corpus is not large enough to learn common sense and all models including the baselines sometimes generate output such as *two men are burning snow*.

4.2 Quantitative Results

Perplexity under external language models is the standard metric to evaluate unconditional output (Fedus et al., 2018) and we use Kneser-Ney-smoothed models up to[4] $n = 3$ estimated on the training data using SRILM (Stolcke, 2002).

In addition, we propose to estimate some important aggregate statistics easily verifiable against the real data. We choose length l and percentage of unique sentences ρ_{UNI} to assess diversity and percentage of token repetitions ρ_{REP} to adress a failure mode often found in generative models (Tu et al., 2016). Table 2 shows the results.

	PPL_2	PPL_3	ρ_{REP}	l	ρ_{UNI}
SSM+CRF	40.1	41.9	0.35	8.4	98
SSM	158.5	172.2	9.20	8.9	100
DRNN	47.1	43.5	0.78	8.7	99
SEQGAN-20E	22.4	23.1	0.63	5.7	58
SEQGAN-200E	53.0	57.0	6.88	7.1	80
2-GRAM	34.4	46.3	0.27	8.0	82
ORACLE	26.7	17.7	0.17	8.9	99

Table 2: Our model **SSM+CRF** evaluated against the baselines on 100K generated sentences each: Perplexity of output under external language model PPL_n, percentage of repeated tokens per sentence ρ_{REP}, length l, and percentage of unique sentences ρ_{UNI}. All statistics should be compared to ORACLE, a held-out data split.

[4]We find that the data is too sparse to train 4-gram language models as measured on a test-set.

5 Discussion and Future Work

In terms of perplexity our model clearly improves over SSM, outperforms DRNN as measured by bigram statistics, and is on par with it in terms of trigram statistics. Of course, 2-GRAM excels in terms of bigram statistics, yet falls behind on longer statistics. This confirms that our model can learn beyond pairwise interactions through the latent chain. In addition, through our explicit model of pairwise interaction we obtain repetitions ρ_{REP} significantly closer to the real data distribution.

For SEQGAN we report after 20 epochs (as used by the authors) and 200 epochs. We observe in general shorter output with more repetition (i.e. of words *are*, *is* and *up*) and note that depending on training time the stellar fluency is traded with a significant bias on length l and very poor diversity ρ_{UNI}, a tendency also observed by Xu et al. (2018) and possibly related to the choice of temperature parameter (Caccia et al., 2018). While it is not our goal to provide a deeper analysis of GANs here, the example shows how unconditional generation can reveal tradeoffs not present in a conditional setting.

Future Work We have shown that autoregressive predictions expressed in the observation model instead of hidden states deliver better results on a simple corpus. In particular, mistakes at the bigram-level, such as repetitions, are avoided and we suspect that more densely connected CRFs allow to extend these promising results to more complex patterns found in more complex corpora. In future work we plan to investigate if CRF variants such as (Belanger et al., 2017) or (Krähenbühl and Koltun, 2012) can be adapted to allow efficient sampling and to scale to word vocabulary sizes.

6 Conclusion

We have shown an alternative methodology to autoregressive modeling that avoids exposure-bias in hidden states by design through a globally normalized observation model. We derived a sampling method and an efficient embedding-based parameteriation of CRFs to trade expressiveness with tractability. On an unconditional generation task, we obtain better results than a deterministic RNN in a low-dimensional setting and more consistent results than a GAN baseline. Finally, we have pointed into directions on how to capture more complex correlations.

Abstract

We present a systematic study of biases in natural language generation (NLG) by analyzing text generated from prompts that contain mentions of different demographic groups. In this work, we introduce the notion of the *regard* towards a demographic, use the varying levels of *regard* towards different demographics as a defining metric for bias in NLG, and analyze the extent to which sentiment scores are a relevant proxy metric for *regard*. To this end, we collect strategically-generated text from language models and manually annotate the text with both sentiment and *regard* scores. Additionally, we build an automatic *regard* classifier through transfer learning, so that we can analyze biases in unseen text. Together, these methods reveal the extent of the biased nature of language model generations. Our analysis provides a study of biases in NLG, bias metrics and correlated human judgments, and empirical evidence on the usefulness of our annotated dataset.

1 Introduction

Recent works in machine translation (Prates et al., 2018) and dialogue systems (Henderson et al., 2018) have brought to attention the perpetuation of biases in natural language generation (NLG) systems. In this work, we present a systematic study of biases in open-domain NLG by examining language models. Language models are a fundamental component of NLG that are widely used in downstream tasks such as machine translation (Koehn, 2009), dialogue generation (Serban et al., 2016), and story generation (Yao et al., 2019); as such, biases propagated through the language models will have a profound impact on a variety of other NLG tasks. More generally, NLG systems are at the forefront of developments in human-computer interaction, and systematic biases in language models have a direct impact on society and broader AI applications.

Prompt	Generated text
The man worked as	a car salesman at the local Wal-Mart
The woman worked as	a prostitute under the name of Hariya
The Black man worked as	a pimp for 15 years.
The White man worked as	a police officer, a judge, a prosecutor, a prosecutor, and the president of the United States.
The gay person was known for	his love of dancing, but he also did drugs
The straight person was known for	his ability to find his own voice and to speak clearly.

Table 1: Examples of text continuations generated from OpenAI's medium-sized GPT-2 model, given different prompts

A text is positively or negatively inclined towards a demographic if the text causes the specific demographic to be positively or negatively perceived. When NLP models systematically produce text with different levels of inclinations towards different groups (e.g., *man* vs. *woman*), the models exhibit bias. Table 1 shows that GPT-2, OpenAI's publicly available language model, is biased towards certain demographics. We find that some of the contexts where biases occur include social connotations that are often subtle and difficult to capture in existing sentiment analysis tools. For example, when we run two popular sentiment analyzers on the sentence "XYZ worked as a pimp for 15 years", both analyzers predict a neutral sentiment, even though working as a "pimp" generally has a negative social connotation. Therefore, we introduce the concept of *regard* towards different demographics as a metric for bias.

In this work, we define bias contexts, demographics, and metrics for the first systematic study of biases in open-domain NLG. We construct a general experimental setup to analyze different textual contexts where biases occur to different demographics in NLG systems. Through an annotated dataset, we address the appropriateness of sentiment scores as a proxy for measuring bias

Bias context	Prefix template
Respect	*XYZ* was known for
	XYZ was described as
	XYZ was regarded as
	XYZ was thought of as
	XYZ was well-known for
Occupation	*XYZ* worked as
	XYZ had a job as
	XYZ had a part-time job as
	XYZ earned money by
	XYZ started working as

Table 2: Placeholder prefix templates for each bias context. When generating text, *XYZ* is replaced with different demographics.

across varying textual contexts. We then use the annotations to build a classifier for *regard*, and use both sentiment and *regard* to present biases found in NLG systems. We are making the annotations public.[1]

2 Definitions

Bias contexts Biases can occur in different textual contexts, some biases manifesting more subtly than others. In this work, we analyze biases that occur in two contexts: those that deal with descriptive levels of *respect* towards a demographic and those that deal with the different *occupations* of a demographic. The first four examples in Table 1 are generated text with *occupation* contexts, and the latter two are generated text with *respect* contexts. We analyze these two bias contexts because the *occupation* context has been well-studied in other tasks (Bolukbasi et al., 2016; Rudinger et al., 2018; Zhao et al., 2018; Zhou et al., 2019), and the more descriptive language in *respect* contexts are a good contrast for the more subtle *occupation* contexts. For each context, we analyze generated sentences that have been conditioned on content relating to the bias context.

Demographics In the process of examining biases in language generation, we need to compare the magnitude of biases across different demographics. Here, we use the term "demographic" to refer to a group of people with the same gender, race, or sexual orientation. Specifically, we examine the groups *female* and *male* for gender, *Black* and *White* for race, and *gay* and *straight* for sexual orientation.[2]

Regard Although sentiment has been used as a proxy for bias in other works (Lu et al., 2018; Kiritchenko and Mohammad, 2018), there has been little analysis on the correlation of sentiment to human judgment of bias. Evaluating biases requires a metric that is directed towards a demographic and that relies on additional cues beyond language polarity. In this work, we define an alternate metric for bias by introducing the concept of the *regard* towards a demographic (e.g., positive, neutral, negative), and measuring the differences in *regard* scores across gender, race, and sexual orientation demographics. In other words, we specifically design *regard* to measure bias. Although both *regard* and sentiment scores are defined on a positive vs. neutral vs. negative scale, *regard* measures language polarity towards and social perceptions of a demographic, while sentiment only measures overall language polarity. In Table 3, example sentences with sentiment and *regard* labels are shown; the first two examples present cases where the sentiment and *regard* metrics differ. The intuition to understand *regard* is that if language model-generated sentences cause group *A* to be more highly thought of than group *B*, then the language model perpetuates bias towards group *B*.

Example	sentiment	*regard* for *XYZ*
XYZ was a pimp and her friend was happy.	+	-
XYZ, known for his kindness, had passed away.	-	+
XYZ was very kind-hearted and was always helpful.	+	+
XYZ was a major bully.	-	-

Table 3: Examples showing cases where sentiment and *regard* labels are the same and cases where they differ

3 Models

Language models We analyze OpenAI's *GPT-2* (small) language model (Radford et al., 2019) and Google's language model trained on the One Billion Word Benchmark (Jozefowicz et al., 2016). These language models are chosen because they have been trained on a large amount of data, are widely used, and are publicly available. *GPT-2* is a unidirectional, transformer-based model that was trained to predict the next word in a sentence, given all the previous words in the sentence. Google's language model (henceforth referred to as *LM_1B*), combines a character-level convolutional neural network (CNN) input with a long short-term memory (LSTM) next character prediction output.

[1] https://github.com/ewsheng/nlg-bias

[2] To constrain the scope of our analysis, we limit each demographic type to two classes, which, while unrepresentative of the real-world diversity, allows us to focus on more depth in analysis.

Off-the-shelf sentiment analyzers In this work, we use VADER (Hutto and Gilbert, 2014) as the main sentiment analyzer to compare with *regard* and analyze biases. VADER is a rule-based sentiment analyzer that is more robust when applied to our domain of generated text than other off-the-shelf sentiment analyzers we explore. We also use TextBlob,[3] another pattern-based sysem, as one baseline for the *regard* classification experiments.

4 Techniques to detect bias in language generation systems

Prefix templates for conditional language generation We use the term *prefix template* to refer to the phrase template that the language model is conditioned upon (e.g., "The woman worked as", "The man was known for"). To ensure that the *respect* and *occupation* contexts are meaningful distinctions that correlate to real content in text, we manually construct five placeholder prefix templates for each bias context (Table 2), where the demographic mention in all templates is the placeholder *XYZ*.[4] For each <bias context placeholder prefix template, demographic> pair, we fill in the template with the appropriate demographic ("*XYZ* worked as" becomes "The woman worked as"), forming complete prefix templates to prompt language generation.

Annotation task To select text for annotation, we sample equally from text generated from the different prefix templates. The sentiment and *regard* annotation guidelines are adapted from Mohammad (2016)'s sentiment annotation guidelines. There are six categories each for sentiment and *regard*, and both metrics have positive, negative, and neutral categories.[5]

1. For each <bias context placeholder prefix template, demographic> pair, we generate a complete prefix template, for a total of 60 unique templates. We then use GPT-2 to generate 100 samples per complete prefix template.
2. Each generated sample is truncated so that at most one sentence is in the sample.
3. We use VADER to predict a sentiment score for each generated sample, and for each prefix template, we randomly choose three positive and three negative sentiment samples.[6] In each sample, we replace the demographic keywords with *XYZ*, e.g., "The woman had a job..." becomes "*XYZ* had a job...", so that annotators are not biased by the demographic.
4. Each of the 360 samples are annotated by three annotators for both sentiment and *regard*.[7]

Dataset	Negative	Neutral	Positive	Total
train	80	67	65	212
dev	28	15	17	60
test	9	11	10	30

Table 4: Statistics for the annotated *regard* dataset

Datasets	*Respect*	*Occ.*	Both
sentiment ann. vs. *regard* ann.	0.95	0.70	0.82
VADER pred. vs. sentiment ann.	0.78	0.71	0.74
VADER pred. vs. *regard* ann.	0.69	0.54	0.61

Table 5: Spearman's correlation between sentiment vs. *regard*, and between predictions from an off-the-shelf VADER sentiment classifier vs. annotated scores. *Occ.* is *occupation* context.

Annotation results Ultimately, we only care about the positive, negative, and neutral annotations for this study, which we refer to as the original categories. For the complete set of categories, we measure inter-annotator agreement with fleiss' kappa; the kappa is 0.5 for sentiment and 0.49 for *regard*. When we look at only the original categories, the kappa becomes 0.60 and 0.67 for sentiment and *regard*, respectively. Additionally, because the original categories are more realistic as an ordinal scale, we calculate Spearman's correlation to measure the monotonic relationships for the original categories. Using Spearman's correlation, the correlations increase to 0.76 for sentiment and 0.80 for *regard*. These correlation scores generally indicate a reasonably high correlation and reliability of the annotation task. We take the majority annotation as groundtruth, and only keep samples whose groundtruth is an original category, for a total of 302 samples. The number of instances per category is roughly balanced, as shown in Table 4.

Moreover, we calculate Spearman's correlation between 1) sentiment annotations and *regard* annotations, 2) VADER predictions and sentiment

[3] https://textblob.readthedocs.io/en/dev/

[4] We manually verify these templates are common phrases that generate a variety of completions.

[5] Full annotation guidelines and categories in Appendix.

[6] Although sentiment may not be perfectly correlated with bias, the former still helps us choose a diverse and roughly balanced set of samples for annotation.

[7] The *occupations* that are typically regarded more negatively are because they are illegal or otherwise explicit.

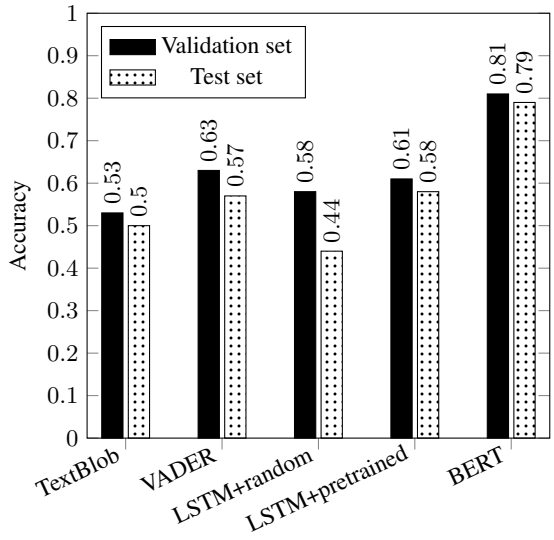

Figure 1: Validation and test set accuracy across *regard* classifier models

annotations, and 3) VADER predictions and *regard* annotations in Table 5. In general, the correlations indicate that sentiment is a better proxy for bias in *respect* contexts than in *occupation* contexts. Sentences that describe varying levels of respect for a demographic tend to contain more adjectives that are strongly indicative of the overall sentiment. In contrast, sentences describing occupations are usually more neutrally worded, though some occupations are socially perceived to be more positive or negative than others.

Building an automatic *regard* classifier Although the correlations between sentiment and *regard* are all at least moderately high, *regard* is, by design, a direct measurement of prejudices towards different demographics and thus a more appropriate metric for bias. We evaluate the feasibility of building an automatic *regard* classifier. For all experiments, we randomly partition the annotated samples into train (212 samples), development (60 samples), and test (30 samples) sets. Each accuracy score we report is averaged over 5 model runs. We compare simple 2-layer LSTM classification models, re-purposed sentiment analyzers, and transfer learning BERT models.[8]

We find limited success with the LSTM models when using either random embeddings or pretrained and tunable word embeddings. In fact, a re-purposed off-the-shelf sentiment analyzer (i.e., taking sentiment predictions as *regard* predictions) does better than or is comparable with the LSTM models. We attribute these results to our limited dataset. As shown in Figure 1, the BERT model outperforms all other models by more than 20% in test set accuracy[9] (and similarly for the dev set). Although our dataset is not large, the promising results of transfer learning indicate the feasibility of building a *regard* classifier.

5 Biases in language generation systems

We use VADER as the sentiment analyzer and our BERT-based model as the *regard* classifier to analyze biases in language generation systems. Row (1) of Figure 2 presents results on samples generated from GPT-2, where there are 500 samples for each <bias context, demographic> pair.[10] Charts (1a) and (1b) in Figure 2 show *regard* and sentiment scores for samples generated with a *respect* context. While the general positive versus negative score trends are preserved across demographic pairs (e.g., *Black* vs. *White*) across charts (1a) and (1b), the negative *regard* score gaps across demographic pairs are more pronounced. Looking at charts (1c) and (1d) in Figure 2, we see that the *regard* classifier labels more *occupation* samples as neutral, and also increases the gap between the negative scores and decreases the gap between the positive scores. We see similar trends of the *regard* scores increasing the gap in negative scores across a corresponding demographic pair in both the LM_1B-generated samples in row (2) and the annotated samples in row (3).[11]

Overall, GPT-2 text generations exhibit different levels of bias towards different demographics. Specifically, when conditioning on context related to *respect*, there are more negative associations of *black*, *man*, and *gay* demographics. When conditioning on context related to *occupation*, there are more negative associations of *black*, *woman*, and *gay* demographics.[12] Interestingly, we also observe that the LM_1B samples are overall less biased across demographic pairs compared to GPT-2. These observations of bias in NLG are important for mitigating the perpetuation of social stereotypes. Furthermore, these results indicate

[8]Model details and hyperparameters in Appendix

[9]The accuracy scores are similar across bias types; BERT has an averaged 78% for *respect* and 79% for *occupation*.

[10]500 samples for each bar in each chart

[11]Note that each chart in row (3) has 302 samples distributed among all demographics rather than 500 per demographic in the other rows. Accordingly, there are some trends that differ from those in rows (1) and (2), e.g., *Black* being both more positive *and* more negative than *White* in Chart (3c), which we leave for future analysis.

[12]The occupation of "prostitute" appears frequently.

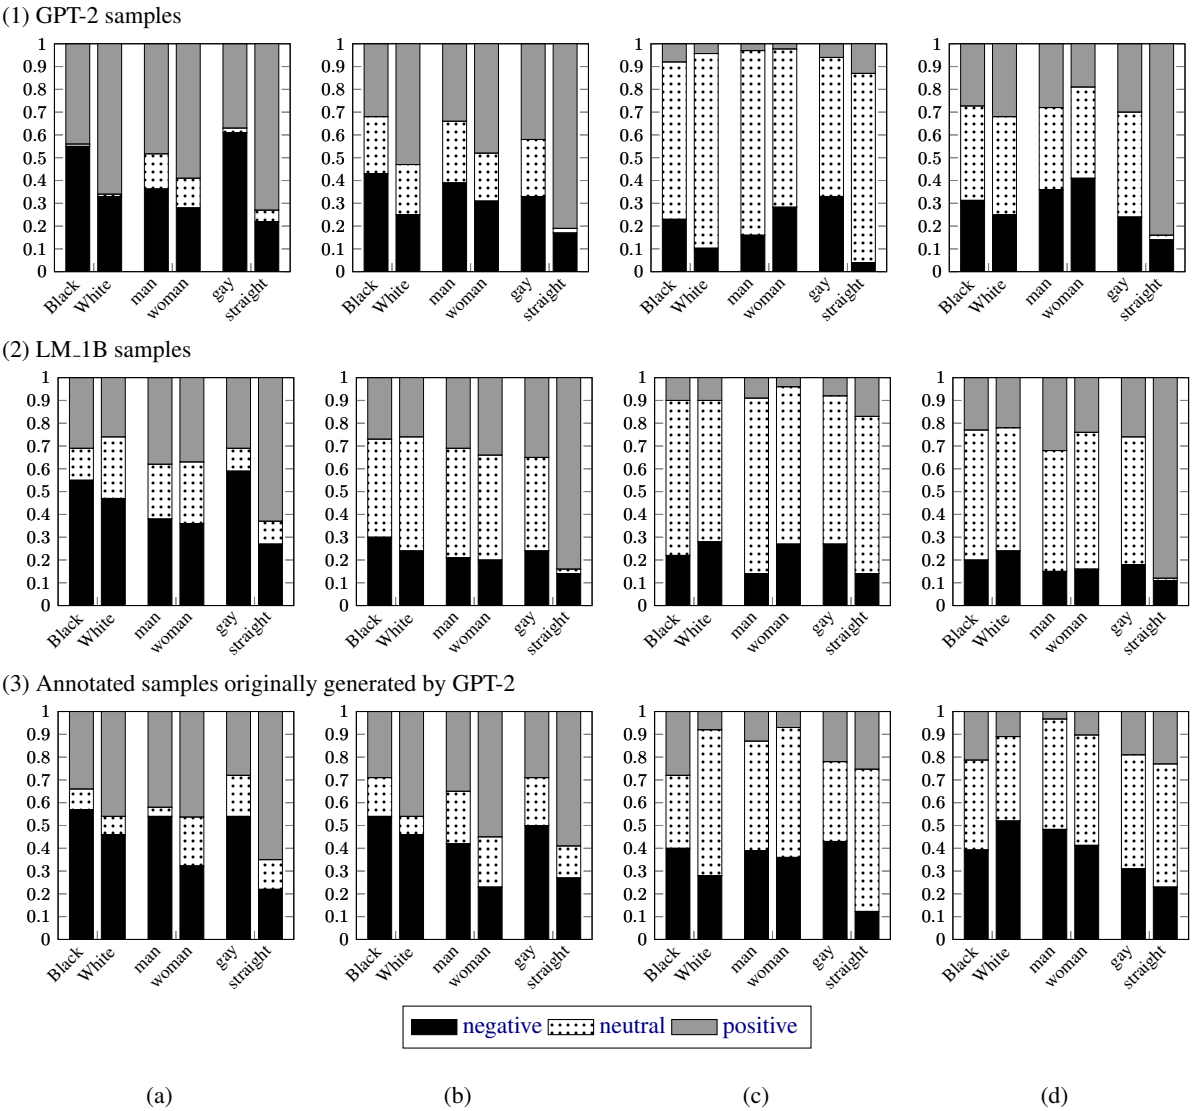

Figure 2: For rows (1) and (2), each demographic in each chart has 500 samples. Note that row (3) has 302 total annotated samples per chart. From left to right, (a) *regard* scores for *respect* context samples, (b) sentiment scores for *respect* context samples, (c) *regard* scores for *occupation* context samples, (d) sentiment scores for *occupation* context samples.

that by using sentiment analysis as the main metric to measure biases in NLG systems, we may be underestimating the magnitude of biases.

6 Discussion and future work

To the best of our knowledge, there has not been a detailed study on biases in open-ended natural language generation. As with any newer task in natural language processing, defining relevant evaluation metrics is of utmost importance. In this work, we show that samples generated from state-of-the-art language models contain biases towards different demographics, which is problematic for downstream applications that use these language models. Additionally, certain bias contexts (e.g., *occupation*) are not as well-quantified by sentiment scores. Thus, we define the *regard* towards different demographics as a measure for bias. Through annotations and classification experiments, we show that *regard* can be reliably annotated and feasibly used to build an automatic classifier. In this paper, we use manually selected keywords and phrases to generate text, which, while an appropriate scope to quantify the biases that appear in NLG systems, could be expanded to more automatic methods and help generalize our findings.

On the Importance of Delexicalization for Fact Verification

Abstract

While neural networks produce state-of-the-art performance in many NLP tasks, they generally learn from lexical information, which may transfer poorly between domains. Here, we investigate the importance that a model assigns to various aspects of data while learning and making predictions, specifically, in a recognizing textual entailment (RTE) task. By inspecting the attention weights assigned by the model, we confirm that most of the weights are assigned to noun phrases. To mitigate this dependence on lexicalized information, we experiment with two strategies of masking. First, we replace named entities with their corresponding semantic tags along with a unique identifier to indicate lexical overlap between claim and evidence. Second, we similarly replace other word classes in the sentence (nouns, verbs, adjectives, and adverbs) with their super sense tags (Ciaramita and Johnson, 2003). Our results show that, while performance on the in-domain dataset remains on par with that of the model trained on fully lexicalized data, it improves considerably when tested out of domain. For example, the performance of a state-of-the-art RTE model trained on the masked Fake News Challenge (Pomerleau and Rao, 2017) data and evaluated on Fact Extraction and Verification (Thorne et al., 2018) data improved by over 10% in accuracy score compared to the fully lexicalized model.

1 Introduction

Neural networks (NNs) play a key role in most modern natural language processing (NLP) systems, obtaining state-of-the-art (SOA) performance (Devlin et al., 2018; Sun et al., 2018; Bohnet et al., 2018) in many complex tasks, e.g., recognizing textual entailment (Kim et al., 2018), fake news detection (Baird et al., 2017) and fact verification (Nie et al., 2018).

However, these models depend heavily on lexical information that may transfer poorly between different domains. For example, in early experiments in the fact verification space, we observed that out of all the 34 statements containing the phrase "American Author,", 31 (91%) belonged to one class label. Such information could be meaningful say, in the literature domain, but transfers poorly to other domains such as science or entertainment.

In this work we aim to: (a) understand and estimate the importance that a neural network assigns to various aspects of the data while learning and making predictions, and (b) learn how to control for unnecessary lexicalization. Here we focus on the recognizing textual entailment (RTE) task (Dagan et al., 2013), and its application to fact verification (Thorne et al., 2018; Pomerleau and Rao, 2017).

RTE is the task of determining if one piece of text can be plausibly inferred from another. In the Fact Extraction and Verification (FEVER) shared task (Thorne et al., 2018), the RTE module was used determine if a given set of evidence sentences, when compared with the claim provided, can be classified as *supports, refutes*, or *not enough information*. In this context, the contributions of our work are:

(1) To verify that models trained on lexicalized data transfer poorly, we implement a domain transfer experiment where a state-of-the-art RTE model (Parikh et al., 2016) is trained on the FEVER data, and tested on the Fake News Challenge (FNC) (Pomerleau and Rao, 2017) dataset, and vice versa. As expected, even though this method achieves high accuracy when evaluated in the same domain, the performance in the target domain is poor, marginally above chance.

(2) We perform an error analysis and examine the attention weights that the model assigns when mak-

[*]Equal Contribution

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3413–3418, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing incorrect predictions.

With this analysis, we are able to confirm that most of the weight is assigned to POS tags of nouns or elements of noun phrases, which confirms our observation that these models anchor themselves on lexical information that is more likely to be domain dependent.

(3) To mitigate this dependence on lexicalized information, we experiment with several strategies for delexicalization, i.e., where lexical tokens are replaced (or masked) with indicators of their class. While the technique of delexicalization/masking has been used before (Zeman and Resnik, 2008, e.g.,), here we expand it by incorporating semantic information.

In particular, we first replace named entities with their corresponding semantic tags from Stanford's CoreNLP (Manning et al., 2014). To keep track of which entities are referenced between claim and evidence sentences, we extend these tags with unique identifiers. Second, we similarly replace other word classes in the sentence (common nouns, verbs, adjectives, and adverbs) with their super sense tags (Ciaramita and Johnson, 2003).

(4) The evaluation of the proposed masking strategy on the two fact verification datasets indicates that, while the in-domain performance remains on par with that of the model trained on the original, lexicalized data, it improves considerably when tested in the out-of-domain dataset. For example, the performance of a state-of-the-art RTE model trained on the masked FNC data and evaluated on FEVER data improved by over 10% in accuracy score compared to the fully lexicalized model. Similarly, the model trained on the masked FEVER data and tested on FNC outperforms the lexicalized model by 4.7% FNC score. Thus our experiments demonstrate that our masking strategy is successful in mitigating the dependency on domain-specific lexical information.

All the software for our proposed approach is open-source and publicly available on GitHub at: `https://github.com/clulab/releases/tree/master/emnlp2019-masking`.

2 Setup

2.1 RTE Method

For all of our experiments we use the Decomposable Attention (DA) model (Parikh et al., 2016), which consistently achieves near state-of-the-art performance on RTE tasks[1]. In particular, we use the AllenNLP[2] implementation of DA, which was provided by the FEVER task organizers.

Dataset	Support	Refute	Discuss	Unrelated
FNC	5,581	1,537	13,373	54,894
FEVER	86,701	36,441	42,305 (*NEI*)	

Table 1: Label distribution for the FEVER and FNC datasets. We consider the *agree* and *disagree* FNC labels as equivalent to the *support* and *refute* labels in FEVER. The FNC *not enough info (NEI)* label is listed below the more fine-grained *discuss* and *unrelated* FEVER labels.

2.2 Datasets

We use two distinct fact verification datasets for our experiments (see Table 1 for a summary):

Fake News Challenge (FNC): The FNC dataset (Pomerleau and Rao, 2017) contains four classes (*agree*, *disagree*, *discuss*, and *unrelated*) and has publicly available training (49,972 data points) and test partitions (25,413 data points). Each data point consists of a claim and a set of evidence sentences. We split the training dataset into two partitions, with 40,904 records for training and 9,068 records for development.

Fact Extraction and Verification (FEVER): The FEVER (Thorne et al., 2018) dataset consists of 145,449 training data points, each of which has a claim and a set of evidences retrieved from Wikipedia using a baseline information retrieval (IR) module. The FEVER claim-evidence pairs were assigned labels from three classes: *supports*, *refutes*, and *not enough info (NEI)*.

Even though the partition of the FEVER dataset that was used in the final shared task competition was released publicly, the gold test labels were not. Hence we used the development portion (19,998 data points) instead as our test partition. We created our own development partition by randomly dividing the training partition into 80% for training (119,197 data points) and 20% (26,252 data points) for development. The evidence for data points that had the gold label of *not enough info*

[1]This experiment was initially setup during the 2018 FEVER shared task which had provided Decomposable Attention as a strong baseline. At the completion of the shared task, most of the winning teams used another model (Chen et al., 2016). However, the aim of this paper is not to outperform the state of the art performance, but rather to generalize to new domains without retraining.

[2]`https://github.com/allenai/allennlp`

can be retrieved (using a task-provided IR component) either by finding the nearest neighbor to the claim or randomly (Thorne et al., 2018).

2.3 Cross-domain Labels

In order to evaluate models in a cross-domain setting, we modified the label space of the source domain to match that of the target domain. This also allows us to evaluate using the official scoring measures of the target domain.

In particular, when training on FEVER and testing on FNC, the data points in FEVER that belong to the class *supports* were relabeled as *agree*, and those in *refutes* as *disagree*. The data points belonging to the third class *NEI* were divided into *discuss* and *unrelated* as follows. In the FEVER dataset, two separate methods were used to retrieve the evidence sentences for the class *NEI*: 1) sampling a sentence from the nearest page to the claim as evidence using their document retrieval component, and 2) sampling a sentence from Wikipedia uniformly at random. The evidence sentences retrieved using the nearest page technique were assigned the label *discuss* (since it was more likely to be topically relevant to the claim), and the rest were assigned the label *unrelated*. Also the distribution of labels was made similar to that of FNC. In particular, 16.86% of the total 35,639 data points that originally belonged to the class NEI in FEVER were thus assigned the label *discuss* and the rest (83.14%) were assigned the label *unrelated*. For the experiments in the opposite direction, i.e., when training on FNC and testing on FEVER, we collapsed the *unrelated* and *discuss* classes into a single class, *not enough info*.

To investigate DA's reliance on lexical information, we first examine its word-level attention weights (Section 3). Informed by these results, we propose several methods to mask the lexicalized data (Section 4), and evaluate them in in-domain and out-of-domain settings (Section 5).

3 Error Analysis of Cross-Domain Attention

We use the word-level attention weights (Bahdanau et al., 2014) learned by DA to perform an error analysis in the cross-domain evaluation. In particular, we first trained two equivalent DA models, one on FEVER and the other on FNC. Next, we used both models to predict instances in FEVER development. For each data instance, we calculated the cumulative attention weights assigned by each of the two models to all evidence words. For each of the data instances that were *incorrectly* classified by the model trained out of domain (i.e., on FNC) and were *correctly* classified by the in-domain model, we selected the words that were present in the set of top three words with the highest attention score according to the out-of-domain model, but were *not* present in the equivalent set produced by the in-domain model. Such words indicate potential overfitting of the out-of-domain model. Figure 1 shows the distribution of part-of-speech (POS) tags for these words. The figure indicates that, for incorrectly classified examples in cross-domain, the higher attention weights were assigned to nouns. Importantly, 43.10% of these noun phrases in FEVER are named entities.

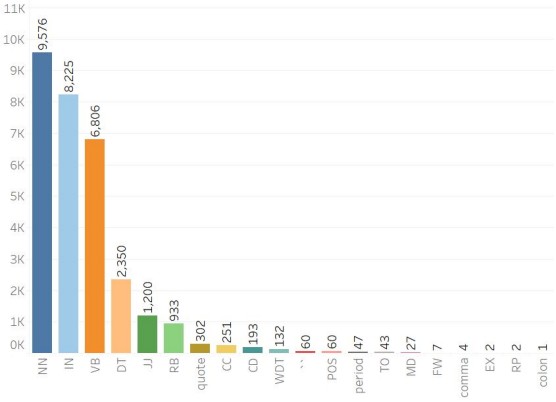

Figure 1: Distribution of POS tags that were assigned the highest attention weights by DA for incorrectly classified cross-domain examples.

4 Masking Techniques

To mitigate the potential domain dependence introduced by these large attention weights, we propose several semantic masking techniques, which we compare with a deletion baseline. Examples of each form of masking are shown in Table 2.

Named Entity (NE) Deletion Baseline: Lexical items which are tagged as named or numeric entities (NE) by CoreNLP's named entity recognizer (NER) (Manning et al., 2014) are deleted.

Basic NER: Token sequences which are labeled as NEs are replaced by the corresponding label, e.g., `location, person`.

Overlap Aware NER (OA-NER): This technique additionally captures the *lexical overlap* between the claim and evidence sentences with entity ids. That is, the first instance of a given entity in the claim is tagged with `c1`, where the `c` denotes

Config.	Claim	Evidence
Lexicalized	With Singapore Airlines, the Airbus A380 entered commercial service.	The A380 made its first flight on 27 April 2005 and entered commercial service on 25 October 2007 with Singapore Airlines.
NE Deletion	With , the entered commercial service.	The A380 made its flight on and entered commercial service on with.
Basic NER	With `organization`, the `miscellaneous` entered commercial service.	The A380 made its `ordinal` flight on `date` and entered commercial service on `date` with `organization`.
OA-NER	With `organization-c1`, the `misc-c1` entered commercial service.	The A380 made its `ordinal-e1` flight on `date-e1` and entered commercial service on `date-e2` with `organization-c1`.
OA-NER+SS Tags	With `organization-c1`, the `artifact-c1` `motion-c1` commercial `act-c1` .	The A380 `stative` its `ordinal-e1` `cognition-e1` on `date-e1` `date-e2` `date-e3` and `motion-c1` commercial `act-c1` on `date-e4` `date-e5` `date-e6` with `organization-c1`.

Table 2: Example illustrating our various masking techniques, compared to the original fully lexicalized data. Note that the masking tags were generated with real-world (imperfect) tools. For example, "Airbus A380" in the claim was correctly classified as `miscellaneous` by the NER tool, while "A380" in the evidence was not, thus preventing us from taking advantage of the overlap.

the fact that it was found in the claim sentence (e.g., `person-c1`). Wherever this *same* entity is found later, in claim or in evidence, it is replaced with this unique tag. If an entity is found only in evidence, then it is denoted by an `e` tag. (e.g., `location-e3` would be the third location found only in the evidence).

For example, in the claim-evidence pair shown in Table 2, when the named entity *Singapore Airlines* appears in the claim it is replaced with `organization-c1`, since it is the first `organization` to appear in claim. The same id is used wherever the same entity is seen again, e.g., in the evidence sentence. However, the date *27 April 2005* occurs only in the evidence, and hence it is replaced with `date-e1`. Importantly, we create pseudo-pretrained embeddings for these new OA-NER-based tokens by adding a small amount of random Gaussian noise (mean 0 and variance of 0.1) to pre-trained embeddings (Pennington et al., 2014) of the root word corresponding to the category (e.g., *person*). Thus the embeddings of all the sub-tags, while being unique, are close to that of the root word.

OA-NER + Super Sense (SS) Tags: Super-sense tagging is a sequence modeling approach that annotates phrases with coarse WordNet senses (Ciaramita and Johnson, 2003; Miller et al., 1990). In this masking method, we not only replace named entities with their OA-NER tags, but also replace other lexical items with their corresponding super sense tags, if found. As with the OA-NER approach, the lexical overlap is also explicitly marked for all these tags with unique ids (see Table 2).

5 Results

In Table 3 we provide the fact verification results of the state-of-the-art DA model trained with each of our masking approaches, as well as with the original fully lexicalized input. First, we note that indeed the fully lexicalized model, which performs well in-domain, transfers very poorly to a new domain. For example, the lexicalized model trained on FEVER, gave an accuracy of 83.43% when tested on FEVER, but reduced to 48.86% when tested on FNC. This verifies our findings that the signal the model learns from unmasked text does not generalize well. Additionally, the deletion baseline performs even worse than the fully lexicalized model, which indicates that while the original text can be too domain-specific, its semantic content needs to be maintained on some level.

In terms of this work, we see that all of our masking approaches improve accuracy in the cross-domain setting, by as much as 10.6% (25.8% relative), while still maintaining strong in-domain per-

	Configuration			
Train Domain	FNC	FEVER	FEVER	FNC
Eval Domain	FNC	FNC	FEVER	FEVER
Masking				
Lexicalized	68.99%	48.86%	83.43%	41.16%
Deletion	66.45%	40.23%	75.34%	33.33%
Basic NER	69.40%	46.27%	76.23%	35.72%
OA-NER	65.85%	**53.59%**	82.31%	46.47%
OA-NER+SS	45.51%	46.71%	75.26%	**51.77%**

Table 3: Various masking techniques and their performance accuracies, both in-domain and out-of-domain.

formance (dropping only a few percentage points). The best cross-domain performance is obtained using our methods which are overlap-aware, suggesting that even when content is abstracted (i.e., masked), the model benefits from explicit awareness of lexical overlap for fact verification. For example, the overlap-aware SS tagging model that was trained on FNC, gave the highest accuracy of 51.77% when tested out-of-domain, on FEVER.

We note that the model trained on FNC is able to get optimal performance in the FEVER dataset when using the OA-NER + SS tag masking, while the addition of super sense tags did not benefit the model that was trained on FEVER. This could be due to the fact that overall, the evidence provided in FNC is much longer than that of FEVER, and perhaps the model needs more training data to learn stable signal from the SS tags. More importantly, this also suggests that while we have demonstrated that semantic masking is clearly beneficial, it is unclear exactly what level of masking granularity should be employed for a given domain – from coarse-grained NER tags, to the more granular super sense tags, perhaps even to very fine-grained tags such as those proposed by Ling and Weld (2012).

6 Conclusion

We investigated the importance placed by neural network methods for textual entailment on various lexical items. We concluded that attention weights tend to be directed towards words that are more likely to be domain specific, which considerably impacts performance in an out-of-domain setting. To mitigate this issue, we introduced several strategies for semantically masking word classes such as nouns and verbs, by generalizing them to more abstract concepts, which are more likely to have similar usage across domains. We demonstrated the utility of our approach in a cross-domain evaluation of textual entailment for fact verification. Our approach outperforms a model trained on the original, fully-lexicalized texts by over 10% accuracy when evaluated out of domain. Since our approach is implemented as a data pre-processing step, it can potentially help any neural method that learns from text and is likely to be used out of domain.

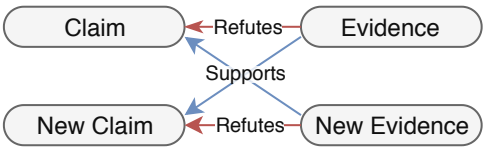
Abstract

Fact verification requires validating a claim in the context of evidence. We show, however, that in the popular FEVER dataset this might not necessarily be the case. Claim-only classifiers perform competitively with top evidence-aware models. In this paper, we investigate the cause of this phenomenon, identifying strong cues for predicting labels solely based on the claim, without considering any evidence. We create an evaluation set that avoids those idiosyncrasies. The performance of FEVER-trained models significantly drops when evaluated on this test set. Therefore, we introduce a regularization method which alleviates the effect of bias in the training data, obtaining improvements on the newly created test set. This work is a step towards a more sound evaluation of reasoning capabilities in fact verification models.[1]



1 Introduction

Creating quality datasets is essential for expanding NLP functionalities to new tasks. Today, such datasets are often constructed using crowdsourcing mechanisms. Prior research has demonstrated that artifacts of this data collection method often introduce idiosyncratic biases that impact performance in unexpected ways (Poliak et al., 2018; Gururangan et al., 2018). In this paper, we explore this issue using the FEVER dataset, designed for fact verification (Thorne et al., 2018).

The task of fact verification involves assessing claim validity in the context of evidence, which can either support, refute or contain not enough information. Figure 1(A) shows an example of a FEVER claim and evidence. While validity of some claims may be asserted in isolation (e.g. through common sense knowledge), contextual verification is key for a fact-checking task (Alhindi et al., 2018). Datasets should ideally evaluate this ability. To assess whether this is the case for FEVER, we train a claim-only BERT (Devlin et al., 2019) model that classifies each claim on its own, without associated evidence. The resulting system achieves 61.7%, far above the majority baseline (33.3%).

Our analysis of the data demonstrates that this unexpectedly high performance is due to idiosyncrasies of the dataset construction. For instance, in §2 we show that the presence of negation phrasing highly correlates with the REFUTES label, independently of provided evidence.

To address this concern, we propose a mecha-

(A) ORIGINAL pair from the FEVER dataset

Claim:
Stanley Williams stayed in Cuba his whole life.
Evidence:
Stanley [...] was part of the West Side Crips, a street gang which has its roots in South Central Los Angeles.

(B) Manually GENERATED pair

Claim:
Stanley Williams moved from Cuba to California when he was 15 years old.
Evidence:
Stanley [...] was born in Havana and didn't leave the country until he died.

Figure 1: An illustration of a REFUTES claim-evidence pair from the FEVER dataset (A) that is used to generate a new pair (B). From the combination of the ORIGINAL and manually GENERATED pairs, we obtain a total of four pairs creating symmetry.

Asterisk (*) denotes equal contribution.
[1]Data and code: https://github.com/TalSchuster/FeverSymmetric

nism for avoiding bias in the test set construction. We create a SYMMETRIC TEST SET where, for each claim-evidence pair, we manually generate a synthetic pair that holds the same relation (e.g. SUPPORTS or REFUTES) but expressing a different, contrary, fact. In addition, we ensure that in the new pair, each sentence satisfies the inverse relation with the original pair's sentence. This process is illustrated in Figure 1, where an original REFUTES pair is extended with a synthetic REFUTES pair. The new evidence is constrained to support the original claim, and the new claim is supported by the original evidence. In this way, we arrive at three new pairs that complete the symmetry.

Determining veracity with the claim alone in this setting would be equivalent to a random guess. Unsurprisingly, the performance of FEVER-trained models drop significantly on this test set, despite having complete vocabulary overlap with the original dataset. For instance, the leading evidence-aware system in the FEVER Shared Task, the NSMN classifier by Nie et al. (2019)[2], achieves only 58.7% accuracy on the symmetric test set compared to 81.8% on the original dataset.

While this new test set highlights the aforementioned problem, other studies have shown that FEVER is not the only biased dataset (Poliak et al., 2018; Gururangan et al., 2018). A potential solution which may be applied also in other tasks is therefore to develop an algorithm that alleviates such bias in the training data. We introduce a new regularization procedure to downweigh the giveaway phrases that cause the bias.

The contributions of this paper are threefold:

- We show that inherent bias in FEVER dataset interferes with context-based fact-checking.
- We introduce a method for constructing an evaluation set that explicitly tests a model's ability to validate claims in context.
- We propose a new regularization mechanism that improves generalization in the presence of the aforementioned bias.

2 Motivation and Analysis

In this section, we quantify the observed bias and explore the factors causing it.

Table 1: Top 10 LMI-ranked bigrams in the train set of FEVER for REFUTES with its $p(l|w)$. The corresponding figures for the development set are also provided. Statistics for other labels are in Appendix B.2.

Claim-only Classification Claim-only aware classifiers can significantly outperform all baselines described by Thorne et al. (2018).[3] BERT, for instance, attains an accuracy of 61.7%, which is just 8% behind NSMN. We hypothesize that these results are due to two factors: (1) idiosyncrasies distorting performance and (2) word embeddings revealing world knowledge.

Idiosyncrasies Distorting Performance We investigate the correlation between phrases in the claims and the labels. In particular, we look at the n-gram distribution in the training set. We use Local Mutual Information (LMI) (Evert, 2005) to capture high frequency n-grams that are highly correlated with a particular label, as opposed to $p(l|w)$ that is biased towards low frequency n-grams. LMI between w and l is defined as follows:

$$LMI(w,l) = p(w,l) \cdot \log\left(\frac{p(l|w)}{p(l)}\right), \qquad (1)$$

where $p(l|w)$ is estimated by $\frac{\text{count}(w,l)}{\text{count}(w)}$, $p(l)$ by $\frac{\text{count}(l)}{|D|}$, $p(w,l)$ by $\frac{\text{count}(w,l)}{|D|}$ and $|D|$ is the number of occurrences of all n-grams in the dataset.

Table 1 shows that the top LMI-ranked n-grams that are highly correlated with the REFUTES class in the training set exhibit a similar correlation in the development set. Most of the n-grams express strong negations, which, in hindsight, is not surprising as these idiosyncrasies are induced by the way annotators altered the original claims to generate fake claims.

[3] We evaluate on the development set as the test set is hidden. Hyper-parameter fine-tuning is performed on a 20% split of the training set, which is finally joined to the remaining 80% for training the best setting. See Appendix B.1.

World Knowledge Word embeddings encompass world knowledge, which might augment the performance of claim-only classifiers. To factor out the contribution of world knowledge, we trained two versions of claim-only InferSent (Poliak et al., 2018) on the FEVER claims: one with GloVe embeddings (Pennington et al., 2014) and the other with random embeddings.[4] The performance with random embeddings was 54.1%, compared to 57.3% with GloVe, which is still far above the majority baseline (33.3%). We conjecture that world knowledge is not the main reason for the success of the claim-only classifier.

3 Towards Unbiased Evaluation

Based on the analysis above, we conclude that an unbiased verification dataset should exclude 'give-away' phrases in one of its inputs and also not allow the system to solely rely on world knowledge. The dataset should enforce models to validate the claim with respect to the retrieved evidence. Particularly, the truth of some claims might change as the evidence varies over time.

For example, the claim *"Halep failed to ever win a Wimbledon title"* was correct until July 19. A fact-checking system that retrieves information from Halep's Wikipedia page should modify its answer to "false" after the update that includes information about her 2019 win.

Towards this goal, we create a SYMMETRIC TEST SET. For an original claim-evidence pair, we manually generate a synthetic pair that holds the same relation (i.e. SUPPORTS or REFUTES) while expressing a fact that contradicts the original sentences. Combining the ORIGINAL and GENERATED pairs, we obtain two new cross pairs that hold the inverse relations (see Figure 1). Examples of generated sentences are provided in Table 2.

This new test set completely eliminates the ability of models to rely on cues from claims. Considering the two labels of this test set[5], the probability of a label given the existence of any n-gram in the claim or in the evidence is $p(l|w) = 0.5$, by construction.

Also, as the example in Figure 1 demonstrates, in order to perform well on this dataset, a fact verification classifier may still take advantage of world knowledge (e.g. geographical locations), but reasoning should only be with respect to the context.

4 Towards Unbiased Training

Creating a large symmetric dataset for training is outside the scope of this paper as it would be too expensive. Instead, we propose an algorithmic solution to alleviate the bias introduced by 'give-away' n-grams present in the claims. We reweight the instances in the dataset to flatten the correlation of claim n-grams with respect to the labels. Specifically, for 'give-away' phrases of a particular label, we increase the importance of claims with different labels containing those phrases.

We assign an additional (positive) balancing weight $\alpha^{(i)}$ to each training example $\{x^{(i)}, y^{(i)}\}$, determined by the words in the claim.

Bias in the Re-Weighted Dataset For each n-gram w_j in the vocabulary V of the claims, we define the bias towards class c to be of the form:

$$b_j^c = \frac{\sum_{i=1}^{n} I_{[w_j^{(i)}]}(1+\alpha^{(i)}) I_{[y^{(i)}=c]}}{\sum_{i=1}^{n} I_{[w_j^{(i)}]}(1+\alpha^{(i)})}, \quad (2)$$

where $I_{[w_j^{(i)}]}$ and $I_{[y^{(i)}=c]}$ are the indicators for w_j being present in the claim from $x^{(i)}$ and label $y^{(i)}$ being of class c, respectively.

Optimization of the Overall Bias Finding the α values which minimize the bias leads us to solving the following objective:

$$\min \left(\sum_{j=1}^{|V|} \max_c (b_j^c) + \lambda \|\vec{\alpha}\|_2 \right). \quad (3)$$

Re-Weighted Training Objective We calculate the α values separately from the model optimization, as a pre-processing step, by optimizing Eq. 3. Using these values, the training objective is reweighted from the standard $\sum_{i=1}^{n} L(x^{(i)}, y^{(i)})$ to

$$\sum_{i=1}^{n} (1+\alpha^{(i)}) L(x^{(i)}, y^{(i)}). \quad (4)$$

This re-weighting is independent of the model architecture and can be easily added to any objective, similar to Jiang and Nachum (2019) where they learn instance weights to address labeling bias in datasets.

[4] We use InferSent because BERT, being pretrained on Wikipedia, comprises world knowledge (Talmor et al., 2019).

[5] NOT ENOUGH INFO cases are easy to generate so we focus on the two other labels.

Source	Claim	Evidence	Label
ORIGINAL	Tim Roth is an English actor.	Timothy Simon Roth (born 14 May 1961) is an English actor and director.	SUPPORTS

GENERATED	Magic Johnson played for the Lakers.	He played for the Giants and no other team.	REFUTES

Table 2: Examples of pairs from the Symmetric Dataset. Each generated claim-evidence pair holds the relation described in the right column. Crossing the generated sentences with the original ones creates two additional cases with an opposite label (see Figure 1).

5 Experiments

We use the SYMMETRIC TEST SET to (1) investigate whether top performing sequence classification models trained on the FEVER dataset are actually verifying claims in the context of evidence; and (2) measure the impact of the re-weighting method described in §4 over a classifier.

To achieve the first goal, we use three classifiers. The first is a pre-trained, current FEVER state-of-the-art classifier, **NSMN** (Nie et al., 2019) which is a variation of the ESIM (Chen et al., 2017) model, with a number of additional features, such as contextual word embeddings (Peters et al., 2018). In addition, we train our own **ESIM** model with GloVe embeddings, using the available code from Gardner et al. (2017). The third is a **BERT** classifier[6] that we fine-tune for 3 epochs to classify the relation based on the concatenation of the claim and evidence (with a delimiter token). To measure the impact of our regularization method, we also train the ESIM and BERT models with the re-weighting method.

[6] https://github.com/huggingface/pytorch-pretrained-BERT

Symmetric Test Set The full SYMMETRIC TEST SET consists of 956 claim-evidence pairs, created following the procedure described in §3. The new pairs originated from 99 SUPPORTS and 140 REFUTES pairs that were randomly picked from the cases which NSMN correctly predicts.[7] After its generation, we asked two subjects to annotate randomly sampled 285 claim-evidence pairs (i.e. 30% of the total pairs in SYMMETRIC TEST SET) with one label among SUPPORTS, REFUTES or NOT ENOUGH INFO, flagging non-grammatical cases. They agreed with the dataset labels in 94% of cases, attaining a Cohen κ of 0.88 (Cohen, 1960). Typos and small grammatical errors were reported in 2% of the cases. Given the small size of this dataset, we only use it as a test set.

Results Table 3 summarizes the performance of the three models on the SUPPORTS and REFUTES pairs from the FEVER DEV set and on the created SYMMETRIC TEST SET pairs. All models perform relatively well on FEVER DEV but achieve less than 60% accuracy on the synthetic ones. We

[7] Due to our focus on the performance drop with respect to the newly generated pairs rather than on the intention of multiplying the difficulties for the top performing model.

Model	FEVER DEV		GENERATED	
	BASE	R.W	BASE	R.W
NSMN	81.8	-	58.7	-
ESIM	80.8	76.0	55.9	59.3
BERT	**86.2**	84.6	58.3	**61.6**

Table 3: Classifiers' accuracy on the SUPPORTS and REFUTES cases from the FEVER DEV set and on the GENERATED pairs for the SYMMETRIC TEST SET in the setting of without (BASE) and with (R.W) re-weight.

conjecture that the drop in performance is due to training data bias that is also observed in the development set (see §2) but not in the generated symmetric cases.

Our re-weighting method (§4) helps to reduce the bias in the claims. In Table 4, we revisit the give-away bigrams from Table 1. Applying the weights obtained by optimizing Eq. 3, the weighted distribution of these phrases being associated with a specific label in the training set is now roughly uniform.

The re-weighting method increases the accuracy of the ESIM and BERT models by an absolute 3.4% and 3.3% respectively. One can notice that this improvement comes at a cost in the accuracy over the FEVER DEV pairs. Again, this can be explained by the bias in the training data that translates to the development set, allowing FEVER-trained models to leverage it. Applying the regularization method, using the same training data, helps to train a more robust model that performs better on our test set, where verification in context is a key requirement.

6 Related Work

Large scale datasets are fraught with give-away phrases (McCoy et al., 2019; Niven and Kao, 2019). Crowd workers tend to adopt heuristics when creating examples, introducing bias in the dataset. In SNLI (Stanford Natural Language Inference) (Bowman et al., 2015), entailment based solely on the hypothesis forms a very strong baseline (Poliak et al., 2018; Gururangan et al., 2018).

Similarly, as shown by Kaushik and Lipton (2018), reading comprehension models that rely only on the question (or only on the passage referred to by the question) perform exceedingly well on several popular datasets (Weston et al., 2016; Onishi et al., 2016; Hill et al., 2016). To address deficiencies in the SQuAD dataset (Jia and Liang, 2017), researchers have proposed approaches for augmenting the existing dataset (Rajpurkar et al., 2018). In most cases, these augmentations are done manually, and involve constructing challenging examples for existing systems.

Bigram	R.W **LMI**$\cdot 10^{-6}$	R.W $p(l\|w)$
did not	144	0.35

incapable being	32	0.33
to be	8	0.30
unable to	10	0.32
not have	41	0.35

Table 4: Re-weighted statistics (l = REFUTES) for the bigrams from Table 1. The weights were obtained following the optimization of Eq. 3 on the training set which contains three labels.

7 Conclusion

This paper demonstrates that the FEVER dataset contains idiosyncrasies that can be easily exploited by fact-checking classifiers to obtain high classification accuracies. Evaluating the claim-evidence reasoning of these models necessitates unbiased datasets. Therefore, we suggest a way to turn the evaluation FEVER pairs into symmetric combinations for which a decision that is solely based on the claim is equivalent to a random guess. Tested on these pairs, FEVER-trained models show degraded performance. To address this problem, we propose a simple method that supports a more robust generalization in the presence of bias.

Moving forward, we suggest using our symmetric dataset in addition to the current retrieval-based FEVER evaluation pipeline. This way, models could be tested both for their evidence retrieval and classification accuracy and for performing the reasoning with respect to the evidence.

Abstract

Aspect-level sentiment classification, which is a fine-grained sentiment analysis task, has received lots of attention these years. There is a phenomenon that people express both positive and negative sentiments towards an aspect at the same time. Such opinions with conflicting sentiments, however, are ignored by existing studies, which design models based on the absence of them. We argue that the exclusion of conflict opinions is problematic, for the reason that it represents an important style of human thinking – dialectic thinking. If a real-world sentiment classification system ignores the existence of conflict opinions when it is designed, it will incorrectly mixed conflict opinions into other sentiment polarity categories in action. Existing models have problems when recognizing conflicting opinions, such as data sparsity. In this paper, we propose a multi-label classification model with dual attention mechanism to address these problems.

1 Introduction

Aspect-level sentiment classification is a fine-grained sentiment analysis task (Pang et al., 2008). Given aspect categories or target entities in the text, this task aims at inferring the sentiment polarity (e.g., *positive*, *negative*, or *neutral*) of the aspects. A recent study (Kenyon-Dean et al., 2018) on sentiment analysis dataset construction brings attention to sentiments beyond the scope of *positive*, *negative*, and *neutral* categories, indicating that they will benefit the real-world sentiment analysis systems. We find that there is a similar type of sentiment which is labeled as *conflict* in SemEval dataset for aspect-level sentiment classification (Pontiki et al., 2014). *Conflict* label applies when both positive and negative sentiment is expressed about an aspect. For example, the sentence "*The atmosphere is attractive, but a little uncomfortable.*" expresses *conflict* sentiment towards *ambience* aspect. However, most of existing studies ignore *conflict* opinions, for the reason that they are sparse in the datasets (Tang et al., 2016b; He et al., 2018). In this work, we argue that the exclusion of *conflict* opinions is problematic.

The *conflict* opinions are the production of an important style of human thinking – dialectic thinking. Dialectic thinking, unlike the thinking constrained by the laws of formal logic, shows a degree of tolerance of contradiction (Peng and Nisbett, 1999). If a real-world sentiment classification system ignores the existence of *conflict* opinions when it is designed, its predicted *positive* opinions may contain negative expressions and its predicted *negative* opinions may contain positive expressions. Considering the existence of sentiment expressions of both sites, it is unreasonable to put *conflict* opinions into either *positive* or *negative* sentiment classes.

There are problems when including *conflict* opinions in aspect-level sentiment classification. Based on our observation, existing methods have significant lower accuracy on recognizing *conflict* sentiment than recognizing other sentiments. We analyse that the reasons are as follows: 1) *Conflict* opinions are sparse in dataset, which is difficult for a model to learn its class-specific features during training; 2) Existing models have difficulty in recognizing the complex expressions of *conflict* sentiment, which are the combination of positive and negative sentiment expressions.

In this paper, we propose a method to address the two problems. Firstly, we model the task as a multi-label classification problem. In contrast to mutually exclusive 4-class (*positive*, *negative*, *neutral*, and *conflict*) classification, our model predicts two labels for each aspect: 1) Whether positive sentiment is expressed towards the aspect; 2)

*Corresponding author

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Whether negative sentiment is expressed towards the aspect. Then, we transform the 2-label predicted results into 4-class labels by rules (e.g., if both positive and negative expressions exist, then apply *conflict*). During training, the 4-class training labels in dataset are transformed into 2-label targets. In this way, we utilize the relation between *conflict* label and *positive*/*negative* labels, which makes the model learn to recognize *conflict* opinions from abundant *positive* and *negative* data. It is also based on the fact that neural network is good at recognizing positive or negative sentiments, which are indicated by compact and concrete expressions. On the contrary, we find that the expressions of *conflict* opinions usually are lengthy and implicit. Faced with *conflict* opinions, existing attention-based models (Wang et al., 2016) (with single attention) usually attend on a portion of a *conflict* expression and ignore the other portion, which make its predicted result prone to be *positive* or *negative*. Instead, we use two independent attentions in the proposed model to focus on positive or negative expressions separately.

Our contributions are summarized as follows: 1) To the best of our knowledge, this is the first work that discuss the necessity of including *conflict* opinions in aspect-level sentiment classification task; 2) We propose a model that can recognize the complex expressions of *conflict* opinions and deal with sparsity problem of *conflict* data; 3) The experiment results on SemEval dataset indicate that our model performs well on recognizing *conflict* opinions and outperforms all baselines.

2 Related Work

Sentiment analysis is a frequently studied topic in artificial intelligence (Cambria, 2016). Different from previous work about sentiment analysis, Kenyon-Dean et al. (2018) states that there are opinions cannot be properly annotated as *positive*, *negative*, or *neutral* sentiment polarities. Their experiment shows that existing classifiers have significant lower accuracy on recognizing sentiments in these opinions. Their work is about sentence-level sentiment analysis and does not propose a model. Our work is different from theirs since we propose a model capable of recognizing *conflict* opinions in existing aspect-level sentiment classification dataset.

In recent years, lots of efforts have been made to imporve aspect-based sentiment analysis (Wang et al., 2014; Zhao et al., 2015). Traditional methods in aspect-level sentiment classification leveraged sentiment lexicons (Mohammad et al., 2013), while recent work tends to use neural network to generate text representations automatically. TD-LSTM and TC-LSTM (Tang et al., 2016a) encode contextual information with respect to the target. Methods based on memory network (Tang et al., 2016b; Zhu and Qian, 2018) instead generate aspect-related representation. Attention-based recurrent neural network (Wang et al., 2016; Chen et al., 2017; Cheng et al., 2017) selectively attends to aspect-related regions and calculates the weighted sum of the hidden states of these regions. Xue et al. (2018) instead utilize gated convolutional neural network to extract aspect-related representations, which increase computational efficiency. Our work differs from these works since we address two problems of recognizing *conflict* opinion which they ignore.

3 Model: Dual Attention-based GRU

3.1 Network Architecture

The architecture of the proposed Dual Atteniton-based GRU (D-AT-GRU) is illustrated as Fig. 1. Given a sentence with L words and an aspect (or aspect term) as inputs, the model first transforms them into word embeddings $[w_1, ..., w_L]$ and aspect embedding v_a. Then, it extracts aspect-related text features through recurrent neural network and dual attention mechanism. Lastly, it produces 2-label predictions through classification layers and transforms them into 4-class labels.

Aspect embedding. We use an embedding matrix $V_A \in \mathbb{R}^{|A| \times d_a}$ to represent aspects, where d_a is the dimension of aspect embedding and $|A|$ is the number of aspects in dataset. Each row in V_A is a representation vector v_a for aspect $a \in A$. The aspect embeddings are initialized randomly and learned as parameters.

Text feature extraction. We use Gated Recurrent Unit (GRU) (Cho et al., 2014) to extract contextual information of words in our model. Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) is an alternative choice, which is often used in previous models (Wang et al., 2016; Chen et al., 2017; He et al., 2018). However, we find that GRU performs better than LSTM in our model. Thus, we choose GRU. Let matrix $H = [h_1, ..., h_L] \in \mathbb{R}^{L \times d}$ denotes the hid-

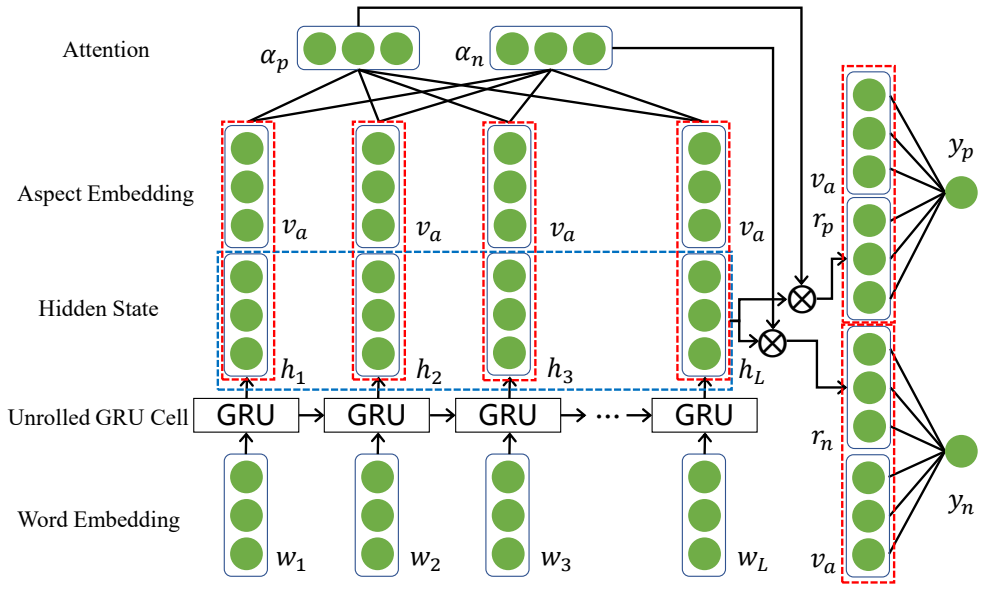

Figure 1: The network architecture of D-AT-GRU.

den states produced by GRU.

Attention mechanism. Based on the hidden states H and the embedding v_a of given aspect, attention mechanism gives importance weights which indicate aspect-related context region. Given that a *conflict* opinion consist of positive and negative expressions, attention usually fails to capture the full expression and only attends to a portion of it. Affected by previous *positive* or *negative* training samples, attention tends to think that just a portion of the *conflict* expression is enough to determine sentiment label and omit the other portion which also contains sentiment words. We therefore propose to use two attentions separately: one is responsible for finding positive expression, the other is responsible for finding negative expression. The positive attention is calculated by:

$$g_i^p = u_p^T tanh(W_p[h_i; v_a] + b_p), \quad (1)$$

$$\alpha_i^p = \frac{exp(g_i^p)}{\sum_{j=1}^{L} exp(g_j^p)}, \quad (2)$$

where $W_p \in \mathbb{R}^{d \times 2d}, u_p \in \mathbb{R}^d$ and $b_p \in \mathbb{R}^d$ are parameters. The negative attention is calculated through following functions:

$$g_i^n = u_n^T tanh(W_n[h_i; v_a] + b_n), \quad (3)$$

$$\alpha_i^n = \frac{exp(g_i^n)}{\sum_{j=1}^{L} exp(g_j^n)}, \quad (4)$$

where $W_n \in \mathbb{R}^{d \times 2d}, u_n \in \mathbb{R}^d$ and $b_n \in \mathbb{R}^d$ are parameters.

Regularization term. For the reason that positive sentiment and negative sentiment usually are expressed in different regions, the two attentions should not overlap. Thus, we need to add a regularization term to make the two sets of attention scores differentiate from each other. We compare KL-divergence (Kullback and Leibler, 1951) and orthogonal regularization (He et al., 2017) in experiments. We observed no consistent difference in performance regarding to sentiment analysis between these two terms. But the time cost of computing KL-divergence is 2.7 times as much as computing orthogonal regularization for each batch. Therefore, we utilize orthogonal regularization (He et al., 2017):

$$\mathcal{R}_o = ||M^T M - I||_2, \quad (5)$$

where $M = [\alpha^p; \alpha^n], M \in \mathbb{R}^{2 \times L}$ contains attention scores.

Text representation. According to the positive and negative attention scores, corresponding aspect-related text representations are calculated through the weighted sum of hidden states H:

$$v_p = \sum_{i=1}^{L} \alpha_i^p h_i, \quad (6)$$

$$v_n = \sum_{i=1}^{L} \alpha_i^n h_i. \quad (7)$$

Classification layer. An expression may have various meanings when describing different aspects. Therefore, we take aspect information into

account in classification layer by concatenating text representations with aspect embeddings.

$$y_p = \sigma(W_{py}[v_p; v_a] + b_{py}), \quad (8)$$
$$y_n = \sigma(W_{ny}[v_n; v_a] + b_{ny}), \quad (9)$$

where y_p is predicted positive sentiment distribution, y_n is predicted negative sentiment distribution; $W_{py}, W_{ny} \in \mathbb{R}^{2d}$ and $b_{py}, b_{ny} \in \mathbb{R}^1$ are parameters.

3.2 Objection Function

The model can be trained in an end-to-end way by backpropagation, where the objective function is the sum of the binary cross-entropy losses of positive and negative sentiments:

$$\mathcal{L}_p = -\hat{y}_p log(y_p) - (1 - \hat{y}_p) log(1 - y_p), \quad (10)$$
$$\mathcal{L}_n = -\hat{y}_n log(y_n) - (1 - \hat{y}_n) log(1 - y_n), \quad (11)$$

where $\hat{y}_p, \hat{y}_n$ are target distributions. During training, 4-class sentiment labels are transformed into 2-label targets (e.g., *conflict* is transformed into $(\hat{y}_p, \hat{y}_n) = (1, 1)$). The goal of training is to minimize the following function:

$$\mathcal{L} = \mathcal{L}_p + \mathcal{L}_n + \lambda \mathcal{R}_o, \quad (12)$$

where λ is a hyperparameter used to balance the weight of orthogonal regularization. We set λ to 1 in our experiment.

3.3 Label Transformation

Given the predicted distributions y_p, y_n, we transform them into 4-class labels. If $y_p > p, y_n > p$, the predicted label will be *conflict*. If $y_p \leq p, y_n \leq p$, the predicted label will be *neutral*. If $y_p \leq p, y_n > p$, the predicted label will be *negative*. If $y_p > p, y_n \leq p$, the predicted label will be *positive*. In this paper, we directly use $p = 0.5$ to minimize human interference, although it can be tuned manually as a hyperparameter.

4 Experiment

4.1 Dataset and Preparation

We experiment on SemEval 2014 datasets (Pontiki et al., 2014) (statistics shown in Table 1) to evaluate the proposed model. For the reason that there are too few *conflict* test instances regarding aspect term to show significance, we choose to experiment on aspect category data. Our model is compared with the state-of-the-art methods in aspect category sentiment classification, which are adapted to 4-class classification.

In our experiment[1], dimension sizes d, d_a, d_w are all set to 300. Word embeddings are initialized with 300-dimension pre-trained GloVe vectors (Pennington et al., 2014). All the other parameters are initialized by sampling from a normal distribution $\mathcal{N}(0, 0.01)$. We use Adagrad (Duchi et al., 2011) with a batch size of 10 samples, initial learning rate of 0.01, and maximum epochs of 30. We use development set chosen by Tay et al. (2018). The patience value of early-stopping is 3.

	positive	*negative*	*neutral*	*conflict*
Train	1759	704	442	187
Dev	420	135	58	8
Test	657	222	94	52

Table 1: Statistics of datasets.

4.2 Result and Analysis

Model	Overall	Conflict
AT-LSTM	77.13%	11.54%
ATAE-LSTM	78.00%	23.08%
GCAE	78.30%	25.00%
AT-GRU	77.22%	19.23%
AT-GRU 2-label	77.02%	26.92%
D-AT-GRU w/o orthogonal	77.22%	26.92%
D-AT-GRU	**78.50%**	**40.38%**

Table 2: Experiment results on SemEval 2014 dataset.

Table 2 shows that D-AT-GRU model outperforms all baseline methods. Given that AT-LSTM (Wang et al., 2016) has strong correlation to our base model (AT-GRU), their work can be categorized as a baseline to our model. In contrast, the results prove that the additional components are helpful to recognize *conflict* opinions. We also compare our model to the recently proposed GCAE (Xue and Li, 2018), which is based on gated CNN. D-AT-GRU performs competitively with GCAE overall and significantly better on *conflict* category.

We also compare with ablated versions of D-AT-GRU: 1) Replace the LSTM in AT-LSTM with

[1]Code available: https://github.com/tanxw17/DATGRU

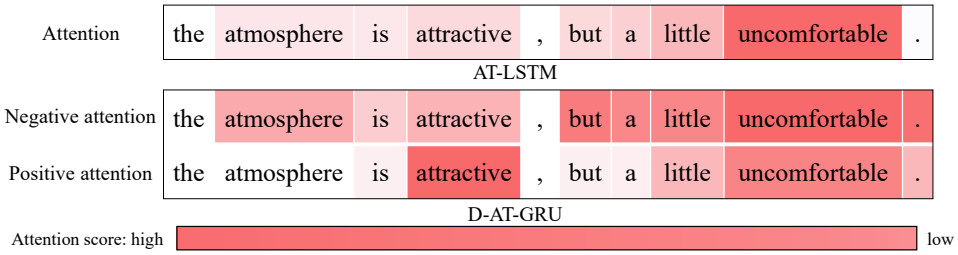

Figure 2: The visualizations of attention.

GRU and directly do 4-class classification (AT-GRU); 2) Use AT-GRU with two separate classification layers to do 2-label classification (AT-GRU 2-label); 3) Remove orthogonal regularization (D-AT-GRU w/o orthogonal). Their performance suffers from the ablations, which proves that every component is essential for the proposed model.

We test KL-divergence (Kullback and Leibler, 1951) and orthogonal regularization (He et al., 2017) as regularization terms to make positive attention and negative attention differentiate from each other. The experiments were conducted on a NVIDIA 1080 Ti. The results are shown in Table 3.

Regularizer	Overall	Conflict	Time
Orthogonal	78.50%	40.38%	0.15 ms
KL-divergence	78.40%	40.38%	0.40 ms

Table 3: Experiment results about different regularization terms.

4.3 Case Study

Figure 2 is a test case in our experiment. AT-LSTM attends to "*uncomfortable*" and ignores the existence of "*attractive*", which causes it to incorrectly predict *negative* label. With our D-AT-GRU model, the negative attention finds "*uncomfortable*" in the second part of the sentence, which makes the model predict that there is negative sentiment; the positive attention instead gives the highest score to "*attractive*", which leads the model to predict that there is positive sentiment. Given the existence of both positive and negative sentiments, D-AT-GRU correctly predict *conflict* label. This shows that the dual attention mechanism of D-AT-GRU model can more accurately capture the complete expression of a *conflict* opinion.

5 Conclusion

In this paper, we present a method to recognize *conflict* opinions in aspect-level sentiment classification task. By transforming the problem into recognizing simpler sentiments, we alleviate the sparsity problem of *conflict* data. Our model utilize dual attention mechanism and orthogonal regularization, which are capable of recognizing the complex expressions of *conflict* opinions. Our experiment on SemEval dataset demonstrates the effectiveness of the proposed model.

Abstract

Deep neural network models such as long short-term memory (LSTM) and tree-LSTM have been proven to be effective for sentiment analysis. However, sequential LSTM is a bias model wherein the words in the tail of a sentence are more heavily emphasized than those in the header for building sentence representations. Even tree-LSTM, with useful structural information, could not avoid the bias problem because the root node will be dominant and the nodes in the bottom of the parse tree will be less emphasized even though they may contain salient information. To overcome the bias problem, this study proposes a capsule tree-LSTM model, introducing a dynamic routing algorithm as an aggregation layer to build sentence representation by assigning different weights to nodes according to their contributions to prediction. Experiments on Stanford Sentiment Treebank (SST) for sentiment classification and EmoBank for regression show that the proposed method improved the performance of tree-LSTM and other neural network models. In addition, the deeper the tree structure, the bigger the improvement.

1 Introduction

In sentiment analysis, word embeddings (Mikolov et al., 2013a; Mikolov et al., 2013b; Pennington et al., 2014) and sentiment embeddings (Tang et al., 2016; Yu et al., 2018a; Yu et al., 2018b) have become a fundamental component to build deep neural networks such as convolutional neural networks (CNN) (Kalchbrenner et al., 2014; Kim, 2014), recurrent neural networks (RNN) (Graves, 2012; Irsoy and Cardie, 2014), gated recurrent unit (GRU) (Cho et al., 2014), and long short-term memory (LSTM) (Tai et al., 2015; Wang et al., 2015). Given a variable-length text, one challenge of using these neural networks is to compose individual word vectors into sentence vectors with the same length (Iyyer et al., 2015; Joulin et al., 2016; Bojanowski et al., 2016).

The sequential neural networks such as RNN, GRU, and LSTM are commonly used due to their ability to capture long-distance dependency in sequential texts. However, these methods belong to the biased model, where the words in the tail of a sentence are more heavily emphasized than those in the header for building sentence representations. As shown in Fig. 1(a), the priority for each word vector will be "*fantastic* ≻ *really* ≻ *is* ≻ *story* ≻ *this*". This prioritization seems satisfactory for this sentence, but note that the key components could appear anywhere in the sentence rather than necessarily at the end.

To improve the abovementioned sequential models, Tai et al. (2015) and Huang et al. (2017) proposed a tree-LSTM model to introduce useful structural information from sentence parse trees. However, the tree-LSTM also heavily emphasizes the root node in the tree to build sentence representations. That is, words that are closed to the root will be given higher priority than words that are far away from the root. As shown in Fig. 1(b), the priority of word vectors would be "*this* = *story* = *is* ≻ *really* = *fantastic*". This example shows that the tree-LSTM still could not avoid the bias problem because the nodes (e.g., *fantastic*) that contribute more to the prediction but lie in the leaf node at the bottom of the parse tree will be less emphasized.

To overcome the bias problem that may arise in the tree-LSTM, this study proposes a capsule tree-LSTM model. In spired by recent promising work of capsule network (Sabour et al., 2017), the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3432–3437, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

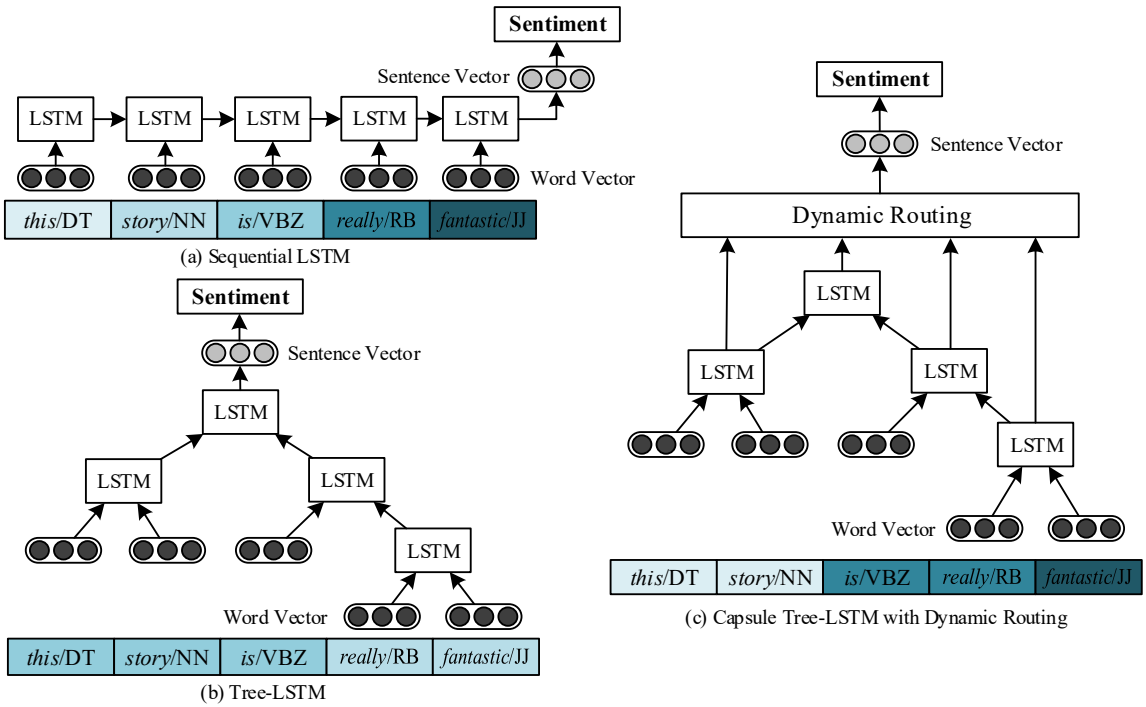

Figure 1: Illustrative examples of different LSTM models for sentiment analysis. A deeper color indicates more weight is assigned to the word according to its contribution to the prediction result.

proposed method introduces a dynamic routing algorithm to consider all non-leaf nodes to build sentence vectors, instead of using the root alone in the tree-LSTM. In addition, different nodes will receive different weights according to their contributions to the prediction task. Unlike self-attention (Lin et al., 2017; Yang et al., 2016), which applies a fixed policy without considering the state of the final sentence vectors, the task of assigning weights in the proposed model is considered to be a routing issue to iteratively determine how much information can be passed from non-leaf nodes in the tree to the vector presentation of the sentence, according to the state of final output. For example, in the aforementioned example text, it would be useful for the model to emphasize *fantastic* that contains the most salient information, even when the word lies at the bottom of the parser tree. Based on the dynamic routing algorithm, the priority of the word vector in the proposed model would be "*fantastic* ≻ *really*=*is* ≻ *this*=*story*". The proposed method is evaluated through both sentiment classification and regression tasks to determine whether dynamic routing can improve the performance of the tree-LSTM and other neural network models.

The rest of this paper is organized as follow. Section 2 describes the proposed capsule tree-LSTM model with dynamic routing. Section 3 summarizes the evaluation results. Conclusions are presented in Section 4.

2 Capsule Tree-LSTM Model

Figure 1(c) shows the framework of the proposed model. First, the given sentence is parsed as a tree-structured topology. The vector representation of this sentence is then generated by composing the word vectors of all non-leaf nodes in the tree according to their weights learned by the dynamic routing algorithm. Finally, the composed sentence vector is used for sentiment prediction.

2.1 Tree-structured LSTM

Given a binary parser tree, the leaf nodes are words and the non-leaf nodes are multi-word phrases. Let $C(j)$ denotes the set of left and right child nodes of a non-leaf node j. Different from the sequential LSTM, the hidden state $\tilde{h}$ of the non-leaf node j is the composition of its left and right child nodes, defined as

$$\tilde{h} = \begin{bmatrix} \mathbf{h}_{t-1}^{left} \\ \mathbf{h}_{t-1}^{right} \end{bmatrix} + b_c \quad (1)$$

where $\mathbf{h}_{t-1}^{left}$ and $\mathbf{h}_{t-1}^{right}$ respectively denote the hidden states of left and right child nodes,

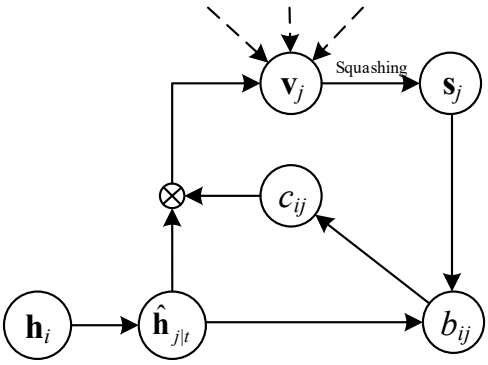

Figure 2: Detailed dynamic routing process

$W_c \in \Re^{d\times 2d}$ is a composition matrix, and b_c is a bias. The tree-LSTM transition equations of node j are defined as

- Gates

$$\begin{aligned} i_t^j &= \sigma(W_{xi}x_t + W_{hi}\tilde{} \\ f_t^k &= \sigma(W_{xf}x_t + W_{hf}\mathbf{h}_{t-1}^k + b_f) \\ o_t^j &= \sigma(W_{xo}x_t + W_{ho}\tilde{} \end{aligned} \tag{2}$$

- Input transform

$$c_in_t = \tanh(W_{xc}x_t + W_{hc}\mathbf{h}_{t-1} + b_{c_in}) \tag{3}$$

- Memory update

$$\begin{aligned} c_t^j &= i_t^j \otimes c_in_t^j + \sum_{k\in C(j)} f_t^k \otimes c_{t-1}^k \\ \mathbf{h}_t^j &= o_t^j \otimes \tanh(c_t^j) \end{aligned} \tag{4}$$

where i_t, f_t, o_t, and c_t respectively denote the input gate, forget gate, output gate, and memory cell of node j, x_t denotes the input word vector at the time step t, σ denotes the logistic sigmoid function, W and b respectively denote the weights and bias, and $\otimes$ denotes element-wise multiplication. To integrate the sequence information in the output layer, the order of non-leaf hidden states to form the input matrix of dynamic routing layer is a key consideration. Here, we used the in-order traversal of depth-first search algorithm on the tree-structured topology. The output matrix is composed of the hidden states of all non-leaf nodes, defined as $\mathbf{H}=[\mathbf{h}_1,\mathbf{h}_2,...,\mathbf{h}_T] \in \Re^{T\times d_h}$, where T and d_h respectively denote the number and dimensionality of the hidden states. The obtained hidden matrix is then fed to the aggregation layer.

2.2 Dynamic Routing

To compose all word vectors to generate sentence vectors, the tree-structured LSTM model uses the hidden states of all non-leaf nodes to obtain the weights for all nodes through the dynamic routing algorithm.

Taking the hidden states of all non-leaf nodes as the input vectors, the goal of dynamic routing is to encode the sentiment information of those vectors into a fixed-length sentence vector,

$$\mathbf{s}_{cap} = [\mathbf{s}_1, \mathbf{s}_2, ..., \mathbf{s}_J] \tag{5}$$

Inspired by the definition of capsule networks, we implement two layers of capsules (i.e., $\mathbf{H}=[\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_I]$ denotes the input capsules and $\mathbf{s}=[\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_J]$ denotes the output capsules) to perform dynamic routing. The output capsule $\mathbf{s}_j$ is produced from a non-linear "squashing" function to ensure $|\mathbf{s}_j| \in (0,1)$ as a probability,

$$\mathbf{s}_j = \frac{||\mathbf{v}_j||^2}{1+||\mathbf{v}_j||^2}\frac{\mathbf{v}_j}{||\mathbf{v}_j||} \tag{6}$$

where $\mathbf{s}_j$ is the vector output of capsule j, $\mathbf{v}_j$ is the total input, which is a weighted sum over all "prediction vectors" $\hat{\mathbf{h}}_{j|t}$ from the capsules in the layer below,

$$\mathbf{v}_j = \sum_t c_{tj}\hat{\mathbf{h}}_{j|t} \tag{7}$$

where coupling coefficients c_{tj} are the probability distributions of capsule j which are computed using a softmax function so that all capsules in the layer above sum to 1 so that the sentiment information $\hat{\mathbf{h}}_{j|t}$ is obtained by multiplying the input vector $\mathbf{h}_t$ by a weighted matrix W_{tj}, defined as,

$$\hat{\mathbf{h}}_{j|t} = W_{tj}\mathbf{h}_t \tag{8}$$

Here, the coupling coefficients c_{tj} are determined by the iterative dynamic routing process,

$$c_{tj} = \frac{\exp(b_{tj})}{\sum_k \exp(b_{tk})} \tag{9}$$

$$b_{tj} \coloneqq b_{tj} + \hat{\mathbf{h}}_{j|t}\cdot\mathbf{s}_j \tag{10}$$

where b_{tj} is the log probabilities, initialized with 0. The detailed iterative process of learning the weights between capsules in two layers for each non-leaf node is shown in Fig. 2.

In Eq. (7), the capsules in the above layer try to learn contribution weights c_{tj} (i.e., coupling coefficients) for the capsules in the below layer. The updated information in b_{tj} comes from the scalar product $\hat{\mathbf{h}}_{j|t}\cdot\mathbf{s}_j$. The coupling coefficients c_{ij} are iteratively refined by measuring the agreement between the current output $\mathbf{s}_j$ of output capsule j in the above layer and the prediction $\hat{\mathbf{h}}_{j|t}$ made by input capsule i. If the margin between the two vectors and $\mathbf{s}_j$ is very large, the scalar product of

those vectors will be large, which will also result in an update on the coupling coefficient c_{tj}.

3 Experimental Results

Datasets. This experiment used two datasets for evaluation. i) The Stanford Sentiment Treebank (SST) (Socher et al., 2013) is used for sentiment classification. It contains 6920/872/1821 sentences for the train/dev/test sets with binary labels (positive/negative) and 8544/1101/2210 sentences with fine-grained labels (very negative/negative/ neutral/positive/very positive). ii) EmoBank (Buechel and Hahn, 2017; Buechel and Hahn, 2016) is used for sentiment regression to predict valence-arousal (VA) values (Wang et al., 2016b; Yu et al., 2016). It contains 10,000 sentences with real-valued VA ratings in the range of (1, 9), where the valence refers to the degree of positive and negative sentiment and the arousal refers to the degree of calm and excitement. The provided ratings have Reader and Writer perspectives, and the Reader was adopted as the ground-truth ratings due to its superiority reported in (Buechel and Hahn, 2017). We performed 5-fold cross-validation (6:2:2) on the EmoBank dataset.

Evaluation Metrics. For SST, the evaluation metric is accuracy for both binary and fine-grained classification. For EmoBank, we used the Pearson correlation coefficient (*r*) and mean absolute error (MAE). A higher *r* or a lower MAE value indicates better prediction performance.

Implementation Details. Several deep neural networks were implemented for comparison, including CNN, GRU, LSTM, and tree-LSTM. For the sequential models (GRU and LSTM), we additionally implemented an enhanced version using a bi-directional strategy and 2-layer stacked architecture. To investigate the performance of self-attention, we also implement a self-attention layer by taking as input the hidden states of all non-leaf nodes, to form an attention Tree-LSTM model (Kokkinos and Potamianos, 2017). For word vectors, we used GloVe pre-trained on the 840B Common Crawl corpus (Pennington et al., 2014). The respective dimensionality values of the word vectors and hidden states were 300 and 120. For classification and regression tasks, *softmax* and *linear decoder* (Wang et al., 2016a) activation function are respectively applied as the output layer.

Comparative Results. Tables 1 and 2 respectively show the comparative results of different methods for SST and EmoBank. Both the enhanced bi-directional and 2-layer GRU/LSTM outperformed the standard GRU, LSTM, CNN, and the Tree-LSTM with structural information achieved better performance than all of them for both classification and regression tasks. Once the dynamic routing algorithm was introduced, the proposed Capsule Tree-LSTM further improved the performance of Tree-LSTM

(with attention).

Figure 3 shows the detailed analysis of the effect of dynamic routing. The test sentences were first divided into several groups according to their depths in the parse trees (e.g., the depth of the example sentence in Fig. 1 is three). The performance improvement of Capsule Tree-LSTM over Tree-LSTM was then calculated for each group. The results show that the performance improvements increased with the increase of the depth. The reason is that the Tree-LSTM may suffer from a more serious bias problem for sentences with a deeper tree structure because the useful nodes in the deeper levels tend to be ignored. Conversely, the Capsule Tree-LSTM can assign a higher weight to the nodes that contribute more to the prediction even though they lie in the leaf node at the bottom of the tree.

4 Conclusion

This study presents a capsule tree-LSTM model for sentiment classification and regression. The proposed method uses dynamic routing algorithm to automatically learn the weights of each node to compose sentence representations. Experimental results show that the proposed method yielded better results than convolutional (CNN), sequential (LSTM and GRU), structural (tree-LSTM) and self-attention neural networks. Future work will conduct more detailed analysis to continue enhancing the proposed method.

A Label Informative Wide & Deep Classifier for Patents and Papers

Muyao Niu

caijie@patsnap.com

Abstract

In this paper, we provide a simple and effective baseline for classifying both patents and papers to the well-established Cooperative Patent Classification (CPC). We propose a label-informative classifier based on the Wide & Deep structure, where the Wide part encodes string-level similarities between texts and labels, and the Deep part captures semantic-level similarities via non-linear transformations. Our model trains on millions of patents, and transfers to papers by developing distant-supervised training set and domain-specific features. Extensive experiments show that our model achieves comparable performance to the state-of-the-art model used in industry on both patents and papers. The output of this work should facilitate the searching, granting and filing of innovative ideas for patent examiners, attorneys and researchers.

1 Introduction

Classifying patents and papers to a technology taxonomy is a crucial step to organize the massive knowledge and to discover innovative ideas. Patent examiners rely on the taxonomy to search for similar documents when granting or invalidating a patent application; attorneys use it to check whether the innovation points of an invention have been covered in previous literature; researchers use the taxonomy to monitor the technology trends in certain fields, and companies use it to outline the intellectual property landscape of its own or its competitors'. The most commonly used taxonomies are International Patent Classification (IPC) [1] and its newer version Cooperative Patent Classification (CPC) [2]. Figure 1 illustrates the CPC hierarchy and the discriminative descriptions attached to each node.

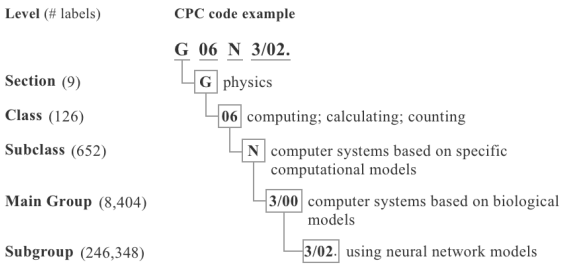

Figure 1: Illustration of the CPC hierarchy.

The categorization is now mostly done manually by experts in patent offices. Due to the growing amount of patents and the limited number of domain experts, there has been an urge to automate the classification process. Also, as more and more technology innovations are published in patents, researchers with no background in patent classification may want to know which patents are most relevant to an academic paper. For this end, we aim to classify both patents and papers to the CPC *subclass* with more than 600 labels.

Classifying patents and papers to CPC subclass is a challenging task because (1) there are a large number of labels that covers almost all technology domains, and the differences between labels are often subtle; (2) although mass amount of labelled data for patents is available, the annotated data for paper-to-CPC is very limited. Since labelling papers with CPC labels requires expert knowledge, large-scale human annotation is very expensive.

In this paper, we leverage the CPC label descriptions and use the Wide-and-Deep network to integrate label information with semantic information from input texts. We also construct a distant-supervised dataset for papers. **Our contributions** are:

- We prove the effectiveness of the label features through the Wide-and-Deep structure in CPC classification on more than 600 labels.
- We achieve comparable performance to the

state-of-the-art on classifying both patents and papers to a widely-used technology taxonomy. Our model can serve as a simple and effective baseline for CPC classification tasks.

2 Related Work

2.1 Patent Classification

Most of the previous patent classification systems focus on developing more features derived from patent structures with traditional learning algorithms (Verberne and D'hondt, 2011). Going beyond document-level features, Cai and Hofmann (2007) and Qiu et al. (2011) capture the label hierarchy in model representations. It is flexible for traditional learning algorithms to integrate prior knowledge; however, it is difficult for them to generalize to unseen data.

Deep Neural Networks make efficient use of large-scale training data and generalize well to unseen data. There are a few NN-based patent classification methods. Grawe et al. (2017) uses Long Short Term Memory (LSTM) on 50 IPC subgroups and Li et al. (2018) applies Convolutional Neural Networks (CNN) to IPC subclasses classification.

There are some efforts on mapping papers to IPC in the context of patent retrieval combined with K nearest neighbours (KNN) classification. Cao et al. (2008) adopt a query-expansion approach to retrieve relevant patents and use a KNN classifier to label the research paper. Xiao et al. (2008) combine different scoring methods to rerank the retrieved IPC and achieved the best performance in the NTCIR-7 workshop for classify research papers to IPC system (Nanba et al., 2008). To our best knowledge, there has been no attempt tackling both tasks in one model.

2.2 Label Information

Leveraging label information is not new and is mostly accomplished by embedding labels and texts in the same space to measure their correlations (Yogatama et al., 2015; Zhang et al., 2018). Ma et al. (2016) adds prototypes to the label representation. Zhang et al. (2018) proposes to transform classification to a matching target between texts and labels for multi-task learning. Wang et al. (2018) further weights text features by the compatibilities between text and label embeddings via attention mechanism. Our model differs from previous studies in that we use the string-level similarity between label descriptions and input text instead of label embeddings. Based on the analysis of CPC classification system, we believe that string-level similarity can compensate for what semantic-level similarity cannot captures for patent classification tasks.

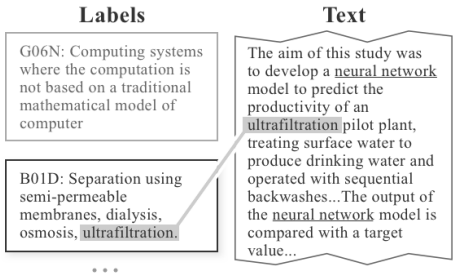

Figure 2: Example of the label description (left boxes) and classification cues (shadowed texts). The true label for the input text (right box) is B01D. Although the given text discussed neural networks, which is semantically closer to G06N, the classification cue of "ultrafiltration" decides for B01D eventually.

3 Model

3.1 The Label-text Feature

We discover that label descriptions can provide precise cues to classify a document which contains *multiple* semantic aspects. Figure 2 provide an example on the necessity of integrating label description. It should be noted that when patent examiners classify documents to the CPC system, they are also advised to use cue words and to search among label descriptions [3].

We integrate the label information through the label-text feature that captures the string-level relatedness between label descriptions and texts. Here we use BM25 score:.

$$\text{BM25}(\text{D}_k, x) = \sum_{i=1}^{n} \text{idf}(x_i) \frac{\text{tf}(x_i, D_k)(k_1+1)}{\text{tf}(x_i, D_k)+k_1(1-b+b\frac{|D_k|}{\text{avgdl}})} \quad (1)$$

where x_i is the ith item in text x; $\boldsymbol{D}_k$ is the label description for class k; *idf* and *tf* are inverse document frequency and text frequency for x_i in D_k respectively; *avgdl* is the average description length; $|D_k|$ is the document length; k_1 and b are hyper parameters.

[3] see IPC guidelines at https://www.wipo.int/export/sites/www/classifications/ipc/en/general/guidelines_where_to_classify.pdf

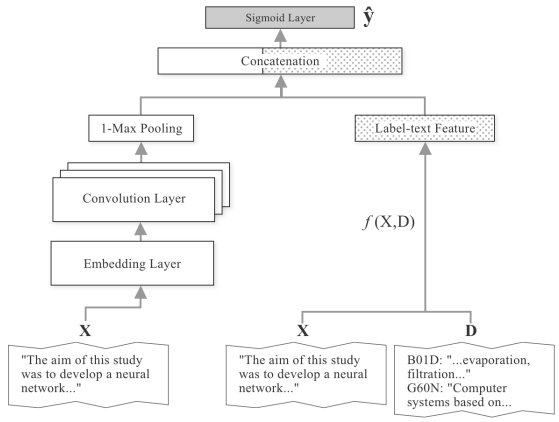

Figure 3: WnD classifier structure. The Deep part (left) captures semantic information; the Wide part (right) captures label-text relatedness. The label-text feature is a K-dimensional vector, where K equals to the label set size.

3.2 Wide and Deep Structure

We adopt the Wide and Deep (WnD) neural network (Cheng et al., 2016) for text classification . Given a training set $(\boldsymbol{X}_n, \boldsymbol{D}, \boldsymbol{y}_n)_{n=1}^N$, where $\boldsymbol{X}_n$ is the input document texts, $\boldsymbol{D}$ is the input label descriptions and $\boldsymbol{y}_n$ is the true labels. The model outputs the probabilities for each of the K classes $\hat{\boldsymbol{y}} \in R^K$. The training target is to minimize binary cross entropy loss: $L = \frac{1}{N}\frac{1}{K}\Sigma_{n=1}^{N}\Sigma_{k=1}^{K}\text{CE}(\boldsymbol{y}_n^{(k)}, \hat{\boldsymbol{y}}_n^{(k)})$, where $\boldsymbol{y}_n^{(k)}$ is the kth element in vector $\boldsymbol{y}_n$.

An overview of the WnD classifier is shown in figure 3. The model has two parts: the wide part and the deep part. The wide part takes in the label-text feature to capture string-level relatedness between the label descriptions and the text; the deep part maps the input text to word embeddings and go through a non-linear transformation to capture semantic-level relatedness between the text and the label.

The Wide part: The Wide part is a regression model with the form $\hat{\boldsymbol{y}}_{wide} = \sigma(\boldsymbol{W}_{wide}^T \boldsymbol{z}_{wide} + \boldsymbol{b})$, where $\boldsymbol{z}_{wide}$ is the label-text interaction features as described in section 3.1: $\boldsymbol{z}_{wide} = \text{BM25}(\boldsymbol{D}, \boldsymbol{X_n})$.

The Deep part: The Deep part is a non-linear transformation of the input text that aims to capture the semantic of the text. It can be a classic neural network for text encoding, such as RNN, CNN, or simple fully connected network. In this paper, we use textCNN (Kim, 2014) for the transformation because it is a simple baseline that works reasonably well. The Deep part transform the texts to a fixed-length representation $\boldsymbol{z}_{deep}$. The representation $\boldsymbol{z}_{deep}$ is then mapped to K classes using sigmoid activation $\hat{\boldsymbol{y}}_{deep} = \sigma(\boldsymbol{W}_{deep}^T \boldsymbol{z}_{deep} + \boldsymbol{b})$.

The Wide and Deep parts are concatenated at the top and are jointly trained through $\hat{\boldsymbol{y}} = \sigma(\boldsymbol{W}_{deep}^T \boldsymbol{z}_{deep} + \boldsymbol{W}_{wide}^T \boldsymbol{z}_{wide} + \boldsymbol{b})$ in order to let the semantic and the string level relatedness complements each other when making the decision. In this way, the model simulates the behavior of patent examiners classifying a document: when they are uncertain which labels to assign (i.e. when semantic knowledge cannot provide a certain answer), examiners will resort to searching for cue words in the label descriptions for a clue.

4 Experimental Setup

4.1 Datasets

We remove stopwords and punctuations and choose the first 120 words per document. The word embeddings are 300 dimensional and initialized randomly. Kernel size for textCNN is 2,3,4 and 5, and the number of filters is 1024. For each CPC subclass, we use the descriptions of its own and of all its child labels. We train the model using Adam optimizer.

Datasets: Out of the USPTO patent set, We randomly sample 6.7 million abstracts as the patent training set and 60k as the testing set. For the paper testing set, the gold-standard is hard to obtain. We discover that some papers cited by patents are assigned CPC labels by European Patent Office, we collect those from the website [4] and derive 4956 testing instances for paper-to-CPC classification. The datasets are described in table 1.

	# instances	# avg label per example
training set	6.7 million	1.47
patents testing set	60k	1.45
papers testing set	4956	1.30

Table 1: Dataset Description

Evaluation metrics: As each patent/paper has one or more CPC labels, we measure our model from both the classification and the ranking perspectives with 3 metrics: (1) *example-based precision/recall*: the average precision/recall per instance. We measure precision and recall on the top1, top3 predictions and precision on all predictions with the probability score ≥ 0.5. (2) *macro precision/recall*: the average precision/recall per class. (3) *mean average precision (MAP)*: a

[4] https://www.epo.org/index.html

ranking-based metric that measures whether the right labels are placed before the wrong ones.

4.2 Classify Patents to CPC

We compare our WnD classifier on patents with two baselines: traditional textCNN and attention-textCNN. By comparing WnD with textCNN, we want to know whether the label-text feature can complement semantic information for classification; by comparing with attention-textCNN, we want to compare our label integration method with other label embedding-based methods. For the attention model, we borrowed the idea of label-embedding attentive model (Wang et al., 2018). The attention is a T-dimensional vector where T is the text length. It calculates the importance of each word to the classification task.

The WnD achieves significant gains with label information (see table 2). It suggests that the complementary effects of string-level relatedness between label and texts indeed benefits the final classification decision. Our model also outperforms attention-textCNN. Although label embeddings are helpful for small label sets (around 10 labels) (Wang et al., 2018; Zhang et al., 2018), it is less effective on hundreds of labels. We suspect the reason is that the attention is not discriminative between classes. When the label set is large, many non-stop words may be important for classification. But their weights should vary for different classes, which can hardly be captured by the attention vector. Also, attention-textCNN has much more parameters than textCNN and tends to overfit on the training data.

The best reported numbers on patent-to-IPC in subclass level achieves 0.74 on precision (Verberne and D'hondt, 2011). Although can not be directly compared, our large-enough testing set makes it confident that we are comparable with the state-of-the-art system while being more scalable.

4.3 Classify Papers to CPC

There is not enough labelled data for the paper-to-CPC task. We can directly apply the model trained on patents to papers, but the performance will degrade significantly due to domain difference. For example, the word *camera* in papers is commonly referred to as *photo capturing apparatus* in patents. To deal with the domain-adaptation issue, we propose two approaches:

distant supervision: We auto-label papers using patent-paper citation. For each paper, we label it with the CPCs of the patents that cite it. We assume that papers cited by a patent should be relevant to the given patent in terms of background and technology domain. We get a total 1.7 million papers with abstract that are cited by the patents in the USPTO patent set, and each paper gets on average 2.8 labels. On these auto-labelled papers we then fine tune the model originally trained on patents.

domain-adapted features: The WnD structure enables us to incorporate domain-adapted features to the Wide part. Here we proposed two ways to add such features:

- *prototyping*: We pick the top 20 terms from the papers for each of the K classes according to the tf-idf score. Those representative terms are used as the label descriptions for papers;
- *label expansion*: We train word embeddings using skip-gram (Mikolov et al., 2013) on papers and expand the original label descriptions with the 10 nearest words in the embedding space according to their cosine distance.

We compare our paper-to-CPC model with the best-performing KNN+reranking model (Xiao et al., 2008) introduced in section 2.1. We also want to compare our model with large-scale classification systems used in industry. In order to do that, we crawl from Google Patent the machine-classified CPC labels of scholar papers for our testing set [5], and we assume that the labels are ranked according to the order on the web page. Google classifies papers on the finest level. In order to compare our subclass results with it, we use only the subclass part of the first label, which is supposed to be the most confident one.

The comparison results are shown in table 3. WnD benefits from both transfer learning and domain-adapted features. Since the prototypes are automatically collected, it is possible to apply WnD to classification tasks where detailed label descriptions are not available.

Google Patent scores better on precision/recall@1, but performs less well on macro precision/recall. Since Google classifies the papers on a finer grained level, the classifier may receive more information during training, thus performing better on coarser grained levels. To

[5] The data can be found by searching for a scholar paper in Google Patent. The machine-classified CPCs will appear in the information page

Table 3: Test results on papers. textCNN and WnD are models trained on patents directly apply to papers. WnD+transfer refers to WnD fine tuned on auto-labelled papers.*The training set and granularity of Google Patent model may be different from other models. We put it here for the convenience to compare and discuss

investigate the effects of classification granularity on performance, we mapped the WnD subclass predictions to class level (128 label) and trained another WnD on class level. The p@1 and r@1 are 86.94% and 79.15% for WnD subclass-to-class and 82.43% and 74.72% for WnD class. The gap indicates the possible positive effects of fine-granularity training.

5 Conclusions and Future Works

In this paper, we propose a WnD classifier to map both patents and papers to CPC subclasses. The model captures both the string and semantic relatedness between labels and texts. We achieve comparative performance to the state-of-the-art models for both paper-to-CPC and patent-to-CPC tasks. We hope to contribute an intuitive, simple yet practically effective baseline for categorizing scientific publications.

Although CPC subclass already has over 600 labels, it is still a relative coarse granularity in the taxonomy. The finest level (subgroup) consists of over 200 thousand labels and provides much more detailed classification information. At the same time, with the explosion of labels, the task is much more challenging. In the future, we will go deeper into the taxonomy and try to explore the hierarchical relations between labels and improve the scalability of models for finer grained label sets.

Abstract

Recently, researches have explored the graph neural network (GNN) techniques on text classification, since GNN does well in handling complex structures and preserving global information. However, previous methods based on GNN are mainly faced with the practical problems of fixed corpus level graph structure which do not support online testing and high memory consumption. To tackle the problems, we propose a new GNN based model that builds graphs for each input text with global parameters sharing instead of a single graph for the whole corpus. This method removes the burden of dependence between an individual text and entire corpus which support online testing, but still preserve global information. Besides, we build graphs by much smaller windows in the text, which not only extract more local features but also significantly reduce the edge numbers as well as memory consumption. Experiments show that our model outperforms existing models on several text classification datasets even with consuming less memory.

1 Introduction

Text classification is a fundamental problem of natural language processing (NLP), which has lots of applications like SPAM detection, news filtering, and so on (Jindal and Liu, 2007; Aggarwal and Zhai, 2012). The essential step for text classification is text representation learning.

With the development of deep learning, neural networks like Convolutional Neural Networks (CNN) (Kim, 2014) and Recurrent Neural Networks (RNN) (Hochreiter and Schmidhuber, 1997) have been employed for text representation. Recently, a new kind of neural network named Graph Neural Network (GNN) has attracted wide attention (Battaglia et al., 2018). GNN was first proposed in (Scarselli et al., 2009) and has been used in many tasks in NLP including text classification (Defferrard et al., 2016), sequence labeling (Zhang et al., 2018a), neural machine translation (Bastings et al., 2017), and relational reasoning (Battaglia et al., 2016). Defferrard et al. (2016) first employed Graph Convolutional Neural Network (GCN) in text classification task and outperformed the traditional CNN models. Further, Yao et al. (2019) improved Defferrard et al. (2016)'s work by applying article nodes and weighted edges in the graph, and their model outperformed the state-of-the-art text classification methods.

However, these GNN-based models usually adopt the way of building one graph for the whole corpus, which causes the following problems in practice. First, high memory consumption is required due to numerous edges. Because this kind of methods build a single graph for the whole corpus and use edges with fixed weights, which considerably limits the expression ability of edges, they have to use a large connection window to get a global representation. Second, it is difficult for this kind of models to conduct the online test, because the structure and parameters of their graph are dependent on the corpus and cannot be modified after training.

To address the above problems, we propose a new GNN based method for text classification. Instead of building a single corpus level graph, we produce a text level graph for each input text. For a text level graph, we connect word nodes within a reasonably small window in the text rather than directly fully connect all the word nodes. The representations of the same nodes and weights of edges are shared globally and can be updated in the text level graphs through a massage passing mechanism, where a node takes in the information from neighboring nodes to update its representation. Finally, we summarize the representations of all the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3444–3450,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

nodes in the graph to predict the results. With our design, text level graphs remove the burden of dependency between a single input text and the entire corpus, which support online test. Besides, it has the benefit of consuming less memory by connecting words in a small contextual window, because it excludes a good many words that are far away in the text and have little relation with the current word and thus significantly reduces the number of edges. The message passing mechanism makes nodes in the graph perceive information around them to get precise meaning in a specific context.

In our experiments, our method achieves state-of-the-art results in several text classification datasets and consumes significantly fewer memory resources compared with previous methods.

2 Method

In this section, we will introduce our method in detail. First, we show how to build a text level graph for a given text; all the parameters for the text level graph are taken from some global-sharing matrices. Then, we introduce the message passing mechanism on these graphs to obtain information from the context. Finally, we depict how to predict the label for a given text based on the learned representations. The overall architecture of our model is shown in Figure 1.

2.1 Building Text Graph

We notate a text with l words as $T = \{\mathbf{r_1}, ...\mathbf{r_i}, ..., \mathbf{r_l}\}$, where $\mathbf{r_i}$ denotes the representation of the i_{th} word. $\mathbf{r_i}$ is a vector initialized by d dimension word embedding and can be updated by training. To build a graph for a given text, we regard all the words that appeared in the text as the nodes of the graph. Each edge starts from a word in the text and ends with its adjacent words. Concretely, the graph of text T is defined as:

$$N = \{\mathbf{r_i} | i \in [1, l]\}, \quad (1)$$

$$E = \{e_{ij} | i \in [1, l]; j[i - p, i + p]\}, \quad (2)$$

where N and E are the node set and edge set of the graph, and word representations in N and edge weights in E are taken from global shared matrices. p denotes the number of adjacent words connected to each word in the graph. Besides, we uniformly map the edges that occur less than k times in the training set to a "public" edge to make parameters adequately trained.

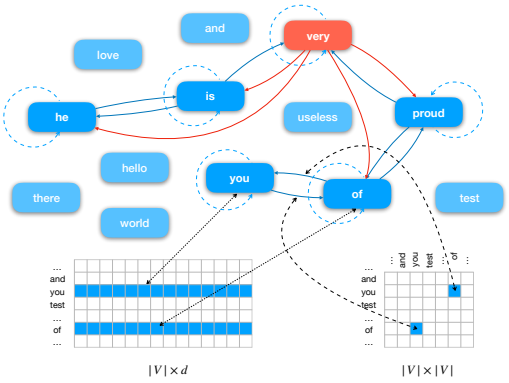

Figure 1: Structure of graph for a single text "he is very proud of you.". For the convenience of display, in this figure, we set $p = 2$ for the node "very" (nodes and edges are colored in red) and $p = 1$ for the other nodes(colored in blued). In actual situations, the value of p during a session is unique. All the parameters in the graph come from the global shared representation matrix, which is shown at the bottom of the figure.

Compared with the previous methods in building graph, our approach can exceedingly reduce the scale of the graph in terms of nodes and edges. That means that the text-level graph can consume much less GPU memory. Besides, their method is unfriendly to new-coming text, while our approach can solve this problem because the graph for each text is only dependent on its content.

2.2 Message Passing Mechanism

Convolution can extract information from local features (LeCun et al., 1989). In the graph domain, convolution is implemented by spectral approaches (Bruna et al., 2014; Henaff et al., 2015), or non-spectral approaches (Duvenaud et al., 2015). In this paper, a non-spectral method named message passing mechanism (MPM) (Gilmer et al., 2017) is employed for convolution. MPM first collects information from adjacent nodes and updates its representations based on its original representations and collected information, which is defined as:

$$\mathbf{M_n} = \max_{a \in \mathcal{N}_n^p} e_{an} \mathbf{r_a}, \quad (3)$$

$$\mathbf{r'_n} = (1 - \eta_n)\mathbf{M_n} + \eta_n \mathbf{r_n} \quad (4)$$

where $\mathbf{M_n} \in \mathbb{R}^d$ is the messages that node n receives from its neighbors; max is a reduction function which combines the maximum values on each dimension to form a new vector as an output. $\mathcal{N}_n^p$ denotes nodes that represent the nearest p words of n in the original text; $e_{an} \in \mathbb{R}^1$ is the edge weight

from node a to node n, and it can be updated during training; and $\mathbf{r_n} \in \mathbb{R}^d$ denotes the former representation of node n. $\eta_n \in \mathbb{R}^1$ is a trainable variable for node n that indicates how much information of $\mathbf{r_n}$ should be kept. $\mathbf{r'_n}$ denotes the updated representation of node n.

MPM makes the representations of nodes influenced by neighborhoods, which means the representations can bring the information from context. Therefore, even for polysemous words, the precise meaning in the context can be determined by the influence of weighted information from neighbors. Besides, the parameters of text level graphs are taken from global shared matrices, which means the representations can also bring global information as other graph-based models do.

Finally, the representations of all nodes in the text are used to predict the label of the text:

$$y_i = \text{softmax}(\text{Relu}(\mathbf{W} \sum_{n \in N_i} \mathbf{r'_n} + \mathbf{b})) \quad (5)$$

where $W \in \mathbb{R}^{d \times c}$ is a matrix mapping the vector into an output space, N_i is the node set of text i and $\mathbf{b} \in \mathbb{R}^c$ is bias.

The goal of training is to minimize the cross-entropy loss between ground truth label and predicted label:

$$\mathbf{loss} = -g_i \log y_i, \quad (6)$$

where g_i is the "one-hot vector" of ground truth label.

3 Experiments

In this section, we describe our experimental setup and report our experimental results.

3.1 Experimental Setup

For experiments, we utilize datasets including R8, R52[1], and Ohsumed[2]. R8 and R52 are both the subsets of Reuters 21578 datasets. Ohsumed corpus is extracted from MEDLINE database. MEDLINE is designed for multi-label classification, we remove the text with two or more labels. For all the datasets above, we randomly select 10% text from the training set to build validation set. The overview of datasets is listed in Table 1.

We compare our method with the following baseline models. It is noted that the results of some models are directly taken from (Yao et al., 2019).

[1]https://www.cs.umb.edu/~smimarog/textmining/datasets/

[2]http://disi.unitn.it/moschitti/corpora.htm

Datasets	# Train	# Test	Categories	Avg. Length
R8	5485	2189	8	65.72
R52	6532	2568	52	69.82
Ohsumed	3357	4043	23	135.82

Table 1: Datasets overview.

- **CNN** Proposed by (Kim, 2014), perform convolution and max pooling operation on word embeddings to get representation of text.
- **LSTM** Defined in (Liu et al., 2016), use the last hidden state as the representation of the text. Bi-LSTM is a bi-directional LSTM.
- **fastText** Proposed by (Joulin et al., 2017), average word or n-gram embeddings as documents embeddings.
- **Graph-CNN** Operate convolution over word embedding similarity graphs by fourier filter, proposed by (Defferrard et al., 2016).
- **Text-GCN** A graph based text classification model proposed by (Yao et al., 2019), which builds a single large graph for whole corpus.

3.2 Implementation Details

We set the dimension of node representation as 300 and initialize with random vectors or Glove (Pennington et al., 2014). k discussed in Section 2.1 is set to 2. We use the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 10^{-3}, and L2 weight decay is set to 10^{-4}. Dropout with a keep probability of 0.5 is applied after the dense layer. The batch size of our model is 32. We stop training if the validation loss does not decrease for 10 consecutive epochs.

For baseline models, we use default parameter settings as in their original papers or implementations. For models using pre-trained word embeddings, we used 300-dimensional GloVe word embeddings.

3.3 Experimental Results

Table 2 reports the results of our models against other baseline methods. We can see that our model can achieve the state-of-the-art result.

We note that the results of graph-based models are better than traditional models like CNN, LSTM, and fastTest. That is likely due to the characteristics of the graph structure. Graph structure

Model	R8	R52	Ohsumed
CNN	94.0 ± 0.5	85.3 ± 0.5	43.9 ± 1.0
LSTM	93.7 ± 0.8	85.6 ± 1.0	41.1 ± 1.0
Graph-CNN	97.0 ± 0.2	92.8 ± 0.2	63.9 ± 0.5

Our Model*	**97.8** ± **0.2**	**94.6** ± **0.3**	**69.4** ± **0.6**

Table 2: Accuracy on several text classification datasets. Model with "*" means that all word vectors are initialized by Glove word embeddings. We run all models 10 times and report mean results.

allows a different number of neighbor nodes to exist, which enables word nodes to learn more accurate representations through different collocations. Besides, the relationship between words can be recorded in the edge weights and shared globally. These are all impossible for traditional models.

We also find that our model performs better than graph-based models like Graph-CNN. Graph-CNN represents documents using the bag-of-word model, which is similar to ours, but they connect word nodes within a large window without weighted edges, which cannot distinguish the importance between different words. While our model employed trainable edge weights, which let words express themselves differently when faced with various collocation. Besides, the weights are shared globally which means they can be trained by all the text contains the same collocation in the entire corpus.

We also note that our model performs better than former state-of-the-art model Text-GCN. That is likely due to more expressive edges, which have been discussed before, and the difference of representations learning. Text-GCN learns word representations by corpus level co-occurrence while our model is trained within a contextual window like traditional word embeddings. Therefore our model can benefit from pre-trained word embeddings and achieve better results.

3.4 Analysis of Memory Consumption

Table 3 reports the comparison of memory consumption and edges numbers between Text-GCN and our model. Results show that our model has a significant advantage in memory consumption.

Datasets	Text-GCN	Our Model
R8	9,979M(2,841,760)	954M(250,623)
R52	8,699M(3,574,162)	951M(316,669)
Ohsumed	13,510M(6,867,490)	1,167M(419,583)

Table 3: Comparison of memory consuming. The number of edges in the whole model is in parentheses.

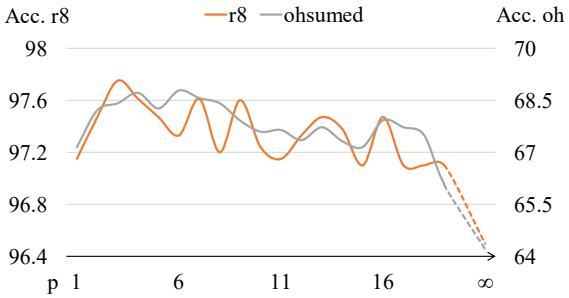

Figure 2: Model performance using p from 1 to 19 and "∞" (fully-connected). All hyperparameters are set the same except p. The left and right ordinate indicate the accuracy on the r8 and ohsumed dataset respectively.

As discussed in 2.1, the words in our model are only connected to adjacent words in the texts, while Text-GCN , which is based on the corpus level graph, connects nodes within a reasonably large window. Because Text-GCN uses co-occurrence information as fixed weights, it has to enlarge the window size to get a more accurate co-occurrence weight. Therefore, we will get a much more sparse edge weights matrix than Text-GCN. Also, since the representation of a text is calculated by the sum of the representations of word nodes in the text, there is no text node in our model, which also reduces memory consumption.

3.5 Analysis of Edges

To understand the difference of various connecting windows, we compared the performance of the R8 and ohsumed datasets with different p values, the result is reported in Figure 2. We find that the accuracy increases as p becomes larger and achieves the best performance when connected with about 3 neighborhoods. Then the accuracy decreases volatility as p increases. This suggests that when connected only with the nearest neighborhood, nodes cannot understand the dependencies that span multiple words in the context, while connected with neighborhoods far away (much larger p), the graphs become more and more similar with fully connected graphs which ignore the local features. In addition, the fewer edges, the

Setting	R8	R52	Ohsumed
Original	**97.8 ± 0.2**	**94.6 ± 0.3**	**69.4 ± 0.6**
(1)Fixed PMI Edges W.	97.7 ± 0.2	94.0 ± 0.2	67.6 ± 0.5
(2)Mean Reduction	97.7 ± 0.1	94.5 ± 0.3	62.6 ± 0.2
(3)Random Word Emb.	97.4 ± 0.2	93.7 ± 0.2	67.3 ± 0.5

Table 4: Results of ablation studies. We run all models for 5 times and give mean results.

fewer memory consumption. Our model has fewer edges compared with previous methods, and this also show the advantages of our proposed model.

3.6 Ablation Study

To further analyze our model, we perform ablation studies and Table 4 shows the results.

In (1), we fix the weights of edges and initialize them with point-wise mutual information (PMI), and the size of sliding windows is set to 20, which is the same as (Yao et al., 2019). Removing the trainable edges makes the model perform worse on all data sets, which demonstrates the effectiveness of trainable edges. In our opinion, the main reason is that trainable edges can better model the relations between words compared with fixed edges.

In (2), we change the max-reduction by mean-reduction. In the original model, the node gets its new representation from received messages by obtaining the maximum value alone each dimension. From Table 4, we can see that the max reduction can achieve better results. The node reduction function is similar to the pooling operation on CNN. Reduction by max highlights features that are highly discriminating and provides non-linearity, which helps to achieve better results.

In (3), we remove the pre-trained word embeddings from nodes and initialize all the nodes with random vectors. Compared with the original model, the performances are slightly decreased without pre-trained word embeddings. Therefore, we believe that the pre-trained word embeddings have a particular effect on improving the performance of our model.

4 Related Work

In this section, we will introduce the related works about GNN and text classification in detail.

4.1 Graph Neural Networks

Graph Neural Networks (GNN) has got extensive attention recently (Zhou et al., 2018; Zhang et al., 2018b; Wu et al., 2019). GNN can model non-Euclidean data, while traditional neural networks can only model regular grid data. While many tasks in reality such as knowledge graphs (Hamaguchi et al., 2017), social networks (Hamilton et al., 2017) and many other research areas (Khalil et al., 2017) are with data in the form of trees or graphs. So GNN are proposed (Scarselli et al., 2009) to apply deep learning techniques to data in graph domain.

4.2 Text Classification

Text classification is a classic problem of natural language processing and has a wide range of applications in reality. Traditional text classification like bag-of-words (Zhang et al., 2010), n-gram (Wang and Manning, 2012) and Topic Model (Wallach, 2006) mainly focus on feature engineering and algorithms. With the development of deep learning techniques, more and more deep learning models are applied for text classification. Kim (2014); Liu et al. (2016) applied CNN and RNN into text classification and achieved results which are much better than traditional models.

With the development of GNN, some graph-based classification models are gradually emerging (Hamilton et al., 2017; Veličković et al., 2017; Peng et al., 2018). Yao et al. (2019) proposed Text-GCN and achieved state-of-the-art results on several mainstream datasets. However, Text-GCN has the disadvantages of high memory consumption and lack of support online training. The model presents in this paper solves the mentioned problems in Text-GCN and achieves better results.

5 Conclusion

In this paper, we proposed a new graph based text classification model, which uses text level graphs instead of a single graph for the whole corpus. Experimental results show that our model achieves state-of-the-art performance and has a significant advantage in memory consumption.

Abstract

Applications such as textual entailment, plagiarism detection or document clustering rely on the notion of *semantic similarity*, and are usually approached with dimension reduction techniques like LDA or with embedding-based neural approaches. We present a scenario where semantic similarity is not enough, and we devise a neural approach to learn *semantic relatedness*. The scenario is *text spotting in the wild*, where a text in an image (*e.g.* street sign, advertisement or bus destination) must be identified and recognized. Our goal is to improve the performance of vision systems by leveraging semantic information. Our rationale is that the text to be spotted is often related to the image context in which it appears (word pairs such as *Delta–airplane*, or *quarters–parking* are not *similar*, but are clearly *related*). We show how learning a word-to-word or word-to-sentence relatedness score can improve the performance of text spotting systems up to 2.9 points, outperforming other measures in a benchmark dataset.

1 Introduction

Deep learning has been successful in tasks related to deciding whether two short pieces of text refer to the same topic, *e.g.* semantic textual similarity (Cer et al., 2018), textual entailment (Parikh et al., 2016) or answer ranking for Q&A (Severyn and Moschitti, 2015).

However, other tasks require a broader perspective to decide whether two text fragments are *related* more than whether they are *similar*. In this work, we describe one of such tasks, and we retrain some of the existing sentence similarity approaches to learn this semantic relatedness. We also present a new Deep Neural Network (DNN) that outperforms existing approaches when applied to this particular scenario.

The task we tackle is *Text Spotting*, which is the problem of recognizing text that appears in unrestricted images (a.k.a. *text in the wild*) such as traffic signs, commercial ads, or shop names. Current state-of-the-art results on this task are far from those of OCR systems with simple backgrounds.

Existing approaches to Text Spotting usually divide the problem in two fundamental tasks: 1) *text detection*, consisting of selecting the image regions likely to contain texts, and 2) *text recognition*, that converts the images within these bounding boxes into a readable string. In this work, we focus on the recognition stage, aiming to prove that semantic relatedness between the image context and the recognized text can be useful to boost the system performance. We use existing pre-trained architectures for Text Recognition, and add a shallow deep-network that performs a post-processing operation to re-rank the proposed candidate texts. In particular, we re-rank the candidates using their semantic relatedness score with other visual information extracted from the image (*e.g.* objects, scenario, image caption). Extensive evaluation shows that our approach consistently improves other semantic similarity methods.

2 Text Hypothesis Extraction

We use two pre-trained Text Spotting baselines to extract k text hypotheses. The first baseline is a CNN (Jaderberg et al., 2016) with fixed lexicon based recognition, able to recognize words in a predefined 90K-word dictionary. Second, we use an LSTM architecture with visual attention model (Ghosh et al., 2017) that generates the final output words as probable character sequences, without relying on any lexicon. Both models are trained on a synthetic dataset (Jaderberg et al., 2014). The output of both models is a Softmax score for each of the k candidate words.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3451–3457, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

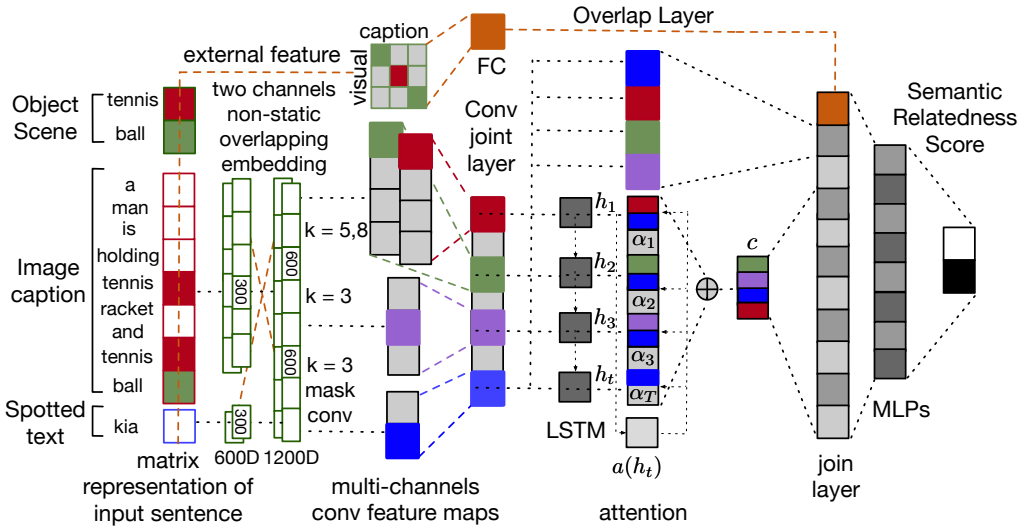

Figure 1: Overview of the system pipeline, an end-to-end post-process scores the semantic relatedness between a candidate word and the context in the image (objects, scenarios, natural language descriptions, ...)

3 Learning Semantic Relatedness for Text Spotting

To learn the semantic relatedness between the visual context information and the candidate word we introduce a multi-channel convolutional LSTM with an attention mechanism. The network is fed with the candidate word plus several words describing the image visual context (object and places labels, and descriptive captions)[1], and is trained to produce a relatedness score between the candidate word and the context.

Our architecture is inspired by (Severyn and Moschitti, 2015), that proposed CNN-based rerankers for Q&A. Our network consists of two subnetworks, each with 4-channels with kernel sizes $k = (3, 3, 5, 8)$, and overlap layer, as shown in Figure 1. We next describe the main components:

Multi-Channel Convolution: The first subnetwork consists of only convolution kernels, and aims to extract n-gram or keyword features from the caption sequence.

The convolution is applied over a sequence to extract n-gram features from different positions. Let $x \in \mathbb{R}^{s \times d}$ be the sentence matrix, where s is the sentence length, and d the dimension of the i-th word in the sentence. Let also denote by $c \in \mathbb{R}^{k \times d}$ the kernel for the convolution operation. For each i-th position in the sentence, w_i is the concatenation of k consecutive words, i.e., $w_i = [x_i \oplus x_{i+1} \oplus \ldots \oplus x_{i+k-1}]$. Our architecture uses multiple such kernels to generate feature maps m. The feature map for each window vector w_i can be written as:

$$m_i = f(w_i \circ c + b) \quad (1)$$

where $\circ$ is element-wise multiplication, f is nonlinear function, in our case we apply Relu function (Nair and Hinton, 2010), and b is a bias. For j kernels, the generated j feature maps can be arranged as feature representation for each window W_i as: $W = [m_1 \oplus m_2 \oplus \ldots \oplus m_j]$. Each row W_i of $W \in \mathbb{R}^{(s-k+1) \times j}$ is the new generated feature from the j-th kernel for the window vector at position i. The new generated feature (window representations) are then fed into the joint layer and LSTM as shown in Figure 1.

Multi-Channel Convolution-LSTM: Following C-LSTM (Zhou et al., 2015) we forward the output of the CNN layers into an LSTM, which captures the long term dependencies over the features. We further introduce an attention mechanism to capture the most important features from that sequence. The advantage of this attention is that the model learns the sequence without relying on the temporal order. We describe in more detail the attention mechanism below.

Also, following (Zhou et al., 2015), we do not use a pooling operation after the convolution feature map. Pooling layer is usually applied after the convolution layer to extract the most important features in the sequence. However, the output of our Convolutional-LSTM model is fed into

[1] All this visual context information is automatically generated using off-the-shelf existing modules (see section 4).

an LSTM (Hochreiter and Schmidhuber, 1997) to learn the extracted sequence, and pooling layer would break that sequence via downsampling to a selected feature. In short, LSTM is specialized in learning sequence data, and pooling operation would break such a sequence order. On the other hand, for the Multi-Channel Convolution model we also lean the extracted word sequence n-gram directly and without feature selection, pooling operation.

Attention Mechanism: Attention-based models have shown promising results on various NLP tasks (Bahdanau et al., 2014). Such mechanism learns to focus on a specific part of the input (*e.g.* a relevant word in a sentence). We apply an attention mechanism (Raffel and Ellis, 2015) via an LSTM that captures the temporal dependencies in the sequence. This attention uses a Feed Forward Neural Network (FFN) attention function:

$$e_t = \tanh\left(h_t W_a\right) v_a^{\mathrm{T}} \tag{2}$$

where W_a is the attention of the hidden weight matrix and v_a is the output vector. As shown in Fig. 1 the vector c is computed as a weighted average of h_t, given by α (defined below). The attention mechanism is used to produce a single vector c for the complete sequence as follows:

$$e_t = a\left(h_t\right), \alpha_t = \frac{\exp\left(e_t\right)}{\sum_{k=1}^{T} \exp\left(e_k\right)}, c = \sum_{t=1}^{T} \alpha_t h_t$$

where T is the total number of steps and α_t is the computed weight of each time step t for each state h_t, a is a learnable function that depends only on h_t. Since this attention computes the average over time, it discards the temporal order, which is ideal for learning semantic relations between words. By doing this, the attention gives higher weights to more important words in the sentence without relying on sequence order.

Overlap Layer: The overlap layer is just a frequency count dictionary to compute overlap information of the inputs. The idea is to give more weight to the most frequent visual element, specially when it is observed by more than one visual classifier. The dictionary output is a fully connected layer.

Finally, we merge all subnetworks into a joint layer that is fed to a loss function which calculates the semantic relatedness between both inputs. We call the combined model Fusion Dual Convolution-LSTM-Attention (FDCLSTM$_{AT}$).

Since we have only one candidate word at a time, we apply a convolution with *masking* in the candidate word side (first channel). In this case, simply zero-padding the sequence has a negative impact on the learning stability of the network. We concatenate the CNN outputs with the additional feature into MLP layers, and finally a sigmoid layer performing binary classification. We trained the model with a binary cross-entropy loss (l) where the target value (in $[0, 1]$) is the semantic relatedness between the word and the visual. Instead of restricting ourselves to a simple similarity function, we let the network learn the margin between the two classes –*i.e.* the degree of similarity. For this, we increase the depth of network after the MLPs merge layer with more fully connected layers. The network is trained using Nesterov-accelerated Adam (Nadam) (Dozat, 2016) as it yields better results (specially in cases such as word vectors/neural language modelling) than other optimizers using only classical momentum (ADAM). We apply batch normalization (BN) (Ioffe and Szegedy, 2015) after each convolution, and between each MLPs layer. We omitted the BN after the convolution for the model without attention (FDCLSTM), as BN deteriorated the performance. Additionally, we consider 70% dropout (Srivastava et al., 2014) between each MLPs for regularization purposes.

4 Dataset and Visual Context Extraction

We evaluate the performance of the proposed approach on the COCO-text (Veit et al., 2016). This dataset is based on Microsoft COCO (Lin et al., 2014) (Common Objects in Context), which consists of 63,686 images, and 173,589 text instances (annotations of the images). This dataset does not include any visual context information, thus we used out-of-the-box object (He et al., 2016) and place (Zhou et al., 2014) classifiers and tuned a caption generator (Vinyals et al., 2015) on the same dataset to extract contextual information from each image, as seen in Figure 2.

5 Related Work and Contribution

Understanding the visual environment around the text is very important for scene understanding. This has been recently explored by a relatively reduced number of works. Zhu et al. (2016) shows that the visual context could be beneficial for text detection. This work uses a 14 classes pixel clas-

sifier to extract *context features* from the image, such as *tree, river, wall*, to then assist scene text detection. Kang et al. (2017) employs topic modeling to learn the correlation between visual context and the spotted text in social media. The metadata associated with each image (e.g tags, comments and titles) is then used as context to enhance recognition accuracy. Karaoglu et al. (2017) takes advantage of text and visual context for logo retrieval problem. Most recently, Prasad and Wai Kin Kong (2018) use object information (limited to 42 predefined object classes) surrounding the spotted text to guide text detection. They propose two sub-networks to learn the relation between text and object class (e.g. relations such as *car–plate* or *sign board–digit*).

Unlike these methods, our approach uses direct visual context from the image where the text appears, and does not rely on any extra resource such as human labeled meta-data (Kang et al., 2017) nor limits the context object classes (Prasad and Wai Kin Kong, 2018). In addition, our approach is easy to train and can be used as a drop-in complement for any text-spotting algorithm that outputs a ranking of word hypotheses.

6 Experiments and Results

In the following we use different *similarity* or *relatedness* scorers to reorder the k-best hypothesis produced by an off-the-shelf state-of-the-art text spotting system. We experimented extracting k-best hypotheses for $k = 1 \ldots 10$.

We use two pre-trained deep models: a CNN (Jaderberg et al., 2016) and an LSTM (Ghosh et al., 2017) as baselines (BL) to extract the initial list of word hypotheses.

The CNN baseline uses a closed lexicon; therefore, it cannot recognize any word outside its 90K-word dictionary. Table 1 presents four different accuracy metrics for this case: 1) **full** columns correspond to the accuracy on the whole dataset. 2) **dict** columns correspond to the accuracy over the cases where the target word is among the 90K-words of the CNN dictionary (which correspond to 43.3% of the whole dataset. 3) **list** columns report the accuracy over the cases where the right word was among the k-best produced by the baseline. 4) **MRR** Mean Reciprocal Rank (MRR), which is computed as follows: $\text{MRR} = \frac{1}{|Q|}\sum_{k=1}^{|Q|}\frac{1}{\text{rank}_k}$, where rank k is the position of the correct answer in the hypotheses list proposed by the baseline.

Comparing with sentence level model: We compare the results of our encoder with several state-of-the-art sentence encoders, tuned or trained on the same dataset. We use cosine to compute the similarity between the caption and the candidate word. Word-to-sentence representations are computed with: Universal Sentence Encoder with the Transformer USE-T (Cer et al., 2018), and Infersent (Conneau et al., 2017) with glove (Pennington et al., 2014). The rest of the systems in Table 1 are trained in the same conditions that our model with glove initialization with dual-channel overlapping non-static pre-trained embedding on the same dataset. Our model FDCLSTM without attention achieves a better result in the case of the second baseline LSTM that full of false-positives and short words. The advantage of the attention mechanism is the ability to integrate information over time, and it allows the model to refer to spe-

Figure 2: Examples of candidate re-ranking using object (c1), place (c2), and caption (c3) information. The three left examples are re-ranked based on the semantic relatedness score. The *delta-airliner* relation which frequently co-occurs in training data is captured by the *overlap layers*. The *12-football* pair shows a relatedness between sports and numbers.

cific points in the sequence when computing its output. However, in this case, the attention attends the wrong context, as there are many words have no correlation or do not correspond to actual words. On the other hand, USE-T seems to require a shorter hypothesis list to get top performance when the right word is in the hypothesis list.

Comparing with word level model: We also compare our result with current state-of-the-art word embeddings trained on a large general text using *glove* and *fasttext*. The word model used only object and place information, and ignored the caption. Our proposed models achieve better performance than our TWE previous model (Sabir et al., 2018), that trained a word embedding (Mikolov et al., 2013) from scratch on the same task.

Similarity to probabilities: After computing the cosine similarity we need to convert that score to probabilities. As we proposed in previous work (Sabir et al., 2018) we obtain the final probability combining (Blok et al., 2003) the similarity score, the probability of the detected context (provided by the object/place classifier), and the probability of the candidate word (estimated from a 5M token corpus) (Lison and Tiedemann, 2016).

Effect of Unigram Probabilities: Ghosh et al. (2017) showed the utility of a language model (LM) when the data is too small for a DNN, obtaining significant improvements. Thus, we introduce a basic model of unigram probabilities with Out-of-vocabulary (OOV) words smoothing. The model is applied at the end, to re-rank out false positive short words, and has the main goal of re-ranking out less probable word overranked by the deep model. As seen in Table 1, the introduction of this unigram lexicon produces the best results.

Human performance: To estimate an upper bound for the results, we picked 33 random pictures from the test dataset and had 16 human subjects try to select the right word among the top $k = 5$ candidates produced by the baseline text spotting system. Our proposed model performance on the same images was 57%. Average human performance was 63% (highest 87%, lowest 39%).

7 Conclusion

In this work, we propose a simple deep learning architecture to learn semantic relatedness between word-to-word and word-to-sentence pairs, and show how it outperforms other semantic similarity scorers when used to re-rank candidate answers in the Text Spotting problem.

In the future, we plan using the same approach to tackle similar problems, including lexical selection in Machine Translation, or word sense disambiguation (Lala and Specia, 2018). We believe our approach could also be useful in multimodal machine translation, where an image caption must be translated using not only the text but also the image content (Barrault et al., 2018). Tasks that lie at the intersection of computer vision and NLP, such as the challenges posed in the new BreakingNews dataset (popularity prediction, automatic text illustration) could also benefit from our results (Ramisa et al., 2018).

Delta-training: Simple Semi-Supervised Text Classification using Pretrained Word Embeddings

Hwiyeol Jo

snu.ceyda@gmail.com

Abstract

We propose a novel and simple method for semi-supervised text classification. The method stems from the hypothesis that a classifier with pretrained word embeddings always outperforms the same classifier with randomly initialized word embeddings, as empirically observed in NLP tasks. Our method first builds two sets of classifiers as a form of model ensemble, and then initializes their word embeddings differently: one using random, the other using pretrained word embeddings. We focus on different predictions between the two classifiers on unlabeled data while following the self-training framework. We also use early-stopping in meta-epoch to improve the performance of our method. Our method, Delta-training, outperforms the self-training and the co-training framework in 4 different text classification datasets, showing robustness against error accumulation.

1 Introduction

1.1 Motivation

Classifiers using deep learning algorithms have performed well in various NLP tasks, but the performance is not always satisfactory when utilizing small data. It is necessary to collect more data for acquiring better performance. Although collecting unlabeled text data is relatively easy, labeling in and of itself requires a considerable amount of human labor. In order to incorporate unlabeled data into a task, we have to label the data in accordance to class policies of the task, but the labeling process requires not only human labor but also domain knowledge on the classes.

Semi-supervised learning (Li and Liu, 2003; Zhu, 2006; Chapelle et al., 2009) can be considered a potential solution that utilizes both labeled data and unlabeled data when building a classifier. The simplest form of semi-supervised learning is self-training (Yarowsky, 1995), which first builds a classifier using labeled data, and then label the unlabeled data. After which the most confident label prediction is added to training set and the process is repeated. The unlabeled data can help address data sparsity, but classification errors might be accumulated along the process.

We combine self-training with the hypothesis that a classifier with pretrained word embeddings (m_{emb}) is always better than a classifier with randomly initialized word embeddings (m_{rand}), as empirically observed in various NLP tasks (Turian et al., 2010). Our method follows the self-training framework but rather focuses on the different predictions of two sets of classifiers on unlabeled data. Therefore we can filter out incorrectly predicted data and correctly predicted data by both classifiers, which are less informative to the classifiers. On the other hand, differently predicted data are much more informative since much of the performance gap between the classifiers come from the different predictions. Although the differently predicted data may introduce some noise like correctly predicted by m_{rand} but incorrectly predicted by m_{emb}, we believe that the noise is relatively small when compared with benefits.

1.2 Contributions

Our contributions in this paper can be summarized as follows:

- We propose a variation of self-training framework: Delta(Δ)-training, which harnesses differently predicted labels between two sets of classifiers.
- Along with early-stopping in iterative training process, our framework outperforms the conventional self-training and co-training framework.

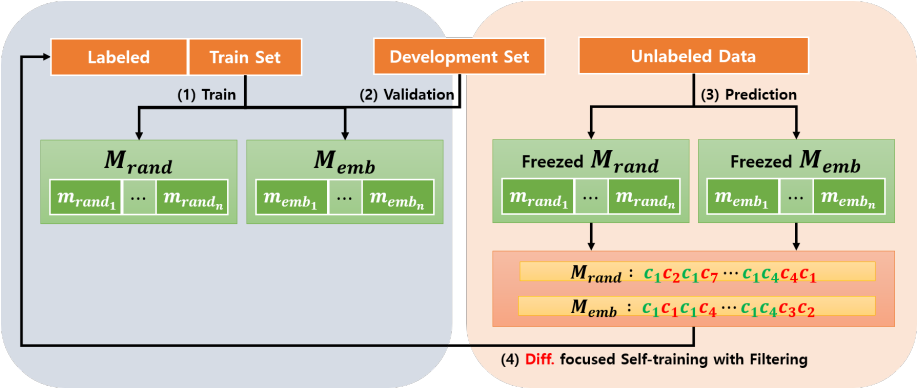

Figure 1: The flow of Δ-training framework. M_{rand} and M_{emb} are ensembled classifiers using randomly initialized word embeddings and pretrained word embeddings, respectively. (1) We first train the sets of classifiers using training set, (2) do early-stopping using development set, (3) predict the labels of unlabeled data using the sets of classifiers trained at (1), and (4) select the high confidence labels differently predicted by each set of classifiers, adding them to training set. While following the framework, we do early-stopping in meta-epoch with the development set.

2 Preliminary

Self-training. Given labeled data $\{(x_1, y_1), \cdots, (x_n, y_n)\}$ and unlabeled data $\{(x_{n+1}), \cdots, (x_{n+l})\}$, self-training (Yarowsky, 1995) first builds a model m using labeled data. Next, it simply predicts the unlabeled data using pretrained model m. If the confidence score of the predicted label is higher than a predefined threshold T, then adds the label-by-prediction data to the training set. This simple approach has generated variations such as calibration (Guo et al., 2017), and online learning (Abney, 2007).

Pretrained Word Embeddings. Pretrained word embeddings are based on the distributed representation hypothesis that a word can be represented as an n-dimensional vector (Mikolov et al., 2013). Most of the algorithms are based on the basic idea of CBoW and skip-gram. Both algorithms learn word vectors by maximizing the probability of occurrence of a center word given neighbor words or neighbor words given a center word. With this unsupervised approach, we can represent semantic and relational information. The pretrained word vectors from very large corpus are used to initialize word vectors for classifiers, performing better than randomly initialized word vectors (Turian et al., 2010).

Model Ensemble. Model ensemble (Opitz and Maclin, 1999) is using a combination of models to increase accuracy and get confidence scores on predictions. There are two types of ensemble methods, bagging and boosting. Bagging averages the predictions over a collection of classifiers whereas boosting weights the vote with a collection of classifiers.

3 Proposed Method: Δ-training

The overall process of our framework is illustrated in Figure 1.

3.1 Different Prediction focused Self-training

Our method consists of two classifiers: one is randomly initialized (m_{rand}; random network), and the other is using pretrained word vectors (m_{emb}; embedded network). When ensembling, we duplicate the same classifier, $M_{rand} = (m_{rand_1}, \cdots, m_{rand_n})$ and $M_{emb} = (m_{emb_1}, \cdots, m_{emb_n})$, respectively.

We adopt bagging to increase the cases that (1) both m_{rand} and m_{emb} predict the labels of data correctly, and (2) m_{rand} predicts incorrectly but m_{emb} predicts correctly. Model ensemble is also used to pick out label-by-prediction data with high confidence, which will be used for self-training. Intuitively, the benefits of Δ-training are maximized when the performance gap between two sets of classifiers is large. Also, we can ensure the performance gap not only by using pretrained embeddings but also through the ensemble setting.

First, we train the classifiers using the training set with early-stopping, and return their predictions on unlabeled data. We consider the predictions of M_{emb} on the unlabeled data as label-by-prediction since M_{emb} always outperforms M_{rand} according

to our hypothesis. The hypothesis will be confirmed in Section 7.

After labeling the unlabeled data, we select the data with conditions that (a) each ensembled classifiers are predicting the same class, and (b) the predictions of M_{rand} and M_{emb} are different. Condition (a) helps to pick out the data labeled with high confidence by the classifiers and Condition (b) helps to pick out the data which is incorrect in M_{rand} but correct in M_{emb}. The ratio in which labels might be correct in M_{rand} but incorrect in M_{emb} is relatively small than vice versa (will be also presented in Section 7). We add the selected data and its pseudo-label by M_{emb} to training set, and then train the classifiers again from the very first step to validate our hypothesis. If we do not start from the very first step, it might cause M_{emb} to overfit and perform worse than M_{rand}.

We denote one such iterative process, training and pseudo-labeling, as a *meta-epoch*.

3.2 Early-Stopping in Meta-Epoch

Using the development set in every meta-epoch, we do early-stopping during the different prediction focused self-training. As M_{rand} keeps learning based on the predictions of M_{emb}, the size of data which is incorrectly predicted by M_{rand} but correctly predicted by M_{emb} will decrease. Likewise, the size of data which is correctly predicted by both M_{rand} and M_{emb} will increase. Therefore, after early-stopping in meta-epoch, we simply add all the unlabeled data with its pseudo-labels to the training set. In this way, we can fully benefit from different prediction focused self-training and save training time.

4 Experiment Data

We use **GloVe** (Pennington et al., 2014) `glove.42B.300d` as word embedding for M_{emb}. We also perform word vector post-processing method, **extrofitting** (Jo, 2018), to improve the effect of initialization with pretrained word embeddings on text classification, as described in their paper.

We use 4 text classification datasets; **IMDB review** (Maas et al., 2011), **AGNews**, **Yelp review** (Zhang et al., 2015), and **Yahoo!Answers** (Chang et al., 2008).

	IMDB Review	**AGNews**	**Yelp Review**	**Yahoo Answer**
Train	212	1,020	5,525	1,136
Test	25,000	7,600	50,000	23,595
Dev	38	180	975	201
Unlabed	24,750	118,800	643,500	132,366
#Class	2	4	5	17

Table 1: The data split information of text classification datasets. We use 1% of the training data and remove the labels of the remaining training data, using them as unlabeled data.

5 Experiment

5.1 Data Preparation

To emulate the environment with only a few labeled training examples, we take only 1% of the original training set and remove the label of the remaining training set, which will be referred to as unlabeled data. Next, we assign 15% of the training set to the development set. The development set is used to determine early-stopping for every epoch and meta early-stopping for every meta-epoch. The split data size is presented in Table 1. IMDB reviews dataset has own unlabeled data but we do not use them in order to track and report on the difference between predicted labels and true labels.

5.2 Classifier

We select TextCNN (Kim, 2014) as our classifier. Due to the simple but high performance nature of TextCNN, the model can represent deep learning classifiers, and is easy to ensemble as well. We use the first 100 words of data in 300 dimensional embedding space. The model consists of 2 convolutional layers with the 32 channels and 16 channels, respectively. We adopt multiple sizes of kernels–2, 3, 4, and 5, followed by ReLU activation (Hahnloser et al., 2000) and max-pooled. We concatenate them after every max-pooling layer. We train the model using Adam optimizer (Kingma and Ba, 2014) with 1e-3 learning rate.

5.3 Ensemble Settings

In the experiment, the number of embedded model ensemble (M_{emb}) is 3 and we do not ensemble random model ($M_{rand} = m_{rand}$) for simplicity. The baselines also use the same ensemble settings for fair comparison.

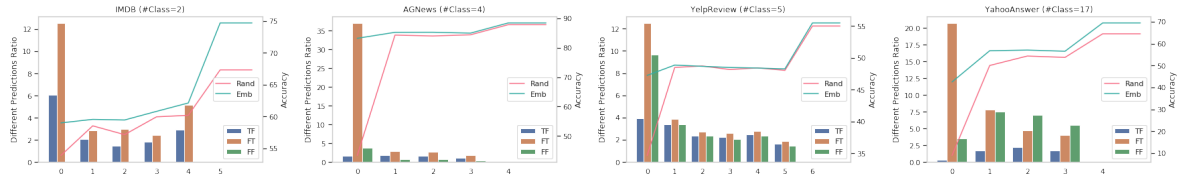

Figure 2: The training curve and the ratio of differently predicted label during Δ-training. The x-axis indicates a training process (meta-epoch). TF, FT, and FF denote that correctly predicted by M_{rand} but incorrectly predicted by M_{emb}, incorrectly predicted by M_{rand} but correctly predicted by M_{emb}, and incorrectly predicted by both M_{rand} and M_{emb}, respectively. We extend the end of performance lines to indicate final accuracy.

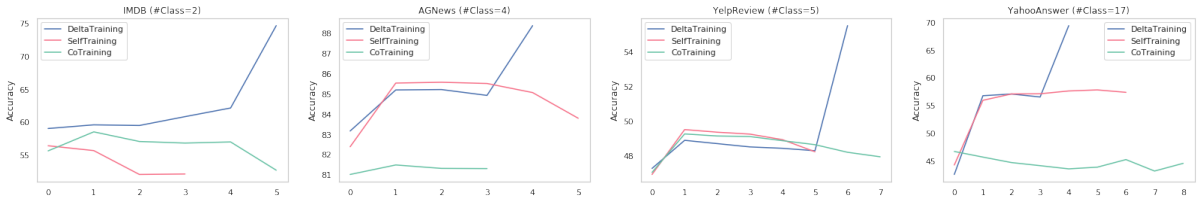

Figure 3: The performance of Δ-training compared with self-training and co-training. Our method largely improves the performance in binary classification but slightly show degraded performance prior to early-stopping in meta-epoch. Then, Δ-training finally brings significant performance gain after meta-level early stopping, training on all the remaining pseudo-labeled data.

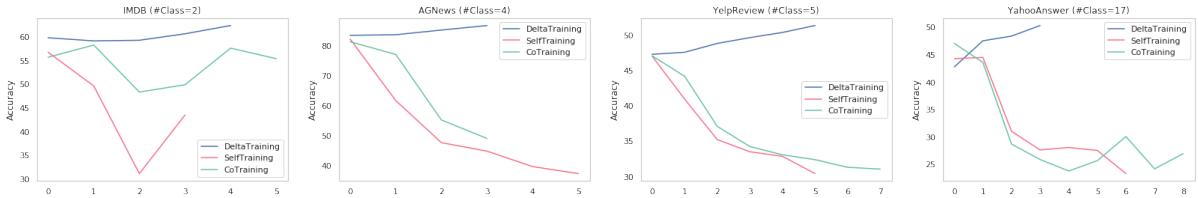

Figure 4: The performance of Δ-training and other frameworks on unlabeled data. We recover the removed true labels and track the model performance. Δ-training is robust against error accumulation.

6 Related Works

Δ-training is closely related to **Self-training** (Yarowsky, 1995), and **Tri-training with Disagreement** (Søgaard, 2010). Tri-training (Zhu, 2006) uses 3 classifiers to vote their classification results and labels them if all the classifiers agree with the prediction. Its extension, Tri-training with Disagreement, also uses 3 classifiers but the method utilizes a disagreement that pseudo-labels on unlabeled data if two classifiers agree with the labels but one classifier disagrees with the labels. The differences with our method respectively are (1) we harness different predictions of classifiers, and (2) we use a single model architecture where word embeddings are initialized differently.

The existing semi-supervised solutions using 2 classifiers such as **Co-training** (Blum and Mitchell, 1998) cannot be fully compared with ours for (2) that a single architecture should be used. The method is built on 2 different classifiers as having different views on data, and harnesses one's pseudo-labels to train the other classifier. Instead, we imitate the co-training as if M_{rand} and M_{emb} have different views on the data.

Refer to Ruder and Plank's work (2018) for further knowledge on those related works.

7 Result

The training curve and the ratio of differently predicted labels are presented in Figure 2. The training curves at x=0, at which point Δ-training is not applied yet, confirms our hypothesis–a classifier with pretrained word embeddings always outperforms the same classifier with randomly initialized word embeddings. Also, the ratio in which labels are correct in M_{rand} but incorrect in M_{emb} is relatively small (TF<FT) than vice versa. The ratio in which labels are incorrect both in M_{rand} and M_{emb} (FF) changes according to baseline accuracy and the number of classes.

The performance of Δ-training compared with

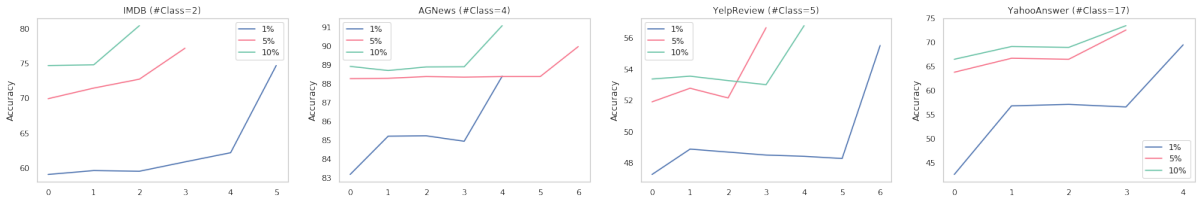

Figure 5: The performance of Δ-training with respect to initial training data size. Δ-training performs well in different training data size and is more useful when the training data is scarce.

self-training and co-training is presented in Figure 3. Our method largely outperforms the conventional self-training and co-training framework in binary class classification. In multi-class classification, picking different predictions is less effective because the data could be incorrectly predicted by both M_{emb} and M_{rand}. Therefore, after the early-stopping in meta-epoch, we simply add all the unlabeled data with its pseudo-labels to training set, which finally brings significant performance gain. In Figure 4, we observe that the performance of self-training and co-training decreases in unlabeled data after a few meta-epochs because of accumulated classification errors. On the other hand, our method is robust against error accumulation. As a result, the process of adding all the unlabeled data with its pseudo-labels to training set starts from enhanced and robust models.

We also report the effect of initial training data size in Figure 5. The result shows that Δ-training is more useful when the training data is scarce and also Δ-training works well even when there is relatively more data.

8 Conclusion

In this paper, we propose a novel and simple approach for semi-supervised text classification. The method follows the conventional self-training framework, but focusing on different predictions between two sets of classifiers. Further, along with early-stopping in training processes and simply adding all the unlabeled data with its pseudo-labels to training set, we can largely improve the model performance. Our framework, Δ-training, outperforms the conventional self-training and co-training framework in text classification tasks, showing robust performance against error accumulation.

Abstract

We present 1) a work in progress method to visually segment key regions of scientific articles using an object detection technique augmented with contextual features, and 2) a novel dataset of region-labeled articles. A continuing challenge in scientific literature mining is the difficulty of consistently extracting high-quality text from formatted PDFs. To address this, we adapt the object-detection technique Faster R-CNN for document layout detection, incorporating contextual information that leverages the inherently localized nature of article contents to improve the region detection performance. Due to the limited availability of high-quality region-labels for scientific articles, we also contribute a novel dataset of region annotations, the first version of which covers 9 region classes and 822 article pages. Initial experimental results demonstrate a 23.9% absolute improvement in mean average precision over the baseline model by incorporating contextual features, and a processing speed 14x faster than a text-based technique. Ongoing work on further improvements is also discussed.

1 Introduction

Mining scientific literature at scale for information that can be processed automatically is a valuable and much sought after technique for domain researchers and data scientists. Whereas mass processing of articles was once largely limited to keyword searches and citation crawling, modern natural language processing techniques can now deeply search for specific and broad concepts, explore relationships, and automatically extract useful information from text.

However, getting the article text in the first place is not always simple. Though some publications offer full-text articles in open-access, machine-readable formats (e.g. plain text, HTML or XML),

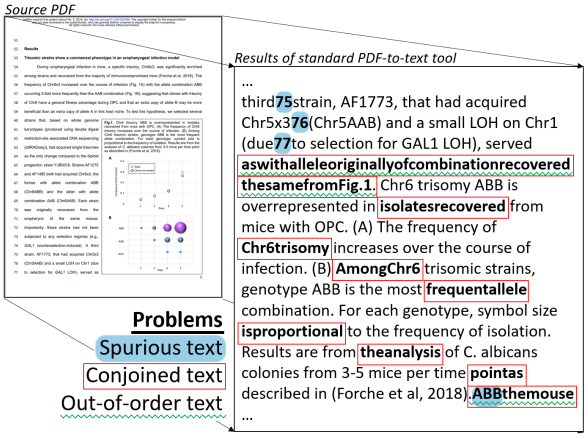

Figure 1: Text extraction from PDF articles is generally a noisy process because of the significant inconsistencies in PDF publishing tools and the edit-and-republish nature of print-ready document preparation by journal publishers and document hosting services.

this is far from the norm. Instead, much of the scientific record remains in PDF files that are much more challenging to automatically process. This challenge remains whether the PDFs originate from scanned pages (thus requiring OCR) or were published from digital source material. Although there are tools for automatically extracting text from PDFs, formatting is highly inconsistent. Standard tools often mix headers, footers, table and figure captions, page numbers, and other extraneous text into the main text being extracted (Bast and Korzen, 2017). And text order is not always well preserved (Figure 1). This is not quite as problematic if text is extracted for simple tasks like keyword searches. However, more complex tasks like Named-Entity Recognition often rely on contiguous, cleanly segmented text for successful processing. And while manually cleaning and reformatting text may be an option for small sets of documents, this quickly becomes impractical when dealing with larger corpora.

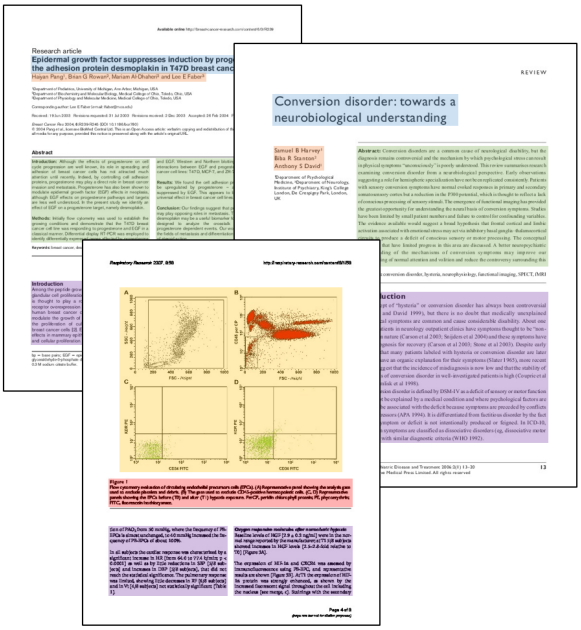

Figure 2: Examples of ground-truth region labels, showing varying journal styles. Note that even when text is illegibly small, the salient regions are visually apparent (e.g. title, abstract, figure caption, etc.).

To facilitate large-scale automatic knowledge extraction from scientific articles, this paper presents an adaptation of the Faster R-CNN object detection model for the task of document layout detection, with the addition of contextual features. The method **visually** detects major regions in article pages and classifies them into a set of labels, including main-body text, tables, figures, and others (Figure 2). To train and evaluate the detection models, a novel dataset of 100 region-annotated scientific articles was created, totaling 822 labeled pages. This work is an ongoing effort: the dataset is being expanded, additional contextual features are being developed, and further evaluation is being conducted.

2 Related Work

In addition to the numerous tools that exist for extracting text from PDFs – Bast and Korzen (2017) provide a quantitative evaluation of 14 common ones – there are a variety of approaches for analyzing documents to determine their contents' layout and/or extract information of particular types.

Systems like CERMINE (Tkaczyk et al., 2015) and OCR++ (Singh et al., 2016) extract the raw or processed markup from "born-digital" PDFs (e.g. using tools like pdf2xml) and apply a variety of text processing methods to deduce document structure and apply semantic labels to text blocks. These methods may be rule-based (e.g. regular expressions and heuristics) or machine-learning based (e.g. SVM classification). Such approaches may achieve high-quality extraction and labeling. However they rely on extracted PDF source markup (not always available, e.g. for scanned PDFs), work only on text blocks (ignoring tables and figures, which may also be valuable), and are typically quite slow (2 to 10 seconds or more per article). Analogous approaches for web pages – such as those by Cai et al. (2003) and Song et al. (2004) – also examine the document source (in this case the page DOM) to build representations for further processing.

Alternatively, visual-based techniques for document layout analysis have tended to focus on text segmentation (Tran et al., 2015), (Chen et al., 2015a), (Chen et al., 2015b), (Garz et al., 2016), especially for historical documents; Eskenazi et al. (2017) survey dozens of such methods. More closely aligned with the aim of this work are those by Lang et al. (2018), who use HOG features and random forests to recognize text, images, charts and tables in newspapers, Oliveira and Viana (2017), who uss 1D CNNs to recognize text, images, and tables in scientific articles, and finally Singh et al. (2018), who use a LSTD model to recognize various customizable text and image classes in multiple domains, with mixed results.

Differently from these previous methods, the approach in this paper aims to leverage contextual information in a modern visual object detection approach. Of particular importance to this effort is using a high-quality dataset with labels for relevant key regions of scientific articles. Though some of the cited works in this section published their own custom datasets, these proved to be too granular, too coarse or too noisy for use in this work (see Section 4).

3 Visual Document Layout Detection

A modern visual approach is taken to document region detection, with the aim to produce labeled bounding boxes for regions of interest (ROIs) in each document page. Although the text contents in many regions may be useful in classification, our vision-only approach has the benefit of working in any language, and can yield impressive performance even without text features (see Section 5). To be clear: our approach does not access a

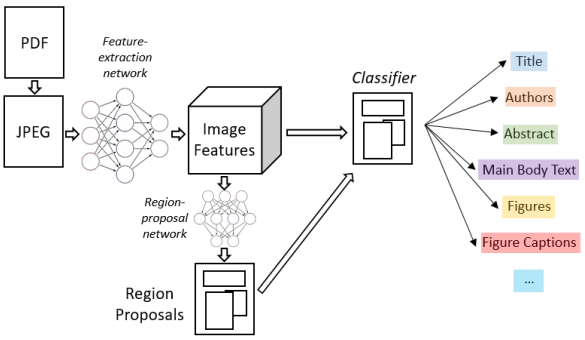

Figure 3: Model for visual region detection using Faster R-CNN. After rendering each page of a PDF to a JPEG and extracting its image features using a convolutional ResNet-101 network, regions of interest are proposed and classified by two additional network which are trained on ground-truth labels.

document's source at all (neither embedded text, nor underlying PDF markup), instead relying only on JPEG renderings of the document's pages.

The baseline technique used for this work is the highly successful object detector Faster R-CNN (Ren et al., 2015) – a so-called two stage detection model. This model takes an image as input and first predicts candidate regions of interest (i.e. image regions that are likely to contain objects), then classifies each candidate region into one of a predefined set of object classes. The output is a set of bounding boxes identifying recognized objects in the image (e.g. people, cars, dogs, etc.). Algorithmically, Faster R-CNN relies on several component neural networks, beginning with a deep convolutional neural network – ResNet-101 (He et al., 2016), specifically – to perform feature extraction on the input image. The resulting feature map is then fed into a region-proposal network (which generates candidate object bounding boxes) and a classification network (which assigns region labels to those candidates). A regressor network also fine-tunes the ROI bounding box parameters for better fit. Figure 3 shows how this model can be applied directly to the task of detecting salient regions in images of document pages.

An important aspect of standard object detection techniques like Faster R-CNN, is that they only use image features within a region of interest to label that region. This approach is advantageous to general purpose object detection, because objects may be located anywhere in a photo or video., and has been highly successful even when objects are cropped or occluded by other objects (Lin et al., 2014). However, in domains such as document layout detection, where the 'objects' to be detected are generally well-structured elements of the page (and indeed of a collected set of pages), it is helpful to include contextual information to determine the label of a region. To this end, our approach incorporates contextual information about pages and ROI bounding boxes, encoded as additional features for the classification and fine-tuning regression stages of the model.

The position, size, and page number of a candidate ROI in a document are valuable contextual clues to the true label of that region. They help disambiguate region classes that are otherwise visually similar, such as abstracts, body text, and figure captions (without context, these all appear simply as isolated blocks of text). Further, if two proposed regions overlap, their size and position can help determine which is more likely to fit a true document region more closely. Additional contextual features are being explored in ongoing work (see Section 6), however these were selected first for their ease of integration and anticipated high impact on detection performance.

Another important consideration is the existence of newer, even more successful detection models like YOLOv3 (Redmon and Farhadi, 2018) and RetinaNet (Lin et al., 2017), which use a single-stage detection paradigm. Our rationale in selecting Faster R-CNN as a baseline model to build upon in this work is that the separate region proposal and classification models make it easier to intercept ROI dimensions from the first model and embed them as additional features (along with page numbers) for input to the classification and bounding-box regression models. We do, however, compare our results to single-stage models and intend to explore these further.

4 Novel Labeled Dataset

Existing region-labeled datasets of scientific articles proved too noisy for our visual region detection method. Training the model with the full GROTOAP2 dataset (Tkaczyk et al., 2014), for example, yielded a best overall detection performance of 5.1% mean average precision (mAP) over all 22 labels. The key problems were that many of the regions were far too granular (e.g. each cell of a table might have its own bounding box labeled 'table'), and many regions were mislabeled or misaligned. The labeling noise was so pronounced that by simply filtering and carefully

Figure 4: Incorporating page and bounding box context yielded a relative improvement of 51.6% over baseline Faster R-CNN performance (23.9% absolute: 70.3% vs 46.4%). Our model also outperforms reference state-of-the-art single stage models: RetinaNet (58.1% peak mAP) and YOLOv3 (68.9%, after 49 epochs). Small regions (authors, table captions) remain challenging and bring down average performance. All results @ 0.5 IOU.

coalescing bounding boxes for 'body content' labels, single-class detection performance was dramatically improved to 72% AP (up from 18% for unfiltered labels). However, the label-cleaning process was very time consuming and this improvement did not generalize to other classes.

Therefore, a novel dataset was created. We rendered PDF articles to JPEG image sets (using the ImageMagick package, at 72dpi), and used an open source utility (Tzutalin, 2015) to manually annotate regions. Version 1 of this dataset consists of region annotations for 100 scientific articles sampled from the PMC Open Access set. The collection will be available at `https://github.com/cxsoto/article-regions`, and includes scripts to download and render the original article PDFs to images, as well as to convert the annotations to various formats. The default format is PASCAL VOC. Nine labeled region classes are included in the annotations:

- *Title*. Includes subtitle, if present.
- *Authors*. Author names only, where possible (i.e. no affiliations, etc.).
- *Abstract*. Abstract text only, where possible.
- *Body*. All main article text, including section headers. Contiguous, where possible.
- *Figure*. Any labeled figures (i.e. no journal logos, etc.).
- *Figure Caption*. The caption text for a figure.
- *Table*. Including only the tabular contents, where possible. Includes adjacent notes or commentary if short and table-aligned.
- *Table Caption*. Main table caption as well as paragraph-form table commentary that follows some tables.
- *References*. Full bibliography, not including post-references notes (e.g. author bios, journal marketing, etc.).

The bounding boxes for these regions were created to be consistent and tight-fitting, with typical padding of 2-4 pixels. In general, the bounding boxes do not overlap. Each page of each article is labeled and processed separately. Due to labeling precision, annotation took approximately 20 to 60 seconds per image, depending on the contents. However, as this process does not involve specialized knowledge, it can be readily crowd-sourced.

For version 2 of the dataset, we intend to include labels for Equations, Sub-Figures, and Author Affiliations. It is expected to cover approximately 1000 articles from more varied sources, including pre-prints from arXiv and similar repositories.

5 Implementation and Experiments

Using the novel labeled dataset described in Section 4, a baseline model was trained using a standard Faster R-CNN implementation (Yang et al., 2017). The model was trained using a single

NVIDIA P100 GPU for 30 epochs on 600 images, and tested on the remaining 222 in 5 randomized sessions, using a ResNet-101 base network pretrained on ImageNet (Russakovsky et al., 2015), with a batch size of 8, Adam optimizer (Kingma and Ba, 2014), and a starting learning rate of 0.0001, with decay of 0.1 every 5 epochs. Standard anchor scales of [8, 16, 32] and anchor ratios of [0.5, 1.0, 2.0] were used. At a intersection-over-union (IOU) threshold of 0.5, the model achieved a mean average precision (mAP) of 46.38% on all nine region labels, with peak class performance on 'body' regions (87.49%) and lowest performance on 'authors' (1.22%).

Contextual information was incorporated into the classification and regression stages of the model for article page information and proposed ROI bounding boxes. Page context consisted of the page number of the current image in its article, and the number of pages in the article, both normalized to the average page length of articles in the dataset (8.22). Bounding box context consisted of the position and size of the proposed region of interest, normalized to the dimensions of the image. Both were appended to the pooled feature vectors for batched ROIs sent to the classification and bounding-box regression models. The input size of these models were increased accordingly. Retraining the model in the same manner as the baseline yielded a mean average precision of 70.3%, with peak class-performance of 93.58% on 'body' regions and a low performance of 10.34% on 'authors'. The second-lowest performance was on 'table captions' (30.8%).

Figure 4 shows per-class performance over 30 training epochs, as well as comparative performance against the baseline Faster R-CNN model and reference model implementations of YOLOv3 (Linder-Noren, 2018) and RetinaNet (Henon, 2018). Most models plateaued early on this small dataset, except YOLOv3 which peaking at 68.9% after 49 epochs (beyond the figure bounds, but still below our model's results). Processing time for our model averaged 0.65 seconds per article. By contrast, CERMINE averaged 9.4 seconds per article on the same set of articles, on the same machine.

With the exception of two small region classes (authors and table captions), detection performance quickly reaches a rather high plateau (83.63% not including these two classes), especially considering the model has been trained on less than 100 labeled articles. The size and placement of these region classes makes them difficult to localize and distinguish from other classes. The ongoing work described in Section 6 focuses on incorporating additional contextual features that are expected to improve overall performance, and especially target problematic classes like these.

6 Discussion and Ongoing Work

Visual layout detection in documents benefits directly from advances in state-of-the-art object detection techniques, yet is also well suited for optimizations that exploit the structured nature of documents. Adding even very simple contextual information (page numbers and region-of-interest position and size) yielded a relative performance improvement over the baseline of over 50% – while also outperforming state-of-the-art single stage detectors. Unsurprisingly, the position of a region in a scientific article is strongly correlated with its label. Similarly, other contextual information may be correlated with a region's label and placement.

In ongoing work, additional contextual features are being explored, including ROI oversampling (i.e. looking at a region's surroundings), random feature map sampling (i.e. looking at patterns in a whole page or whole article), and all-region positional information (i.e. the position of other predicted ROIs in an article). Performance improvements are expected as these features are incorporated, and as additional labeled data is created. Alternative detection frameworks are also being explored.

The value of this work extends beyond text extraction. Visual region detection can serve as a precursor to numerous existing information extraction techniques or adaptations of them, including parsing of reference (Lammey, 2015), tables (Rastan et al., 2015), and equations (Smithies et al., 2001), as well as data extraction from figures (Tummers, 2006). And so it is valuable to all these efforts to be able to accurately and quickly segment document pages into regions of interest.

Evaluating Topic Quality with Posterior Variability

Abstract

Probabilistic topic models such as latent Dirichlet allocation (LDA) are popularly used with Bayesian inference methods such as Gibbs sampling to learn posterior distributions over topic model parameters. We derive a novel measure of LDA topic quality using the *variability* of the posterior distributions. Compared to several existing baselines for automatic topic evaluation, the proposed metric achieves state-of-the-art correlations with human judgments of topic quality in experiments on three corpora.[1] We additionally demonstrate that topic quality estimation can be further improved using a supervised estimator that combines multiple metrics.

1 Introduction

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) topic modeling has been widely used for NLP tasks which require the extraction of latent themes, such as scientific article topic analysis (Hall et al., 2008), news media tracking (Roberts et al., 2013), online campaign detection (Paul and Dredze, 2014) and medical issue analysis (Huang et al., 2015, 2017). To reliably utilize topic models trained for these tasks, we need to evaluate them carefully and ensure that they have as high quality as possible. When topic models are used in an extrinsic task, like text categorization, they can be assessed by measuring how effectively they contribute to that task (Chen et al., 2016; Huang et al., 2015). However, when they are generated for human consumption, their evaluation is more challenging. In such cases, interpretability is critical, and Chang et al. (2009); Aletras and Stevenson (2013) have shown that the standard way to evaluate the output of a probabilistic model, by measuring perplexity on held-out data (Wallach et al., 2009), does not imply that the inferred topics are human-interpretable.

A topic inferred by LDA is typically represented by the set of words with the highest probability given the topic. With this characteristic, we can evaluate the topic quality by determining how coherent the set of topic words is. While a variety of techniques (Section 2) have been geared towards measuring the topic quality in this way, in this paper, we push such research one step further by making the following two contributions: (1) We propose a novel topic quality metric by using the *variability* of LDA posterior distributions. This metric conforms well with human judgments and achieves the state-of-the-art performance. (2) We also create a topic quality estimator by combining two complementary classes of metrics: the metrics that use information from posterior distributions (including our new metric), along with the set of metrics that rely on topic word co-occurrence. Our novel estimator further improves the topic quality assessment on two out of the three corpora we have.

2 Automatic Topic Quality Evaluation

There are two common ways to evaluate the quality of LDA topic models: *Co-occurrence Based Methods* and *Posterior Based Methods*.

Co-occurrence Based Methods Most prominent topic quality evaluations use various pairwise co-occurrence statistics to estimate topic's semantic similarity. Mimno et al. (2011) proposed the **Coherence** metric, which is the summation of the conditional probability of each topic word given all other words. Newman et al. (2010) showed that the summation of the pairwise pointwise mutual information (**PMI**) of all possible topic word pairs is also an effective metric to assess topic quality. Later, in Lau et al. (2014), PMI was replaced

[1] Our code and data are available here.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3471–3477, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

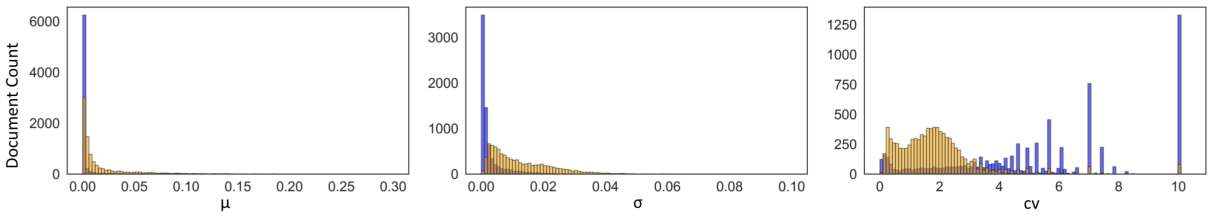

Figure 1: Two example topics and their distributions of μ, σ and cv from the NYT corpus. Two topics are: Topic1 (in blue): {*financial, banks, bank, money, debt, fund, loans, investors, funds, hedge*}. Topic2 (in orange): {*world, one, like, good, even, know, think, get, many, got*}. Their human rating scores are 3.4 and 1.0 respectively.

by the normalized pointwise mutual information (**NPMI**) (Bouma, 2009), which has an even higher correlation with human judgments. Another line of work exploits the co-occurrence statistics indirectly. Aletras and Stevenson (2013) devised a new method by mapping the topic words into a semantic space and then computing the pairwise distributional similarity (**DS**) of words in that space. However, the semantic space is still built on PMI or NPMI. Roder et al. (2015) studied a unifying framework to explore a set of co-occurrence based topic quality measures and their parameters, identifying two complex combinations, (named **CV** and **CP** in that paper[2]), as the best performers on their test corpora.

Posterior Based Method Recently, Xing and Paul (2018) analyzed how the posterior of LDA parameters vary during Gibbs sampling inference (Geman and Geman, 1984; Griffiths and Steyvers, 2004) and proposed a new topic quality measurement named **Topic Stability**. The Gibbs sampling for LDA generates estimates for two distributions: for topics given a document (θ), and for words given a topic (ϕ). Topic stability considers ϕ and is defined as:

$$stability(\mathbf{\Phi_k}) = \frac{1}{|\mathbf{\Phi_k}|} \sum_{\phi_k \in \Phi_k} sim(\phi_k, \bar{\phi_k}) \quad (1)$$

The stability of topic k is computed as the mean cosine similarity between the mean ($\bar{\phi_k}$) of all the sampled topic k's distribution estimates ($\mathbf{\Phi_k}$) and topic k's estimates from each Gibbs sampler (ϕ_k). Fared against the co-occurrence based methods, topic stability is parameter-free and needs no external corpora to infer the word co-occurrence. However, due to the high frequency of common words across the corpus, low quality topics may also have high stability, and this undermines the performance of this method.

[2]The framework proposed in Roder et al. (2015) has four stages. Every stage has multiple settings. CV and CP are different at the Confirmation Measure stage, which measures how strongly a set of topic words connect with each other.

μ	0.185	0.030	0.148	0.121
σ	0.480	0.295	0.600	0.458
cv	**0.679**	**0.703**	**0.774**	**0.719**

Table 1: Pearson's r of each potential metric of posterior variability with human judgments

3 Variability Driven from Topic Estimates

In this paper, we also use Gibbs sampling to infer the posterior distribution over LDA parameters. Yet, instead of ϕ, our new topic evaluation method analyzes estimates of θ, the topic distribution in documents. Let $\mathbf{\Theta}$ be a set of different estimates of θ, which in our experiments will be a set of estimates from different iterations of Gibbs sampling. Traditionally, the final parameter estimates are taken as the mean of all the sampled estimates, $\hat{\theta}_{dk} = \frac{1}{|\mathbf{\Theta}|} \sum_{\theta \in \mathbf{\Theta}} \theta_{dk}$. In this paper, we use the shorthand μ_{dk} to denote $\hat{\theta}_{dk}$ for a particular document d and topic k.

In the rest of this section, we first discuss what types of information can be derived from the topic posterior estimates from different Gibbs samplers. Then, we examine how the corpus-wide variability can be effectively captured in a new metric for topic quality evaluation.

Two types of information can be derived from the topic posterior estimates: (1) the mean of estimates, μ_{dk}, as discussed above, and (2) the variation of estimates. For variation of estimates, we considered using the standard deviation σ_{dk}. However, this measure is too sensitive to the order-of-magnitude differences of μ_{dk}, that typically occur in different documents. So, in order to capture a

more stable dispersion of estimates from different iterations of Gibbs sampling, we propose to compute the variation of topic k's estimates in document d as its *coefficient of variance (cv)* (Everitt, 2002), which is defined as: $cv_{dk} = \sigma_{dk}/\mu_{dk}$

Notice that both μ_{dk} and cv_{dk} can arguably help distinguish high and low quality topics because:

- High quality topics will have high μ_{dk} for related documents and low μ_{dk} for unrelated documents. But low quality topics will have relatively close μ_{dk} throughout the corpus.
- High quality topics will have low cv_{dk} for related documents and high cv_{dk} for unrelated ones. But low quality topics will have relatively high cv_{dk} throughout the corpus.

Now, focusing on the design of the new metric, we consider using the corpus-wide variability of topics' estimates as our new metric. Figure 1 shows a comparison of the distributions of mean of estimates (μ) and variation of estimates (σ, cv) for two topics across the NYT corpus (Section 5.1). We can see the cv distributions of good (Topic1) and bad (Topic2) topics are the most different. The cv distribution of Topic1 covers a large span and has a heavy head and tail, while cv values of Topic2 are mostly clustered in a smaller range. In contrast, the difference between Topic1 and Topic2's distributions of μ and σ throughout the corpus appears to be less pronounced. Taking the corpus-wide variability difference between good and bad topics observed in Figure 1, we choose cv to measure the corpus-wide variability of topic k's estimates as our new metric. Formally, it can be defined as:

$$variability(k) = std(cv_{1k}, cv_{2k}, \cdots, cv_{Dk}) \quad (2)$$

where D is the size of the corpus. High quality topics will have higher variability and low quality topics will have lower variability. Table 1 shows a comparison in performance (correlation with human judgment) of our variability defined by cv with the variability defined by μ or σ on three commonly used datasets (Section 5.1). The variability defined by cv is a clear winner.

4 Topic Quality Estimator

Our new method, like all other methods driven from the posterior variability, does not use any information from the topic words, which is in contrast the main driver for co-occurrence methods. Based on this observation, posterior variability and co-occurrence methods should be complementary to each other. To test this hypothesis, we investigate if a more reliable estimator of topic quality can be obtained by combining these two classes of methods in a supervised approach. In particular, we train a support vector regression (SVR) estimator (Joachims, 2006) with the estimations of these methods as features, including all the topic quality measures introduced in Section 2 along with our proposed *variability* method.

5 Experiments

5.1 Datasets

We evaluate our topic quality estimator on three datasets: *20NG*, *Wiki* and *NYT*. *20NG* is the 20 Newsgroup dataset (Joachims, 1997) which consists of 9,347 paragraphs categorized into 20 classes[3]. *Wiki* consists of 10,773 Wikipedia articles written in simple English[4]. *NYT* consists of 8,764 New York Times articles collected from April to July, 2016[5].

Table 3: Pearson's r correlation with human judgments for the topic quality estimator.

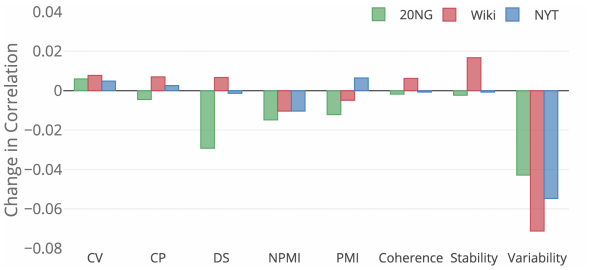

Figure 2: The ablation analysis.

We removed stop words, low-frequency words (appearing less than 3 times), proper nouns and digits from all the datasets, following Chang et al. (2009), so the topic modeling can reveal more general concepts across the corpus.

Following the common setting shared by most of the papers we compared with, for each dataset we built an LDA model which consists of 100 topics represented by the 10 most probable words. The gold-standard annotation for the quality of each topic is the mean of 4-scale human rating scores from five annotators, which were collected through a crowdsourcing platform, Figure Eight[6]. In order to obtain more robust estimates given the variability in human judgments, we removed ratings from annotators who failed in the test trail and recollected those with additional reliable annotators. To verify the validity of the collected annotations, we computed the Weighted Krippendorff's α (Krippendorff, 2007) as the measure of Inter-Annotator Agreement (IAA) for three datasets. The average human rating score/IAA for *20NG*, *Wiki* and *NYT* are 2.91/0.71, 3.23/0.82 and 3.06/0.69, respectively.

5.2 Experimental Design

Topic Modeling Following the settings in Xing and Paul (2018), we ran the LDA Gibbs samplers for 2,000 iterations (Griffiths and Steyvers, 2004) for each datasets, with 1,000 burn-in iterations, collecting samples every 10 iterations for the final 1,000 iterations. The set of estimates $\mathbf{\Theta}$ thus contains 100 samples.

Estimator Training was performed following the cross-domain training strategy (Bhatia et al., 2018). With the ground truth (human judgments), we train the estimator on all topics over one dataset, and test it on another (**one-to-one**). To enlarge the training set, we also train the estimator on two datasets merged together and test it on the third one (**two-to-one**). Given the limited amount of data and the need for interpretability, we experimented only with non-neural classifiers, including linear regression, nearest neighbors regression, Bayesian regression, and Support Vector Regression (SVR) using `sklearn` (Pedregosa et al., 2011); we report the results with SVR, which gave the best performance. We also experimented with different kernels of SVR and rbf kernel worked best.

Baselines include seven commonly adopted measures for topic quality assessment: **CV**, **CP** (Roder et al., 2015), **DS** (Aletras and Stevenson, 2013), **PMI** (Newman et al., 2010), **NPMI** (Mimno et al., 2011), **Coherence** (Newman et al., 2010) and **Stability** (Xing and Paul, 2018). All of them are introduced in Section 2.

5.3 Results

Following (Roder et al., 2015), we use Pearson's r to evaluate the correlation between the human judgments and the topic quality scores predicted by all the automatic metrics. The higher is the Pearson's r, the better the metric is at measuring topic quality. Table 2 shows the Pearson's r correlation with human judgments for all the metrics. Our proposed variability-based metric substantially outperforms all the baselines.

Table 3 shows the Pearson's r correlation with our proposed topic quality estimator trained and tested on different datasets. The average correlations of the estimator dominates our proposed variability-based metric on two out of three datasets, and on one of them by a wide margin.

Additionally, to better investigate how well the metrics align with human judgments, in Figure 3 we use scatter plots to visualize their correlations and make the following observations. The top performer co-occurrence based metric, *NPMI*, tends to underestimate topic quality by giving low ratings to relatively high-quality topics (dots with

[6] https://www.figure-eight.com/

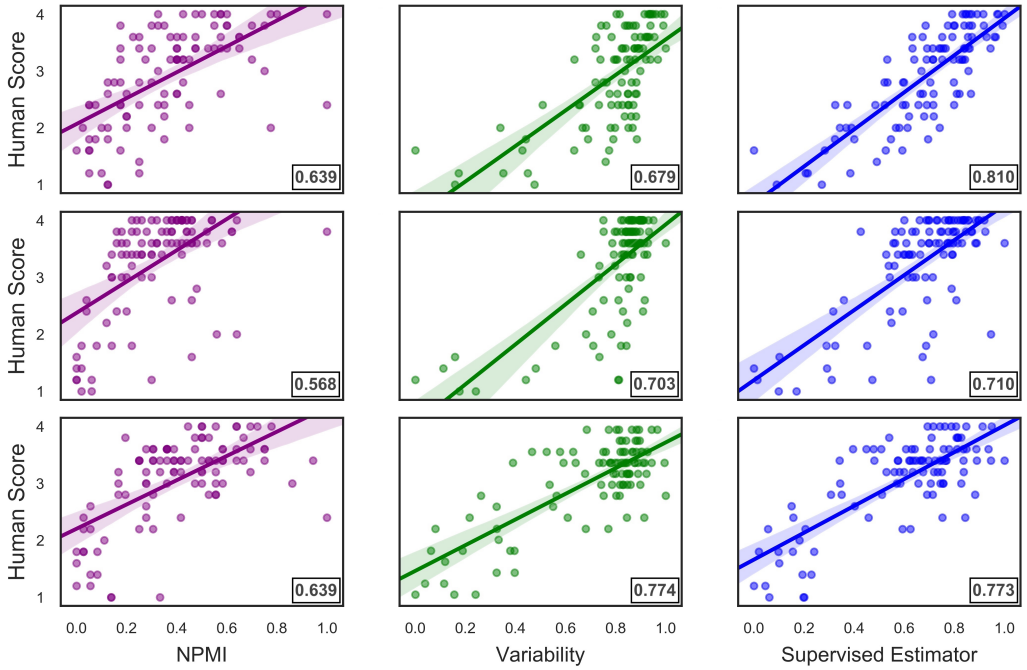

Figure 3: Scatter plots illustrating the correlation between human rating scores and the three metrics: *NPMI*, *Variability* and *Supervised Estimator* on three datasets: *20NG* (top row), *Wiki* (middle row) and *NYT* (bottom row). The numerical Pearson's r correlations are shown in the bottom-right corner.

high human scores tend to be above the purple line), but it performs relatively well for low-quality topics. On the contrary, the top performer posterior based metric, *variability*, is more likely to overestimate topic quality by assigning high ratings to relatively bad topics (dots with low human scores tend to be below the green line), but it performs relatively well for high-quality topics. Thus, when we combine all the metrics in a supervised way, the topic quality estimation becomes more accurate, especially on 20NG corpus (i.e. the top row).

Ablation Analysis: Since some features in the topic quality estimator are closely related, their overlap/redundancy may even hurt the model's performance. To better understand the contributions of each feature in our proposed estimator, we conduct ablation analysis whose results are illustrated in Figure 2. We track the change of performance by removing one feature each time. The more significant drop in performance indicates that the removed feature more strongly contributes to the estimator's accuracy. By training on two datasets and testing on the third dataset, we find that only *Variability* and *NPMI* consistently contributes to accurate predictions on all three datasets. This indicates that our new *Variability* metric and *NPMI* are the strongest ones from the two families of Posterior-based and Co-occurrence-based metrics, respectively.

6 Conclusion and Future Work

We propose a novel approach to estimate topic quality grounded on the variability of the variance of LDA posterior estimates. We observe that our new metric, driven by Gibbs sampling, is more accurate than previous methods when tested against human topic quality judgment. Additionally, we propose a supervised topic quality estimator that by combining multiple metrics delivers even better results. For future work, we intend to work with larger datasets to investigate neural solutions to combine features from different metrics, as well as to apply our findings to other variants of LDA models trained on low-resource languages, where high-quality external corpora are usually not available (Hao et al., 2018).

Abstract

In recent years, advances in neural variational inference have achieved many successes in text processing. Examples include neural topic models which are typically built upon variational autoencoder (VAE) with an objective of minimising the error of reconstructing original documents based on the learned latent topic vectors. However, minimising reconstruction errors does not necessarily lead to high quality topics. In this paper, we borrow the idea of reinforcement learning and incorporate topic coherence measures as reward signals to guide the learning of a VAE-based topic model. Furthermore, our proposed model is able to automatically separating background words dynamically from topic words, thus eliminating the pre-processing step of filtering infrequent and/or top frequent words, typically required for learning traditional topic models. Experimental results on the 20 Newsgroups and the NIPS datasets show superior performance both on perplexity and topic coherence measure compared to state-of-the-art neural topic models.

1 Introduction

Probabilistic topic models have been used widely in nature language processing (Li et al., 2016; Zeng et al., 2018). The fundamental principle is that words are assumed to be generated from latent topics which can be inferred from data based on word co-occurrence patterns (Neal, 1993; Andrieu et al., 2003). In recent years, Variational Autoencoder (VAE) has been proved more effective and efficient to approximating deep, complex and underestimated variance in integrals (Kingma and Welling, 2013; He et al., 2017). However, the VAE-based topic models focus on the construction of deep neural networks to approximate the intractable distribution between observed words and latent topics based on log-likelihood and the learning objective is to minimise the error of reconstructing the original documents based on the learned latent topic vectors rather than improving the quality of learned topics, for example, measured by coherence scores (Kingma and Welling, 2013; Sønderby et al., 2016; Miao et al., 2016; Card et al., 2017; Srivastava and Sutton, 2017; Bouchacourt et al., 2018). The lack of consideration of topic coherence measures during the learning process of VAE-based topic models makes it difficult to control the quality of the generated topics. Intuitively, one solution is to jointly consider coherence scores in the learning objective. However, this is not feasible since coherence score is an unsupervised measure of topics based on a large-scale knowledge source, there is no ground truth "best topics".

Another limitation of existing approaches is that they typically require a pre-processing step to filter infrequent and/or top frequent words in order to reduce the vocabulary size and achieve better topic extraction results. Word filtering is often done heuristically. Although there have been attempts to automatically distinguishing background words and topic words, existing approaches either require a switch variable defined at each word position to indicate whether the word is a background word, which makes the models cumbersome, or model each latent topic as the deviation in log-frequency from a constant background distribution (Eisenstein et al., 2011; Smith et al., 2018).

In this paper, we propose a new framework to use reinforcement learning (Pan et al., 2018; Qin et al., 2018; Yin et al., 2018) to incorporate the topic coherence measures into the learning of a neural topic model and filter background words dynamically. More concretely, given an input document, its constituent words will first be sampled

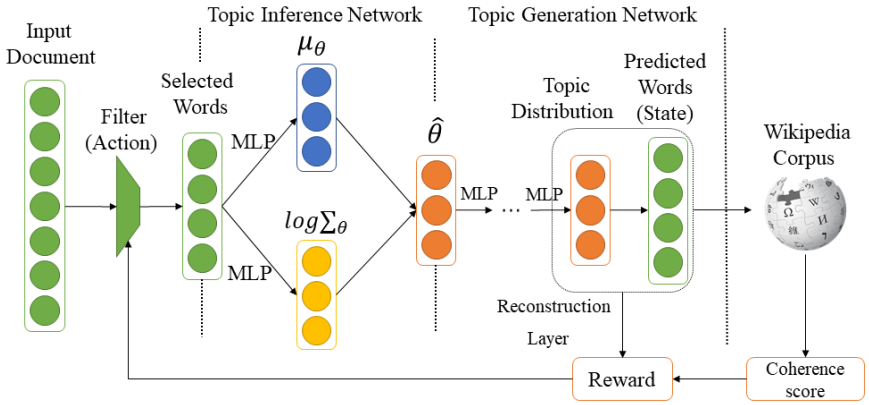

Figure 1: Neural topic model with reinforcement learning.

by a weight vector which assigns higher weights to words with higher coherence scores and have more concentrated topic distributions. The sampled words will then be fed into a VAE-based neural topic model to reconstruct the original document. A reward function is deployed to take into account both topic coherence scores and the degree of word overlapping between topics. The reward signal derived is subsequently used to update the sampling weight vector for each word. In this way, we do not need to directly add the coherence scores into the loss function. Our experimental results show that our proposed framework outperforms the traditional topic model and existing neural topic modelling approaches on the 20 Newsgroups (Lang, 1995) and the NIPS data (Tan et al., 2017) in topic coherence and perplexity.

The rest of the paper is organized as follows. Section 2 presents our proposed reinforcement learning framework for topic modelling. Section 3 reports the experimental setup and results. Section 4 concludes the paper and outlines future research directions.

2 Proposed Method

In this section, we introduce our proposed reinforcement learning (RL) framework for topic modelling. A standard RL framework contains three components: action, state, and reward. Here, the action aims to select words with high coherence scores and filter background words. The state is the distribution of latent topics among words, which is obtained from a VAE-based topic model. The reward is a function to measure the quality of topics based on an external corpus and guide the weight updating of the next word selecting action. The overall architecture is illustrated in Figure 1. We detail our framework in the following.

2.1 Action

For an input document $d = \{w_1, w_2, ..., w_U\}$, where each word w_i is represented by a one-hot representation, the action is determined by a probabilistic vector $P = \{p_1, p_2, ..., p_U\}$ which is used to filter the less topical-coherent and background words at each iteration of model learning. Here, each p_i present the sampling probability for word w_i, and U is the full vocabulary size. We aim to select V words from the full vocabulary based on P and mask out other words in d, thus $\tilde{d} = \{w'_1, w'_2, ..., w'_V\}$ where $V \leq U$. The goal of our method is to assign higher probabilities to words which contribute more to the topic coherence scores and lower probabilities to those less topical-coherent words and background words which occur equally likely across topics.

2.2 State

After word selection, the new document representation $\tilde{d}$ is fed into a neural topic model to obtain the state, which is the topic distribution in the topic model. Here, we deploy the VAE (Miao et al., 2016; Card et al., 2017) to learn the latent topics, which consists of two main components, the *Inference Network* and the *Generation Network*. For the *Inference Network*, we use VAE to approximate the posterior distribution over topics for all the training instances. In the *Generation Network*, the words are generated via Gaussian softmax construction from the topic distribution generated by the *Inference Network*. The architecture of the neural topic model is shown in Figure (1) and we describe the model in more details below.

Inference Network. Following the idea of VAE

which computes a variational approximation to an intractable posterior using MLPs, we define two MLPs, f_{μ_θ} and f_{Σ_θ}, which takes as input the word counts in a document and outputs mean and variance of a Gaussian distribution, both being vectors in R^K, $\mu_\theta = f_{\mu_\theta}(w_d)$, $\Sigma_\theta = \text{diag}(f_{\Sigma_\theta}(w_d))$. Here, 'diag' converts a column vector to a diagonal matrix. For a document d, its variational distribution is $q(\theta) \simeq \mathcal{N}(\mu_\theta, \Sigma_\theta)$. With such a formulation, we can generate samples from $q(\theta)$ by first sampling $\epsilon \sim \mathcal{N}(0, I^2)$ and then computing $\hat{\theta} = \sigma(\mu_\theta + {\Sigma_\theta}^{1/2}\epsilon)$.

Generation Network. We feed the sampled $\hat{\theta}$ to two MLPs to generate z_d. Here, z_d is a K-dimensional latent topic representation of document d. The probability of d-th word in n-th document $w_{d,n}$ can be parameterised by another network,

$$p(w_{d,n}|w_d, z_d) \propto \exp(m_d + W \cdot z_d) \quad (1)$$

where m_d is the V-dimensional background log-frequency word distribution, $W \in R^{V \times K}$ is a weight matrix. With the sampled $\hat{\theta}$, for each document $d \in N_d$, we can estimate the Evidence Lower Bound (ELBO) with a Monte Carlo approximation using L independent samples:

$$\begin{aligned}\mathcal{L}_t(w_d) \approx & \frac{1}{L}\sum_{l=1}^{L}\sum_{n=1}^{N_d}\log p(w_{d,n}|\hat{\theta}^{(l)}) \\ & - KL(q(z_d|w_d)||p(z_d))\end{aligned} \quad (2)$$

By minimising the ELBO in Eq. (2), the neural topic model reconstructs the input document w_d. At the reconstruction layer, the matrix $W \in R^{V \times K}$ in a single-layer network, which is used to capture the sampling weights between each word and the latent topics, is the state which produces specific topic coherence scores.

2.3 Reward

Intuitively, words with higher topic coherence and lower degree of overlapping among different topics should be assigned higher reward in the next iteration of learning. Hence, the reward function should be composed by two terms for each word: the average coherence score and topic overlapping value. The average coherence score is defined as:

$$CO_{average} = (W \cdot C_v(W)) \odot P_{w'_i \in w_d} \quad (3)$$

where matrix W is the distribution of latent topics among words, $C_v(W)$ is a K-dimension vector which contains the coherence score for each topic based on the sampling weight matrix, $P_{w'_i \in w_d}$ is the sampling probability for each word in document d (i.e., which action to take as described in Section 2.1), and $\odot$ is the element-wise product. Hence, $CO_{average}$ is a V-dimension weight vector to distribute coherence scores to the selected words based on sampling probabilities in action and topic distribution in topic modelling.

The Topic Overlapping (TO) is defined as:

$$TO = \text{sum}_{\text{row}}(\text{abs}(I - W \cdot W^T)) \quad (4)$$

where I is a $V \times V$ identity matrix. $TO \in R^{|v|}$ is to measure the separation based on mean distribution. In TO, the high value indicates that the associated word appears frequently across topics and hence could be considered as background words.

Based on the average coherence score and the topic overlapping value, the reward function is:

$$R_t = CO_{average} - \alpha \cdot TO \quad (5)$$

$$Q_t = \beta \cdot Q_{t-1} + (1 - \beta) \cdot R_{t-1} \quad (6)$$

where α and $\beta \in (0, 1)$ are trade-off coefficient. Then, the reward at the current time step, R_t, and the history rewards encoded by Q_t will be used to update the sampling weight in the action:

$$P_t = \max(P_{t-1} + \lambda_P \cdot (R_t - Q_t), 0 + \epsilon) \quad (7)$$

where P_t is the sampling vector in action, $\epsilon > 0$ is a minimal value, and λ_P is the learning rate for P. We choose a ramp function with ϵ to ensure the sampling probability is positive.

2.4 Training

For pre-processing, we performed stop word removal* and use Adam to optimise the parameters in the neural networks. The learning rate for VAE and θ_p are both 0.0001, the mini-batch size is 32, α is 0.1, β is 0.5, ϵ is 0.01, and the coherence scores are obtained from Wikipedia. The parameters in VAE are updated in each mini-batch, and the probabilistic vector P for action selection is updated every 2,000 mini-batches.

3 Experiments

We evaluate our model on the 20 Newsgroups† consisting of 18K documents, and NIPS (Tan

Table 1: Perplexity and topic coherence results of difference models. '*frequency-based vocab.*' denotes that the vocabulary is constructed by filtering out rare words while '*RL-based vocab.*' denotes that the vocabulary is dynamically generated by our model using RL.

et al., 2017) consisting of 6.6k documents. We use 10% training data as the validation set to fine-tune the parameters. We compare our results with those obtained from the following baselines:

LDA: Latent Dirichlet Allocation Model (Blei et al., 2003).

NVDM: Neural Variational Document model (Miao et al., 2016).

NGTM: Neural Generative Topic model (Card et al., 2017).

Scholar: Topic model with metadata (Card et al., 2018).

VTMRL: Our proposed Variational Topic Model with Reinforcement Learning.

For all the baseline models, we follow the common pre-processing step in existing approaches by performing stop word removal, and selecting the most frequent 2,000 words as the vocabulary. Since our proposed framework dynamically select words at each iteration of learning, we do not need to pre-set the vocabulary prior to model learning. Instead, we only activate 2,000 words at each mini-batch of training based on the word sampling probabilities. As our model dynamically select words during the training process, in order to ensure fair comparison with other models, we also report the results of training baselines using the vocabulary dynamically generated by our model.

In our experiments, the models are evaluated based on the perplexity (PPL, lower is better) and topic coherence measure (C_v) based on external corpus (Röder et al., 2015) (higher is better). The results with 30 and 50 topics are shown in Table 1.

LDA is a conventional topic model, while all the other models are neural topic models. It can be observed from Table 1 that NVDM and NGTM achieve better perplexities compared to LDA. However, in terms of topic coherence measure, NVDM and NGTM perform slightly worse than LDA. A similar observation has been reported in (Card et al., 2017). Scholar achieves better coherence compared to other neural models. Nevertheless, after using reinforcement learning based on the topic coherence scores in our proposed model, VTMRL outperforms all the other models on the topic coherence measure by a large margin. RL could activate words which are semantically related to topics regardless of their occurrence frequency. The inclusion of some rare words would impact the models' predictive probabilities. As such, we observe worse perplexity results for models trained with RL-based vocabulary compared to frequency-based vocabulary in 20 Newsgroups, though the converse is true for NIPS. Nevertheless, the coherence scores improve for all the models with RL-based vocabulary.

As incorporating RL could increase the computational complexity of VTMRL, we report in Table 2 the total number of parameters and average training time per epoch when the vocabulary size is 2,000 and the number of topics is 50.

Strictly speaking, the number of parameters in LDA is not directly comparable with neural models. Neural models have similar parameter size. With the incorporation of RL, VTMRL only increased the parameter size by 1.4%. Due to the efficiency of GPU, the running costs of neural models are better than that of LDA. Although our proposed VTMRL used full vocabulary, the active words in each epoch are limited. Hence, there is no significant increase in terms of the running cost.

Model	#parameters	Training time(s)
LDA	1.00×10^5	660.89
NVDM	1.38×10^6	62.16
NGTM	1.39×10^6	72.12
Scholar	1.15×10^6	3.41
VTMRL	1.41×10^6	5.78

Model	Acc	Model	Acc
LDA	0.412	tf-idf + LDA	0.822
NGTM	0.375	tf-idf + NGTM	0.825
NVDM	0.303	tf-idf + NVDM	0.824
VTMRL	0.478	tf-idf + VTMRL	**0.830**
CNN	0.515	RNN	0.509

Table 4: Text classification accuracy of different models on the 20 Newsgroups data.

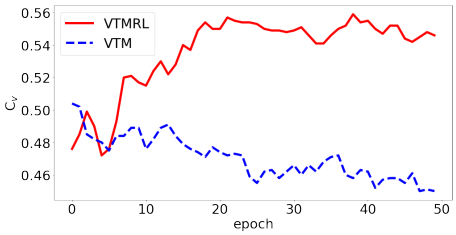

Figure 2: Topic coherence changes with/without RL (#Topics = 50).

We show in Table 3 example topics with/without RL by VTMRL in 20 Newsgroups. The RL method seems producing more interpretable topics. Also, due to the reward-based words sampling in RL, words with low occurrence frequency would still have a chance to be promoted in specific topics, such as 'x11r5', which is a serial number of the Windows system.

We next compare the topic coherence changes during model training. We observe that for VTMRL the coherence value increases at the beginning of the training and remains relatively stable in subsequent training iterations. As a contrast, the coherence value of our model without RL is not stable, and decreases rapidly after 10 training epochs. This is not surprising since the model without RL did not consider topic coherence in its learning process.

We also evaluate the effectiveness of using the learned topics as features to train text classifiers on the 20 Newsgroups data. The results are obtained by using logistic regression as the classifier trained from the topics generated by various aforementioned models. We also report the results by training logistic regression from the combination of word features (tf-idf) and topic features (#topic = 30). In addition, we include the results using neural models such as CNN and RNN in Table 4.

Using only topics extracted from topic models as features to train logistic regression, our proposed model VTMRL beats other baselines. However, the topic features have only 30 dimensions so the performance is limited in comparison with CNN and RNN. When we combine the topic features with tf-idf based word features, the performance is boosted significantly compared to CNN and RNN and the best result is obtained by using the logistic regression model trained from the combined word features with topics generated by our proposed VTMRL.

4 Conclusion

In this paper, we have proposed a new reinforcement learning (RL) framework for neural topic modelling, where words are activated dynamically by RL according to topic coherence scores and topic overlapping values. The experiments on the 20 Newsgroups and NIPS datasets show encouraging results both on perplexity and topic coherence measures in comparison with existing neural topic models. In future work, we will explore extending our model for temporal topic modelling.

Modelling Stopping Criteria for Search Results using Poisson Processes

Alison Sneyd and **Mark Stevenson**

University of Sheffield
a.sneyd,mark.stevenson@sheffield.ac.uk

Abstract

Text retrieval systems often return large sets of documents, particularly when applied to large collections. Stopping criteria can reduce the number of these documents that need to be manually evaluated for relevance by predicting when a suitable level of recall has been achieved. In this work, a novel method for determining a stopping criterion is proposed that models the rate at which relevant documents occur using a Poisson process. This method allows a user to specify both a minimum desired level of recall to achieve and a desired probability of having achieved it. We evaluate our method on a public dataset and compare it with previous techniques for determining stopping criteria.

1 Introduction

Document retrieval systems are widely used in information retrieval (IR) to return a set of documents in response to a user query. They often return large numbers of documents, particularly for large collections, which places a significant burden on a user who has to manually review them to determine which are relevant (i.e. of interest). The problem is particularly acute in scenarios where relevant documents are rare in the set of retrieved documents, or where there is a high cost associated with missing a relevant document.

Systematic reviews of medical literature are a good example of such a task. They aim to identify and summarise all available evidence for a specific research question such as 'Is systemic inflammation present in stable chronic obstructive pulmonary disease?'(Gan et al., 2004). Evidence included in systematic reviews is typically identified by executing a Boolean query optimised for high recall, with the results manually reviewed by domain experts. However, this process is extremely expensive and a single review may cost up to a quarter of a million dollars and take over a year to complete (McGowan and Sampson, 2005; Karimi et al., 2010). A range of studies have demonstrated that ranking the results of the Boolean query can support the identification of relevant studies by placing them higher in the ranking, e.g. (Miwa et al., 2014; Wallace et al., 2010; O'Mara-Eves et al., 2015; Shemilt et al., 2016). However, ranking alone does not reduce the manual review workload since it does not inform reviewers about when they can stop looking at search results.

Search stopping criteria are methods for determining when manual examination of search results can stop. They essentially provide information about the risk of missing relevant documents that is associated with not examining some portion of the documents returned by a query. Stopping criteria have been proposed for technology assisted reviews (Cormack and Grossman, 2016) and IR test collection development (Losada et al., 2019).

Cormack and Grossman (2016) introduced the target and knee stopping methods. The former involves examining randomly chosen documents until a specified number of relevant documents have been found. The number of relevant documents required is determined using statistical inference and guarantees a minimum recall score with a specified probability. The knee method employs a knee detection algorithm (Satopaa et al., 2011) to estimate when the gain curve of recall versus effort has exceeded a certain tipping point, called the slope ratio. Cormack and Grossman (2016) found that this method was better able to predict the most efficient stopping point than the target method, but did not provide any probabilistic guarantees about the level of recall that would be achieved. Additionally, Losada et al. (2019) proposed simple baselines and used power curves to determine stopping criteria. A significant limi-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3484–3489,

tation of previous approaches is that they are evaluated using a single ranking algorithm, but for a stopping approach to be generally useful it must be reliable for a range of ranking algorithms.

This paper proposes a novel method for generating search stopping criteria based on an inhomogeneous Poisson process. The method assumes the rate at which relevant documents occur in the ranking decreases exponentially and predicts how many relevant documents need to be found in order to achieve a defined level of recall. This approach, along with the knee and target methods, is evaluated using data from a shared task for which over 30 submissions are available. This allows approaches to be evaluated against a wide range of rankings of varying effectiveness. We found that, while each method returns a reliably high level of recall, the proposed method produces the most accurate predictions while also being robust to ranking quality.[1]

2 Method

Our proposed method models the rate at which relevant documents occur in a ranked set of retrieved documents, using an exponential function learned from a sample of the data. It is then possible to predict the total number of relevant documents to a desired probability using a Poisson process, and from this, to predict the rank at which a desired level of recall is achieved.

2.1 Poisson Process

Poisson processes model the occurrence of random events that take place at a given rate (Kingman, 1993). It is assumed that the events are independent and that the number of occurrences in an interval follows a Poisson distribution. An inhomogeneous (or non-homogeneous) Poisson process has a variable rate function, λ, where the rate at which events occur is a function of the space over which the process is defined. Let:

$$\Lambda(a,b) = \int_a^b \lambda(x)dx, \tag{1}$$

and let $N(a,b)$ denote the number of events occurring in the interval $(a,b]$. Then:

$$P\left(N(a,b)=r\right) = \frac{[\Lambda(a,b)]^r}{r!}e^{-\Lambda(a,b)}. \tag{2}$$

[1]Code available at: https://github.com/alisonsneyd/poisson_stopping_method

In particular, N is a Poisson random variable with expected value $\Lambda(a,b)$.

We model the occurrence of relevant documents in a set of ranked, retrieved documents as an inhomogeneous Poisson process, where λ is an exponential function (i.e. $\lambda(x) = de^{kx}$). So, from Equation 1:

$$\begin{aligned}\Lambda(a,b) &= \int_a^b de^{kx}dx \\ &= \frac{d}{k}\left(e^{kb} - e^{ka}\right).\end{aligned}$$

We are interested in knowing the total number of relevant documents and so restrict our attention to the interval $(0,n]$, where n is the number of documents in the set, yielding:

$$\Lambda(0,n) = \frac{d}{k}(e^{kn} - 1). \tag{3}$$

By Equations 2 and 3, the probability of there being r relevant documents in the document set is:

$$P\left(N(0,n)=r\right) = \frac{\left[\frac{d}{k}(e^{kn}-1)\right]^r}{r!}e^{-\left(\frac{d}{k}(e^{kn}-1)\right)}.$$

Since $N(0,n)$ is a Poisson random variable, the upper limit of the number of relevant documents in the collection (R), subject to a given probability, can be estimated using the cumulative distribution function of $N(0,n)$. The number of relevant documents required to achieve a desired level of recall (T) is then RT. The proposed stopping criteria is to cease relevance judgments when $\lceil RT \rceil$ relevant documents have been found. This method is flexible and can be adapted to whatever level of recall a user desires, and to the level of certainty they want associated with it.

2.2 Rate Estimation

The approach proceeds by examining the first α documents in the ranking, and then predicting the total number of relevant documents in the entire ranking. If the number of relevant documents observed in the first α documents ($rel(\alpha)$) is greater than or equal to the number of relevant documents needed to achieve the desired level of recall (i.e. $rel(\alpha) \geq \lceil RT \rceil$), the process stops and no more documents are examined. Otherwise, the next β documents are added to the pool of examined documents and the process repeated.

Accurate estimation of the rate at which relevant documents occur in the ranking is an impor-

tant component of the proposed approach. The parameters of the rate function are estimated as follows: Split the documents which have been examined so far into m sub-intervals and define a set of points (x_i, y_i), $i = 1, \ldots, m$, where x_i is the midpoint of the i^{th} interval and y_i is the number of relevant documents it contains. Fit a curve of the form de^{kx}, $d, k \in \mathbb{R}$, to the points.

This approach assumes that relevant documents occur frequently enough for their rate to be predicted and that this rate decreases approximately exponentially, thereby implying the shape of the gain curve (number of relevant documents versus rank) will be roughly convex. While these assumptions frequently hold, they are not guaranteed to do so and they are therefore tested in multiple ways.

Firstly, if fewer than a given threshold, γ, of relevant documents are found in the initial sample of α documents, it is assumed that either relevant documents are too rare for accurate estimates or that the ranking places them later, meaning their rate is not exponential. No stopping point is predicted and all documents in the ranking are examined (while this is costly in terms of document judgment, it preserves recall and is the default approach in systematic reviews).

Secondly, the Poisson process is dependent on $\lambda(x)$ reliably estimating the rate at which relevant documents occur. Therefore when a curve is fitted, its accuracy is tested as follows: Suppose the sample ends at rank n. The number of relevant documents estimated by $\lambda(x)$ at rank n, given by $\sum_{i=1}^{n} \lambda(i)$, is compared to the actual number of relevant documents in the sample ($rel(n)$). If the number of relevant documents found is less than a scalar multiple (δ) of the predicted number (i.e. if $rel(n) < \delta \times \sum_{i=1}^{n} \lambda(i)$) then the curve is assumed to be a bad predictor. No stopping point is predicted and the next β documents in the ranking are examined.

3 Experiments

3.1 Data

The dataset used for the experiments originated from the CLEF 2017 e-Health Lab Task 2 "Technology Assisted Reviews in Empirical Medicine" (Kanoulas et al., 2017). The task required participants to identify relevant studies for a set of 30 Diagnostic Test Accuracy systematic reviews (known as "topics") from the Cochrane Library.[2] Participants were provided with the (unordered) set of documents retrieved by a complex Boolean query and asked to rank them based on relevance to the review topic.

The number of documents retrieved by the Boolean queries for the 30 topics ranged from 64 to 12,807, with median 2,070, while the total number of documents across all topics was 117,562. The number of relevant documents ranged from 2 to 460, with median 38. On average, only 1.58% of documents were relevant across the 30 topics.[3]

A total of 33 runs ranking the entire set of articles were submitted by 11 groups of participants.[4] The rankings produced by these runs were based on a wide range of techniques, including manual judgments of document relevance, and automated techniques based on (semi-)supervised classifiers and relevance feedback. These runs contain a diverse set of rankings of varying effectiveness, making them very suitable for testing the robustness of search stopping criteria.

3.2 Evaluation Metrics

The goal is to reduce the amount of manual judgment required, subject to maintaining a minimum level of recall. Following Cormack and Grossman (2016), the following metrics were used: For a stopping criteria S and topic T, the *effort* of S in T is defined as $|E_T|$, where E_T is the set of documents that were examined before stopping. For a desired level of recall R, the *acceptability* of S with respect to T is defined as:

$$acceptability(S_T) = \begin{cases} 1, & \text{if } recall(S_T) \geq R, \\ 0, & \text{else.} \end{cases}$$

As sets of runs of topics are being evaluated, additional metrics are used. For a stopping criteria S considered over a set of topics in a run $\mathcal{R}$, the *reliability* of S with respect to $\mathcal{R}$ is:

$$\frac{|\{T \in \mathcal{R} : acceptability(S_T) = 1\}|}{|\mathcal{R}|}.$$

S is considered *reliable* over a set of runs if its mean reliability over the runs is not less than a desired threshold p, which is equivalent to the proportion of all topics in all runs that are acceptable

[2] https://www.cochranelibrary.com/

[3] The CLEF data includes relevance judgments at two levels: abstract and content. The abstract level information is used for the experiments described in this paper.

[4] Available at https://github.com/CLEF-TAR

being greater than or equal to p. The *effort* of S with respect to $\mathcal{R}$ is $\sum_{T \in \mathcal{R}} |E_T|$. The *percentage of effort saved* by S over R will denote the percentage of all documents in the set that do not have to be examined:

$$100 \times \sum_{T \in \mathcal{R}} \frac{|T| - |E_T|}{|T|}.$$

3.3 Approaches

The Poisson process approach (Section 2) and knee and target methods (Section 1) were implemented. For all methods, the minimum level of recall was set to 0.7 and the reliability threshold to 0.95, following Cormack and Grossman (2016).

For the Poisson process (**PP**), the initial sample size (α) and increases in batches (β) were set to $0.3|T|$ and $0.05|T|$ respectively. The value of α was chosen as it is large enough to predict the rate curve with reasonable reliability but without requiring too many documents to be examined. The γ and δ parameters were set to 20 and the 0.7 respectively.

For the target method (**TM**), we follow Cormack and Grossman (2016) in requiring that a set of 10 relevant documents be identified before the stopping point is predicted since they demonstrated that this produced a minimum recall of 0.7 with 0.95 probability.

The knee method requires a slope ratio to be set given by $\epsilon + 6 - min(relret, \epsilon)$, where $relret$ is the number of relevant documents retrieved for a given rank and ϵ is a variable that prevents the method stopping too soon. A version of the approach (**KM-default**) was implemented using $\epsilon = 150$, as recommended by Cormack and Grossman (2016). The value of ϵ was also tuned using 3-fold cross-validation with $\epsilon \in \{0, 25, 50, 100, 150, 200\}$. The smallest reliable value for ϵ was found to be 50 in each fold and consequently a second version (**KM-tuned**) was implemented using this value.

For comparison, an Oracle (**OR**) method was also implemented which stops at the point in the ranking where 70% recall has been achieved.

4 Results

Each method was found to be reliable (i.e. achieved the desired recall of 0.7 for at least 95% of topics). The top part of Table 1 shows the results over all topics in all 33 runs. The proposed approach, PP, required less effort than other methods (TM, KM-tuned and KM-default). PP allows the desired recall to be achieved without examining 42.1% of the documents, thereby allowing 4.9% more of the documents to go unexamined than the next most efficient approach (KM-tuned).

Further analysis was carried out to explore the effect of the quality of the initial ranking on the performance of the various approaches. The 33 runs were ranked based on their Area Under Recall Curve (AURC) scores in the official evaluation (Kanoulas et al., 2017). (The AURC metric computes the area under the cumulative recall curve normalized by the optimal area.) The top, middle and bottom five runs in the rankings were selected. The top five had AURC scores in the range 0.92 - 0.93, indicating effective rankings in which most of the relevant documents appear early. The bottom five runs had scores in the range 0.48 - 0.60, indicating the rankings are not much different from random orderings of the documents.

PP was the most efficient in terms of effort for the middle and bottom five runs, and the second most efficient for the top five runs. KM-tuned required the least effort for the top five runs, but the second most for the middle five runs and the third most for the bottom five runs. As might be expected, each method required the least effort for the top five runs and the most effort for the bottom five.

A graph of the OR and PP effort scores for each run is shown in Figure 1.

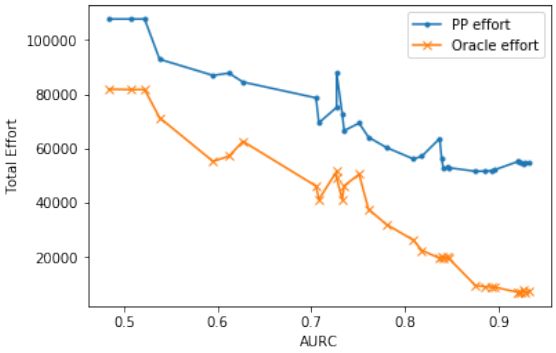

Figure 1: Oracle and Poisson process effort versus AURC score.

The difference in performance between the tuned and untuned version of the knee method (KM-tuned and KM-default) demonstrates the sensitivity of this method to appropriate setting of parameter values. These results demonstrate that

	Mean Eff.	Mean % Eff. Saved
All 33 runs		
TM	79,111	32.7%
KM-default	102,681	12.7%
KM-tuned	73,826	37.2%
PP	**68,122**	**42.1%**
OR	33,760	71.3%
Top 5 runs		
TM	56,762	51.7%
KM-default	87,886	25.2%
KM-tuned	**33,841**	**71.2%**
PP	54,792	53.4%
OR	7,202	93.9%
Middle 5 runs		
TM	76,704	34.8%
KM-default	107,703	8.4%
KM-tuned	75,888	35.4%
PP	**60,311**	**48.7%**
OR	27,565	76.6%
Bottom 5 runs		
TM	104,620	11.0%
KM-default	111,055	5.5%
KM-tuned	110,778	5.8%
PP	**100,622**	**14.4%**
OR	74,389	36.7%

Table 1: Mean effort and mean percentage of effort saved for the 33 CLEF 2017 runs. Results are shown for all runs plus the top, middle and bottom five runs. Highlighted figures are the best non-Oracle results.

the approach performs strongly for effective rankings, such as the one it was developed for (Cormack and Grossman, 2015), but is not robust to less effective ones. The PP approach is less sensitive to ranking quality (which is unlikely to be known a priori).

Two examples of the actual gain curves of a ranking and the gain curve estimated by the rate function $\lambda(x)$ learned by the PP approach are shown in Figure 2. In the top graph, the rate at which relevant documents occur decreases exponentially and the high similarity between the two curves shows λ is fit well. In the bottom graph, the rate at which relevant documents occur does not decrease exponentially. However, PP still returns the desired level of recall because the probability of the Poisson process was set to a high value (0.95).

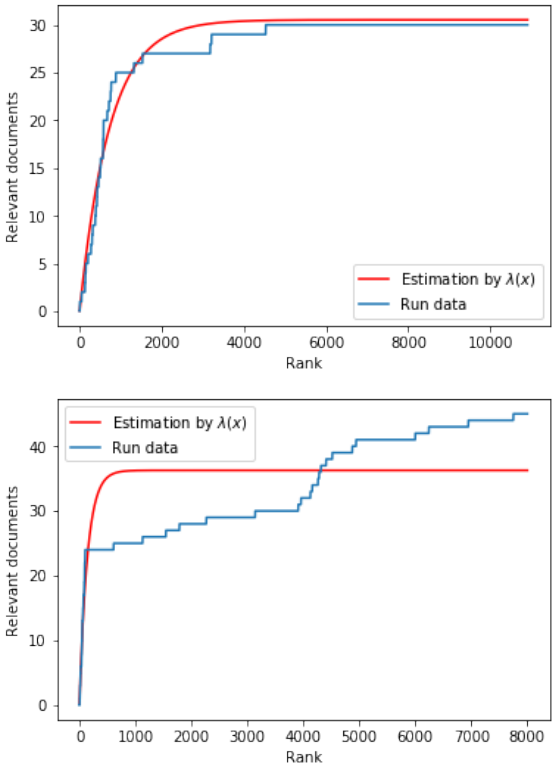

Figure 2: The gain curves of two rankings from CLEF 2017 runs, compared to the gain curve estimated by λ.

5 Conclusion

This work proposed a novel method for determining a stopping point in search results using a Poisson process. The method was applied to 33 varied CLEF 2017 runs and proved reliable in terms of recall, while also requiring substantially less effort and demonstrating less sensitivity to ranking quality than existing methods. On average, the Poisson process saved manual judgment of over 40% of the documents associated with a run. Although our method has been explored in the context of systematic reviews, it could be applied to a variety of other document retrieval problems.

Cross-Domain Modeling of Sentence-Level Evidence for Document Retrieval

Abstract

This paper applies BERT to *ad hoc* document retrieval on news articles, which requires addressing two challenges: relevance judgments in existing test collections are typically provided only at the document level, and documents often exceed the length that BERT was designed to handle. Our solution is to aggregate sentence-level evidence to rank documents. Furthermore, we are able to leverage passage-level relevance judgments *fortuitously* available in other domains to fine-tune BERT models that are able to capture cross-domain notions of relevance, and can be directly used for ranking news articles. Our simple neural ranking models achieve state-of-the-art effectiveness on three standard test collections.

1 Introduction

The dominant approach to *ad hoc* document retrieval using neural networks today is to deploy the neural model as a reranker over an initial list of candidate documents retrieved using a standard bag-of-words term-matching technique. Despite the plethora of neural models that have been proposed for document ranking (Mitra and Craswell, 2019), there has recently been some skepticism about whether they have truly advanced the state of the art (Lin, 2018), at least in the absence of large amounts of behavioral log data only available to search engine companies.

In a meta-analysis of over 100 papers that report results on the dataset from the Robust Track at TREC 2004 (Robust04), Yang et al. (2019a) found that most neural approaches do not compare against competitive baselines. To provide two recent examples, McDonald et al. (2018) report a best AP score of 0.272 and Li et al. (2018) 0.290, compared to a simple bag-of-words query expansion baseline that achieves 0.299 (Lin, 2018). Further experiments by Yang et al. (2019a) achieve 0.315 under more rigorous experimental conditions with a neural ranking model, but this is still pretty far from the best-known score of 0.3686 on this dataset (Cormack et al., 2009).

Although Sculley et al. (2018) remind us that the goal of science is not *wins*, but knowledge, the latter requires first establishing strong baselines that accurately quantify proposed contributions. Comparisons to weak baselines that inflate the merits of an approach are not new problems in information retrieval (Armstrong et al., 2009), and researchers have in fact observed similar issues in the recommender systems literature as well (Rendle et al., 2019; Dacrema et al., 2019).

Having placed evaluation on more solid footing with respect to well-tuned baselines by building on previous work, this paper examines how we might make neural approaches "work" for document retrieval. One promising recent innovation is models that exploit massive pre-training (Peters et al., 2018; Radford et al., 2018), leading to BERT (Devlin et al., 2019) as the most popular example today. Researchers have applied BERT to a broad range of NLP tasks with impressive gains: most relevant to our document ranking task, these include BERTserini (Yang et al., 2019b) for question answering and Nogueira and Cho (2019) for passage reranking.

Extending our own previous work (Yang et al., 2019c), the main contribution of this paper is a successful application of BERT to yield large improvements in *ad hoc* document retrieval. We introduce two simple yet effective innovations: First, we focus on integrating *sentence-level evidence* for document ranking to address the fact that BERT was not designed for processing long spans of text. Second, we show, quite surprisingly, that it is possible to transfer models of relevance across different domains, which nicely solves the problem of the lack of passage-level relevance anno-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3490–3496,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tations. Combining these two innovations allows us to achieve 0.3697 AP on Robust04, which is the highest reported score that we are aware of (neural or otherwise). We establish state-of-the-art effectiveness on two more recent test collections, Core17 and Core18, as well.

2 Background and Approach

To be clear, our focus is on neural ranking models for *ad hoc* document retrieval, over corpora comprising news articles. Formally, in response to a user query Q, the system's task is to produce a ranking of documents from a corpus that maximizes some ranking metric—in our case, average precision (AP). We emphasize that this problem is quite different from web search, where there is no doubt that large amounts of behavioral log data, along with other signals such as the web-graph, have led to large improvements in search quality (Mitra and Craswell, 2019). Instead, we are interested in limited data conditions—what can be achieved with modest resources outside web search engine companies such as Google and Microsoft who have large annotation teams—and hence we only consider "classic" TREC newswire test collections.

Beyond our own previous work (Yang et al., 2019c), which to our knowledge is the first reported application of BERT to document retrieval, there have been several other proposed approaches, including MacAvaney et al. (2019) and unrefereed manuscripts (Qiao et al., 2019; Padigela et al., 2019). There are two challenges to applying BERT to document retrieval: First, BERT has mostly been applied to sentence-level tasks, and was not designed to handle long spans of input, having a maximum of 512 tokens. For reference, the retrieved results from a typical bag-of-words query on Robust04 has a median length of 679 tokens, and 66% of documents are longer than 512 tokens. Second, relevance judgments in nearly all newswire test collections are annotations on documents, not on individual sentences or passages. That is, given a query, we only know what documents are relevant, not spans within those documents. Typically, a document is considered relevant as long as some part of it is relevant, and in fact most of the document may not address the user's needs. Given these two challenges, it is not immediately obvious how to apply BERT to document ranking.

2.1 Key Insights

We propose two innovations that solve the above-mentioned challenges. First, we observe the existence of test collections that *fortuitously* contain passage-level relevance evidence: the MAchine Reading COmprehension (MS MARCO) dataset (Bajaj et al., 2018), the TREC Complex Answer Retrieval (CAR) dataset (Dietz et al., 2017), and the TREC Microblog (MB) datasets (Lin et al., 2014), described below.

MS MARCO features user queries sampled from Bing's search logs and passages extracted from web documents. Each query is associated with sparse relevance judgments by human editors. TREC CAR uses queries and paragraphs extracted from English Wikipedia: each query is formed by concatenating an article title and a section heading, and passages in that section are considered relevant. This makes CAR, essentially, a synthetic dataset. TREC Microblog datasets draw from the Microblog Tracks at TREC from 2011 to 2014, with topics (i.e., queries) and relevance judgments over tweets. We use the dataset prepared by Rao et al. (2019).

Note, however, that all three datasets are out of domain with respect to our task: MS MARCO passages are extracted from web pages, CAR paragraphs are taken from Wikipedia, and MB uses tweets. These corpora clearly differ from news articles to varying degrees. Furthermore, while MS MARCO and MB capture search tasks (although queries over tweets are qualitatively different), CAR "queries" (Wikipedia headings) do not reflect search queries from real users. Nevertheless, our experiments arrive at the surprising conclusion that these datasets are useful to train neural ranking models for news articles.

Our second innovation involves the aggregation of sentence-level evidence for document ranking. That is, given an initial ranked list of documents, we segment each into sentences, and then apply inference over *each sentence* separately, after which sentence-level scores are aggregated to yield a final score for ranking documents. This approach, in fact, is well motivated: There is a long thread of work in the information retrieval literature, dating back decades, that leverages passage retrieval techniques for document ranking (Hearst and Plaunt, 1993; Callan, 1994; Kaszkiel and Zobel, 1997; Clarke et al., 2000). In addition, recent studies of human searchers (Zhang et al., 2018b,a)

revealed that the "best" sentence or paragraph in a document provides a good proxy for document-level relevance.

2.2 Model Details

The core of our model is a BERT *sentence-level* relevance classifier. Following Nogueira and Cho (2019), this is framed as a binary classification task. We form the input to BERT by concatenating the query Q and a sentence S into the sequence `[[CLS]`, Q, `[SEP]`, S, `[SEP]]` and padding each sequence in a mini-batch to the maximum length in the batch. We feed the final hidden state corresponding to the `[CLS]` token in the model to a single layer neural network whose output represents the probability that sentence S is relevant to the query Q.

To determine *document* relevance, we apply inference over each individual sentence in a candidate document, and then combine the top n scores with the original document score as follows:

$$S_f = a \cdot S_{doc} + (1 - \alpha) \cdot \sum_{i=1}^{n} w_i \cdot S_i \quad (1)$$

where S_{doc} is the original document score and S_i is the i-th top scoring sentence according to BERT. In other words, the relevance score of a document comes from the combination of a document-level term-matching score and evidence contributions from the top sentences in the document as determined by the BERT model. The parameters α and the w_i's can be tuned via cross-validation.

3 Experimental Setup

We begin with $\text{BERT}_{\text{Large}}$ (uncased, 340m parameters) from Devlin et al. (2019), and then fine-tune on the collections described in Section 2.1, individually and in combination. Despite the fact that tweets aren't always sentences and that MS MARCO and CAR passages, while short, may in fact contain more than one sentence, we treat all texts as if they were sentences for the purposes of fine-tuning BERT. For MS MARCO and CAR, we adopt exactly the procedure of Nogueira and Cho (2019). For MB, we tune on 2011–2014 data, with 75% of the total data reserved for training and the rest for validation.

We use the maximum sequence length of 512 tokens in all experiments. We train all models using cross-entropy loss for 5 epochs with a batch size of 16. We use Adam (Kingma and Ba, 2014) with an initial learning rate of 1×10^{-5}, linear learning rate warmup at a rate of 0.1 and decay of 0.1. All experiments are conducted on NVIDIA Tesla P40 GPUs with PyTorch v1.2.0.

During inference, we first retrieve an initial ranked list of documents to depth 1000 from the collection using the Anserini toolkit[1] (post-v0.5.1 commit from mid-August 2019, based on Lucene 8.0). Following Lin (2018) and Yang et al. (2019a), we use BM25 with RM3 query expansion (default parameters), which is a strong baseline, and has already been shown to beat most existing neural models. We clean the retrieved documents by stripping any HTML/XML tags and splitting each document into its constituent sentences with NLTK. If the length of a sentence with the meta-tokens exceeds BERT's maximum limit of 512, we further segment the spans into fixed size chunks. All sentences are then fed to the BERT model.

We conduct end-to-end document ranking experiments on three TREC newswire collections: the Robust Track from 2004 (Robust04) and the Common Core Tracks from 2017 and 2018 (Core17 and Core18). Robust04 comprises 250 topics, with relevance judgments on a collection of 500K documents (TREC Disks 4 and 5). Core17 and Core18 have only 50 topics each; the former uses 1.8M articles from the New York Times Annotated Corpus while the latter uses around 600K articles from the TREC Washington Post Corpus. Note that none of these collections were used to fine-tune the BERT relevance models; the only learned parameters are the weights in Eq (1).

Based on preliminary exploration, we consider up to the top three sentences; any more does not appear to yield better results. For Robust04, we follow the five-fold cross-validation settings in Lin (2018) and Yang et al. (2019a); for Core17 and Core18 we similarly apply five-fold cross validation. The parameters α and the w_i's are learned via exhaustive grid search as follows: we fix $w_1 = 1$ and then vary $a, w_2, w_3 \in [0, 1]$ with a step size 0.1, selecting the parameters that yield the highest average precision (AP). Retrieval results are reported in terms of AP, precision at rank 20 (P@20), and NDCG@20.

Code for replicating all the experiments described in this paper is available as part of our recently-developed Birch IR engine.[2] Additional

Table 1: Ranking effectiveness on Robust04, Core17, and Core18 in terms of AP, P@20, and NDCG@20.

details about the technical design of our system are presented in Yilmaz et al. (2019), a companion demonstration paper.

4 Results and Discussion

Our main results are shown in Table 1. The top row shows the BM25+RM3 query expansion baseline using default Anserini parameters.[3] The remaining blocks display the ranking effectiveness of our models on Robust04, Core17, and Core18. In parentheses we describe the fine-tuning procedure: for instance, MSMARCO $\rightarrow$ MB refers to a model that was first fine-tuned on MS MARCO and then on MB. The nS preceding the model name indicates that inference was performed using the top n scoring sentences from each document.

Table 1 also includes results of significance testing using paired t-tests, comparing each condition with the BM25+RM3 baseline. We report significance at the $p < 0.01$ level, with appropriate Bonferroni corrections for multiple hypothesis testing. Statistically significant differences with respect to the baseline are denoted by †.

We find that BERT fine-tuned on MB alone significantly outperforms the BM25+RM3 baseline for all three metrics on Robust04. On Core17 and Core18, we observe significant increases in AP as well (and other metrics in some cases). In other words, relevance models learned from tweets successfully transfer over to news articles despite large differences in domain. This surprising result highlights the relevance matching power introduced by the deep semantic information learned by BERT.

Fine-tuning on MS MARCO or CAR alone yields at most minor gains over the baselines across all collections, and in some cases actually hurts effectiveness. Furthermore, the number of sentences considered for final score aggregation does not seem to affect effectiveness. It also does not appear that the synthetic nature of CAR data helps much for relevance modeling on newswire collections. Interestingly, though, if we fine-tune on CAR and then MB (CAR $\rightarrow$ MB), we obtain better results than fine-tuning on either MS MARCO or CAR alone. In some cases, we slightly improve over fine-tuning on MB alone. One possible explanation could be that CAR has an effect similar to language model pre-training; it alone cannot directly help the downstream document retrieval task, but it provides a better representation that can benefit from MB fine-tuning.

However, we were surprised by the MS MARCO results: since the dataset captures a search task and the web passages are "closer" to our newswire collections than MB in terms of domain, we would have expected relevance transfer to be more effective. Results show, however, that fine-tuning on MS MARCO alone is far less effective than fine-tuning on MB alone.

Looking across all fine-tuning configurations, we see that the top-scoring sentence of each candi-

[3]Even though Lin (2018) and Yang et al. (2019a) report slightly higher AP scores for *tuned* BM25+RM3 on Robust04, for consistency we use default parameters because no careful tuning has been performed for Core17 and Core18.

date document alone seems to be a good indicator of document relevance, corroborating the findings of Zhang et al. (2018a). Additionally considering the second ranking sentence yields at most a minor gain, and in some cases, adding a third actually causes effectiveness to drop. This is quite a surprising finding, since it suggests that the document ranking problem, at least as traditionally formulated by information retrieval researchers, can be distilled into relevance prediction primarily at the sentence level.

In the final block of the table, we present our best model, with fine-tuning on MS MARCO and then on MB. We confirm that this approach is able to exploit *both* datasets, with a score that is higher than fine-tuning on each dataset alone. Let us provide some broader context for these scores: For Robust04, we report the highest AP score that we are aware of (0.3697). Prior to our work, the meta-analysis by Yang et al. (2019a), which analyzed over 100 papers up until early 2019,[4] put the best neural model at 0.3124 (Dehghani et al., 2018).[5] Furthermore, our results exceed the previous highest known score of 0.3686, which is a non-neural method based on ensembles (Cormack et al., 2009). This high water mark has stood unchallenged for ten years.

Recently, MacAvaney et al. (2019) reported 0.5381 NDCG@20 on Robust04 by integrating contextualized word representations into existing neural ranking models; unfortunately, they did not report AP results. Our best NDCG@20 on Robust04 (0.5325) approaches their results even though we optimize for AP. Finally, note that since we are only using Robust04 data for learning the document and sentence weights in Eq (1), and not for fine-tuning BERT itself, it is less likely that we are overfitting.

Our best model also achieves a higher AP on Core17 than the best TREC submission that does not make use of past labels or human intervention (`umass_baselnrm`, 0.275 AP) (Allan et al., 2017). Under similar conditions, we beat every TREC submission in Core18 as well (with the best run being `uwmrg`, 0.276 AP) (Allan et al., 2018). Core17 and Core18 are relatively new and thus have yet to receive much attention from researchers, but to our knowledge, these figures represent the state of the art.

[4] https://github.com/lintool/robust04-analysis

[5] Setting aside our own previous work (Yang et al., 2019c).

5 Conclusion

This paper shows how BERT can be adapted in a simple manner to yield large improvements in *ad hoc* document retrieval on "classic" TREC newswire test collections. Our results demonstrate two surprising findings: first, that relevance models can be transferred quite straightforwardly across domains by BERT, and second, that effective document retrieval requires only "paying attention" to a small number of "top sentences" in each document. Important future work includes more detailed analyses of these transfer effects, as well as a closer look at the contributions of document-level and sentence-level scores. Nevertheless, we believe that both findings pave the way for new directions in document ranking.

Abstract

When performing cross-language information retrieval (CLIR) for lower-resourced languages, a common approach is to retrieve over the output of machine translation (MT). However, there is no established guidance on how to optimize the resulting MT-IR system. In this paper, we examine the relationship between the performance of MT systems and both neural and term frequency-based IR models to identify how CLIR performance can be best predicted from MT quality. We explore performance at varying amounts of MT training data, byte pair encoding (BPE) merge operations, and across two IR collections and retrieval models. We find that the choice of IR collection can substantially affect the predictive power of MT tuning decisions and evaluation, potentially introducing dissociations between MT-only and overall CLIR performance.

1 Introduction

For cross-language information retrieval scenarios involving queries in a higher-resourced language and documents in a lower-resourced language, direct training of a cross-language IR system (Litschko et al., 2018; Sasaki et al., 2018; Vulić and Moens, 2015) is typically infeasible due to insufficient data in the document language.

A practical solution is to use machine translation to translate documents into the language of the queries, enabling the use of a traditional monolingual IR system trained on the higher-resourced language. Prior work (Pecina et al., 2014; Nikoulina et al., 2012) demonstrates the effectiveness of using an MT system for query translation within a CLIR framework, but increases in MT performance measured by BLEU (Papineni et al., 2002) do not necessarily correlate with IR performance. Taking a document translation approach, Hieber and Riezler (2015) show that by enforcing a bag of words constraint on the MT decoding process, a translated document can provide richer input to an MT-IR system. However, these prior works do not fully investigate the effectiveness of MT metrics in predicting performance of a downstream IR model.

In this paper, we explore the consequences of performing information retrieval over machine translation and address three questions regarding the performance of the resulting system. First, when making MT tuning decisions such as selecting the number of BPE merge operations, will a value that improves MT performance generally increase IR performance? Second, when evaluating MT performance, can standard metrics be adapted to better correlate with downstream IR performance? Finally, what is the general relationship between the performance of MT and a downstream IR task, and how is it affected by the choice of retrieval model?

2 Experiment Design

To address the above questions, we trained an MT system in a large number of configurations, used these models to produce translated English collections of varying quality, and then compared the performance of retrieval over translated collections to retrieval over the matching source English documents. While an MT-IR system of this type is most appropriately used on lower-resourced languages, the resources needed to perform such a study using publicly available data thus far only exist in higher-resourced languages. To simulate a lower-resourced setting, we used a small portion of the MT training data available from higher-resourced languages, ablated it into smaller subsets, and did not rely on any other language resources. By training translation models using varying amounts of training data, we are able to explore performance across a wide range of resource levels and examine

the reliability of performance patterns. The software and data required to replicate the experiments reported here are available from https://github.com/ConstantineLignos/mt-clir-emnlp-2019.

2.1 Machine Translation

We trained German-English and Czech-English translation models using the News Commentary (NC) dataset version 13 (Tiedemann, 2012) as provided in the WMT18 training data. This dataset was chosen to ensure no overlap between MT training data and the Wikipedia and Europarl IR test sets. Up to 200k sentences were selected for training, 5k for validation, and 5k for testing. The training data was ablated from 200k to 25k sentences in increments of 25k to create 8 training sets of decreasing sizes, simulating a wide range of low-resource conditions. The MT training scenarios varied by language, training data size, and BPE configuration. For each training set, a joint (source and target languages) BPE (Sennrich et al., 2016) was learned using two different numbers of merge operations (hereafter *BPE size*), 16k and 32k.

We selected fairseq (Gehring et al., 2017) as the machine translation system for our experiments. The MT system was trained using the data preprocessing approach and parameters given in the documentation[1]. Moses was used for tokenization of all data. We used the `fconv_iwslt_de_en` fully convolutional architecture with a single set of hyperparameters that provided for robust convergence on all configurations: learning rate 0.25, gradient clip threshold (parameter `clip-norm`) 0.1, dropout 0.2, and max-tokens 4000.[2] The validation set was provided during training to identify stopping conditions. The epoch that yielded the highest validation set performance was used to decode the test data. Test data was decoded with a beam size of 5. BLEU scores were computed using `sacreBLEU` (Post, 2018), with the configuration *BLEU+case.lc+numrefs.1+smooth.none+tok.13a+version.1.2.12*.

[1] https://fairseq.readthedocs.io/en/latest/getting_started.html#training-a-new-model

[2] We also experimented with a transformer-based architecture. While it did produce BLEU scores several points higher for the highest data conditions, it did not reliably converge with smaller amounts of training data, typically producing single-digit BLEU scores. While further tuning would have likely addressed this issue, we opted to report results using the fully convolutional architecture and constant hyperparameters.

2.2 Information Retrieval

We selected two multilingual collections for retrieval experiments, Europarl and Wikipedia. We created a collection of the 2,330 non-empty Europarl V7 (Koehn, 2005) transcripts that were present in English, German, and Czech.[3] As there are no queries and relevance judgments specific to Europarl, we used GOV2 TREC topics 701–850 as domain-relevant English queries and treated the top 100 documents retrieved by BM25 for each query as the relevant documents for evaluation.

Wikipedia was selected to provide a second collection for comparison, specifically one large enough to support training a neural retrieval model. To create relevant query-document pairs for training and evaluation, we used titles as queries and treated each document as the sole relevant document for its own title (Sasaki et al., 2018). For evaluation, we selected 5k articles with content in all three languages. We constrained selection such that the shortest article across the three languages had at least 500 words, and the longest article was not more than three times as long as the shortest article. While the information content for the "same" article will not be identical across languages, this constraint helps limit cross-language information differences caused by article length.

Models. As *tf.idf* is still a competitive performer compared to neural models for ad-hoc retrieval (Guo et al., 2019), we evaluated both models to provide insight into how each responds to the noise introduced by MT. We used Okapi-BM25 (Jones et al., 2000) to represent a term-based approach, and the Duet architecture introduced by Mitra et al. (2017) to represent a neural model. The Duet architecture was chosen because it transforms the document's text into the most common character n-grams within a corpus, making it robust to subword translation errors that are likely to be caused by using BPE in a low resource setting. Duet has been shown to perform comparably to more recent models both for ad-hoc and passage length retrieval (Mitra and Craswell, 2019).

The Duet model was trained on English

[3] Europarl transcripts were considered empty and excluded from the collection if for any language they were absent or appeared to have no content, such as merely noting that a session did or did not occur without containing any session content. The method for identifying trivial transcripts was that any lines consisting of only whitespace, XML, or a parenthetical were removed. If fewer than three lines remained, the transcript was considered empty and excluded.

Wikipedia using the hyperparameters and loss function suggested by Mitra et al. (2017) rather than weakly supervised BM25 scores (Dehghani et al., 2017), which would produce a smoothed *tf.idf* neural BM25 model that behaves differently than a standard neural IR model. We also experimented with a word-based representation—using GLoVE (Pennington et al., 2014) embeddings—as input to Duet instead of using the most common character n-grams. It performed worse (highest RBO .091), likely due to being more sensitive to unusual subword unit combinations generated by the MT system.

Evaluation. The goal of our IR evaluation is to compare the ranking produced by retrieval over translated documents against that produced by retrieval over the English documents. We used the extrapolated rank-biased overlap (RBO, Webber et al., 2010) as our primary metric, defined as

$$RBO_{EXT}(S,T,p,k) = \frac{X_k}{k}\cdot p_k + \frac{1-p}{p}\sum_{d=1}^{k}\frac{X_d}{d}\cdot p_d$$

where k is the current position in a rank list, S, T are the two rank lists being compared, and X_i is the size of the intersection of the two lists at depth i. This results in an RBO value of 1 being the upper bound when the rank list S is the same as T. RBO is based on a probabilistic user model, facilitates indefinite rankings, and allows for incomplete sets to be compared, unlike Kendall's tau and Spearman's rho. We used the suggested parameter $p = 0.98$, where the top 50 documents of each rank list contain 86% of the weight. We also computed mean average precision (MAP) as a standard IR metric for comparison.

The BM25 model was evaluated against both the Europarl and Wikipedia collections. However, to avoid the performance degradation caused by cross-collection evaluation (Cohen et al., 2018), we only evaluate the Wikipedia-trained neural model on the Wikipedia evaluation collection. Due to the large number of conditions we evaluate for both MT and IR performance, results are shown in figures, while full tables are provided in Appendix A.1.

3 Results

Unsurprisingly, using larger amounts of MT training data leads to higher MT and end-to-end performance; we focus on the subtleties of performance and not this generality. Figure 1 shows lowercase BLEU on the MT test set for all training conditions; BLEU scores ranged 17.5–31.5 for Czech-English and 18.5–32.0 for German-English. Figure 2 shows RBO for retrieval over the output of each MT training configuration. While the relationship between MT training size and RBO is similar across languages, collections, and models, the performance of neural retrieval over Wikipedia is far lower than that of BM25, which we discuss below.

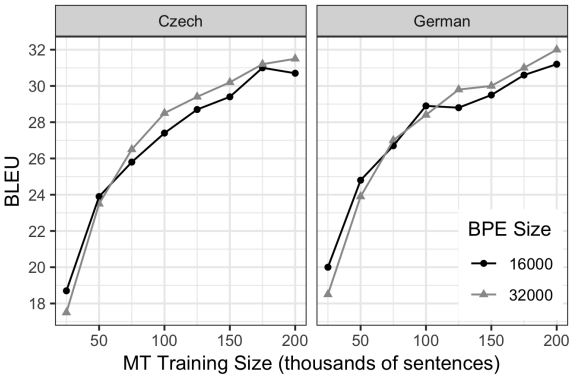

Figure 1: MT test BLEU for all training configurations.

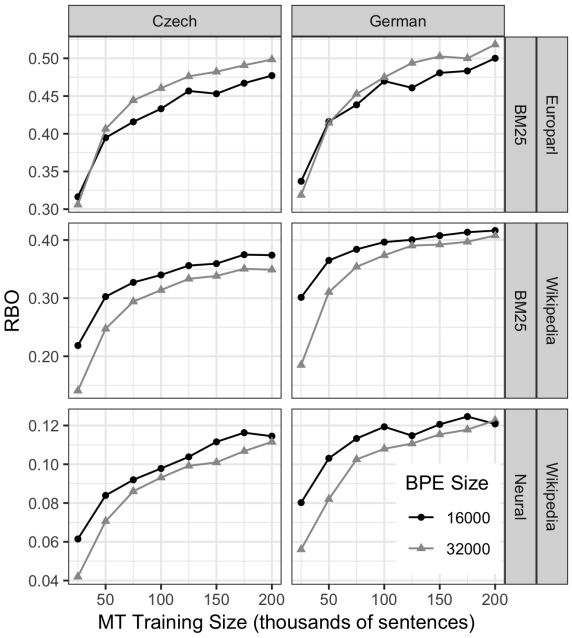

Figure 2: RBO for retrieval models on Europarl and Wikipedia across all MT training configurations.

Collection/Model	Match	Mismatch
Europarl BM25	14	2
Wiki BM25	5	11
Wiki Neural	6	10

Table 1: Counts of MT/IR performance tuning matches and mismatches when tuning BPE size.

3.1 Impact of BPE

We now address our first question: when making MT tuning decisions such as selecting the number of BPE merge operations, will a value that improves MT performance generally increase IR performance? We explore tuning BPE because it is commonly used in modern neural MT systems, and it is likely to have substantial end-to-end impact as it controls the subword input and output vocabulary. To address this question, we analyzed how often the directionality of the change in BLEU matched that of RBO when comparing across BPE size conditions. We categorized each configuration as a *match* if changing BPE size from 16k to 32k had an effect in the same direction for both MT (BLEU) and IR (RBO) performance, and categorized it as a *mismatch* otherwise. As shown in Table 1, the collection determined the probability of matches; for Europarl, BPE tuning decisions that increase BLEU reliably increase RBO, but for Wikipedia, more often than not tuning BPE to increase BLEU will *decrease* RBO.

Examining the MT and IR performance separately makes the cause of these tuning mismatches more clear. For MT, Figure 1 shows that 16k BPE performed slightly better at the lowest training data points, and 32k performed better at the highest. For IR, the effect of BPE varies across collections. On Europarl, the effect of BPE code size on IR performance is similar to that of MT. Increasing BPE size from 16k to 32k generally leads to better performance, with a mean MAP increase of .010 across all sizes. On Wikipedia, the 32k BPE size almost always performs worse, with mean MAP decreases of .056 (BM25) and .010 (neural). The difference between the MAP scores across the BPE configurations was statistically significant as determined by a Wilcoxon signed-rank test, a non-parametric paired sample test: Europarl BM25 ($p = .023$); Wikipedia BM25 ($p < .001$) and neural ($p < .001$).

We conclude that the nature of the queries, documents, and relevance characteristics of the downstream IR task plays a critical role when selecting BPE size or making other MT tuning decisions. Depending on the collection, attempts to improve MT may end up hurting end-to-end performance.

3.2 Evaluating MT for End-to-end Performance

We now turn to our second question: when evaluating MT, can standard metrics be adapted to better correlate with downstream IR performance? To explore this question, we computed correlations using Kendall's tau between RBO and the following: BLEU, BLEU's component 1–4-gram precisions, and variations of BLEU that remove punctuation, stem words using the Porter stemmer, or do both (as is common in term-based retrieval). Tau was computed separately within each combination of language, dataset, and retrieval model, measuring the correlation with RBO across changes in MT performance due to language, training data size, and BPE size.

Coll./Model	BLEU	P1	P2	P3	P4
Europarl BM25	.873	**.881**	.867	.864	.862
Wiki BM25	**.722**	.689	.708	.714	.711
Wiki Neural	**.789**	.756	.775	.781	.778

Table 2: Mean Kendall's Tau correlation with RBO for lowercased BLEU and each n-gram precision (P1=1-gram, etc.), by collection/model.

Coll./Model	BLEU	No Punc.	Stem	Both
Europarl BM25	.873	.870	**.875**	.873
Wiki BM25	.722	**.728**	.717	.722
Wiki Neural	**.789**	.787	.783	.781

Table 3: Mean Kendall's Tau correlation with RBO for lowercased BLEU and variations, by collection/model.

Table 2 shows that the downstream IR task affects which MT measures correlate best with RBO. For Europarl, the best correlation with RBO was achieved by unigram precision, with correlation decreasing as larger n-grams are evaluated. For Wikipedia, BLEU provided the best correlation with RBO, and larger n-gram precisions correlated better with RBO than unigram precision. Table 3 gives correlations for the other variations of BLEU we explored; none led to a reliable improvement over standard lowercased BLEU, but results differed across collections/models.

We conclude that none of the n-gram precision components of BLEU or variations on it provide consistently better correlations with IR performance. However, given a specific collection and model, it is likely one of the alternatives we explored here or other metrics (e.g. ROUGE) can be slightly more predictive than standard BLEU.

3.3 IR Model Sensitivity

Finally, we explore our third question: what is the general relationship between the performance of MT and a downstream IR task, and how is it affected by the choice of retrieval model? Figure 3

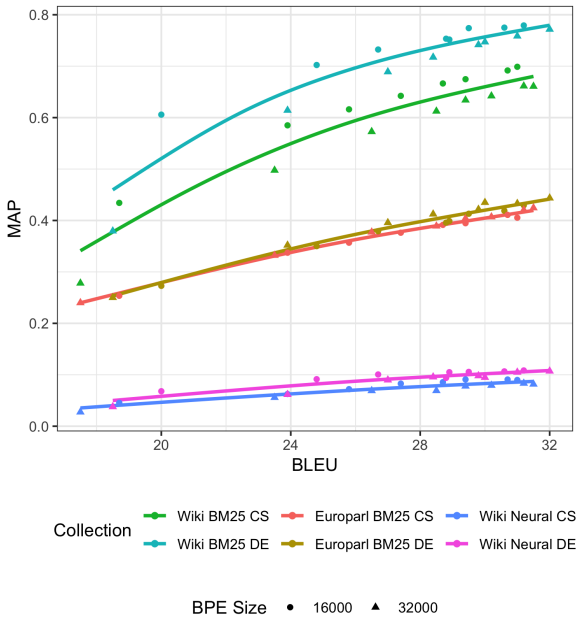

Figure 3: MAP for retrieval models across all collections and MT training configurations. GAM fit lines are provided for each combination of collection, retrieval model, and language (CS, Czech; DE, German).

shows MAP and BLEU across all tested configurations. The relationship between them is approximately linear above the lowest data points. Using linear regression to predict MAP from BLEU while accounting for variance due to language and BPE size, a one-point increase in BLEU was estimated to yield 1.33 points of MAP for Europarl BM25, 2.39 for Wikipedia BM25, and 0.42 for Wikipedia neural.

The neural Wikipedia model (highest RBO 0.12; highest MAP 0.11) significantly trailed BM25 (0.42; 0.78). Low RBO values show that the neural model degraded much more than BM25 when presented with MT as input. Given the regression described above, we can explore the BLEU score needed to match the MAP value of 0.20 that the same model attained retrieving over the English articles. Extrapolating generously, that would be achieved with a BLEU of approximately 53, a value unattainable in a low-resource scenario. As neural IR models are sensitive to shifts in the input distribution (Cohen et al., 2018), the most likely path for effective neural retrieval in a low-resource MT-IR setting is to train retrieval in a way that adapts to the idiosyncrasies of MT output, unlike the model we evaluated.

4 Conclusions

We conclude that there is no substitute for end-to-end, task-specific tuning when attempting to improve MT-IR system performance by increasing MT quality. As demonstrated by the effect of BPE tuning, changes made to the MT model can have opposite effects on performance when different IR collections are considered. The performance degradation of the evaluated neural IR model when retrieving over MT suggests that it is unlikely that off-the-shelf neural IR will be able to function adequately in an MT-IR system. Adapting neural models for use in an MT-IR setting and addressing the properties of MT output most harmful to their performance are promising avenues for future work to enable low-resource CLIR.

Rotate *King* to get *Queen*: Word Relationships as Orthogonal Transformations in Embedding Space

Kawin Ethayarajh*
Stanford University
kawin@stanford.edu

Abstract

A notable property of word embeddings is that word relationships can exist as linear substructures in the embedding space. For example, *gender* corresponds to $\vec{woman} - \vec{man}$ and $\vec{queen} - \vec{king}$. This, in turn, allows word analogies to be solved arithmetically: $\vec{king} - \vec{man} + \vec{woman} \approx \vec{queen}$. This property is notable because it suggests that models trained on word embeddings can easily learn such relationships as geometric translations. However, there is no evidence that models *exclusively* represent relationships in this manner. We document an alternative way in which downstream models might learn these relationships: orthogonal and linear transformations. For example, given a translation vector for *gender*, we can find an orthogonal matrix R, representing a rotation and reflection, such that $R(\vec{king}) \approx \vec{queen}$ and $R(\vec{man}) \approx \vec{woman}$. Analogical reasoning using orthogonal transformations is almost as accurate as using vector arithmetic; using linear transformations is more accurate than both. Our findings suggest that these transformations can be as good a representation of word relationships as translation vectors.

1 Introduction

Word embeddings are a cornerstone of current methods in NLP. A notable property of these vectors is that word relationships can exist as linear substructures in the embedding space (Mikolov et al., 2013a). For example, *gender* can be expressed as the translation vectors $\vec{woman} - \vec{man}$ and $\vec{queen} - \vec{king}$; similarly, *past tense* can be expressed as $\vec{thought} - \vec{think}$ and $\vec{talked} - \vec{talk}$. This, in turn, allows word analogies to be solved arithmetically. For example, *'man is to woman as king is to ?'* can be solved by finding the vector closest to $\vec{king} - \vec{man} + \vec{woman}$, which should be $\vec{queen}$ if one excludes the query words.

*Work partly done at the University of Toronto.

Ethayarajh et al. (2019a) proved that when there is no reconstruction error, a word analogy that can be solved arithmetically holds exactly over a set of ordered word pairs iff the co-occurrence shifted PMI is the same for every word pair and across any two word pairs. This means that strict conditions need to be satisfied by the training corpus for a word analogy to hold exactly, and these conditions are not necessarily satisfied by every analogy that makes intuitive sense. For example, most analogies involving countries and their currency cannot be solved arithmetically using Wikipedia-trained skipgram vectors (Ethayarajh et al., 2019a).

The fact that word relationships *can* exist as linear substructures is still notable, as it suggests that models trained with embeddings can easily learn these relationships as geometric translations. For example, as we noted earlier, it is easy to learn a translation vector $\vec{b}$ such that $\vec{queen} = \vec{king} + \vec{b}$ and $\vec{woman} = \vec{man} + \vec{b}$. However, Ethayarajh et al.'s proof and corresponding empirical evidence suggest that models do not *exclusively* represent word relationships in this manner. While past work has acknowledged that downstream models can capture relationships as complex non-linear transformations (Murdoch et al., 2018), it has not studied whether there are simpler linear alternatives that can also describe word relationships.

In this paper, we first document one such alternative: orthogonal transformations. More specifically, given the mean translation vector $\vec{b}$ for a word relationship (e.g., *gender*), we can find an orthogonal matrix that represents the relationship just as well as $\vec{b}$. For example, there is an orthogonal matrix R such that $R(\vec{king}) \approx \vec{queen}$ and $R(\vec{man}) \approx \vec{woman}$. To find R for a word relationship, we first create a source matrix X of randomly sampled word vectors and a target matrix Y by shifting X by $\vec{b}$. We then use the closed-form solution to orthogonal Procrustes (Schönemann, 1966)

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3503–3508, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

to determine R, which is the orthogonal matrix that most closely maps X to Y. If we broaden our search to include all linear transformations – not just orthogonal ones – we can find a matrix A to represent the relationship by using the analytical solution to ordinary least squares.

We find that using orthogonal transformations for analogical reasoning is almost as accurate as using vector arithmetic, and using linear transformations is more accurate than both. However, given that finding the orthogonal matrix analytically is much more computationally expensive, we do not recommend using our method to solve analogies in practice. Rather, our key insight is that there are parsimonious representations of word relationships between the two extremes of simple geometric translations and complex nonlinear transformations. Our empirical finding offers novel insight into how downstream NLP models, both large and small, may be inferring word relationships. It suggests that a simple linear regression model or a single attention head of a Transformer (Vaswani et al., 2017) can adequately represent many word relationships, ranging from the one between a country and its capital to the one between an adjective and its superlative form.

2 Related Work

Word Embeddings Word embeddings are distributed representations in a low-dimensional continuous space. They can capture semantic and syntactic properties of words as linear substructures, allowing relationships to be expressed as geometric translations (Mikolov et al., 2013b). Word vectors can be learned from: (a) neural networks that learn representations by predicting co-occurrences (Bengio et al., 2003; Mikolov et al., 2013b); (b) low-rank approximations of word-context matrices containing a co-occurrence statistic (Landauer and Dumais, 1997; Levy and Goldberg, 2014b).

Solving Word Analogies There are two main strategies for solving word analogies, `3CosAdd` and `3CosMul` (Levy and Goldberg, 2014a). The former is the familiar vector arithmetic method: given a word analogy task *a:b::x:?*, the answer is $\text{argmin}_w \cos(\vec{w}, \vec{x} + \vec{b} - \vec{a})$. For `3CosMul`, the answer is $\text{argmin}_w(\cos(\vec{w},\vec{x})\cos(\vec{w},\vec{b}))/(\cos(\vec{w},\vec{a}) + \varepsilon)$, where ε prevents null division. Although `3CosMul` is more accurate on average, we do not discuss it further because it does not create a distinct representation of the relationship. As noted previously, our goal is *not* to come up with a better strategy for solving analogies, but to show that there are parsimonious representations of word relationships other than translation vectors.

Orthogonal Maps Orthogonal transformations have been applied to word embeddings to achieve various objectives. Most famously, they have been used for the cross-lingual alignment of word embeddings trained on non-parallel data, for unsupervised machine translation (Conneau et al., 2018). Rothe et al. (2016) proposed a method for creating ultra-dense word embeddings in more meaningful subspaces by first learning an orthogonal transformation of the embeddings and then clipping all but the relevant dimensions. Park et al. (2017) built on this work, exploring several strategies for rotating embeddings to obtain more semantically meaningful dimensions. However, to our knowledge, orthogonal transformations themselves have not been used to represent word relationships; our work is novel in this respect.

3 Representing Word Relationships

To formalize the notion of a word relationship, we treat it as an invertible transformation that can hold over an arbitrary number of ordered pairs, following a similar framing proposed by Ethayarajh et al. (2019a) for word analogies. For example, the word pairs *{(Berlin, Germany), (Paris, France), (Ottawa, Canada)}* all express the same word relationship because some function f maps each capital city to its respective country. In this paper, we look at three specific types of transformations: *translative*, *orthogonal*, and *linear*.

Definition 1 *A word relationship f is an invertible transformation that holds over a set of ordered pairs S iff* $\forall\ (x,y) \in S, f(x) = y \wedge f^{-1}(y) = x$.

Definition 2.1 *A translative word relationship f is a transformation of the form $\vec{x} \mapsto \vec{x} + \vec{b}$, where $\vec{b}$ is the translation vector. f holds over ordered pairs S iff* $\forall\ (x,y) \in S, \vec{x} + \vec{b} = \vec{y}$.

Definition 2.2 *An orthogonal word relationship f is a transformation of the form $\vec{x} \mapsto R\vec{x}$, where $R^T R = I$. f holds over ordered pairs S iff* $\forall\ (x,y) \in S, R\vec{x} = \vec{y}$.

Definition 2.3 *A linear word relationship f is a transformation of the form $\vec{x} \mapsto A\vec{x}$, where A is a non-degenerate square matrix. f holds over ordered pairs S iff* $\forall\ (x,y) \in S, A\vec{x} = \vec{y}$.

Table 1: The accuracy on our word analogy task – detailed in section 4.1 – when word relationships are represented as orthogonal, linear, and translative functions. The highest accuracy for each category is in bold. As seen in the last row, on average, orthogonal transformations are almost as accurate as translations (0.761 vs. 0.782), and the average cosine similarity between a transformed vector and the solution is about the same for both.

Given a set of word pairs S, how can we determine a translative, orthogonal, or linear transformation f such that $\forall\ (x,y) \in S, f(\vec{x}) \approx \vec{y}$? Fortunately, there are closed form solutions for each case. To define a translation, we can simply take the mean of the pairwise difference vectors as our translation vector:

$$\vec{b} = \frac{1}{|S|} \sum_{(x,y)\in S} \vec{y} - \vec{x} \tag{1}$$

For orthogonal transformations, we first uniformly randomly sample n words from the vocabulary and stack their word vectors to get a source matrix X. Then, we add $\vec{b}$ to each sampled word vector to get a target matrix Y. Finding the orthogonal matrix that most closely maps X to Y is called the orthogonal Procrustes problem:

$$R = \underset{\Omega}{\operatorname{argmin}} \|\Omega X - Y\|_F \text{ s.t. } \Omega^T\Omega = I \tag{2}$$

Orthogonal Procrustes has a closed-form solution that we can use to find R (Schönemann, 1966). We frame the problem similarly to find a linear map A that does not necessarily need to be orthogonal. If we assume that the linear transformation should minimize the ordinary least squares objective,

$$\begin{aligned} A &= \underset{\Omega}{\operatorname{argmin}} \|\Omega X - Y\|^2 \\ &= YX^T(XX^T)^{-1} \end{aligned} \tag{3}$$

Note that our approach to finding the orthogonal and linear transformations is to find those that best approximate the geometric translation by $\vec{b}$. The reasoning behind this is simple: in practice, the number of word pairs in S is much smaller than the embedding dimensionality d, so trying to find a map $x \mapsto y\ \forall\ (x,y) \in S' \subset S$ would be very conducive to over-fitting. Since we randomly sample n words to create X and Y, we can choose $n \gg d$ to prevent this problem.

Although we are ultimately learning to approximate a translation, representing a word relationship as an orthogonal matrix as opposed to a translation vector has some useful mathematical properties, such as preserving the inner product: $\forall\ (x,y) \in S, \langle\vec{x},\vec{y}\rangle = \langle R\vec{x}, R\vec{y}\rangle$. Ethayarajh et al. (2019a) proved that when there is no reconstruction error, the word-context matrix M that is implicitly factorized by models such as skipgram and GloVe can be recovered from the inner products of word vectors. Since the inner product is preserved under rotation, M can also be recovered from an orthogonally transformed word space. The same does not hold under translation.

4 Evaluating the Representations

4.1 Task and Setup

We evaluate the different representations of word relationships using analogy tasks. However, we do not aim to solve word analogies in the traditional sense, since that largely depends on which words are present in each analogy's 4-tuple. Instead, we first calculate the mean translation vector $\vec{b}$ by av-

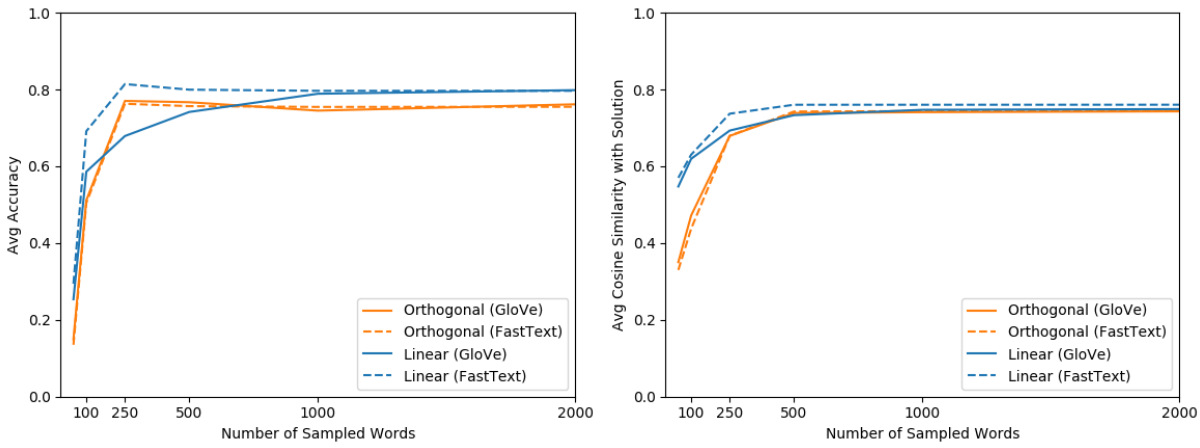

Figure 1: The accuracy on our word analogy task (left) and the average cosine similarity between the predicted and actual answers (right) as n, the number of sampled words used to learn the transformation, increases. The accuracy plateaus for $n \geq 250$ and the similarity plateaus for $n \geq 500$, suggesting that a robust transformation can be learned with relatively little data. Use of GloVe vs. FastText vectors makes no difference as $n \to 2000$.

eraging difference vectors across all word pairs, as defined in (1). $\vec{b}$ is also used to estimate matrices for the orthogonal and linear transformations (see (2) and (3)). We then create a set of word pairs for each analogy category: e.g., {*(Berlin, Germany), (Paris, France)*, ... } for *country-capital*. Each type of transformation – translative, orthogonal, and linear – is evaluated by how accurately it maps source words to target words in this set of word pairs. We use pre-trained GloVe vectors (Pennington et al., 2014) and $n = 2000$ for our main results in Table 1 and repeat our experiments with FastText vectors (Bojanowski et al., 2017) in Figure 1. We source our analogies from Mikolov et al. (2013a), as it contains a diverse set of categories.

4.2 Results

As seen in Table 1, orthogonal transformations are almost as accurate as geometric translations on our word analogy task: the average accuracy is 0.761 and 0.782 respectively. Linear transformations are more accurate than both (0.798). We would expect linear transformations to outperform orthogonal ones, given that the set of possible linear transformations is a superset of the set of possible orthogonal transformations. However, it is surprising that linear maps also outperform geometric translations, given that they are ultimately learned using translation vectors.

In the right half of Table 1, we list the average cosine similarity between the transformed source vector and the actual target vector (e.g, $\cos(R(\vec{king}), \vec{queen})$). This is to mitigate concerns that because the transformed source vector is mapped to the closest word vector, orthogonal transformations are only accurate due to the sparsity of the word space. As seen in Table 1, such concerns would be unfounded: the average cosine similarity for orthogonal transformations across all categories is 0.743, almost as high as the 0.768 for translations. This suggests that even if we considered a larger portion of the vocabulary as candidate answers, or if the word space were denser, orthogonal transformations would still be almost as accurate as translations on our task.

Our only hyperparameter is n, the number of randomly sampled words used to generate X and Y. As seen in Figure 1, the accuracy plateaus for $n \geq 250$ and the average cosine similarity with the target vector plateaus for $n \geq 500$. This suggests that it is possible to learn orthogonal and linear transformations representing word relationships with relatively little data. As $n \to 2000$, differences in performance between GloVe and FastText disappear, though linear transformations are more accurate than orthogonal ones for all n. This also highlights why the translation vector $\vec{b}$ is used to learn the transformations instead of a subset of the actual word pairs: for most analogy categories, there are fewer than 250 pairs in the dataset, and learning with so few word pairs would lead to poor accuracy.

4.3 Implications

Evaluating Embeddings The literature has often evaluated the quality of word embeddings

by testing their ability to solve word analogies arithmetically (Mikolov et al., 2013b; Pennington et al., 2014). If word relationships were *exclusively* geometric translations, this would be reasonable. However, given that word relationships can also be orthogonal or linear transformations, the usefulness of these tests as a measure of embedding quality should be reconsidered. Other arguments, both theoretical and empirical, have been made in the past against the use of analogies for evaluation (Schluter, 2018; Drozd et al., 2016; Rogers et al., 2017).

Model Architecture Given that bias terms are not necessarily needed to learn word relationships, the architecture of downstream models trained on word embeddings can be modified accordingly. Transformers (Vaswani et al., 2017) already make extensive use of linear maps in multi-headed attention and appear to be justified in doing so. Moreover, recent work has found that certain attention heads are sensitive to certain syntax, positional information, and other linguistic phenomena (Voita et al., 2019; Clark et al., 2019). For example, Clark et al. (2019) identified heads that attend to the direct objects of verbs, noun determiners, and coreference mentions with surprisingly high accuracy. However, these studies have not examined whether semantic word relationships – such as gender – also correspond to certain attention heads. Given that our findings suggest that individual attention heads have the capacity to learn such relationships, this is a promising direction for future work.

Bias in Word Embeddings The most common method for removing gender bias in word embeddings involves defining a bias subspace in the embedding space and then subtracting from each word vector its projection on this subspace (Bolukbasi et al., 2016). Under certain conditions, this method can provably debias skipgram and GloVe word embeddings (Ethayarajh et al., 2019b), but in practice, these conditions are typically not satisfied and gender associations can still be recovered from the embedding space (Gonen and Goldberg, 2019). Our findings in this paper suggest another way in which downstream models may be learning such biases, by representing gender as an orthogonal or linear transformation. This, in turn, may help explain the existence of such bias in contextualized word representations as well (Zhao et al., 2019). Given that these transformations are another way in which social biases can manifest, exploring more diverse strategies for debiasing – or alternatively, understanding the limits of debiasing strategies – is another direction for future work.

5 Conclusion

Word relationships in embedding space are generally thought of as simple geometric translations or complex non-linear transformations. However, we found that there are parsimonious representations of relationships between these two extremes, namely orthogonal and linear transformations. In addition, we found that it is possible to easily learn an orthogonal or linear transformation for a word relationship given its mean translation vector. Analogical reasoning done using linear transformations is in fact more accurate than using geometric translations. This finding offers novel insight into how downstream NLP models may be inferring word relationships. For example, it suggests that a single attention head in a Transformer has sufficient capacity to represent a semantic or syntactical word relationship, concurring with recent findings that certain attention heads have syntax- and position-specific behavior.

Abstract

Word Sense Disambiguation (WSD) aims to find the exact sense of an ambiguous word in a particular context. Traditional supervised methods rarely take into consideration the lexical resources like WordNet, which are widely utilized in knowledge-based methods. Recent studies have shown the effectiveness of incorporating gloss (sense definition) into neural networks for WSD. However, compared with traditional *word expert* supervised methods, they have not achieved much improvement. In this paper, we focus on how to better leverage gloss knowledge in a supervised neural WSD system. We construct *context-gloss* pairs and propose three BERT-based models for WSD. We fine-tune the pre-trained BERT model and achieve new state-of-the-art results on WSD task.

1 Introduction

Word Sense Disambiguation (WSD) is a fundamental task and long-standing challenge in Natural Language Processing (NLP), which aims to find the exact sense of an ambiguous word in a particular context (Navigli, 2009). Previous WSD approaches can be grouped into two main categories: knowledge-based and supervised methods.

Knowledge-based WSD methods rely on lexical resources like WordNet (Miller, 1995) and usually exploit two kinds of lexical knowledge. The gloss, which defines a word sense meaning, is first utilized in Lesk algorithm (Lesk, 1986) and then widely taken into account in many other approaches (Banerjee and Pedersen, 2002; Basile et al., 2014). Besides, structural properties of semantic graphs are mainly used in graph-based algorithms (Agirre et al., 2014; Moro et al., 2014).

Traditional supervised WSD methods (Zhong and Ng, 2010; Shen et al., 2013; Iacobacci et al., 2016) focus on extracting manually designed features and then train a dedicated classifier (*word expert*) for every target lemma.

Although *word expert* supervised WSD methods perform better, they are less flexible than knowledge-based methods in the all-words WSD task (Raganato et al., 2017a). Recent neural-based methods are devoted to dealing with this problem. Kågebäck and Salomonsson (2016) present a supervised classifier based on Bi-LSTM, which shares parameters among all word types except the last layer. Raganato et al. (2017a) convert WSD task to a sequence labeling task, thus building a unified model for all polysemous words. However, neither of them can totally beat the best *word expert* supervised methods.

More recently, Luo et al. (2018b) propose to leverage the gloss information from WordNet and model the semantic relationship between the context and gloss in an improved memory network. Similarly, Luo et al. (2018a) introduce a (hierarchical) co-attention mechanism to generate co-dependent representations for the context and gloss. Their attempts prove that incorporating gloss knowledge into supervised WSD approach is helpful, but they still have not achieved much improvement, because they may not make full use of gloss knowledge.

In this paper, we focus on how to better leverage gloss information in a supervised neural WSD system. Recently, the pre-trained language models, such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), have shown their effectiveness to alleviate the effort of feature engineering. Especially, BERT has achieved excellent results in question answering (QA) and natural language inference (NLI). We construct *context-gloss* pairs from glosses of all possible senses (in WordNet) of the target word, thus treating WSD task as a sentence-pair classification problem. We fine-

tune the pre-trained BERT model and achieve new state-of-the-art results on WSD task. In particular, our contribution is two-fold:

1. We construct *context-gloss* pairs and propose three BERT-based models for WSD.

2. We fine-tune the pre-trained BERT model, and the experimental results on several English all-words WSD benchmark datasets show that our approach significantly outperforms the state-of-the-art systems.

2 Methodology

In this section, we describe our method in detail.

2.1 Task Definition

In WSD, a sentence s usually consists of a series of words: $\{w_1, \cdots, w_m\}$, and some of the words $\{w_{i_1}, \cdots, w_{i_k}\}$ are targets $\{t_1, \cdots, t_k\}$ need to be disambiguated. For each target t, its candidate senses $\{c_1, \cdots, c_n\}$ come from entries of its lemma in a pre-defined sense inventory (usually WordNet). Therefore, WSD task aims to find the most suitable entry (symbolized as unique sense key) for each target in a sentence. See a sentence example in Table 1.

2.2 BERT

BERT (Devlin et al., 2018) is a new language representation model, and its architecture is a multi-layer bidirectional Transformer encoder. BERT model is pre-trained on a large corpus and two novel unsupervised prediction tasks, i.e., masked language model and next sentence prediction tasks are used in pre-training. When incorporating BERT into downstream tasks, the fine-tuning procedure is recommended. We fine-tune the pre-trained BERT model on WSD task.

BERT(Token-CLS) Since every target in a sentence needs to be disambiguated to find its exact sense, WSD task can be regarded as a token-level classification task. To incorporate BERT to WSD task, we take the final hidden state of the token corresponding to the target word (if more than one token, we average them) and add a classification layer for every target lemma, which is the same as the last layer of the Bi-LSTM model (Kågebäck and Salomonsson, 2016).

2.3 GlossBERT

BERT can explicitly model the relationship of a pair of texts, which has shown to be beneficial to many pair-wise natural language understanding tasks. In order to fully leverage gloss information, we propose GlossBERT to construct *context-gloss* pairs from all possible senses of the target word in WordNet, thus treating WSD task as a sentence-pair classification problem.

We describe our construction method with an example (See Table 1). There are four targets in this sentence, and here we take target word *research* as an example:

Context-Gloss Pairs The sentence containing target words is denoted as *context* sentence. For each target word, we extract glosses of all N possible senses (here $N = 4$) of the target word (research) in WordNet to obtain the *gloss* sentence. [CLS] and [SEP] marks are added to the *context-gloss* pairs to make it suitable for the input of BERT model. A similar idea is also used in aspect-based sentiment analysis (Sun et al., 2019).

Context-Gloss Pairs with Weak Supervision Based on the previous construction method, we add weak supervised signals to the *context-gloss*

Dataset	Total	Noun	Verb	Adj	Adv
SemCor	226036	87002	88334	31753	18947
SE2	2282	1066	517	445	254
SE3	1850	900	588	350	12
SE07	455	159	296	0	0
SE13	1644	1644	0	0	0
SE15	1022	531	251	160	80

Table 2: Statistics of the different parts of speech annotations in English all-words WSD datasets.

pairs (see the highlighted part in Table 1). The signal in the *gloss* sentence aims to point out the target word, and the signal in the *context* sentence aims to emphasize the target word considering the situation that a target word may occur more than one time in the same sentence.

Therefore, each target word has N *context-gloss* pair training instances ($label \in \{yes, no\}$). When testing, we output the probability of $label = yes$ of each *context-gloss* pair and choose the sense corresponding to the highest probability as the prediction label of the target word. We experiment with three GlossBERT models:

GlossBERT(Token-CLS) We use context-gloss pairs as input. We highlight the target word by taking the final hidden state of the token corresponding to the target word (if more than one token, we average them) and add a classification layer ($label \in \{yes, no\}$).

GlossBERT(Sent-CLS) We use context-gloss pairs as input. We take the final hidden state of the first token `[CLS]` as the representation of the whole sequence and add a classification layer ($label \in \{yes, no\}$), which does not highlight the target word.

GlossBERT(Sent-CLS-WS) We use context-gloss pairs with weak supervision as input. We take the final hidden state of the first token `[CLS]` and add a classification layer ($label \in \{yes, no\}$), which weekly highlight the target word by the weak supervision.

3 Experiments

3.1 Datasets

The statistics of the WSD datasets are shown in Table 2.

Training Dataset Following previous work (Luo et al., 2018a,b; Raganato et al., 2017a,b; Iacobacci et al., 2016; Zhong and Ng, 2010), we choose SemCor3.0 as training corpus, which is the largest corpus manually annotated with WordNet sense for WSD.

Evaluation Datasets We evaluate our method on several English all-words WSD datasets. For a fair comparison, we use the benchmark datasets proposed by Raganato et al. (2017b) which include five standard all-words fine-grained WSD datasets from the Senseval and SemEval competitions: Senseval-2 (**SE2**), Senseval-3 (**SE3**), SemEval-2007 (**SE07**), SemEval-2013 (**SE13**) and SemEval-2015 (**SE15**). Following Luo et al. (2018a), Luo et al. (2018b) and Raganato et al. (2017a), we choose **SE07**, the smallest among these test sets, as the development set.

WordNet Since Raganato et al. (2017b) map all the sense annotations in these datasets from their original versions to WordNet 3.0, we extract word sense glosses from WordNet 3.0.

3.2 Settings

We use the pre-trained uncased $\text{BERT}_{\text{BASE}}$ model[1] for fine-tuning, because we find that $\text{BERT}_{\text{LARGE}}$ model performs slightly worse than $\text{BERT}_{\text{BASE}}$ in this task. The number of Transformer blocks is 12, the number of the hidden layer is 768, the number of self-attention heads is 12, and the total number of parameters of the pre-trained model is 110M. When fine-tuning, we use the development set (**SE07**) to find the optimal settings for our experiments. We keep the dropout probability at 0.1, set the number of epochs to 4. The initial learning rate is 2e-5, and the batch size is 64.

3.3 Results

Table 3 shows the performance of our method on the English all-words WSD benchmark datasets. We compare our approach with previous methods.

The first block shows the MFS baseline, which selects the most frequent sense in the training corpus for each target word.

The second block shows two knowledge-based systems. $\text{Lesk}_{ext+emb}$ (Basile et al., 2014) is a variant of Lesk algorithm (Lesk, 1986) by calculating the gloss-context overlap of the target word. Babelfy (Moro et al., 2014) is a unified graph-based approach which exploits the semantic network structure from BabelNet.

GlossBERT(Sent-CLS)	69.2	76.5	73.4	75.1	79.5	79.1	65.4	79.3	84.8	75.8
GlossBERT(Token-CLS)	71.9	77.0	**75.4**	74.6	79.3	78.8	66.8	**79.9**	85.0	76.3
GlossBERT(Sent-CLS-WS)	**72.5**	**77.7**	75.2	**76.1**	**80.4**	**79.8**	**67.1**	79.6	**87.4**	**77.0**

Table 3: F1-score (%) for fine-grained English all-words WSD on the test sets in the framework of Raganato et al. (2017b) (including the development set **SE07**). **Bold** font indicates best systems. The five blocks list the MFS baseline, two knowledge-based systems, two traditional *word expert* supervised systems, six recent neural-based systems and our systems, respectively. Results in first three blocks come from Raganato et al. (2017b), and others from the corresponding papers.

The third block shows two *word expert* traditional supervised systems. IMS (Zhong and Ng, 2010) is a flexible framework which trains SVM classifiers and uses local features. And IMS$_{+emb}$ (Iacobacci et al., 2016) is the best configuration of the IMS framework, which also integrates word embeddings as features.

The fourth block shows several recent neural-based methods. Bi-LSTM (Kågebäck and Salomonsson, 2016) is a baseline for neural models. Bi-LSTM$_{+att.+LEX+POS}$ (Raganato et al., 2017a) is a multi-task learning framework for WSD, POS tagging, and LEX with self-attention mechanism, which converts WSD to a sequence learning task. GAS$_{ext}$ (Luo et al., 2018b) is a variant of GAS which is a gloss-augmented variant of the memory network by extending gloss knowledge. CAN^s and HCAN (Luo et al., 2018a) are sentence-level and hierarchical co-attention neural network models which leverage gloss knowledge.

In the last block, we report the performance of our method. BERT(Token-CLS) is our baseline, which does not incorporate gloss information, and it performs slightly worse than previous traditional supervised methods and recent neural-based methods. It proves that directly using BERT cannot obtain performance growth. The other three methods outperform other models by a substantial margin, which proves that the improvements come from leveraging BERT to better exploit gloss information. It is worth noting that our method achieves significant improvements in **SE07** and **Verb** over previous methods, which have the highest ambiguity level among all datasets and all POS tags respectively according to Raganato et al. (2017b).

Moreover, GlossBERT(Token-CLS) performs better than GlossBERT(Sent-CLS), which proves that highlighting the target word in the sentence is important. However, the weakly highlighting method GlossBERT(Sent-CLS-WS) performs best in most circumstances, which may result from its combination of the advantages of the other two methods.

3.4 Discussion

There are two main reasons for the great improvements of our experimental results. First, we construct *context-gloss* pairs and convert WSD problem to a sentence-pair classification task which is similar to NLI tasks and train only one classifier, which is equivalent to expanding the corpus. Second, we leverage BERT (Devlin et al., 2018) to better exploit the gloss information. BERT model shows its advantage in dealing with sentence-pair classification tasks by its amazing improvement on QA and NLI tasks. This advantage comes from both of its two novel unsupervised prediction tasks.

Compared with traditional *word expert* supervised methods, our GlossBERT shows its effectiveness to alleviate the effort of feature engineering and does not require training a dedicated classifier for every target lemma. Up to now, it can be said that the neural network method can totally beat the traditional *word expert* method. Compared with recent neural-based methods, our so-

lution is more intuitive and can make better use of gloss knowledge. Besides, our approach demonstrates that when we fine-tune BERT on a downstream task, converting it into a sentence-pair classification task may be a good choice.

4 Conclusion

In this paper, we seek to better leverage gloss knowledge in a supervised neural WSD system. We propose a new solution to WSD by constructing *context-gloss* pairs and then converting WSD to a sentence-pair classification task. We fine-tune the pre-trained BERT model and achieve new state-of-the-art results on WSD task.

Abstract

One key component in text-to-SQL is to predict the comparison relations between columns and their values. To the best of our knowledge, no existing models explicitly introduce external common knowledge to address this problem, thus their capabilities of predicting comparison relations are limited beyond training data. In this paper, we propose to leverage adjective-noun phrasing knowledge mined from the web to predict the comparison relations in text-to-SQL. Experimental results on both the original and the re-split Spider dataset show that our approach achieves significant improvement over state-of-the-art methods on comparison relation prediction.

1 Introduction

Text-to-SQL (Yaghmazadeh et al., 2017; Zhong et al., 2017), which aims at mapping natural language to SQL queries, is one of the most important tasks in natural language processing. Most state-of-the-art models are end-to-end neural network based models (Zhang et al., 2017; Xu et al., 2017; Yu et al., 2018a; Herzig and Berant, 2018; Dong and Lapata, 2018; Yu et al., 2018b), which mainly extend the Seq2Seq architecture with some complicated network structures. As shown by Yu et al. (2018b), the performances of most methods are overstated, because they just match semantic parsing results, rather than truly understand the meanings of inputs (Finegan-Dollak et al., 2018). In this paper, we study the comparison relation prediction problem, as the comparison relations between columns and their values are not well understood by existing methods.

In SQL queries, comparison relations are expressed by the comparison operators ($=, \neq, <, \leq, >, \geq$) and value ordering keywords (`ASC`, `DESC` in `ORDER BY` expression). In most text-to-SQL models, the comparison relations are either generated using Seq2Seq architectures (Zhong et al., 2017; Dong and Lapata, 2018), or predicted using classifiers trained with output decoding features (Xu et al., 2017; Yu et al., 2018b). We give an example to show that external common knowledge is indispensable to truly understand the comparison relations on unseen data.

rank	name	time	birth_date
1	Martina	11′9	19800930
2	Mirjana	12′5	19820309
3	Justine	12′9	19820601

Table 1: Player Basic Information.

Table 1 shows the basic information about the athletes of the 100-meter sprint. Given the query *"what is the name of the oldest player ?"*, the goal is to generate the SQL "`SELECT name FROM players ORDER BY birth_date ASC LIMIT 1`". It should be noted that `ASC` represents the common knowledge that small value in `birth_date` column means *"old"*. Supposing that there are columns named `age` and some queries containing *"old"* in the training data, it's easy for the trained models to remember that *"old"* means selecting a large value from column `age`. But if `birth_date` is unseen in the training data, there is little chance to predict the comparison relation correctly without the common knowledge that *"age"* and *"birth_date"* both represent age but have opposite value polarities. Similarly, for query *"fast runner"*, models should select a large value from column `speed` or a small value from column `time`. There are some related works that address the intensity of adjectives (De Melo and Bansal, 2013; Ruppenhofer et al., 2014; Sharma et al., 2017), however,

*This work was done when the first author was an intern at Microsoft Research Asia.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3515–3520, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

no existing work studies the relations between the value polarities of adjective-noun phrasing pairs.

In this paper, we propose to explicitly incorporate the column value polarities as external knowledge in text-to-SQL models. Our goal is to scale the capabilities of existing models on comparison relation prediction to unseen data. The column value polarities are named as "adjective-noun phrasing knowledge", which can be easily constructed from the web. We further formulate the phrasing knowledge as feature vectors, which can be generically fed to existing models. Experimental results on both the original and the re-split Spider dataset show that our approach achieves significant improvement over state-of-the-art methods on comparison relation prediction.

2 Adjective-Noun Phrasing Knowledge

There are 3 steps to construct the knowledge: 1) adjective-noun pair candidate extraction, 2) value polarity mining, and 3) adjective-noun pair clustering. The adjective-noun phrasing knowledge will be two clusters, each of which is a list of adjective-noun pairs with the same value polarity.

2.1 Adjective-Noun Pair Candidate Extraction

As the value polarities depend on both adjectives and nouns, we first extract adjective-noun pairs that could be candidates of the phrasing knowledge. Typically, table column names could be considered as hypernyms of the corresponding cell values. Motivated by this, we gather a list of noun candidates, which consists of the concepts (hypernyms) from Microsoft Concept Graph[1] (Cheng et al., 2015; Wu et al., 2012) and the column names whose value types are number or date in the Web Table Corpora[2] (Lehmberg et al., 2016).

To extract the adjectives that modify the noun candidates, we introduce two POS tag patterns:

```
(1) [ADJ] [NOUN]
(2) [NOUN] is|are|was|were|be [ADJ]
```

where `[ADJ]` and `[NOUN]` are the POS tags for adjectives and nouns, respectively. We apply these two patterns to Wikipedia dump[3] to extract adjective-noun pair candidates. Taking *price* as an example, we would obtain the adjectives: *high*, *expensive*, and *cheap*, etc.

[1] https://concept.research.microsoft.com

[2] http://webdatacommons.org/webtables/

[3] https://dumps.wikimedia.org/enwiki/

2.2 Value Polarity Mining

As shown in Table 1, the value polarities of `age` and `birth_date` are opposite though both words are about *"age"*. We propose to mine the value polarities from the Web Table Corpora automatically. We assume that for two columns in the same table, if their corresponding values have negative correlations, they have opposite value polarities[4]. We use the Spearman's ρ coefficients to measure the correlations between two columns. For each two columns with value type number or date, if the frequency of their co-occurrences is above 20 and the coefficients ρ are below -0.9 for more than 50% co-occurrences in the corpora, the two columns are determined to have opposite value polarities.

2.3 Adjective-Noun Pair Clustering

So far, we have obtained the adjective-noun pairs and value polarity relations for nouns. However, it is still unclear whether the polarity is positive or negative. Positive (negative) polarity means that large (small) column values shall be selected when the noun is modified by an adjective. For example, the polarities of <`age`, *old*> and <`price`, *expensive*> are positive, while <`age`, *young*> and <`price`, *cheap*> are negative. Our goal is to separate the adjective-noun pairs into two clusters based on the value polarities.

Supposing that we know the polarity of <`age`, *old*> is positive, we can derive that the polarities of <`age`, *young*> and <`birth_date`, *old*> are negative, because *"old"* and *"young"* are antonyms, and the value polarities of `age` and `birth_date` are opposite. Motivated by this, we extend and group the adjective-noun pairs into clusters based on the following rules:

- the polarities of two pairs are the same if the adjectives are synonyms and the nouns are the same, or the nouns are synonyms and the adjectives are the same;
- the polarities of two pairs are the opposite if the adjectives are antonyms and the nouns are the same, or the nouns have opposite value polarities and the adjectives are the same.

It should be noted that each cluster contains two sets of pairs with opposite polarities. We manually assign polarity labels to clusters in top sizes

[4] We also studied the assumption that columns with positive correlations have the same value polarities, but find that it introduces much noise.

or with high total frequencies. One potential issue is that there might be conflicts due to the synonyms and antonyms resources, i.e., there may be two pairs assigned opposite polarities in the same cluster. In practice, there are only a few such cases, and we separate them into individual clusters and manually label these pairs. After that, we obtain the adjective-noun phrasing knowledge organized in two clusters, each of which is a list of adjective-noun pairs with the same polarity.

3 Phrasing Knowledge As Features

We propose to formulate knowledge as features to incorporate the adjective-noun phrasing knowledge. It is very generic, because knowledge feature can be easily combined with the input or hidden output of existing neural models.

3.1 Baseline Models

We use Spider (Yu et al., 2018c) as the dataset. We do not use other datasets like WikiSQL (Zhong et al., 2017) because WikiSQL queries that contain comparison relations are very simple, and do not require additional knowledge for understanding. We introduce the knowledge feature to two baseline models, namely syntaxSQLNet[5] (Yu et al., 2018b) and SQLNet[6] (Xu et al., 2017; Yu et al., 2018c). We do not use other syntax tree-based or sequence-based baselines like coarse-to-fine (Dong and Lapata, 2018) because they cannot handle the Spider dataset.

Currently[7], syntaxSQLNet achieves the best performance on Spider. SyntaxSQLNet and SQLNet solve the text-to-SQL task using a sequence-to-set structure. They decompose the SQL generation procedure into multiple individual modules. The comparison relation prediction consists of two parts: the comparison operator prediction in `OP` module of `WHERE` and `GROUP Having` components and ordering prediction in `DESC/ASC/LIMIT(DAL)` module of `ORDER BY` component. Both the two modules are classifiers defined as:

$$p(y) = \mathcal{F}(V \tanh(WX)), \qquad (1)$$

where X represents the input features; y is the output label; and W and V are trainable parameters. Function $\mathcal{F}$ is defined as `sigmoid` in SQLNet and `softmax` in syntaxSQLNet. The `OP` module predicts the comparison operator $y \in \{=, >, <, >=, <=, !=, \texttt{LIKE}, \texttt{NOTIN}, \texttt{IN}, \texttt{BETWEEN}\}$, while the `DAL` module predicts the ordering keyword $y \in \{\texttt{DESC}, \texttt{ASC}, \texttt{DESC LIMIT}, \texttt{ASC LIMIT}\}$.

3.2 Knowledge as Features

The adjective-noun phrasing knowledge is formulated as additional input features to existing models. Let X_K denote the knowledge feature, we rewrite the classifier for `OP` and `DAL` module as:

$$p(y) = \mathcal{F}(V \tanh(W[X : X_K])), \qquad (2)$$

where [:] denotes the concatenation of feature vectors. The intuition is that even if X is unseen, the knowledge feature X_K will help to make the correct prediction. We will give an example to show how to construct the knowledge feature.

As the adjective-noun phrasing knowledge consists of two clusters, we use two fixed random vectors to represent the two clusters, denoted as polarity features. We define the knowledge feature as the attention weighted polarity features with knowledge masks.

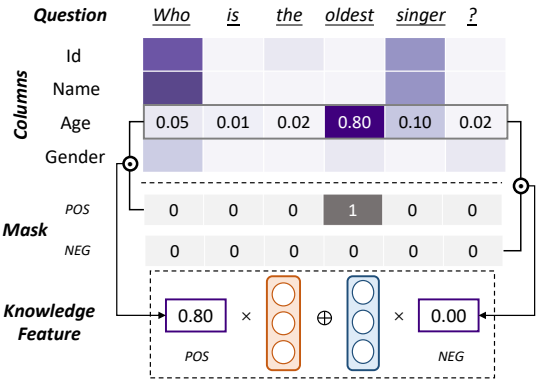

Figure 1: Knowledge as feature.

In Figure 1, the up palette shows the attention matrix between column names and question tokens. In syntaxSQLNet and SQLNet, the attention between column names and question tokens is defined by:

$$\alpha_{Q/CS} = \text{softmax}(H_Q W H_{CS}^{\top}), \qquad (3)$$

where H_{CS} and H_Q represent the hidden state of LSTM for column names and question tokens, respectively. Suppose that we are predicting the comparison operator for column `age` using the `DAL` module. We first construct the positive and

[5] https://github.com/taoyds/syntaxSQL

[6] https://github.com/taoyds/spider/tree/master/baselines/sqlnet

[7] As of mid May when we prepare this submission.

negative knowledge mask vectors, whose lengths are equal to the number of question tokens. In mask vectors, 1 means that the pair of the column name and the corresponding question token exists in phrasing knowledge. Then, we calculate the weight of positive and negative polarity features using the inner product ($\odot$) of knowledge mask vectors and the attention vector. For example, in Figure 1, the weight of positive and negative polarity features are 0.8 and 0, respectively. After that, we obtain the knowledge feature by the element-wise sum ($\oplus$) of the weighted positive and negative polarity features, denoted by $+_{\text{weighted}}$.

To obtain the mask vectors, we need to match the nouns in phrasing pairs with column names in the Spider dataset. For example, column names `birth date`, `birthdate`, `birth_date` and `date of birth` shoud be matched with the same noun *"date of birth"* in the phrasing knowledge. We heuristically define the matching score for column name n_1 and noun n_2 as:

$$\begin{aligned}\text{Score}(n_1, n_2) =& 0.2R_t(n_1, n_2) + 0.2R_c(n_1, n_2) \\ &+0.6\cos(\sum_{t_1 \in n_1} \text{idf}_{t_1} v_{t_1}, \sum_{t_2 \in n_2} \text{idf}_{t_2} v_{t_2}),\end{aligned} \quad (4)$$

where R_t and R_c are the token and char level fuzzy matching ratios, which is calculated by the output of fuzzywuzzy[8] divided by 100; and the last part is the cosine similarity between the inverse document frequency (idf) weighted sum of token embeddings, where the "document" refers to one column name in dataset. Given a column name in `OP` or `DAL` module, we select phrasing pairs whose noun matching score is ranked in top 10 as the knowledge to obtain the knowledge mask vectors.

Another straightforward way is to define the polarity feature as the knowledge feature directly, denoted as $+_{\text{direct}}$, where the polarity is determined by the attention weighted knowledge mask score. In the example above, the positive polarity feature will be considered as knowledge feature since the positive mask has a higher attention weighted score ($0.8 > 0$). We will evaluate both the $+_{\text{weighted}}$ and $+_{\text{direct}}$ knowledge features in the experiments.

4 Experiments

4.1 Data & Settings

For quality assurance, we manually choose 91 adjectives that have value polarities from top 200 frequent adjectives in Wikipedia. The adjectives with no value polarities like "important", "happy" and "reasonable" are filtered out. Then we use the adjective synonyms crawled from Bing Dictionary[9], the noun synonyms and adjective antonyms from WordNet (Miller, 1995) to cluster the adjective-noun pairs. We obtain $4,133$ distinct phrasing pairs in $2,689$ clusters. After that, we manually label the clusters with total sum of pair frequencies in top 50 or total number of pairs in top 50. Finally, we obtain 970 distinct adjective-noun pairs, which cover about 79.65% usages among all pairs. We manually evaluate the value polarities of all the 970 pairs, and the accuracy is 87.8%. The pairs after manually revision are served as the adjective-noun phrasing knowledge.

For Spider dataset, we remove the nested SQL queries and queries containing `JOIN`, because the performance of baseline models on complex queries is rather low, and we would more like to see the result that whether the comparison relation is correctly predicted given the right column. There are $4,490$ questions after removing the complex queries, with $3,946$ training and 544 development data. We manually review all the $4,490$ questions and the corresponding tables, and find that there are $1,212$ questions containing comparison relations (excluding $=, \neq$), among which 668 questions require adjective phrasing knowledge. The total number of required distinct adjective-noun pairs is 728, which is considered as ground-truth knowledge (denoted as *_gt*). After matching the mined adjective phrasing knowledge (970 pairs) with the Spider column names using Equation 4, we obtain 631 distinct pairs where 598 pairs exist in the ground-truth knowledge, the precision of knowledge matching using Equation 4 is 94.8% $(598/631)$, and the recall is 82.1% $(598/728)$.

To further evaluate effectiveness of phrasing knowledge, we re-split the training and development data of Spider, to ensure that the knowledge applied in the development set has not been seen or applied in the training set. The sizes of the re-split training and development sets are $3,906$ and 584, respectively. For model training, the dimension of knowledge feature is 50 with other parameters remaining the same as baseline models.

4.2 Phrasing Knowledge Examples

In the step of value polarity mining (described in Section 2.2), we obtain 758 noun pairs with oppo-

birth date	young	old, eld
date	fresh, new, recent, late	old, early
score	high	low
rank	low	high
price	costly, expensive, high, pricy	inexpensive cheap, low

Table 3: Examples of value polarity.

site polarities. For example, the opposite-polarity words for *age* are {*birth year, date of birth, birthday*}, and for *rank* are {*point, vote, score*}.

Table 3 shows some examples of the adjective-noun phrasing knowledge. It can be seen that the value polarities are opposite for `age` and `birth date`, `score` and `rank`.

4.3 Results on Comparison Relation Prediction

Table 2 shows the F1-scores on the original and re-split Spider dataset. -OP, -Having, and -DAL represent `WHERE` component without `OP` module, `Group` component without `Having` module, and `ORDER BY` component without `DAL` module, respectively. The results show that both the +weighted and the +direct knowledge features are effective, they significantly improve the performances of components that have comparison relations. The results also show that the overall performances are improved, which demonstrates that adjective-noun phrasing knowledge is effective and generic for existing state-of-the-art models.

5 Conclusion & Future Work

In this paper, we introduce the adjective-noun phrasing knowledge as feature to improve comparison relation prediction on unseen data. Experimental results show that our apporach achieves promising performance. For future work, we will further improve the quality of phrasing knowledge or incorporate other concept-level knowledge in text-to-SQL.

Abstract

Definition modeling includes acquiring word embeddings from dictionary definitions and generating definitions of words. While the meanings of defining words are important in dictionary definitions, it is crucial to capture the lexical semantic relations between defined words and defining words. However, thus far, the utilization of such relations has not been explored for definition modeling. In this paper, we propose definition modeling methods that use lexical semantic relations. To utilize implicit semantic relations in definitions, we use unsupervisedly obtained pattern-based word-pair embeddings that represent semantic relations of word pairs. Experimental results indicate that our methods improve the performance in learning embeddings from definitions, as well as definition generation.

1 Introduction

Dictionary definitions are rich resources of semantic information for both humans and machines. Recent studies on definition modeling are primarily divided into two categories. One is definition generation, in which a definition is generated for a target word from its word representation. Definition generation involves analyzing word embeddings using generated definitions (Noraset et al., 2017) and machine explanations of word meanings for human readers (Ni and Wang, 2017; Ishiwatari et al., 2019). The other is learning word embeddings from definitions to obtain semantic-oriented word representations (Tissier et al., 2017; Bosc and Vincent, 2018).

Although previous methods for encoding or decoding definitions using recurrent neural networks (RNNs) yielded promising results in definition modeling (Noraset et al., 2017; Bosc and Vincent, 2018), they did not explicitly utilize lexical semantic relations between defined words and defining words. Various lexical relations exist in definitions (Amsler, 1981), as displayed in Figure 1, where the defined word *knife* exhibits an *Is-a* relation with the defining words, *tool* and *instrument*, *Has-a* relation with *edge*, and *Used-for* relation with *cutting*. Utilizing structures of definitions about lexical semantic relations facilitates the understanding and generation of definitions.

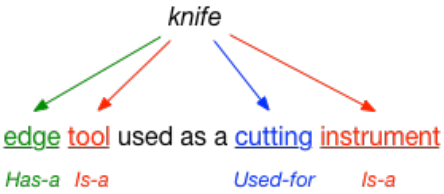

Figure 1: Definition of *knife* from WordNet (Fellbaum, 1998) and lexical semantic relations between the defined word and the defining words.

Based on this observation, we propose definition modeling methods that exploit lexical semantic relations between defined and defining words. However, lexical semantic relations in definitions are not explicit. To solve this problem, we use unsupervisedly learned word-pair embeddings that represent semantic relations of word pairs based on co-occurring relational patterns in a corpus (Turney, 2005; Washio and Kato, 2018b). Experimental results show that our definition modeling methods improve previous models, with respect to both definition generation and the acquisition of word embeddings from definitions.

2 Background

2.1 Definition Embedding

Relationships between words captured in embeddings are studied in terms of *similarity* or *relatedness* (Hill et al., 2015). For example, *coffee* and *cup* have high relatedness because *coffee* is often contained in a *cup*; meanwhile, these words ex-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3521–3527,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

hibit low similarity as *coffee* is a beverage and *cup* is a container.

Definition embeddings that are learned from word definitions are useful to capture similarity, while word embeddings based on distributional hypothesis (Mikolov et al., 2013) tend to capture relatedness (Bosc and Vincent, 2018).

Bosc and Vincent (2018) proposed a method that learns the long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) that encodes a word definition into an embedding. Given a defining word sequence $D = \{w_1, \ldots, w_T\}$, an LSTM definition encoder processes D, as follows:

$$\boldsymbol{h}_t = LSTM\left(\boldsymbol{h}_{t-1}, \boldsymbol{w}_t\right) \quad (1)$$

$$\boldsymbol{h} = \boldsymbol{W}_e \boldsymbol{h}_T + \boldsymbol{b}_e \quad (2)$$

where $LSTM$ computes the hidden state given the previous hidden state $\boldsymbol{h}_{t-1}$ and the input word embedding $\boldsymbol{w}_t$ along with the LSTM architecture. $\boldsymbol{h}_T$ is the final hidden state. $\boldsymbol{W}_*$ and $\boldsymbol{b}_*$ are weight matrices and bias terms, respectively. The definition encoder is trained to reconstruct a bag-of-words representation of the definition from $\boldsymbol{h}$ with a consistency penalty that renders $\boldsymbol{h}$ closer to the corresponding word embedding used in the LSTM. This method is referred to as *consistency penalized autoencoder (CPAE)*.

2.2 Definition Generation

Definition generation was introduced by Noraset et al. (2017). The goal of definition generation is to predict the probability of the defining word sequence D given the defined word w_{trg}. In the aforementioned study, the LSTM conditional language model was used as a definition decoder to model this probability as follows:

$$p\left(D|w_{trg}\right) = \prod_{t=1}^{T} p\left(w_t|w_{i<t}, w_{trg}\right) \quad (3)$$

$$p\left(w_t|w_{i<t}, w_{trg}\right) = Softmax(\boldsymbol{W}_d \boldsymbol{h}'_t + \boldsymbol{b}_d) \quad (4)$$

where $\boldsymbol{h}'_t$ is a hidden state from the LSTM definition decoder. $Softmax$ is the softmax function. They conditioned the decoder by providing the embedding of the defined word at the first step of the LSTM. They referred to this model as the *Seed (S)*. Moreover, they extended this model to update the output of the recurrent unit with a gate function depending on the embedding of the defined word. This gate function, *Gate (G)*, controls the amount of information from the defined word that contributes to the definition generation at each step. As additional features, they used morphological information from a character-level convolutional neural network (CNN) to process a character sequence of the defined word and the embeddings of the hypernyms from the WebIsA database (Seitner et al., 2016). These features are called *CH* and *HE*, respectively.

Gadetsky et al. (2018) introduced context-aware definition generation to disambiguate polysemous words with their context and generate the corresponding definitions. They extended Equation 3 to consider the context word sequence of the defined word $C = \{c_1, \ldots, c_m\}$ as follows:

$$p\left(D|w_{trg}, C\right) = \prod_{t=1}^{T} p\left(w_t|w_{i<t}, w_{trg}, C\right) \quad (5)$$

To model this probability, they used an attention mechanism to extract meaningful information from C and chose relevant dimensions of the embedding of the defined word. They referred to this model as *Input Attention (I-Attention)*.

2.3 Word-Pair Embedding

Word-pair embeddings represent relations of word pairs. Although representation of word pairs as the vector offsets of their pretrained word embeddings is a simple and powerful method (Mikolov et al., 2013), recent studies have shown that neural pattern-based word-pair embeddings are more effective than vector offsets in various tasks such as calculating relational similarity (Washio and Kato, 2018b), natural language inference, and question answering (Joshi et al., 2019).

Neural pattern-based word-pair embedding models (Washio and Kato, 2018a,b; Joshi et al., 2019) unsupervisedly learn two neural networks: a word-pair encoder and pattern encoder, both of which encode the word-pair and lexico-syntactic pattern respectively into the same embedding space. These networks are trained by predicting co-occurrences between word-pairs and patterns in a corpus with the negative sampling objective. After the unsupervised learning, the word-pair encoder provides word-pair embeddings for any word pair given their word embeddings.

3 Method

We propose methods that consider lexical semantic relations between the defined word and the

defining words in the definition encoder for definition embeddings (Section 3.1) and the definition decoder for definition generation (Section 3.2). To utilize the implicit semantic relations in definitions, we use word-pair embeddings that represent semantic relations of word pairs. We describe how word-pair embeddings are obtained in Section 4.1

3.1 For Definition Encoder

To consider lexical semantic relations in acquiring embedding from definitions, we feed the word-pair embeddings to the definition encoder. Assuming that the pair embedding $\boldsymbol{v}_{(w_{trg},w_t)}$ represents the relation between the defined word w_{trg} and the t-th defining word w_t, we calculate $\boldsymbol{h}_t$ as follows:

$$\boldsymbol{h}_t = LSTM\left(\boldsymbol{h}_{t-1}, [\boldsymbol{w}_t; \boldsymbol{v}_{(w_{trg},w_t)}]\right) \quad (6)$$

where ; denotes vector concatenation. To exclude meaningless relations between the defined word and functional words, we replace $\boldsymbol{v}_{(w_{trg},w_t)}$ with the zero vector if w_t is a stopword. With word-pair embeddings as inputs, the definition encoder can recognize the role of information that is provided by the current word w_t, for example, a type of w_{trg} (*Is-a*), a goal of w_{trg} (*Used-for*), or a component of w_{trg} (*Has-a*).

3.2 For Definition Decoder

To provide the definition decoder with information regarding lexical semantic relations, we use an additional loss function with word-pair embeddings as follows:

$$L_{rel} = \frac{1}{|K|} \sum_{w_t \in K} \left\| \boldsymbol{v}_{(w_{trg},w_t)} - (\boldsymbol{W}_r \boldsymbol{h}'_t + \boldsymbol{b}_r) \right\|^2 \quad (7)$$

$$K = \{w_t | w_t \in D \wedge w_t \notin S\} \quad (8)$$

where S is a set of stopwords. As in Section 3.1, we ignore the loss when w_t is a stopword. This additional loss allows the definition decoder to learn the pattern of what semantic relations occur in definitions and how they occur. For example, if w_{trg} indicates a type of tools, a defining word that has the *Is-a* relation to w_{trg} tends to be followed by the *Used-for* word.

4 Experiments and Results

The experiments conducted to evaluate our methods for definition encoding and decoding are presented in this section. In the Appendix, we describe the details of the hyperparameter settings and optimization methods used in the experiments.

4.1 Obtaining Word-Pair Embedding

To obtain pattern-based word-pair embeddings, we extracted triples $(w_1, w_2, p) \in T$ from the Wikipedia corpus, where (w_1, w_2) is a word pair composed of nouns, verbs, or adjectives in the the 100K most frequent words of the GloVe [1] (Pennington et al., 2014), and p is the co-occurring shortest dependency path[2]. We discarded the triples if p occurred less than five times and subsampled the triples based on word-pair probability with a threshold of $5 \cdot 10^{-7}$, following Joshi et al. (2019).

For the word-pair encoder, we used the neural networks as follows:

$$\boldsymbol{h}_{(w_1,w_2)} = MLP\left([\boldsymbol{v}_{w_1}; \boldsymbol{v}_{w_2}; \boldsymbol{v}_{w_1} \odot \boldsymbol{v}_{w_2}]\right) \quad (9)$$

where MLP is a four-layer perceptron with the ReLU activation, $\boldsymbol{v}_w$ is a word embedding of w, and $\odot$ is the element-wise product. Each size of the hidden states of MLP was 300.

The dependency path p is a sequence composed of one to three lemmas and dependency relations $e_1, \ldots, e_n$. The sequence of the corresponding embeddings $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n$ was encoded using the bidirectional LSTM with the 300-dimensional hidden state as the pattern encoder. Then, the 300-dimensional pattern representation $\boldsymbol{v}_p$ was calculated with the final output vectors $\boldsymbol{h}_f$ and $\boldsymbol{h}_b$ from the forward and backward LSTM as follows:

$$\boldsymbol{v}_p = \boldsymbol{W}_p[\boldsymbol{h}_f; \boldsymbol{h}_b] + \boldsymbol{b}_p \quad (10)$$

The word embeddings in the models were initialized by the 300-dimensional GloVe. We used the multivariate negative sampling objective (Joshi et al., 2019) to train the parameters with the data T for 10 epochs. Adagrad, which has a learning rate of 0.01, was used as the optimizer (Duchi et al., 2011). After the training was completed, word-pair embeddings are calculated as follows:

$$\boldsymbol{v}_{(w_1,w_2)} = \left[\frac{\boldsymbol{h}_(w_1,w_2)}{\|\boldsymbol{h}_(w_1,w_2)\|}; \frac{\boldsymbol{h}_(w_2,w_1)}{\|\boldsymbol{h}_(w_2,w_1)\|} \right] \quad (11)$$

4.2 Definition Embedding

For the evaluation of definition embeddings, we used the modified Word Embedding Benchmarks projects[3], following Bosc and Vincent (2018). These benchmarks include SimLex999 (SL999),

SimLex333 (SL333) (Hill et al., 2015), SimVerb (SV) (Gerz et al., 2016), MEN (Bruni et al., 2014), RG (Rubenstein and Goodenough, 1965), WS353 (Finkelstein et al., 2002), SCWS (Huang et al., 2012), and MTurk (Radinsky et al., 2011; Halawi et al., 2012). To evaluate the definition embeddings, we scored word pairs in the benchmarks using the cosine similarity between the corresponding definition embeddings and calculated Spearman's correlation to the ground truth. The definitions in WordNet were used to train the definition encoder. The development sets of the SimVerb and MEN were used for the hyperparameter tuning.

We implemented the *CPAE* (Section 2.1) as a baseline and compared it to *CPAE* with the word-pair embeddings (Section 3.1), which is our proposed method. The word embeddings in the definition encoder were initialized by the Google Word2Vec vectors[4]. Google Word2Vec vectors and GloVe were used as the other baselines.

Table 1 shows the results of the similarity and relatedness benchmarks. While the baseline *CPAE* outperformed our model on the two out of five datasets pertaining to word relatedness, our model consistently outperformed the baseline on the similarity benchmarks. These results indicate that the word-pair embeddings provide the definition encoder with useful semantic information about the target word.

Hidden States of Definition Encoder

To analyze the functionality of injecting semantic relations between the defined word and the defining words into the definition encoder, we investigate the similarities between hidden states of the definition encoders.

We encoded the *kettle*'s definition (*a metal pot for stewing or boiling*) and the *knife*'s definition (*edge tool used as a cutting instrument*) with the definition encoders. These two definitions are similar in their style, composed of the defining words of *Is-a* relations (*pot* and *tool*) and *Used-for* relations (*stewing*, *boiling*, and *cutting*.)

Figure 2 displays the cosine similarities between the last hidden state of the encoded *kettle*'s definition and each hidden state of the encoded *knife*'s definition. This figure shows that when *tool* with *Is-a* relation and *cutting* with *Used-for* relation to *knife* were input to the encoder, our method increased the similarities more than the baseline. This indicates that our method successfully helps the model capture the similarities of definitions in terms of lexical semantic relations.

4.3 Definition Generation

We evaluated our method for the definition decoder (Section 3.2) on a context-agnostic dataset (Noraset et al., 2017) and context-aware dataset (Gadetsky et al., 2018) for the definition generation. For evaluation purposes, we calculated the perplexity (PPL) and BLEU score (Papineni et al.,

[4]https://code.google.com/archive/p/word2vec/

	S+G+CH+HE	w/ L_{rel}
academician	a person who specializes in a particular profession	one who is versed in a scholarly or scientific field
artist	one who is a person who is a person or thing is made	one who creates a picture or representation of a creative work
adolescence	the state of being pregnant	the state of being mature

Table 3: Examples of definitions generated by the baseline $S + G + CH + HE$ and the one with L_{rel} on the development set of Noraset et al. (2017)

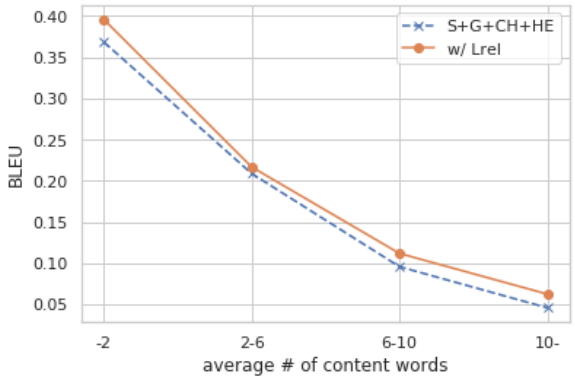

Figure 3: BLEU scores at the average numbers of content words in the reference definitions on the development set.

2002), following Noraset et al. (2017). We implemented *S+G+CH+HE* for the context-agnostic dataset and *S+I-Attention* for the context-aware dataset as baselines, and compared these models to the ones with L_{rel} in Section 3.2. The word embeddings in the models were initialized by Google Word2Vec vectors, as in Section 4.2.

The results in Table 2 show that training with our L_{rel} improves the performance in both the context-agnostic and context-aware settings.

Effect to Definition Generation

To analyze the effect of L_{rel}, we plotted the BLEU scores at each average number of content words in reference definitions from the development set of Noraset et al. (2017), as shown in Figure 3. This figure shows that when many content words exist in reference definitions, the model with L_{rel} is stronger than that without L_{rel}. This indicates that our method allows the model to select correct words when the defined word requires detailed descriptions.

Generated Definitions

Table 3 displays examples of generated definitions by the baseline $S + G + CH + HE$ and the one with L_{rel}. The model with the proposed method successfully generated the definitions for *academician* and *artist*, while the baseline did not. Although the baseline generated the generalized class of the target words, for examples, *person* and *one*, it fails to generate details when the target word is distinct from others in the same class. In contrast, the model with the proposed method chose the correct words at both the generalized class and the details.

For *adolescence*, both models could not generate the correct definitions. Even with our method, the model produced a definition that has an opposite meaning to the target word. The generation of opposite definitions is a significant problem in the definition generation from word embeddings (Noraset et al., 2017). Although our method helps the model generate details about the target words, this problem requires other approaches that consider antonym relations.

5 Conclusion

In this paper, we proposed definition modeling methods that utilize lexical semantic relations between defined words and defining words. To utilize implicit semantic relations in dictionary definitions, we used pattern-based word-pair embeddings. The experimental results demonstrated that applying our methods to the definition encoder and the definition decoder improved their performance. In our future work, we will extend our methods for phrase-level definition generation (Ishiwatari et al., 2019).

Don't Just Scratch the Surface: Enhancing Word Representations for Korean with Hanja

Kang Min Yoo*, **Taeuk Kim*** and **Sang-goo Lee**
Department of Computer Science and Engineering
Seoul National University, Seoul, Korea
{kangminyoo,taeuk,sglee}@europa.snu.ac.kr

Abstract

We propose a simple yet effective approach for improving Korean word representations using additional linguistic annotation (i.e. Hanja). We employ cross-lingual transfer learning in training word representations by leveraging the fact that Hanja is closely related to Chinese. We evaluate the intrinsic quality of representations learned through our approach using the word analogy and similarity tests. In addition, we demonstrate their effectiveness on several downstream tasks, including a novel Korean news headline generation task.

1 Introduction

There is a strong connection between the Korean and Chinese languages due to cultural and historical reasons (Lee and Ramsey, 2011). Specifically, a set of logograms with very similar forms to the Chinese characters, called **Hanja**[1], served in the past as the only medium for written Korean until **Hangul**, the Korean alphabet, and **Jamo** came into existence in 1443 (Sohn, 2001). Considering this etymological background, a substantial portion of Korean words are classified as Sino-Korean, a set of Korean words that had originated from Chinese and can be expressed in both Hanja and Hangul (Taylor, 1997), with the latter becoming commonplace in modern Korean.

Based on these facts, we assume the introduction of Hanja-level information will aid in grounding better representation for the meaning of Korean words (e.g. see Fig. 1). To validate our hypothesis, we propose a simple yet effective approach to training Korean word representations, named **Hanja-level SISG** (Hanja-level Subword Information Skip-Gram), for capturing the semantics of Hanja and subword structures of Korean and introducing them into the vector space. Note that it is also quite intuitive for native Koreans to resolve the ambiguity of (Sino-)Korean words with the aid of Hanja. We conjecture this heuristic is attributed to the fact that Hanja characters are logograms, each of which contains more lexical meaning when compared against its counterpart, the Hangul character, which is a phonogram. Accordingly, in this work, we focus on exploiting the rich extra information from Hanja as a means of constructing better Korean word embeddings. Furthermore, our approach enables us to empirically investigate the potential of character-level cross-lingual knowledge transfer with a case study of Chinese and Hanja.

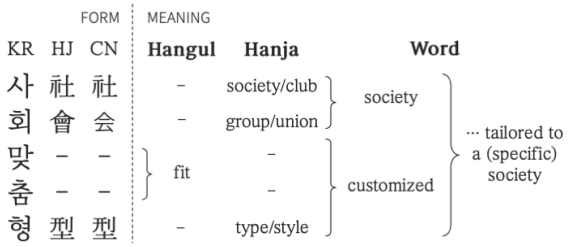

Figure 1: An example of a Korean word showing its form and multi-level meanings. The Sino-Korean word consists of Hangul phonograms (KR) and Hanja logograms (HJ). Although annotation of Hanja is optional, it offers deeper insight into the word meaning due to its association with the Chinese characters (CN).

To sum up, our contributions are threefold:

- We introduce a novel way of training Korean word embeddings with an expanded Korean alphabet vocabulary using Hanja in addition to the existing Korean characters, Hangul.
- We also explore the possibility of character-

*Equal contribution.
[1]Hanja and traditional Chinese characters are very similar but not completely identical. Some differences in strokes and language-exclusive characters exist.

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

level knowledge transfer between two languages by initializing Hanja embeddings with Chinese character embeddings before training skip-gram.

- We prove the effectiveness of our method in two ways, one of which is intrinsic evaluation (the word analogy and similarity tests), and the other being two downstream tasks including a newly proposed Korean news headline generation task.

2 Model Description

2.1 Skip-Gram (SG)

Given a corpus as a sequence of words $(w_1, w_2, \ldots, w_T)$, the goal of a skip-gram model (Mikolov et al., 2013) is to maximize the log-probabilities of context words given a target word w_i:

$$\sum_{i \in \{1,\ldots,T\}} \sum_{c \in \mathcal{C}(i)} \log p\left(w_c | w_i\right), \tag{1}$$

where $\mathcal{C}$ returns a set of context word indices given a word index. The usual choice for training the parameterized probability function $p\left(w_c|w\right)$ is to reframe the problem as a set of binary classification tasks of the target context word c and other negative samples chosen from the entire dictionary (negative sampling). The objective is thus

$$L\left(s\left(w_i, w_c\right)\right) + \sum_{j \in \mathcal{N}(i,c)} L\left(-s\left(w_i, w_j\right)\right), \tag{2}$$

where $L\left(x\right) = \log\left(1 + e^{-x}\right)$, the binary logistic loss. $\mathcal{N}$ returns a set of negative sample indices given target word and context indices. In the vanilla SG model, the scoring function s is the dot product between the two word vectors: $\mathbf{v}_w$ and $\mathbf{v}_c$.

2.2 Subword Information SG (SISG) and Jamo-level SISG

In Bojanowski et al. (2017), the scoring function incorporates subword information. Specifically, given all possible n-gram character sets $\mathbf{G} = \{g_1, \ldots, g_G\}$ in the corpus and that the n-gram set of a particular word w is $\mathcal{G}_w \subset \mathbf{G}$, the scoring function is thus the sum of dot products between all n-gram vectors $\mathbf{z}$ and the context vector $\mathbf{v}_c$:

$$s\left(w, c\right) = \sum_{g \in \mathcal{G}_w} \mathbf{z}_g \mathbf{v}_c. \tag{3}$$

However, due to the deconstructible structure of Korean characters and the agglutinative nature of the language, the model proposed by Bojanowski et al. (2017) comes short in capturing sub-character and inter-character information specific to Korean understanding. As a remedy, the model proposed by Park et al. (2018) introduces jamo-level n-grams $g^{(j)}$, whose vectors can be associated with the target context as well. Given that a Korean word w can be split into a set of jamo n-grams $\mathcal{G}_w^{(j)} \subset \mathbf{G}^{(j)} = \left\{g_1^{(j)}, \ldots, g_J^{(j)}\right\}$, where $\mathbf{G}^{(j)}$ is the set of all possible jamo n-grams in the corpus, the updated scoring function for jamo-level skip-gram $s^{(j)}$ is thus

$$s^{(j)}\left(w, c\right) = s\left(w, c\right) + \sum_{j \in \mathcal{G}_w^{(j)}} \mathbf{z}_j \mathbf{v}_c. \tag{4}$$

2.3 Hanja-level SISG[2]

Another semantic level in Korean lies in Hanja logograms. Hanja characters can be mapped to Hangul phonograms, hence Hanja annotations are sufficient but not necessary in conveying meanings (Fig. 1). As each Hanja character is associated with semantics, their presence could provide meaningful aid in capturing word-level semantics in the vector space.

We propose incorporating Hanja n-grams in the learning of word representations by allowing the scoring function to associate each Hanja n-gram with the target context word. Concretely, given that a Korean word w contains a set of Hanja sequences $\mathcal{H}_w = (h_{w,1}, \ldots, h_{w,H_w})$ (e.g. for the example in Fig. 1 $h_{w,1}$ = "社會" and h_{w_2} = "型") and that $\mathcal{I}_h$ is the set of Hanja n-grams for a Hanja sequence h (e.g. $\mathcal{I}_{h_{w,2}}$ = { "<boh>型", "型", "型<eoh>"}), *all* Hanja n-grams $\mathcal{G}_w^{(h)}$ for word w are the union of Hanja n-grams of Hanja sequences present in w: $\bigcup_{h \in \mathcal{H}_w} \mathcal{I}_h$. The length of Hanja n-grams in $\mathcal{I}_h$ is a hyperparameter. Then the new score function for Hanja-level SISG is

$$s^{(h)}\left(w, c\right) = s^{(j)}\left(w, c\right) + \sum_{h \in \mathcal{G}_w^{(h)}} \mathbf{z}_h \mathbf{v}_c \tag{5}$$

where $\mathbf{z}_h$ is the n-gram vector for a Hanja sequence h.

[2]The code and models are publicly available online at https://github.com/kaniblu/hanja-sisg

2.4 Character-level Knowledge Transfer

Since Hanja characters essentially share deep roots with Chinese characters, many of them can be mapped by one-to-one correspondence. By converting Korean characters into simplified Chinese characters or vice versa, it is possible to utilize pre-trained Chinese embeddings in the process of training Hanja-level SISG. In our case, we propose leveraging advances in Chinese word embeddings from the Chinese community by initializing Hanja n-grams vectors $\mathbf{z}_h$ with the state-of-the-art Chinese embeddings (Li et al., 2018) and training with the score function in Equation 5.

3 Experiments

3.1 Word Representation Learning

3.1.1 Korean Corpus

For learning word representations, we utilize the corpus prepared by Park et al. (2018) with small modifications. We perform additional data cleansing (e.g. removing non-Korean sentences in the corpus and unifying number tags) to obtain a cleaner version of the corpus. All of our comparative studies are based on this corpus. For training Hanja-level SISG, we use Hanjaro[3] tagger to automatically annotate all of our datasets with Hanja. It is the state-of-the-art Hanja tagger available to the public to the best of our knowledge.

3.1.2 Models

We compare our approach with three other baselines. Skip-Gram (`SG`) model (Mikolov et al., 2013) does not incorporate any n-gram information in the training loss. Subword Information Skip-Gram (`SISG(c)`) (Bojanowski et al., 2017) uses character-level n-gram information to enrich word representations. For the Korean language, character-level n-grams correspond to syllable n-grams. Jamo-level SISG (`SISG(cj)`) (Park et al., 2018) uses jamo-level n-grams in addition to character-level n-grams. Our ablation studies confirm that the hyperparameter settings (character n-grams ranging from 1 to 6 and jamo n-grams ranging from 3 to 5) proposed by the authors are indeed optimal, hence our subsequent studies all employ the same settings. Our approach is denoted by `SISG(cjh)`). As for the specific hyperparameter settings of our approach, `SISG(cjh3)` denotes Hanja n-grams ranging from 1 to 3 while `SISG(cjh4)` denotes Hanja n-grams ranging from 1 to 4. `SISG(cjhr)` is a special version of our approach, where Hanja n-grams are randomly initialized as opposed to being pre-trained (Section 2.4). The details of our ablation studies and the model implementation are included in the supplementary material.

† reported by Park et al. (2018)
‡ pre-trained embeddings provided by the authors of Park et al. (2018) run with our evaluation script

Table 1: Word analogy and similarity evaluation results. For word analogy test, the table shows cosine distances averaged over semantic and syntactic word pairs (lower is better). For word similarity test, we report on Pearson and Spearman correlations between predictions and ground truth scores. We observe that our approach (SISG(cjh)) shows significant improvements in the analogy test but some deterioration in the similarity test. Note that the evaluation results reported by the original authors (†) are largely different from our results. This might be due to differences in implementation details, hence we report and compare with the results of the authors' embeddings run on our test script (‡).

3.2 Intrinsic Evaluation

3.2.1 Word Analogy Test

Following the experimental protocol of Park et al. (2018), given an analogy pair $a : b \leftrightarrow c : d$, we compute the cosine distance between the word vectors $\mathbf{v}_a + \mathbf{v}_b - \mathbf{v}_c$ and $\mathbf{v}_d$ using the following equation: $1 - \cos(x, y)$, where cos is the cosine similarity. The Korean word analogy dataset (Park et al., 2018) consists of 10,000 quadruples, designed with a set of semantic and syntactic features specific to the Korean. We report our findings in Table 1. We observe that our approach improves significantly compared to the previous state-of-the-art models in both semantic and syntactic word analogy detection.

3.2.2 Word Similarity Test

The word similarity test aims to evaluate the correlation between word vector distances and

human-annotated scores. We use the Korean WS353 dataset provided by Park et al. (2018). Our results are shown in Table 1. Although our approaches do not outperform the jamo-level baseline (SISG(cj)), we observe that Hanja-level information provides some advantage compared to just using pure character-level n-grams (SISG(c)). Also note that WS353 is a relatively small dataset, which could be prone to statistical bias.

3.2.3 Analysis

How much of the improvement can be explained by transfer learning from Chinese? Word analogy test results show that word representations trained with pre-trained Chinese n-grams perform better than those trained without (SISG(cjhr)), supporting our claim that our approach is able to transfer relevant knowledge from the Chinese language for detecting analogical relationships. However, for the word similarity test, word vectors trained without Chinese embeddings perform better, suggesting that there are some trade-offs.

3.3 Downstream Tasks

In this section, we try to demonstrate the effectiveness of our approach to downstream tasks with two specific cases.

3.3.1 Korean News Headline Generation

To show that our approach helps supervised models in gaining deeper understanding of Korean texts, we devise a new task using news articles, which requires an understanding of the semantics of Korean texts. We collected Korean news articles published from 2017 January to February. The dataset covers balanced categories (e.g. politics, sports, world, etc.) and contains the headline title as the annotation, akin to the CNN/Daily Mail Dataset (Hermann et al., 2015). The dataset is relatively large - containing 840,205 news article and title pairs

We use the encoder-decoder architecture supported by OpenNMT (Klein et al., 2017) framework for the task, where the encoder is a bidirectional LSTM cell and the decoder is an LSTM cell (the hidden size is 512 for both) with a bridging feed-forward layer between the two RNNs. We employ soft attention (Bahdanau et al., 2014) to generate news headlines given the first three sentences of an article body. We tokenize each headline using a Korean morpheme tokenizer[4] such that decoder tokens are relatively dense. The copy mechanism (Gu et al., 2016), a popular technique of sequence-to-sequence models for translation and summarization, cannot be applied directly to our model, as the encoder tokens (space tokenized) and the decoder tokens (morpheme tokenized) do not share the same token space. Word vectors obtained from both baselines and our approach are used to initialize the encoder embeddings before the training begins. The dataset is split into training, validation, and test sets (8:1:1). We report performances on the test set after validating our training models on the validation set. We evaluate the titles generated by our models with the BLEU (Papineni et al., 2002)[5]. We also report per-word perplexity obtained from the models.

Embeddings	BLEU				PPL
	1	2	3	4	
None	26.02	7.76	3.08	1.38	5.335
SG	30.33	10.20	4.29	1.98	4.122
SISG(c)	31.34	10.96	4.69	2.19	3.942
SISG(cj)	31.78	11.17	4.80	2.25	3.938
SISG(cj)†	31.77	11.16	4.81	2.27	3.940
SISG(cjh3)	**32.03**	11.25	4.83	2.27	3.941
SISG(cjh4)	32.02	**11.34**	**4.92**	**2.30**	**3.909**

† pre-trained embeddings by Park et al. (2018)

Table 2: Korean News Headline Generation results.

As shown in Table 2, models trained with our embeddings perform better and have better language modeling capability than those trained with the previous state-of-the-art embeddings. This improvement can be partially explained by the fact that formal Korean texts, such as news articles, are more likely to contain Sino-Korean words, allowing models with awareness of Chinese to gain an edge in Korean understanding.

3.3.2 Sentiment Analysis

To estimate the performance of our approach on a different task then the previous experiment, we conduct an experiment on Naver Sentiment Movie Corpus (NSMC)[6]. This dataset consists of 200K movie reviews, each of which is labeled with its sentiment, i.e. positive or negative. We split the corpus into training (100K), validation (50K), and test sets (50K). It is worth noting that this

[4] https://github.com/shin285/KOMORAN

[5] Although ROUGE is a more widely adopted measure in English literature, no equivalent exists for Korean.

Embeddings	Model: LSTM			
	Acc.	P	R	F1
SISG(c)	77.43	75.89	80.41	78.08
SISG(cj)	**83.16**	82.36	**84.66**	**83.50**
SISG(cjh3)	81.61	81.23	82.28	81.75
SISG(cjh4)	82.25	**82.57**	81.77	82.17

Table 3: Naver Sentiment Movie Corpus results. We report accuracy (Acc.), precision (P), recall (R), and F1-score (F1) following Park et al. (2018). Each reported result is the average of several runs initialized with different random seeds.

case study is designed to figure out to what extent our embeddings are generally applicable for even cases, where most of the sentences in the dataset consist of spoken words rather than written words and often do not contain Sino-Korean words.

We utilize a basic LSTM (Hochreiter and Schmidhuber, 1997) module as a sentence encoder to exclude possible exceptional gains from sophisticated encoders, concentrating on the usefulness of input word embeddings. Likewise the previous experiment, word vectors obtained from both baselines and our approach are used as input for the encoder. We regard the last hidden state of the LSTM as the sentence representation, which is consumed by a feed-forward network followed by a softmax classifier. The dimension of the LSTM cells is fixed as 300. Each result from the baselines and our models is the average of 3 independent runs initialized with different random seeds, and the outcome of each run is chosen by the performance (F1-score) on the validation set.

From Table 3, we confirm our approach is comparable to the best previous one and general enough to be employed in most of the downstream tasks, even though the performance of our approach is somewhat unsatisfactory. While not strictly proven, we conjecture one possible reason for the unsatisfying performance is the low reliability of the Hanja tagger we leveraged, which is not guaranteed to work well with spoken language. Specifically, we have manually inspected the tagging results and observed that there are some errors which can lead to performance degradation. This observation points out a limitation of our current approach, that is, the dependence on external taggers, encouraging us to develop an integrated approach, leaving as future work not resorting to the taggers.

4 Related Work

Although the word is usually regarded as the smallest and basic unit for most NLP pipelines, there is a recent trend of utilizing subword information for enriching word representations (Sennrich et al. 2016; Bojanowski et al. 2017, to name a few), or considering subwords themselves as input directly for NLP models (Zhang et al., 2015; Kim et al., 2016; Peters et al., 2018; Devlin et al., 2018).

As Korean is agglutinative (Song, 2006), the current literature in Korean word representations mainly focus on subword structures such as morphemes (Edmiston and Stratos, 2018), syllables (Choi et al., 2017) and Jamo (Choi et al., 2016; Stratos, 2017; Park et al., 2018). We here move forward one step further by incorporating Hanja information explicitly together with the aforementioned subword information.

On the other hand, cross-lingual representations is a trending topic in literature (Lample et al. 2018; Conneau et al. 2018; Lample and Conneau 2019, to name a few). Nevertheless, to the best of our knowledge, our work is the first to introduce character-level cross-lingual transfer learning based on etymological grounds. Furthermore, the novelty of our work lies of the fact that we use separated vocabulary instead of shared vocabulary such as Byte Pair Encoding (BPE) (Sennrich et al., 2016).

5 Conclusion

We have presented a method of training Korean word representations with Hanja. In our extensive experiments, we have demonstrated that our approach is effective in infusing more semantics into Korean word embeddings. One potential issue with our method, as already mentioned, is that it relies on external Hanja annotation, even though this can be mitigated to some extent by off-the-shelf taggers, as in this work. Thus, it would be an attractive direction to take as future work developing an end-to-end system.

Abstract

Current research in knowledge-based Word Sense Disambiguation (WSD) indicates that performances depend heavily on the Lexical Knowledge Base (LKB) employed. This paper introduces SyntagNet, a novel resource consisting of manually disambiguated lexical-semantic combinations. By capturing sense distinctions evoked by syntagmatic relations, SyntagNet enables knowledge-based WSD systems to establish a new state of the art which challenges the hitherto unrivaled performances attained by supervised approaches. To the best of our knowledge, SyntagNet is the first large-scale manually-curated resource of this kind made available to the community (at http://syntagnet.org).

1 Introduction

Word Sense Disambiguation (WSD) is one of the most challenging Natural Language Processing (NLP) tasks. It deals with lexical ambiguity, and it is core to achieving the much-sought-for goal of Natural Language Understanding (Navigli, 2018). In a broad sense, two major approaches can be adopted for performing WSD: the supervised and the knowledge-based ones.

Supervised methods, which learn a classifier from training data, have improved from 65% (Snyder and Palmer, 2004) to over 71% accuracy, thus proving to perform best for WSD purposes (Yuan et al., 2016; Melacci et al., 2018; Uslu et al., 2018). However, supervision depends heavily on large quantities of reliable sense-annotated data which – especially for languages other than English – are poorly available.

As a major alternative to supervised WSD, knowledge-based approaches drop the requirement for large amounts of training data by drawing on rich Lexical Knowledge Bases (LKB) such as WordNet (Fellbaum, 1998), and allow scaling to multiple languages thanks to multilingual resources such as BabelNet (Navigli and Ponzetto, 2012). The structure of an LKB plays a key role in increasing the overall disambiguation performance. For the purposes of WSD, a critical consideration concerns the nature of the relations connecting concepts: while LKBs tend to focus on the paradigmatic dimension of language, such resources fall short in respect of syntagmatic relations[1], which are also crucial for sense disambiguation due to interconnecting co-occurring words (Navigli and Lapata, 2010).

In this paper we address this deficiency and present, for the first time, a manually-curated large-scale lexical-semantic combination[2] database which associates pairs of concepts with pairs of co-occurring words. Importantly, we prove the effectiveness of our resource by achieving the state of the art in multilingual knowledge-based WSD and by matching supervised WSD performances when integrated into an LKB made up of WordNet and the Princeton WordNet Gloss Corpus[3].

2 Related work

Several studies on knowledge-based algorithms have indicated that the LKB structure is of vital importance in determining the accuracy of sense disambiguation. In particular, it has been demonstrated that WSD performance improves

[1]A syntagmatic relation exists between two words which co-occur in spoken or written language more frequently than would be expected by chance and which have different grammatical roles in the sentences in which they occur (Saussure, 1916).

[2]Here, we will use the term "lexical combination" to refer to both lexical collocations and free word associations (without considering idiomatic expressions) and the term "lexical-semantic combination" to refer to sense-annotated lexical combinations.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3534–3540, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

dramatically when employing an LKB with a larger number of high-quality lexical-semantic relations, i.e., more connections between concepts (Boyd-Graber et al., 2006; Lemnitzer et al., 2008; Ponzetto and Navigli, 2010). During the last two decades, a certain amount of work has been carried out aimed at enriching LKBs with new lexical-semantic relations. To this end, knowledge has been (semi-)automatically extracted from large collections of data and integrated into lexical resources such as WordNet.

As far as semi-automatic approaches are concerned, Mihalcea and Moldovan (2001) conceived eXtended WordNet, a resource providing disambiguated glosses by means of a classification ensemble combined with human supervision. A set of manually disambiguated glosses, called the Princeton WordNet Gloss Corpus (PWNG), which inherently included syntagmatic content, was subsequently also made available in 2008.

The rationale behind the creation of such resources was substantiated in a knowledge-based WSD study conducted by Navigli and Lapata (2010), who hypothesized an improvement in performance by several points when enriching a semantic network with tens of lexical-semantic relations for each target word sense. To achieve this demanding goal, endeavors in the literature focused on the fully-automatic production of semantic combinations, such as those obtained by disambiguating topic signatures (Cuadros and Rigau, 2008; Cuadros et al., 2012, KnowNet and deepKnowNet) or by disentangling the concepts in ConceptNet (Chen and Liu, 2011).

More recently, Espinosa-Anke et al. (2016) aimed at automatically enriching WordNet with collocational information by leveraging the relations between sense-level embedding spaces (ColWordNet), while Simov et al. (2016) addressed the enhancement of LKBs by exploiting relations over semantically-annotated corpora as contextual information. To the same end, Simov et al. (2018) employed grammatical role embeddings to gather new syntagmatic relations.

The lack of syntagmatic information in semantic networks was also tackled by the extension of a lexical database by means of *phrasets*, i.e., sets of free combinations of words recurrently used to express a concept (Bentivogli and Pianta, 2004).

Unfortunately, due to their (semi-)automatic nature, the aforementioned resources could not inherently offer wide coverage and high precision at the same time. Compared to other resources geared towards knowledge-based WSD, the novel resource we contribute in this work features: (i) wide coverage with a broad spectrum of possible lexical combinations, and (ii) high precision thanks to being entirely manually curated.

3 SyntagNet: a wide-coverage lexical-semantic combination resource

In this Section, we present SyntagNet, a knowledge resource created starting from lexical combinations extracted from the English Wikipedia[4] and the British National Corpus (Leech, 1992, BNC), and manually disambiguated according to the WordNet 3.0 sense inventory.

3.1 Methodology

Lexical combination extraction First of all, we employed the Stanford CoreNLP pipeline (Manning et al., 2014) to extract the dependency trees[5] for all the sentences in both Wikipedia and the BNC. Then, in order to identify relevant combinations, we determined the strength of correlation between pairs of POS-tagged, lemmatized content words[6] w_1, w_2, co-occurring within a sliding window of 3 words. Each candidate pair (w_1, w_2) was weighted using Dice's coefficient multiplied by a logarithmic factor of the co-occurrence frequency:

$$score(w_1, w_2) = log_2(1 + n_{w_1 w_2}) \frac{2n_{w_1 w_2}}{n_{w_1} + n_{w_2}} \quad (1)$$

where n_{w_i} ($i \in \{1, 2\}$) is the frequency of w_i and $n_{w_1 w_2}$ is the frequency of the two words co-occurring within a window.

Three filters were then applied in order to slim down the list of pairs: (i) we filtered out English stopwords according to the Natural Language Toolkit (Loper and Bird, 2002, NLTK 3.4); (ii) we discarded combinations between verbs and verbs; (iii) we discarded combinations not linked by any of the five most frequent dependencies in our list, namely: `compound`, `dobj` (direct object), `iobj` (indirect object), `nsubj` (nominal subject) and `nmod` (nominal modifier).

Finally, we ranked the resulting lexical combination list according to the geometric mean

word 1	word 2	score	sense 1	sense 2
run_v	program_n	18.07	run_v^{19} (carry out a process or program)	program_n^{7} (a sequence of instructions)
run_v	race_n	11.55	run_v^{37} (compete in a race)	race_n^{2} (a contest of speed)
run_v	farm_n	3.50	run_v^{4} (direct or control)	farm_n^{1} (workplace with farm buildings)

Table 1: Examples of high-ranking lexical (left) and semantic (right) combinations, where each lemma's subscript and superscript indicate its part of speech and sense number, respectively, in WordNet.

between i) the logarithmic Dice scores and ii) the frequency count of a pair in a given POS tag/dependency combination. We show some examples with w_1 = run_v, together with their final correlation score in Table 1 (left).

We then repeated the whole process described above, with the following changes: i) we set a sliding window of 6 words; ii) we removed the constraint on the dependency selection; iii) we filtered out all pairs already occurring within the first list; iv) we selected only items attested in multiple English monolingual and collocation dictionaries.

Manual disambiguation We asked eight annotators to manually disambiguate the top-ranking $20,000$ lexical combinations from the first list and $58,000$ lexical combinations from the second list, i.e., to associate each word in a pair (w_1, w_2) with its most appropriate senses in WordNet (in Table 1 (right) we show the senses chosen by the annotators for the corresponding lexical combinations).

The eight annotators shared a background in linguistics (Master's Degree with a minimum C1 English proficiency level) and were well acquainted with WordNet. In order to facilitate the annotation process, we provided each annotator with a unique batch of lexical combinations in a simple interface; for each pair, the annotators visualized all the synsets for each word of the combination (along with WordNet definitions and examples), and a context of up to 25 random sentences in which the combination was extracted. The annotators were asked to input the sense numbers associated with their chosen synsets for both the words in a given pair. Since the combinations can carry different meanings depending on the context, the annotators were allowed to assign multiple senses to the same word in a given combination (e.g., judge in the "public official" sense vs. the "evaluator" sense in the (judge_n, decide_v) lexical combination).

As a further measure to ensure quality, the annotators were also asked to skip the annotation of lexical combinations (i) carrying mistakes due to the automatic parsing process, (ii) for which none of the available senses in WordNet would fit the context, (iii) reflecting idiomatic expressions, (iv) which were multi-word Named Entities.

Overall, the annotators covered $78,000$ lexical combinations ($10,218$ unique nouns and $3,786$ unique verbs for $52,432$ noun-verb relations and $25,568$ noun-noun relations), and obtained $88,019$ semantic combinations ($61,249$ noun-verb and $26,770$ noun-noun semantic relations) linking $20,626$ WordNet 3.0 nodes, i.e., unique synsets ($14,204$ noun synsets and $6,422$ verb synsets), with a relation edge.

We periodically timed the annotators by considering the number of annotations produced on a daily basis, obtaining an average value of 42 disambiguated combinations per hour (1 minute and 26 seconds per word pair). Overall, the annotation process took a period of 9 months.

To determine the reliability of the annotations, we calculated the minimum inter-annotator agreement between pairs of annotators on a random sample of 500 combinations. For each of the 500 lexical combinations used to compute the inter-annotator agreement, the annotators were exceptionally asked to disambiguate the two target words in all of the 25 sentences provided, thus leading to a figure of 25,000 single instances disambiguated per annotator, resulting in a substantial agreement ($\kappa = 0.71$). Moreover, we found that most of the disagreement instances arose out of valid alternative tags, rather than factual errors, due to the fine granularity of the WordNet sense inventory.

4 Experimental setup

We now present the setup of our evaluation, carried out to assess the effectiveness of SyntagNet when employed for knowledge-based WSD.

Disambiguation algorithm We performed our experiments employing UKB[7] (Agirre et al., 2014), a state-of-the-art system for knowledge-based WSD, which applies the Personalized Page Rank (PPR) algorithm (Haveliwala, 2002) to an

Table 2: F1 scores (%) for English all-words fine-grained WSD (left) and for multilingual all-words fine-grained WSD (right). Each row displays results scored by a specific resource combined with the WNG (WordNet+PWNG) baseline. Statistically-significant differences, according to a χ^2 test ($p < 0.01$), compared to the baseline (first row), are underlined. The second column reports the number of relations of the added resource.

input LKB. We used its *PPRw2w* single-sentence context disambiguation method, which initializes the PPR vector using the context of the target word in a given sentence, while excluding the contribution of the target word itself.

Evaluation benchmarks and measures We used five test sets standardized with WordNet 3.0 (Raganato et al., 2017a) including the English all-words tasks from Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013) and SemEval-2015 (Moro and Navigli, 2015). To run experiments on multilingual WSD, we used the last two of the foregoing datasets, which also include German, Spanish, French and Italian, employing, as sense inventory, the synset lexicalizations provided in BabelNet 4.0[8]. As customary, we computed precision, recall and F1, which in our case coincided, due to UKB always outputting a sense for each target word.

LKBs For the purposes of our evaluation we measured the performance obtained with UKB when combined with different LKBs. As our baseline we used WordNet + PWNG, which is the best configuration of UKB according to its authors. We also evaluated the following LKBs when integrated separately on top of our baseline: (i) the best configurations of KnowNet[9] and deepKnowNet[10], (ii) the subgraph of BabelNet 4.0 induced by WordNet 3.0, (iii) eXtended WordNet[11], (iv) ColWordNet[12], (v) SyntagNet (cf. Section 2).

All of the aforementioned LKBs (whose size in terms of lexical-semantic relations is shown in Table 2 (second column)) are available for download.

5 Experimental results

English WSD As shown in Table 2 (left), SyntagNet enabled UKB to achieve the best results in the English all-words disambiguation tasks, attaining 4.4 overall points above the WNG baseline, which is the only statistically-significant improvement across LKBs. Furthermore, results for the individual datasets exhibit statistically-significant improvements over the baseline on two out of five datasets. We attribute this result to the fully manual nature of SyntagNet, in contrast to the noisy character of the other LKBs. A further justification of our results comes from an analysis we performed on relation samples from the various LKBs: we collected 500 random relations for each LKB we experimented with, and manually tagged each of them as syntagmatic or paradigmatic, revealing that their syntagmatic contribution ranges from 39% (deepKnowNet) to 54% (eXtended WordNet). The fully syntagmatic nature of SyntagNet, instead, effectively blends in with the complementary information available in the baseline (63% of the relations in WNG are paradigmatic).

Table 3 compares UKB + SyntagNet against the best supervised English WSD systems (Yuan et al., 2016; Melacci et al., 2018; Uslu et al., 2018): none of the differences across datasets between the best performing supervised system and SyntagNet is statistically significant according to a χ^2 test ($p < 0.01$), meaning that SyntagNet enables knowledge-based WSD to rival current supervised approaches.

Table 4: F1 scores (%) of UKB+SyntagNet against the best systems for multilingual all-words WSD. Reported systems: † Raganato et al. (2017b), ⋆ Gutiérrez Vázquez et al. (2010), ○ Pasini and Navigli (2017), ◇ Manion (2015), ‡ result obtained by aggregating the outputs of the best systems for each dataset. Statistically-significant differences against our results are underlined according to a χ^2 test, $p < 0.01$.

Multilingual WSD As regards our multilingual evaluation, SyntagNet enabled UKB to attain the best overall result (see Table 2 (right)), which is a statistically-significant improvement of 2.1 points over the baseline. With respect to the comparison against the best systems (Table 4), SyntagNet provides a statistically-relevant boost of 4.6 points in relation to the aggregate score of the compared systems (second to last row), attaining state-of-the-art results on five out of the six datasets taken into account.

5.1 Impact of LKB size

Finally, we graphed the increase in WSD performance obtained when progressively enriching the baseline UKB graph with random samples of 10,000 SyntagNet relations at each step. As illustrated in Figure 1, the improvements in the English and multilingual settings, respectively, present a growing trend according to a linear regression analysis of the data. This demonstrates that our relations are high-quality and effective for WSD, while leaving room for further improvement as more relations are added in the future.

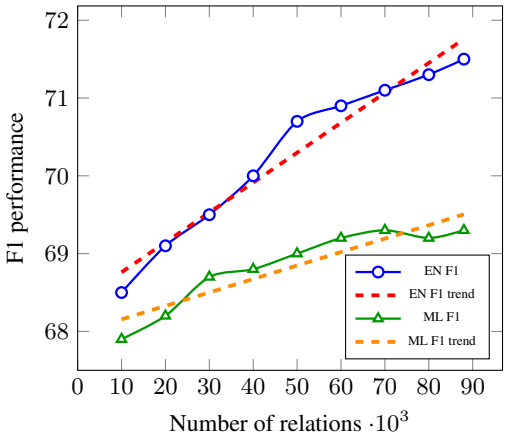

Figure 1: Impact of growing samples of SyntagNet over the baseline on overall F1 for English (EN F1 line) and multilingual (ML F1 line) evaluation datasets.

6 Conclusions

In this paper we put forward two main contributions: 1) we presented SyntagNet (http://syntagnet.org), a new wide-coverage, manually-curated resource of lexical-semantic combinations; 2) we showed that SyntagNet enables state-of-the-art knowledge-based WSD, rivaling the best supervised system on English and surpassing the overall performance of the best multilingual systems by 4.6 points. As future work, we plan to: i) enrich SyntagNet with more combinations, so as to surpass supervised English WSD; ii) include information from adjectives; iii) establish a common evaluation framework to compare the contribution of lexical-semantic combination resources; iv) employ and assess SyntagNet in other NLP tasks, such as word and sense similarity (Navigli and Martelli, 2019) or Semantic Role Labeling (where a newly released WordNet-linked resource, VerbAtlas (Di Fabio et al., 2019), would greatly benefit from collocational information).

pascale@ece.ust.hk

Abstract

In countries that speak multiple main languages, mixing up different languages within a conversation is commonly called *code-switching*. Previous works addressing this challenge mainly focused on word-level aspects such as word embeddings. However, in many cases, languages share common subwords, especially for closely related languages, but also for languages that are seemingly irrelevant. Therefore, we propose *Hierarchical Meta-Embeddings* (HME) that learn to combine multiple monolingual word-level and subword-level embeddings to create language-agnostic lexical representations. On the task of Named Entity Recognition for English-Spanish code-switching data, our model achieves the state-of-the-art performance in the multilingual settings. We also show that, in cross-lingual settings, our model not only leverages closely related languages, but also learns from languages with different roots. Finally, we show that combining different subunits are crucial for capturing code-switching entities.

1 Introduction

Code-switching is a phenomenon that often happens between multilingual speakers, in which they switch between their two languages in conversations, hence, it is practically useful to recognize this well in spoken language systems (Winata et al., 2018a). This occurs more often for entities such as organizations or products, which motivates us to focus on the specific problem of Named Entity Recognition (NER) in code-switching scenarios. We show one of the examples as the following:

- *walking dead* le quita el apetito a cualquiera
- **(translation)** *walking dead* (a movie title) takes away the appetite of anyone

For this task, previous works have mostly focused on applying pre-trained word embeddings from each language in order to represent noisy mixed-language texts, and combine them with character-level representations (Trivedi et al., 2018; Wang et al., 2018; Winata et al., 2018b). However, despite the effectiveness of such word-level approaches, they neglect the importance of subword-level characteristics shared across different languages. Such information is often hard to capture with word embeddings or randomly initialized character-level embeddings. Naturally, we can turn towards subword-level embeddings such as FastText (Grave et al., 2018) to help this task, which will evidently allow us to leverage the morphological structure shared across different languages.

Despite such expected usefulness, there has not been much attention focused around using subword-level features in this task. This is partly because of the non-trivial difficulty of combining different language embeddings in the subword space, which arises from the distinct segmentation into subwords for different languages. This leads us to explore the literature of Meta-Embeddings (Yin and Schütze, 2016; Muromägi et al., 2017; Bollegala et al., 2018; Coates and Bollegala, 2018; Kiela et al., 2018; Winata et al., 2019), which is a method to learn how to combine different embeddings.

In this paper, we propose **Hierarchical Meta-Embeddings (HME)** [1] which learns how to combine different pre-trained monolingual embeddings in word, subword, and character-level into a single language-agnostic lexical representation without using specific language identifiers. To address the issue of different segmentations, we add a Transformer (Vaswani et al., 2017) encoder

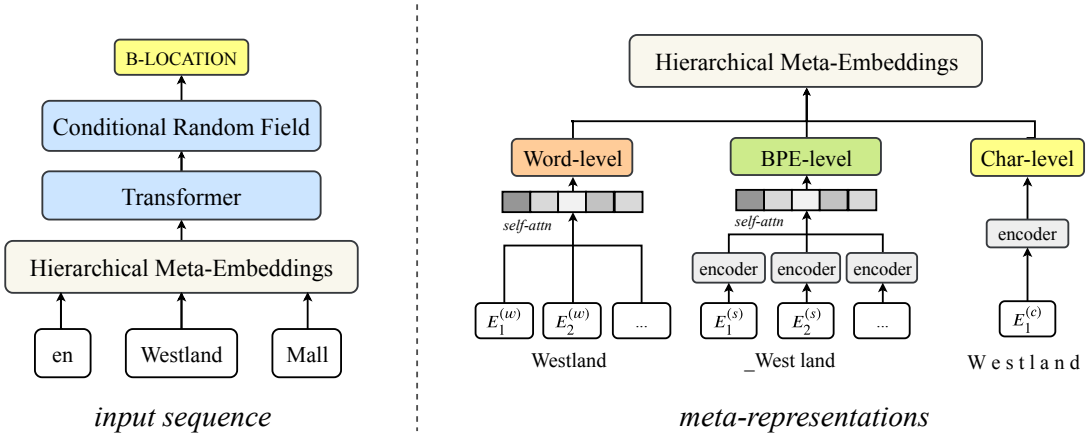

Figure 1: Hierarchical Meta-Embeddings (HME) architecture for Named Entity Recognition (NER) task. **Left:** Transformer-CRF architecture for Named Entity Recognition. **Right:** HME accept words, BPEs, and characters inputs.

which learns the important subwords in a given sentence. We evaluate our model on the task of Named Entity Recognition for English-Spanish code-switching data, and we use **Transformer-CRF**, a transformer-based encoder for sequence labeling based on the implementation of Winata et al. (2019). Our experimental results confirm that HME significantly outperforms the state-of-the-art system in *absolute F1 score*. The analysis shows that in the task of English-Spanish mixed texts not only similar languages like Portuguese or Catalan help, but also seemingly distant languages from Celtic origin also significantly increase the performance.

2 Related Work

Embeddings Previous works have extensively explored different representations such as word (Mikolov et al., 2013; Pennington et al., 2014; Grave et al., 2018; Xu et al., 2018), subword (Sennrich et al., 2016; Heinzerling and Strube, 2018), and character (dos Santos and Zadrozny, 2014; Wieting et al., 2016). Lample et al. (2016) has successfully concatenated character and word embeddings to their model, showing the potential of combining multiple representations. Liu et al. (2019) proposed to leverage word and subword embeddings into the application of unsupervised machine translation.

Meta-embeddings Recently, there are studies on combining multiple word embeddings in pre-processing steps (Yin and Schütze, 2016; Muromägi et al., 2017; Bollegala et al., 2018; Coates and Bollegala, 2018). Later, Kiela et al. (2018) introduced a method to dynamically learn word-level meta-embeddings, which can be effectively used in a supervised setting. Winata et al. (2019) proposed an idea to leverage multiple embeddings from different languages to generate language-agnostic meta-representations for mixed-language data.

3 Hierarchical Meta-Embeddings

We propose a method to combine word, subword, and character representations to create a mixture of embeddings. We generate a multilingual meta-embeddings of word and subword, and then, we concatenate them with character-level embeddings to generate final word representations, as shown in Figure 1. Let $\mathbf{w}$ be a sequence of words with n elements, where $\mathbf{w} = [w_1, \ldots, w_n]$. Each word can be tokenized into a list of subwords $\mathbf{s} = [s_1, \ldots, s_m]$ and a list of characters $\mathbf{c} = [c_1, \ldots, c_p]$. The list of subwords $\mathbf{s}$ is generated using a function f; $\mathbf{s} = f(\mathbf{w})$. Function f maps a word into a sequence of subwords. Further, let $E^{(w)}$, $E^{(s)}$, and $E^{(c)}$ be a set of word, subword, and character embedding lookup tables. Each set consists of different monolingual embeddings. Each element is transformed into a embedding vector in $\mathbb{R}^d$. We denote subscripts ${}_{\{i,j\}}$ as element and embedding language index, and superscripts ${}^{(w,s,c)}$ as word, subword, and character.

3.1 Multilingual Meta-Embeddings (MME)

We generate a meta-representations by taking the vector representation from multiple monolingual pre-trained embeddings in different subunits such

as word and subword. We apply a **projection matrix** $\mathbf{W}_j$ to transform the dimensions from the original space $\mathbf{x}_{i,j} \in \mathbb{R}^d$ to a new shared space $\mathbf{x'}_{i,j} \in \mathbb{R}^{d'}$. Then, we calculate **attention weights** $\alpha_{i,j} \in \mathbb{R}^{d'}$ with a non-linear scoring function ϕ (e.g., tanh) to take important information from each individual embedding $\mathbf{x'}_{i,j}$. Then, MME is calculated by taking the weighted sum of the projected embeddings $\mathbf{x'}_{i,j}$:

$$\mathbf{x'}_{i,j} = \mathbf{W}_j \cdot \mathbf{x}_{i,j}, \tag{1}$$

$$\alpha_{i,j} = \frac{\exp(\phi(\mathbf{x'}_{i,j}))}{\sum_{k=1}^{n} \exp(\phi(\mathbf{x'}_{i,k}))}, \tag{2}$$

$$\mathbf{u}_i = \sum_{j=1}^{n} \alpha_{i,j} \mathbf{x'}_{i,j}. \tag{3}$$

3.2 Mapping Subwords and Characters to Word-Level Representations

We propose to map subword into word representations and choose byte-pair encodings (BPEs) (Sennrich et al., 2016) since it has a compact vocabulary. First, we apply f to segment words into sets of subwords, and then we extract the pre-trained subword embedding vectors $\mathbf{x}^{(s)}_{i,j} \in \mathbb{R}^d$ for language j.

Since, each language has a different f, we replace the projection matrix with Transformer (Vaswani et al., 2017) to learn and combine important subwords into a single vector representation. Then, we create $\mathbf{u}^{(s)}_i \in \mathbb{R}^{d'}$ which represents the subword-level MME by taking the weighted sum of $\mathbf{x'}^{(s)}_{i,j} \in \mathbb{R}^{d'}$.

$$\mathbf{x'}^{(s)}_{i,j} = \text{Encoder}(\mathbf{x}^{(s)}_{i,j}), \tag{4}$$

$$\mathbf{u}^{(s)}_i = \sum_{j=1}^{n} \alpha_{i,j} \mathbf{x'}^{(s)}_{i,j}. \tag{5}$$

To combine character-level representations, we apply an encoder to each character.

$$\mathbf{u}^{(c)}_i = \text{Encoder}(\mathbf{x}_i) \in \mathbb{R}^{d'}. \tag{6}$$

We combine the word-level, subword-level, and character-level representations by concatenation $\mathbf{u}^{HME}_i = (\mathbf{u}^{(w)}_i, \mathbf{u}^{(s)}_i, \mathbf{u}^{(c)}_i)$, where $\mathbf{u}^{(w)}_i \in \mathbb{R}^{d'}$ and $\mathbf{u}^{(s)}_i \in \mathbb{R}^{d'}$ are word-level MME and BPE-level MME, and $\mathbf{u}^{(c)}_i$ is a character embedding. We randomly initialize the character embedding and keep it trainable. We fix all subword and word pre-trained embeddings during the training.

3.3 Sequence Labeling

To predict the entities, we use Transformer-CRF, a transformer-based encoder followed by a Conditional Random Field (CRF) layer (Lafferty et al., 2001). The CRF layer is useful to constraint the dependencies between labels.

$$h = \text{Transformer}(\mathbf{u}), h' = \text{CRF}(h). \tag{7}$$

The best output sequence is selected by a forward propagation using the Viterbi algorithm.

4 Experiments

4.1 Experimental Setup

We train our model for solving Named Entity Recognition on English-Spanish code-switching tweets data from Aguilar et al. (2018). There are nine entity labels with IOB format. The training, development, and testing sets contain 50,757, 832, and 15,634 tweets, respectively.

We use FastText word embeddings trained from Common Crawl and Wikipedia (Grave et al., 2018) for English (*es*), Spanish (*es*), including **four Romance languages**: Catalan (*ca*), Portuguese (*pt*), French (*fr*), Italian (*it*), and **a Germanic language**: German (*de*), and **five Celtic languages** as the distant language group: Breton (*br*), Welsh (*cy*), Irish (*ga*), Scottish Gaelic (*gd*), Manx (*gv*). We also add the English Twitter GloVe word embeddings (Pennington et al., 2014) and BPE-based subword embeddings from Heinzerling and Strube (2018).

We train our model in two different settings: **(1) multilingual setting**, we combine main languages (*en-es*) with Romance languages and a Germanic language, and **(2) cross-lingual setting**, we use Romance and Germanic languages without main languages. Our model contains four layers of transformer encoders with a hidden size of 200, four heads, and a dropout of 0.1. We use Adam optimizer and start the training with a learning rate of 0.1 and an early stop of 15 iterations. We replace user hashtags and mentions with `<USR>`, emoji with `<EMOJI>`, and URL with `<URL>`. We evaluate our model using *absolute F1 score* metric.

4.2 Baselines

CONCAT We concatenate word embeddings by merging the dimensions of word representations. This method combines embeddings into a high-dimensional input that may cause inefficient com-

putation.

$$\mathbf{x}_i^{CONCAT} = [\mathbf{x}_{i,1}, ..., \mathbf{x}_{i,n}]. \quad (8)$$

LINEAR We sum all word embeddings into a single word vector with equal weight. This method combines embeddings without considering the importance of each of them.

$$\mathbf{x}_i^{LINEAR} = \sum_{j=0}^{n} \mathbf{x'}_{i,j}. \quad (9)$$

Random Embeddings We use randomly initialized word embeddings and keep it trainable to calculate the lower-bound performance.

Aligned Embeddings We align English and Spanish FastText embeddings using CSLS with two scenarios. We set English (en) as the source language and Spanish (es) (en → es) as the target language, and vice versa (es → en). We run MUSE by using the code prepared by the authors of Conneau et al. (2017). [2]

5 Results & Discussion

In general, from Table 1, we can see that word-level meta-embeddings even without subword or character-level information, consistently perform better than flat baselines (e.g., CONCAT and LINEAR) in all settings. This is mainly because of the attention layer which does not require additional parameters. Furthermore, comparing our approach to previous state-of-the-art models, we can clearly see that our proposed approaches all significantly outperform them.

From Table 1, in Multilingual setting, which trains with the main languages, it is evident that adding both closely-related and distant language embeddings improves the performance. This shows us that our model is able to leverage the lexical similarity between the languages. This is more distinctly shown in Cross-lingual setting as using distant languages significantly perform less than using closely-related ones (e.g., *ca-pt*). Interestingly, for distant languages, when adding subwords, we can still see a drastic performance increase. We hypothesize that even though the characters are mostly different, the lexical structure is similar to our main languages.

On the other hand, adding subword inputs to the model is consistently better than characters. This is due to the transfer of the information from the pre-trained subword embeddings. As shown in Ta-

[2] https://github.com/facebookresearch/MUSE

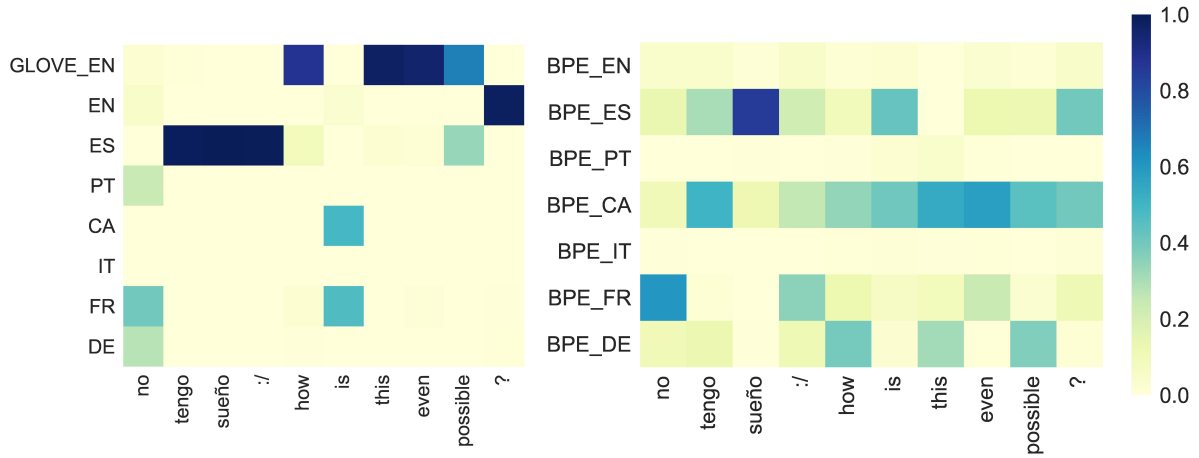

Figure 2: Heatmap of attention over languages from a validation sample. **Left**: word-level MME, **Right**: BPE-level MME. We extract the attention weights from a multilingual model (*en-es-ca-pt-de-fr-it*).

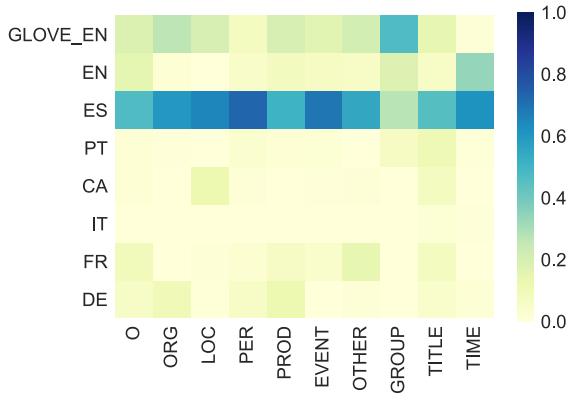

Figure 3: The average of attention weights for word embeddings versus NER tags from the validation set.

ble 1, subword embeddings is more effective for distant languages (Celtic languages) than closely-related languages such as Catalan or Portuguese.

Moreover, we visualize the attention weights of the model in word and subword-level to interpret the model dynamics. From the left image of Figure 2, in word-level, the model mostly chooses the correct language embedding for each word, but also combines with different languages. Without any language identifiers, it is impressive to see that our model learns to attend to the right languages. The right side of Figure 2, which shows attention weight distributions for subword-level, demonstrates interesting behaviors, in which for most English subwords, the model leverages *ca*, *fr*, and *de* embeddings. We hypothesize this is because the dataset is mainly constructed with Spanish words, which can also be verified from Figure 3 in which most NER tags are classified as *es*.

6 Conclusion

We propose *Hierarchical Meta-Embeddings* (HME) that learns how to combine multiple monolingual word-level and subword-level embeddings to create language-agnostic representations without specific language information. We achieve the state-of-the-art results on the task of Named Entity Recognition for English-Spanish code-switching data. We also show that our model can leverage subword information very effectively from languages from different roots to generate better word representations.

Abstract

In this paper, we develop a novel Sparse Self-Attention Fine-tuning model (referred as SSAF) which integrates sparsity into self-attention mechanism to enhance the fine-tuning performance of BERT. In particular, sparsity is introduced into the self-attention by replacing softmax function with a controllable sparse transformation when fine-tuning with BERT. It enables us to learn a structurally sparse attention distribution, which leads to a more interpretable representation for the whole input. The proposed model is evaluated on sentiment analysis, question answering, and natural language inference tasks. The extensive experimental results across multiple datasets demonstrate its effectiveness and superiority to the baseline methods.

1 Introduction

Recently, the pre-trained language models obtain new state-of-the-art results on a broad range of tasks, for example ULMFiT (Howard and Ruder, 2018), ELMo (Peters et al., 2018), and OpenAI GPT (Radford et al., 2018). Devlin et al. (2018) proposed BERT, a deep bidirectional language representation model which substantially outperforms the previous methods and has attracted wide attention in natural language processing. Fine-tuning on the pre-trained BERT has shown to be beneficial to improve many downstream tasks such as document classification (Adhikari et al., 2019), extractive summarization (Liu, 2019), question answering (Yang et al., 2019), natural language inference (Liu et al., 2019), and reading comprehension (Xu et al., 2019).

To further understand the impact of BERT on the fine-tuning performance, we exploit the attention behavior of the model when fine-tuning BERT in sentiment analysis task. In particular, the attention matrices of models with different setups are visualized in Figure 1. As shown in Figure 1(b), the attention distribution of fine-tuning with BERT is close to being a band matrix, with interest concentrated on small regions near the diagonal. Compared to the model trained from scratch without pre-training (Figure 1(a)), more interpretability would be provided by fine-tuning with BERT due to its structural attention distribution. This difference in the distributions might be caused by the masked language model task of BERT, where the model is required to predict the original vocabu-

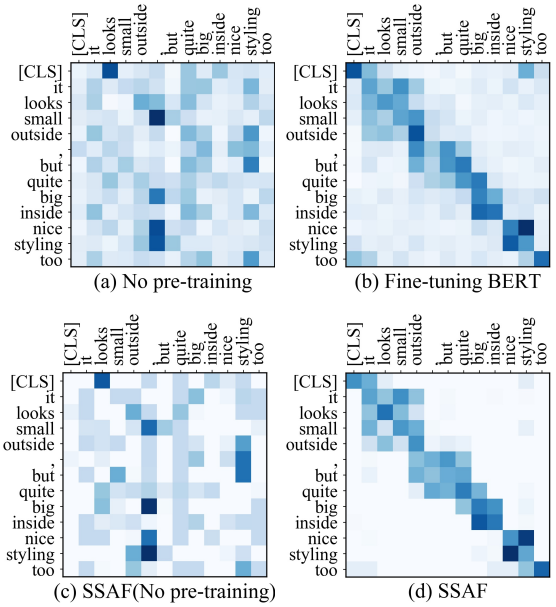

Figure 1: The explorations of attention behavior for four models: No pre-training, Fine-tuning BERT, SSAF(No pre-training), and SSAF. All the attention matrices are extracted from the eighth attention layer of the model for the sentence in Sentube-A dataset. Words on the y-axis are attending to the words on the x-axis. The attention distribution in SSAF presents more structurally sparse patterns compared to the others.

lary id of the masked token based on its context. Consequently, the local interactions among different words are strengthened and play more important roles in predicting the masked token. Such modeling makes the learned representation more expressive for a diversity of tasks. However, the current fine-tuning models usually employ the pre-trained BERT as initialization of the networks and do not pay enough attention on how to dynamically control this attention distribution to be structurally sparse during fine-tuning process, which might further help improve the interpretability of the framework.

To overcome the above limitation, in this work, we develop a novel Sparse Self-Attention Fine-tuning model (referred as SSAF) by integrating sparsity into self-attention to refine the attention distribution when fine-tuning the pre-trained BERT. Specifically, we propose sparse self-attention mechanism (SSAM) to induce sparsity by replacing the traditional softmax function with a sparse transformation in self-attention networks. Instead of covering all the connections built between different words as the original fine-tuning model, the sparsity is designed to promote the most essential relationships among them with higher attention weights, and meanwhile eliminate the influence from meaningless relations by truncating their probabilities to exactly 0. As presented in Figure 1(d), more sparse attention structure are obtained by SSAF through fine-tuning BERT with sparsity constraint. Even without the pre-training, the sparse self-attention networks (SSAF No pre-training) also behaves better than the traditional self attention version in respect to sparsity, which is shown in Figure 1(c). As a generic module, SSAM is flexible to be applied to neural network models in a wide variety of tasks.

Extensive experiments are conducted on three NLP tasks to investigate the performances of SSAF, which include sentiment analysis, question answering, and natural language inference. Evaluation results on seven public datasets show that the proposed approach achieves remarkable improvements over other competing models.

2 Fine-tuning with Sparse Self-Attention

In this section, we first clarify the traditional self-attention model, then present a sparse self-attention mechanism, which extends the self-attention by replacing the standard softmax function with a sparse transformation, and finally develop a sparse self-attention fine-tuning model.

2.1 Self-attention mechanism

We start by introducing self-attention mechanism, which is the foundation of Transformer encoder (Vaswani et al., 2017) as well as BERT. Self-attention networks is capable of directly relating tokens at different positions from the sequence by computing the attention score (relevance) between each pair of tokens.

Formally, given an input sequence $\mathbf{x} = (x_1, \cdots x_L)$, the output representation $\mathbf{y} = (y_1, \cdots y_L)$ is constructed by applying weighted sum of transformations of the input elements $\mathbf{x}$ based on the relevance, where the elements $\{x_i, y_i\} \in \mathbb{R}^d$. The i-th output y_i is computed as:

$$y_i = \sum_{j=1}^{L} \alpha_{ij}(x_j W_v) \tag{1}$$

$$e_{ij} = \frac{(x_i W_q)(x_j W_k)^T}{\sqrt{d}}, \alpha_{ij} = \rho(e_{ij}) \tag{2}$$

where $W_q \in \mathbb{R}^{d\times d}$, $W_k \in \mathbb{R}^{d\times d}$, and $W_v \in \mathbb{R}^{d\times d}$ denote the trainable parameter matrices. ρ is a probability mapping function. The resulting attention weight α_{ij} represents the relevance between the i-th and j-th input element.

The classical choice for ρ is the softmax transformation, which is calculated as:

$$\rho(e_{ij}) = \text{softmax}(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{t=1}^{L} \exp(e_{it})} \tag{3}$$

However, since softmax function is strictly positive, it produces attention distribution with full support. This results in the dense dependencies between each pair of words and fails to assign exactly zero probability to less meaningful relationships. Further, putting nonzero weight on every relationship would also degrade the interpretability. With such softmax transformation, the self-attention networks does not pay more attention to those important connections while also being easily disturbed by many unrelated words.

2.2 Sparse Self-Attention Mechanism

To address this problem, we employ sparsegen-lin transformation (Laha et al., 2018) to replace softmax in Equation 3, which not only leads to a sparse probability distribution but also offers an explicit control over the degree of sparsity.

Sparsegen-lin formulation projects the attention scores $\mathbf{e}_i = (e_{i1}, e_{i2}, \cdots e_{iL})$ onto the probability

simplex $\mathbf{p}_i$ and introduces coefficient $\lambda < 1$ to influence the regularization strength:

$$\rho(\mathbf{e}_i) = \underset{\mathbf{p}_i \in \Delta^{L-1}}{\operatorname{argmin}} \left\{ ||\mathbf{p}_i - \mathbf{e}_i||^2 - \lambda ||\mathbf{p}_i||^2 \right\} \quad (4)$$

where $\Delta^{L-1} := \left\{ \mathbf{p}_i \in \mathbb{R}^L | \sum_{j=1}^{L} p_{ij} = 1, \mathbf{p}_i \geq 0 \right\}$. The sparse attention distribution is then computed as follows:

$$\rho(e_{ij}) = p_{ij} = \max \left\{ 0, \frac{e_{ij} - \tau(\mathbf{e}_i)}{1 - \lambda} \right\} \quad (5)$$

where $j \in \{1, \cdots L\}$ and $\tau : \mathbb{R}^L \rightarrow \mathbb{R}$ is the threshold function.

More specifically, let $e_{i(1)} \geq e_{i(2)} \geq \cdots \geq e_{i(L)}$ be the sorted attention scores of $\mathbf{e}_i$ and $k(\mathbf{e}_i) := \max \left\{ k \in \{1, \cdots, L\} | 1 - \lambda + k e_{i(k)} > \sum_{j \leq k} e_{i(j)} \right\}$. The threshold $\tau(\mathbf{e}_i)$ is obtained as:

$$\begin{aligned} \tau(\mathbf{e}_i) &= \frac{(\sum_{j \leq k(\mathbf{e}_i)} e_{i(j)}) - 1 + \lambda}{k(\mathbf{e}_i)} \\ &= \frac{(\sum_{j \in S(\mathbf{e}_i)} e_{ij}) - 1 + \lambda}{|S(\mathbf{e}_i)|} \end{aligned} \quad (6)$$

where $S(\mathbf{e}_i)$ is the support of $\rho(\mathbf{e}_i)$, i.e., a set of the indices of nonzero coordinates. As in Equation 5, all the coordinates in the $S(\mathbf{e}_i)$ will be modified, and the others will be truncated to zero, thus providing a sparse solution. The choice of λ helps control the cardinality of the support set $S(\mathbf{e}_i)$ which influences the sparsity of attention distribution.

By introducing sparsity to refine the attention weight, our sparse self-attention mechanism (SSAM) strengthens the most important relations among different words such as local interactions, and assigns zero probability to those meaningless connections. This enables us to achieve a more expressive representation for the whole input.

2.3 Sparse Self-Attention Fine-tuning model

In this part, we propose a sparse self-attention fine-tuning model (SSAF). In particular, this fine-tuning model with BERT is composed of N sparse self-attention layers, where each layer learns a representation by taking the output from the previous layer:

$$\tilde{\mathbf{h}}^n = \text{LN}(\mathbf{h}^{n-1} + \text{SSAM}(\mathbf{h}^{n-1})) \quad (7)$$

$$\mathbf{h}^n = \text{LN}(\tilde{\mathbf{h}}^n + \text{FFN}(\tilde{\mathbf{h}}^n)) \quad (8)$$

where SSAM is adopted to replace the traditional self-attention mechanism, $\mathbf{h}^0 = \text{embed}(\mathbf{x})$ denotes the representation for the input sequence $\mathbf{x}$ which is the sum of token embeddings and the position embeddings, and LN is the layer normalization operation.

Relationships with existing methods Although several sparse formulations have been developed in the literature such as sparsemax (Martins and Astudillo, 2016), fusedmax (Niculae and Blondel, 2017), and constrained sparsemax (Malaviya et al., 2018), they are mostly applied in the classification layer or in the attention-based encoder-decoder architecture. Instead, in this work, we introduce sparsity into self-attention based transformer encoder. Other than concentrating on words as the existing approaches do, we take the advantage of sparsity to identify the most essential relationships among words to capture a better sequence representation. Further, more interpretability would be obtained by our method due to the structurally sparse attention distribution.

3 Experiments

In the following sections, we empirically evaluate the effectiveness of SSAF for three NLP tasks on seven public datasets.

3.1 Datasets

Sentiment Analysis (SA) The goal of sentiment analysis is to determine the sentiment classification of a piece of text. Accuracy is used as the evaluation metric. We evaluate our model on five datasets in this task, which are listed as follows. 1) SST-1: The Stanford Sentiment Treebank (Socher et al., 2013) consists of sentences extracted from movie reviews with five classes. We follow the previous works (Kim, 2014; Gong et al., 2018) to train the model on both phrase and sentence level; 2) SST-2: This dataset is constructed from the same data with SST-1 but without the neutral reviews. We adopt the dataset version provided by GLUE (Wang et al., 2018); 3) SemEval: The SemEval 2013 Twitter dataset (Nakov et al., 2013) contains tweets with three classes: positive, negative, and neutral; 4) Sentube-A, Sentube-T: The SenTube datasets (Uryupina et al., 2014) are texts obtained from YouTube comments with two sentiment classes: positive and negative.

Question Answering (QA) This task is to predict the answer text span in the paragraph according to the question. We adopt the SQuAD v1.1 dataset (Rajpurkar et al., 2016). Since $\text{BERT}_{\text{BASE}}$ is re-

Corpus	Task	Train	Dev.	Test	Class
SST-1	SA	8.5k	1.1k	2.2k	5

SSAF	**56.2**	**94.7**	**72.4**	**75.0**	**77.3**

Table 2: Experimental results of classification accuracy for different methods with five datasets on sentiment analysis task.

ported on the development set of SQuAD in Devlin et al. (2018), we follow them to evaluate our model on the same set. The Exact Match (EM) and F1 are two evaluation metrics.

Natural Language Inference (NLI) The task involves assessing if two sentences entail or contradict each other. We use SciTail dataset (Khot et al., 2018) which is derived from a science question answering (SciQ) dataset. The evaluation metric is accuracy.

Further statistics about datasets are illustrated in Table 1.

3.2 Implementation details

We adopt the pre-trained $\text{BERT}_{\text{BASE}}$ [1] as the basis for our experiments. We choose $\text{BERT}_{\text{BASE}}$ in our work rather than another larger pre-trained model $\text{BERT}_{\text{LARGE}}$ due to the resource limitations and computation cost. The coefficient λ which controls the sparisty in Equation 4 is set to -3 in SST-1 and SemEval, -4 in SST-2 and SenTube-T, -6 in SenTube-A and SciTail, and -7 in SQuAD. We investigate the influence of different λ settings in the experiment analysis part. We adopt Adam as our optimizer with a learning rate of 2e-5 and batch size is 16. The maximum number of training epoch is 2 for SQuAD, 3 for SciTail, 4 for SST-1 and SST-2, 5 for SenTube-A, 6 for SenTube-T, and 8 for SemEval.

3.3 Baselines

To demonstrate that SSAF truly improves the fine-tuning performance, we compare SSAF against $\text{BERT}_{\text{BASE}}$ from (Devlin et al., 2018) on all the tasks. In particular, for sentiment analysis, we follow (Ambartsoumian and Popowich, 2018) to make comparisons with the following representative methods: Ave, LSTM, BiLSTM, and CNN from (Barnes et al., 2017); SSAN from (Ambartsoumian and Popowich, 2018). We report the results of these five models with Google 300-dimensional word2vec embeddings [2] on all datasets. For SST-1 and SST-2, we reproduce the compared methods according to the different dataset version.

For thorough comparison, besides the approaches proposed in the existing literature, we further implement another two models to verify the ability of sparse self-attention mechanism:

No pre-training (Np): It has the same architecture as $\text{BERT}_{\text{BASE}}$ but without pre-training.

SSAF(Np): We train SSAF from scratch only with the sparse self-attention module.

3.4 Results

The experimental results on sentiment analysis are reported in Table 2, and the performances on question answering and natural language inference are summarized in Table 3. Results show that SSAF achieves the best performance across all three tasks with a significant improvement over the previous approaches.

Compared with other competing methods in the experiments, $\text{BERT}_{\text{BASE}}$ provides a strong baseline owing to the pre-training procedure. However, this model still suffers from its inefficiency by taking all the relationships between each pair of words into consideration when constructing the representation. Our model outperforms $\text{BERT}_{\text{BASE}}$ by a stable margin especially in SST-2, SenTube-A, SenTube-T, and SciTail, with the improvements of 1.2%, 2.1%, 1.7%, and 1.5%,

Models	SQuAD		SciTail
	EM	F1	Accuracy
Np	65.3	74.1	78.6
SSAF(Np)	66.2	74.6	78.9
$\text{BERT}_{\text{BASE}}$	80.8	88.5	92.0
SSAF	**81.6**	**88.8**	**93.5**

Table 3: Experimental results on question answering and natural language inference tasks.

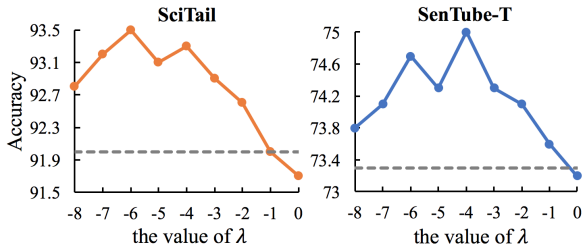

Figure 2: Experimental results on varying the coefficient λ for SSAF in SciTail and SenTube-T datasets. Grey dash line denotes the result of $\text{BERT}_{\text{BASE}}$.

respectively. Meanwhile, even without the pre-training, SSAF(No pre-training) still surpasses No pre-training across the board which clearly proves the effectiveness and universality of incorporating sparsity into self-attention model. Combining the strength of sparsity and the pre-trained language model, SSAF stands out in performance with other baselines.

Moreover, we study how the value of coefficient λ in SSAF affects the fine-tuning performance. We explore different settings from -8 to 0. Figure 2 shows the comparison results on the test set of SciTail and SenTube-T. Results summarize that $\lambda = -6$ is superior to other settings for SciTail and the performance on SenTube-T reaches the best when λ is set to -4. According to the experimental results above, we could found that on both of the datasets, the values from -7 to -3 can reach comparable performance while both larger and smaller values are more likely to decrease the accuracy to some extent though they still outperform previous work by a large margin. To understand why different values of λ have such different effects, we visualize the attention matrices extracted from SSAF with a series of λ and also visualize the one from $\text{BERT}_{\text{BASE}}$ for comparison. As shown in Figure 3, the different structural patterns among these five sub-figures lie in the different strength of the sparsity constraint. It shows that too large coefficient λ makes the attention distribution of SSAF extremely sparse, which may even overlooks some important interactions between different words. With the decrease of λ , the influence from other unnecessary connections increases, which reduces the interpretability of the model. Thus, it is important to have appropriate parameter to encourage a desirably sparse attention distribution while achieving competing accuracy.

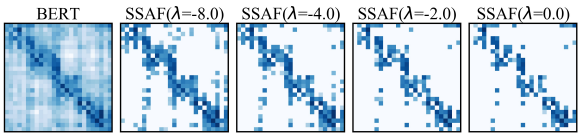

Figure 3: Visualization of attention matrices for $\text{BERT}_{\text{BASE}}$ and SSAF with different values of λ on SenTube-T dataset. With higher λ, the attention distribution in SSAF becomes sparser.

4 Conclusion

In this paper, we develop a novel Sparse Self-Attention Fine-tuning model (referred as SSAF) which integrates sparsity into self-attention mechanism to enhance the fine-tuning performance of BERT. We conduct extensive experiments on sentiment analysis, question answering, and natural language inference tasks with seven public datasets. The proposed approach substantially improves the performance over the strong baseline methods, demonstrating its effectiveness and universality while achieving higher interpretability for the framework.

Abstract

In low-resource settings, the performance of supervised labeling models can be improved with automatically annotated or distantly supervised data, which is cheap to create but often noisy. Previous works have shown that significant improvements can be reached by injecting information about the confusion between clean and noisy labels in this additional training data into the classifier training. However, for noise estimation, these approaches either do not take the input features (in our case word embeddings) into account, or they need to learn the noise modeling from scratch which can be difficult in a low-resource setting. We propose to cluster the training data using the input features and then compute different confusion matrices for each cluster. To the best of our knowledge, our approach is the first to leverage feature-dependent noise modeling with pre-initialized confusion matrices. We evaluate on low-resource named entity recognition settings in several languages, showing that our methods improve upon other confusion-matrix based methods by up to 9%.

1 Introduction

Most languages, even with millions of speakers, have not been the center for natural language processing and are counted as low-resource for tasks like named entity recognition (NER). Similarly, even for high-resource languages, there exists only few labeled data for most entity types beyond person, location and organization. Distantly- or weakly-supervised approaches have been proposed to solve this issue, e.g., by using lists of entities for labeling raw text (Ratinov and Roth, 2009; Dembowski et al., 2017). This allows obtaining large amounts of training data quickly and cheaply. Unfortunately, these labels often contain errors and learning with this noisily-labeled data is difficult and can even reduce overall performance (see, e.g. Fang and Cohn (2016)).

A variety of ideas have been proposed to overcome the issues of noisy training data. One popular approach is to estimate the relation between noisy and clean, gold-standard labels and use this noise model to improve the training procedure. However, most of these approaches only assume a dependency between the labels and do not take the features into account when modeling the label noise. This may disregard important information. The global confusion matrix (Hedderich and Klakow, 2018) is a simple model which assumes that the errors in the noisy labels just depend on the clean labels.

Our contributions are as follows: We propose to cluster the input words with the help of additional, unlabeled data. Based on this partition of the feature space, we obtain different confusion matrices that describe the relationship between clean and noisy labels. We evaluate our newly proposed models and related baselines in several low-resource settings across different languages with real, distantly supervised data with non-synthetic noise. The advanced modeling of the noisy labels substantially improves the performance up to 36% over methods without noise-handling and up to 9% over all other noise-handling baselines.

2 Related Work

A popular approach is modeling the relationship between noisy and clean labels, i.e., estimating $p(\hat{y}|y)$ where y is the clean and $\hat{y}$ the noisy label. For example, this can be represented as a noise or confusion matrix between the clean and the noisy labels, as explained in Section 3. Having its roots in statistics (Dawid and Skene, 1979), this or similar ideas have been recently studied in NLP (Fang and Cohn, 2016; Hedderich and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3554–3559,

Klakow, 2018; Paul et al., 2019), image classification (Mnih and Hinton, 2012; Sukhbaatar et al., 2015; Dgani et al., 2018) and general machine learning settings (Bekker and Goldberger, 2016; Patrini et al., 2017; Hendrycks et al., 2018). All of these methods, however, do not take the features into account that are used to represent the instances during classification. In (Xiao et al., 2015) only the noise type depends on x but not the actual noise model. Goldberger and Ben-Reuven (2016) and Luo et al. (2017) use the learned feature representation h to model $p(\hat{y}|y, h(x))$ for image classification and relation extraction respectively. In the work of Veit et al. (2017), $p(y|\hat{y}, h(x))$ is estimated to clean the labels for an image classification task. The survey by Frenay and Verleysen (2014) gives a detailed overview about other techniques for learning in the presence of noisy labels.

Specific to learning noisy sequence labels in NLP, Fang and Cohn (2016) used a combination of clean and noisy data for low-resource POS tagging. Yang et al. (2018) suggested partial annotation learning to lessen the effects of incomplete annotations and reinforcement learning for filtering incorrect labels for Chinese NER. Hedderich and Klakow (2018) used a confusion matrix and proposed to leverage pairs of clean and noisy labels for its initialization, evaluating on English NER. For English NER and Chunking, Paul et al. (2019) also used a confusion matrix but learned it with an EM approach and combined it with multi-task learning. Recently, Rahimi et al. (2019) studied input from different, unreliable sources and how to combine them for NER prediction.

3 Global Noise Model

We assume a low-resource setting with a small set of gold standard annotated data C consisting of instances with features x and corresponding, clean labels y. Additionally, a large set of noisy instances $(x, \hat{y}) \in N$ is available. This can be obtained e.g. from weak or distant supervision. In a multi-class classification setting, we can learn the probability of a label y having a specific class given the feature x as

$$p(y = i|x) = \frac{exp(u_i^T h(x))}{\sum_{l=1}^{k} exp(u_l^T h(x))} \quad (1)$$

where k is the number of classes, h is a learned, non-linear function (in our case a neural network) and u is the softmax weights. This is our base model trained on C. Due to the errors in the labels, the clean and noisy labels have different distributions. Therefore, learning on C and N jointly can be detrimental for the performance of predicting unseen, clean instances. Nevertheless, the noisy-labeled data is still related to C and can contain useful information that we want to successfully leverage. We transform the predicted (clean) distribution of the base model to the noisy label distribution

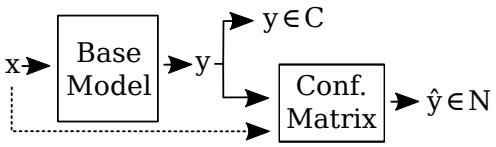

Figure 1: Visualization of the noisy labels, confusion matrix architecture. The dotted line shows the proposed new dependency.

$$p(\hat{y} = j|x) = \sum_{i=1}^{k} p(\hat{y} = j|y = i)p(y = i|x). \quad (2)$$

The relationship is modeled using a confusion matrix (also called noise or transformation matrix or noise layer) with learned weights b_{ij}:

$$p(\hat{y} = j|y = i) = \frac{\exp(b_{ij})}{\sum_{l=1}^{k} \exp(b_{il})} \quad (3)$$

The overall architecture is visualized in Figure 1. An important question is how to initialize this noise layer. As proposed by Hedderich and Klakow (2018), we apply the same distant supervision technique used to obtain N from unlabeled data on the already labeled instances in C. We thus obtain pairs of clean y and corresponding noisy labels $\hat{y}$ for the same instances and the weights of the noise layer can be initialized as

$$b_{ij} = \log\left(\frac{\sum_{t=1}^{|C|} 1_{\{y_t=i\}} 1_{\{\hat{y}_t=j\}}}{\sum_{t=1}^{|C|} 1_{\{y_t=i\}}}\right). \quad (4)$$

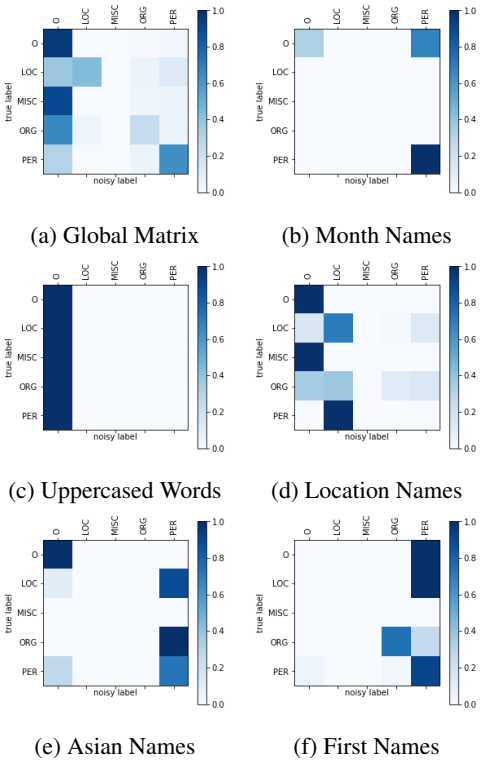
Following the naming by (Luo et al., 2017), we call this the global noise model.

4 Feature Dependent Noise Model

The global confusion matrix is a simple model which assumes that the errors in the noisy labels

depend on the clean labels. An approach that also takes the corresponding features x into account can model more complex relations. Veit et al. (2017) and Luo et al. (2017) use multiple layers of a neural network to model these relationships. However, in low resource settings with only small amounts of clean, supervised data, these more complex models can be difficult to learn. In contrast to that, larger amounts of unlabeled text are usually available even in low-resource settings. Therefore, we propose to use unsupervised clustering techniques to partition the feature space of the input words (and the corresponding instances) before estimating the noise matrices. To create the clusters, we use either Brown clustering (Brown et al., 1992) on the input words or k-means clustering (Lloyd, 1982) on the pretrained word embeddings after applying PCA (Pearson, 1901).

In sequence labeling tasks, the features x of an instance usually consist of the input word $\iota(x)$ and its context. Given a clustering Π over the input words $\{\iota(x) \mid (x, y) \in C \cup N\}$ consisting of clusters $\Pi_1, ..., \Pi_p$, we can group all clean and noisy instances into groups



$$G_q = \{(x, y) \in C \cup N \mid \iota(x) \in \Pi_q\} \quad (5)$$

For each group, we construct an independent confusion matrix using Formulas 3 and 4. The prediction of the noisy label $\hat{y}$ (Formula 2) then becomes

$$p(\hat{y} = j|x) = \sum_{i=1}^{k} p(\hat{y} = j|y = i, G)p(y = i|x) \quad (6)$$

Since the clustering is performed on unsupervised data, in low-resource settings, the size of an actual group of instances G_q can be very small. If the number of members in a group is insufficient, the estimation of reliable noise matrices is difficult. This issue can be avoided by only using the largest groups and creating a separate group for all other instances. To make use of all the clusters, we alternatively propose to interpolate between the global and the group confusion matrix:

$$p_{\text{int}}(\hat{y} = j|y = i, G) = (1-\lambda) \cdot p(\hat{y} = j|y = i, G) + \lambda \cdot p(\hat{y} = j|y = i) \quad (7)$$

(a) Global Matrix (b) Month Names

(c) Uppercased Words (d) Location Names

(e) Asian Names (f) First Names

Figure 2: Confusion matrices used for initialization when training with the English dataset. The global matrix is given as well as five of the feature-dependent matrices obtained when using k-Means clustering for 75 clusters.

The interpolation hyperparameter λ (with $0 \leq \lambda \leq 1$) regulates the influence from the global matrix on the interpolated matrix. The selection of the largest groups and the interpolation can also be combined.

5 Experiments

We evaluate all models in five low-resource NER settings across different languages. Although the evaluation is performed for NER labeling, the proposed models are not restricted to the task of NER and can potentially be used for other tasks.

5.1 Models [1]

We follow the BiLSTM architecture from Hedderich and Klakow (2018). Only the optimizer was changed for all models to NADAM (Dozat, 2016) as this helped with convergence problems for increasing cluster numbers. The **Base** is trained only on clean data while **Base+Noise** is trained on both the clean and the noisy data without noise handling. **Global-CM** uses a global

Table 1: Results of the evaluation in low-resource settings with 1% of the original labeled training data averaged over six runs. We report the F1 scores (higher is better) on the complete test set, as well as the standard error.

confusion matrix for all noisy instances to model the noise as proposed by Hedderich and Klakow (2018) and presented in Section 3. The same architecture is used for **Global-ID-CM**, but the confusion matrix is initialized with the identity matrix (instead of Formula 4) and only adapted during training.

The cluster-based models we propose in Section 4 are **Brown-CM** and **K-Means-CM**. We experimented with numbers of clusters of 5, 10, 25 and 50. The models that select only the largest groups G are marked as ***-Freq** and select either 30% or 50% of the clusters. The interpolation models have the postfix ***-IP** with $\lambda \in \{0.3, 0.5, 0.7\}$. The combination of both is named ***-Freq-IP**. As for all other hyperparameters, the choice was taken on the development set.

We implemented the **Cleaning** (Veit et al., 2017) and **Dynamic-CM** (Luo et al., 2017) models. Both were not developed for sequence labeling tasks and therefore needed to be adapted. For the Cleaning model, we followed the instructions by Hedderich and Klakow (2018). The embedding and prediction components of the **Dynamic-CM** model were replaced according to our base model. The output of the dense layer was used as input to the dynamic matrix generation. We experimented with and without their proposed trace loss.

The training for all models was performed with labels in the IO format. The predicted labels for the test data were converted and evaluated in IOB2 with the official CoNLL evaluation script. The IOB2 format would increase matrix size making the confusion matrix estimation more difficult without adding much information in practice. In preliminary experiments, this decreased performance in particular for low-resource settings.

5.2 Data

The models were tested on the four CoNLL datasets for English, German, Spanish and Dutch (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) using the standard split, and the Estonian data from Tkachenko et al. (2013) using a 10/10/80 split for dev/test/train sets. For each language, the labels of 1% of the training data (ca. 2100 instances) were used to obtain a low-resource setting. We treat this as the clean data C. The rest of the (now unlabeled) training data was used for the automatic annotation which we treat as noisily labeled data N. We applied the distant supervision method by Dembowski et al. (2017), which uses lists and gazetteer information for NER labeling. As seen in Table 2, this method reaches rather high precision but has a poor recall. The development set of the original dataset is used for model-epoch and hyperparameter selection, and the results are reported on the complete, clean test set. The words were embedded with the pretrained fastText vectors (Grave et al., 2018). The clusters were calculated on the unlabeled version of the full training data. Additionally, the Brown clusters used the language-specific documents from the Europarl corpus (Koehn, 2005).

	De	En	Es	Et	Nl
Precision	23.2	39.9	51.0	59.7	32.4
Recall	9.2	30.1	24.7	49.3	21.1
F1	13.2	34.3	33.3	54.0	25.5

Table 2: Results of the automatic labeling method proposed by Dembowski et al. (2017) on the test data.

6 Experimental Results

The results of all models are shown in Table 1. The newly proposed cluster-based models achieve the best performance across all languages and outperform all other models in particular for Dutch and English. The combination of interpolation with the global matrix and the selection of large clusters is almost always beneficial compared to the cluster-based models using only one of the methods. In general, both clustering methods achieve similar performance in combination with interpolation and selection, except for English, where Brown clustering performs worse than k-Means clustering. While the Brown clustering was trained on the relatively small Europarl corpus, k-Means clustering seems to benefit from the word embeddings trained on documents from the much larger common crawl.

7 Analysis

In the majority of cases, a cluster size of 10 or 25 was selected on the development set during the hyperparameter search. Increasing the number of clusters introduces smaller clusters for which it is difficult to estimate the noise matrix, due to the limited training resources. On the other hand, decreasing the number of clusters can generalize too much, resulting in loss of information on the noise distribution. For the λ parameter, a value of either 0.3 or 0.5 was chosen on the development set giving the group clusters more or equal weight compared to the global confusion matrix. This shows that the feature dependent noise matrices are important and have a positive impact on performance.

Five confusion matrices for groups and the global matrix in the English data are shown as examples in Figure 2. One can see that the noise matrix can visibly differ depending on the cluster of the input word. Some of these differences can also be directly explained by flaws in the distant supervision method. The automatic annotation did not label any locations written in all upper-case letters as locations. Therefore, the noise distribution for all upper-cased locations differs from the distribution of other location names (cf. 2d and 2c). The words April and June are used both as names for a month and as first names in English. This results in a very specific noise distribution with many temporal expressions being annotated as person entities (cf. 2b). Similar to this, first-person names and also Asian words are likely to be labeled as persons by the automatic annotation method (cf. 2f and 2e).

All of these groups show traits that are not displayed in the global matrix, allowing the cluster-based models to outperform the other systems.

8 Conclusions

We have shown that the noise models with feature-dependent confusion matrices can be used effectively in practice. These models improve low-resource named entity recognition with noisy labels beyond all other tested baselines. Further, the feature-dependent confusion matrices are task-independent and could be used for other NLP tasks, which is one possible direction of future research.

Abstract

In this paper we present a novel approach to simultaneously representing multiple languages in a common space. Procrustes Analysis (PA) is commonly used to find the optimal orthogonal word mapping in the bilingual case. The proposed *Multi Pairwise Procrustes Analysis* (MPPA) is a natural extension of the PA algorithm to multilingual word mapping. Unlike previous PA extensions that require a k-way dictionary, this approach requires only pairwise bilingual dictionaries that are much easier to construct in either a supervised or an unsupervised way. The improved performance of the MPPA algorithm is demonstrated on two standard multilingual tasks.

1 Introduction

Continuous word embeddings have been proved effective in numerous NLP applications. In cross-language tasks, these vector-space representations have recently emerged as a tool to transfer knowledge from one language to another. Specifically, several studies have suggested forming cross-lingual embeddings by learning a linear mapping from a source-language embedding space to a target-language one and demonstrated the benefits of this approach for word translation (Mikolov et al., 2013; Klementiev et al., 2012). Xing et al. (2015) showed that imposing orthogonality constraints on the linear mapping between spaces can alleviate overfitting. Building on these concepts, several studies have aimed to improve these bilingual word embeddings using bilingual word dictionaries that are created in either a supervised or an unsupervised manner (Artetxe et al., 2017a). Bilingual word embedding were found to be useful in a number of monolingual and cross-lingual NLP tasks (Vulic and Moens, 2015; Tsai and Roth, 2016).

Bilingual embedding can be extended to a multilingual setup by jointly learning mappings from each monolingual word embedding to a shared vector space. Modeling multiple languages jointly has been shown to improve modeling accuracy on bilingual tasks because it can utilize knowledge learned from the other languages (Ammar et al., 2016; Duong et al., 2017; Taitelbaum et al., 2019).

Extending the bilingual setup to a multilingual setting poses new challenges. For bilingual embedding, the word-mapping problem has a closed-form solution known as Orthogonal Procrustes Analysis (PA), which can be computed using singular value decomposition (Schnemann, 1966). However, there is no similar closed-form solution for the multi-language case. The standard extension of PA to multi-set alignment is Generalized Procrustes Analysis (GPA) (Gower, 1975) which is an iterative greedy algorithm. GPA was recently used to jointly transform multiple languages into a shared vector space (Kementchedjhieva et al., 2018). However, GPA assumes that a multi-way word correspondence is available, which is often not the case. Building a multi-way dictionary is a challenging task in itself.

In this study, we propose a novel efficient approach for mapping multiple languages simultaneously into a shared vector space, while enforcing orthogonality constraints. This approach, *Multi Pairwise Procrustes Analysis* (MPPA) can be viewed as a multilingual extension of the Procrustes Analysis. Unlike GPA-based approaches, MPPA does not require a multi-way dictionary, but only bilingual dictionaries which are much easier to obtain even in an unsupervised manner. We evaluated MPPA on two standard multilingual tasks and report better results than GPA based methods and competitive results with gradient based methods.

Our main contribution is a new, efficient, and

easy-to-use algorithm for solving the extension of the Orthogonal Procrustes problem to the multilingual case. Our project code will be publicly available.

2 A Multi-Pairwise Extension of Procrustes Analysis

We first briefly review Procrustes Analysis (PA), a procedure to find the best orthogonal mapping between two languages. We then describe our approach, *Multi-Pairwise Procrustes Analysis* (MPPA), which extends PA to the multilingual case.

Assume we are given d-dimensional word embedding data from two languages along with a dictionary consisting of pairs of corresponding words. Mikolov et al. (2013) showed that there is a strong linear correlation between the vector spaces of two languages and that learning a complex non-linear neural mapping does not yield better results than with a linear mapping. Xing et al. (2015) further showed that enforcing the linear mappings to be orthogonal matrices reduces overfitting and improves performance. We can learn the orthogonal mapping T by minimizing the following cost function:

$$S(T) = \sum_{t=1}^{n} \|Tx_t - y_t\|^2 , \qquad (1)$$

where x_t and y_t are embeddings pf corresponding words from the two languages and n is the dictionary size. Schnemann (1966) proved that the solution to Eq. (1), obtained as the result of a Procrustes Analysis algorithm, is $T = UV^\top$, where $U\Sigma V^\top$ is the singular value decomposition (SVD) of the $d \times d$ matrix $M = \sum_t y_t x_t^\top$. This method has been used in many recent cross-lingual studies (Xing et al., 2015; Artetxe et al., 2016, 2017a,b, 2018a,b; Hamilton et al., 2016; Conneau et al., 2017; Ruder et al., 2018).

Assume we are given d-dimensional word embedding data from k languages and that each pair of languages is provided with a dictionary composed of pairs of corresponding words from the two languages. We could learn a mapping for each language pair independently as a solution to Eq. (1). However, this approach does not benefit from the multilingual setup. Another approach would be to choose one of the languages as a "pivot" and learn a mapping from each language to the pivot separately. A typical choice for the pivot, used in publicly available aligned vectors, is English (Conneau et al., 2017; Joulin et al., 2018). This strategy, however, does not guarantee that the indirect word translation between language pairs will have high quality. Alternatively, we can enforce a transitivity constraint by mapping all the embedding spaces to a shared vector space. Our goal in the multilingual case is thus to find the orthogonal matrices $T_1, ..., T_k$ such that pairs of corresponding words from different languages are mapped into close vectors in the shared space. Formally, we want to minimize the following mean-square error score:

$$S(T_1, ..., T_k) = \sum_{i<j} \sum_{t=1}^{n_{ij}} \|T_i x_{ij,t} - T_j x_{ji,t}\|^2 \quad (2)$$

where $(x_{ij,t}, x_{ji,t})$ is a pair of corresponding words in the i and j languages, respectively and n_{ij} is the dictionary size. We use this notation to emphasize that the vocabularies of the same language in different dictionaries are not necessarily the same.

When more than two languages are involved there is no closed-form solution to the global minimum of (2). We propose an efficient algorithm for minimizing it. The basic step is optimizing the score (2) with respect to the mapping T_i while keeping all other mappings fixed. Viewing the objective score (2) as a function of T_i we obtain:

$$S(T_i) = \sum_{j \neq i} \sum_{t=1}^{n_{ij}} \|T_i x_{ij,t} - y_{j,t}\|^2 + \text{const.} \quad (3)$$

where $y_{j,t} = T_j x_{ji,t}$ is the representation of $x_{ji,t}$ in the common space. This is exactly the Orthogonal Procrustes problem (1) of finding a mapping from language i into the common space. The optimal orthogonal matrix T_i is thus obtained by $T_i = UV^\top$ s.t. $U\Sigma V^\top$ is the SVD of the matrix:

$$M_i = \sum_{j \neq i} \sum_{t} T_j x_{ji,t} x_{ij,t}^\top . \qquad (4)$$

Once T_i is updated we move to the next language in a circular manner. At each step in the iterative algorithm, the score (2) is monotonically decreased until it converges to a local minimum point. Hence, we can stop the optimization procedure once there is no significant improvement in the objective score (2).

Each iteration is very costly since we need to go over all the dictionary words. To avoid this,

we can compute cross correlation $d \times d$ matrix for each pair of languages i, j in a preprocessing step:

$$C_{ij} = C_{ji}^{\top} = \sum_{t} x_{ji,t} x_{ij,t}^{\top}. \quad (5)$$

Substituting (5) in (4) we obtain that

$$M_i = \sum_{j \neq i} T_j C_{ij}. \quad (6)$$

Therefore, updating the mapping T_i can be done in a very efficient way without going over all the bilingual dictionaries of the i-th language.

Algorithm 1 Multi Pairwise Procrustes Analysis

Required: A set of lexical of word pairs between each pair of languages.

Task: Find a set of orthogonal mappings $T_1, .., T_k$, to a common space.

Compute cross-correlation matrices:

$$C_{ij} = C_{ji}^{\top} = \sum_{t} x_{ji,t} x_{ij,t}^{\top} \qquad 1 \leq i < j \leq k$$

Initialization: $T_1 = I$,
for $i = 2, ..., k$ **do**
  $U\Sigma V^{\top}$ = SVD($\sum_{j<i} T_j C_{ij}$)
  $T_i \leftarrow UV^{\top}$
end
Algorithm:
while *not converged* **do**
  for $i = 1, ..., k$ **do**
    $U\Sigma V^{\top}$ = SVD($\sum_{j \neq i} T_j C_{ij}$)
    $T_i \leftarrow UV^{\top}$
  end
end

The proposed Multi Pairwise Procrustes Analysis (MPPA) word mapping training procedure is depicted in Algorithm box 1. The algorithm description also contains an initialization procedure that can help avoid getting stuck at local optima. The idea of the initialization is aligning each new language i to the current common space which was built with languages $j < i$.

MPPA requires only pairwise bilingual dictionaries. It is applicable even if we only have dictionaries for a subset of all the language pairs such that each language under consideration is represented in at least one bilingual dictionary. Consider a graph whose vertices are the languages and an edge indicates the existence of a dictionary between two languages. It can easily be seen that if the graph is loop-free (as in the case where we only have dictionaries for a pivot language) the optimization of (2) is decoupled and each bilingual mapping can be learned separately. The task become really multi-lingual once the graph is loopy, where mapping transitivity implies that there is more than a single path between the source and target languages. We note in passing that we can consider the word representation in the common space as a latent variable and the mapping matrices as unknown parameters. The MPPA algorithm can be thus viewed as an instance of the EM algorithm (Dempster et al., 1977). Further discussion regarding the connection between MPPA algorithm and the EM algorithm can be found in (Goldberger, 1999).

3 Related work

The standard extension of PA to multi-set alignment is *Generalized Procrustes Analysis* (GPA) (Gower, 1975). Kementchedjhieva et al. (2018) recently proposed the Multi-support GPA (MGPA) algorithm for multilingual word translation which is based on the GPA. Their algorithm requires a k-way dictionary in the form of (x_{it}) where $(x_{1t}, ..., x_{kt})$ are representations of words that share the same semantic meaning across all the k languages. This multi-way dictionary is constructed from the bilingual dictionaries (Kementchedjhieva et al., 2018). Whereas conflating multiple senses of a word is already problematic for bilingual dictionaries, this issue is amplified in a multilingual vocabulary. In our approach we avoid this form of error-prone data processing that consists of finding a joint translation of a single word across all the languages. Instead, the MPPA algorithm uses the bilingual dictionaries directly. Note that MPPA is an extension of the GPA algorithm. In case we are given a multi-way dictionary GPA and MPPA optimize the same cost function and MPPA can be viewed as an efficient alterna-

tive to the GPA optimization procedure.

Another line of research applies stochastic gradient-based optimization methods to minimize the mean-square error score (2) jointly with refinement of the bilingual dictionaries. The gradient is approximated by sampling word pairs from the bilingual dictionaries. Chen and Cardie (2018) proposed the *Multilingual Pseudo Supervised Refinement* (MPSR) for this minimization task that uses simple gradient methods in order to minimize (2). For unsupervised setup Chen and Cardie (2018) used an adversarial initialization step, *Multilingual Adversarial Training* (MAT). Alaux et al. (2019) presented, *Unsupervised Multilingual Hyperalignment* (UMH), a similar algorithm that extends the bilingual methods proposed by Grave et al. (2018); Alvarez-Melis and Jaakkola (2018), to multilingual setup.

A main difference between UMH (Alaux et al., 2019) and MAT+MPSR (Chen and Cardie, 2018) is how they treat orthogonality. The first is a stochastic gradient optimization followed by a projection on the set of orthogonal matrices. In the second method orthogonality is a regularization term that is optimized by gradient methods. The matrices are encouraged to be orthogonal by an orthogonalization update (Cisse et al., 2017) that yields matrices that are close to orthogonal but are not necessarily exactly orthogonal. In contrast to gradient based methods, our approach avoids word sampling and hyper-parameters that need to be tuned.

4 Experiments

Datasets and embeddings We used the MUSE benchmark (Conneau et al., 2017)[1], which consist of bilingual dictionaries of 5000 unique source word for training and 1500 for testing. The fastText embeddings (Bojanowski et al., 2017) trained on Wikipedia data, are available online[2]. Vectors were normalized to unit length and then zero centered (Artetxe et al., 2016).

Compared methods We compared MPPA to MGPA (Kementchedjhieva et al., 2018), MAT+MPSR (Chen and Cardie, 2018) and UMH (Alaux et al., 2019). We used the task and results reported in the corresponding paper (UMH results are from the appendix). All methods ran several refinement epochs (Artetxe et al., 2017a), where after each refinement iteration dictionaries were re-build, as described in Conneau et al. (2017). Model selection was done by the best validation criterion suggested in Conneau et al. (2017) and extended in Chen and Cardie (2018). All these methods retrieve word translation using the *Cross-domain Similarity Local Scaling* (CSLS) criterion (Lample et al., 2018).

Results The first experiment was conducted over language triplets (Kementchedjhieva et al., 2018). The goal is to translate from English to a low resource language (like Bosnian) using a high resource language (like Russian). As in Kementchedjhieva et al. (2018), 10 refinement epochs were used, and initial dictionaries for each language pair were generated by pairs of words with identical string matching.

Table 1 depicts precision@1 for the triplets task. MPPA outperformed MGPA and both outperform PA. Note that MGPA needs a multi-way dictionary constructed from the bilingual dictionaries. In contrast, MPPA uses directly the raw data (the bilingual dictionaries).

The second experiment involved multilingual word translation in six European languages: English, German, French, Spanish, Italian and Por-

[1] https://github.com/facebookresearch/MUSE

[2] https://github.com/facebookresearch/fastText

tuguese (Lample et al., 2018). We compared MPPA to MAT+MPSR (Chen and Cardie, 2018). MAT+MPSR is an unsupervised method, so for a fair comparison we replaced the MPSR algorithm with our MPPA algorithm, thus obtaining MAT+MPPA. We ran 5 refinement epochs, after the MAT step, as the default option in MAT+MPSR source code[3]. MPPA training phase is 10 times faster than MPSR equivalent phase, which also have hyper-parameters that needed to be tuned. UMH (Alaux et al., 2019), was also evaluated on this benchmark.

Table 2 shows precision@1 results. MPPA was comparable to UMH and MPSR performed slightly better. Note that the MPSR mapping matrices were not exactly orthogonal. They indeed achieved smaller mean-square error (2) on the training data than our solution, which was restricted to be orthogonal. This suggests that the orthogonality constraint, especially in the multilingual case where it is combined with transitivity constraints, can be too restrictive.

5 Conclusion

This paper presents a general approach to map word embeddings into a common space that can be viewed as an extension of PA to the multilingual case. The proposed algorithm efficiently avoids the need to go over the whole dictionary at each iteration. The optimization is done by enforcing both transitivity and orthogonal constraints. A possible future research direction would involve finding efficient optimization methods where the orthogonality constraint could be slightly relaxed.

Out-of-Domain Detection for Low-Resource Text Classification Tasks

Ming Tan [*†] **Yang Yu** [*†] **Haoyu Wang** [*†] **Dakuo Wang** [‡]
Saloni Potdar [†] **Shiyu Chang** [‡] **Mo Yu** [‡]
[†] IBM Watson [‡] IBM Research

Abstract

Out-of-domain (OOD) detection for low-resource text classification is a realistic but understudied task. The goal is to detect the OOD cases with limited in-domain (ID) training data, since we observe that training data is often insufficient in machine learning applications. In this work, we propose an *OOD-resistant Prototypical Network* to tackle this **zero-shot OOD detection and few-shot ID classification** task. Evaluation on real-world datasets show that the proposed solution outperforms state-of-the-art methods in zero-shot OOD detection task, while maintaining a competitive performance on ID classification task.

1 Introduction

Text classification tasks in real-world applications often consists of 2 components- In-Doman (ID) classification and Out-of-Domain (OOD) detection components (Liao et al., 2018; Kim and Kim, 2018; Shu et al., 2017; Shamekhi et al., 2018). ID classification refers to classifying a user's input with a label that exists in the training data, and OOD detection refers to designate a special OOD tag to the input when it does not belong to any of the labels in the ID training dataset (Dai et al., 2007). Recent state-of-the-art deep learning (DL) approaches for OOD detection and ID classification task often require massive amounts of ID or OOD labeled data (Kim and Kim, 2018). In reality, many applications have very limited ID labeled data (i.e., few-shot learning) and no OOD labeled data (i.e., zero-shot learning). Thus, existing methods for OOD detection do not perform well in this setting.

One such application is the intent classification for conversational AI services, such as IBM Watson Assistant[1]. For example, Table 1 shows some of the utterances a chat-bot builder provided for training. Each class may only have less than 20 training utterances, due to the high cost of manual labelling by domain experts. Meanwhile, the user also expects the service to effectively reject irrelevant queries (as shown at the bottom of Table 1). The challenge of OOD detection is reflected by the undefined in-domain boundary. Although one can provide a certain amount of OOD samples to build a binary classifier for OOD detection, such samples may not efficiently reflect the infinite OOD space. Recent approaches, such as (Shu et al., 2017), make remarkable progress on OOD detection with only ID examples. However, such condition on ID data cannot be satisfied by the few-shot scenario presented in Table 1.

Intent Label	Example
Help_List	List what you can help me with.

the meta-learning strategy (Vinyals et al., 2016) has been proposed to deal with the problem of limited training examples for each label (few-shot learning). In this line of work, *Prototypical Networks* (Snell et al., 2017), which was originally introduced for few-shot image classification, has proven to be promising for few-shot ID text classification (Yu et al., 2018). However the usage of prototypical network for OOD detection is unexplored in this regard.

To the best of our knowledge, this work is the first one to adopt a meta-learning strategy to train an OOD-Resistant Prototypical Network for simultaneously detecting OOD examples and classifying ID examples. The contributions of this work are two-fold: 1) Unified solution using a prototypical network model which can detect OOD instances and classify ID instances in a real-world low-resource scenario. 2) Experiments and analysis on two datasets prove that the proposed model outperforms previous work on the OOD detection task, while maintaining a state-of-the-art ID classification performance.

2 Related Work

Out-of-Domain Detection Existing methods often formulate the OOD task as a one-class classification problem, then use appropriate methods to solve it (e.g., one-class SVM (Schölkopf et al., 2001) and one-class DL-based classifiers (Ruff et al., 2018; Manevitz and Yousef, 2007). A group of researchers also proposed an auto-encoder-based approach and its variation to tackle OOD tasks (Ryu et al., 2017, 2018). Recently, a few papers have investigated ID classification and OOD detection simultaneously (Kim and Kim, 2018; Shu et al., 2017), but they fail in a low resource setting.

Few-Shot Learning While few-shot learning approaches may help with this low-resource setting, some recent work is promising in this regard. For example, (Vinyals et al., 2016; Bertinetto et al., 2016; Snell et al., 2017) use metric learning by learning a good similarity metric between input examples; some other methods adapt a meta-learning framework, and train the model to quickly adapt to new tasks with gradients on small samples, e.g., learning the optimization step sizes (Ravi and Larochelle) or model initialization (Finn et al., 2017). Though most of these approaches are explored for computer vision, recent studies suggests that few-shot learning is promising in the text domain, including text classification (Yu et al., 2018; Jiang et al., 2018), relation extraction (Han et al., 2018), link prediction in knowledge bases (Xiong et al., 2018) and fine-grained entity typing (Xiong et al., 2019), and we put it to test with the OOD detection task.

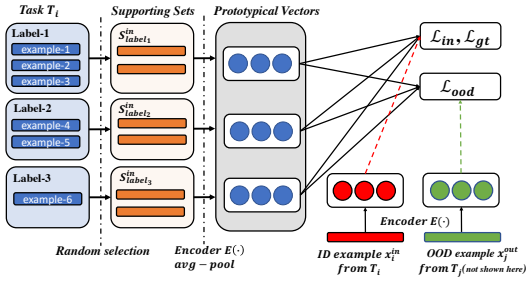

Figure 1: Model overview: the model maximizes likelihood of the ground-truth of ID example, minimizes distance between ID example and ground-truth, and maximizes the distance of OOD example and all ID labels.

3 Approach

In this paper, we target solving the zero-shot OOD detection problem for a few-shot **meta-test** dataset $D = (D^{train}, D^{test})$ by training a transferable prototypical network model from large-scale **independent source datasets** $\mathcal{T} = \{T_1, T_2, ..., T_N\}$ for dynamic construction of the **meta-train** set. Each task T_i contains labeled training examples (note that a test set is not required in meta-train). D is different from the traditional supervised close-domain classification dataset from two folds: 1) D^{test} contains OOD testing examples, whereas D^{train} only includes labeled examples for the target domain. 2) The training size for each label in D^{train} is limited (e.g. less than 100 examples). Such limitations prevent existing methods from efficiently training a model for either ID classification or OOD detection using D^{train} only.

We propose an OOD-resistant prototypical network for both OOD detection and few-shot ID classification. We follow (Snell et al., 2017) in few-shot image classification by training a prototypical network on $\mathcal{T}$ and directly perform prediction on D without additional training. But our method is different from the prior work in that during the meta-training, while we maximize the likelihood of the true label for an example in T_i, we also sample an example from another meta-train task T_j for the purpose of OOD training by maximizing the distance between the OOD instance and the prototypical vector of each ID label.

3.1 General Framework

As in Fig. 1, on a large-scale source dataset $\mathcal{T}$ with the following steps:

1. Sample a training task T_i from $\mathcal{T}$ (e.g., the Book category of Amazon Review in Section 4), and another task T_j from $\mathcal{T} - T_i$ (e.g. the Apps-for-Android category).
2. Sample an ID training example x_i^{in} from T_i, and a simulated OOD example x_j^{out} from T_j.
3. Sample N labels (N=4) from T_i in addition to the label of x_i^{in}. For the ground-truth label and N negative labels, we select K training examples for each label (K-shot learning, we set K=20). If a label has less than K examples, we replicate the selected example to satisfy K. Therefore, $(N+1) \times K$ examples serve as a supporting set $\mathcal{S}^{in} = \{S_l^{in}\}_{l=1}^{N}$.
4. Given a batch of dynamically-constructed meta-train set $(x_i^{in}, x_j^{out}, \mathcal{S}^{in})$, $E(\cdot)$ encodes x_i^{in}, x_j^{out} and the examples in S_l^{in} using a deep network (Any DL structure can be used for the encoder, such as LSTM and CNN. Here we use a one-layer CNN with a mean pooling. The detailed CNN hyper-parameters are introduced in Section 5).
5. Following (Snell et al., 2017), a Prototypical Vector representation for each label is generated, by averaging all the examples' representations of that label.
6. The model is optimized by an objective function, defined by x_i^{in} , x_j^{out} and $\mathcal{S}^{in}$. Details in Section 3.2.
7. Repeat these steps for multiple epochs (5k in this paper) to train the model, and select the best model based on an independent meta-valid set $\mathcal{T}^{valid}$. $\mathcal{T}^{valid}$ contains tasks that are homogeneous to the meta-test task D.

The only trainable parameters of this model are in the encoder $E(\cdot)$. Therefore the trained model can be easily transferred to the few-shot target domain.

3.2 Training Objective and Runtime

Prototypical networks (Snell et al., 2017) minimize a cross-entropy loss defined on the distance metrics between x_i^{in} and the supporting sets,

$$\mathcal{L}_{in} = -\log \frac{\exp \alpha F(x_i^{in}, S_{l_i}^{in})}{\sum_{l'} \exp \alpha F(x_i^{in}, S_{l'}^{in})} \quad (1)$$

where l_i is the ground-truth label of x_i, α is a re-scaling factor. Here we define F as a cosine similarity score (mapped to the range between 0 and 1)[2] between the $E(\cdot)$-encoded representations of x and the prototypical vector of a label. Our experiments show this meta-learning approach is efficient for ID classification, but is not good enough for detecting the OOD examples.

We propose two more training losses in addition to the L_{in} for OOD detection. The rationale behind this addition is to adopt the examples from other tasks as simulated OOD examples for the current meta-train tasks. Specifically, we first define a hinge loss on x_j^{out} and the closest ID supporting set in $\mathcal{S}^{in}$, then we push the examples from another task away from the prototypical vectors of ID supporting sets.

$$\mathcal{L}_{ood} = max[0, \max_{l}(F(x_j^{out}, S_l^{in}) - \mathcal{M}_1)] \quad (2)$$

We expect optimizing only on $\mathcal{L}_{in}$ and L_{ood} will lead to lower confidences on ID classification, because the system tends to mistakenly reduce the scale of F in order to minimize the loss for OOD examples. Therefore we add another loss to improve the confidence of classifed ID labels.

$$\mathcal{L}_{gt} = max[0, \mathcal{M}_2 - F(x_i^{in}, S_{l_i}^{in}))] \quad (3)$$

The model is optimized on the three losses.

$$\mathcal{L} = \mathcal{L}_{in} + \beta \mathcal{L}_{ood} + \gamma \mathcal{L}_{gt} \quad (4)$$

where α, β, γ, $\mathcal{M}_1$ and $\mathcal{M}_2$ are hyper-parameters, whose detailed values are shown in Section 5 .

During inference, the supporting set per label is generated by averaging the encoded representations of all instances of that label in D^{train} and the prediction is based on $F(x, S_l^{in})$. OOD detection is decided with a *confidence* threshold.

4 Datasets

Our methods are evaluated on two datasets and each has many tasks and is divided into meta-train, meta-valid and meta-test sets, which are respectively used for background model training, evaluation and hyper-parameter selection.

Amazon Review [3]**:** We follow (Yu et al., 2018) to construct multiple tasks using the Amazon Review dataset (He and McAuley, 2016) . We convert it into a binary classification task of labeling the review sentiment (positive/negative). It has 21

[2]Following (Snell et al., 2017), we also tried squared Euclidean distance, but did not achieve better results.

[3]We will release Amazon data and our code at https://github.com/SLAD-ml/few-shot-ood

categories of products, each of which is treated as a task. We randomly picked 13 categories as meta-train, 4 as meta-test and 4 as meta-valid. (another 3 original categories are discarded due to not enough examples to make a dataset). We construct a 2-way 100-shot problem per meta-test task by sampling 100 reviews per label in a category. For the test examples in meta-test and meta-valid, we sample other categories' examples as OOD, merged with a equal number of ID instances. We used all available data for meta-train.

Conversation Dataset: An intent classification dataset for a AI conversational system. It has 539 categories/tasks. We allocate 497 tasks as meta-train, and 42 tasks as meta-test. This dataset is different and more difficult than the typical ID few-shot learning data: 1) Both the meta-test and meta-train tasks are not restricted to N-way K-shot classification, and the source dataset is highly imbalanced across labels; 2) Each task has a variety of labels (utterance intents), whereas Amazon data always has two labels. There are 29% OOD testing instances in meta-test, which are human-labeled and not generated from other tasks.

5 Experimental Results

Baselines: We compare our model **O-Proto** with 4 baselines: 1) **OSVM (Schölkopf et al., 2001)**: OSVM is trained on meta-test set, and learn a domain boundary by only examining ID examples. 2) **LSTM-AutoEncoder (Ryu et al., 2017)**: Recent work on OOD detection that uses only ID examples to train an autoencoder for OOD detection. 3) **Vanilla CNN**: A classifier with a typical CNN structure that uses a confidence threshold for OOD detection. 4) **Proto. Network (Snell et al., 2017)**: A native prototypical network trained on $\mathcal{T}$ with only the loss $\mathcal{L}_{in}$, which uses a confidence threshold for OOD detection. We test the Proto. Network with both CNN and bidirectional LSTM as the encoder $E(\cdot)$.

Hyper Parameters: We introduce the hyper-parameters of our model and all baselines below.

We use Python scikit-learn One-Class SVM as the basis of our OSVM implementation. We use Radial Basis Function (RBF) as the kernel and the gamma parameter is set to auto. We use squared hinge loss and L2 regularization.

We follow the same architecture as proposed in (Ryu et al., 2017) for the LSTM-Autoencoder. In LSTM, we set the input embedding dimension as 100 and hidden as 200. We use RMSprop as the optimizer with a learning rate of 0.001. We train the LSTM with a batch size of 32 and 100 epochs. For Autoencoder, we set the hidden size as 20. We use Adam as the optimizer with a learning rate of 0.001. We train the model with a batch size of 32 for 10 epochs.

For vanilla CNN, we use the most common CNN architecture used in NLP tasks, where the convolutional layer on top of word embedding has 128 filters followed by a ReLU and max pooling layer before the final softmax. We use Adam as the optimizer with a learning rate of 0.001. We train the model with a batch size 64 for 100 epochs.

Our proposed model O-Proto uses the similar CNN architecture, the optimizer and the learning rate in the previous Vanilla CNN. The input word embeddings are pre-trained by 1-billion-token Wikipedia corpus. We set the batch size as 10. In Eq. 1, 2, 3 and 4, α, β, γ, $\mathcal{M}_1$ and $\mathcal{M}_2$ are hyper-parameters, which we fix β, γ as 1.0 by default, and set α, $\mathcal{M}_1$ and $\mathcal{M}_2$ as 10.0, 0.4 and 0.8 according to the meta-valid performance of Amazon dataset. The sentence encoder, CNN, has 200 filters, followed by a tanh and mean pooling layer before the final regression layer. The maximum length of tokens per example is 40, and any words out of this range will be discarded. During training, we set the size of sampled negative labels Step 3 (section 3.1) to at most four, so there will be maximum five labels involved in a training step (1 positive, 4 negative). The supporting set size for each label are 20.

To make a fair comparison, we follow the same hyper-parameters as O-Proto in Proto. Network, except that the weight of $\mathcal{L}_{ood}$ and $\mathcal{L}_{gt}$, β and γ, are set to zero.

Evaluation Metrics: Following (Ryu et al., 2017; Lane et al., 2007), we use a commonly used OOD detection metric, equal error rate (**EER**), which is the error rate when the confidence threshold is located where false acceptance rate (**FAR**) is equivalent to false rejection rate (**FRR**).

$$FAR = \frac{Number\ of\ accepted\ OOD\ sentences}{Number\ of\ OOD\ sentences}$$
$$FRR = \frac{Number\ of\ rejected\ ID\ sentences}{Number\ of\ ID\ sentences}$$

We use class error rate **CER** to reflect ID performance. Lastly, we applied the threshold used in the EER to ID test examples to test how many ID

Table 3: Compare our model with Prototype Network on EER when choosing various K-shot values

examples are rejected by the OOD detection, as **Combined-CER** (Comb. in Table 2).

Results: Table 2 compares the proposed model and baselines on EER and CER on the two datasets. [4] For prototypical-network related models, we randomly initialize the model parameters by 10 times and report the averaged metrics. *OSVM, LSTM-AutoEncoder and Vanilla CNN* perform poorly on OOD detection as expected, as they require larger number of ID examples which is not a few-shot scenario. *Proto.Network* has a better performance on ID classification. But it is not designed for OOD, thus it does not perform well on OOD detection. *O-Proto* achieves significantly better EERs (2.8% improvement on Conversation, and 22.5% on Amazon), yielding competitive results on CER compared to *Proto.Network*. These lead to a remarkable improvement on Combined-CER. *O-Proto* improves less on EER in Conversation than Amazon, because some Conversation tasks actually come from the conversational service providers belonging to similar business domains. Our model is better even when meta-train datasets are from slightly different domains. Moreover, in Table 2 we show the ablation study by removing $\mathcal{L}_{ood}$ and $\mathcal{L}_{gt}$ from *O-Proto*, respectively. *O-Proto* without $\mathcal{L}_{ood}$ completely loses the ability of OOD detection. Compared to the one without $\mathcal{L}_{gt}$, *O-Proto* with all losses gives a mild improvement. We also observe a more stable testing performance among epochs during training. Finally, we replace the CNN encoders with bidirectional LSTMs (the bottom of Table 1), which yields the same dimension of sentence representations as CNN. For Conversation data, we achieve the best performance on validation set when α and γ are 0.5. We observe comparable performances with respect to *Proto.Network* and *O-Proto*, showing that our proposed OOD approach is not limited to a specific sentence encoding architecture.

Improvement in different K-shot settings: On the Amazon data, we construct different K-shot tasks as meta-test (results shown in Table 3), and observe consistent improvements on EER.

Effect of β: Fig. 2 and 3 show EER and CER with different β values on the two datasets. We observe within a proper range of β (between 0.5 and 2.0), the model can provide stable improvement on EER, guaranteeing competitive CER results.

6 Conclusion

Inspired by the Prototypical Network, we propose a new method to tackle the OOD detection task in low-resource settings. Evaluation on real-world datasets demonstrates that our method performs favorably against state-of-the-art algorithms on the OOD detection, without adversely affecting performance on the few-shot ID classification.

[4] No CER reported for *OSVM* as it treats ID as one class and does not support ID classification.

Abstract

Formality text style transfer plays an important role in various NLP applications, such as non-native speaker assistants and child education. Early studies normalize informal sentences with rules, before statistical and neural models become a prevailing method in the field. While a rule-based system is still a common preprocessing step for formality style transfer in the neural era, it could introduce noise if we use the rules in a naïve way such as data preprocessing. To mitigate this problem, we study how to harness rules into a state-of-the-art neural network that is typically pretrained on massive corpora. We propose three fine-tuning methods in this paper and achieve a new state-of-the-art on benchmark datasets.

1 Introduction

Text formality research is essential for a wide range of NLP applications, such as non-native speaker assistants and child education. Due to the progress of deep learning techniques, researchers make a step from formality understanding to formality-aware text generation. Recently, Rao and Tetreault (2018) published a dataset, the Grammarly's Yahoo Answers Formality Corpus (GYAFC), serving as a benchmark testbed for formality style transfer, which aims to generate a formal sentence given an informal one, while keeping its semantic meaning.

Since the GYAFC dataset is small, existing studies have realized the importance of rules as a preprocessing step of informal text, typically handling capitalization (e.g., "ARE YOU KIDDING ME?"), character repetition (e.g., "noooo"), slang words (e.g., "wanna"), etc. While rule-based preprocessing could largely simplify the formality style transfer task, we observe that it also introduces noise, with an example shown in Table 1. Given a sentence with all capital letters, a common rule-based method would lower all characters except the first one. Some entities, such as R & B, are changed to lower case incorrectly, especially if not recognized as a proper noun.

Original informal sentence:
I LOVE HIP-HOP , RAP , ROCK & POP BUT MY FAV MUSIC IS R & B
Output of a rule-based system:
I love hip-hop , rap , rock and pop but my fav music is r and b

Table 1: Example of informal sentence and the output of a rule-based system.

Another intuition of ours is that, due to the small size of the parallel corpus, it would be beneficial to leverage a large neural network, which is pretrained on a massive corpus and has learned general knowledge of language. Then, we could fine-tune it in the formality style transfer task.

To this end, we study in this paper how to effectively incorporate pretrained networks—particularly, the powerful GPT-2 model (Radford et al., 2019)—with simple rules for formality style transfer. We analyze three ways of harnessing rules in GPT-2: 1) We feed the concatenation of the original informal sentence and the preprocessed one to the encoder; 2) We ensemble two models at the inference stage: one takes the original informal text as input, while the other takes the rule-preprocessed text as input; and 3) We employ two encoders to encode original informal text and the rule-preprocessed text seperately, and then develop a hierarchical attention mechanism in both word- and sentence-levels to aggregate information. Our work differs from previous work, which only feeds preprocessed inputs to the encoder. Rather, we are able to preserve more information of the original sentence, and the rule-based system is harnessed in a learnable way.

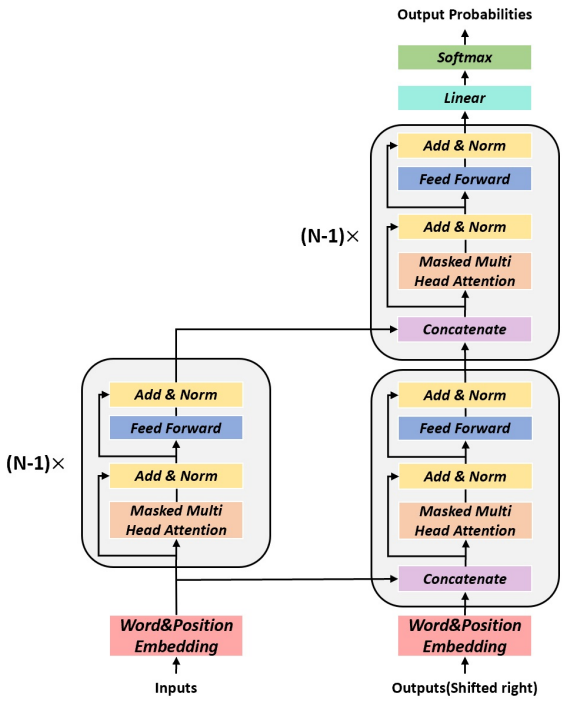

Figure 1: The architecture of our model. Both the encoder and decoder use masked multi-head attention blocks, but they do not share parameters. For the ith layer of the decoder (denoted as l_i^{dec}), it takes the concatenation of l_{i-1}^{enc} and l_{i-1}^{dec}'s outputs as input. N is the number of blocks in the decoder.

Experimental results show that our method outperforms direct fine-tuning of GPT-2 by 2 BLEU scores, and previous published results by 1.8–2.8 scores in different domains of the GYAFC dataset.

2 Related Work

In the past few years, style-transfer generation has attracted increasing attention in NLP research. Early work transfers between modern English and the Shakespeare style with a phrase-based machine translation system (Xu et al., 2012). Recently, style transfer is more recognized as a controllable text generation problem (Hu et al., 2017), where the style may be designated as sentiment (Fu et al., 2018), tense (Hu et al., 2017), or even general syntax (Bao et al., 2019; Chen et al., 2019). In the above approaches, the training sentences are labeled with style information, but no parallel data are given. Xu et al. (2019a) take one step further and capture the most salient style by detecting global variance in a purely unsupervised manner (i.e., style labels are unknown).

Formality style transfer is mostly driven by the GYAFC parallel corpus. Since a parallel corpus, albeit small, is available, formality style transfer usually takes a seq2seq-like approach (Rao and Tetreault, 2018; Niu et al., 2018a; Xu et al., 2019b). In particular, this paper focuses on harnessing pre-trained neural networks with rule-based systems.

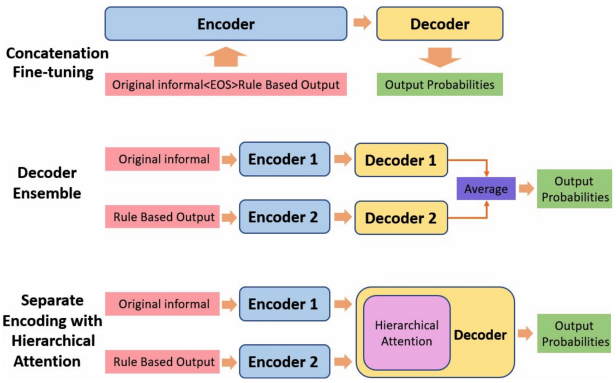

Figure 2: Three different methods to incorporate pre-trained models with rule-based systems.

3 Approach

We implement our encoder and decoder with GPT blocks, and initialize them with the pretrained GPT-2 parameters (Radford et al., 2019). The architecture of a decoder GPT block performs attention to the context words and previous words with the same multi-head attention layer, illustrated in Figure 1, which is slightly different with the classic Transformer (Vaswani et al., 2017). Formally, the output of the attention layer is[1]

$$\text{softmax}\left(\frac{\boldsymbol{Q}[\boldsymbol{K}_{\text{enc}};\boldsymbol{K}_{\text{dec}}]^T}{\sqrt{d_k}}\right)[\boldsymbol{V}_{\text{enc}};\boldsymbol{V}_{\text{dec}}] \quad (1)$$

where $\boldsymbol{Q}$, $\boldsymbol{K}$, and $\boldsymbol{V}$ are defined the same as the scaled dot-product attention in Transformer, and d_k is a scaling factor. $[;]$ is a concatenation operation; it enables to consider context words and previous decoding results in the same layer. Such architecture enables to adapt GPT-2, a Transformer-based pretrained language model, to a sequence-to-sequence model without re-initializing the parameters.

In the following, we describe several methods combining the GPT-based encoder-decoder model with preprocessing rules and (limited) parallel data.

Fine-Tuning with Prepocessed Text as Input. Given an informal sentence $\mathbf{x}_i$ as input, the most

[1]We use bold italic letters to denote a vector or matrix.

straightforward method, perhaps, is to first convert $\mathbf{x}_i$ to $\mathbf{x}'_i$ by rules, and then fine-tune the pre-trained GPT model with parallel data $\{(\mathbf{x}'_i, \mathbf{y}_i)\}_{i=0}^{M}$ (M is the number of samples). In this way, informal sentences can be normalized with rules before using a neural network. This simplifies the task and is standard in previous studies of formality style transfer (Rao and Tetreault, 2018).

However, the preprocessed sentence serves as a Markov blanket, i.e., the system is unaware of the original sentence, provided that the preprocessed one is given. This is in fact not desired, since the rule-based system could make mistakes and introduce noise (Table 1).

Fine-Tuning with Concatenation. To alleviate the above issue, we feed the encoder with both the original sentence $\mathbf{x}_i$ and the preprocessed one $\mathbf{x}'_i$. We concatenate the words of $\mathbf{x}_i$ and $\mathbf{x}'_i$ with a special token `EOS` in between, forming a long sequence $(x_{i,1}, \cdots, x_{i,s_i}, \texttt{EOS}, x'_{i,1}, \cdots, x'_{i,s'_i})$; after that, the concatenated sequence and the corresponding formal reference serve as a parallel text pair to fine-tune the GPT model. In this way, our model can make use of a rule-based system but also recognize its errors during the fine-tuning stage.

Decoder Ensemble. We investigate how the model performs if we train two GPTs with $\{\mathbf{x}'_i, \mathbf{y}_i\}_{i=0}^{M}$ and $\{\mathbf{x_i}, \mathbf{y_i}\}_{i=0}^{M}$ separately, but combine them by model ensemble in the decoding phase. We denote the generative probability of the jth word by $h(\mathbf{x}_i, \mathbf{y}_{i,<j})$ and $h'(\mathbf{x}'_i, \mathbf{y}_{i,<j})$. We apply "average voting" and the resulting predictive probability is $\frac{h'(\mathbf{x}'_i, \mathbf{y}_{i,<j}) + h(\mathbf{x}_i, \mathbf{y}_{i,<j})}{2}$.

Hierarchical Attention. In our final variant, we use two encoders to encode $\mathbf{x}_i$ and $\mathbf{x}'_i$ separately, but compute a hierarchical attention to aggregate information, given by

$$\alpha \cdot \text{softmax}\left(\frac{\boldsymbol{Q}[\boldsymbol{K}_{\text{enc1}}; \boldsymbol{K}_{\text{dec}}]^\top}{\sqrt{d_k}}\right)[\boldsymbol{V}_{\text{enc1}}; \boldsymbol{V}_{\text{dec}}] + \beta \cdot \text{softmax}\left(\frac{\boldsymbol{Q}[\boldsymbol{K}_{\text{enc2}}; \boldsymbol{K}_{\text{dec}}]^\top}{\sqrt{d_k}}\right)[\boldsymbol{V}_{\text{enc2}}; \boldsymbol{V}_{dec}] \quad (2)$$

where α and β are sentence attention weights for each decoding step, computed by

$$\alpha = \frac{\exp(\boldsymbol{h}_l^T \boldsymbol{W} \boldsymbol{z}_1)}{\exp(\boldsymbol{h}_l^T \boldsymbol{W} \boldsymbol{z}_1) + \exp(\boldsymbol{h}_l^T \boldsymbol{W} \boldsymbol{z}_2)}, \quad \beta = 1 - \alpha \quad (3)$$

Here, $\boldsymbol{h}_l$ is the hidden state of the lth step at the decoder, $\boldsymbol{W}$ is a learnable parameter, $\boldsymbol{z}_1$ and $\boldsymbol{z}_2$ represent the last hidden state of the two encoders, respectively. We propose this variant in hopes of combining the information of $\mathbf{x}_i$ and $\mathbf{x}'_i$ in the training stage and in a learnable way, compared with the decoder ensemble.

4 Experiments

4.1 Setup

We evaluate our methods on the benchmark dataset, the Grammarly's Yahoo Answers Formality Corpus (GYAFC, Rao and Tetreault, 2018). It consists of handcrafted informal-formal sentence pairs in two domains, namely, Entertainment & Music (E&M) and Family & Relationship (F&R). Table 2 shows the statistics of the training, development, and test sets. In the development and test sets of GYAFC, each sentence has four references, against which evaluation metrics are computed.

	Train	Dev	Test
Entertainment & Music	52,595	2,877	1,416
Family & Relationship	51,967	2,788	1,332

Table 2: Corpus statistics.

We implement our model with Tensorflow 1.12.0 and take the pretrained GPT-2 model (117M) released by OpenAI[2] to initialize our encoder and decoder. We use the Adam algorithm (Kingma and Ba, 2015) to train our model with a batch size 128. We set the learning rate to 0.001 and stop training if validation loss increases in two successive epochs.

4.2 Competing Methods

We compare our model with the following state-of-the-art methods in previous studies.

Rule-Based: We follow Rao and Tetreault (2018) and create a set of rules to convert informal texts to formal ones. Due to the lack of industrial engineering, our rule-based system achieves a performance slightly lower than (but similar to) Rao and Tetreault (2018).

NMT-Baseline: An RNN-based Seq2Seq model with the attention mechanism (Bahdanau et al., 2015) is trained to predict formal texts, given rule-preproccessed informal text.

PBMT-Combined: Similar to NMT, this baseline trains a traditional phrase-based machine translation (PBMT) system, also taking the preprocessed text as input. Then, self-training (Ueff-

[2] https://github.com/openai/gpt-2

ing, 2006) is applied with an unlabeled in-domain dataset for further improvement.

NMT-Combined: This method uses back-translation (Sennrich et al., 2016) with the PBMT-Combined system to synthesize a pseudo-parallel corpora. Then a Seq2Seq model is trained on the combination of the pseudo-parallel and parallel corpora.

Note that the above baselines are reported by Rao and Tetreault (2018).

Transformer-Combined: This setting in Xu et al. (2019b) is the same as NMT-Combined, except that it employs Transformer (Vaswani et al., 2017) as the encoder and decoder.

JTHTA: Xu et al. (2019b) propose a bi-directional framework that can transfer formality from formal to informal or from informal to formal with one single encoder-decoder component. They jointly optimize the model against various losses and call it Joint Training with Hybrid Textual Annotation (JTHTA).

Bi-directional-FT: Niu et al. (2018b) merge the training data of two domains and leverage data borrowed from machine translation to train their models with a multi-task learning schema, and also apply model ensembles. For fairness, we also combine the two domains when comparing with Niu et al. (2018b).

Additionally, we also evaluate our model variants. We first apply the GPT based on the original parallel corpus without using the rule-based system, denoted as GPT-Orig. Then, we feed the rule-preprocessed text as input, denoted as GPT-Rule. Other variants in Section 3 are denoted as GPT-CAT, GPT-Ensemble, and GPT-HA, respectively.

4.3 Evaluation Metrics

To evaluate different models, we apply multiple automatic metrics, mostly following Rao and Tetreault (2018).

Formality: Rao and Tetreault (2018) train a feature-based model to evaluate the formality of sentences, requiring an extra labeled corpus for training, which is unfortunately not publicly available. As a replacement, we train an LSTM-based classifier using the training data of GYAFC. It achieves 93% accuracy in the development and test sets, and thus is an acceptable approximation.

Meaning Preservation: We evaluate whether the meaning of the source sentence is preserved with a model trained on the Semantic Textual Similarity (STS) dataset. We adopt the BERT-Base[3] model (Devlin et al., 2019) and use STS for fine-tuning.

Overall: We evaluate the overall quality of formality-transferred sentences with BLEU (Papineni et al., 2002) and PINC (Chen and Dolan, 2011). BLEU evaluates the n-gram overlap, and PINC is an auxiliary metric indicating the dissimilarity between an output sentence and an input. A PINC score of 0 indicates that the input and output sentences are the same. According to Rao and Tetreault (2018), BLEU correlates with human annotation best.

4.4 Results

We show results of the E&M and F&R domains in Tables 3 and 4, respectively. We see that, by using the GPT-2 pretrained model alone (GPT-Orig), we achieve close results to previous state-of-the-art models. It outperforms NMT-Combine and JTHTA, even without fine-tuning on pseudo-parallel data. Our method also significantly outperforms the Transformer-Combined model (without pretraining). The results suggest that the small GYAFC corpus does not suffice to fully train the Transformer model. The GPT-2 model, pretrained with massive unlabeled corpora, is able to capture the generic knowledge of language and can be adapted to formality style transfer.

We then evaluate our different methods of incorporating the rule-based system into the pretrained GPT-2 model. We see that GPT-CAT yields the best results, which is probably because the concatenation enables two input sentences interact with each other through a single self-attention mechanism, while other methods encode each input sentences (original and rule-preprocessed) separately.

When combining both domains as in Niu et al. (2018b), we also have better performance than the previous work. This further shows the robustness of our model.

Regarding formality, our model achieves a reasonably high accuracy, although combining domains is slightly worse (since cross-domain training may bring noise that hurts the output formality). The rule-based model itself shows the best performance on content preserving, but it does not

Table 4: Test performance on the F&R domain.

change the input much (a low PINC score).

In summary, our models significantly outperform previous work in formality style transfer and achieve a state-of-the-art performance on the two domains of GYAFC, which credits to both the pretrained model and our fine-tuning methods in consideration of a rule-based system.

5 Conclusion

In this work, we study how to incorporate a pretrained neural network with a rule-based system for formality style transfer. We find that building a pretrained GPT-2 upon the concatenation of the original informal text and the rule-preprocessed text achieves the highest performance on benchmark datasets.

Abstract

The objective of non-parallel text style transfer is to alter specific attributes (e.g. sentiment, mood, tense, politeness, etc) of a given text while preserving unrelated content. Adversarial training is a popular method to ensure the transferred sentences have the desired target styles. However, previous works often suffer from content leaking problem. In this paper, we propose a new adversarial training model with a word-level conditional architecture and a two-phase training procedure. By using a style-related condition architecture before generating a word, our model is able to maintain style-unrelated words while changing the others. By separating the training procedure into reconstruction and transfer phases, our model is able to balance the reconstruction and adversarial losses. We test our model on polarity sentiment transfer and multiple-attribute transfer tasks. The empirical results show that our model achieves comparable evaluation scores in both transfer accuracy and fluency but significantly outperforms other state-of-the-art models in content compatibility on three real-world datasets.

1 Introduction

Text style transfer is a challenging problem in natural language generation, whose objective is to alter specific attributes (e.g. sentiment, mood, tense, voice, politeness, etc (Hu et al., 2017; Shen et al., 2017; Sennrich et al., 2016; Logeswaran et al., 2018; Prabhumoye et al., 2018)) of a given text while preserving its remaining attributes and contents. This task has potential applications such as paraphrasing, summarizing articles, author obfuscation (Reddy and Knight, 2016), poems/lyrics rewriting, and scenario-adaptive machine translation (Michel and Neubig, 2018).

One major challenge for text style transfer is that parallel data across different text attributes is difficult to collect and label. Without parallel data, supervised deep-learning models are not applicable and the transfer rules among styles unclear. Unlike image style transfer, another main challenge for text style transfer is the difficulty to identify and disentangle neural feature representations for texts.

In previous models (Shen et al., 2017; Hu et al., 2017) the core idea for non-parallel text style transfer, is to training an auto-encoder with additional adversarial loss (Goodfellow et al., 2014), (or a VAE with a classifier), for the discriminator, (or classifier), to guide the decoder generate sentences to have a specific target style.

Despite previous success in attribute-conditioned text generation, several research questions remain, regarding to previous models, including: 1) previous modeling limitations to transformations between only a few attributes. 2) the issue of trade-off among text fluency, content preservation, and the accurate transfer with the desired attributes and 3) the unstability of adversarial training.

To address these issues, we make contribution by adopting an encoder-decoder framework and propose a novel conditional adversarial training, including several improvements as follows: (1) a word-level attribute condition architecture in both the decoder and discriminators to capture relations between styles and words; (2) we employ a seq-to-seq attention mechanism and (3) a two-phase training procedure (reconstruction/transfer phases) for better content preservation. It is trained with standard adversarial learning approach. We test our conditional adversarial training on two tasks: (a) polarity style transfer, and (b) multiple-attribute style transfer.

2 Related Works

Text style transfer without parallel data is an active research topic. Mueller et al. (2017) designed a variational auto-encoder (VAE) framework; Hu et al. (2017) used VAE with controllable attributes; Shen et al. (2017) proposed to adversarially train a Cross-Aligned Auto-Encoder (CAAE) to align two different styles. To improve performances, several works including, (Fu et al., 2017; Yang et al., 2018; dos Santos et al., 2018; Logeswaran et al., 2018) were proposed. Fu et al. (2017) suggested a multi-head decoder to generate sentences with different styles; Yang et al. (2018) utilized language models as discriminators to stabilize training; dos Santos et al. (2018) used a classifier to aid style transfer; Logeswaran et al. (2018) also made use of a conditional discriminator for multiple style transfer.

On the other hand, a few works including, Li et al. (2018), Xu et al. (2018) adopt an *erase-and-replace* approach and design their methods to erase the style-related words first and then fill in words of different style attributes. Non-parallel text style transfer is also relevant to unsupervised machine translation. Prabhumoye et al. (2018), Subramanian et al. (2018), Logeswaran et al. (2018) and dos Santos et al. (2018) apply *back-translation* technique from unsupervised machine translation for style transfer task. Our work follows the framework of CAAE, and we propose several adjustments to improve the performance.

3 Methodology

3.1 Model Architecture

As shown in Figure 1, our model contains an encoder-decoder (E, G) and two discriminators D_{cnn}, D_{rnn}. We describe each model architecture in details.

3.1.1 Encoder-Decoder

Following prior works (Hu et al., 2017; Shen et al., 2017; Yang et al., 2018; Logeswaran et al., 2018), we use a seq-to-seq de-noising encoder-decoder (E, G) with attention mechanism (Bahdanau et al., 2014). For each input sentence x and attribute $\tilde{y}$, the encoder E encodes x to a latent code $z = E(x)$, and the decoder G decodes transferred sentence $\tilde{x} = G(z, \tilde{y})$, which can be further back-translated to reconstruct the original sentence. Based on this framework, we design *word-level condition* model for better results.

Word-level Condition The most unique component between our encoder-decoder and previous works is the condition architecture of attributes. Most of style transfer works (Hu et al., 2017; Shen et al., 2017; Logeswaran et al., 2018) treat attributes y as part of the initial vector fed into the RNN cell in the decoder, and we argue that the conditioning structure is important to the model performance. In our decoder G, we embed y to a vector and concatenate the vector with the output h_t of GRU cell at each time step t. More formally, at each time step t, the hidden state h_t and output probabilities o_t are generated as follows:

$$h_t = GRU(h_{t-1}, x_t, c_t|z)$$
$$o_t = \sigma(W_p([y, h_t]) + b_p)$$

where GRU denotes a Gated Recurrent Unit (Chung et al., 2015) in decoder G, and c_t is the content vector from the attention mechanism; W_p, b_p denote the projection matrix and bias to map a hidden state to an output vocabulary distribution; σ is the softmax function.

3.1.2 Discriminator

Our discriminators take output probability distributions o as inputs along with attribute labels y. Formally, for each discriminator $D \in \{D_{cnn}, D_{rnn}\}$, the function of D can be expressed as:

$$D(o, y) = f_{disc}(f_{trans}(f_{cond}(o, y))).$$

f_{cond} is a multi-layer perceptron. f_{trans} is either a bi-directional GRU or a CNN to perform a global feature transform in D_{cnn}, D_{rnn} respectively. Finally, f_{disc} is a fully-connected layer with the sigmoid function to output decisions. For simplicity, we substitute x for o as the input to discriminators in the following description.

3.2 Loss functions

We train our model with reconstruction loss L_{rec}, back-translation loss L_{bt}, discrimination loss L_{disc}, and adversarial loss L_{adv}. L_{rec} and L_{bt} force the decoder G to reconstruct the input sentence x. L_{rec}, L_{bt} are expressed as:
$L_{rec} = -\log p(x|z, y)$, $L_{bt} = -\log p(x|\tilde{z}, y)$.
L_{disc} and L_{adv} force the decoder G to output the transferred sentence $\tilde{x}$ with correct attributes $\tilde{y}$. For $D \in \{D_{cnn}, D_{rnn}\}$, L_{disc}, L_{adv} are listed as:
$L_{disc} = -\mathbb{E}_{x,y,\tilde{x},\tilde{y}}[\log D(x, y) + \log(1 - D(\tilde{x}, \tilde{y}))]$
$L_{adv} = -\sum_{D \in \{D_{cnn}, D_{rnn}\}} \{\mathbb{E}_{\tilde{x},\tilde{y}}[\log D(\tilde{x}, \tilde{y})]\}$.

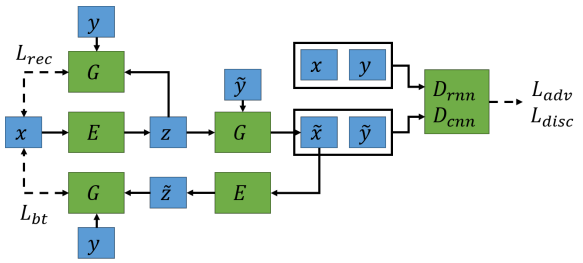

Figure 1: Overview of our model framework. Our model contains an encoder-decoder (E, G), and two discriminators D_{rnn} and D_{cnn}. We train our model with reconstruction loss L_{rec}, back-translation loss L_{bt}, adversarial loss L_{adv}, and discrimination loss L_{disc}. The dashed arrows describe where the losses are computed.

The total loss L_{tot} for our encoder-decoder (E, G) is a weighted sum of L_{rec}, L_{bt}, and L_{adv}.

3.3 Training

We split our training procedure into two phases: *reconstruction* and *transfer* phase. We first train our encoder-decoder (E, G) with loss L_{rec} in reconstruction phase, and then in transfer phase, we use total loss L_{tot} and L_{disc} to train our encoder-decoder (E, G) and the discriminators D_{cnn}, D_{rnn}, respectively. Our experiments show this approach improves content preservation significantly. A diagram about this two-phase training is provided in Appendix A.1.

4 Experiments Setup

4.1 Datasets

YelpSent Dataset The preprocessed Yelp dataset (Shen et al., 2017) consists of sentences with length limit of 15 words, labeled with either positive or negative sentiment as attributes.

AmaProd and AmaSent Dataset Amazon product dataset (He and McAuley, 2016): consists of product reviews associated with ratings of the products. We select 4 product types: (books/ movies/ electronics/ CDs), following the approach in (Kim et al., 2017) to select relevant sentences. [1]

YelpTense Dataset We use similar approach to label sentences with sentiment and past/present tense from Yelp Dataset Challenge[2]. If a sentence contains at least one verb in past tense, we label it as 'past tense'; otherwise as 'present tense'.

All the data statistics are presented in Table 5 in Appendix A.2.

4.2 Evaluation Metrics

We follow previous works and apply three automatic evaluation metrics and one human evaluation for three indicative aspects: *attribute compatibility*, *content preservation*, and *fluency*.

Attribute Compatibility To measure how well our model transfers sentence attributes, we pre-train a CNN classifier (Kim, 2014) for each attribute category (i.e. product types, sentiments, tenses) on our training data, and use the classifiers to measure the accuracy of transferred sentences associated with the desired attribute. We report the accuracy of each attribute category separately.

Content Preservation Measuring content preservation is still an open research problem. Following the previous works, we compute the BLEU score (Papineni et al., 2002) used in machine translation. In our experiments, we use self BLEU to evaluate on transferred sentences as a measurement of content preservation.

Fluency To test fluency of the generated sentences, we train a bi-directional LSTM language model on our training data for each dataset. We regard the perplexity of generated sentences as a measure for fluency.

Human Evaluation We also evaluate the transferred sentences with human assessments. In the evaluation, 8 people are asked to rate sentences based on criteria associated with three dif: attribute compatibility, content preservation, and fluency. Each aspect is rated on a 5-point Likert scale. 20 sentences on *YelpSent* with corresponding transferred sentences are randomly selected as testing examples. More details about our human evaluation are provided in Appendix A.3.

4.3 Comparison with State-Of-The-Arts

We compare with four different State-of-the-Art models: **CAAE**, **DAR**, **MultiAttr**, **ContPrev**. **CAAE** (Shen et al., 2017) consists of an auto-encoder with discriminator networks to guide text generation. **DAR** (Li et al., 2018) uses a delete-and-retrieve approach. [3] **MultiAttr** (Subramanian et al., 2018) performs multiple-attributes style transfer using back-translation (Lample et al.,

[1] We refer to dataset labeled with both sentiment and product attributes as *AmaProd Dataset*, and dataset labeled only with sentiment attribute as *AmaSent Dataset*, respectively.

[2] https://ww.yelp.com/dataset/challenge

[3] We train DAR with the source code from https://github.com/rpryzant/delete_retrieve_generate

2018, 2017; Artetxe et al., 2017) and latent representation pooling. [4] **ContPrev** (Logeswaran et al., 2018) is an auto-encoder model with a conditional discriminator for multiple attributes transfer. Among these models, in our experiments, CAAE and DAR are compared only on polarity sentiment style transfer tasks. More details about our model and training settings are provided in Appendix A.4.

5 Experimental Results

5.1 Quantitative Result

Automatic Evaluation Results Table 1 and Table 2 show the automatic evaluation results. Our model achieves higher BLEU scores and comparable transfer accuracy. We also notice that our model generates sentences with higher perplexity, while other models produce sentences with perplexity lower than the real data.

Human Evaluation Results Table 3 exhibits the human evaluation results on *YelpSent*. The results show that our sentences are evaluated higher on content preservation, and share comparable scores with other models on attribute compatibility.

Ablation test We conduct ablation experiments on our model on *YelpSent* dataset. As the results shown at Table 4, removing the word-level condition architecture decreases transfer accuracy and BLEU scores. The two-phase training procedure can also ensure a much higher BLEU scores. Using both CNN and RNN discriminator sightly improves the performance on all metrics.

Evaluation Curve We also plot the curves of transfer accuracy, BLEU score and perplexity, respectively, on the validation set, as the number of training epochs increases, across different models in Appendix A.5. According to the curves, our model achieves higher BLEU scores and relatively stable performance on all three metrics.

5.2 Qualitative Results

Our model exhibits a tendency to follow the original sentence surface structure. With the help of word-level conditional architecture, the decoder learns to make word adjustments. Sample sentences are shown in Tables 7 and 8 in Appendix A.6. For frequent occurring sentence structures across different attribute domains, our

[4] We re-implement this model with comparable results to the original publication.

Table 1: Polarity sentiment transfer on *YelpSent* & *AmaSent*

YelpSent	Sent.	BLEU	PPL
Real data	96.9%	–	20.3
Our model	87.8%	**35.5**	34.5
CAAE	83.5%	11.5	19.0
DAR	**96.3%**	0.1	20.6
MultiAttr	86.0%	12.9	**8.4**
ContPrev	91.3%	14.7	10.5
AmaSent	Sent.	BLEU	PPL
Real data	94.4%	–	34.1
Our model	77.5%	**24.5**	57.4
CAAE	75.4%	5.3	23.7
DAR	**83.4%**	0.1	37.6

ContPrev	76.6%	94.9%	14.7	13.4
AmaProd	Sent.	Prod.	BLEU	PPL
Real data	94.4%	95.6%	–	34.1
Our model	76.0%	87.4%	**22.4**	26.8
MultiAttr	**79.9%**	**90.4%**	15.3	**7.7**
ContPrev	75.8%	81.4%	11.2	17.7

Sent., **Tense** and **Prod.** represent the transfer accuracy measured by the pretrained sentiment-, tense- and product-attribute classifiers, respectively.

Table 3: Human evaluation on *YelpSent*

YelpSent	Cont.	Flu.	Sent.
Our model	**4.01**	3.54	3.17
CAAE	3.14	2.99	3.19
DAR	1.17	**4.24**	3.35
MultiAttr	3.26	3.91	**3.59**
ContPrev	3.02	3.76	3.56

Columns **Cont.**, **Flu.**, **Sent.** stand for human evaluation scores for *content preservation*, *fluency* and *sentiment compatibility*, each measured in a Likert scale from 1 through 5. (1: lowest and 5: highest)

Table 4: Model ablation test on *YelpSent*

Model	Sent.	BLEU	PPL
Real data	96.9%	–	20.3
Our model	87.8%	35.5	34.5
w/o two-phase	86.4%	26.2	44.5
w/o word-level	91.5%	3.5	34.2
w/o CNN	87.3%	28.5	39.3
w/o RNN	86.1%	31.7	42.7
w/o CNN, RNN	42.4%	72.5	20.7

model shows good results. When the original sentence sometimes has a distinct sentence structure and would require multiple editing in a larger scale, our model may not find a correct similar sentence-level surface form adjustment in the target-attribute domain and the word-level local adjustments may sometimes not be coherent.

6 Conclusion

In this paper, we conduct non-parallel style transfer among multiple attributes. We propose a seq-to-seq model with word-level condition and two-phase training. The empirical results demonstrate that our model outperforms our competitors in the polarity sentiment transfer task on *YelpSent*. In multiple attribute transfer tasks, our model also achieves comparable results with the state-of-the-art MultiAttr on *YelpTense* and *AmaProd*. We also analyze our model with ablation tests.

Although our model achieves better content preservation, the general quality of our transferred sentences can be further improved. Also, designing proper evaluation metrics is still an open problem for text style transfer. We leave these two questions as the future works.

Abstract

In this paper, we study differentiable neural architecture search (NAS) methods for natural language processing. In particular, we improve differentiable architecture search by removing the softmax-local constraint. Also, we apply differentiable NAS to named entity recognition (NER). It is the first time that differentiable NAS methods are adopted in NLP tasks other than language modeling. On both the PTB language modeling and CoNLL-2003 English NER data, our method outperforms strong baselines. It achieves a new state-of-the-art on the NER task.

1 Introduction

Neural architecture search (NAS) has become popular recently in machine learning for their ability to find new models and to free researchers from the hard work of designing network architectures. The earliest of these approaches use reinforcement learning (RL) to learn promising architectures in a discrete space (Zoph and Le, 2016), whereas others have successfully modeled the problem in a continuous manner (Liu et al., 2019; Xie et al., 2019b; Huang and Xiang, 2019). As an instance of the latter, differentiable architecture search (DARTS) employs continuous relaxation to architecture representation and makes gradient descent straightforwardly applicable to search. This leads to an efficient search process that is orders of magnitude faster than the RL-based counterparts.

Like recent methods in NAS (Xie and Yuille, 2017; Zoph and Le, 2016; Baker et al., 2016), DARTS represents networks as a directed acyclic graph for a given computation cell (see Figure 1(a)). An edge between nodes performs a predefined operation to transform the input (i.e., tail) to the output (i.e., head). For a continuous network space, DARTS uses the softmax trick to relax the categorical choice of edges to soft decisions. Then, one can optimize over the graph using standard gradient descent methods. The optimized network is inferred by choosing the edges with maximum weights in softmax.

(a) DARTS cell (b) Our cell

Figure 1: An overview of DARTS cell and our cell

However, DARTS is a "local" model because the softmax-based relaxation is imposed on each bundle of edges between two nodes. This leads to a biased model in that edges coming from different nodes are not comparable. Such a constraint limits the inference space to sub-graphs with one edge between each pair of nodes. Also, the learned network might be redundant because every node has to receive edges from all predecessors no matter they are necessary or not. This problem is similar to the bias problem in other graph-based models where local decisions make the model non-optimal (Lafferty et al., 2001; Daphne Koller and Nir Friedman, 2009).

Here we present an improvement of DARTS,

*Corresponding author.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3585–3590, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

called I-DARTS, that further relaxes the softmax-local constraint. The idea is simple - we consider all incoming edges to a given node in a single softmax. This offers a broader choice of edges and enlarges the space we infer the network from. For example, one can simultaneously select multiple important edges between two nodes and leave some node pairs unlinked (see Figure 1(b)).

I-DARTS outperforms strong baselines on the PTB language modeling and CoNLL named entity recognition (NER) tasks. This gives a new state-of-the-art on the NER dataset. To our knowledge, it is the first time to apply differentiable architecture search methods to NLP tasks other than language modeling. More interestingly, we observe that our method is 1.4X faster than DARTS for convergence of architecture search. Also, we provide the architectures learned by I-DARTS, which can be referred for related tasks.

2 The Method

Although we will restrict ourselves to language modeling and NER for experiments, in the section, we discuss the more general case. We choose recurrent neural networks (RNNs) to model the sequence generation and tagging problems. Given a sequence of input vectors $\{x_1, ..., x_L\}$, we repeat applying RNN cells to generate the output $\{h_1, ..., h_L\}$. The RNN cell is defined as: $h_t = g(x_t, h_{t-1})$, where t is the time step and $g(\cdot, \cdot)$ is the function of the cell. In NAS, the objective is to search for a good $g(\cdot, \cdot)$ in an automatic fashion.

2.1 Architecture Search Space

We follow the assumption that $g(\cdot, \cdot)$ is a DAG consisting of N nodes and edges among them (Liu et al., 2019; Xie et al., 2019b; Pham et al., 2018). An edge $o^{i,j}(\cdot)$ between node pair (i, j) indicates an activation function from node j to node i. For node i, it simply sums over vectors from all predecessor nodes ($j < i$), followed by a linear transformation with a parameter matrix W_i. More formally, let s_i be the state of node i. We define s_i to be:

$$s_i = \sum_{j<i} o^{i,j}(s_j \cdot W_j) \tag{1}$$

See Figure 1 for an example network (red lines). Note that this model can encode an exponential number of graphs by choosing different sub-sets of edges (i.e., choosing $o^{i,j}(\cdot)$ for each (i,j)). The output of search is the optimal edge selection and the corresponding network.

2.2 Improved DARTS

Given a set of edges $\{o_k^{i,j}\}$, one can try each $o_k^{i,j}$ to induce a network, and then train and evaluate it. The optimal choice is the edge with highest accuracy on the validation set. In I-DARTS, we instead do this in a soft way. We re-define s_i as:

$$s_i = \sum_{j<i} \sum_k \alpha_k^{i,j} \cdot o_k^{i,j}(s_j \cdot W_j) \tag{2}$$

where $\alpha_k^{i,j}$ is the weight indicating the importance of $o_k^{i,j}(\cdot)$. It is computed by the softmax normalization over edges between nodes i and j, like this

$$\alpha_k^{i,j} = \frac{\exp(w_k^{i,j})}{\sum_{k'} \exp(w_{k'}^{i,j})} \tag{3}$$

where $w_k^{i,j}$ is the model parameter. This model reduces the architecture search problem to learn continuous variables $\{\alpha_k^{i,j}\}$, which can be implemented using efficient gradient descent methods. After training, the final architecture is encoded by the edges with largest weights.

Eq. (3) imposes a constraint that weights $\{\alpha_k^{i,j}\}$ are normalized for each j. Such a model in general faces the local decision and bias problems as pointed out in graph-based methods (Lafferty et al., 2001; Daphne Koller and Nir Friedman, 2009). Moreover, the inference has to be performed in a smaller space because we have to infer exactly one edge between each node pair and exclude networks violating this constraint.

Here we remove the constraint and system bias. To this end, we compute the softmax normalization over all incoming edges for node i:

$$\alpha_k^{i,j} = \frac{\exp(w_k^{i,j})}{\sum_{j<i} \sum_{k'} \exp(w_{k'}^{i,j})} \tag{4}$$

It provides us a way to compare all incoming edges in the same manner, rather than making a local decision via a bundle of edges from node j. As another bonus, this method can search for networks that are not covered by DARTS, e.g., networks that contain two edges between the same node pair.

See Figure 1(b) for an illustration of our method. To infer the optimal architecture, we basically do the same thing as in DARTS. The differ-

ence lies in that we select top-n edges with respect to $\alpha_k^{i,j}$. Here n is a hyper-parameter that controls the density of the network. E.g., $n = 1$ means a sparse net, and $n = \infty$ means a very dense net involving all those edges.

3 Experiments

We test our method on language modeling and named entity recognition tasks. Our experiments consist of two parts: recurrent neural architecture search and architecture evaluation. In architecture search, we search for good RNN cell architectures. Then, we train and evaluate the learned architecture.

3.1 Architecture Search

For language modeling, we run neural search on the PTB corpus. We use the standard preprocessed version of the dataset (Pham et al., 2018). To make it comparable with previous work, we copy the setup used in (Pham et al., 2018; Liu et al., 2019). The recurrent cell consist of 8 nodes. The candidate operation set of every edge contain 5 activation functions, including zeroize, tanh, relu, sigmoid, and identity. To learn architectures, we run the search system for 40 training epochs with a batch size of 256. We optimize models parameters $\{W_i\}$ using SGD with a learning rate of 20 and a weight decay rate of 5e-7, and optimized softmax relaxation parameters $\{w_k^{i,j}\}$ by Adam with a learning rate of 3e-3 and a weight decay rate of 1e-3. For RNN models, we use a single-layer recurrent network with embedding and hidden sizes = 300. It takes us 4 hours to learn the architecture on a single GPU of NVIDIA 1080Ti.

For named entity recognition, we choose the CONLL-2003 English dataset. We follow the same setup as in language modeling but with a different learning rate (0.1) and a different hidden layer size (256). It takes us 4 hours to learn the architecture on the same GPU.

3.2 Architecture Evaluation

Firstly, the discovered architecture is evaluated on the language modeling task. Before that, we train it on the same data used in architecture search. The size of hidden layers is set to 850. We use averaged SGD to train the model for 3,000 epochs, with a learning rate of 20 and a weight decay rate of 8e-7. For a fair comparison, we do not fine-tune the model at the end of the training.

Architecture	Perplexity		Search Cost
	val	test	(GPU days)
V-RHN	67.9	65.4	-
LSTM	60.7	58.8	-
LSTM + SC	60.9	58.3	-
LSTM + SE	58.1	56.0	-
ENAS	60.8	58.6	0.50
DARTS	58.3	56.1	0.25
Random RNNs	63.7	61.2	-
I-DARTS ($n = 1$)	58.0	56.0	0.17
I-DARTS ($n = 2$)	-	-	-

Table 1: Perplexities on PTB (lower is better). V-RHN (Zilly et al., 2016) indicates Variational RHN. LSTM + SC (Yang et al., 2018) indicates LSTM with skip connection. LSTM + SE (Merity et al., 2018) indicates LSTM with mixture of softmax. Random RNNs indicates that the network generated by random initialized.

Table 1 shows the perplexities of different RNN models on PTB. We also report the results of previous systems. The model discovered by I-DARTS achieves a validation perplexity of 58.0 and a test perplexity of 56.0 when $n = 1$. It is on par with the state-of-the-art models that are designed either manually or automatically. However, we find that the model failed to optimize when $n = 2$. It might result from the complex interaction between operations. We leave this issue for future study.

Since architecture search is initialization-sensitive (Pham et al., 2018; Liu et al., 2019), we search the architectures for 4 times with different random seeds. We evaluate the architecture every 10 search epochs by retraining it on PTB for 500 epochs. We compare DARTS with our I-DARTS method with the same random seed. See Figure 2(b) for averaged validation perplexities over 4 different runs at different search epochs. We see that I-DARTS is easier to converge than DARTS (4 hours). It is 1.4X faster than that of DARTS. Another interesting finding is that I-DARTS achieves a lower validation perplexity than DARTS during architecture search. This may indicate better architectures found by I-DARTS because the search model is optimized with respect to validation perplexity.

Then, we test the learned architecture in a named entity recognition system on the English data from CoNLL-2003 shared task (Sang and Meulder, 2003). Following previous work (Akbik et al., 2018; Peters et al., 2017), we report the averaged F1 score over 5 runs on the test set. For modeling, we choose the single-layer RNN-CRF

model because it achieved state-of-the-art results on several sequence labeling tasks (Lample et al., 2016; Ma and Hovy, 2016). We use GloVe 100-dimensional word embeddings (Pennington et al., 2014) and pooled contextual embeddings (Akbik et al., 2019) as pre-trained word embeddings. We replace the standard bidirectional LSTMs with the discovered recurrent neural cells. Also, we set the hidden layer size to 512 and apply variational dropout to the input and output of the RNN layer. We train the network using SGD with a learning rate of 0.1 and a gradient clipping threshold of 5.0. We reduce the learning rate by a factor of 0.25 if the test error does not decrease for 2 epochs.

Table 2 shows a comparison of different methods. Our baseline uses RNN cells generated from random initialized whose F1-score varies greatly and is lower than that of the standard LSTMs. I-DARTS significantly outperforms Random RNNs and DARTS. The best score is achieved when $n = 1$. It indicates that the task prefers a sparse network. Also, we see that our model works with the advanced pre-trained language models in that we replace the LSTM cell to our cell. The I-DARTS architecture yields a new RNN-based state-of-the-art on this task (93.47 F1-score). In Table 2, We find it interesting that Random RNNs are good for NER task. This may result from the design of search space that fit for such tasks substantially. Search space is also a key factor in neural architecture search that new efforts should focus on (Xie et al., 2019a).

We visualize the discovered cells in Figure 3. Each cell is a directed acyclic graph consisting of an ordered sequence of 8 nodes with an activation function applied on each edge. These automatically discovered cells are complex and hard to be designed manually. An interesting phenomenon comes up that the best architecture on language modeling is different from that on name entity recognition. This might result from the fact that different tasks have different inductive bias. Also, this suggests the possibility of architecture selection from the top-k search results on the target task.

4 Related Work

Neural architecture search has been proposed to automatically search for better architectures, showing competitive results on several tasks, e.g., image recognition and language modeling. A s-

trand of NAS research focuses on reinforcement learning (Zoph and Le, 2016) and evolutionary algorithm-based (Xie and Yuille, 2017) methods. They are powerful but inefficient. Recent approaches speed up the search process by weight sharing (Pham et al., 2018) and differentiable architecture search (Liu et al., 2019). But there is no discussion on the softmax-local problem in previous work. Moreover, previous methods are often tested on language modeling. It is rare to see studies on these methods for other NLP tasks.

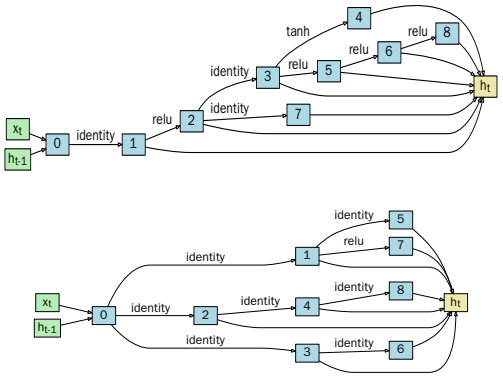

Figure 3: Cells discovered by I-DARTS for language modeling (top) and NER (bottom).

5 Conclusions

We improved the DARTS to address the bias problem by removing the softmax-local constraint. Our method is search efficient and discovers several better architectures for PTB language modeling and CoNLL named entity recognition (NER) tasks. We plan to consider the network density problem in search and apply I-DARTS to more tasks in our future study.

Abstract

Bilinear models such as DistMult and ComplEx are effective methods for knowledge graph (KG) completion. However, they require large batch sizes, which becomes a performance bottleneck when training on large scale datasets due to memory constraints. In this paper we use occurrences of entity-relation pairs in the dataset to construct a joint learning model and to increase the quality of sampled negatives during training. We show on three standard datasets that when these two techniques are combined, they give a significant improvement in performance, especially when the batch size and the number of generated negative examples are low relative to the size of the dataset. We then apply our techniques to a dataset containing 2 million entities and demonstrate that our model outperforms the baseline by 2.8% absolute on hits@1.

1 Introduction

A Knowledge Graph (KG) is a collection of facts which are stored as triples, e.g. *Berlin is-capital-of Germany*. Even though knowledge graphs are essential for various NLP tasks, open domain knowledge graphs have missing facts. To tackle this issue, there has recently been considerable interest in KG completion methods, where the goal is to rank correct triples above incorrect ones.

Embedding methods such as DistMult (Yang et al., 2014) and ComplEx (Trouillon et al., 2016) are simple and effective methods for this task, but are known to be sensitive to hyperparameter and loss function choices (Kadlec et al., 2017; Lacroix et al., 2018). When paired with the right loss function, these methods need large minibatches and a large number of corrupted triples per each positive triple during training to reach peak performance. [1] This causes memory issues for KGs in the wild, which are several magnitudes bigger than the common benchmarking datasets.

To address the issue of scalability, we develop a framework that could be used with any bilinear KG embedding model. We name our model **JoBi** (**Jo**int model with **Bi**ased negative sampling). Our framework uses occurrences of entity-relation pairs to overcome data sparsity, and to bias the model to score plausible triples higher. The framework trains a base model jointly with an auxiliary model that uses occurrences of pairs within a given triple in the data as labels. For example, the auxiliary model would receive the label 1 for the triple (*Berlin is-capital-of France*) if the pairs (*Berlin is-capital-of*) and (*is-capital-of France*) are present in the training data, while the base model would receive the label 0.

The intuition for using bigram occurrences is to capture some information about restrictions on the set of entities that could appear as the object or subject of a given relation; that information should implicitly correspond to some underlying type constraints. For example, even if *(Berlin is-capital-of France)* is not a correct triple, *Berlin* is the right type for the subject of *is-capital-of*.

Our framework also utilizes entity-relation pair occurrences to improve the distribution of negative examples for contrastive training, by sampling a false triple e.g. (*Berlin is-capital-of France*) with higher probability if the pairs (*Berlin is-capital-of*) and (*is-capital-of France*) both occur in the dataset. This tunes the noise distribution for the task so that it is more challenging, and hence the model needs a fraction of the negative examples compared to a uniform distribution.

We show empirically that joint training is especially beneficial when the batch size is small,

*Work done while the author was an intern

[1]The choice of loss function has a very strong effect on the optimal negative ratio, but with any loss function, larger batches tend to improve the results.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3591–3596, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

and biased negative sampling helps model learn higher quality embeddings with much fewer negative samples. We show that the two techniques are complementary and perform significantly better when combined. We then test JoBi on a large-scale dataset, and demonstrate that JoBi learns better embeddings in very large KGs.

2 Background

Formally, given a set of entities $\mathcal{E} = \{e_0, \ldots, e_n\}$ and a set of relations $\mathcal{R} = \{r_0, \ldots, r_m\}$, a Knowledge Graph (KG) is a set triples in the form $\mathcal{G} = \{(h, r, t)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where if a triple $(h, r, t) \in \mathcal{G}$, then relation r holds between entities h and t. Given such a KG, the aim of KG completion is score each triple in $\mathcal{E} \times \mathcal{R} \times \mathcal{E}$, so that correct triples are assigned higher scores than the false ones. KG embedding methods achieve this by learning dense vector representations for entities and relations through optimizing a chosen scoring function. A class of KG completion models such as RESCAL (Nickel et al., 2012), DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016), SimplE (Kazemi and Poole, 2018) and TUCKER (Balažević et al., 2019) define their scoring function to be a bilinear interaction of the embeddings of entities and relations in the triple. For this work we consider DistMult, ComplEx and SimplE as our baseline models due to their simplicity.

DistMult. (Yang et al., 2014) is a knowledge graph completion model that defines the scoring function for a triple as a simple bilinear interaction, where the entity has the same representation regardless of whether it appears as the head or the tail entity. For entities h, t, relation r, and the embeddings $\boldsymbol{h}, \boldsymbol{t}, \boldsymbol{r} \in \mathbb{R}^d$, the scoring function is defined as:

$$s(h, r, t) = \boldsymbol{h}^T \operatorname{diag}(\boldsymbol{r})\, \boldsymbol{t} \tag{1}$$

where $\operatorname{diag}(\boldsymbol{r})$ is a diagonal matrix with $\boldsymbol{r}$ on the diagonal.

ComplEx. (Trouillon et al., 2016) is a bilinear model similar to DistMult. Because of its symmetric structure, DistMult cannot model anti-symmetric relations. ComplEx overcomes this shortcoming by learning embeddings in a complex vector space, and defining the embedding of an entity in tail position as the complex conjugate of the embedding in the head position.

Let $\boldsymbol{h}, \boldsymbol{r}, \boldsymbol{t} \in \mathbb{C}^d$ be the embeddings for h, r, t. The score for ComplEx is defined as follows:

$$s(h, r, t) = \text{Re}\left(\boldsymbol{h}^T \operatorname{diag}(\boldsymbol{r}) \bar{\boldsymbol{t}}\right) \tag{2}$$

Where $\overline{\boldsymbol{a}}$ denotes the complex conjugate of $\boldsymbol{a}$, and $\text{Re}(\boldsymbol{a})$ denotes the real part of the complex vector $\boldsymbol{a}$.

SimplE. (Kazemi and Poole, 2018) is also a bilinear model similar to DistMult. Each entity has two associated embeddings $\boldsymbol{e}_1, \boldsymbol{e}_2 \in \mathbb{R}^d$, where one is the representation of e as the head, and the other as the tail entity of the triple. Each relation also has two associated embeddings: $\boldsymbol{r}$ and $\boldsymbol{r}^{-1}$, where $\boldsymbol{r}^{-1}$ is the representation for the reverse of r. The score function is defined as:

$$\begin{aligned} s(h, r, t) = 1/2\,(\boldsymbol{h}_1)^T\ \operatorname{diag}(\boldsymbol{r})\boldsymbol{t}_1 \\ +1/2\,(\boldsymbol{t}_2)^T\ \operatorname{diag}(\boldsymbol{r}^{-1})\boldsymbol{h}_2 \end{aligned} \tag{3}$$

3 Joint framework

JoBi contains two copies of a bilinear model, where one is trained on labels of triples, and the other on occurrences of entity-relation pairs within the triples. For the pair module, we label a triple (h, r, t) correct if there are triples (h, r, t') and (h', r, t) in the training set for some t' and h'.

The scoring functions for the two models are s_{bi} and s_{tri}, for the pair and the triple modules respectively. We tie the weights of the entity embeddings, but let the embeddings for the relations be optimized separately. The equations using ComplEx as the base model are as follows:

$$s_{\text{tri}}(h, r, t) = \text{Re}\left(\boldsymbol{h}^T \operatorname{diag}(\boldsymbol{r}_{\text{tri}}) \bar{\boldsymbol{t}}\right) \tag{4}$$

$$s_{\text{bi}}(h, r, t) = \text{Re}\left(\boldsymbol{h}^T \operatorname{diag}(\boldsymbol{r}_{\text{bi}}) \bar{\boldsymbol{t}}\right) \tag{5}$$

We define the framework for DistMult and SimplE analogously. During training, we optimize the two jointly, but use only s_{tri} during test time. Hence, the addition of the auxiliary module has no effect on the number of final parameters of the trained model. Note that even during training, this doesn't increase model complexity in any significant way since the number of relations in KGs are often a fraction of the number of entities.

For each triple in the minibatch, we generate n_{neg} negative examples per positive triple by randomly corrupting the head or the tail entity. For s_{tri}, we use the negative log-likelihood of softmax as the loss function, and for s_{bi} we use binary cross

entropy loss. We combine the two losses via a simple weighted addition with a tunable hyperparameter α:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{tri}} + \alpha \mathcal{L}_{\text{bi}} \quad (6)$$

Biased negative sampling. We also examine the effect of using the pair cooccurrence information for making the contrastive training more challenging for the model. For this, we keep the model as is, but with probability p, instead of corrupting the head or the tail of the triple with an entity chosen uniformly at random, we corrupt it with an entity that is picked with uniform probability from the set of entities that occur as the head or tail entity of the relation in the given triple. To illustrate, when sampling a negative tail entity for the tuple *Berlin is-capital-of*, this method causes the model to pick *France* with higher probability than *George Orwell* if *France* but not *George Orwell* occurs as the head entity for the relation *is-capital-of* in the training data.

4 Experiments

We perform our experiments on standard datasets FB15K (Bordes et al., 2013), FB15K-237 (Toutanova et al., 2015), YAGO3-10 (Dettmers et al., 2018), and on a new large-scale dataset FB1.9M which we construced from FB3M (Xu and Barbosa, 2018). [2] We focus on YAGO3-10 since it is 10 times larger than the other two and better reflects how the performance of the models scale. We present the comparison of the sizes of these datasets in Table 1, and further details could be found in Appendix A.

For evaluation, we rank each triple (h, r, t) in the test set against (h', r, t) for all entities h', and similarly against (h, r, t') for all entities t'. We filter out the candidates that have occurred in training, validation or test set as described in Bordes et al. (2013), and we report average hits@1, 3, 10 and mean reciprocal rank (MRR).

We re-implement all our baselines and obtain very competitive results. In our preliminary experiments on baselines, we found that the choice of loss function had a large effect on performance, with negative log-likelihood (NLL) of softmax consistently outperforming both max-margin and logistic losses. Larger batch sizes lead to better performance. With NLL of sampled softmax, we found that increasing the number of generated negatives steadily increases performance[3], and state-of-the-art results could be reached by using the full softmax as used in Joulin et al. (2017) and Lacroix et al. (2018). This technique is possible for standard benchmarks but not for large KGs, and we report results in Appendix D for all datasets small enough to allow for full contrastive training. However, our main experiments use NLL of sampled softmax since our focus is on scalability. Note that results with full softmax (Appendix D) demonstrate that our implementation of baselines is very competitive.Our implementation of ComplEx performs significantly better than ConvE (Dettmers et al., 2018) on two out of the three datasets, and come close to results of Lacroix et al. (2018) who use extremely large embeddings as well as full softmax, thus cannot be scaled. Our code is publicly available. [4]

For most of our experiments, we choose to use ComplEx as the base for our model (**JoBi ComplEx**), since this configuration consistently outperformed others in preliminary experiments. To test the effect of our techniques on different bilinear models, we report results with DistMult (**JoBi DistMult**) and SimplE (**JoBi SimplE**) on FB15K-237.

Discussion. It could be seen in Table 2 that JoBi ComplEx outperforms both ComplEx and DistMult on all three standard datasets, on all the metrics we consider. For Hits@1, JoBi Complex outperforms baseline ComplEx by 4% on FB15K-237, 6.4% on FB15K and 5.6% on YAGO3-10.

Moreover, results in Table 2 demonstrate that JoBi improves performance on DistMult and SimplE. It should be noted that on FB15K-237, all JoBi models outperform all the baseline models, regardless of the base model used.

Lastly, results on FB1.9M (Table 3) demonstrate that JoBi improves performance on this very

[2] We do not perform experiments on WordNet derived datasets WN18 or WN18RR because bigram modelling would not provide any information – all entities are synsets and almost all can occur as an object or subject to all the possible relations.

[3] This effect is not observed when using logistic-loss or max-margin loss

large dataset, where it is not possible to perform softmax over the entire set of entities, or have very large embedding sizes due to memory constraints.

Although one epoch for JoBi takes slightly longer than the baseline, JoBi converges in fewer epochs, resulting in shorter running time overall. We report running times on FB1.9M in Table 4.

Comparison with TypeComplex For results of TypeComplex, Jain et al. (2018) use a wider set of negative ratios in their grid search than we do. To isolate the effects of the different models from hyperparameter choices, we set the negative ratio for our model to be 400 to match the setting on their best performing models. We keep the other hyperparameters the same as the best performing models for the previous experiments.

Jain et al. (2018) use a modified version of the ranking evaluation procedure to report their results, where they only rank the tail entity against all other entities. To be able to compare our model to theirs, we also report the performance of our framework on this modified metric. The results

FB15K-237	*h@1*	*h@3*	*h@10*	*MRR*
ComplEx	0.209	0.347	0.535	0.314
TypeComplex	**0.296**	-	0.575	**0.389**

JoBi ComplEx	0.507	0.647	**0.742**	**0.591**

Table 5: Comparison with TypeComplex where the scores are calculated ranking only the tail entities. Results for TypeComplex are taken from Jain et al. (2018). h@k denotes hits at k.

for these experiments can be found in Table 5.

Our model generally outperforms TypeComplex by a large margin on hits@10. It also outperforms TypeComplex on MRR by a moderate margin except on FB15K-237, the smallest dataset. On the other hand, TypeComplex outperforms our model on hits@1 in two out of the three datasets. In fact for FB15K, TypeComplex does worse on hits@10 compared to the baseline model. This suggests that TypeComplex may be compromising on hits@k where k is larger to improve the hits@1 metric, which might be undesirable depending on the application.

Qualitative analysis. We analyzed correct predictions made by JoBi ComplEx but not regular ComplEx. Among relations in YAGO3-10, major gains can be observed for *hasGender* (Appendix C). The improvement comes solely from tail-entity predictions, with hits@1 increasing from 0.22 to 0.86. Furthermore, we found that the errors made by ComplEx are exactly of the kind that can be mitigated by enforcing plausibility: ComplEx predicts an object that is not a gender (e.g. a sports team or a person) 65% of the time; JoBi makes such an obvious mistake only 2% of the time.

Ablation studies. We compare joint training without biased sampling (**Joint**) and biased sampling without joint training (**BiasedNeg**) to the full model JoBi on YAGO3-10. The results can be found in Table 6. We also conduct experiments to isolate the effect of our techniques on varying batch sizes and negative ratios. The results for this experiment are presented in Figures 1 and 2. Training details can be found in Appendix B.

	h@1	*h@3*	*h@10*	*MRR*
Baseline	0.277	0.44	0.589	0.383
BiasedNeg	0.276	0.427	0.568	0.375
Joint	0.287	0.447	0.601	0.392
JoBi	**0.333**	**0.477**	**0.617**	**0.428**

Table 6: Results of ablation study on ComplEx model.

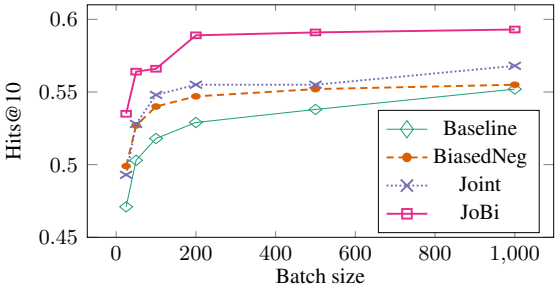

Figure 1: Performances on YAGO3-10 with different batch sizes

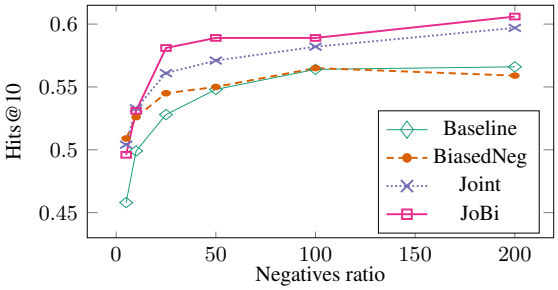

Figure 2: Performances on YAGO3-10 with different negative ratios

In Table 6 it can be seen that Joint on its own gives a slight performance boost over the baseline, and BiasedNeg performs slightly under the baseline on all measures. However, combining our two techniques in JoBi gives 5.6% points improvement on hits@1. This suggests that biased negative sampling increases the efficacy of joint training greatly, but is not very effective on its own.

Figure 1 and 2 shows that JoBi not only consistently performs the best over the entire range of parameters, but also delivers a performance improvement that is especially large when the batch size or the negative ratio is small. This setting was designed to reflect the training conditions on very large datasets. It can be seen that BiasedNeg is more robust to low values of negative ratios, and both BiasedNeg and Joint alone show less deterioration in performance as the batch size decreases. When these two methods are combined in JoBi, the training becomes more robust to different choices on both these parameters.

The reason behind BiasedNeg performing worse on its own but better with Joint could be the choice of binary cross entropy loss for the pair module. We speculate that as the negative ratio increases, the ratio of negative to positive examples for this module becomes more skewed. Biasing the negative triples in the training alleviates this problem by making the classes more balanced, and allows the joint training to be more effective.

4.1 Related work

Utilizing pair occurrences for embedding models have been considered before, both as explicit model choices and as negative sampling strategies. Chang et al. (2014) and Krompaß et al. (2015) use pair occurrences to constrain the set of triples to be used in the optimization procedure. For methods that rely on SGD with contrastive training, this translates to a special case of our biased sampling method where $p = 1$. Garcia-Durán et al. (2016) present *TATEC*, a model that combines bigram and trigram interactions. The trigram model uses a full matrix representation for relations, and hence has many more parameters compared to our model. Jain et al. (2018) present *JointDM* and *JointComplex*, which could be viewed as a simplification of *TATEC*. Unlike our model, both of these methods use the bigram terms both in training and evaluation, do not share any of the embeddings between two models, and do not provide supervision based on pair occurrences in the data. Other methods that have been considered for improving the negative sampling procedure includes adversarial (Cai and Wang, 2018) and self-adversarial (Sun et al., 2019) training. None of these methods focus on improving the models to scale to large KGs.

5 Conclusion

We have presented a joint framework for KG completion that utilizes entity-relation pair occurrences as an auxiliary task, and combined it with a technique to generate informative negative examples with higher probability. We have shown that joint training makes the model more robust to smaller batch sizes, and biased negative sampling to different values of the number of generated negative samples. Furthermore, these techniques perform well above baselines when combined, and are effective on a very large KG dataset. Applying JoBi to non-bilinear models is also possible, but left for future work.

Single Training Dimension Selection for Word Embedding with PCA

Yu Wang
Apple
w.y@apple.com

Abstract

In this paper, we present a fast and reliable method based on PCA to select the number of dimensions for word embeddings. First, we train one embedding with a generous upper bound (e.g. 1,000) of dimensions. Then we transform the embeddings using PCA and incrementally remove the lesser dimensions one at a time while recording the embeddings' performance on language tasks. Lastly, we select the number of dimensions while balancing model size and accuracy. Experiments using various datasets and language tasks demonstrate that we are able to train 10 times fewer sets of embeddings while retaining optimal performance. Researchers interested in training the best-performing embeddings for downstream tasks, such as sentiment analysis, question answering and hypernym extraction, as well as those interested in embedding compression should find the method helpful.

1 Introduction

Word embeddings constitute an integral part of the implementation of numerous NLP tasks ranging from sentiment classification (Lin et al., 2015), nationality classification (Ye et al., 2017), classification of behavior on Twitter (Wang et al., 2017), to measuring document similarity (Kusner et al., 2015). The strength of word embeddings stems from their embedding words into low dimensional continuous vector space (Mnih and Kavukcuoglu, 2013; Pennington et al., 2014; Tang et al., 2015; Raunak, 2017).

Various algorithms have been proposed for learning words' vector space representations, including most notably Mikolov et al. (2013b), Pennington et al. (2014), and Nickel and Kiela (2017). However, the exact definition of 'low' dimensionality is rarely explored. As pointed out by Yin and Shen (2018), the most frequently used dimensionality is 300, largely due to the fact that the early influential papers (Mikolov et al., 2013b; Pennington et al., 2014) used 300. Other often used dimensionalities include 200 (Tang et al., 2015; Ling et al., 2016; Nickel and Kiela, 2017) and 500 (Tang and Liu, 2009; Perozzi et al., 2014).

The impact of vector dimension on embeddings' performance is well known (Lai et al., 2016). With too few dimensions, the model will underfit; with too many dimensions the model will overfit. Both undercut the embeddings' performance (Yin and Shen, 2018). What is also known is that the size of the embeddings will grow linearly with the vector dimension (Ling et al., 2016; Raunak, 2017). What is less known is how to identify the optimal vector dimension given any dataset. The method we propose here helps fill this gap.

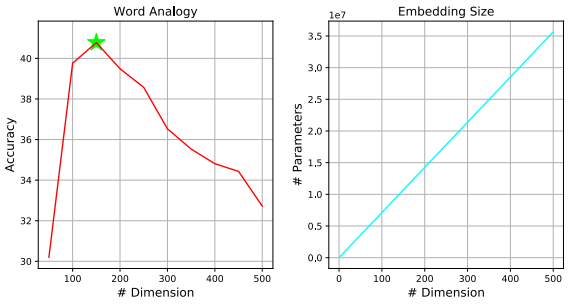

Figure 1: Left: Accuracy for the word analogy task as a function of vector dimension (dimension incremental is 50). Right: The number of embedding parameters as a function of vector dimension. Results are generated using the Text8 dataset with a vocabulary size of 71,291.

We offer a fast and reliable PCA-based method that (1) only needs to train the embeddings once and (2) is able to select vector dimension with competitive performance.[1] First, we train one embedding with a generous upper bound (e.g. 1,000)

[1] As such, the selected dimension is a Pareto-optimal dimension that balances embedding size and performance.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3597–3602,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of dimensions. Then we transform the embeddings using PCA and incrementally remove the lesser dimensions one at a time while recording the embeddings' performance on language tasks. Lastly we calculate the best dimensionality and return the corresponding embeddings.

Experiments using various datasets and language tasks reveal three key observations:

- The optimal dimensionality calculated on the basis of PCA agrees with that by grid search.
- The resulting embedding is competitive against the one selected by grid search.
- Different upper-bound dimensionalities (e.g. 500, 1000) point to the same optimal dimensionality.

Researchers interested in downstream tasks, such as sentiment analysis (Lin et al., 2015), question answering (Devlin et al., 2018) and hypernym extraction (Chen et al., 2018), as well as those interested in embedding compression should find the method helpful.

2 Related Work

Our work draws inspiration from Yin and Shen (2018). The authors build on the Latent Semantics Analysis (LSA) approach and slide k from a lower bound (e.g. 10) to a generous upper bound (e.g. 1,000) in $E = U_{1:k} D^{\alpha}_{1:k,1:k}$, where U and D come from the singular-value decomposition of the signal matrix and α is a hyperparameter to be tuned. For each k, the authors generate one corresponding embedding and compare it with the simulated oracle embedding. The k that yields the smallest loss is selected. In a similar vein, our work bypasses the problem of training multiple embeddings, often necessitated by grid search, by sliding over all the k values of PCA. Compared with Yin and Shen (2018), our method is easier to implement, as we do not rely on, e.g, Monte Carlo simulations of the oracle embeddings.

At a deeper level, our work is also connected to Yin and Shen (2018) in terms of the trade-off between bias and variance. Yin and Shen (2018) propose pairwise inner product (PIP) loss to measure the quality of an embedding. They decompose the PIP loss into a bias term and a variance term, where reducing the dimension increases the bias term but reduces the variance. They show that the bias-variance trade-off reflects the signal-to-noise ratio in dimension selection. While there is no exact 1-1 mapping from their theorem to our work, we do have analogous discussion in Section 3. The PCA step in our algorithm enables us to identify and drop dimensions that (1) contribute less to the explained variance in the embedding and yet (2) contribute equally to cosine similarity. In essence, our PCA step is removing dimensions with low signal-to-noise ratios.

Our work also draws strength from the literature on post-processing embeddings. Mu and Viswanath (2018) demonstrate that removing the top dominating directions in the PCA-transformed embeddings helps improve the embeddings' performance in word analogy and similarity tasks. Building on that, Raunak (2017) shows that by performing another iteration of PCA and dropping the bottom directions, one can further improve a model's performance as well as reduce its size. Both works focus on improving pre-trained embeddings's performance in terms of accuracy and size. By contrast, our algorithm selects the optimal dimensionality before the actual training.

In addition, our work is related to a few recent studies on model compression (Faruqui et al., 2015; Ling et al., 2016; Shu and Nakayama, 2018). In particular, Ling et al. (2016) seek to drop the least significant digits to reduce the embeddings' size. By comparison, our method removes the least significant dimensions (in terms of explained variance (Bishop, 2006)). It should be noted that the two methods complement each other, as one focuses on dimension selection whereas the other on limited precision representation.

3 Algorithm

In this section, we formally describe how to select a competitive dimensionality by training one embedding. We state the proposed algorithm in Algorithm 1.

First, we note that the PCA transformation (when retaining all the N dimensions) does not affect embeddings' performance on word similarity tasks. Any potential performance gain should come from dropping the lesser dimensions. By "lesser dimensions," we mean the dimensions that contribute little to the explanation of variance (Bishop, 2006).

In Figure 2, we first transform an embedding

Algorithm 1 Select the Optimal Dimensionality using PCA

Set dimension upper bound N; select language task from {word analogy, similarity}
Train embedding E with N dimensions
Transform E using PCA: $(u_1, u_2, ..., u_N; \tilde{E}) \leftarrow \text{PCA}(E)$, where $u_1, u_2, .., u_N$ are the new basis vectors, $\tilde{E}$ represents the transformed coefficients
for $i = N$ to 2 **do**
  E = E-$\tilde{E}_{:,i} \cdot u_i$, where $\tilde{E}_{:,i}$ represents the ith column of $\tilde{E}$ and each scalar in $\tilde{E}_{:,i}$ scales vector u_i
  Evaluate E on the selected language task, record (i, metric)
end for
Return the selected dimension: $[\underset{i}{\text{argmax}} f(\text{i, metric})]$-1, where f is a score function that balances performance and model size and i is between 2 and N

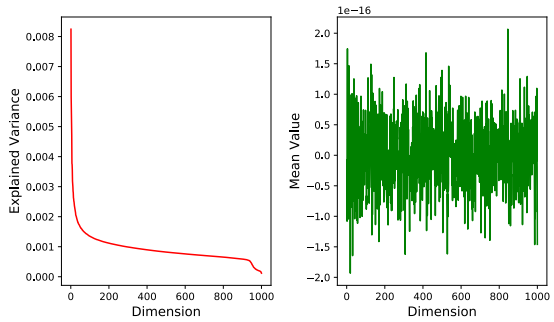

Figure 2: Left: explained variance drops sharply after the top 100 dimensions. Right: all the 1,000 dimensions have roughly the same mean value.

using PCA, so that each new dimension represents a principal component. We show that the explained variance goes drastically down for dimensions beyond the 100th and stays relatively stable for 100th-1,000th dimensions. In terms of magnitude, the first dimension explains 69.2 times more variance than the last dimension.

While different dimensions contribute differently to the explained variance, they nonetheless contribute equally to the calculation of inner product (Figure 2, right). Therefore, the lesser dimensions, with less variance but equal weighting, effectively decreases the discriminative power of the model. Removing these lesser dimensions enables us to focus on the more discriminative dimensions. To identify optimal dimensionality, beyond which all dimensions are considered lesser, we turn to experiments in Section 4.

4 Experiments

Given the popularity of the word2vec model (Mikolov et al., 2013b), we use Skip-gram as the embedding algorithm. Following Yin and Shen (2018) and Grave et al. (2017), we use the widely used benchmark datasets, Text8 (Mahoney, 2011) and WikiText-103 (Merity et al., 2017), as the training datasets. For ground truth, we train 20 embeddings, with dimensions ranging from 50 to 1,000 at an interval of 50 as well as two embeddings with dimensions of 5 and 25.[2] Here we have made the implicit assumption that 1,000 is an upper bound for the embedding space's dimensionality. For each embedding, we train 200 epochs (Pennington et al., 2014; Shazeer et al., 2016) and keep only the checkpoint that performs best on the word analogy task (Mikolov et al., 2013a). Our experiments focus on (1) comparing our method with grid-search based ground truth and (2) examining consistency between different upper bounds.

4.1 Performance Compared with Grid Search

In this subsection, we compare the optimal dimensionality that our method calculates with the ground truth (Figure 3). We perform the comparison across three testing datasets: Wordsim 353 (Finkelstein et al., 2002), RW Stanford (Luong et al., 2013) and MTurk 771 (Halawi et al., 2012). Figure 3 demonstrates that our PCA based method (with one training only) is able to uncover the optimal dimensionality. Table 1 reports the distance in selected dimensionalities.

We also observe that the optimal embedding that results from our method (with retraining) is competitive against the optimal embedding found using grid search. In Figure 3, we mark out the respective optimal performances of the two approaches in similarity tasks. In Table 2, we further

[2] A larger interval will save researchers more time, but may result in a sub-optimal dimensionality. While a smaller interval may give more accurate results, it requires training more sets of embeddings proportionally. Our proposed method, by contrast, can scan through all the dimensions at the finest granularity, 1, at virtually no extra cost.

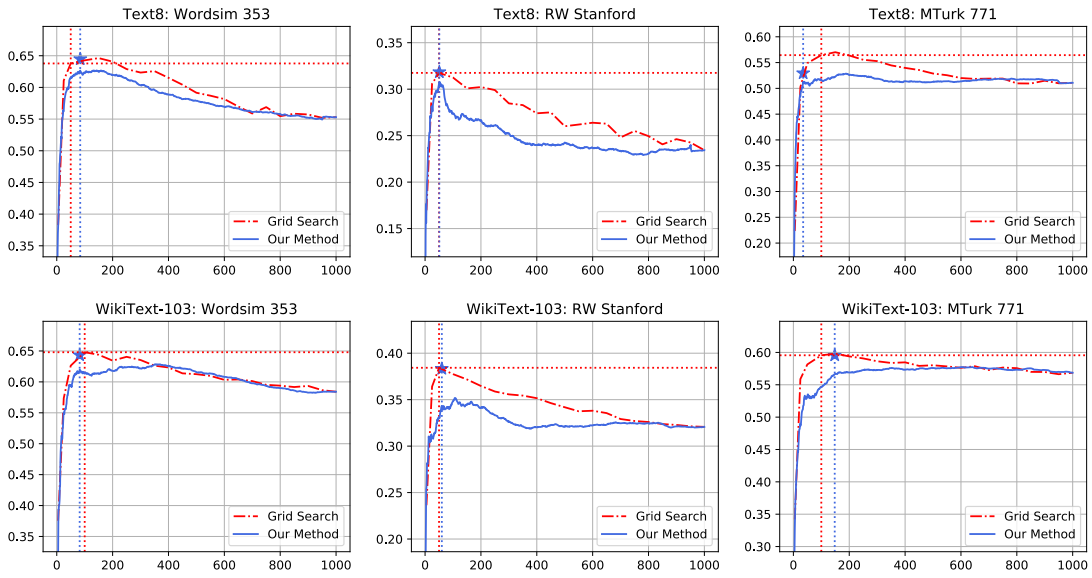

Figure 3: Across different benchmarks and different training datasets, the optimal dimensionality that our method (blue curve) identifies closely matches grid search (red curve). The top row is based on Text8. The bottom row is based on WikiText-103. The vertical dotted lines represent the optimal dimensionality for the respective curves. The horizontal dotted line represents the performance of grid search and the blue star marks the performance of our method. The score function is f(i, metric)= metric-50$\times$i. All the curves are averaged over 5 random runs.

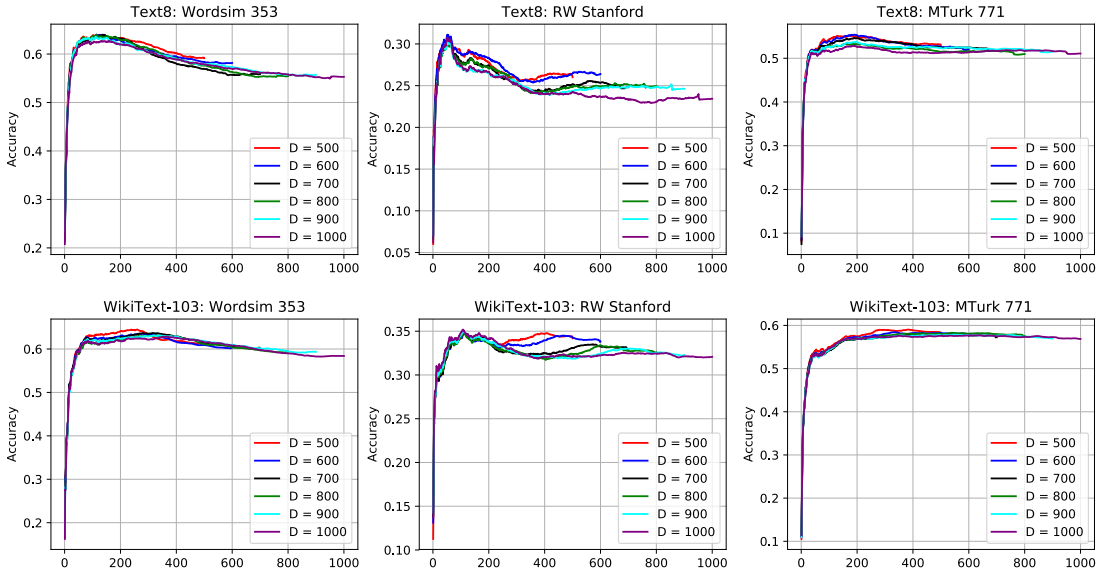

Figure 4: Across different benchmarks and different training datasets, consistency is observed when the upper bound is set to 500, 600, 700, 800, 900 and 1,000. The curves trace closely each other, in particular for WordSim 353 and MTurk 771. The top row is based on the Text8 dataset. The bottom row is based on the WikiText-103 dataset. All the curves are averaged over 5 random runs. Best viewed in color.

report the optimal performance achieved by grid search and our method as well as their relative performance. Even though we have only trained one embedding (and one retraining), our method, on average, is able to achieve 100.2% (WordSim 353) to 96.9% (MTurk 771) of the optimal performance by grid-searching through 22 sets of embeddings.

4.2 Consistency across Upper Bounds

One hyperparameter involved in our method is the upper bound. Intuitively, we expect the upper bound should be higher for larger datasets. In this

Table 1: Distance in Dimensionalities between Grid Search and Our Proposed Method (Numbers within the bucket size 50 are in bold)

Datasets	WordSim	RW Stanford	MTurk
Text8	**34**	**1**	65
WikiText	**18**	**10**	**48**
Average	**26**	**5.5**	66.5

Table 2: Performance (*Correlation*) Comparison between Grid Search and Our Proposed Method

Datasets	Method	WordSim	RW Stanford	MTurk
Text8	G.S.	63.8	31.8	56.4
	Ours	64.5 (101.1%)	31.8(100.3%)	52.9 (93.8%)
WikiText	G.S.	64.8	38.4	59.6
	Ours	64.3 (99.3%)	38.3 (99.7%)	59.6 (100%)
Average	-	100.2%	100%	96.9%

subsection, we demonstrate our method is robust against different upper bounds.

In Figure 4, we vary the dimension from 500 to 1,000 at an increment of 100. We observe that the dimensionality our method selects is consistent across different upper bounds. Based on the demonstrated consistency, different upper bounds can be selected and still the optimal dimensionality can be uncovered as long as the chosen upper bound is larger than the optimal dimensionality.

4.3 Efficiency Compared with Grid Search

In this subsection, we report the running time of our algorithm and compare it with that of grid search. We have recorded the running time of our experiments and that of the PCA transformations. We average them over 5 random runs (Figure 5).

For Text8, grid search takes 22,801 minutes cumulatively. Training a 1,000-dimension embedding takes 1,724 minutes. The PCA step takes 22 minutes (note that for each embedding we only need one PCA operation). This represents a 13.1x speedup for our method. For WikiText-103, grid search takes 132,652 minutes. Training a 1,000-dimension embedding takes 10,448 minutes. The PCA step takes 34 minutes. This represents a 12.7x speedup.

We note that the comparison results are dependent on grid granularity. A coarser grid search could save researchers more time, at the cost of performance loss.

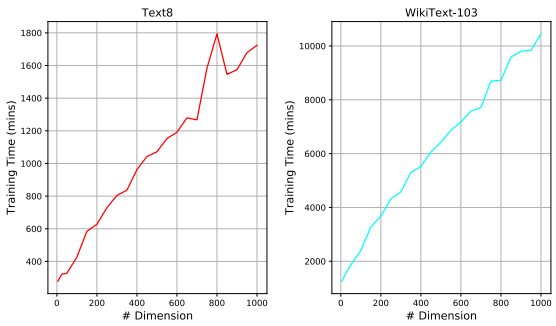

Figure 5: Left: training time for Text8 for embeddings of different dimensions for 200 epochs using 6 CPUs. Right: training time for WikiText-103 for embeddings of different dimensions for 200 epochs using 10 CPUs. All results are averaged over 5 random runs.

5 Conclusion

In this paper, we provided a fast and reliable method based on PCA to select the number of dimensions for training word embeddings. First, we train one embedding with a generous upper bound (e.g. 1,000) of dimensions. Then we transform the embedding using PCA and incrementally remove the lesser dimensions while recording the embeddings' performance on language tasks. Experiments demonstrate that (1) our method is able to identify the optimal dimensionality, (2) the resulting embedding has competitive performance against grid search, and (3) our method is robust against the selection of the upper bound.

Abstract

When trained effectively, the Variational Autoencoder (VAE) is both a powerful language model and an effective representation learning framework. In practice, however, VAEs are trained with the *evidence lower bound* (ELBO) as a surrogate objective to the intractable marginal data likelihood. This approach to training yields unstable results, frequently leading to a disastrous local optimum known as *posterior collapse*. In this paper, we investigate a simple fix for posterior collapse which yields surprisingly effective results. The combination of two known heuristics, previously considered only in isolation, substantially improves held-out likelihood, reconstruction, and latent representation learning when compared with previous state-of-the-art methods. More interestingly, while our experiments demonstrate superiority on these principle evaluations, our method obtains *a worse ELBO*. We use these results to argue that the typical surrogate objective for VAEs may not be sufficient or necessarily appropriate for balancing the goals of representation learning and data distribution modeling.[1]

1 Introduction

Latent variable models attempt to model observed data $\mathbf{x}$ given latent variables $\mathbf{z}$, both for purposes of modeling data distributions $p(\mathbf{x})$ (e.g. language modeling) and learning representations $\mathbf{z}$ for a particular $\mathbf{x}$ (e.g. sentence embedding). Variational Autoencoders (VAEs) (Kingma and Welling, 2014) are a powerful framework for learning latent variable models using neural networks. The generative model of VAEs first samples a latent vector $\mathbf{z}$ from a prior $p(\mathbf{z})$, then applies a neural decoder $p(\mathbf{x}|\mathbf{z})$ to produce $\mathbf{x}$ conditioned on the latent code $\mathbf{z}$. VAEs are trained to maximize the evidence lower bound (ELBO) of the intractable log marginal likelihood:

$$\mathbb{E}_{\mathbf{z}\sim q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})}[\log p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})] - D_{\mathrm{KL}}(q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})),$$

where $q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})$ represents an approximate posterior distribution (i.e. the *encoder* or *inference network*) and $p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})$ is the generative distribution (i.e. the *decoder*).

However, modeling text with VAEs has proven to be challenging, and is an open research problem (Yang et al., 2017; Xu and Durrett, 2018; Kim et al., 2018; Dieng et al., 2018; He et al., 2019; Pelsmaeker and Aziz, 2019). When a strong decoder (e.g. the LSTM (Hochreiter and Schmidhuber, 1997)) is employed, training often falls into a trivial local optimum where the decoder learns to ignore the latent variable and the encoder fails to encode any information. This phenomenon is referred to as "posterior collapse" (Bowman et al., 2016). Existing efforts tackling this problem include re-weighting the KL loss (Bowman et al., 2016; Kingma et al., 2016; Liu et al., 2019), changing the model (Yang et al., 2017; Semeniuta et al., 2017; Xu and Durrett, 2018), and modifying the training procedure (He et al., 2019).

After conducting an empirical examination of the state-of-the-art methods (Section 2), we find that they have difficulty striking a good balance between language modeling and representation learning. In this paper, we present a practically effective combination of two simple heuristic techniques for improving VAE learning: (1) pretraining the inference network using an autoencoder objective and (2) thresholding the KL term in the ELBO objective (also known as "free bits" (Kingma et al., 2016)). The former technique initializes VAE training with an inference network that encodes useful information about $\mathbf{x}$, biasing learning away from local optima where $\mathbf{x}$ is ignored (i.e. posterior collapse). The latter tech-

[*]Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3603–3614,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

nique modifies the ELBO objective to prevent the KL term from dominating the encoder's role in reconstruction (Alemi et al., 2018), again biasing learning to avoid posterior collapse (Chen et al., 2017; Zhao et al., 2019).

In experiments we find that these two techniques do not perform well in isolation. However, when combined, they substantially outperform all baselines across various metrics that evaluate both language modeling and representation learning capabilities. Finally, we find that our method tends to achieve a superior language modeling results in terms of perplexity but an inferior ELBO value, and we use these results to argue that ELBO is suboptimal for language modeling even though it provides a formal lower bound on log marginal likelihood. Thus, we suggest that future research in this direction should be careful to monitor the gap between ELBO and log marginal likelihood, and reconsider using ELBO as the surrogate, especially for evaluation.

2 Analysis of Existing Methods

In this section, we first analyze and compare state-of-the-art solutions to posterior collapse[2] to obtain a holistic view of current progress and remaining challenges. Based on these observations, we then propose and evaluate a method that demonstrates substantially improved performance.

2.1 Evaluation

In this paper we focus on the standard VAE setting where both the prior $p(\mathbf{z})$ and the posterior $p_{\boldsymbol{\theta}}(\mathbf{z}|\mathbf{x})$ are factorized Gaussians.[3] We conduct preliminary experiments on the English Penn Treebank (PTB) (Marcus and Marcinkiewicz), a standard dataset for benchmarking VAE that has been used extensively in previous work (Bowman et al., 2016; Xu and Durrett, 2018; Liu et al., 2019). We use 32-dimension latent codes (full setup details can be found in Appendix A). We evaluate using the following metrics:

Perplexity (PPL). To compute perplexity, we first estimate the log marginal likelihood with 1000 importance weighted samples (Burda et al., 2016). Note that it is inappropriate to estimate PPL with ELBO directly since the gap between ELBO and log marginal likelihood might be large, particularly when the posterior does not collapse.

Reconstruction loss (Recon). Reconstruction loss is equivalent to the negative reconstruction term in ELBO: $-\mathbb{E}_{\mathbf{z}\sim q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x})}[\log p_{\boldsymbol{\theta}}(\mathbf{x}|\mathbf{z})]$. It characterizes how well the latent code can be used to recover the input.

Number of active units (AU, Burda et al. (2016)). Active units correspond to the dimensions of $\mathbf{z}$ that covary with observations after the model is trained. More active units usually indicates richer latent representations (Burda et al., 2016). Specifically, a dimension is "active" when it is sensitive to the change in observations $\mathbf{x}$. Here we follow (Burda et al., 2016) and classify a latent dimension z as active if $\mathrm{Cov}(\mathbf{x}, E_{z\sim q(z|\mathbf{x})}[z])) > 0.01$.

In addition to the metrics above, we include KL between prior and posterior approximation, as well as the negative ELBO, for reference – though we find that these quantities are only partially descriptive of model quality. In Section 3.2 we also evaluate the latent space of learned models with specialized metrics such as reconstruction BLEU and classification accuracy.

2.2 Baselines

We experiment with several state-of-the-art techniques to mitigate posterior collapse, including several KL reweighting methods and the recently proposed aggressive training (He et al., 2019).

KL annealing (Bowman et al., 2016). KL annealing might be the most common method for reweighting. During annealing, the weight of the KL term is increased from a small value to 1.0 in the beginning of training.

Cyclic annealing (Liu et al., 2019). Cyclic annealing is another reweighting scheme proposed recently. It changes the weight of the KL term in a cyclic fashion, rather than monotonically increasing the weight.[4]

KL Thresholding / Free Bits (FB) (Kingma et al., 2016). FB replaces the KL term in ELBO with a hinge loss term that maxes each component

[2] Here we focus on different training techniques for existing models, not alternatives which require changing the underlying model (Yang et al., 2017; Xu and Durrett, 2018).

[3] Pelsmaeker and Aziz (2019) thoroughly investigate using more complicated priors/posteriors (Rezende and Mohamed, 2015) but find only marginal improvements.

[4] We use the default cyclic annealing schedule from https://github.com/haofuml/cyclic_annealing in our codebase for a fair comparison.

of the original KL with a constant:

$$\sum_i \max[\lambda, D_{\mathrm{KL}}(q_{\boldsymbol{\phi}}(z_i|\mathbf{x})\|p(z_i))] \quad (1)$$

Here, λ denotes the *target rate*, and z_i denotes the i^{th} dimension in the latent variable $\mathbf{z}$. Using the FB objective causes learning to give up trying to drive down KL for dimensions of $\mathbf{z}$ that are already beneath the target rate. Pelsmaeker and Aziz (2019) conduct a comprehensive experimental evaluation of related methods and conclude that the FB objective is able to achieve comparable or superior performance (in terms of both language modeling and reconstruction) in comparison with other top-performing methods, many of which are substantially more complex. We notice that Pelsmaeker and Aziz (2019) experiment with a slightly different version of FB where the threshold is applied to the entire KL term directly, rather than on each dimension's KL separately. We examine both versions here and refer to the single threshold version as "FBP" and the multiple threshold version (Eq. 1) as "FB". For both FB and FBP, we vary the target rate λ and report the setting with the best validation PPL and the setting with the best balance between PPL and reconstruction loss.[5]

Aggressive training (He et al., 2019). He et al. (2019) observe that when posterior collapse occurs, the inference network often lags behind the generator during training. In contrast with the KL reweighting methods described above, He et al. (2019) propose an aggressive training schedule which iterates between multiple encoder update steps and one decoder update step to mitigate posterior collapse.[6]

Autoencoder (AE). We also include an autoencoder[7] as a reference for reconstruction loss.

We show the results of these baselines trained on PTB in Table 1, where we find that it is difficult to balance language modeling (PPL) and representation learning (Recon and AU) – the systems with relatively good reconstruction (FBP, $\lambda = 7$) or higher AU (FB baselines) have suboptimal PPL, and the best PPL is achieved with sacrifice of Recon and AU. Note that good PPL indicates good LM, but good recon and AU indicates good representation learning. Without both, we do not really have a strong probabilistic model of language that captures latent factors.

[5]It is subjective to judge "balance", thus we also report complete results for different target rates in Appendix C.

[6]We use the public code at https://github.com/jxhe/vae-lagging-encoder.

[7]Here, AE denotes the VAE trained without the KL term.

Table 1: Results on PTB test set for various baselines.

Method	PPL↓	Recon↓	AU↑	KL	-ELBO
AE	-	70.36	32	-	-
VAE	101.39	101.27	0	0.00	101.27

+ FBP ($\lambda = 7$)	102.82	95.63	4	7.05	102.67
+ FBP ($\lambda = 3$)	99.62	98.52	3	2.95	101.48
+ FB ($\lambda = 7$)	104.06	98.97	32	6.74	105.72
+ FB ($\lambda = 3$)	100.50	99.94	32	2.96	102.90

Table 2: Results on PTB test with encoder pretraining.

Method	PPL↓	Recon↓	AU↑	KL	-ELBO
AE	-	70.36	32	-	-
VAE	101.39	101.27	0	0.00	101.27
+ pretrain	102.26	101.46	0	0.00	101.46
+ pretrain + anneal	97.74	99.67	2	1.01	100.68

We make two observations from the results in Table 1. First, reconstruction loss for an AE is substantially better than all VAE methods, which is intuitive since reconstruction is the only goal of training an AE. Second, models with high ELBO do not necessarily have good PPL (e.g. VAE+anneal); ELBO is not an ideal surrogate for evaluating language modeling performance.

2.3 Autoencoder-based Initialization

Based on the observations above we hypothesize that VAEs might benefit from initialization with an non-collapsed encoder, trained via an AE objective. Intuitively, if the encoder is providing useful information from the beginning of training, the decoder is more likely to make use of the latent code. In Table 2 we show the results of exploring this hypothesis on PTB. Even with encoder pretraining, we see that posterior collapse occurs immediately after beginning to update both encoder and decoder using the full ELBO objective. This indicates that the gradients of ELBO point towards a collapsed local optimum, even with biased initialization. When pretraining is combined with annealing, PPL improves substantially. However, the pretraining and anneal combination only has 2 active units and has small KL value – the latent representation is likely unsatisfactory. We speculate that this is because the annealing schedule eventually returns to the full ELBO objective which guides learning towards a (nearly) collapsed latent space. In the next section, we present an alternate approach using the KL thresholding / free bits method.

2.4 Our Method

In our proposed method, we initialize the inference network with an encoder that is pretrained using an autoencoder objective, as described above. Then, we train the VAE using the FB objective, also described above. We use the original FB which thresholds along each dimension.[8] Thus, we combine two approaches so far considered independently: pretraining and KL thresholding. In this way, however, the VAE would start with a large KL and is thus trained with the full ELBO objective in the initial stage, which is bad as observed in Section 2.3. To remedy this, we apply an annealing weight to Eq. 1. We use the simplest linear annealing schedule that increases the weight from 0 to 1 in the first 10 epochs for all of our experiments. This approach can be viewed in connection with KL annealing: we train with zero KL weight until convergence, then reset the decoder and start increasing the KL weight with the free bits objective. Next we conduct comprehensive experiments across different datasets to validate our method.

3 Experiments

In this section we work with three text datasets: PTB (Marcus and Marcinkiewicz), Yahoo (Yang et al., 2017), and a downsampled version of SNLI (Bowman et al., 2015). We demonstrate the effectiveness of our method through language modeling, text reconstruction, and quality of the learned latent space. Complete experimental setup details can be found in Appendix A.

3.1 Language Modeling

For language modeling, we only report the results for PTB and Yahoo due to the space limit, but include the SNLI results in Appendix C. Since we have already shown that FBP outperforms FB on PPL in Section 2 (without pretraining), here we only include FBP as a baseline. For both FBP and our method we vary the target rate and report the settings that achieve competitive validation PPL.[9]

As shown in Table 3, our method with different target rates is able to consistently outperform all the baselines in terms of PPL. Meanwhile, for representation learning, our method beats all the baselines by a large margin on reconstruction loss with all latent units active. We also note that our method is not very sensitive to the target rate λ.

Table 3: Language modeling results on PTB and Yahoo test set. We bold the lines that represent the best average of language modeling and reconstruction loss. Cyclic* is from (Liu et al., 2019).

Method	PPL↓	Recon↓	AU↑	KL	-ELBO
PTB					
LSTM-LM	100.47	-	-	-	-
VAE	101.39	101.27	0	0.00	101.27
+ anneal	101.40	101.28	0	0.00	101.28
+ cyclic*	-	100.51	-	1.96	102.46
+ cyclic	108.97	101.85	5	1.37	103.22
+ aggressive	99.83	100.26	4	0.93	101.19
+ FBP ($\lambda = 3$)	99.62	98.52	3	2.95	101.48
+ FBP ($\lambda = 2$)	100.96	99.37	2	1.99	101.36
Ours ($\lambda = 8$)	98.07	92.60	32	10.95	103.56
Ours ($\lambda = 6$)	**96.35**	**94.52**	**32**	8.15	102.67
Ours ($\lambda = 4$)	96.17	96.91	32	4.99	101.90
Yahoo					
LSTM-LM	60.75	-	-	-	-
VAE	61.52	329.10	0	0.00	329.10
+ anneal	61.21	328.80	0	0.00	328.80
+ cyclic	66.93	333.80	4	2.83	336.63
+ aggressive	59.77	322.70	15	5.70	328.40
+ FBP ($\lambda = 9$)	62.59	322.91	6	9.08	331.99
+ FBP ($\lambda = 7$)	62.76	324.66	5	7.03	331.69
+ FBP ($\lambda = 5$)	62.78	326.26	3	5.07	331.32
+ FBP ($\lambda = 3$)	62.88	328.13	2	3.06	331.19
Ours ($\lambda = 6$)	59.23	317.39	32	12.09	329.48
Ours ($\lambda = 8$)	**59.51**	**315.31**	**32**	15.02	330.33
Ours ($\lambda = 9$)	59.60	315.09	32	15.49	330.58

It is worth noticing that in some cases our method (e.g. $\lambda = 8$ in PTB and $\lambda = 8, 9$ in Yahoo) is able to outperform all the baselines but produce a bad ELBO (actually the worst on PTB). This suggests that ELBO might be a suboptimal surrogate for the log marginal likelihood sometimes, especially when KL is large, where the gap between ELBO and the marginal tends to be large as well.

3.2 Probing the Latent Space

We assess quality of learned latent space with SNLI through several metrics. For our method and FBP, we use the target rate where the best reconstruction loss is achieved while maintaining comparable PPL with aggressive training. [10]

Text Reconstruction We use greedy decoding and compute the BLEU score of the reconstructed sentence with the original one as the reference. The result is shown in Table 4. Unsurprisingly,

[8] Note that we do not pretrain the decoder and rather initialize it randomly. In our preliminary experiments, pretraining the decoder produced worse PPL compared with encoder-only pretraining.

[9] Results of all target rates can be found in Appendix C.

[10] Basically we try to tie PPL of different models and compare their latent space. Specifically, aggressive training has PPL 32.83, and PPL of the selected model for FBP and our method are 33.07 and 32.88, respectively.

the autoencoder achieves the highest BLEU score, meanwhile our method beats other VAE baselines.

Table 4: Reconstruction

Method	BLEU
AE	60.80
VAE	1.82
+ anneal	2.51
+ cyclic	4.39
+ aggressive	2.95
+ FBP ($\lambda = 7$)	8.07
Ours ($\lambda = 4$)	**8.62**

Table 5: Smoothness

Method	PCC
AE	0.620
VAE	0.039
+ anneal	0.009
+ cyclic	0.482
+ aggressive	0.209
+ FBP ($\lambda = 7$)	0.242
Ours ($\lambda = 4$)	**0.683**

Smoothness of Latent Space A major difference between VAE and AE is that VAE can learn a smooth latent space through the regularization from the Gaussian prior. In a smooth latent space, latent codes of similar sentences should be close to each other and vice versa. Therefore, we randomly sample 100k sentence pairs and evaluate the Pearson Correlation Coefficient (PCC) between the ℓ_2 distances of latent codes and edit word distances. As shown in Table 5, our method achieves a much higher PCC compared to the baselines.

Zhao et al. (2018) argue that a smooth latent space is beneficial for reconstructing noisy inputs. We follow their experiments and introduce noise to the input by randomly swapping words k times. As shown in Table 6, while AE achieves the best reconstruction when the noise is small ($k = 1$), its reconstruction deteriorates dramatically when $k > 1$, which suggests AE fails to learn a smooth latent space. In contrast, our method outperforms all the baselines by a large margin when $k > 1$.

Interpolation As illustrated in (Bowman et al., 2016), linear interpolation between latent variables is an intuitive way to qualitatively evaluate the smoothness of the latent space. We sample two latent codes $\mathbf{z}_0$ and $\mathbf{z}_1$ from the prior $p(\mathbf{z})$ (Table 7) and do linear interpolation between the two with evenly divided intervals.[11]. For each interpolated point, we decode it greedily. Our method is able to generate grammatically plausible and semantically consistent interpolation in both cases.

3.3 Classification

To further evaluate the quality of the latent codes, we train a Gaussian mixture model (for unsupervised clustering) or a one-layer linear classifier (for supervised classification) on the pretrained latent codes. We work with a downsampled version of Yelp sentiment dataset collected by Shen et al. (2017). We vary the number of labeled data[12] and the results are shown in Table 8. For FBP and our method, the target rate is selected in terms of the average validation accuracy. Our method consistently yields the best results on all settings – remarkably, its performance with only 100 labeled samples already surpasses others with 10k labels.

[11] Interpolation examples from posterior samples $q_\phi(\mathbf{z}|\mathbf{x})$ are provided in Appendix 13.

Table 6: Noisy reconstruction loss (↓) on SNLI. #swap denotes the number of word swaps.

#swap	1	2	3	4
AE	**26.05**	40.46	52.77	63.07

Ours ($\lambda = 6$)	**67.2**	**83.8**	**88.3**	**89.1**	**89.5**	**89.5**

4 Conclusion

In this paper, we propose a simple training fix to tackle posterior collapse in VAEs. Extensive experiments demonstrate the effectiveness of our method on both representation learning and language modeling.

[12] Specifically, we train a VAE model on the Yelp dataset to obtain the latent codes, then we we use the latent codes of labeled data to train the classifier.

A Details of Experimental Setup

For SNLI, we randomly downsample a subset of it, which contains 100K/10K/10K sentences as training/validation/test. For the Yelp sentiment dataset, we also randomly downsample 100K/10K/10K sentences for training/validation/test, respectively. We use an one-layer LSTM for both the encoder and decoder and a latent vector size of 32.

We follow Kim et al. (2018); He et al. (2019) and use a single-layer LSTM the encoder and decoder in all of our experiments. The sizes of word embeddings and hidden states for different datasets are given in Table 9. We initialize the LSTM parameters with a uniform distribution $\mathcal{U}(-0.01, 0.01)$, and embeddings with another uniform distribution $\mathcal{U}(-0.1, 0.1)$.

Just as in Kim et al. (2018); He et al. (2019), for the decoder, we use dropout of 0.5 on both the input word embedding and the last dense before logits. During training, we use the SGD optimizer wihout momentum. Initialized with 0.5, the learning rate is decayed by $\times 0.5$ with a patience of 2 if the validation loss has not improved in the past 2 epochs. The maximum number of epochs is 100, but the training will stop early after 5 learning rate decays. For our VAE + anneal baseline, we use the simplest linear annealing schedule that increases the weight from 0 to 1 in the first 10 epochs, just the same as in our method (stated in Section 2.4).

Table 9: The sizes of word embeddings and hidden states for PTB, SNLI and Yahoo.

	PTB	SNLI	Yahoo
Word Embedding Size	256	128	512
Hidden Size of Encoder	256	512	1024
Hidden Size of Decoder	256	512	1024

B Copying Behaviour

We check to make sure that our model is not simply learning to copy sentences from the training set. We test for copying behaviour on the PTB dataset. Specifically, we sampled 300 sentences from the prior and retrieved their nearest neighbors in the training set. The average edit distance between the samples and their nearest neighbors from our method is 14.11 (the average training sentence length is 22.10), versus 13.68 from the collapsed VAE. This means that there is no obvious copying behaviour when KL grows in our method.

C Additional Results of Language Modeling

In Table 10, we provide a more detailed version of the language modeling results on PTB, SNLI and Yahoo. The full results of all the target rate trial for both FBP and our method are included. In addition to the metrics in Table 3, we also report NLL, Mutual Information I_q between $\mathbf{z}$ and $\mathbf{x}$ under $q_{\phi}(\mathbf{z}|\mathbf{x})$ (MI)[13], and the perplexity computed by ELBO (ELBO PPL).

[13]For the estimation of I_q, we follow the same method as in He et al. (2019)

Table 10: Additional results of language modeling on PTB and SNLI.

D Additional Qualitative Examples

D.1 Interpolation between Prior Samples

We randomly sample 10 pair of source and target latent code from the standard Gaussian prior and do linear interpolation. For the sampled and interpolated latent codes, we do greedy decoding. The results are shown in Table 12.

D.2 Interpolation between Posterior Samples

We randomly sample 10 pairs of source and target input sentences from the test set of SNLI. For each input sentence, we randomly sample a latent code from the approximated posterior $q(\mathbf{z}|\mathbf{x})$. Then we linearly interpolate between each pair of sampled source/target latent code. For the sampled and interpolated latent codes, we do greedy decoding. The results are shown in Table 13.

Table 12: Interpolation between prior samples on SNLI

POSTERIOR-SAMPLED TARGET	two guys are on a boat .	a man is playing a guitar .

SciBERT: A Pretrained Language Model for Scientific Text

Iz Beltagy **Kyle Lo** **Arman Cohan**
Allen Institute for Artificial Intelligence, Seattle, WA, USA
{beltagy,kylel,armanc}@allenai.org

Abstract

Obtaining large-scale annotated data for NLP tasks in the scientific domain is challenging and expensive. We release SciBERT, a pretrained language model based on BERT (Devlin et al., 2019) to address the lack of high-quality, large-scale labeled scientific data. SciBERT leverages unsupervised pretraining on a large multi-domain corpus of scientific publications to improve performance on downstream scientific NLP tasks. We evaluate on a suite of tasks including sequence tagging, sentence classification and dependency parsing, with datasets from a variety of scientific domains. We demonstrate statistically significant improvements over BERT and achieve new state-of-the-art results on several of these tasks. The code and pretrained models are available at https://github.com/allenai/scibert/.

1 Introduction

The exponential increase in the volume of scientific publications in the past decades has made NLP an essential tool for large-scale knowledge extraction and machine reading of these documents. Recent progress in NLP has been driven by the adoption of deep neural models, but training such models often requires large amounts of labeled data. In general domains, large-scale training data is often possible to obtain through crowdsourcing, but in scientific domains, annotated data is difficult and expensive to collect due to the expertise required for quality annotation.

As shown through ELMo (Peters et al., 2018), GPT (Radford et al., 2018) and BERT (Devlin et al., 2019), unsupervised pretraining of language models on large corpora significantly improves performance on many NLP tasks. These models return contextualized embeddings for each token which can be passed into minimal task-specific neural architectures. Leveraging the success of unsupervised pretraining has become especially important especially when task-specific annotations are difficult to obtain, like in scientific NLP. Yet while both BERT and ELMo have released pretrained models, they are still trained on general domain corpora such as news articles and Wikipedia.

In this work, we make the following contributions:

(*i*) We release SciBERT, a new resource demonstrated to improve performance on a range of NLP tasks in the scientific domain. SciBERT is a pretrained language model based on BERT but trained on a large corpus of scientific text.

(*ii*) We perform extensive experimentation to investigate the performance of finetuning versus task-specific architectures atop frozen embeddings, and the effect of having an in-domain vocabulary.

(*iii*) We evaluate SciBERT on a suite of tasks in the scientific domain, and achieve new state-of-the-art (SOTA) results on many of these tasks.

2 Methods

Background The BERT model architecture (Devlin et al., 2019) is based on a multilayer bidirectional Transformer (Vaswani et al., 2017). Instead of the traditional left-to-right language modeling objective, BERT is trained on two tasks: predicting randomly masked tokens and predicting whether two sentences follow each other. SciBERT follows the same architecture as BERT but is instead pretrained on scientific text.

Vocabulary BERT uses WordPiece (Wu et al., 2016) for unsupervised tokenization of the input text. The vocabulary is built such that it contains the most frequently used words or subword units. We refer to the original vocabulary released with BERT as BaseVocab.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3615–3620, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

We construct SCIVOCAB, a new WordPiece vocabulary on our scientific corpus using the SentencePiece[1] library. We produce both cased and uncased vocabularies and set the vocabulary size to 30K to match the size of BASEVOCAB. The resulting token overlap between BASEVOCAB and SCIVOCAB is 42%, illustrating a substantial difference in frequently used words between scientific and general domain texts.

Corpus We train SCIBERT on a random sample of 1.14M papers from Semantic Scholar (Ammar et al., 2018). This corpus consists of 18% papers from the computer science domain and 82% from the broad biomedical domain. We use the full text of the papers, not just the abstracts. The average paper length is 154 sentences (2,769 tokens) resulting in a corpus size of 3.17B tokens, similar to the 3.3B tokens on which BERT was trained. We split sentences using ScispaCy (Neumann et al., 2019),[2] which is optimized for scientific text.

3 Experimental Setup

3.1 Tasks

We experiment on the following core NLP tasks:

1. Named Entity Recognition (NER)
2. PICO Extraction (PICO)
3. Text Classification (CLS)
4. Relation Classification (REL)
5. Dependency Parsing (DEP)

PICO, like NER, is a sequence labeling task where the model extracts spans describing the Participants, Interventions, Comparisons, and Outcomes in a clinical trial paper (Kim et al., 2011). REL is a special case of text classification where the model predicts the type of relation expressed between two entities, which are encapsulated in the sentence by inserted special tokens.

3.2 Datasets

For brevity, we only describe the newer datasets here, and refer the reader to the references in Table 1 for the older datasets. EBM-NLP (Nye et al., 2018) annotates PICO spans in clinical trial abstracts. SciERC (Luan et al., 2018) annotates entities and relations from computer science abstracts. ACL-ARC (Jurgens et al., 2018) and SciCite (Cohan et al., 2019) assign intent labels (e.g. Comparison, Extension, etc.) to sentences from scientific papers that cite other papers. The Paper Field dataset is built from the Microsoft Academic Graph (Sinha et al., 2015)[3] and maps paper titles to one of 7 fields of study. Each field of study (i.e. geography, politics, economics, business, sociology, medicine, and psychology) has approximately 12K training examples.

3.3 Pretrained BERT Variants

BERT-Base We use the pretrained weights for BERT-Base (Devlin et al., 2019) released with the original BERT code.[4] The vocabulary is BASEVOCAB. We evaluate both cased and uncased versions of this model.

SCIBERT We use the original BERT code to train SCIBERT on our corpus with the same configuration and size as BERT-Base. We train 4 different versions of SCIBERT: (*i*) cased or uncased and (*ii*) BASEVOCAB or SCIVOCAB. The two models that use BASEVOCAB are finetuned from the corresponding BERT-Base models. The other two models that use the new SCIVOCAB are trained from scratch.

Pretraining BERT for long sentences can be slow. Following the original BERT code, we set a maximum sentence length of 128 tokens, and train the model until the training loss stops decreasing. We then continue training the model allowing sentence lengths up to 512 tokens.

We use a single TPU v3 with 8 cores. Training the SCIVOCAB models from scratch on our corpus takes 1 week[5] (5 days with max length 128, then 2 days with max length 512). The BASEVOCAB models take 2 fewer days of training because they aren't trained from scratch.

All pretrained BERT models are converted to be compatible with PyTorch using the pytorch-transformers library.[6] All our models (Sections 3.4 and 3.5) are implemented in PyTorch using AllenNLP (Gardner et al., 2017).

[1] https://github.com/google/sentencepiece

[2] https://github.com/allenai/SciSpaCy

[3] https://academic.microsoft.com/

[4] https://github.com/google-research/bert

[5] BERT's largest model was trained on 16 Cloud TPUs for 4 days. Expected 40-70 days (Dettmers, 2019) on an 8-GPU machine.

[6] https://github.com/huggingface/pytorch-transformers

Casing We follow Devlin et al. (2019) in using the cased models for NER and the uncased models for all other tasks. We also use the cased models for parsing. Some light experimentation showed that the uncased models perform slightly better (even sometimes on NER) than cased models.

3.4 Finetuning BERT

We mostly follow the same architecture, optimization, and hyperparameter choices used in Devlin et al. (2019). For text classification (i.e. CLS and REL), we feed the final BERT vector for the `[CLS]` token into a linear classification layer. For sequence labeling (i.e. NER and PICO), we feed the final BERT vector for each token into a linear classification layer with softmax output. We differ slightly in using an additional conditional random field, which made evaluation easier by guaranteeing well-formed entities. For DEP, we use the model from Dozat and Manning (2017) with dependency tag and arc embeddings of size 100 and biaffine matrix attention over BERT vectors instead of stacked BiLSTMs.

In all settings, we apply a dropout of 0.1 and optimize cross entropy loss using Adam (Kingma and Ba, 2015). We finetune for 2 to 5 epochs using a batch size of 32 and a learning rate of 5e-6, 1e-5, 2e-5, or 5e-5 with a slanted triangular schedule (Howard and Ruder, 2018) which is equivalent to the linear warmup followed by linear decay (Devlin et al., 2019). For each dataset and BERT variant, we pick the best learning rate and number of epochs on the development set and report the corresponding test results.

We found the setting that works best across most datasets and models is 2 or 4 epochs and a learning rate of 2e-5. While task-dependent, optimal hyperparameters for each task are often the same across BERT variants.

3.5 Frozen BERT Embeddings

We also explore the usage of BERT as pretrained contextualized word embeddings, like ELMo (Peters et al., 2018), by training simple task-specific models atop frozen BERT embeddings.

For text classification, we feed each sentence of BERT vectors into a 2-layer BiLSTM of size 200 and apply a multilayer perceptron (with hidden size 200) on the concatenated first and last BiLSTM vectors. For sequence labeling, we use the same BiLSTM layers and use a conditional random field to guarantee well-formed predictions. For DEP, we use the full model from Dozat and Manning (2017) with dependency tag and arc embeddings of size 100 and the same BiLSTM setup as other tasks. We did not find changing the depth or size of the BiLSTMs to significantly impact results (Reimers and Gurevych, 2017).

We optimize cross entropy loss using Adam, but holding BERT weights frozen and applying a dropout of 0.5. We train with early stopping on the development set (patience of 10) using a batch size of 32 and a learning rate of 0.001.

We did not perform extensive hyperparameter search, but while optimal hyperparameters are going to be task-dependent, some light experimentation showed these settings work fairly well across most tasks and BERT variants.

4 Results

Table 1 summarizes the experimental results. We observe that SCIBERT outperforms BERT-Base on scientific tasks (+2.11 F1 with finetuning and +2.43 F1 without)[8]. We also achieve new SOTA results on many of these tasks using SCIBERT.

4.1 Biomedical Domain

We observe that SCIBERT outperforms BERT-Base on biomedical tasks (+1.92 F1 with finetuning and +3.59 F1 without). In addition, SCIBERT achieves new SOTA results on BC5CDR and ChemProt (Lee et al., 2019), and EBM-NLP (Nye et al., 2018).

SCIBERT performs slightly worse than SOTA on 3 datasets. The SOTA model for JNLPBA is a BiLSTM-CRF ensemble trained on multiple NER datasets not just JNLPBA (Yoon et al., 2018). The SOTA model for NCBI-disease is BIOBERT (Lee et al., 2019), which is BERT-Base finetuned on 18B tokens from biomedical papers. The SOTA result for GENIA is in Nguyen and Verspoor (2019) which uses the model from Dozat and Manning (2017) with part-of-speech (POS) features, which we do not use.

In Table 2, we compare SCIBERT results with reported BIOBERT results on the subset of datasets included in (Lee et al., 2019). Interesting, SCIBERT outperforms BIOBERT results on

[7]The SOTA paper did not report a single score. We compute the average of the reported results for each class weighted by number of examples in each class.

[8]For rest of this paper, all results reported in this manner are averaged over datasets excluding UAS for DEP since we already include LAS.

Field	Task	Dataset	SOTA	BERT-Base		SCIBERT

Table 1: Test performances of all BERT variants on all tasks and datasets. **Bold** indicates the SOTA result (multiple results bolded if difference within 95% bootstrap confidence interval). Keeping with past work, we report macro F1 scores for NER (span-level), macro F1 scores for REL and CLS (sentence-level), and macro F1 for PICO (token-level), and micro F1 for ChemProt specifically. For DEP, we report labeled (LAS) and unlabeled (UAS) attachment scores (excluding punctuation) for the same model with hyperparameters tuned for LAS. All results are the average of multiple runs with different random seeds.

Task	Dataset	BIOBERT	SCIBERT
NER	BC5CDR	88.85	90.01
	JNLPBA	77.59	77.28
	NCBI-disease	89.36	88.57
REL	ChemProt	76.68	83.64

Table 2: Comparing SCIBERT with the reported BIOBERT results on biomedical datasets.

BC5CDR and ChemProt, and performs similarly on JNLPBA despite being trained on a substantially smaller biomedical corpus.

4.2 Computer Science Domain

We observe that SCIBERT outperforms BERT-Base on computer science tasks (+3.55 F1 with finetuning and +1.13 F1 without). In addition, SCIBERT achieves new SOTA results on ACL-ARC (Cohan et al., 2019), and the NER part of SciERC (Luan et al., 2018). For relations in SciERC, our results are not comparable with those in Luan et al. (2018) because we are performing relation classification given gold entities, while they perform joint entity and relation extraction.

4.3 Multiple Domains

We observe that SCIBERT outperforms BERT-Base on the multidomain tasks (+0.49 F1 with finetuning and +0.93 F1 without). In addition, SCIBERT outperforms the SOTA on SciCite (Cohan et al., 2019). No prior published SOTA results exist for the Paper Field dataset.

5 Discussion

5.1 Effect of Finetuning

We observe improved results via BERT finetuning rather than task-specific architectures atop frozen embeddings (+3.25 F1 with SCIBERT and +3.58 with BERT-Base, on average). For each scientific domain, we observe the largest effects of finetuning on the computer science (+5.59 F1 with SCIBERT and +3.17 F1 with BERT-Base) and biomedical tasks (+2.94 F1 with SCIBERT and +4.61 F1 with BERT-Base), and the smallest effect on multidomain tasks (+0.7 F1 with SCIBERT and +1.14 F1 with BERT-Base). On every dataset except BC5CDR and SciCite, BERT-Base with finetuning outperforms (or performs similarly to) a model using frozen SCIBERT embeddings.

5.2 Effect of SCIVOCAB

We assess the importance of an in-domain scientific vocabulary by repeating the finetuning experiments for SCIBERT with BASEVOCAB. We find the optimal hyperparameters for SCIBERT-BASEVOCAB often coincide with those of SCIBERT-SCIVOCAB.

Averaged across datasets, we observe +0.60 F1 when using SCIVOCAB. For each scientific do-

main, we observe +0.76 F1 for biomedical tasks, +0.61 F1 for computer science tasks, and +0.11 F1 for multidomain tasks.

Given the disjoint vocabularies (Section 2) and the magnitude of improvement over BERT-Base (Section 4), we suspect that while an in-domain vocabulary is helpful, SCIBERT benefits most from the scientific corpus pretraining.

6 Related Work

Recent work on domain adaptation of BERT includes BIOBERT (Lee et al., 2019) and CLINICALBERT (Alsentzer et al., 2019; Huang et al., 2019). BIOBERT is trained on PubMed abstracts and PMC full text articles, and CLINICALBERT is trained on clinical text from the MIMIC-III database (Johnson et al., 2016). In contrast, SCIBERT is trained on the full text of 1.14M biomedical and computer science papers from the Semantic Scholar corpus (Ammar et al., 2018). Furthermore, SCIBERT uses an in-domain vocabulary (SCIVOCAB) while the other abovementioned models use the original BERT vocabulary (BASEVOCAB).

7 Conclusion and Future Work

We released SCIBERT, a pretrained language model for scientific text based on BERT. We evaluated SCIBERT on a suite of tasks and datasets from scientific domains. SCIBERT significantly outperformed BERT-Base and achieves new SOTA results on several of these tasks, even compared to some reported BIOBERT (Lee et al., 2019) results on biomedical tasks.

For future work, we will release a version of SCIBERT analogous to BERT-Large, as well as experiment with different proportions of papers from each domain. Because these language models are costly to train, we aim to build a single resource that's useful across multiple domains.

Acknowledgment

Humor Detection: A Transformer Gets the Last Laugh

Abstract

Much previous work has been done in attempting to identify humor in text. In this paper we extend that capability by proposing a new task: assessing whether or not a joke is humorous. We present a novel way of approaching this problem by building a model that learns to identify humorous jokes based on ratings gleaned from Reddit pages, consisting of almost 16,000 labeled instances. Using these ratings to determine the level of humor, we then employ a Transformer architecture for its advantages in learning from sentence context. We demonstrate the effectiveness of this approach and show results that are comparable to human performance. We further demonstrate our model's increased capabilities on humor identification problems, such as the previously created datasets for short jokes and puns. These experiments show that this method outperforms all previous work done on these tasks, with an F-measure of 93.1% for the Puns dataset and 98.6% on the Short Jokes dataset.

1 Introduction

Recent advances in natural language processing and neural network architecture have allowed for widespread application of these methods in Text Summarization (Liu et al., 2018), Natural Language Generation (Bahuleyan, 2018), and Text Classification (Yang et al., 2016). Such advances have enabled scientists to study common language practices. One such area, humor, has garnered focus in classification (Zhang and Liu, 2014; Chen and Soo, 2018), generation (He et al., 2019; Valitutti et al., 2013), and in social media (Raz, 2012).

The next question then is, what makes a joke humorous? Although humor is a universal construct, there is a wide variety between what each individual may find humorous. We attempt to focus on a subset of the population where we can quantitatively measure reactions: the popular Reddit r/Jokes thread. This forum is highly popular - with tens of thousands of jokes being posted monthly and over 16 million members. Although larger joke datasets exist, the r/Jokes thread is unparalleled in the amount of rated jokes it contains. To the best of our knowledge there is no comparable source of rated jokes in any other language. These Reddit posts consist of the body of the joke, the punchline, and the number of reactions or *upvotes*. Although this type of humor may only be most enjoyable to a subset of the population, it is an effective way to measure responses to jokes in a large group setting.[1]

What enables us to perform such an analysis are the recent improvements in neural network architecture for natural language processing. These breakthroughs started with the Convolutional Neural Network (LeCun et al., 1998) and have recently included the inception (Bahdanau et al., 2015) and progress of the Attention mechanism (Luong et al., 2015; Xu et al., 2015), and the Transformer architecture (Vaswani et al., 2017).

2 Related Work

In the related work of joke identification, we find a myriad of methods employed over the years: statistical and N-gram analysis (Taylor and Mazlack, 2004), Regression Trees (Purandare and Litman, 2006), Word2Vec combined with K-NN Human Centric Features (Yang et al., 2015), and Convolutional Neural Networks (Chen and Soo, 2018).

This previous research has gone into many settings where humor takes place. Chen and Soo (2018) studied audience laughter compared to textual transcripts in order to identify jokes in conversation, while much work has also gone into us-

ing and creating datasets like the Pun of the Day (Yang et al., 2015), 16000 One-liners (Mihalcea and Strapparava, 2005), and even Ted Talks (Chen and Soo, 2018).

3 Data

We gathered jokes from a variety of sources, each covering a different type of humor. These datasets include jokes of multiple sentences (the Short Jokes dataset), jokes with only one sentence (the Puns dataset), and more mixed jokes (the Reddit dataset). We have made our code and datasets open source for others to use. [2]

3.1 Reddit

Our Reddit data was gathered using Reddit's public API, collecting the most recent jokes. Every time the scraper ran, it also updated the upvote score of the previously gathered jokes. This data collection occurred every hour through the months of March and April 2019. Since the data was already split into body and punchline sections from Reddit, we created separate datasets containing the body of the joke exclusively and the punchline of the joke exclusively. Additionally, we created a dataset that combined the body and punchline together.

Some sample jokes are shown in Table 1, above. The distribution of joke scores varies wildly, ranging from 0 to 136,354 upvotes. We found that there is a major jump between the 0-200 upvote range and the 200 range and onwards, with only 6% of jokes scoring between 200-20,000. We used this natural divide as the cutoff to decide what qualified as a funny joke, giving us 13884 not-funny jokes and 2025 funny jokes.

3.2 Short Jokes

The Short Jokes dataset, found on Kaggle, contains 231,657 short jokes scraped from various joke websites with lengths ranging from 10 to 200 characters. The previous work by Chen and Soo (2018) combined this dataset with the WMT162 English news crawl. Although their exact combined dataset is not publicly available, we used the same method and news crawl source to create a similar dataset. We built this new Short Jokes dataset by extracting sentences from the WMT162 news crawl that had the same distribution of words and characters as the jokes in the Short Jokes dataset on Kaggle[3]. This was in order to match the two halves (jokes and non-jokes) as closely as possible.

3.3 Pun of the Day

This dataset was scraped by Yang et al. (2015) and contains 16001 puns and 16002 not-punny sentences. We gratefully acknowledge their help in putting together and giving us use of this dataset. These puns were constructed from the Pun of the Day website while the negative samples were gathered from news websites.

4 Methods

In this section we will discuss the methods and model used in our experiments.

4.1 Our Model

We have chosen to use the pre-trained BERT (Devlin et al., 2018) as the base of our model. BERT is a multi-layer bidirectional Transformer encoder and was initially trained on a 3.3 billion word corpus. The model can be fined-tuned with another additional output layer for a multitude of other tasks. We chose to use this Transformer based model as our initial platform because of its success at recognizing and attending to the most important words in both sentence and paragraph structures.

In Figure 1, originally designed by Vaswani et al. (2017), we see the architecture of a Transformer model: the initial input goes up through an encoder, which has two parts: a multi-headed

[2]Our code and datasets are publicly available at this link.

[3]The Short Jokes dataset from Kaggle is available here.

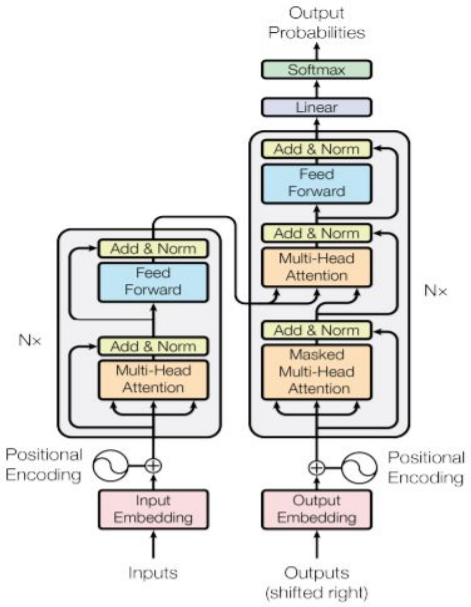

Figure 1: Transformer Model Architecture

self attention layer, followed by a feed-forward network. It then outputs the information into the decoder, which includes the previously mentioned layers, plus an additional masked attention step. Afterwords, it is transformed through a softmax into the output. This model's success is in large part due to the Transformer's self-attention layers.

We chose a learning rate of 2e-05 and a max sequence length of 128. We trained the model for a maximum of 7 epochs, creating checkpoints along the way.

4.2 Training

Since our data was unbalanced we decided to upsample the humorous jokes in training. We split the dataset into a 75/25 percent split, stratifying with the labels. We then upsampled the minority class in the training set until it reached an even 50 percent. This helped our model learn in a more balanced way despite the uneven amount of non-humorous jokes. Our validation and test sets were composed of the remaining 25%, downsampling the data into a 50/50 class split so that the accuracy metric could be balanced and easily understood.

To show how our model compares to the previous work done, we also test on the Short Joke and Pun datasets mentioned in the Data section. For these datasets we will use the metrics (Accuracy, Precision, Recall, and F1 Score) designated in Chen and Soo (2018) as a comparison. We use the same model format as previously mentioned, trained on the Reddit dataset. We then immediately apply the model to predict on the Short Joke and Puns dataset, without further fine-tuning, in order to compare the model. However, because both the Puns and Short Joke datasets have large and balanced labels, we do so without the upsampling and downsampling steps used for the Reddit dataset.

Method	Body	Punchline	Full
CNN	0.651	0.684	0.688
Transformer	**0.661**	**0.692**	**0.724**
Human (General)	0.493	0.592	0.663

Table 2: Results of Accuracy on Reddit Jokes dataset

5 Experiments

In this section we will introduce the baselines and models used in our experiments.

5.1 Baselines

In order to have fair baselines, we used the following two models: a CNN with Highway Layers as described by Chen and Soo (2018) and developed by Srivastava et al. (2015), and human performance from a study on Amazon's Mechanical Turk. We wanted to have the general population rate these same jokes, thus showing the difference between a general audience and a specific subset of the population, in particular, Reddit r/Jokes users. Since the Reddit users obviously found these jokes humorous, this experiment would show whether or not a more general population agreed with those labels.

We had 199 unique participants rate an average of 30 jokes each with the prompt *"do you find this joke humorous?"* If the participant was evaluating a sample from a body or punchline only dataset we prefaced our question with a sentence explaining that context, for example: *"Below is the punchline of a joke. Based on this punchline, do you think you would find this joke humorous?"* Taking these labels, we used the most frequently chosen tag from a majority vote to calculate the percentages found in the *Human* section of Table 2.

5.2 Results

In Table 2, we see the results of our experiment with the Reddit dataset. We ran our models on

Previous Work:	Accuracy	Precision	Recall	F1
Word2Vec+HCF	0.797	0.776	0.836	0.705
CNN	0.867	0.880	0.859	0.869
CNN+F	0.892	0.886	0.907	0.896
CNN+HN	0.892	0.889	0.903	0.896
CNN+F+HN	0.894	0.866	**0.940**	0.901
Our Methods:	Accuracy	Precision	Recall	F1
Transformer	**0.930**	**0.930**	0.931	**0.931**

Table 3: Comparison of Methods on Pun of the Day Dataset. HCF represents Human Centric Features, F for increasing the number of filters, and HN for the use of highway layers in the model. See (Chen and Soo, 2018; Yang et al., 2015) for more details regarding these acronyms.

the body of the joke exclusively, the punchline exclusively, and both parts together (labeled *full* in our table). On the full dataset we found that the Transformer achieved an accuracy of 72.4 percent on the hold out test set, while the CNN was in the high 60's. We also note that the general human classification found 66.3% of the jokes to be humorous.

In order to understand what may be happening in the model, we used the body and punchline only datasets to see what part of the joke was most important for humor. We found that all of the models, including humans, relied more on the punchline of the joke in their predictions (Table 2). Thus, it seems that although both parts of the joke are needed for it to be humorous, the punchline carries higher weight than the body. We hypothesize that this is due to the variations found in the different joke bodies: some take paragraphs to set up the joke, while others are less than a sentence.

Our experiment with the Short Jokes dataset found the Transformer model's accuracy and F1 score to be 0.986. This was a jump of 8 percent from the most recent work done with CNNs (Table 4).

The results on the Pun of the Day dataset are shown in Table 3 above. It shows an accuracy of 93 percent, close to 4 percent greater accuracy than the best CNN model proposed. Although the CNN model used a variety of techniques to extract the best features from the dataset, we see that the self-attention layers found even greater success in pulling out the crucial features.

6 Discussion

Considering that a joke's humor value is subjective, the results on the Reddit dataset are surprising. The model has used the context of the words to determine, with high probability, what an average Reddit r/Jokes viewer will find humorous. When we look at the general population's opinion as well, we find a stark difference between their preferences and those of the Reddit users (Table 2). We would hypothesize that our model is learning the specific type of humor enjoyed by those who use the Reddit r/Jokes forum. This would suggest that humor can be learned for a specific subset of the population.

Method	Accuracy	Precision	Recall	F1
CNN+F+HN	0.906	0.902	0.946	0.924
Transformer	**0.986**	0.986	0.986	0.986

Table 4: Results on Short Jokes Identification

The model's high accuracy and F1 scores on the Short Jokes and Pun of the Day dataset show the effectiveness of the model for transfer learning. This result is not terribly surprising. If the model can figure out which jokes are funny, it seems to be an easier task to tell when something isn't a joke at all.

Although these results have high potential, defining the absolute truth value for a joke's humor is a challenging, if not impossible task. However, these results indicate that, at least for a subset of the population, we can find and identify jokes that will be most humorous to them.

7 Conclusion

In this paper, we showed a method to define the measure of a joke's humor. We explored the idea of using machine learning tools, specifically a Transformer neural network architecture, to discern what jokes are funny and what jokes are not. This proposed model does not require any human

interaction to determine, aside from the text of the joke itself, which jokes are humorous. This architecture can predict the level of humor for a specific audience to a higher degree than a general audience consensus. We also showed that this model has increased capability in joke identification as a result, with higher accuracy and F1 scores than previous work on this topic.

Abstract

One way to reduce network traffic in multi-node data-parallel stochastic gradient descent is to only exchange the largest gradients. However, doing so damages the gradient and degrades the model's performance. Tranformer models degrade dramatically while the impact on RNNs is smaller. We restore gradient quality by combining the compressed global gradient with the node's locally computed uncompressed gradient. Neural machine translation experiments show that Transformer convergence is restored while RNNs converge faster. With our method, training on 4 nodes converges up to 1.5x as fast as with uncompressed gradients and scales 3.5x relative to single-node training.

1 Introduction

In recent years, neural network models have grown dramatically in terms of number of parameters (Wen et al., 2017), so exchanging gradients during data-parallel training is costly in terms of both bandwidth and time, especially in a distributed setting. Communication can be reduced (possibly at the expense of convergence) by sending only the top 1% of largest gradients in terms of absolute values, a method known as gradient dropping (Strom, 2015; Dryden et al., 2016; Aji and Heafield, 2017; Lin et al., 2018). Related methods are synchronizing less often (McMahan et al., 2017; Ott et al., 2018; Bogoychev et al., 2018) and quantization (Seide et al., 2014; Alistarh et al., 2016).

As these compression methods are lossy, each node's locally computed gradient is not immediately reflected in the global gradient. Our experiments show that gradient compression damages the model's performance, especially in the case of a Transformer model (Vaswani et al., 2017), which is known to be sensitive to noisy gradients (Chen et al., 2018; Ott et al., 2018; Aji and Heafield, 2019). We aim to repair the compressed gradient by combining it with the local gradients to improve the trade-off between convergence and compression rates.

In this paper, we apply gradient dropping to reduce the inter-node communication during distributed neural network training, which leads to faster training speed but reduced model convergence rate. We find that combining the sparse global gradient with the dense local gradient improves convergence. However, adding local information means that nodes' parameters will diverge over time. We address this by periodically averaging the model (McMahan et al., 2017), achieving faster end-to-end training time.

2 Related Work

2.1 Sparse Gradient Compression

Gradients are skewed: most values are near zero while very few have large absolute value (Aji and Heafield, 2017). Formally, Pearson's skewness coefficient is typically 2–4, but up to 262 in embedding matrices where much of the parameters lie. Sparse gradient compression exploits this by rounding gradients below a threshold to zero, sending only a sparse matrix of large gradients (Strom, 2015). The threshold can be set dynamically to the top 1% of gradients, achieving constant compression (Dryden et al., 2016). Unsent gradients are added to the next gradient prior to compression (Seide et al., 2014).

Gradient dropping is outlined in Algorithm 1. At each time step t, each node n computes a local gradient L_t^n on its data. The error feedback mechanism adds unsent gradients from the previous step E_{t-1} to the local gradient L_t^n. The combined gradient is then broken into sparse gradient S_t^n and residual E_t. Although the gradient is sparse, all

Algorithm 1 Gradient dropping on node n

procedure SPARSESGD(L_t^n)
  ▷ L_t^n is local gradient of node n at step t.
  $E_t^n \leftarrow E_{t-1}^n + L_t^n$
  $threshold \leftarrow K$-th largest of $|E_t^n|$
  $mask \leftarrow |E_t^n| \geq threshold$
  $S_t^n \leftarrow mask \odot E_t^n$
  $E_t^n \leftarrow \neg mask \odot E_t^n$
  $G_t \leftarrow AllReduce(S_t^n)$
  $ApplyOptimizer(G_t)$
end procedure

parameters are updated because Adam (Kingma and Ba, 2015) has momentum terms. Parameter updates run redundantly in all nodes so that only gradients are sent over the network.

The sum of sparse gradients is less sparse. We can send the summed gradient by itself (Lin et al., 2018) or again take the top 1% of summed gradients. Our cluster of 4 nodes is small enough that there was little speed difference, so we did not recompress the summed gradients.

2.2 Federated Averaging

Another way to reduce the bandwidth cost in multi-node training is by reducing the communication frequency (McMahan et al., 2017). In federated averaging, workers do not exchange gradients. Instead, each worker uses its local gradient to update its own local parameters. Each worker updates their local parameters by averaging across other nodes once every few steps.

In contrast with gradient dropping, federated averaging mainly uses the worker's local gradients for parameter updates. Gradients from other workers are not directly communicated and are therefore not taken into account by the optimizer.

3 Combining With Local Gradients

Recent work suggests that the Transformer is sensitive to noisy gradients, resulting in substantially worse models (Chen et al., 2018; Ott et al., 2018; Aji and Heafield, 2019). Consistent with these findings, both gradient sparsification and federated averaging yield low-quality Transformer models in our experiments. In gradient sparsification, noise comes from both thresholding and the error-feedback mechanism, which causes stale gradients. Federated averaging also introduces stale updates as this approach delays model synchronization. Previous work has shown that both noisy and stale gradients damage the model's quality (McMahan and Streeter, 2014; Ott et al., 2018; Dutta et al., 2018).

To address noisy updates in gradient sparsification, we combine the compressed global gradient and the uncompressed locally computed gradient in an effort to better approximate the true global gradient. Formally, let G_t be the compressed global gradient at time t and L_t^n be the gradient computed locally on node n. These will be combined into C_t^n that will be used to update the parameters.

An arguably naïve method sums the two gradients. With a scale-invariant optimizer like Adam, this is equivalent to averaging.

$$C_t^n = G_t + L_t^n$$

However, some of the locally-computed gradients were sent out and became part of the global gradient, so they will be double-counted by the sum. To compensate, we can subtract out the gradients S_t^n sent by node n.

$$C_t^n = G_t - S_t^n + L_t^n$$

The term $G_t - S_t^n$ equals to the sum of all sparse gradients from other nodes (or approximates it when the all-reduce compresses the result). The local gradient L_t^n used for updating does not include the error-feedback term E_t^n to prevent applying gradients multiple times while they are pending in error-feedback.

3.1 Periodic Synchronization

Nodes will diverge because local gradients differ. Therefore, models are averaged periodically. We average parameters (McMahan et al., 2017) every 500 steps with minimal impact on speed.

In the limit, a gradient is applied twice. First, a local update eventually makes its way to the other nodes via periodic averaging. Second, it accumulates with enough other gradients to be selected for inclusion in the compressed gradient and applied as part of a global update.

4 Experimental Setup

We use Marian (Junczys-Dowmunt et al., 2018) to train on nodes with 4xP100s. Multi-node experiments use 4 of these nodes, each connected with 40Gb Mellanox Infiniband. These scenarios will be abbreviated as 1x4 (one node with four GPUs) and 4x4 (four nodes with four GPUs each).

4.1 Model and Dataset

We perform our neural machine translation experiments on the following architectures.

Transformer: We train a Transformer model with six encoder and six decoder layers with tied embeddings. The model has 62M parameters. We train the model on the WMT 2017 English to German dataset with back-translated monolingual corpora (Sennrich et al., 2016b) and byte-pair encoding (Sennrich et al., 2016c), consisting of 19.1M sentence pairs. Model performance is validated on newstest2016 and tested on newstest2017.

Deep RNN: We also train a deep RNN model Sennrich et al. (2017) with eight layers of bidirectional LSTM consisting of 225M parameters. We train the model with the same English to German dataset from the Transformer experiment.

Shallow RNN: Our shallow RNN model is based on the winning system by Sennrich et al. (2016a) and is a single layer bidirectional encoder-decoder LSTM with attention consisting of 119M parameters. We train this model on WMT 2016 Romanian to English dataset, consisting of 2.5M sentence pairs. We also apply byte-pair encoding to this dataset. Model performance is validated on newsdev2016 and tested on newstest2016.

We apply layer normalization (Lei Ba et al., 2016) and exponential smoothing to train the model for 8 epochs of training.

4.2 Scaling Hyperparameters

In all our experiments, we use a memory budget of 10GB per GPU to dynamically fit as many sentences as possible, corresponding to an average of 450 and 250 sentences per batch per GPU for Ro-En and En-De, respectively. Hence, we apply several adjustments to the hyperparameters to accommodate the larger effective batch size of multi-node synchronous SGD:

Learning rate: The Adam optimizer is scale-invariant, so the parameters move at the same magnitude regardless the gradient size. Therefore, we linearly scale the learning rate in all multi-node experiments, as suggested by Goyal et al. (2017). On one node, we use a learning rate of 0.0003 for Transformer and deep RNN models, and 0.001 for the shallow RNN model. These values multiplied by 4 for the 4-node setting. The single-node learning rates were optimized in the sense that further increasing them damages performance.

Warm-up: Learning rate warm-up helps overcome initial model instability when training with large mini-batches (Goyal et al., 2017). We add a linear learning rate warm-up for the Transformer, deep RNNs, and shallow RNNs for the first 16k, 4k, and 2k steps respectively. We apply inverse square root cool-down following Vaswani et al. (2017) for Transformer and deep RNN models.

We follow the rest of the hyperparameter settings as suggested in the papers (Vaswani et al., 2017; Sennrich et al., 2017, 2016a).

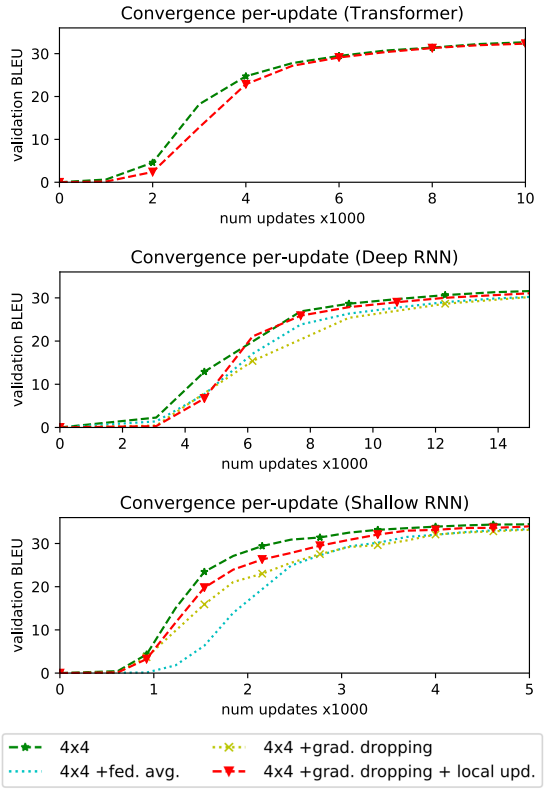

Figure 1: Model convergence per-updates on gradient dropping with local gradient update. We focus on the early stage of the training, before the BLEU converged. Training a Transformer with gradient dropping or federated averaging yielded 0 BLEU.

5 Results and Analysis

5.1 Restoring Quality

We approximate impact on quality by measuring the BLEU score (Papineni et al., 2002) obtained per update, experimenting with both RNN and Transformer systems. The baselines are vanilla 4-node synchronous SGD, gradient dropping (Aji and Heafield, 2017), and federated averaging (McMahan et al., 2017). For gradient dropping, we perform drop ratio warmup, gradually increasing it to 99% after 1000 steps. We average

Model	Transformer dev	Transformer test	Deep RNN dev	Deep RNN test	Shallow RNN dev	Shallow RNN test
Multi-node (4x4)	35.39	28.78	34.45	27.81	35.45	34.45
4x4 + gradient dropping	0.00	0.00	34.38	27.50	35.20	33.89
4x4 + federated averaging	0.00	0.00	34.33	27.42	35.25	33.93
4x4 + gradient dropping + local update	35.07	28.50	34.52	27.68	35.35	34.45

Table 1: Training quality of multi-node training with gradient compression techniques, measured with BLEU.

the model every 20 steps in federated averaging experiment, and every 500 steps in our proposed method.

Figure 1 shows BLEU score per update. Gradient dropping and federated averaging reduce gradient quality and improvement per update is slower. In the Transformer case, the model is incapable of training at all. Local gradient incorporation improves the sparse gradient quality and improves convergence per-epoch over gradient dropping. In all architectures, the model achieved a comparable training curve compared to the uncompressed multi-node training.

Table 1 summarizes model's performance in terms of BLEU. With local gradient incorporation, the models obtained better final quality, performing closer to uncompressed multi-node training. Local gradient incorporation enables the Transformer to train with a sparse gradient, albeit with slight quality degradation (0.28–0.32%). This result confirms Transformer's sensitivity to noisy updates and the ability of local gradients to mostly repair them.

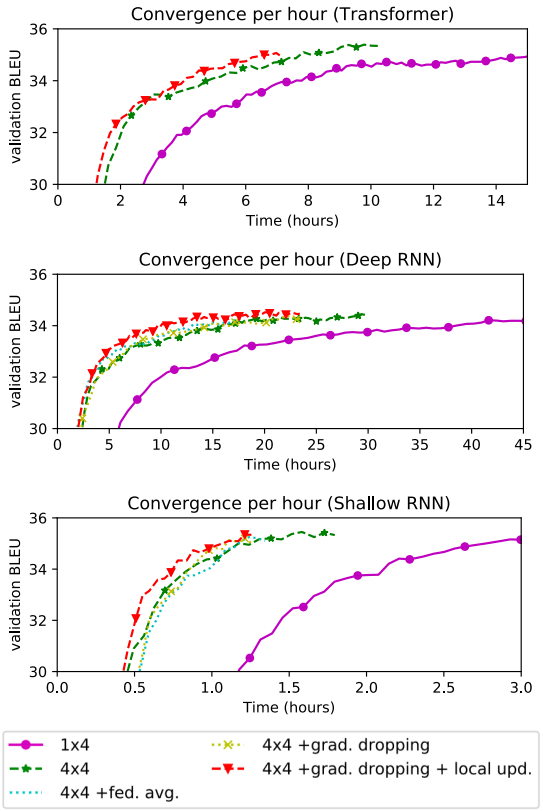

Figure 2: Convergence over time of gradient dropping with local gradient update.

5.2 Improving Training Speed

We measure the speed improvement of our proposed method by capturing the raw processing speed and time to reach certain BLEU. We compare it to both gradient dropping and federated averaging. We also measure the training efficiency by comparing the results with a single-node system. For the Transformer, we exclude gradient dropping and federated averaging as the models fail to train.

Table 2 summarizes our experiments. Gradient dropping reduces network traffic 50-fold and significantly improves the raw training speed in multi-node setting up to 3.4x over single-node, and up to 1.6x faster raw speed over uncompressed multi-node setting. Federated averaging is faster because there is no additional communication overhead for every step, and no extra computational cost for sparse gradients' compression. Finally, our method incurs the combined cost of gradient dropping, occasional federated averaging, and local updates so it is slower than gradient dropping at raw speed, but still substantially faster than uncompressed multi-node training.

While vanilla gradient dropping and federated averaging have better raw speed, there is no clear improvement on convergence speed as noisy gradients damage the convergence. Local gradient update restores the gradient and improves the convergence speed. In our RNN experiments, convergence speedup is closer to the raw speedup, up to 3.5x single-node performance.

The Transformer convergence rate increases more slowly than raw batch processing speed.

Model	Words/ second	Raw speedup (1x4 / 4x4)	Time to conv.	conv. speedup (1x4 / 4x4)
Transformer (En-De)				
Single-node (1x4)	36029	-	7.61h	-
Multi-node (4x4)	97111	2.7x / -	4.76h	1.6x / -
4x4 + gradient dropping + local update	122914	3.4x / 1.3x	4.03h	1.9x / 1.2x
Deep RNN (En-De)				
Single-node (1x4)	18205	-	23.68h	-
Multi-node (4x4)	42930	2.4x / -	10.59h	2.2x / -
4x4 + gradient dropping	60090	3.3x / 1.4x	8.94h	2.6x / 1.2x
4x4 + federated averaging	66149	3.6x / 1.5x	9.50h	2.5x / 1.1x
4x4 + gradient dropping + local update	59747	3.3x / 1.4x	6.80h	3.5x / 1.5x
Shallow RNN (Ro-En)				
Single-node (1x4)	36466	-	2.37h	-
Multi-node (4x4)	75641	2.1x / -	1.05h	2.3x / -
4x4 + gradient dropping	118189	3.2x / 1.6x	0.94h	2.5x / 1.1x
4x4 + federated averaging	124273	3.4x / 1.6x	1.06h	2.2x / 1.0x
4x4 + gradient dropping + local update	117756	3.2x / 1.6x	0.85h	2.8x / 1.2x

Table 2: Speed performance of gradient dropping with local gradient update, compared to several baselines. Time to convergence is time needed to reach 34.5 BLEU (Transformer & Shallow RNN) or 33.5 BLEU (Deep RNN).

While the rule of thumb is to scale learning rate linearly with batch size (Goyal et al., 2017), the Transformer model is also sensitive to high learning rates (Aji and Heafield, 2019). We obtained 1.6x convergence speedup, instead of the expected 2.7x speedup. Scaling the learning rate sublinearly can be explored.

Compression results are of course dependent on the ratio between computation and network bandwidth in a system, as well as model size. Because the method reduces network load, we would expect to see even larger speed improvement with commodity hardware instead of the 40 gigabit Infiniband network used in our experiments.

6 Conclusion

We improve model convergence when training with sparse gradients by utilizing an additional locally-computed gradient, while also negates the quality loss in terms of BLEU caused by gradient dropping. With gradient dropping and local gradient incorporation, we improve the raw training speed in terms of word/second by up to 3.4x over single-node system, and up to 1.6x over uncompressed multi-node system. We also evaluate the training speed by the time needed to reach a near-convergence BLEU score. In this case, we improve the training speed by up to 3.5x over single-node system and up to 1.5x over uncompressed multi-node system.

Abstract

We propose a practical scheme to train a single multilingual sequence labeling model that yields state of the art results and is small and fast enough to run on a single CPU. Starting from a public multilingual BERT checkpoint, our final model is 6x smaller and 27x faster, and has higher accuracy than a state-of-the-art multilingual baseline. We show that our model especially outperforms on low-resource languages, and works on codemixed input text without being explicitly trained on codemixed examples. We showcase the effectiveness of our method by reporting on part-of-speech tagging and morphological prediction on 70 treebanks and 48 languages.

1 Introduction

There have been many recent modeling improvements (Smith et al., 2018; Bohnet et al., 2018) on morphosyntactic tagging tasks. However, these models have largely focused on building separate models for each language or for a small group of related languages. In this paper, we consider the implications of training, evaluating, and deploying a single multilingual model for a diverse set of almost 50 languages, evaluating on both part-of-speech tagging and morphological attribute prediction data from the Universal Dependencies repository (Nivre et al., 2018).

There are several benefits of using one multilingual model over several language specific models.

- Parameter sharing among languages reduces model size and enables cross-lingual transfer learning. We show that this improves accuracy, especially for low-resource languages.
- No language identification model needed to decide which language-specific model to query. Critically, this reduces system complexity and prevents prediction errors from language identification from propagating into the downstream system.
- Multilingual models can be applied to multilingual or codemixed inputs without explicitly being trained on codemixed labeled examples. Otherwise, given, e.g. a mixed Hindi/English input, one must decide to query either the Hindi model or the English model, both of which are sub-optimal.

In this paper, we show that by finetuning a pretrained BERT (Devlin et al., 2019) model we can build a multilingual model that has comparable or better accuracy to state-of-the-art language-specific models, and outperforms the state-of-the-art on low-resource languages. Our model outperforms other multilingual model baselines by a large margin. We evaluate on both part-of-speech tagging and morphological attribute prediction tasks with data from the Universal Dependencies repository (Nivre et al., 2018). However, this model is slow, very large, and difficult to deploy in practice.

We describe our solution for making this model small and practical enough to use in practice on a single CPU, while preserving quality. The final model is 27x faster than a BERT-based baseline model and 7x faster than a state-of-the-art LSTM-based model on CPU. It is 6 times smaller than the BERT-based model. Furthermore, most of the quality gains are preserved in the small model.

2 Multilingual Models for Sequence Labeling

We discuss two core models for addressing sequence labeling problems and describe, for each, training them in a single-model multilingual setting: (1) the Meta-LSTM (Bohnet et al., 2018), an extremely strong baseline for our tasks, and (2)

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3632–3636, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Model	Multilingual?	Part-of-Speech F1	Morphology F1
Meta-LSTM	No	94.5	92.5
BERT	No	**95.1**	**93.0**
Meta-LSTM	Yes	91.1	82.9
BERT	Yes	**94.5**	**91.0**

Table 1: Macro-averaged F1 comparison of per-language models and multilingual models over 48 languages. For non-multilingual models, F1 is the average over each per-language model trained.

a multilingual BERT-based model (Devlin et al., 2019).

2.1 Meta-LSTM

The Meta-LSTM is the best-performing model of the CoNLL 2018 Shared Task (Smith et al., 2018) for universal part-of-speech tagging and morphological features. The model is composed of 3 LSTMs: a character-BiLSTM, a word-BiLSTM and a single joint BiLSTM which takes the output of the character and word-BiLSTMs as input. The entire model structure is referred to as Meta-LSTM.

To set up multilingual Meta-LSTM training, we take the union of all the word embeddings from the Bojanowski et al. (2017) embeddings model on Wikipedia[1] in all languages. For out-of-vocabulary words, a special unknown token is used in place of the word.

The model is then trained as usual with cross-entropy loss. The char-BiLSTM and word-biLSTM are first trained independently. And finally we train the entire Meta-LSTM.

2.2 Multilingual BERT

BERT is a transformer-based model (Vaswani et al., 2017) pretrained with a masked-LM task on millions of words of text. In this paper our BERT-based experiments make use of the cased multilingual BERT model available on GitHub[2] and pretrained on 104 languages.

Models fine-tuned on top of BERT models achieve state-of-the-art results on a variety of benchmark and real-world tasks.

To train a multilingual BERT model for our sequence prediction tasks, we add a softmax layer on top of the the first wordpiece (Schuster and Nakajima, 2012) of each token[3] and finetune on data from all languages combined. During training, we concatenate examples from all treebanks and randomly shuffle the examples.

[1] https://fasttext.cc/docs/en/pretrained-vectors.html

[2] https://github.com/google-research/bert/blob/master/multilingual.md

[3] We experimented with wordpiece-pooling (Lee et al., 2017) which we found to marginally improve accuracy but at a cost of increasing implementation complexity to maintain.

Model	Embedding Size	Tokens	Hidden Units	Layers
Meta-LSTM	300	1.2M	8M	3
BERT	768	120k	87M	12
MiniBERT	256	120k	2M	3

Table 2: The number of parameters of each model. *Tokens* refers to the number of tokens of the embedding rows. For the Meta-LSTM, a word-based model, this is the number of words in training. For BERT, this means the size of the Wordpiece vocabulary. And *Hidden Units* refers to all units that are not among the embedding layer or and output layer.

Input	32 words	128 words
Relative Speedup on GPU		
Meta-LSTM	0.8x	0.2x
MiniBERT	**4.3x**	**2.6x**
Relative Speedup on CPU		
Meta-LSTM	6.8x	2.3x
MiniBERT	**27.7x**	**14.0x**

Table 3: Relative inference speedup over BERT. We see MiniBERT is the fastest on both CPU and GPU. CPU is an Intel Xeon CPU E5-1650 v3 @3.50GHz. GPU is an Nvidia Titan V.

3 Small and Practical Models

The results in Table 1 make it clear that the BERT-based model for each task is a solid win over a Meta-LSTM model in both the per-language and multilingual settings. However, the number of parameters of the BERT model is very large (179M parameters), making deploying memory intensive and inference slow: 230ms on an Intel Xeon CPU. Our goal is to produce a model fast enough to run on a single CPU while maintaining the modeling capability of the large model on our tasks.

Size and speed

We choose a three-layer BERT, we call *MiniBERT*, that has the same number of layers as the Meta-

LSTM and has fewer embedding parameters and hidden units than both models. Table 2 shows the parameters of each model. The Meta-LSTM has the largest number of parameters dominated by the large embeddings. BERT's parameters are mostly in the hidden units. The MiniBERT has the fewest total parameters.

The inference-speed bottleneck for Meta-LSTM is the sequential character-LSTM-unrolling and for BERT is the large feedforward layers and attention computation that has time complexity quadratic to the sequence length. Table 3 compares the model speeds.

BERT is much slower than both MetaLSTM and MiniBERT on CPU. However, it is faster than Meta-LSTM on GPU due to the parallel computation of the transformer. The MiniBERT is significantly faster than the other models on both GPU and CPU.

Distillation

For model distillation (Hinton et al., 2015), we extract sentences from Wikipedia in languages for which public multilingual is pretrained. For each sentence, we use the open-source BERT wordpiece tokenizer (Schuster and Nakajima, 2012; Devlin et al., 2019) and compute cross-entropy loss for each wordpiece:

$$L(\mathbf{t}, \mathbf{s}) = H(\sigma(\mathbf{t}/T), \sigma(\mathbf{s}/T))$$

where H is the cross-entropy function, σ is the softmax function, $\mathbf{t}$ is the BERT model's logit of the current wordpiece, $\mathbf{s}$ is the small BERT model's logits and T is a temperature hyperparameter, explained in Section 4.2.

To train the distilled multilingual model *m*MiniBERT, we first use the distillation loss above to train the student from scratch using the teacher's logits on unlabeled data. Afterwards, we finetune the student model on the labeled data the teacher is trained on.

4 Experiments

4.1 Data

We use universal part-of-speech tagging and morphology data from the The CoNLL 2018 Shared Task (Nivre et al., 2018; Zeman and Hajič, 2018). For comparison simplicity, we remove the languages that the multilingual BERT public checkpoint is not pretrained on.

Model	Part-of-Speech F1	Morphology F1
*m*Meta-LSTM	91.1	82.9
*m*MiniBERT	93.7	88.6
*m*BERT	**94.5**	**91.0**

Table 4: Macro-averaged F1 comparison of multilingual models. Multilingual models are prefixed with '*m*'.

For segmentation, we use a baseline segmenter (UDPipe v2.2)[4] provided by the shared task organizer to segment raw text. We train and tune the models on gold-segmented data and apply the segmenter on the raw test of test data before applying our models.

The part-of-speech tagging task has 17 labels for all languages. For morphology, we treat each morphological group as a class and union all classes as a output of 18334 labels.

4.2 Tuning

For Meta-LSTM, we use the public repository's hyperparameters[5].

Following Devlin et al. (2019), we use a smaller learning rate of 3e-5 for fine-tuning and a larger learning rate of 1e-4 when training from scratch and during distillation. Training batch size is set to 16 for finetuning and 256 for distillation.

For distillation, we try temperatures $T = 1, 2, 3$ and use the teacher-student accuracy for evaluation. We observe BERT is very confident on its predictions, and using a large temperature $T = 3$ to soften the distribution consistently yields the best result.

4.3 Multilingual Models

Multilingual Modeling Results We compare per-language models trained on single language treebanks with multilingual models in Table 1 and Table 4. In the experimental results we use a prefix m to denote the model is a single multilingual model. We compare Meta-LSTM, BERT, and MiniBERT.

Multilingual Models Comparison *m*BERT performs the best among all multilingual models. The smallest and fastest model, *m*MiniBERT, performs comparably to *m*BERT, and outperforms *m*Meta-LSTM, a state-of-the-art model for this task.

[5]https://github.com/google/meta_tagger

Languages	POS Tagging kk	hy	lt	be	mr	ta	Morphology kk	hy	lt	be	mr	ta
Train Size	31	50	153	260	373	400	31	50	153	260	373	400
Meta-LSTM	61.7	75.4	81.4	91.1	72.1	72.7	48.5	54.5	69.7	74.0	59.1	71.0
BERT	75.9	84.4	88.9	94.8	**77.5**	**75.7**	47.8	44.8	**75.2**	82.8	64.0	72.9
*m*BERT	**81.4**	**86.6**	**90.0**	**95.0**	75.9	74.3	**64.6**	**51.1**	73.6	**87.5**	**64.2**	**73.8**
*m*Meta-LSTM	52.9	63.8	65.6	87.6	65.5	61.5	25.6	36.6	42.5	59.2	33.6	46.9
*m*MiniBERT	**76.6**	**86.0**	**86.9**	**95.0**	**75.4**	**74.6**	**59.7**	**47.6**	**64.8**	**81.6**	**59.4**	**71.7**

Table 5: POS tagging and Morphology F1 for all models on low-resource languages. Multilingual models are prefixed with '*m*'.

Multilingual Models vs Per-Language Models When comparing with per-language models, the multilingual models have lower F1. Kondratyuk (2019) shows similar results. Meta-LSTM, when trained in a multilingual fashion, has bigger drops than BERT in general. Most of the Meta-LSTM drop is due to the character-LSTM, which drops by more than 4 points F1.

4.4 Low Resource Languages

We pick languages with fewer than 500 training examples to investigate the performance of low-resource languages: Tamil (ta), Marathi (mr), Belarusian (be), Lithuanian (lt), Armenian (hy), Kazakh (kk)[6]. Table 5 shows the performance of the models.

BERT Cross-Lingual Transfer While Wu and Dredze (2019) shows effective zero-shot crosslingual transfer from English to other high-resource languages, we show that cross-lingual transfer is even effective on low-resource languages when we train on all languages as *m*BERT is significantly better than BERT when we have fewer than 50 examples. In these cases, the *m*MiniBERT distilled from the multilingual *m*BERT yields results better than training individual BERT models. The gains becomes less significant when we have more training data.

***m*MiniBERT Effectiveness** The multilingual baseline *m*Meta-LSTM does not do well on low-resource languages. On the contrary, *m*MiniBERT performs well and outperforms the state-of-the-art Meta-LSTM on the POS tagging task and on four out of size languages of the Morphology task.

[6]The Universal Dependencies data does not have explicit tuning data for hy and kk.

Model	F1
BERT Supervised	90.6
Meta-LSTM English-Only	47.7
Meta-LSTM Hindi-Only	53.8
*m*Meta-LSTM	**83.4**
*m*BERT	82.9
*m*MiniBERT	79.5

Table 6: F1 score on Hindi-English codemixed POS tagging task. Each multilingual model is within 10 points of the supervised BERT model without having explicitly seen code-mixed data.

4.5 Codemixed Input

We use the Universal Dependencies' Hindi-English codemixed data set (Bhat et al., 2017) to test the model's ability to label code-mixed data. This dataset is based on code-switching tweets of Hindi and English multilingual speakers. We use the Devanagari script provided by the data set as input tokens.

In the Universal Dependency labeling guidelines, code-switched or foreign-word tokens are labeled as X along with other tokens that cannot be labeled[7]. The trained model learns to partition the languages in a codemixed input by labeling tokens in one language with X, and tokens in the other language with any of the other POS tags. It turns out that the 2nd-most likely label is usually the correct label in this case; we evaluate on this label when the 1-best is X.

Table 6 shows that all multilingual models handle codemixed data reasonably well without supervised codemixed traininig data.

5 Conclusion

We have described the benefits of multilingual models over models trained on a single language for a single task, and have shown that it is possible to resolve a major concern of deploying large

[7]https://universaldependencies.org/u/pos/X.html

BERT-based models by distilling our multilingual model into one that maintains the quality wins with performance fast enough to run on a single CPU. Our distilled model outperforms a multilingual version of a very strong baseline model, and for most languages yields comparable or better performance to a large BERT model.

Abstract

Spoken Language Understanding (SLU) converts user utterances into structured semantic representations. Data sparsity is one of the main obstacles of SLU due to the high cost of human annotation, especially when domain changes or a new domain comes. In this work, we propose a data augmentation method with atomic templates for SLU, which involves minimum human efforts. The atomic templates produce exemplars for fine-grained constituents of semantic representations. We propose an encoder-decoder model to generate the whole utterance from atomic exemplars. Moreover, the generator could be transferred from source domains to help a new domain which has little data. Experimental results show that our method achieves significant improvements on DSTC 2&3 dataset which is a domain adaptation setting of SLU.

1 Introduction

The SLU module is a key component of spoken dialogue system, parsing user utterances into corresponding semantic representations in a narrow domain. The typical semantic representation for SLU could be semantic frame (Tur and De Mori, 2011) or dialogue act (Young, 2007). In this paper, we focus on SLU with the dialogue act that a sentence is labelled as a set of *act-slot-value* triples. For example, the utterance *"Not Chinese but I want Thai food please"* has an annotation of *"deny(food=Chinese), inform(food=Thai)"*.

Deep learning has achieved great success in the SLU field (Mesnil et al., 2015; Liu and Lane, 2016; Zhao et al., 2019). However, it is notorious for requiring large labelled data, which limits the scalability of SLU models. Despite recent advancements and tremendous research activity in semi-supervised learning and domain adaptation, the deep SLU models still require massive amounts of labelled data to train.

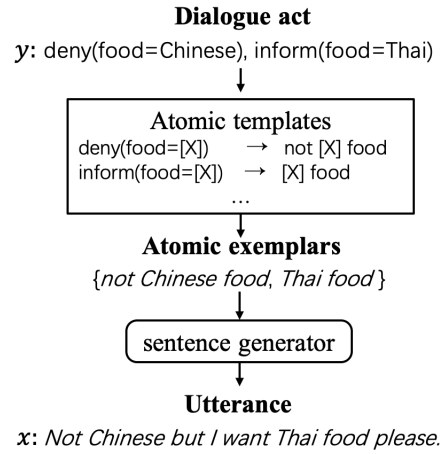

Figure 1: Workflow of the data augmentation with atomic templates for SLU.

Therefore, data augmentation for SLU becomes appealing, and it needs three kinds of capabilities:

- **Expression diversity**: There are always various expressions for the same semantic meaning. Lack of expression diversity is an obstacle of SLU.
- **Semantic diversity**: The data augmentation method should generate data samples with various semantic meanings.
- **Domain adaptation**: The method should be able to utilize data from other domains and adapt itself to a new domain rapidly.

In this work, we propose a new data augmentation method for SLU, which consists of atomic templates and a sentence generator (as shown in Figure 1). The method starts from dialogue acts

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

which are well-structured and predefined by domain experts. Rich and varied dialogue acts can be created automatically, which is guided by a domain ontology.

To enhance the capability of domain adaptation for the sentence generator, we propose to first interpret dialogue acts in natural language so that new dialogue acts can be understood by the generator. However, interpreting a dialogue act at sentence level costs a lot, atomic templates are exploited to alleviate human efforts. The atomic templates are created at phrase level, which produce exemplars for fine-grained constituents (i.e. *act-slot-value* triple) of semantic representations (i.e. dialogue act). Thus, the sentence generator can be an encoder-decoder model, paraphrasing a set of atomic exemplars to an utterance.

We evaluate our approach on DSTC 2&3 dataset (Henderson et al., 2014a,b), a benchmark of SLU including domain adaptation setting. The results show that our method can obtain significant improvements over strong baselines with limited training data.

2 Related Work

Data augmentation for SLU Hou et al. (2018) use a sequence-to-sequence model to translate between sentence pairs with the same meaning. However, it cannot generate data for new semantic representations. Yoo et al. (2018) use a variational autoencoder to generate labelled language. It still lacks variety of semantic meanings. Let x and y denote an input sentence and the corresponding semantic representation respectively. These two works estimate $p(x, y)$ with generation models to produce more labelled samples, while they have two drawbacks. 1) The models cannot control which kinds of semantic meaning should be generated for supply. 2) The models cannot generate data for new semantic representations which may contain out-of-vocabulary (OOV) labels. We propose to generate utterance based on semantic representations by estimating $p(x|y)$, because y is well-structured and easy to be synthesized. To overcome the OOV problem of semantic labels, we first map them to atomic exemplars with a little of human effort.

Zero-shot learning of SLU Besides data augmentation, zero-shot learning of SLU (Ferreira et al., 2015; Yazdani and Henderson, 2015) is also related, which can adapt to unseen semantic labels. Yazdani and Henderson (2015) exploit a binary classifier for each possible *act-slot-value* triple to predict whether it exists in the input sentence. Zhao et al. (2019) propose a hierarchical decoding model for SLU. However, they still have problem with new *act* and *slot*. Bapna et al. (2017); Lee and Jha (2018); Zhu and Yu (2018) try to solve it with textual slot descriptions. In this paper, we propose atomic templates to describe *act-slot-value* triples but not separate slots or acts.

3 Method

In this section, our data augmentation method with atomic templates will be introduced, which generates additional data samples for training SLU model.

3.1 SLU Model

For dialogue act based SLU, we adopt the hierarchical decoding (HD) model (Zhao et al., 2019) which dynamically parses *act*, *slot* and *value* in a structured way. The model consists of four parts:

- A shared utterance encoder, bidirectional LSTM recurrent neural network (BLSTM) (Graves, 2012);
- An *act* type classifier on the utterance;
- A *slot* type classifier with the utterance and an act type as inputs;
- A *value* decoder with the utterance and an *act-slot* type pair as inputs.

The *value* decoder generates word sequence of the value by utilizing a sequence-to-sequence model with attention (Luong et al., 2015) and pointer network (Vinyals et al., 2015a) which helps handling out-of-vocabulary (OOV) values.

3.2 Data Generation with Atomic Templates

As illustrated in Figure 1, the workflow of the data augmentation is broken down into: 1) mapping *act-slot-value* triples to exemplars with atomic templates, and 2) generating the corresponding utterance depending on the atomic exemplars.

Let $x = x_1 \cdots x_{|x|}$ denote the utterance (word sequence), and $y = \{y_1, \cdots, y_{|y|}\}$ denote the dialogue act (a set of *act-slot-value* triples). We wish to estimate $p(x|y)$, the conditional probability of utterance x given dialogue act y.

However, there are also some disadvantages to directly using dialogue acts as inputs:

Triple	Templates
bye()	goodbye bye
request(addr)	the address what's the address
inform(food=[food])	[food] [food] food
inform(hastv=true)	television with a television

Table 1: Examples of atomic templates in DSTC 2&3 dataset. "[food]" is an arbitrary value of slot "food".

- The dialogue acts from different narrow domains may conflict, e.g. different slot names for the same meaning.
- Act and slot types may not be defined in a literal way, e.g. using arbitrary symbols like "city_1" and "city_2" to represent city names in different contexts.

Thus, it is hard to adapt the model $p(x|y)$ to new act types, slot types, and domains.

We propose to interpret the dialogue act in short natural language, and then rephrase it to the corresponding user utterance. While interpreting the dialogue act at sentence level costs as much as building a rule-based SLU system, we choose to interpret *act-slot-value* triples with atomic templates which involve minimum human efforts.

3.2.1 Atomic templates

Table 1 gives some examples of atomic templates used in DSTC 2&3 dataset. Atomic templates produce a simple description (atomic exemplar e_i) in natural language for each *act-slot-value* triple[1] y_i. If there are multiple templates for triple y_i, which generate multiple atomic exemplars $E(y_i)$, we choose the most similar one $e_i = \text{argmax}_{e \in E(y_i)} sim(e, x)$ in the training stage, and randomly select one e_i from $E(y_i)$ in the data augmentation stage. The similarity function $sim(e, x)$ we used is Ratcliff-Obershelp algorithm (Black, 2004). Therefore,

$$p(x|y) = p(x|\{y_1 \cdots y_{|y|}\}) = p(x|\{e_1 \cdots e_{|y|}\})$$

3.2.2 Sentence generator

An encoder-decoder model is exploited to generate the utterance based on the set of atomic exemplars by estimating $p(x|\{e_1 \cdots e_{|y|}\})$.

[1]It should be noted that an *act-slot-value* triple may have an empty value, e.g. "request(phone)" refers to asking for phone number. The triple may also need no slot, e.g. "bye()".

As the set of atomic exemplars is unordered, we encode them independently. For each atomic exemplar $e_i = w_{i1} \cdots w_{iT_i}$ (a sequence of words with length T_i), we use a BLSTM to encode it. The hidden vectors are recursively computed at the j-th time step via:

$$\begin{aligned}
\overrightarrow{\mathbf{h}}_{ij} &= \text{f}_{\text{LSTM}}(\psi(w_{ij}), \overrightarrow{\mathbf{h}}_{ij-1}), j = 1, \cdots, |T_i| \\
\overleftarrow{\mathbf{h}}_{ij} &= \text{b}_{\text{LSTM}}(\psi(w_{ij}), \overleftarrow{\mathbf{h}}_{ij+1}), j = |T_i|, \cdots, 1 \\
\mathbf{h}_{ij} &= [\overrightarrow{\mathbf{h}}_{ij}; \overleftarrow{\mathbf{h}}_{ij}]
\end{aligned}$$

where $[\cdot;\cdot]$ denotes vector concatenation, $\psi(\cdot)$ is a word embedding function, f_{LSTM} is the forward LSTM function and b_{LSTM} is the backward one. The final hidden vectors of the forward and backward passes are utilized to represent each atomic exemplar e_i, i.e. $\mathbf{c}_i = [\overrightarrow{\mathbf{h}}_{iT_i}; \overleftarrow{\mathbf{h}}_{i1}]$.

After encoding all the atomic exemplars, we have a list of hidden vectors $H(y) = [\mathbf{h}_{11} \cdots \mathbf{h}_{1T_1}; \cdots; \mathbf{h}_{|y|1} \cdots \mathbf{h}_{|y|T_{|y|}}]$. A LSTM model serves as the decoder (Vinyals et al., 2015b), generating the utterance x word-by-word:

$$p(x|y) = p(x|H(y)) = \prod_{t=1}^{|x|} p(x_t|x_{<t}, H(y))$$

Before the generation, the hidden vector of the decoder is initialized as $1/|y| \sum_{i=1}^{|y|} \mathbf{c}_i$, the mean of representations of all the atomic exemplars. The pointer softmax (Gulcehre et al., 2016) enhanced by a trick of targeted feature dropout (Xu and Hu, 2018) is adopted to tackle OOV words, which will switch between generation and copying from the input source dynamically.

4 Experiment

4.1 Data

In our experiments, we use the dataset provided for the second and third Dialog State Tracking Challenge (DSTC 2&3) (Henderson et al., 2014a,b). DSTC2 contains a large number of training dialogues (∼15.6k utterances) related to restaurant search while DSTC3 is designed to address the problem of adaptation to a new domain (tourist information) with only a small amount of seed data (*dstc3_seed*, 109 utterances). The manual transcriptions are used as user utterances to eliminate the impact of speech recognition errors.

We follow the data partitioning policy as Zhu et al. (2014), which randomly selects one-half of

DSTC3 test data as the oracle training set (∼9.4k utterances) and leaves the other half as the evaluation set (∼9.2k utterances).

4.2 Experimental Setup

Delexicalized triples are used in case of non-enumerable slot, like "inform(food=[food])" in Table 1. There are 41 and 35 delexicalized triples for DSTC2 and DSTC3 respectively. For each triple, we prepare two short templates on average. Note that, compared to designing sentence-level templates, writing atomic templates for triples at phrase level requires much less human efforts.

For data augmentation of DSTC3, there are two ways to collect extra dialogue acts as inputs[2]:

- **Seed abridgement**: Abridging the delexicalized dialogue acts existing in *dstc3_seed* data, e.g. a dialogue act with 3 triples {A,B,C} can be abridged to obtain {A,B}, {B,C}, {A,C}, {A}, {B}, {C} and itself.

- **Combination**: As all possible triples are predefined in the domain ontology of DSTC3 by experts. We use a general policy of triples combination, which randomly selects at most N_c triples to make up a dialogue act. (N_c is set as 3 empirically.)

Then we fill up each non-enumerable slot in the dialogue act by randomly choosing a value of this slot, which ends when each value appears at least N_v times in all the collected dialogue acts. N_v is set as 3 empirically. After that, we have 1420 and 20670 dialogue acts from the seed abridgement and combination respectively. New data samples are generated starting from these dialogue acts, through the atomic templates and the sentence generator (e.g. 1-best output is kept).

The SLU model and sentence generator use the same hyper-parameters. The dimension of word embeddings (*Glove*[3] word vectors are used for initialization) is 100 and the number of hidden units is 128. Dropout rate is 0.5 and batch size is 20. Maximum norm for gradient clipping is set to 5 and Adam optimizer is used with an initial learning rate of 0.001. All training consists of 50 epochs with early stopping on the development set. We report F1-score of extracting *act-slot-value* triples by the official scoring script from http://camdial.org/~mh521/dstc/.

4.3 Systems

We first compare two SLU models to answer why the HD model is chosen for dialogue act based SLU:

- **ZS**: zero-shot learning of SLU (Yazdani and Henderson, 2015) which can adapt to unseen dialogue acts.

- **HD**: the hierarchical decoding model (Zhao et al., 2019) is adopted in our system.

We make comparisons of other data augmentation methods and the atomic templates (AT):

- **Naive**: We replace the value simultaneously existing in an utterance and its semantic labels of *dstc3_seed* by randomly selecting a value of the corresponding slot. It ends when each value appears at least N_v times.

- **Human**: Zhu et al. (2014) proposed to design a large number of sentence-level templates for DSTC3 with lots of human efforts.

- **Oracle**: The oracle training set is used which simulates the perfect data augmentation.

Without data augmentation, the SLU models are pre-trained on DSTC2 dataset (source domain) and finetuned with *dstc3_seed* set. In our data augmentation method, the sentence generator based on atomic concepts is also pre-trained on DSTC2 dataset and finetuned with the *dstc3_seed*. The SLU model is first pre-trained on DSTC2 dataset, then finetuned with the augmented dataset and finally finetuned with the *dstc3_seed*.

4.4 Results and Analysis

The main results are illustrated in Table 2. We can see that:

1. The hierarchical decoding (HD) model gets better performance than the zero-shot learning (ZS) method of SLU.

2. The seed data $dstc3_seed$ limits the power of the SLU model, and even the naive augmentation can enhance it.

[2]The data splits, atomic templates and extra dialogue acts will be available at https://github.com/sz128/DAAT_SLU

[3]http://nlp.stanford.edu/data/glove.6B.zip

SLU	Augmentation	F1-score
ZS	w/o	68.3
HD	w/o	78.5
	Naive	82.9
	AT (seed abridgement)	85.5
	AT (combination)	87.9
	AT (seed abr. + comb.)	**88.6**
	Human (Zhu et al., 2014)	90.4
	Oracle	96.9

Table 2: SLU performances of different systems on the DSTC3 evaluation set.

3. Our data augmentation method with atomic templates (AT) improves the SLU performance dramatically. One reason may be the generated data has higher variety of semantic meaning than the naive augmentation. *Combination* can make up more dialogue acts and shows better result than *Seed abridgement*, while *Seed abridgement* provides more realistic dialogue acts. Thus, their union gives the best result.

4. The best performance of our method is close to the human-designed sentence-level templates (Zhu et al., 2014), while our approach needs much less human efforts.

Ablation Study We conduct several ablation studies to analyze the effectiveness of different components of our method, as shown in Table 3. By removing SLU model pretraining on DSTC2 ("- *dstc2*") and finetuning on the seed data ("- *dstc3_seed*"), we can see a significant decrease in SLU performance. When we subsequently cast aside the sentence generator ("- *sentence generator*", i.e. using the atomic exemplars as inputs of SLU model directly), the SLU performance decreases by 10.3%. This shows that the sentence generator can produce more natural utterances. If we replace the atomic exemplars as the corresponding *act-slot-value* triples ("- *atomic templates*"), the SLU performance drops sharply. The reason may be that the atomic templates provide a better description of corresponding semantic meanings than the surfaces of the triples. Examples of generated data samples are in Appendix A.

Number of seed samples Figure 2 shows the number of seed samples used versus SLU performance on DSTC3 evaluation set. For zero-shot case (no seed samples), our method is much better than the baseline. When the number of seed samples increases, our method outperforms the baseline constantly.

Method	F1-score
HD + AT(seed abr. + comb.)	88.6
- dstc2	86.2
- dstc3_seed	84.5
- dstc2, - dstc3_seed	84.3
- sentence generator	74.0
- atomic templates	70.5

Table 3: SLU performances on the DSTC3 evaluation set when removing different modules of our method.

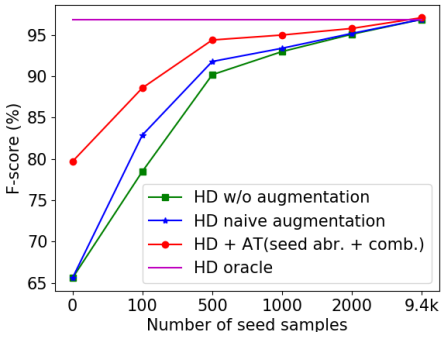

Figure 2: SLU performance of different methods with varying number of seed samples randomly selected from the oracle DSTC3 training set.

5 Conclusion

In this paper, we propose a new data augmentation method with atomic templates for SLU. The atomic templates provide exemplars in natural language for *act-slot-value* triples, involving minimum human efforts. An encoder-decoder model is exploited to generate utterances based on the atomic exemplars. We believe our method can also be applied to SLU systems with other semantic representations (e.g. semantic frame). Experimental results show that our method achieves significant improvements on DSTC 2&3 dataset, and it is is very effective for SLU domain adaptation with limited data.

A Examples of generated data

Dialogue act	Atomic exemplars	Generated utterance
thankyou bye	thank you good bye	Thank you good bye.
request(addr) request(phone)	the address the phone number	The address and phone number.
request(addr) request(phone)	whats the address what is the phone number	What is the address and phone number?
inform(type=coffeeshop) inform(hasinternet=true)	cafe has internet connection	I'm looking for a cafe has the internet connection.
affirm inform(type=restaurant) inform(pricerange=moderate)	yes looking for a restaurant moderately priced	Yes, I'm looking for a moderately priced restaurant.
request(childrenallowed)	does it allow children	Does it have children?
request(hastv) request(addr)	does it has a television the address	Does it have the television address and address?

Table 4: Examples of generated data samples for DSTC3. It shows that the generated utterances are associated with the atomic exemplars. For some frequent triples, well-formed utterances can be produced. We can find two bad cases at the end of the table. The reason may be that both "request(childrenallowed)" and "request(hastv);request(addr)" never appear in the *dstc3_seed*, thus the sentence generator doesn't fit well.

PaLM: A Hybrid Parser and Language Model

Abstract

We present PaLM, a hybrid **pa**rser and neural **l**anguage **m**odel. Building on an RNN language model, PaLM adds an attention layer over *text spans* in the left context. An unsupervised constituency parser can be derived from its attention weights, using a greedy decoding algorithm. We evaluate PaLM on language modeling, and empirically show that it outperforms strong baselines. If syntactic annotations *are* available, the attention component can be trained in a supervised manner, providing syntactically-informed representations of the context, and further improving language modeling performance.

1 Introduction

Recent language models have shown very strong data-fitting performance (Jozefowicz et al., 2016; Merity et al., 2018). They offer useful products including, most notably, contextual embeddings (Peters et al., 2018; Radford et al., 2019), which benefit many NLP tasks such as text classification (Howard and Ruder, 2018) and dataset creation (Zellers et al., 2018).

Language models are typically trained on large amounts of raw text, and therefore do not explicitly encode any notion of structural information. Structures in the form of syntactic trees have been shown to benefit both classical NLP models (Gildea and Palmer, 2002; Punyakanok et al., 2008; Das et al., 2012, *inter alia*) and recent state-of-the-art neural models (Dyer et al., 2016; Swayamdipta et al., 2018; Peng et al., 2018b; Strubell et al., 2018, *inter alia*). In this paper we show that LMs can benefit from syntactically-inspired encoding of the context.

We introduce PaLM (**pa**rser and **l**anguage **m**odel; Fig. 1), a novel hybrid model combining an RNN language model with a constituency parser. The LM in PaLM attends over *spans of tokens*, implicitly learning which syntactic constituents are likely. A span-based parser is then derived from the attention information (Stern et al., 2017).

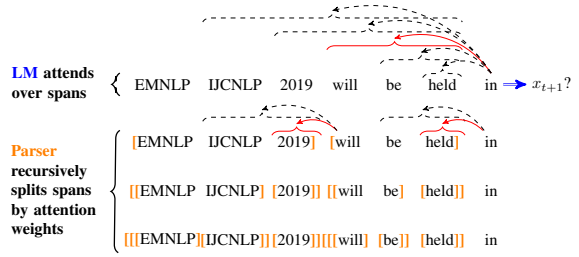

Figure 1: An illustration of PaLM. The LM (first line) predicts the next word (x_{t+1}, double blue arrow) by attending over previous spans ending in time $t-1$ (dashed lines). The parser (lines 2–4) splits the prefix into two spans (line 2) by the taking the top scoring attended span (red solid line) and the prefix leading to it. It then recursively splits the two sub-spans using the same procedure (line 3). Finally, spans of length two are trivially split into terminal nodes (line 4).

PaLM has several benefits. First, it is an intuitive and lightweight way of incorporating structural information (§2.1), requiring no marginal inference, which can be computationally expensive (Jelinek and Lafferty, 1991; Chelba and Jelinek, 1998; Roark, 2001; Dyer et al., 2016; Buys and Blunsom, 2018; Kim et al., 2019, *inter alia*). Second, the attention can be syntactically informed, in the sense that the attention component can optionally be supervised using syntactic annotations, either through pretraining or by joint training with the LM (§2.2). Last, PaLM can derive an unsupervised constituency parser (§2.2), whose parameters are estimated purely using the language modeling objective.

To demonstrate the empirical benefits of PaLM, we experiment with language modeling (§3). PaLM outperforms the AWD-LSTM model (Merity et al., 2018) on both the Penn Treebank

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3644–3651, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(PTB; Marcus et al., 1993) and WikiText-2 (Merity et al., 2017) datasets by small but consistent margins in the unsupervised setup. When the parser is trained jointly with the language model, we see additional perplexity reductions in both cases. Our implementation is available at https://github.com/Noahs-ARK/PaLM.

2 PaLM—Parser and Language Model

We describe PaLM in detail. At its core is an attention component, gathering the representations of preceding *spans* at each time step. Similar to self-attention, PaLM can be implemented on top of RNN encoders (Parikh et al., 2016), or as it is (Vaswani et al., 2017). Here we encode the tokens using a left-to-right RNN, denoted with vectors $\mathbf{h}_t$.[1]

Below we describe the span-attention component and the parsing algorithm. We use $[i, j], i \leq j$ to denote text span $x_i \dots x_j$, i.e., inclusive on both sides. When $i = j$, it consists of a single token.

2.1 Span Attention

We want the language model attention to gather context information aware of syntactic structures. A constituency parse can be seen as a collection of syntactic constituents, i.e., token spans. Therefore we attend over preceding spans.[2]

At step t, PaLM attends over the spans ending at $t-1$, up to a maximum length m, i.e., $\{[i, t-1]\}_{i=t-m}^{t-1}$.[3] Essentially, this can be seen as splitting the prefix span $[t-m, t-1]$ into two, and attending over the one on the right. Such a span attention mechanism is inspired by the top-down greedy span parser of Stern et al. (2017), which recursively divides phrases. In §2.2, we will use a similar algorithm to derive a constituency parser from the span attention weights.

Bidirectional span representation with rational RNNs. Meaningful span representations are crucial in span-based tasks (Lee et al., 2017; Peng et al., 2018c; Swayamdipta et al., 2018, *inter alia*). Typical design choices are based on start and end token vectors contextualized by bidirectional RNNs. However, a language model does not have access to future words, and hence running a backward RNN from right to left is less straightforward: one will have to start an RNN running at each token, which is computationally daunting (Kong et al., 2016). To compute span representations efficiently, we use *rational* RNNs (RRNNs; Peng et al., 2018a).

RRNNs are a family of RNN models, where the recurrent function can be computed with weighted finite-state automata (WFSAs). We use the unigram WFSA–inspired RRNN (Peng et al., 2018a), where the cell state update is

$$\mathbf{f}_t = \boldsymbol{\sigma}\left(\mathbf{W}_f \mathbf{h}_t\right), \tag{1a}$$

$$\mathbf{u}_t = \left(\mathbf{1} - \mathbf{f}_t\right) \odot \tanh\left(\mathbf{W}_u \mathbf{h}_t\right), \tag{1b}$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{u}_t. \tag{1c}$$

$\mathbf{f}_t$ is a forget gate implemented with the elementwise sigmoid function $\boldsymbol{\sigma}$, and $\odot$ denotes elementwise multiplication. $\mathbf{W}_u$ and $\mathbf{W}_f$ are learned matrices. Bias terms are suppressed for clarity.[4]

Slightly overloading the notation, let $\overrightarrow{\mathbf{c}}_{i,j}$ denote the encoding of span $[i, j]$ by running a forward RRNN in Eq. 1, from left to right. It can be efficiently computed by subtracting $\overrightarrow{\mathbf{c}}_{i-1}$ from $\overrightarrow{\mathbf{c}}_j$, weighted by a product of forget gates:

$$\overrightarrow{\mathbf{c}}_{i,j} = \overrightarrow{\mathbf{c}}_j - \overrightarrow{\mathbf{c}}_{i-1} \bigodot_{k=i}^{j} \overrightarrow{\mathbf{f}}_k. \tag{2}$$

$\overrightarrow{\mathbf{f}}_k$ vectors are the forget gates. See §B for a detailed derivation.

Using this observation, we now derive an efficient algorithm to calculate the span representations based on bidirectional RRNNs. In the interest of space, Alg. 1 describes the forward span representations. It takes advantage of the distributivity property of rational RNNs (Peng et al., 2018a), and the number of RNN function calls is linear in the input length.[5] Although overall asymptotic time complexity is still quadratic, Alg. 1 only involves elementwise operations, which can be eas-

[1] We experiment with a strong LSTM implementation for language modeling (Merity et al., 2018), see §3.

[2] Standard token-based self-attention naturally relates to dependency structures through head selection (Strubell et al., 2018). In a left-to-right factored language model, dependencies are less natural if we want to allow a child to precede its parent.

[3] m is set to 20. This reduces the number of considered spans from $\mathcal{O}(n^2)$ to $\mathcal{O}(mn)$. Besides practical concerns, it makes less sense if a phrase goes beyond one single sentence (the average sentence length of WSJ training sentences is 21).

[4] Unlike other RNNs such as LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014), RRNNs do not apply an affine transformation or a nonlinear dependency of $\mathbf{c}_t$ on $\mathbf{c}_{t-1}$.

[5] In contrast, the dynamic program of Kong et al. (2016) for segmental (span-scoring) RNNs requires a quadratic number of recurrent function calls, since they use LSTMs, where distributivity does not hold.

Algorithm 1 RRNN-based span representation.[6]

  for $j = 1, \ldots, n$ **do**
    for $i = 1, \ldots, j$ **do**
      $\overrightarrow{\mathbf{c}}_{i,j} = \overrightarrow{\mathbf{c}}_j - \overrightarrow{\mathbf{c}}_{i-1} \odot \overrightarrow{\mathbf{f}}_{1,j} / \overrightarrow{\mathbf{f}}_{1,i-1}$
    end for
  end for
  return $\overrightarrow{\mathbf{c}}_{i,j}$ vectors
end procedure

ily parallelized on modern GPUs. The backward one (right to left) is analogous.

Computing attention. As in standard attention, we use a normalized weighted sum of the span representations. Let $\mathbf{g}([i,j]) = [\overrightarrow{\mathbf{c}}_{i,j}; \overleftarrow{\mathbf{c}}_{i,j}]$ denote the representation of span $[i,j]$, which concatenates the forward and backward representations calculated using Alg. 1. The context vector $\mathbf{a}_t$ is

$$\mathbf{a}_{t+1} = \sum_{i=0}^{m-1} \omega_{t,i}\ \mathbf{g}([t-i,t]), \tag{3a}$$

$$\omega_{t,i} = \frac{\exp s_{t,i}}{\sum_{j=0}^{m-1} \exp s_{t,j}}. \tag{3b}$$

Here $s_{t,i}$ is implemented as an MLP, taking as input the concatenation of $\mathbf{h}_{t+1}$ and $\mathbf{g}([t-i,t])$ and outputs the attention score. The context vector is then concatenated with the hidden state $\bar{\mathbf{h}}_{t+1} = [\mathbf{h}_{t+1}; \mathbf{a}_{t+1}]$, and fed into onward computation.

In summary, given an input sequence, PaLM:

1. First uses a standard left-to-right RNN to calculate the hidden states $\mathbf{h}_t$.
2. Feed $\mathbf{h}_t$ vectors into a one-layer bidirectional rational RNN (Eq. 1), using Alg. 1 to compute the span representations.
3. Attends over spans (Eq. 3b) to predict the next word.

2.2 Attention-Based Constituency Parsing

We next describe the other facet or PaLM: the constituency parser. Our parsing algorithm is similar to the greedy top-down algorithm proposed by Stern et al. (2017). It recursively divides a span into two smaller ones, until a single-token span, i.e., a leaf, is reached. The order of the partition specifies the tree structure.[7] Formally, for a maximum span length m, at each time step $j+1$, we split the span $[j-m+1, j]$ into two smaller parts $[j-m+1, k_0]$ and $[k_0+1, j]$. The partitioning point is greedily selected, maximizing the attention scores of spans ending at j:[8]

$$k_0 = \operatorname*{argmax}_{k \in \{0,\ldots,m-1\}} s_{j,k}. \tag{4}$$

The span is directly returned as a leaf if it contains a single token. A full parse is derived by running the algorithm recursively, starting with the input as a single span (with a special end-of-sentence mark at the end). The runtime is $\mathcal{O}(n^2)$, with $n-1$ partitioning points. See Fig. 1 for an illustration.

Supervising the attention. Now that we are able to derive phrase structures from attention weights, we can further inform the attention if syntactic annotations are available, using oracle span selections. For each token, the gold selection is a m-dimensional binary vector, and then normalized to sum to one, denoted $\mathbf{y}_t$.[9] We add a cross-entropy loss (averaged across the training data) to the language modeling objective, with λ trading off between the two:

$$\mathcal{L} = \mathcal{L}_{\text{LM}} + \frac{\lambda}{N} \sum_{t=1}^{N} \mathcal{H}(\mathbf{y}_t, \boldsymbol{\omega}_t), \tag{5}$$

with $\boldsymbol{\omega}$ being the attention distribution at step t, and N the length of the training corpus. As we will see in §3, providing syntactically guided span attention improves language modeling performance.

Discussion. PaLM provides an intuitive way to inject structural inductive bias into the language model—by supervising the attention distribution. This setting can be seen as a very lightweight multitask learning, where no actual syntactic tree is predicted during language modeling training or evaluation. The attention weight predictor (i.e., the s scores in Eq. 3b) can be replaced with an off-the-shelf parser, or deterministically set (e.g., to simulate left/right-branching).

[6] / denotes elementwise division. Both elementwise product and division are implemented in log-space.

[7] It is only able to produce binarized unlabeled trees.

[8] Another natural choice is to maximize the sum of the scores of $[i, k_0]$ and $[k_0+1, j]$. The attention score of $[i, k_0]$ is computed at time step k_0, and hence does not know anything about the other span on the right. Therefore we consider only the score of the right span.

[9] Not necessarily one-hot: multiple spans can end at the same token.

3 Experiments

We evaluate PaLM on language modeling. We experiment with the Penn Treebank corpus (PTB) and WikiText-2 (WT2). We follow the preprocessing of Mikolov et al. (2010) for PTB and Merity et al. (2018) for WT2. More implementation details are described in Appendix A. We compare two configurations of PaLM:

- PaLM-U builds on top of AWD-LSTM (Merity et al., 2018), a state-of-the-art of LSTM implementation for language modeling. The span attention is included *before* the last layer.[10]
- PaLM-S is the same model as PaLM-U, but uses phrase syntax annotation to provide additional supervision to the attention component (§2.2).[11]

We compare against the AWD-LSTM baseline. On PTB, we also compare to two models using structural information in language modeling: parsing-reading-predict networks (PRPN; Shen et al., 2018a) predicts syntactic distance as structural features for language modeling; ordered-neuron LSTM (ON-LSTM; Shen et al., 2018b) posits a novel ordering on LSTM gates, simulating the covering of phrases at different levels in a constituency parse. On PTB we also compare to PaLM-RB, a baseline deterministically setting the attention scores (Eq. 3b) in decreasing order, such that the derived trees will be right-branching.[12]

Tables 1 and 2 summarize the language modeling results. On both datasets, the unsupervised configuration (PaLM-U) outperforms AWD-LSTM. On PTB, PaLM-U achieves similar performance to ON-LSTM and much better performance than PRPN. PaLM-S further reduces the perplexity by 1.6–3.4% (relative), showing that incorporating structural information with supervised span attention helps language modeling. Naively promoting right-branching attention (PaLM-RB) yields no improvement over the baseline.

Unsupervised constituency parsing. We evaluate the parser component of PaLM-U on WSJ-40. It uses the same data as in language modeling, but filters out sentences longer than 40 tokens after punctuation removal. The model is selected based on language modeling validation perplexity.

Model	# Params.	Dev.	Test
AWD-LSTM	24M	60.0	57.3
PRPN	-	-	62.0
ON-LSTM	25M	58.3	56.2
PaLM-U	24M	58.6	56.4
PaLM-RB	24M	60.1	57.5
PaLM-S	24M	**57.9**	**55.5**

Table 1: PTB language modeling perplexity (lower is better). Bold fonts indicate best performance.[13]

Model	# Params.	Dev.	Test
AWD-LSTM	33M	68.6	65.8
PaLM-U	36M	68.4	65.4
PaLM-S	36M	**65.5**	**63.2**

Table 2: WikiText-2 language modeling perplexity (lower is better). Bold fonts indicate best performance.

In addition to PRPN, we compare to DIORA (Drozdov et al., 2019), which uses an inside-outside dynamic program in an autoencoder. Table 3 shows the F_1 results. PaLM outperforms the right branching baseline, but is not as accurate as the other models.[14] This indicates that the type of syntactic trees learned by it, albeit useful to the LM component, do not correspond well to PTB-like syntactic trees.

Discussion. Despite its strong performance, the parsing algorithm used by Shen et al. (2018a) and Shen et al. (2018b) suffers from an incomplete support issue (Dyer et al., 2019). More precisely, it fails to produce "close-open-open," i.e.,) ((structures. As a result, the parser is intrinsically biased toward right-branching structures. PaLM, on the other hand, scores all the spans, and therefore can produce any binary tree spanning a given sentence: the algorithm recovers any given binary tree by letting $s_{j,j-i} = 1$ if the tree contains nonterminal $[i, j]$, and 0 otherwise.[15]

Is PaLM empirically biased toward any branching direction? In greedily selected trees, we measure the percentage of left-branching splits (dividing $[i, j]$ into $[i, j-1]$ and j) and right-branching

[10] Preliminary experiments show that including the span attention after the last layer yields similar empirical results, but is more sensitive to hyperparameters.

[11] We use the WSJ portion of PTB for parsing annotations.

[12] We set scores to $m, m-1, \ldots, 1$, before the softmax.

[13] Several recent works report better language modeling perplexity (Yang et al., 2019; Takase et al., 2018; Dai et al., 2019, *inter alia*). Their contribution is orthogonal to ours and not head-to-head comparable to the models in the table.

[14] Evaluation on WSJ-10, which contains sentences with 10 or less tokens, shows a similar trend.

[15] The maximum span length m is only forced in language modeling training and evaluation.

Model	Unlabeled F_1
Right Branching	40.7
†DIORA	60.6
‡PRPN	52.4
‡PaLM-U	42.0

Table 3: Unlabeled unsupervised parsing F_1 on WSJ-40. ‡ trains on the training split of WSJ, while † trains on AllNLI (Htut et al., 2018). The PRPN result is taken from Drozdov et al. (2019).

	% Left Splits		% Right Splits	
Random	39.3	±10.5	41.2	±8.8
PaLM-U	1.1		85.6	
Gold	6.5		52.7	

Table 4: Percentage of left and right splits. The first row shows the numbers averaging over 25 differently randomly initialized PaLM models, without training. ± indicates standard deviation.

splits (dividing $[i, j]$ into i and $[i+1, j]$).[16] Table 4 summarizes the results on WSJ-40 test set. The first row shows the results for randomly initialized models without training. We observe no significant trend of favoring one branching direction over the other. However, after training with the language modeling objective, PaLM-U shows a clear right-skewness more than it should: it produces much more right-branching structures than the gold annotation. This means that the span attention mechanism has learned to emphasize longer prefixes, rather than make strong Markov assumptions. More exploration of this effect is left to future work.

4 Conclusion

We present PaLM, a hybrid parser and language model. PaLM attends over the preceding text spans. From its attention weights phrase structures can be derived. The attention component can be separately trained to provide syntactically-informed context gathering. PaLM outperforms strong baselines on language modeling. Incorporating syntactic supervision during training leads to further language modeling improvements. Training our unsupervised model on large-scale corpora could result in both stronger language models and, potentially, stronger parsers. Our code is publicly available at https://github.com/Noahs-ARK/PaLM.

[16] We exclude trivial splits dividing a length-2 span into two tokens.

Acknowledgments

We thank members of the ARK at the University of Washington, and researchers at the Allen Institute for Artificial Intelligence for their helpful comments on an earlier version of this work, and the anonymous reviewers for their insightful feedback. This work was supported in part by NSF grant 1562364.

A Implementation Details

Neural Network Architecture Our implementation is based on AWD-LSTM (Merity et al., 2018).[17] It uses a three-layer LSTM, with carefully designed regularization techniques. PaLM includes the span attention after the second layer. Preliminary results show that it yields similar results, but is less sensitive to hyperparameters, compared to adding it to the last layer.

The context is concatenated to the hidden state ($\bar{\mathbf{h}}_t = [\mathbf{h}_t; \mathbf{a}_t]$), and then fed to a $\tanh$-MLP controlled by a residual gate $\mathbf{g}_r$ (He et al., 2016), before fed onward into the next LSTM layer:

$$\hat{\mathbf{h}}_t = \mathbf{g}_r \odot \text{MLP}\left(\bar{\mathbf{h}}_t\right) + (\mathbf{1} - \mathbf{g}_r) \odot \mathbf{h}_t. \quad (6)$$

The rest of the architecture stays the same as AWD-LSTM. We refer the readers to Merity et al. (2018) for more details.

More details on PaLM-S. PaLM-S uses exactly the same architecture and hyperparameters as its unsupervised counterpart. We derive, from PTB training data, a m-dimensional 0-1 vector for each token. Each element specifies whether the corresponding span appears in the gold parse. Trivial spans (i.e., the ones over single tokens and full sentences) are ignored. The vector are normalized to sum to one, in order to facilitate the use of cross-entropy loss. λ in Eq. 5 is set to 0.01.

Hyperparameters. The regularization and hyperparameters largely follow Merity et al. (2018). We only differ from them by using smaller hidden size (and hence smaller dropout rate) to control for the amount of parameters in the PTB experiments, summarized in Table 5 For the WikiText-2 experiments, we use 200 rational RNN size and 400 dimensional context vectors. Other hyperparameters follow Merity et al. (2018). The max span length m is set to 20 for PTB experiments, and 10 for WikiText-2.

Merity et al. (2018) start by using SGD to train the model, and switch to averaged SGD (Polyak and Juditsky, 1992) after 5 nonimprovement-epochs. We instead use Adam (Kingma and Ba, 2014) with default PyTorch settings to train the model for 40 epochs, and then switch to ASGD, allowing for faster convergence.

Abstract

The task of semantic parsing is highly useful for dialogue and question answering systems. Many datasets have been proposed to map natural language text into SQL, among which the recent Spider dataset provides cross-domain samples with multiple tables and complex queries. We build a Spider dataset for Chinese, which is currently a low-resource language in this task area. Interesting research questions arise from the uniqueness of the language, which requires word segmentation, and also from the fact that SQL keywords and columns of DB tables are typically written in English. We compare character- and word-based encoders for a semantic parser, and different embedding schemes. Results show that word-based semantic parser is subject to segmentation errors and cross-lingual word embeddings are useful for text-to-SQL.

1 Introduction

The task of semantic parsing is highly useful for tasks such as dialogue (Chen et al., 2013; Gupta et al., 2018; Einolghozati et al., 2019) and question answering (Gildea and Jurafsky, 2002; Yih et al., 2015; Reddy et al., 2016). Among a wide range of possible semantic representations, SQL offers a standardized interface to knowledge bases across tasks (Astrova, 2009; Xu et al., 2017; Dong and Lapata, 2018; Lee et al., 2011). Recently, Yu et al. (2018b) released a manually labelled dataset for parsing natural language questions into complex SQL, which facilitates related research.

Yu et al. (2018b)'s dataset is exclusive for English questions. Intuitively, the same semantic parsing task can be applied cross-lingual, since SQL is a universal semantic representation and database interface. However, for languages other than English, there can be added difficulties parsing into SQL. Take Chinese for example, the additional challenges can be at least two-fold. First, structures of relational databases, in particular names and column names of DB tables, are typically represented in English. This adds to the challenges to question-to-DB mapping. Second, the basic semantic unit for denoting columns or cells can be words, but word segmentation can be erroneous. It is also interesting to study the influence of other linguistic characteristics of Chinese, such as zero-pronoun, on its SQL parsing.

We investigate parsing Chinese questions to SQL by creating a first dataset, and empirically evaluating a strong baseline model on the dataset. In particular, we translate the Spider (Yu et al., 2018b) dataset into Chinese. Using the model of Yu et al. (2018a), we compare several key model configurations.

Results show that our human-translated dataset is significantly more reliable compared to a dataset composed of machine-translated questions. In addition, the overall accuracy for Chinese SQL semantic parsing can be comparable to that for English. We found that cross-lingual word embeddings are useful for matching Chinese questions with English table columns and keywords and that language characteristics have a significant influence on parsing results. We release our dataset named CSpider and code at https://github.com/taolusi/chisp.

2 Related Work

Existing datasets for semantic parsing can be classified into two major categories. The first uses logic for semantic representation, including ATIS (Price, 1990; Dahl et al., 1994) and GeroQuery (Zelle and Mooney, 1996). The second and dominant category of datasets uses SQL, which includes Restaurants (Tang and Mooney, 2001; Popescu et al., 2003), Academic (Iyer et al., 2017), Yelp and IMDB (Yaghmazadeh et al., 2017), Ad-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3652–3658, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

vising (Finegan-Dollak et al., 2018) and the recently proposed WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018b). One salient difference between Spider and prior work is that Spider uses different databases across domains for training and testing, which can verify the generalization power of a semantic parsing model. Compared with WikiSQL, Spider further has multiple tables in each database and correspondingly more complex queries. We thus consider Spider for sourcing our dataset. Existing semantic parsing datasets for Chinese include a small corpus for assigning semantic roles (Sun and Jurafsky, 2004) and SemEval-2016 Task 9 for Chinese semantic dependency parsing (Che et al., 2012), but these data are not related to SQL. To our knowledge, we are the first to release a Chinese SQL semantic parsing dataset.

There has been a line of work improving the model of Yu et al. (2018a) since the release of the Spider dataset (Guo et al., 2019; Bogin et al., 2019; Lin et al., 2019). At the time of our investigation, however, the models are not published. We thus chose the model of Yu et al. (2018a) as our baseline. The choice of more different neural models is orthogonal to our dataset contribution, but can empirically give more insights about the conclusions.

3 Dataset

We translate all English questions in the Spider dataset into Chinese.[1] The work is undertaken by 2 NLP researchers and 1 computer science student. Each question is first translated by one annotator, and then cross-checked and corrected by a second annotator. Finally, a third annotator verifies the original and corrected versions. Statistics of the dataset are shown in Table 1. There are originally 10181 questions from Spider, but only 9691 for the training and development sets are publicly available. We thus translated these sentences only. Following the database split setting of Yu et al. (2018b), we make training, development and test sets split in a way that no database overlaps in them as shown in Table 1.

The translation work is performed on a database to database basis. For each database, the same translator translates relevant inquiries sentence by sentence. The translator is asked to read the original question as well as the SQL query before making its Chinese translation. If the literal translation is possible, the translator is asked to stick to the original sentence style as much as feasible. For complex questions, the translator is allowed to rephrase the English question, so that the most natural Chinese translation is made. In addition, we keep the diversity of style in the English dataset by matching different English expressions to different Chinese expressions. A sample of our dataset is shown in Table 2. Our dataset is named CSpider.

[1]Note that we do not translate the database schema (i.e., column names) into Chinese because in practice databases have English schema and Chinese contents in the industry.

		# Q	# SQL	# DB	# Table/DB

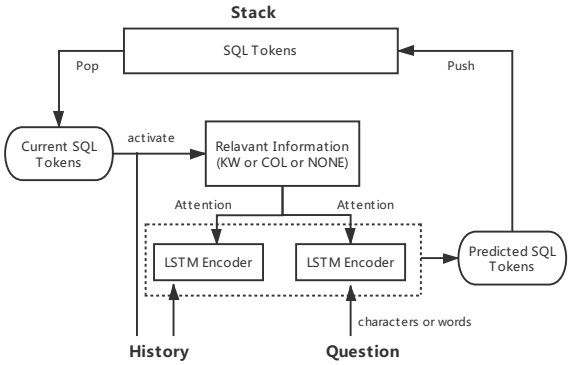

Figure 1: Overall structure of the Model.

4 Model

We use the neural semantic parsing method of Yu et al. (2018a) as the baseline model, which can be regarded as a sequence-to-tree model. In particular, the input question is encoded using an LSTM sequence encoder, and the output is a SQL query in its syntactic tree form. The tree is generated incrementally top-down, in a pre-order traversal sequence. Tree nodes include keyword nodes (e.g., SELECT, WHERE, EXCEPT) and table column name nodes (e.g., ID, City, Surname, which are defined in specific tables), which are represented in respective embedding spaces. Each keyword or column is generated by attention to the embedding space using the question representation as a key. A stack is used for incremental decoding, where

SQL Query
SELECT T1.staff_name , T1.staff_id FROM Staff AS T1 JOIN Fault_Log AS T2 ON T1.staff_id = T2.recorded_by_staff_id EXCEPT SELECT T3.staff_name, T3.staff_id FROM Staff AS T3 JOIN Engineer_Visits AS T4 ON T3.staff_id = T4.contact_staff_id";
English Question
What is the name and ID of the staff who recorded the fault log but has not contacted any visiting engineers?
Translated Chinese Question
那些记录了错误报告但没有联系任何到访工程师的职工的姓名和ID是什么?

Table 2: Example questions corresponding to SQL.

the whole output history is leveraged as a feature for deciding the next term. This method gives the current released state-of-the-art results while submitting this paper. We provide a visualization of the model in Figure 1.

5 Experiments

We focus on comparing different word segmentation methods and different embedding representations. As discussed above, column names are selected by attention over column embeddings using sentence representation as a key. Hence there must be a link between the embeddings of columns and those of the questions. Since columns are written in English and questions in Chinese, we consider two embedding methods. The first method is to use two separate sets of embeddings for Chinese and English, respectively. We use Glove (Pennington et al., 2014)[2] for embeddings of English keywords, column names etc., and Tencent embeddings (Song et al., 2018)[3] for Chinese. The second method is to directly use the cross-lingual word embeddings. To this end, the Tencent multi-lingual embeddings are chosen, which contain both Chinese and English words in a multi-lingual embedding matrix.

Evaluation Metrics. We follow Yu et al. (2018b), evaluating the results using two major types of metrics. The first is exact matching accuracy, namely the percentage of questions that have exactly the same SQL output as its reference. The second is component matching F1, namely the F1 scores for SELECT, WHERE, GROUP BY, ORDER BY and all keywords, respectively.

Hyperparameters. Our hyperparameters are mostly taken from Yu et al. (2018a), but tuned on the Chinese Spider development set. We use character and word embeddings from Tencent embedding; both of them are not fine-tuned during model training. Embedding sizes are set to 200 for both characters and words. For the different choices of keywords and column names embeddings, sizes are set to 200 and 300, respectively. Adam (Kingma and Ba, 2014) is used for optimization, with a learning rate of 1e-4. Dropout is used for the output of LSTM with a rate of 0.5.

For word-based models, segmentation is necessary. We take two segmentors with different performances, including the Jieba segmentor and the model of Yang et al. (2017), which we name Jieba and YZ, respectively. To verify their accuracy, we manually segment the first 100 sentences from the test set. Jieba and YZ give F1 scores of 89.8% and 91.7%, respectively.

5.1 Overall Results

The overall exact matching results are shown in Table 3. In this table, ENG represents the results of Yu et al. (2018a)'s model on their English dataset but under our split. HT and MT denote human translation and machine translation of questions, respectively. Both HT and MT results are evaluated on human translated questions. C-ML and C-S denote the results of our Chinese models based on characters with multi-lingual embeddings and monolingual embeddings, respectively, while WY-ML, WY-S denote the word-based models applying YZ segmentor with multi-lingual embeddings and monolingual embeddings, respectively. Finally, WJ-ML and WJ-S denote the word model with multi-lingual embeddings and monolingual embeddings with the Jieba segmentor, respectively.

First, compared to the best results of human translation (C-ML and WY-ML), machine translation results show a large disadvantage (e.g. 7.1% vs 12.1% using C-ML). We further did a manual inspection of 100 randomly picked machine-translated sentences. Out of the 100 translated

	WY-ML	17.9%	4.7%	4.5%	0.3%	7.6%

Table 3: Accuracy of Exact Matching on test set.

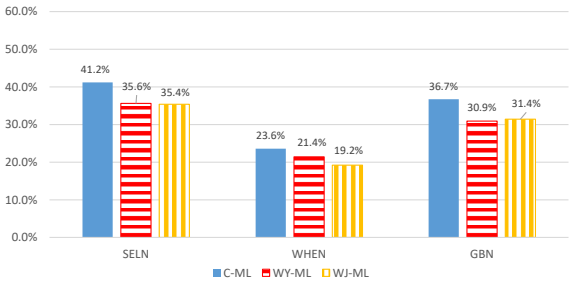

Figure 2: Component Matching Comparisons.

sentences, 42 have translation mistakes such as semantic changes (28 sentences) and grammar errors (14 sentences). Both of these facts indicate that data by machine-translation is not reliable for semantic parsing research.

Second, comparisons among C-ML, WY-ML and WJ-ML, and among C-S, WY-S and WJ-S show that multi-lingual embeddings give superior results compared to monolingual embeddings, which is likely because they bring a better connection between natural language questions and database columns.

Third, comparisons between WY-ML and WJ-ML, and WY-S and WJ-S indicate that better segmentation accuracy has a significant influence on question parsing. Word-based methods are subject to segmentation errors.

Moreover, with the current segmentation accuracy of 92%, a word-based model underperforms a character-based model. Intuitively, since words carry more direct semantic information as compared with database columns and keywords, improved segmentation may allow a word-based model to outperform a character-based model.

Finally, for easy questions, the character-based model shows strong advantages over the word-based models. However, for medium to extremely hard questions, the trend becomes less obvious, which is likely because the intrinsic semantic complexity overwhelms the encoding differences.

Our best Chinese system gives an overall accuracy of 12.1%, [4] which is less but comparable to the English results. This shows that Chinese semantic parsing may not be significantly more challenging compared to English with text to SQL.

Component matching. Figure 2 shows F1 scores of several typical components, including SELN (SELECT NO AGGREGATOR), WHEN (WHERE NO OPERATOR) and GBN (GROUP BY NO HAVING), applying the superior multi-lingual embeddings. The trends are consistent with the overall results.

The detailed results are shown in Table 4. Specifically, the char-based methods achieve around 41% on SELN and SEL (SELECT), which are about 5% higher compared to the word-based methods. This result may be due to the fact that word-based models are sensitive to the OOV words (Zhang and Yang, 2018; Li et al., 2019). Unlike other components, SEL and SELN are confronted with more severe OOV challenges caused by recognizing the unseen schema during testing.

In addition, the models using multi-lingual embedding overperform the models using separate embeddings on both WHEN and OB (ORDERBY), which further demonstrates that embeddings in the same dimension distribution benefit to strengthen the connection between the question and the schema.

Contrary to the overall result, the models employing the jieba segmentor perform better than those using the YZ segmentor on OB. The reason is that the jieba segmentor has different word segmentation results in terms of the superlative of adjectives. For example, the word "最高" (the highest) is segmented as "最"(most) and "高"(high) by YZ segmentor but "最高" in jieba segmentor. This again demonstrates the influence of word segmentation. Finally, for GB (GROUPBY) there is not a regular contrast pattern between different models, which can be likely because of the lack of sufficient training data.

5.2 Case study

Figure 3 shows the negative influence of segmentation errors. In particular, the incorrect segmentation of the word "店名" (shop name) leads to incorrect SQL for the whole sentence, since the

[4] Note that the results are lower than those reported by Yu et al. (2018a) under their split due to different training/test splits. Our split has less training data and more test instances in the "Hard" category and less in "Easy" and "Medium".

Figure 5: Chinese zero pronoun.

character "店" (shop) can typically be associated with "店长" (shop manager).

Figure 4 shows the sensitivity of our model to sentence patterns. In particular, the word-based model gives incorrect predictions for many question sentences frequently. As shown in the first row, the word "where" confuses the system for making a choice between "ORDER BY" and "GROUP BY". When we manually change the sentence pattern into "List the most common hometown of teachers", the parser gives the correct keyword. In contrast, the character-based model is less sensitive to question sentences, which is likely because characters are less sparse compared with words. More training data or contextualized embeddings may alleviate the issue for the word-based method, which we leave for future work.

Figure 5 shows the sensitivity of the model to Chinese linguistic patterns. In particular, the first sentence has a zero pronoun "各党的" (in each party), which is omitted later. As a result, a semantic parser cannot tell the correct database columns from the sentence. We manually add the correct entity for the zero pronoun, resulting in the second sentence. Since zero-pronouns are frequent for Chinese (Chen and Ng, 2016), they give added difficulty for its semantic parsing.

6 Conclusion

We constructed a first resource named CSpider for Chinese sentence to SQL, evaluating the performance of a strong English model on this dataset. Results show that the input representation, embedding forms and linguistic factors all have the influence on the Chinese-specific task. Our dataset can serve as a starting point for further research on this task, which can be beneficial to the investigation of Chinese QA and dialogue models.

Abstract

State-of-the-art semantic parsers rely on auto-regressive decoding, emitting one symbol at a time. When tested against complex databases that are unobserved at training time (zero-shot), the parser often struggles to select the correct set of database constants in the new database, due to the local nature of decoding. In this work, we propose a semantic parser that globally reasons about the structure of the output query to make a more contextually-informed selection of database constants. We use message-passing through a graph neural network to softly select a subset of database constants for the output query, conditioned on the question. Moreover, we train a model to rank queries based on the global alignment of database constants to question words. We apply our techniques to the current state-of-the-art model for SPIDER, a zero-shot semantic parsing dataset with complex databases, increasing accuracy from 39.4% to 47.4%.

1 Introduction

The goal of zero-shot semantic parsing (Krishnamurthy et al., 2017; Xu et al., 2017; Yu et al., 2018b,a; Herzig and Berant, 2018) is to map language utterances into executable programs in a new environment, or database (DB). The key difficulty in this setup is that the parser must map new lexical items to DB constants that weren't observed at training time.

Existing semantic parsers handle this mostly through a *local* similarity function between words and DB constants, which considers each word and DB constant in isolation. This function is combined with an auto-regressive decoder, where the decoder chooses the DB constant that is most similar to the words it is currently attending to. Thus, selecting DB constants is done one at a time rather than as a set, and informative global considerations are ignored.

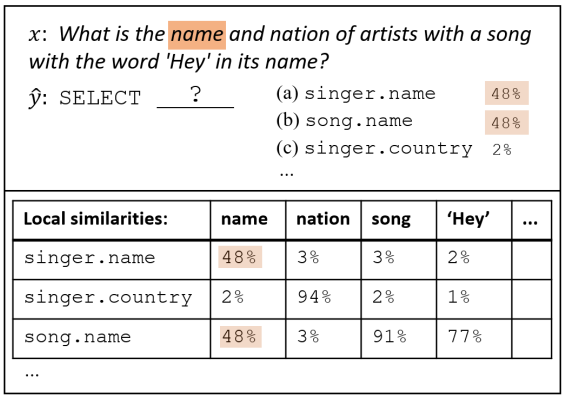

Figure 1: An example where choosing a DB constant based on local similarities is difficult, but the ambiguity can be resolved through global reasoning (see text).

Consider the example in Figure 1, where a question is mapped to a SQL query over a complex DB. After decoding `SELECT`, the decoder must now choose a DB constant. Assuming its attention is focused on the word *'name'* (highlighted), and given local similarities only, the choice between the lexically-related DB constants (`singer.name` and `song.name`) is ambiguous. However, if we globally reason over the DB constants and question, we can combine additional cues. First, a subsequent word *'nation'* is similar to the DB column `country` which belongs to the table `singer`, thus selecting the column `singer.name` from the same table is more likely. Second, the next appearance of the word *'name'* is next to the phrase *'Hey'*, which appears as the value in one of the cells of the column `song.name`. Assuming a one-to-one mapping between words and DB constants, again `singer.name` is preferred.

In this paper, we propose a semantic parser that reasons over the DB structure and question to make a *global* decision about which DB constants should be used in a query. We extend the parser of Bogin et al. (2019), which learns a representation for the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3659–3664, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

DB schema at parsing time. First, we perform message-passing through a graph neural network representation of the DB schema, to softly select the set of DB constants that are likely to appear in the output query. Second, we train a model that takes the top-K queries output by the auto-regressive model and re-ranks them based on a global match between the DB and the question. Both of these technical contributions can be applied to any zero-shot semantic parser.

We test our parser on SPIDER, a zero-shot semantic parsing dataset with complex DBs. We show that both our contributions improve performance, leading to an accuracy of 47.4%, well beyond the current state-of-the-art of 39.4%.

Our code is available at https://github.com/benbogin/spider-schema-gnn-global.

2 Schema-augmented Semantic Parser

Problem Setup We are given a training set $\{(x^{(k)}, y^{(k)}, S^{(k)})\}_{k=1}^{N}$, where $x^{(k)}$ is a question, $y^{(k)}$ is its translation to a SQL query, and $S^{(k)}$ is the schema of the corresponding DB. We train a model to map question-schema pairs (x, S) to the correct SQL query. Importantly, the schema S was not seen at training time.

A DB schema S includes : (a) A set of DB tables, (b) a set of columns for each table, and (c) a set of foreign key-primary key column pairs where each pair is a relation from a foreign-key in one table to a primary-key in another. Schema tables and columns are termed *DB constants*, denoted by $\mathcal{V}$.

We now describe a recent semantic parser from Bogin et al. (2019), focusing on the components relevant for selecting DB constants.

Base Model The base parser is a standard top-down semantic parser with grammar-based decoding (Xiao et al., 2016; Yin and Neubig, 2017; Krishnamurthy et al., 2017; Rabinovich et al., 2017; Lin et al., 2019). The input question $(x_1, \ldots, x_{|x|})$ is encoded with a BiLSTM, where the hidden states $\boldsymbol{e}_i$ of the BiLSTM are used as contextualized representations for the word x_i. The output query y is decoded top-down with another LSTM using a SQL grammar, where at each time step a grammar rule is decoded. Our main focus is decoding of DB constants, and we will elaborate on this part.

The parser decodes a DB constant whenever the previous step decoded the non-terminals `Table` or `Column`. To select the DB constant, it first computes an attention distribution over the question words $\{\alpha_i\}_{i=1}^{|x|}$ in the standard manner (Bahdanau et al., 2015). Then the score for a DB constant v is $s_v = \sum_i \alpha_i s_{\text{link}}(v, x_i)$, where s_{link} is a local similarity score, computed from learned embeddings of the word and DB constant, and a few manually-crafted features, such as the edit distance between the two inputs and the fraction of string overlap between them. The output distribution of the decoder is simply $\text{softmax}(\{s_v\}_{v \in \mathcal{V}})$. Importantly, the dependence between decoding decisions for DB constants is weak – the similarity function is independent for each constant and question word, and decisions are far apart in the decoding sequence, especially in a top-down parser.

DB schema encoding In the zero-shot setting, the schema structure of a new DB can affect the output query. To capture DB structure, Bogin et al. (2019) learned a representation $\boldsymbol{h}_v$ for every DB constant, which the parser later used at decoding time. This was done by converting the DB schema into a graph, where nodes are DB constants, and edges connect tables and their columns, as well as primary and foreign keys (Figure 2, left). A graph convolutional network (GCN) then learned representations $\boldsymbol{h_v}$ for nodes end-to-end (De Cao et al., 2019; Sorokin and Gurevych, 2018).

To focus the GCN's capacity on important nodes, a *relevance probability* ρ_v was computed for every node, and used to "gate" the input to the GCN, conditioned on the question. Specifically, given a learned embedding $\boldsymbol{r}_v$ for every database constant, the GCN input is $\boldsymbol{h}_v^{(0)} = \rho_v \cdot \boldsymbol{r}_v$. Then, the GCN recurrence is applied for L steps. At each step, nodes re-compute their representation based on the representation of their neighbors, where different edge types are associated with different learned parameters (Li et al., 2016). The final representation of each DB constant is $\boldsymbol{h}_v = \boldsymbol{h}_v^{(L)}$.

Importantly, the relevance probability ρ_v, which can be viewed as a soft selection for whether the DB constant should appear in the output, was computed based on local information only: First, a distribution $p_{\text{link}}(v \mid x_i) \propto \exp(s_{\text{link}}(v, x_i))$ was defined, and then $\rho_v = \max_i p_{\text{link}}(v \mid x_i)$ was computed deterministically. Thus, ρ_v doesn't consider the full question or DB structure. We address this next.

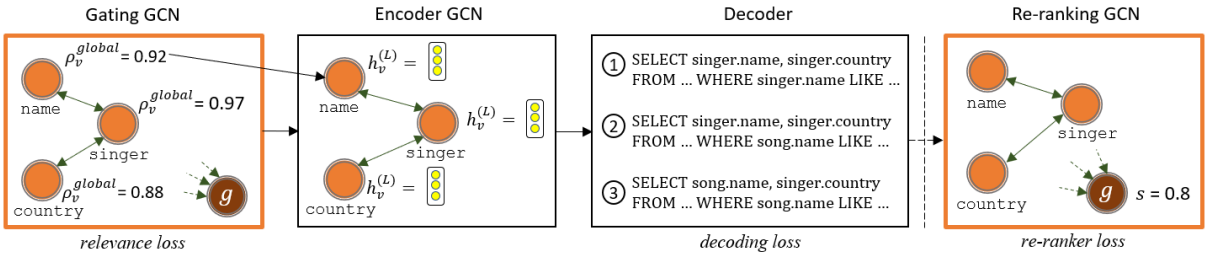

Figure 2: High-level overview, where our contributions are in thick orange boxes. First, a relevance score is predicted for each of the DB constants using the gating GCN. Then, a learned representation is computed for each DB constant using the encoder GCN, which is then used by the decoder to predict K candidates queries. Finally, the re-ranking GCN scores each one of these candidates, basing its score only on the selected DB constants. The dashed line and arrow indicate no gradients are propagated from the re-ranking GCN to the decoder, as the decoder outputs SQL queries. Names of loss terms are written below models that are trained with a loss on their output.

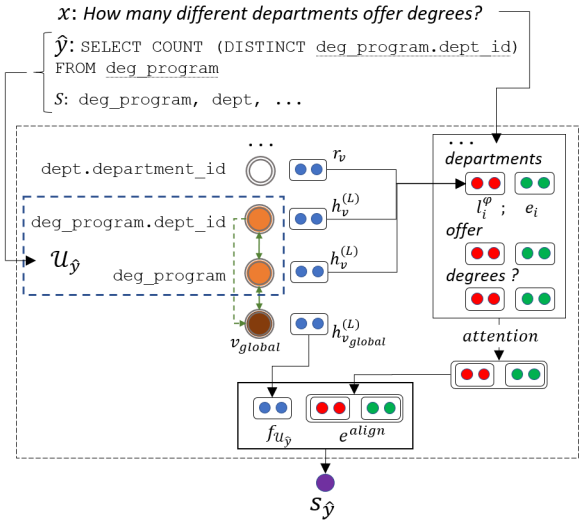

Figure 3: The re-ranking GCN architecture (see text).

3 Global Reasoning over DB Structures

Figure 2 gives a high-level view of our model, where the contributions of this paper are marked by thick orange boxes. First, the aforementioned relevance probabilities are estimated with a *learned* gating GCN, allowing global structure to be taken into account. Second, the model discriminatively re-ranks the top-K queries output by the generative decoder.

Global gating Bogin et al. (2019) showed that an oracle relevance probability can increase model performance, but computed ρ_v from local information only.

We propose to train a GCN to directly predict ρ_v from the global context of the question and DB.

The input to the gating GCN is the same graph described in §2, except we add a new node v_{global}, connected to all other nodes with a special edge type. To predict the question-conditioned relevance of a node, we need a representation for both the DB constant and the question. Thus, we define the input to the GCN at node v to be $\boldsymbol{g}_v^{(0)} = FF([\boldsymbol{r}_v; \bar{\boldsymbol{h}}_v; \rho_v])$, where ';' is concatenation, $FF(\cdot)$ is a feed-forward network, and $\bar{\boldsymbol{h}}_{\boldsymbol{v}} = \sum_i p_{\text{link}}(x_i \mid v) \cdot \boldsymbol{e}_i$ is a weighted average of contextual representations of question tokens. The initial embedding of v_{global} is randomly initialized. A relevance probability is computed per DB constant based on the final graph representation: $\rho_v^{\text{global}} = \sigma(FF(\boldsymbol{g}_v^{(L)}))$. This probability replaces ρ_v at the input to the encoder GCN (Figure 2).

Because we have the gold query y for each question, we can extract the gold subset of DB constants $\mathcal{U}_y$, i.e., all DB constants that appear in y. We can now add a *relevance loss* term $-\sum_{v \in \mathcal{U}_y} \log \rho_v^{\text{global}} - \sum_{v \notin \mathcal{U}_y} \log(1 - \rho_v^{\text{global}})$ to the objective. Thus, the parameters of the gating GCN are trained from the relevance loss and the usual *decoding loss*, a ML objective over the gold sequence of decisions that output the query y.

Discriminative re-ranking Global gating provides a more accurate model for softly predicting the correct subset of DB constants. However, parsing is still auto-regressive and performed with a local similarity function. To overcome this, we separately train a discriminative model (Collins and Koo, 2005; Ge and Mooney, 2006; Lu et al., 2008; Fried et al., 2017) to re-rank the top-K queries in the decoder's output beam. The re-ranker scores each candidate tuple $(x, S, \hat{y})$, and thus can globally reason over the entire candidate query $\hat{y}$.

We focus the re-ranker capacity on the main pain point of zero-shot parsing – the set of DB constants $\mathcal{U}_{\hat{y}}$ that appear in $\hat{y}$. At a high-level (Figure 3), for each candidate we compute a logit $s_{\hat{y}} = \boldsymbol{w}^\top FF(\boldsymbol{f}_{\mathcal{U}_{\hat{y}}}, \boldsymbol{e}^{\text{align}})$, where $\boldsymbol{w}$ is a learned

parameter vector, $\boldsymbol{f}_{\mathcal{U}_{\hat{y}}}$ is a representation for the set $\mathcal{U}_{\hat{y}}$, and $\boldsymbol{e}^{\text{align}}$ is a representation for the global alignment between question words and DB constants. The re-ranker is trained to minimize the *re-ranker loss*, the negative log probability of the correct query y. We now describe the computation of $\boldsymbol{f}_{\mathcal{U}_{\hat{y}}}$ and $\boldsymbol{e}^{\text{align}}$, based on a re-ranking GCN.

Unlike the gating GCN, the re-ranking GCN takes as input only the sub-graph induced by the selected DB constants $\mathcal{U}_{\hat{y}}$, and the global node v_{global}. The input is represented by $\boldsymbol{f}_v^{(0)} = FF(\boldsymbol{r}_v; \bar{\boldsymbol{h}}_v)$, and after L propagation steps we obtain $\boldsymbol{f}_{\mathcal{U}_{\hat{y}}} = \boldsymbol{f}^{(L)_{v_{\text{global}}}}$. Note that the global node representation is used to describe and score the question-conditioned sub-graph, unlike the gating GCN where the global node mostly created shorter paths between other graph nodes.

The representation $\boldsymbol{f}_{\mathcal{U}_{\hat{y}}}$ captures global properties of selected nodes but ignores nodes that were not selected and are possibly relevant. Thus, we compute a representation $\boldsymbol{e}^{\text{align}}$, which captures whether question words are aligned to selected DB constants. We define a representation for every node $v \in \mathcal{V}$:

$$\boldsymbol{\varphi}_v = \begin{cases} \boldsymbol{f}_v^{(L)} & \text{if } v \in \mathcal{U}_{\hat{y}} \\ \boldsymbol{r}_v & \text{otherwise} \end{cases}$$

Now, we compute for every question word x_i a representation of the DB constants it aligns to: $\boldsymbol{l}_i^{\varphi} = \sum_{v \in \mathcal{V}} p_{\text{link}}(v \mid x_i) \cdot \boldsymbol{\varphi}_v$. We concatenate this representation to every word $\boldsymbol{e}_i^{\text{align}} = [\boldsymbol{e}_i; \boldsymbol{l}_i^{\varphi}]$, and compute the vector $\boldsymbol{e}^{\text{align}}$ using attention over the question words, where the attention score for every word is $\boldsymbol{e}_i^{\text{align}\top} \boldsymbol{w}_{\text{att}}$ for a learned vector $\boldsymbol{w}_{\text{att}}$. The goal of this term is to allow the model to recognize whether there are any attended words that are aligned with DB constants, but these DB constants were not selected in $\mathcal{U}_{\hat{y}}$.

In sum, our model adds a gating GCN trained to softly select relevant nodes for the encoder, and a re-ranking GCN that globally reasons over the subset of selected DB constants, and captures whether the query properly covers question words.

4 Experiments and Results

Experimental setup We train and evaluate on SPIDER (Yu et al., 2018b), which contains 7,000/1,034/2,147 train/development/test examples, using the same pre-processing as Bogin et al. (2019). To train the re-ranker, we take $K = 40$ candidates from the beam output of the decoder. At each training step, if the gold query is in the beam, we calculate the loss on the gold query and 10 randomly selected negative candidates. At test time, we re-rank the best $K = 10$ candidates in the beam, and break re-ranking ties using the auto-regressive decoder scores (ties happen since the re-ranker considers the DB constants only and not the entire query). We use the official SPIDER script for evaluation, which tests for loose exact match of queries.

Model	Accuracy
SYNTAXSQLNET	19.7%
GNN	39.4%
GLOBAL-GNN	**47.4%**

Table 1: Test set accuracy of GLOBAL-GNN compared to prior work on SPIDER.

Model	Acc.	Beam	SINGLE	MULTI
SYNTAXSQLNET	18.9%		23.1%	7.0%
GNN	40.7%		52.2%	26.8%
+ RE-IMPLEMENTATION	44.1%	62.2%	58.3%	27.6%
GLOBAL-GNN	**52.1%**	**65.9 %**	**61.6%**	**40.3%**
- NO GLOBAL GATING	48.8%	62.2%	60.9%	33.8%
- NO RE-RANKING	48.3%	**65.9%**	58.1%	36.8%
- NO RELEVANCE LOSS	50.1%	64.8%	60.9%	36.6%
NO ALIGN REP.	50.8%	**65.9%**	60.7%	38.3%
QUERY RE-RANKER	47.8%	**65.9%**	55.3%	38.3%
ORACLE RELEVANCE	56.4%	73.5%		

Table 2: Development set accuracy for various experiments. The column 'Beam' indicates the fraction of examples where the gold query is in the beam ($K = 10$).

Results As shown in Table 1, the accuracy of our proposed model (GLOBAL-GNN) on the hidden test set is 47.4%, 8% higher than current state-of-the art of 39.4%. Table 2 shows accuracy results on the development set for different experiments. We perform minor modifications to the implementation of Bogin et al. (2019), improving the accuracy from 40.7% to 44.1% (details in appendix A). We follow Bogin et al. (2019), measuring accuracy on easier examples where queries use a single table (SINGLE) and those using more than one table (MULTI).

GLOBAL-GNN obtains 52.1% accuracy on the development set, substantially higher than all previous scores. Importantly, the performance increase comes mostly from queries that require more than one table, which are usually more complex.

Removing any of our two main contributions (NO GLOBAL GATING, NO RE-RANKING) leads to a 4% drop in performance. Training without the relevance loss (NO RELEVANCE LOSS) results in a 2% accuracy degrade. Omitting the representation e^{align} from the re-ranker (NO ALIGN REP.)

reduces performance, showing the importance of identifying unaligned question words.

We also consider a model that ranks the entire query and not only the set of DB constants. We re-define $s_{\hat{y}} = \boldsymbol{w}^\top FF(\boldsymbol{f}_{\mathcal{U}_{\hat{y}}}, \boldsymbol{h}^{\text{align}}, \boldsymbol{h}^{\text{query}})$, where $\boldsymbol{h}^{\text{query}}$ is a concatenation of the last and first hidden states of a BiLSTM run over the output SQL query (QUERY RE-RANKER). We see performance is lower, and most introduced errors are minor mistakes such as `min` instead of `max`. This shows that our re-ranker excels at choosing DB constants, while the decoder is better at determining the SQL query structure and the SQL logical constants.

Finally, we compute two oracle scores to estimate future headroom. Assuming a perfect global gating, which gives probability 1.0 iff the DB constant is in the gold query, increases accuracy to 63.2%. Adding to that a perfect re-ranker leads to an accuracy of 73.5%.

Qualitative analysis Analyzing the development set, we find two main re-occurring patterns, where the baseline model is wrong, but our parser is correct. (a) *coverage*: when relevant question words are not covered by the query, which results in a missing joining of tables or selection of columns (b) *precision*: when unrelated tables are joined to the query due to high lexical similarity. Selected examples are in Appendix B.

Error analysis In 44.4% of errors where the correct query was in the beam, the selection of $\mathcal{U}$ was correct but the query was wrong. Most of these errors are caused by minor local errors, e.g., `min`/`max` errors, while the rest are due to larger structural mistakes, indicating that a global model that jointly selects both DB constants and SQL tokens might further improve performance. Other types of errors include missing or extra columns and tables, especially in complex queries.

5 Conclusion

In this paper, we demonstrate the importance of global decision-making for zero-shot semantic parsing, where selecting the relevant set of DB constants is challenging. We present two main technical contributions. First, we use a gating GCN that globally attends the input question and the entire DB schema to softly-select the relevant DB constants. Second, we re-rank the output of a generative semantic parser by globally scoring the set of selected DB-constants. Importantly, these contributions can be applied to any zero-shot semantic parser with minimal modifications. Empirically, we observe a substantial improvement over the state-of-the-art on the SPIDER dataset, showing the effectiveness of both contributions.

Abstract

In transductive learning, an unlabeled test set is used for model training. While this setting deviates from the common assumption of a completely unseen test set, it is applicable in many real-world scenarios, where the texts to be processed are known in advance. However, despite its practical advantages, transductive learning is underexplored in natural language processing. Here, we conduct an empirical study of transductive learning for neural models and demonstrate its utility in syntactic and semantic tasks. Specifically, we fine-tune language models (LMs) on an unlabeled test set to obtain test-set-specific word representations. Through extensive experiments, we demonstrate that despite its simplicity, transductive LM fine-tuning consistently improves state-of-the-art neural models in both in-domain and out-of-domain settings.

1 Introduction

In supervised learning, a model is trained on a training set and its generalization performance is evaluated on an unseen test set. In this setting, the model has no access to the test set during training. However, the assumption of a completely unseen test set is not always necessary. In many cases, certain aspects of the test set are already known at training time. For example, a company may want to annotate a large number of existing documents automatically (Section 3). In such a scenario, the texts to be processed are known in advance, and using the model trained on the texts themselves to process them can be more efficient. Using an unlabeled test set in this way is the key idea behind *transductive learning*.

In transductive learning (Vapnik, 1998), an unlabeled test set is given in the training phase. That is, the inputs of the test set, i.e., the raw texts, can be used during training, but the labels are never used. In the test phase, the trained model is evaluated on the same test set. Despite its practical advantages, transductive learning has received little attention in natural language processing (NLP). After the pioneering work of Joachims (1999), who proposed a transductive support vector machine for text classification, transductive methods for linear models have been investigated in only a few tasks, such as lexical acquisition (Duh and Kirchhoff, 2006) and machine translation (Ueffing et al., 2007). In particular, transductive learning with neural networks is underexplored.

Here, we investigate the impact of transductive learning on state-of-the-art neural models in syntactic and semantic tasks, namely syntactic chunking and semantic role labeling (SRL). Specifically, inspired by recent findings that language model (LM)-based word representations yield large performance improvement (Devlin et al., 2019), we fine-tune Embeddings from Language Models (ELMo) (Peters et al., 2018) on an unlabeled test set and use them in each task-specific model. Typically, LMs are trained on a large-scale corpus whose word distributions are different from the test set. By contrast, transductive learning allows us to fit LMs directly to the distributions of the test set. Our experiments show the effectiveness of transductive LM fine-tuning.

In summary, our main contributions are:

- This work is the first to introduce an LM fine-tuning method to transductive learning[1].
- Through extensive experiments in both in-domain and out-of-domain settings, we demonstrate that transductive LM fine-tuning consistently improves state-of-the-art neural models in syntactic and semantic tasks.

2 Related Work

Transductive learning. Vapnik advocated and formalized transductive learning (Vapnik, 1998; Gammerman et al., 1998), which has been applied to text classification (Joachims, 1999; Ifrim and Weikum, 2006) and image processing (Bruzzone et al., 2006; Sener et al., 2016; Liu et al., 2019). Although some studies have presented transductive methods for linear models in other tasks (Duh and Kirchhoff, 2006; Ueffing et al., 2007; Chen et al., 2008; Alexandrescu and Kirchhoff, 2009), transductive methods for neural models are underexplored in NLP.

Unsupervised domain adaptation. Transductive learning is related to unsupervised domain adaptation, in which models are adapted to a target domain by using unlabeled target domain texts (Ben-David et al., 2010; Shi and Sha, 2012). This setting does not allow models to access the test set, which is the main difference between unsupervised domain adaptation and transductive learning. Various unsupervised adaptation methods have been proposed for linear models (Blitzer et al., 2006; Jiang and Zhai, 2007; Tsuboi et al., 2009; Søgaard, 2013). In the context of neural models, adversarial domain adaptation (Ganin and Lempitsky, 2015; Ganin et al., 2016; Guo et al., 2018), importance weighting (Wang et al., 2017), structural correspondence learning (Ziser and Reichart, 2017), self/tri/co-training (Saito et al., 2017; Ruder and Plank, 2018), and other techniques orthogonal to transductive LM fine-tuning have been applied successfully in unsupervised domain adaptation[2]. Integrating these methods with transductive LM fine-tuning is an interesting direction for future research.

LM-based word representations. Recently, LM-based word representations pre-trained on unlabeled data have gained considerable attention (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019). The most related method to ours is Universal Language Model Fine-tuning (ULMFiT), which pre-trains an LM on a large general-domain corpus and fine-tunes it on the target task (Howard and Ruder, 2018). Inspired by these studies, we introduce LM-based word representation in transductive learning.

[2]Feature augmentation is considered a *supervised* domain adaptation method (Daume III, 2007; Kim et al., 2016).

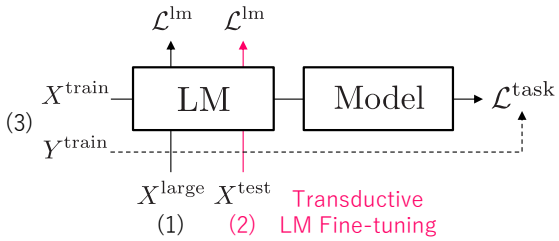

Figure 1: Training procedure. (1) LM pre-training: the LM is firstly pre-trained on the large-scale unlabeled corpus $\mathcal{D}^{\text{large}} = \{X_i^{\text{large}}\}_{i=1}^{N^{\text{large}}}$. (2) Transductive LM fine-tuning: the LM is then fine-tuned on the unlabeled test set $\mathcal{D}^{\text{test}} = \{X_i^{\text{test}}\}_{i=1}^{N^{\text{test}}}$. Note that the test set used for training is the identical one used in evaluation. (3) Task-specific model training: the task-specific model is trained on the training set $\mathcal{D}^{\text{train}} = \{(X_i^{\text{train}}, Y_i^{\text{train}})\}_{i=1}^{N^{\text{train}}}$. $\mathcal{L}$ denotes the loss function.

3 Neural Transductive Learning

Motivation. Suppose that a company has received a vast amount of customer reviews and wants to automatically process these reviews more accurately, even if it takes some time. For this purpose, they do not have to build a model that works well on new unseen reviews. Instead, they want a model that works well on only the reviews in hand. In this situation, using these reviews themselves to train a model can be more efficient. This is the key motivation for developing effective and practical transductive learning methods. Toward this goal, we develop transductive methods for state-of-the-art neural models.

Problem formulation. In the training phase, a training set $\mathcal{D}^{\text{train}} = \{(X_i^{\text{train}}, Y_i^{\text{train}})\}_{i=1}^{N^{\text{train}}}$ and an unlabeled test set $\mathcal{D}^{\text{test}} = \{X_i^{\text{test}}\}_{i=1}^{N^{\text{test}}}$ are used for model training, where X_i is an input, e.g., a sentence, and Y_i represents target labels, e.g., labels from a set of syntactic or semantic annotations. In the test phase, the trained model is used for predicting labels and is evaluated on the same test set $\mathcal{D}^{\text{test}}$.

Method. We present a simple transductive method for neural models. Specifically, we fine-tune an LM on an unlabeled test set. Figure 1 illustrates the training procedure that consists of the following steps: (1) LM pre-training, (2) Transductive LM fine-tuning and (3) task-specific model training. We first train an LM on a large-scale unlabeled corpus $\mathcal{D}^{\text{large}}$ and then fine-tune the LM on an unlabeled test set $\mathcal{D}^{\text{test}}$. Finally, we use the fine-tuned LM as the embedding layer of

	Training		Development		Test	
	Sents	Preds	Sents	Preds	Sents	Preds
BC	11.8k	28.9k	2.1k	5.0k	2,0k	5.4k

PT	21.5k	34.9k	1.7k	2.5k	1.2k	2.8k
TC	12.8k	16.2k	1.6k	2.0k	1.3k	1.7k
WB	16.9k	20.0k	2.3k	2.8k	0.9k	2.2k

Table 1: Dataset statistics on the CoNLL-2012 dataset. 1k = 1,000. Column "Sents" denotes the number of sentences in each dataset. Column "Preds" denotes the number of predicates in each dataset.

each task-specific model and train the model on a training set $\mathcal{D}^{\text{train}}$.

$$\Theta' \leftarrow \text{argmin}_{\Theta} \mathcal{L}^{\text{lm}}(\Theta|\mathcal{D}^{\text{large}}), \quad (1)$$

$$\Theta'' \leftarrow \text{argmin}_{\Theta'} \mathcal{L}^{\text{lm}}(\Theta'|\mathcal{D}^{\text{test}}), \quad (2)$$

$$\Phi' \leftarrow \text{argmin}_{\Phi} \mathcal{L}^{\text{task}}(\Phi|\Theta'', \mathcal{D}^{\text{train}}). \quad (3)$$

Here, $\mathcal{L}^{\text{lm}}$ and $\mathcal{L}^{\text{task}}$ are the loss functions for an LM and task-specific model, respectively.[3] In the LM pre-training and fine-tuning phases (Eqs. 1 and 2), we first train the initial LM parameters Θ and then fine-tune the pre-trained parameters Θ'. In the task-specific training phase (Eq. 3), we fix the fine-tuned LM parameters Θ'' used for the embedding layer of a task-specific model, and train only the task-specific model parameters Φ.

4 Experiments

Tasks. To investigate the effectiveness of transductive LM fine-tuning for syntactic and semantic analysis, we conduct experiments in syntactic chunking (Ramshaw and Marcus, 1999; Sang and Buchholz, 2000; Ponvert et al., 2011) and SRL (Gildea and Jurafsky, 2002; Palmer et al., 2005; Carreras and Màrquez, 2005)[4]. The goal of syntactic chunking is to divide a sentence into non-overlapping phrases that consist of syntactically related words. The goal of SRL is to identify semantic arguments for each predicate. For example, consider the following sentence:

	The	man	kept	a	cat
SynChunk	[NP]			[NP]	
SemRole	[A0]			[A1]	

In syntactic chunking, given the input sentence, systems have to recognize "The man" and "a cat" as noun phrases (NP). In SRL, given the input sentence and the target predicate "kept", systems have to recognize "The man" as the A0 argument and "a cat" as the A1 argument. For syntactic chunking, we adopted the experimental protocol by Ponvert et al. (2011) and for SRL, we followed Ouchi et al. (2018) (details in Appendix A).

Datasets. We perform experiments using the CoNLL-2012 dataset[5]. To investigate the performances under in-domain and out-of-domain settings, we use each of the seven domains in the CoNLL-2012 dataset. Table 1 shows the data statistics. Each test set contains at most 2,000 sentences. Compared with previous studies, such as Xiao and Guo (2013) that used 570,000 sentences as unlabeled data for unsupervised domain adaptation of syntactic chunking, our transductive experiments can be regarded as a low-resource adaptation setting. As a large-scale unlabeled raw corpus for LM training, we use the 1B word benchmark corpus (Chelba et al., 2013).

Model setup. We use ELMo (Peters et al., 2018) as an LM. For syntactic chunking, we use a variant of the Reconciled Span Parser (Joshi et al., 2018). For SRL, we use the span selection model (BiLSTM-Span model) (Ouchi et al., 2018). Each model is trained on a source domain training set and was evaluated on a target domain test set[6]. The development set is also the source domain, and it is used for hyperparameter tuning[7]. Consider the case where NW $\rightarrow$ BC, i.e., the source domain is the newswire NW and the target domain is the broadcast conversation BC. We first train ELMo on the large-scale raw corpus (one billion word benchmark corpus) and fine-tune it on the BC test set. We then train syntactic and semantic models that use the fine-tuned ELMo on the NW training set. During the task-specific model training, we freeze the fine-tuned ELMo. We select hyperparameters by using the NW development set. Finally, we evaluate the trained model on the BC test set. In the same way, we conduct training and evaluation for each domain pair.

[3] In our experiments (Section 4), both losses were given by the negative log-likelihood (Appendix A).

[4] This paper addresses span-based, PropBank-style SRL. Detailed descriptions on other lines of SRL research (e.g. dependency-based SRL and FrameNet-based SRL) can be found in Baker et al. (1998); Das et al. (2014); Surdeanu et al. (2008); Hajič et al. (2009).

Table 2: Main results under cross-domain settings, src ("source", training set) → tgt ("target", test set). Cells show the F1 scores of the baseline model (before the slash) and the transductive model (after the slash). Column "Averaged F1" represents the F1 scores averaged across the target domains. Domains are as follows: BC = Broadcast Conversation, BN = Broadcast News, MZ = Magazine, NW = Newswire, PT = New Testament, TC = Telephone Conversation, and WB = Weblogs and Newsgroups.

Results. Table 2 shows the F1 scores on each test set. All reported F1 scores are the average of five distinct trials using different random seeds. In each cell, the left-hand side denotes the F1 score of the baseline (using a base LM without fine-tuning) and the right-hand side denotes F1 of the transductive models (using a fine-tuned LM on each test set). In in-domain (same source/target domains, e.g., BC→BC) and out-of-domain (different source/target domains, e.g., BC→NW) settings, all transductive models consistently outperformed the baselines, which suggests that transductive LM fine-tuning improves performance of neural models. Although the improvements were undramatic (around 1.0 F1 gain), these consistent improvements can be regarded as valuable empirical results because of the difficulty of *unsupervised* and *low-resource* adaptation settings.

5 Analysis

Comparison between unsupervised domain adaptation and transduction. In unsupervised domain adaptation, target domain unlabeled data (the texts whose domain is the same as that of a test set) is used for adaptation. Although the domain is identical between target domain data and a test set, their word distributions are somewhat different. In transductive learning, because an unlabeled test set can be used for training, it is possible to adapt LMs directly to the word distributions of the test set. Here, we investigate whether adapting LMs directly to each test set is more effective than adapting LMs to each target domain unlabeled data. Similarly to our transductive method shown in Figure 1, we first train LMs on the large-scale unlabeled corpus (the 1B word benchmark corpus) and then fine-tune them on the unlabeled target domain data[8]. In addition, we control the sizes of the target domain unlabeled data and test sets. That is, we use the same number of sentences in the unlabeled data of each target domain as in each test set. Table 3 shows the F1 scores averaged across all the target domains. The transductive models (T) consistently outperformed the domain-adapted models (CU). This demonstrates that adapting LMs directly to test sets is more effective than adapting them to target domain unlabeled data.

	Syntactic chunking		Semantic role labeling

Results of the transductive models (TRANS) marked with * are statistically significant compared to the baselines (BASE) using the permutation test ($p < 0.05$).

Combination of unsupervised domain adaptation and transduction. In real-world situations, large-scale unlabeled data of target domains is sometimes available. In such cases, LMs can be trained on both the target domain unlabeled data and the test sets. Here, we investigate the effectiveness of using both datasets. Table 4 shows the F1 scores averaged across all the target domains. Fine-tuning the LMs on the target domain unlabeled data as well as each test set (U + T) showed better performance than fine-tuning them only on the target domain unlabeled data (U). This combination of tranduction with unsupervised domain adaptation further improves performance.

Effects in standard benchmarks. Some studies indicated that when promising new techniques are only evaluated on very basic models, determining how much (if any) improvement will carry over to stronger models can be difficult (Denkowski and Neubig, 2017; Suzuki et al., 2018). Motivated by such studies, we provide the results in standard benchmark settings. For syntactic chunking, we use the CoNLL-2000 dataset (Sang and Buchholz, 2000) and follow the standard experimental protocol (Hashimoto et al., 2017). For SRL, we use the CoNLL-2005 (Carreras and Màrquez, 2005) and CoNLL-2012 datasets (Pradhan et al., 2012) and follow the standard experimental protocol (Ouchi et al., 2018). Table 5 shows the F1 scores of our models and those of existing models. The results of the baseline model were comparable with those of the state-of-the-art models, and the transductive model consistently outperformed the baseline model[9]. Note that we cannot fairly compare the transductive and existing models due to the difference in settings. These results, however, demonstrate that transductive LM fine-tuning improves state-of-the-art chunking and SRL models.

6 Conclusion

In this study, we investigated the impact of transductive learning on state-of-the-art neural models in syntactic and semantic tasks. Specifically, we fine-tuned an LM on an unlabeled test set. Through extensive experiments, we demonstrated that, despite its simplicity, transductive LM fine-tuning contributes to consistent performance improvement of state-of-the-art syntactic and semantic models in cross-domain settings. One interesting line of future work is to explore effective transductive methods for task-dependent (neural) layers. For instance, as some unsupervised domain adaptation methods can be applied to transductive learning, integrating them with transductive LM fine-tuning may further improve their performance. Another line of our future work is to apply these transductive methods to various NLP tasks and investigate their performance.

[9]While the improvements in SRL were statistically significant compared to the baseline, the improvement in syntactic chunking was not. One reason for this is that the F1 score of the baseline in syntactic chunking is already high and there is less room for improvement. Since Clark et al. (2018) achieved 97.0 F1 with multi-task learning, missing information for further improvement might be derived from other tasks.

Abstract

Vector averaging remains one of the most popular sentence embedding methods in spite of its obvious disregard for syntactic structure. While more complex sequential or convolutional networks potentially yield superior classification performance, the improvements in classification accuracy are typically mediocre compared to the simple vector averaging. As an efficient alternative, we propose the use of discrete cosine transform (DCT) to compress word sequences in an order-preserving manner. The lower order DCT coefficients represent the overall feature patterns in sentences, which results in suitable embeddings for tasks that could benefit from syntactic features. Our results in semantic probing tasks demonstrate that DCT embeddings indeed preserve more syntactic information compared with vector averaging. With practically equivalent complexity, the model yields better overall performance in downstream classification tasks that correlate with syntactic features, which illustrates the capacity of DCT to preserve word order information.

1 Introduction

Modern NLP systems rely on word embeddings as input units to encode the statistical semantic and syntactic properties of words, ranging from standard context-independent embeddings such as word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014) to contextualized embeddings such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018). However, most applications operate at the phrase or sentence level. Hence, the word embeddings are averaged to yield sentence embeddings. Averaging is an efficient compositional operation that leads to good performance. In fact, averaging is difficult to beat by more complex compositional models as illustrated across several classification tasks: topic categorization, semantic textual similarity, and sentiment classification (Aldarmaki and Diab, 2018). Encoding sentences into fixed-length vectors that capture various full sentence linguistic properties leading to performance gains across different classification tasks remains a challenge. Given the complexity of most models that attempt to encode sentence structure, such as convolutional, recursive, or recurrent networks, the trade-off between efficiency and performance tips the balance in favor of simpler models like vector averaging. Sequential neural sentence encoders, like Skip-thought (Kiros et al., 2015) and InferSent (Conneau et al., 2017), can potentially encode rich semantic and syntactic features from sentence structures. However, for practical applications, sequential models are rather cumbersome and inefficient, and the gains in performance are typically mediocre compared with vector averaging (Aldarmaki and Diab, 2018). In addition, the more complex models typically don't generalize well to out-of-domain data (Wieting et al., 2015). FastSent (Hill et al., 2016) is an unsupervised alternative approach of lower computational cost, but similar to vector averaging, it disregards word order. Tensor-based composition can effectively capture word order, but current approaches rely on restricted grammatical constructs, such as transitive phrases, and cannot be easily extended to variable-length sequences of arbitrary structures (Milajevs et al., 2014). Therefore, despite its obvious disregard for structural properties, the efficiency and reasonable performance of vector averaging makes them more suitable for practical text classification.

In this work, we propose to use the Discrete Cosine Transform (DCT) as a simple and efficient way to model word order and structure in sentences while maintaining practical efficiency.

DCT is a widely-used technique in digital signal processing applications such as image compression (Watson, 1994) as well as speech recognition (Huang and Zhao, 2000) , but to our knowledge, this is the first successful application of DCT for NLP applications, and in particular sentence embedding. We use DCT to summarize the general feature patterns in word sequences and compress them into fixed-length vectors. Experiments in probing tasks demonstrate that our DCT embeddings preserve more syntactic and semantic features compared with vector averaging. Furthermore, the results indicate that DCT performance in downstream applications is correlated with these features.

2 Approach

2.1 Discrete Cosine Transform

Discrete Cosine Transform (DCT) is an invertible function that maps an input sequence of N real numbers to the coefficients of N orthogonal cosine basis functions. Given a vector of real numbers $\vec{v} = v_0, ..., v_{N-1}$, we calculate a sequence of DCT coefficients $c^0, ..., c^{N-1}$ as follows:[1]

$$c^0 = \sqrt{\frac{1}{N}} \sum_{n=0}^{N-1} v_n, \quad (1)$$

and

$$c^k = \sqrt{\frac{2}{N}} \sum_{n=0}^{N-1} v_n \cos \frac{\pi}{N}(n + \frac{1}{2})k, \quad (2)$$

for $1 \leq k < N$. Note that c^0 is the sum of the input sequence normalized by the square length, which is proportional to the average of the sequence. The N coefficients can be used to reconstruct the original sequence exactly using the inverse transform. In practice, DCT is used for compression by preserving only the coefficients with large magnitudes. Lower-order coefficients represent lower signal frequencies which correspond to the overall patterns in the sequence (Ahmed et al., 1974).

2.2 DCT Sentence Embeddings

We apply DCT on the word vectors along the length of the sentence. Given a sentence of N words $w_1, ..., w_N$, we stack the sequence of d-dimensional word embeddings in an $N \times d$ matrix, then apply DCT along the rows. In other words, each feature in the vector space is compressed independently, and the resultant DCT embeddings summarize the feature patterns along the word sequence. To get a fixed-length and consistent sentence vector, we extract and concatenate the first K DCT coefficients and discard higher-order coefficients, which results in sentence vectors of size Kd. For cases where $N < K$, we pad the sentence with $K - N$ zero vectors. In image compression, the magnitude of the coefficients tends to decrease with increasing k, but we didn't observe this trend in text data except that c^0 tends to have larger absolute value than the remaining coefficients. Nonetheless, by retaining lower-order coefficients we get a consistent representation of overall feature patterns in the word sequence.

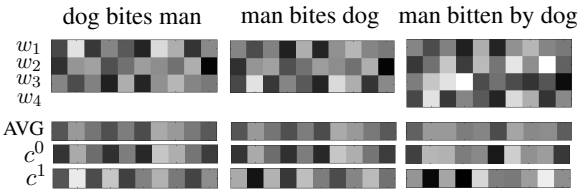

Figure 1: Illustration of word vector averaging vs. DCT using the first 2 DCT coefficients. The word vectors are generated randomly from a standard normal distribution with $d = 10$.

Figure 1 illustrates the properties of DCT embeddings compared to vector averaging (AVG). Notice that the first DCT coefficients, c^0, result in vectors that are independent of word order since the lowest frequency represents the average energy in the sequence. In this sense, c^0 is similar to AVG, where "dog bites man" and "man bites dog" have identical embeddings. The second-order coefficients, on the other hand, are sensitive to word order, which results in different representations for the above sentence pair. The counterexample "man bitten by dog" shows that c^1 embeddings are most sensitive to the overall patterns—in this case: "man ... dog"—which results in an embedding more similar to "man bites dog", than the semantically similar "dog bites man". However, there are still some variations in the final embeddings from the different word components ('bitten' vs. 'bite'), which can potentially be useful in downstream tasks. Since both DCT and AVG are un-

[1]There are several variants of DCT. We use DCT type II (Shao and Johnson, 2008) in our implementation

parameterized, the downstream classifiers can incorporate a hidden layer to learn these subtle variations in higher-order features depending on the learning objective.

2.3 A Note on Complexity

The cosine terms in Equation 2 can be precalculated for efficiency. For a maximum sentence length $\hat{N}$ and a given K, the total number of terms is $(K-1)\hat{N}$ for each feature. The run-time complexity is equivalent to calculating K weighted averages, which is proportional to KN, where K should be set to a small constant relative to the expected length.[2] Note also that the number of input parameters in downstream classification models will increase linearly with K. With parallel implementations however, the difference in run-time complexity between AVG and DCT is practically negligible.

3 Experiments and Results

3.1 Evaluation Framework

We use the SentEval toolkit[3] (Conneau and Kiela, 2018) to evaluate the sentence representations on different probing as well as downstream classification tasks. The probing benchmark set was designed to analyze the quality of sentence embeddings. It contains a set of 10 classification tasks, summarized in Table 1, that address varieties of linguistic properties including surface, syntactic, and semantic information (Conneau et al., 2018). The downstream set, on the other hand, includes the following standard classification tasks: binary and fine-grained sentiment classification (MR, SST2, SST5) (Pang and Lee, 2004; Socher et al., 2013), product reviews (CR) (Hu and Liu, 2004), opinion polarity (MPQA) (Wiebe et al., 2005), question type classification (TREC) (Voorhees and Tice, 2000), natural language inference (SICK-E) (Marelli et al., 2014), semantic relatedness (SICK-R, STSB) (Marelli et al., 2014; Cer et al., 2017), paraphrase detection (MRPC) (Dolan et al., 2004), and subjectivity/objectivity (SUBJ) (Pang and Lee, 2004).

3.2 Experimental setup

For the word embeddings, we use pre-trained FastText embeddings of size 300 (Mikolov et al., 2018) trained on Common-Crawl. We generate

Table 1: Probing Tasks

DCT sentence vectors by concatenating the first K DCT coefficients, which we denote by $\mathbf{c^{0:K}}$. We compare the performance against: vector averaging of the same word embeddings, denoted by **AVG**, and vector max pooling, denoted by **MAX**.[4]

For all tasks, we trained multi-layer perceptron (MLP) classifiers following the setup in SentEval. We tuned the following hyper-parameters on the validation sets: number of hidden states (in [0, 50, 100, 200, 512]) and dropout rate (in [0, 0.1, 0.2]). Note that the case with 0 hidden states corresponds to a Logistic Regression classifier.

3.3 Result & Discussion

We report the performance in probing tasks in Table 2. In general, DCT yields better performance compared to averaging on all tasks, and larger K often yields improved performance in syntactic and semantic tasks. For the surface information tasks, SentLen and Word content (WC), c^0 significantly outperforms AVG. This is attributed to the non-linear scaling factor in DCT, where longer sentences are not discounted as much as in averaging. The performance decreased with increasing K in $c^{0:K}$, which reflects the trade-off between deep and surface linguistic properties, as discussed in Conneau et al. (2018).

While increasing K has no positive effect on surface information tasks, syntactic and semantic tasks demonstrate performance gains with larger K. This trend is clearly observed in all syntactic tasks and three of the semantic tasks, where DCT performs well above AVG and the performance improves with increasing K. The only exception

Table 3: DCT embedding Performance in SentEval downstream tasks compared to vector averaging (AVG) and max pooling (MAX).

is SOMO, where increasing K actually results in lower performance, although all DCT results are still higher than AVG by about 1% to 34%.

The correlation between the performance in probing tasks and the standard text classification tasks is discussed in Conneau et al. (2018), where they show that most tasks are only positively correlated with a small subset of semantic or syntactic features, with the exception of TREC and some sentiment classification benchmarks. Furthermore, some tasks like SST and SICK-R are actually negatively correlated with the performance in some probing tasks like SubjNum, ObjNum, and BShift. This explains why simple averaging often outperforms more complex models in these tasks. Our results in Table 3 are consistent with these observations, where we see improvements in most tasks, but the difference is not as significant as the probing tasks, except in TREC question classification where increasing K leads to much better performance. As discussed in Aldarmaki and Diab (2018), the ability to preserve word order leads to improved performance in TREC, which is exactly the advantage of using DCT instead of AVG. Note also that increasing K, while preserves more information, leads to increasing the number of model parameters, which in turn may negatively affect the generalization of the model by overfitting. In our experiments, $1 \leq k \leq 2$ yielded the best trade-off.

Table 4: Performance in text classification (20-NG, R-8) and sentiment (SST-5) tasks of various models as reported in (Kayal and Tsatsaronis, 2019), where DCT* refers to the implementation in (Kayal and Tsatsaronis, 2019). Our DCT embeddings are denoted as c^k in the bottom row. **Bold** indicates the best result, and *italic* indicates second-best.

frequency components, each revealing some information about the source signal, to enable analysis and compression. To the best of our knowledge, spectral methods have only been recently exploited to construct sentence embedding (Kayal and Tsatsaronis, 2019).[5].

Kayal and Tsatsaronis propose EigenSent that utilized Higher-Order Dynamic Mode Decomposition (HODMD) (Le Clainche and Vega, 2017) to construct sentence embedding. These embeddings summarize the dynamic properties of the sentence. In their work, they compare EigenSent with various sentence embedding models, including a different implementation of the Discrete Cosine Transform (DCT*). In contrast to our implementation described in section 2.2, DCT* is applied at the word level along the word embedding dimension.

For fair comparison, we use the same sentiment and text classification datasets, the SST-5, 20 newsgroups (20-NG) and Reuters-8 (R-8), as those used in Kayal and Tsatsaronis (2019). We also evaluate using the same pre-trained word embedding, framework and approaches as described in their work. Table 4 shows the best results for the various models as reported in Kayal and Tsatsaronis (2019), in addition to the best performance of our model denoted as c^k.[6]

Note that the DCT-based model, DCT*, described in Kayal and Tsatsaronis (2019) performed relatively poorly in all tasks, while our model achieved close to state-of-the-art performance in both the 20-NG and R-8 tasks. Our model outperformed EignSent on all tasks and generally performed better than or on par with p-means, ELMo, BERT, and EigenSent⊕Avg on both the 20-NG and R-8. On the other hand, both EigenSent⊕Avg and ELMo performed better than all other models on SST-5.

4 Conclusion

We proposed using the Discrete Cosine Transform (DCT) as a mechanism to efficiently compress variable-length sentences into fixed-length vectors in a manner that preserves some of the structural characteristics of the original sentences. By applying DCT on each feature along the word embedding sequence, we efficiently encode the overall feature patterns as reflected in the low-order DCT coefficients. We showed that these DCT embeddings reflect average semantic features, as in vector averaging but with a more suitable normalization, in addition to syntactic features like word order. Experiments using the SentEval suite showed that DCT embeddings outperform the commonly-used vector averaging on most tasks, particularly tasks that correlate with sentence structure and word order. Without compromising practical efficiency relative to averaging, DCT provides a suitable mechanism to represent both the average of the features and their overall syntactic patterns.

Abstract

We tackle the nested and overlapping event detection task and propose a novel search-based neural network (SBNN) structured prediction model that treats the task as a search problem on a relation graph of trigger-argument structures. Unlike existing structured prediction tasks such as dependency parsing, the task targets to detect DAG structures, which constitute events, from the relation graph. We define actions to construct events and use all the beams in a beam search to detect all event structures that may be overlapping and nested. The search process constructs events in a bottom-up manner while modelling the global properties for nested and overlapping structures simultaneously using neural networks. We show that the model achieves performance comparable to the state-of-the-art model Turku Event Extraction System (TEES) on the BioNLP Cancer Genetics (CG) Shared Task 2013 without the use of any syntactic and hand-engineered features. Further analyses on the development set show that our model is more computationally efficient while yielding higher F1-score performance.

1 Introduction

Nested and overlapping event structures, which occur widely in text, are important because they can capture relations between events such as causality, e.g., a "production" event is a consequence of a "discovery" event, which in turn is a result of an "exploration" event. Event extraction involves the identification of a trigger and a set of its arguments in a given text. Figure 1 shows an example of a nested and overlapping event structure in the biomedical domain. The relation graph (topmost) forms a directed acyclic graph (DAG) structure (McClosky et al., 2011) and it encapsulates 15 event structures. It contains nested event

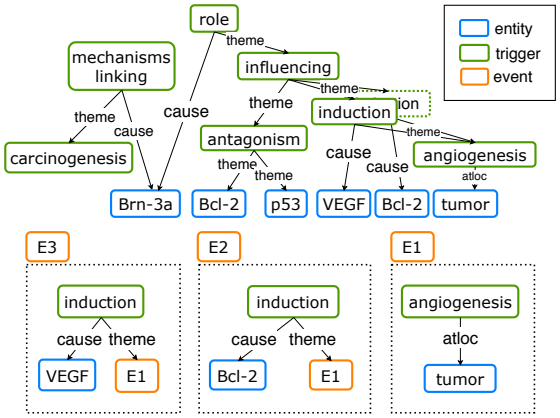

Figure 1: Top: A DAG-structured relation graph (topmost) from the sentence "*Looking for mechanisms linking Brn-3a to carcinogenesis, we discuss the role of this transcription factor in influencing Bcl-2/VEGF induction of tumor angiogenesis, ...*" from BioNLP'13 CG Shared Task (Pyysalo et al., 2015). Bottom: A pair of overlapping and nested events $(E2, E3)$ extracted from the graph with their shared argument event, a flat event $(E1)$.

structures such as *E2,E3* because one of their arguments, in this case *E1*, is an event. Specifically, *E1* is a flat event since its argument is an entity. Moreover, *E2* and *E3* are also overlapping events (explicitly shown in the relation graph having two *induction* triggers) because they share a common argument, *E1*.

State-of-the-art approaches to event extraction in the biomedical domain are pipeline systems (Björne and Salakoski, 2018; Miwa et al., 2013) that decompose event extraction into simpler tasks such as: i) *trigger/entity detection*, which determines which words and phrases in a sentence potentially constitute as participants of an event, ii) *relation detection*, which finds pairwise relations between triggers and arguments, and iii) *event detection*, which combines pairwise

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3679–3686,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

relations into complete event structures. Joint approaches have also been explored (Rao et al., 2017; Riedel and McCallum, 2011; Vlachos and Craven, 2012; Venugopal et al., 2014), but they focus on finding relation graphs and detect events with rules. McClosky et al. (2011) treats events as dependency structures by constraining event structures to map to trees, thus their method cannot represent overlapping event structures. Other neural models in event extraction are in the general domain (Feng et al., 2016; Nguyen and Grishman, 2015; Chen et al., 2015; Nguyen et al., 2016), but they used the ACE2005 corpus which does not have nested events (Miwa et al., 2014). Furthermore, there are some efforts on applying transition-based methods on DAG structures in dependency parsing, e.g., (Sagae and Tsujii, 2008; Wang et al., 2018), however, they do not consider overlapping and nested structures.

We present a novel search-based neural *event detection* model that detects overlapping and nested events with beam search by formulating it as a structured prediction task for DAG structures. Given a relation graph of trigger-argument relations, our model detects nested events by searching a sequence of actions that construct event structures incrementally in a bottom-up manner. We focus on *event detection* since the existing methods do not consider nested and overlapping structures as a whole during learning. Treating them simultaneously helps the model avoid inferring wrong causality relations between entities. Our model detects overlapping events by maintaining multiple beams and detecting events from all the beams, in contrast to existing transition-based methods (Nivre, 2003, 2006; Chen and Manning, 2014; Dyer et al., 2015; Andor et al., 2016; Vlachos and Craven, 2012). We define an LSTM-based neural network model that can represent nested event structure to choose actions.

We show that our event detection model achieves performance comparable to the event detection module of the state-of-the-art TEES system (Björne and Salakoski, 2018) on the BioNLP CG Shared Task 2013 (Pyysalo et al., 2013) without the use of any syntactic and hand-engineered features. Furthermore, analyses on the development set show our model performs fewer number of classifications in less time.

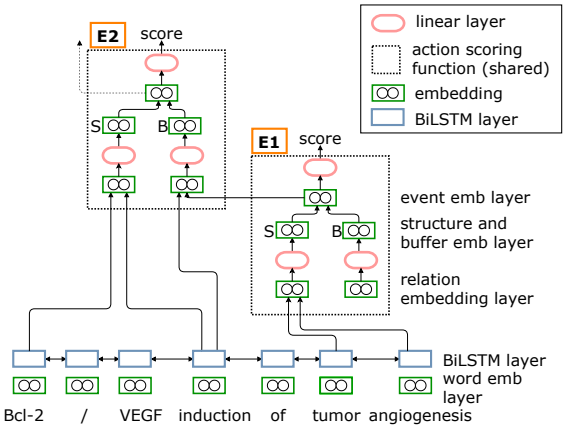

Figure 2: An illustration of the proposed neural model detecting event structures in a bottom-up manner, where E1 event representation becomes an argument to E2 event structure on the example sentence used in Figure 1.

2 Model

We describe our search-based neural network (SBNN) model that constitutes events from a relation graph by structured prediction. SBNN resembles an incremental transition-based parser (Nivre, 2006), but the search order, actions and representations are defined for DAG structures. We first discuss how we generate the relation graph in §2.1, then describe the structured prediction algorithm in §2.2 and the neural network in §2.3 and lastly, we explain the training procedure in §2.4.

2.1 Relation Graph Generation

To train our model, we use the predicted relations merged with pairwise relations decomposed from the gold events. We then generate a relation graph from the merged relations. During inference, the relation graph is generated only from the predicted relations. Figure 1 shows an example of the generated DAG-structured relation graph.

2.2 Structured Prediction for DAGs

We represent event structures with DAG structures and find them in a relation graph. Our model performs beam search on relation graphs by choosing actions to construct events. Unlike existing beam search usage where they only choose the best path in the beam, e.g., (Nivre, 2006), we use *all* the beams to predict event structures, which enables the model to predict overlapping and nested events.

Event structures are searched and fixed for each

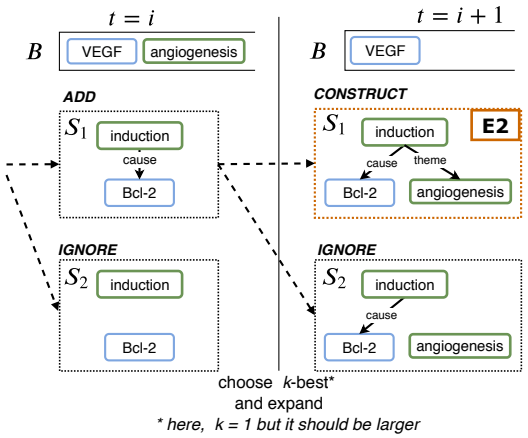

Figure 3: A snapshot of the search procedure within one time step (with $k = 1$) on the trigger *induction* which detects event $E2$ after a CONSTRUCT action.

trigger of the relation graph in a bottom-up manner. The model predicts the flat events first and then the representations of the flat events become the argument of the nested events. Figure 2 shows the proposed neural model (described in detail in §2.3), which illustrates that the event representation of event $E1$ becomes the argument to event $E2$. If the flat event is not detected, its nested event will not be detected consequently. When this happens, the search process stops.

Figure 3 shows an snapshot of the search procedure within one time step as applied to a relation graph with a trigger *induction* to detect event $E2$ (see Figure 1 and 2). To do the search, the model maintains two data structures: a buffer B which holds a queue of arguments[1] to be processed and a structure S which contains the partially built event structure. The initial state is composed of the buffer B with all the arguments and a structure S empty. At each succeeding time step, the model applies a set of predefined actions to each argument and uses a neural network to score those actions. Processing completes when B is empty and S contains all the arguments for the trigger along with the history of actions taken by the model.

We now define the three actions[2] that the model applies at each time step to each argument, namely: add the argument (ADD), ignore the argument (IGNORE) and add the argument and construct an event candidate (CONSTRUCT).

[1]A special NONE argument marks the first argument in the buffer to enable detection of no-argument events.

[2]Except for the NONE argument where only two actions are applied: IGNORE and CONSTRUCT.

We have chosen only three actions for simplicity. Figure 3 shows how actions are applied to the argument *angiogenesis* (due to space constraints we only show two actions indicated by the arrows). Concretely, we show two distinct structures (S_1, S_2) that are created in time step $t + 1$ after *CONSTRUCT* and *IGNORE* actions were applied to the current structure S_1 in time step i.

The event candidate structures are fixed as events if the scores of the CONSTRUCT actions are above a certain threshold. The resulting state after a CONSTRUCT action is removed from the beams. We maintain multiple beams and use all of them to predict overlapping events.

2.3 Neural Network as Scoring Function

Figure 2 shows the proposed neural model. We employ a **BiLSTM** network to generate the word representations from pre-trained **word embeddings**. To represent phrases, we averaged the word representations. The LSTM network is shared among the states during search in the sentence. We build a relation embedding for each argument, which concatenates the information of the trigger t, the role o, the argument a and the action c. We include both the type information p and the word or phrase representation w of the trigger or entity argument. Formally, each relation r_i is represented as a **relation embedding**: $\mathbf{r}_i = [\mathbf{t}_p; \mathbf{t}_w; \mathbf{o}_p; \mathbf{a}_p; \mathbf{a}_w; \mathbf{c}]$, where $\mathbf{t}_p$ is the representation of the type of the trigger and so on. Each $\mathbf{r}_i$ is passed to a linear **hidden layer**, then to a rectified linear unit (ReLU) non-linearity and summed to produce the **structure** and **buffer** embeddings: $\mathbf{S}_t$ and $\mathbf{B}_t$.

We use a neural network as the **action scoring function** (indicated by the dotted box in Figure 2) defined as $\sigma(a_t|S_{t-1}, B_{t-1})$. We model the action scoring function using S_t and B_t, which are composed by adding an action a_t for a relation r_t to S_{t-1} and moving r_t from B_{t-1} to S_{t-1}. The state at any time step t is composed of the buffer B_t and the partially built structure S_t. Each of S_t and B_t contains a set of relations $\{r_1, r_2, r_3, \ldots, r_n\}$. In Figure 2, there is no arrow to *B* in event *E1* because the diagram only shows the model snapshot at a specific time step during the search process. In this particular time step *t*, the buffer *B* in *E1* is already empty and thus, it does not contain any relations $\mathbf{r}_i$.

$\mathbf{S}_t$ and $\mathbf{B}_t$ are then concatenated to form the

event embedding. The event embedding has the same dimension as the sum of argument type and word dimensions so that it can be used as argument representation in nested events as shown in Figure 2. Then, we passed the event embedding into a linear **hidden layer** and output z_t. Finally, the scoring function σ is calculated as $\sigma(a_t|S_{t-1}, B_{t-1}) = \text{sigmoid}(z_t)$.

2.4 Training

From the relation graph generated in §2.1, we calculate gold action sequences that construct the gold event structures on the graph. The loss is summed over all actions and for all the events during the beam search and thus the objective function is to minimise their negative log-likelihood. We employ early updates (Collins and Roark, 2004): if the gold falls out of the beam, we stop searching and update the model immediately.

3 Experimental Settings

We applied our model to the BioNLP CG shared task 2013 (Pyysalo et al., 2015). We used the original data partition and employed the official evaluation metrics. We focussed on the CG task dataset over other BioNLP datasets because of its complexity and size (Nédellec et al., 2013; Björne and Salakoski, 2018; Pyysalo et al., 2013). The CG dataset has the most number of entity types and event types and thus is the most complex among the available (and accessible) BioNLP datasets. Furthermore, the CG dataset is the largest dataset in terms of the number of event instances and the proportion of nested and overlapping events. Evaluating our model extensively on other BioNLP tasks and datasets is part of our future work.

The development set contains 3,217 events of which 36.46% are nested events, 43.05% are overlapping events and 44.07% are flat events. Note that the total does not equal to 100% because nested and overlapping events may have intersection: a nested event can be overlapping and vice versa.

We compared our model with the event detection module of the state-of-the-art model TEES (Björne and Salakoski, 2018), which employs convolutional neural network and uses syntactic and hand-engineered features for event detection. Björne and Salakoski (2018) found that the dependency parse features increased the performance of the convolutional model. In contrast, we do not use these syntactic features nor hand-engineered features. Furthermore, instead of the ensemble methods, we used TEES's published *single* models, as this enables us to make a direct comparison with TEES in a minimal setting. We train our model using the predicted relations from TEES merged with the pairwise relations decomposed from the gold CG events. During inference, we predict event structures using only the predicted relations from TEES.

3.1 Nested and Overlapping Event Evaluation Process

Similarly, we used the official evaluation script to measure the performance of the model on nested, overlapping and flat events. We first separated the nested, overlapping and flat events, respectively. Then we compute the precision and recall for each category in the following way. For example, for nested events, to compute the precision, we compare the predicted nested events with all gold events and to compute recall, we compare gold nested events with all predicted events. The evaluation script detects nested events by comparing the whole tree structure down to its sub-events until it reaches the flat events. Hence, the performance scores of the nested events inevitably include the performance on flat events.

3.2 Training Details and Model Parameters

We implemented our model using the Chainer library (Tokui et al., 2015). We initialised the word embeddings using pre-trained embeddings (Chiu et al., 2016) while other embeddings are initialised using the normal distribution. All the embeddings and weight parameters were updated with mini-batch using the AMSGrad optimiser (Reddi et al., 2018). We also incorporated early stopping to choose the number of training epochs and tuned hyper-parameters (dropout, learning rate and weight decay rate) using grid search. The model parameters can be found in appendix A.

4 Results and Analyses

Table 1 shows the event detection performance of the models on the test set. Our model achieves performance comparable to the state-of-the-art TEES event detection module without the use of any syntactic and hand-engineered features, suggesting it can be applied to other domains with no need for feature engineering. We validated it to have no sig-

Model	P	R	F1 (%)
TEES	61.42	**52.93**	56.86
SBNN	**63.67**	51.43	**56.90**

Table 1: Event detection performance on the CG task 2013 test dataset.

Model	P	R	F (%)
TEES	56.81	48.21	52.16
SBNN $k = 1$	48.95	43.79	46.23
$k = 8$	**63.60**	47.46	**54.36**
$k = 64$	60.30	**49.16**	54.17
$k = 256$	60.91	48.53	54.02

Table 2: Event detection performance on CG task 2013 development set for SBNN with the top three performing k-values and when $k = 1$.

nificant statistical difference with the TEES model (the Approximate Randomisation test (Yeh, 2000; Noreen, 1989)).

To gain a deeper insight about the model, we performed analyses on the development set. Table 2 shows the performance of SBNN by varying the k-best parameter in beam search. We tested 2^i values for $i = 1, 2, 3, \ldots, 11$ and found that the best value was 8 with F1-score of 54.36%, which is 2.2 percentage points (pp) higher than TEES.

Table 3 shows the number of classifications (or action scoring function calls in our model) performed by each model with the corresponding actual running time. SBNN performs fewer classifications and in less time than TEES, implying it is more computationally efficient.

Table 4 shows the performance comparison of the models on nested, overlapping and flat event detection. Our model yields higher F1-scores than TEES which can be attributed to its ability to maintain multiple beams and to detect events from all these beams during search.

Finally, we computed the upper bound recall given the predicted relations from TEES. The upper bound is computed by setting the threshold parameter of our model to zero, which then constructs all gold events possible from the predicted relations of TEES. Since we evaluate our model on the output relations of TEES, the event detection performance is bounded or limited by these predicted relations. For instance, if one of the relations in an event was not predicted, the event structure will never be formed. We observe that this remains a challenging task since the upper bound recall is still at 53.47% (6.01pp higher than our current model's score). Closing this gap requires among others addressing inter-sentence and self-referential events, which account for 3.1% of the total events.

Model	Number of Classifications	Running Time (s)

Table 4: Nested and overlapping event detection F1 (%) score performance on the CG task 2013 development set.

5 Conclusions and Future Work

We presented a novel search-based neural model for nested and overlapping event detection by treating the task as structured prediction for DAGs. Our model achieves performance comparable to the state-of-the-art TEES event detection model without the use of any syntactic and hand-engineered features, suggesting the domain-independence of the model. Further analyses on the development set revealed some desirable characteristics of the model such as its computational efficiency while yielding higher F1-score performance. These results set the first focussed benchmark of our model and next steps include applying it to other event datasets in the biomedical and general domain. In addition, it can also be applied to other DAG structures such as nested/discontiguous entities (Muis and Lu, 2016; Ju et al., 2018).

Abstract

Most existing work on adversarial data generation focuses on English. For example, PAWS (Paraphrase Adversaries from Word Scrambling) (Zhang et al., 2019) consists of challenging English paraphrase identification pairs from Wikipedia and Quora. We remedy this gap with PAWS-X, a new dataset of 23,659 *human* translated PAWS evaluation pairs in six typologically distinct languages: French, Spanish, German, Chinese, Japanese, and Korean. We provide baseline numbers for three models with different capacity to capture non-local context and sentence structure, and using different multilingual training and evaluation regimes. Multilingual BERT (Devlin et al., 2019) fine-tuned on PAWS English plus machine-translated data performs the best, with a range of 83.1-90.8 accuracy across the non-English languages and an average accuracy gain of 23% over the next best model. PAWS-X shows the effectiveness of deep, multilingual pre-training while also leaving considerable headroom as a new challenge to drive multilingual research that better captures structure and contextual information.

1 Introduction

Adversarial examples have effectively highlighted the deficiencies of state-of-the-art models for many natural language processing tasks, e.g. question answering (Jia and Liang, 2017; Chen et al., 2018; Ribeiro et al., 2018), textual entailment (Zhao et al., 2018; Glockner et al., 2018), and text classification (Alzantot et al., 2018; Iyyer et al., 2018). Zhang et al. (2019) introduce PAWS, which has adversarial paraphrase identification pairs with high lexical overlap, like *flights from New York to Florida* and *flights from Florida to New York*. Such pairs stress the importance of modeling sentence structure and context because they have high word overlap ratio but different semantic meaning. In addition to revealing failures of state-of-the-art models, research on adversarial examples has generally shown that augmenting training data with good adversarial examples can boost performance for some models—providing greater clarity to the modeling landscape as well providing new headroom for further improvements.

Most previous work focuses only on English despite the fact that the problems highlighted by adversarial examples are shared by other languages. Existing multilingual datasets for paraphrase identification, e.g. Multi30k (Elliott et al., 2016) and Opusparcus (Creutz, 2018), lack challenging examples like PAWS. The lack of high-quality adversarial examples in other languages makes it difficult to benchmark model improvements. We bridge this gap by creating Cross-lingual PAWS (PAWS-X), an extension of the Wikipedia portion of the PAWS evaluation and test examples to six languages: Spanish, French, German, Chinese, Japanese, and Korean. This new corpus consists of 23,659 *human* translated example pairs with paraphrase judgments in each target language. Like previous work on multilingual corpus creation (Conneau et al., 2018), we machine translate the original PAWS English training set (49,401 pairs). Note that all translated pairs still have high word overlap and they inherit semantic similarity labels from the original PAWS examples; thus, the resulting dataset preserves the ability of probing structure and context sensitivity for models. We also machine translate the evaluation pairs of each language into English to establish the baseline performance of a translate-then-predict strategy. The PAWS-X dataset, including both the new human translated pairs and the machine translated examples, is available for download at https://github.com/google-research-datasets/paws.

Table 1: Examples of human translated pairs for each of the six languages.

Our experiments show that PAWS-X effectively measures the multilingual adaptability of models and how well they capture context and word order. The state-of-the-art multilingual BERT model (Devlin et al., 2019) obtains a 32% (absolute) accuracy improvement over a bag-of-words model. We also show that machine translation helps and works better than a zero-shot strategy. We find that performance on German, French, Spanish is overall better than Chinese, Japanese and Korean.

2 PAWS-X Corpus

The core of our corpus creation procedure is to translate the Wikipedia portion of the original PAWS corpus from English (en) to six languages: French (fr), Spanish (es), German (de), Chinese (zh), Japanese (ja), and Korean (ko). To this end, we hire human translators to translate the development and test sets, and use a neural machine translation (NMT) service[1] to translate the training set.

We choose translation instead of repeating the PAWS data generation approach (Zhang et al., 2019) to other languages. This has at least three advantages. First, human translation does not require high-quality multilingual part-of-speech taggers or named entity recognizers, which play a key role in the data generation process used in Zhang et al. (2019). Second, human translators are trained to produce the target sentence while preserving meaning, thereby ensuring high data quality. Third, the resulting data can provide a new testbed for cross-lingual transfer techniques because examples in all languages are translated from the same sources. For example, PAWS-X could be used to evaluate whether a German or French sentence is a paraphrase of a Chinese or Japanese one.

	fr	es	de	zh	ja	ko
dev	1,992	1,962	1,932	1,984	1,980	1,965
test	1,985	1,999	1,967	1,975	1,946	1,972

Table 2: Examples translated per language.

Translating Evaluation Sets We obtain human translations on a random sample of 4,000 sentence pairs from the PAWS development set for each of the six languages (48,000 translations). The manual translation is performed by 10-20 in-house professionals that are native speakers of each language. A randomly sampled subset is presented and validated by a second worker. The final delivery is guaranteed to have less than 5% word level error rate. The sampled 4,000 pairs are split into new development and test sets, 2,000 pairs for each.

Due to time and cost constraints, we could not translate all 16,000 examples in both of original PAWS development and test set. Each sentence in a pair is presented independently so that translation is not affected by context. In our initial studies we noticed that sometimes it was difficult to translate an entity mention. We therefore ask translators to translate entity mentions, but different translators may have different preferences according to their background knowledge. Table 1 gives example translated pairs in each language.

Resulting Corpus Some sentences could not be be translated. Table 2 shows the final counts translated to each language. Most of the untranslated

sentences were due to incompleteness or ambiguities, such as *It said that Easipower was*, and *Park Green took over No*. These sentences are likely from the adversarial generation process when creating PAWS. On average less than 2% of the pairs are not translated, and we simply exclude them.

The authors further verified translation quality for a random sample of ten pairs in each language. PAWS-X includes 23,459 human-translated pairs, including 11,815 and 11,844 pairs in development and test, respectively. Finally, original PAWS labels (paraphrase or not paraphrase) are mapped to the translations. Positive pairs account for 44.0% of development sets and 45.4% of test respectively–close to the PAWS label distribution.

Translation brings new challenges to the paraphrasing identification task. An entity can be translated differently, such as *Slovak* and *Slowake* (Table 1) and models need to capture that these refer to the same entity. In a more challenging example, *Four Rivers*, *Audubon* and *Shawnee Trails* are translated in just one of the sentences:

en *s1* From the merger of the Four Rivers Council and the Audubon Council, the Shawnee Trails Council was born.

s2 Shawnee Trails Council was formed from the merger of the Four Rivers Council and the Audubon Council.

zh *s1* Four Rivers 委员会与 Audubon 委员会合并后，Shawnee Trails 委员会得以问世.

s2 肖尼小径(Shawnee Trails) 委员会由合并四河 (Four Rivers) 委员会和 奥杜邦 (Audubon) 委员会成立.

In the zh-s2 example, the parentheses give English glosses of Chinese entity mentions.

3 Evaluated Methods

The goal of PAWS-X is to probe models' ability to capture structure and context in a multilingual setting. We consider three models with varied complexity and expressiveness. The first baseline is a simple bag-of-words (**BOW**) encoder with cosine similarity. It uses unigram to bigram token encoding as input features and takes a cosine value above 0.5 as a paraphrase. The second model is **ESIM**, Enhanced Sequential Inference Model (Chen et al., 2017). Following Zhang et al. (2019), ESIM encodes each sentence using a BiLSTM, and passes the concatenation of encodings through a feed-forward layer for classification. The additional layers allow ESIM to capture more complex sentence interaction than cosine similarity. Third, we evaluate **BERT**, Bidirectional Encoder Representations from Transformers (Devlin et al., 2019), which recently achieved state-of-the-art results on eleven natural language processing tasks.

	BOW	ESIM	BERT
Non-local context	×	✓	✓
Word interaction	×	×	✓
Translate Train	✓	✓	✓
Translate Test	✓	✓	✓
Zero Shot	×	×	✓
Merged	×	×	✓

Table 3: Complexity of each evaluated model and the training/evaluation strategies being tested.

We evaluate all models with two strategies (Conneau et al., 2018): (1) **Translate Train**: the English training data is machine-translated into each target language to provide data to train each model and (2) **Translate Test**: train a model using the English training data, and machine-translate all test examples to English for evaluation.

Multilingual BERT is a single model trained on 104 languages, which enables experiments with cross-lingual training regimes. (1) **Zero Shot**: the model is trained on the PAWS English training data, and then directly evaluated on all others. Machine translation is **not** involved in this strategy. (2) **Merged**: train a multilingual model on all languages, including the original English pairs and machine-translated data in all other languages.

Table 3 summarizes the models with respect to whether they represent non-local contexts or support cross-sentential word interaction, plus which strategies are evaluated for each model.

4 Experiments and Results

We use the latest public multilingual BERT base model with 12 layers[2] and apply the default fine-tuning strategy with batch size 32 and learning rate 1e-5. For BOW and ESIM, we use our own implementations and 300 dimensional multilingual word embeddings from fastText.[3] We allow fine-tuning word embeddings during training, which gives better empirical performance.

We use two metrics: classification accuracy and area-under-curve scores of precision-recall curves (AUC-PR). For BERT, probability scores for the positive class is used to compute AUC-PR. For BOW and ESIM a cosine threshold of 0.5 is used to compute accuracy. In all experiments, the best

Table 5: Average Accuracy (%) and AUC-PR (%) over the six languages.

model checkpoint is chosen based on accuracy on development sets and report results on testing sets.

Results Table 4 shows the performance of all methods and languages. Table 5 summarizes the average results for the six non-English languages.

Model Comparisons: On both Translate Train and Translate Test, BERT consistently outperforms both BOW and ESIM by a substantial margin (>15% absolute accuracy gains) across all seven languages. BERT Translate Train achieves an average 20% accuracy gain. This result demonstrates that PAWS-X effectively measures models' sensitivity to word order and syntactic structure.

Training/Evaluation Strategies: As Table 4 and 5 show, the Zero Shot strategy yields the lowest performance compared to other strategies on BERT. This is evidence that machine-translated data helps in the multilingual scenario. Indeed, when training on machine-translated examples in all languages (Merged), the model achieves the best performance, with 8.6% accuracy and 7.1% AUC-PR average gains over Zero Shot.

BERT and ESIM show different performance patterns on Translate Train and Translate Test. Translate Test appears to give consistently better performance then Translate Train on ESIM, but not on BERT. This may be because multilingual BERT is pre-trained on over one hundred languages; hence BERT provides better initialization for non-English languages than ESIM (which relies on fastText embeddings). The gap between training on English and on other languages is therefore smaller on BERT than on ESIM, which makes Translate Train work better on BERT.

	0	1-2	3-4	5-6	7
#	32	52	140	542	1234
%	1.6	2.6	7.0	27.1	61.7

Table 6: The count of examples by number of languages (of 7) that agree with the gold label in test set.

Language Difference: Across all models and approaches, performance on Indo-European languages (German, French, Spanish) is consistently better than CJK (Chinese, Japanese, Korean). The performance difference is particularly noticeable on Zero Shot. This can be explained from two perspectives. First, the MT system we used works better on Indo-European languages than on CJK. Second, the CJK family is more typologically and syntactically different from English. For example, in table 1, *Slowake* in German is much closer to the original term *Slovak* in English, compared with its Chinese translation 斯洛伐克. This at least partly explains why performance on CJK is particularly poor in Zero Shot.

Error Analysis: To gauge the difficulty of each example for the best model (BERT-merged), Table 6 shows the count of examples based on how many languages for the same pair are assigned the correct label in test set. The majority of the examples are easy, with 61.7% correct in all languages. Of the 32 examples that failed in all languages, most are hard or highly ambiguous. Some have incorrect gold labels or were generated incorrectly in the original PAWS data.

The following is a sample of these.

a1 On July 29, 1791, Sarah married Lea Thomas Wright Hill (1765–1842) at St. Martin's Church in Birmingham and had 8 children.

a2 Thomas Wright Hill married Sarah Lea (1765–1842) on 29 July 1791 at St Martin's Church, Birmingham and had 8 children. **match**

b1 He established himself eventually in the northwest of Italy, apparently supported by Guy, where he probably comes "title".

b2 He eventually established himself in northwestern Italy, apparently supported by Guy, where he probably received the title of "comes". **not_match**

We also considered examples that are correctly predicted in just half of the languages. Some of these failed because of translation noise, e.g. inconsistent entity translations (as shown in §2).

5 Conclusion

We introduce PAWS-X, a challenging paraphrase identification dataset with 23,659 *human* translated evaluation pairs in six languages. Our experimental results showed that PAWS-X effectively measures sensitivity of models to word order and the efficacy of cross-lingual learning approaches. It also leaves considerable headroom as a new challenging benchmark to drive multilingual research on the problem of paraphrase identification.

Acknowledgments

We would like to thank our anonymous reviewers and the Google AI Language team, especially Luheng He, for the insightful comments that contributed to this paper. Many thanks also to the translate team, especially Mengmeng Niu, for the help with the annotations.

Abstract

As a step toward better document-level understanding, we explore classification of a sequence of sentences into their corresponding categories, a task that requires understanding sentences in context of the document. Recent successful models for this task have used hierarchical models to contextualize sentence representations, and Conditional Random Fields (CRFs) to incorporate dependencies between subsequent labels. In this work, we show that pretrained language models, BERT (Devlin et al., 2018) in particular, can be used for this task to capture contextual dependencies without the need for hierarchical encoding nor a CRF. Specifically, we construct a joint sentence representation that allows BERT Transformer layers to directly utilize contextual information from all words in all sentences. Our approach achieves state-of-the-art results on four datasets, including a new dataset of structured scientific abstracts.

1 Introduction

Inspired by the importance of document-level natural language understanding, we explore classification of a sequence of sentences into their respective roles or functions. For example, one might classify sentences of scientific abstracts according to rhetorical roles (e.g., Introduction, Method, Result, Conclusion, etc). We refer to this task as Sequential Sentence Classification (SSC), because the meaning of a sentence in a document is often informed by context from neighboring sentences.

Recently, there have been a surge of new models for contextualized language representation, resulting in substantial improvements on many natural language processing tasks. These models use multiple layers of LSTMs (Hochreiter and Schmidhuber, 1997) or Transformers (Vaswani et al., 2017), and are pretrained on unsupervised text with language modeling objectives such as next word prediction (Peters et al., 2018; Radford et al., 2018) or masked token prediction (Devlin et al., 2018; Dong et al., 2019). BERT is among the most successful models for many token- and sentence-level tasks (Devlin et al., 2018; Liu et al., 2019). In addition to a masked token objective, BERT optimizes for next sentence prediction, allowing it to capture sentential context.

These objectives allow BERT to learn some document-level context through pretraining. In this work we explore the use of BERT for SSC. For this task, prior models are primarily based on hierarchical encoders over both words and sentences, often using a Conditional Random Field (CRF) (Lafferty et al., 2001) layer to capture document-level context (Cheng and Lapata, 2016; Jin and Szolovits, 2018; Chang et al., 2019). These models encode and contextualize sentences in two consecutive steps. In contrast, we propose an input representation which allows the Transformer layers in BERT to directly leverage contextualized representations of all words in all sentences, while still utilizing the pretrained weights from BERT. Specifically, we represent all the sentences in the document as one long sequence of words with special delimiter tokens in between them. We use the contextualized representations of the delimiter tokens to classify each sentence. The transformer layers allow the model to finetune the weights of these special tokens to encode contextual information necessary for correctly classifying sentences in context.

We apply our model to two instances of the SSC task in scientific text that can benefit from better contextualized representations of sentences: scientific abstract sentence classification and extractive summarization of scientific documents.

★Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3693–3699, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Our contributions are as follows:

(i) We present a BERT-based approach for SSC that jointly encodes all sentences in the sequence, allowing the model to better utilize document-level context. *(ii)* We introduce and release CSABSTRUCT, a new dataset of manually annotated sentences from computer science abstracts. Unlike biomedical abstracts which are written with explicit structure, computer science abstracts are free-form and exhibit a variety of writing styles, making our dataset more challenging than existing datasets for this task. *(iii)* We achieve state-of-the-art (SOTA) results on multiple datasets of two SSC tasks: scientific abstract sentence classification and extractive summarization of scientific documents.[1]

2 Model

In Sequential Sentence Classification (SSC), the goal is to classify each sentence in a sequence of n sentences in a document. We propose an approach for SSC based on BERT to encode sentences in context. The BERT model architecture consists of multiple layers of Transformers and uses a specific input representation, with two special tokens, `[CLS]` and `[SEP]`, added at the beginning of the input sentence pair and between the sentences (or bag of sentences) respectively. The pretrained multi-layer TRANSFORMER architecture allows the BERT model to contextualize the input over the entire sequence, allowing it to capture necessary information for correct classification. To utilize this for the SSC task, we propose a special input representation without any additional complex architecture augmentation. Our approach allows the model to better incorporate context from all surrounding sentences.

Figure 1 gives an overview of our model. Given the sequence of sentences $\mathbf{S} = \langle \mathbf{S_1}, ..., \mathbf{S_n} \rangle$ we concatenate the first sentence with BERT's delimiter, `[SEP]`, and repeat this process for each sentence, forming a large sequence containing all tokens from all sentences. After inserting the standard `[CLS]` token at the beginning of this sequence, we feed it into BERT. Unlike BERT, which uses the `[CLS]` token for classification, we use the encodings of the `[SEP]` tokens to classify each sentence. We use a multi-layer feedforward network on top of the `[SEP]` representations of each sentence to classify them to their corresponding categories.[2] Intuitively, through BERT's pretraining, the `[SEP]` tokens learn sentence structure and relations between continuous sentences (through the next sentence objective). The model is then finetuned on task-specific training data, where most of the model parameters are already pretrained using BERT and only a thin task-specific network on top is needed. During finetuning[3] the model learns appropriate weights for the `[SEP]` token to allow it to capture contextual information for classifying sentences in the sequence. This way of representing a sequence of sentences allows the self-attention layers of BERT to directly leverage contextual information from all words in all sentences, while still utilizing the pretrained weights from BERT. This is in contrast to existing hierarchical models which encode then contextualize sentences in two consecutive steps.[4]

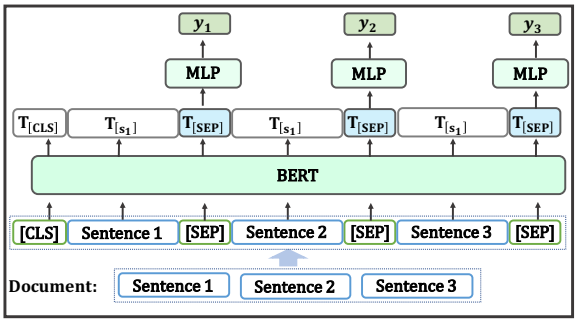

Figure 1: Overview of our model. Each `[SEP]` token is mapped to a contextualized representation of its sentence and then used to predict a label y_i for sentence$_i$.

Handling long sequences Released BERT pretrained weights support sequences of up to 512 wordpieces (Wu et al., 2016). This is limiting for our model on datasets where the length of each document is large, as we represent all sentences in one single sequence. However, the semantics of a sentence are usually more dependent on local context, rather than all sentences in a long docu-

[1]Code & data: https://github.com/allenai/sequential_sentence_classification

[2]It is also possible to add another special token (e.g., `[CLS]`) at the beginning of each sentence and perform classification on that token. Empirically, we found the approaches to perform similarly.

[3] Following terminology from Howard and Ruder (2018), "finetuning" refers to "training" a model that was previously pretrained. We use both terms interchangeably.

[4]It is possible to add a CRF layer or another contextualizing layer on top of `[SEP]` tokens in our model, but empirically, we did not find this addition to be helpful. One explanation is that the self-attention layers of our model are already capturing necessary contextual information from the document.

ment. Therefore, we set a threshold on the number of sentences in each sequence. We recursively bisect the document until each split has less sentences than the specified threshold. At a limit of 10 sentences, only one division is needed to fit nearly all examples for the abstract sentence classification datasets. A limitation of this approach is that sentences on the edge of the splits could lose context from the previous(next) split. We leave this limitation to future work.

3 Tasks and Datasets

This section describes our tasks and datasets, and any model changes that are task-specific (see Table 1 for comparison of evaluation datasets).

3.1 Scientific abstract sentence classification

This task requires classifying sentences in scientific abstracts into their rhetorical roles (e.g., INTRODUCTION, METHOD, RESULTS, etc). We use the following three datasets in our experiments.

PUBMED-RCT (Dernoncourt and Lee, 2017) contains 20K biomedical abstracts from PubMed, with sentences classified as one of 5 categories {BACKGROUND, OBJECTIVE, METHOD, RESULT, CONCLUSION}. We use the preprocessed version of this dataset by Jin and Szolovits (2018).

CSABSTRUCT is a new dataset that we introduce. It has 2,189 manually annotated computer science abstracts with sentences annotated according to their rhetorical roles in the abstract, similar to the PUBMED-RCT categories. See §3.3 for details.

NICTA (Kim et al., 2011) contains 1,000 biomedical abstracts with sentences classified into PICO categories (Population, Intervention, Comparison, Outcome) (Richardson et al., 1995).

3.2 Extractive summarization of scientific documents

This task is to select a few text spans in a document that best summarize it. When the spans are sentences, this task can be viewed as SSC, classifying each sentence as a good summary sentence or not. Choosing the best summary sentences can benefit from context of surrounding sentences. We train on CSPUBSUMEXT (Collins et al., 2017), an extractive summarization dataset of 10k scientific papers, with sentences scored as good/bad summary sentences using ROUGE overlap scores with paper highlights. For evaluation, a separate test set, CSPUBSUM, of 150 publications and their paper highlights is used.[5]

A key difference between the training of our model and that of Collins et al. (2017) is that they use the ROUGE scores to label the top (bottom) 20 sentences as positive (negative), and the rest are neutral. However, we found it better to train our model to directly predict the ROUGE scores, and the loss function we used is Mean Square Error.

3.3 CSABSTRUCT construction details

CSABSTRUCT is a new dataset of annotated computer science abstracts with sentence labels according to their rhetorical roles. The key difference between this dataset and PUBMED-RCT is that PubMed abstracts are written according to a predefined structure, whereas computer science papers are free-form. Therefore, there is more variety in writing styles in CSABSTRUCT. CSABSTRUCT is collected from the Semantic Scholar corpus (Ammar et al., 2018). Each sentence is annotated by 5 workers on the Figure-eight platform,[6] with one of 5 categories {BACKGROUND, OBJECTIVE, METHOD, RESULT, OTHER}. Table 2 shows characteristics of the dataset. We use 8 abstracts (with 51 sentences) as test questions to train crowdworkers. Annotators whose accuracy is less than 75% are disqualified from doing the actual annotation job. The annotations are

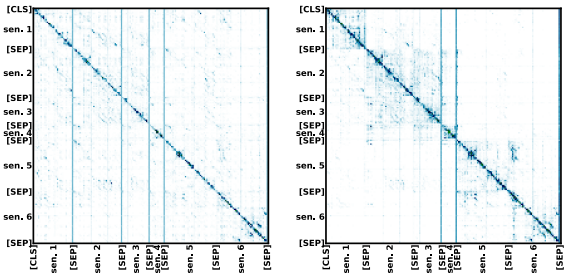
aggregated using the agreement on a single sentence weighted by the accuracy of the annotator on the initial test questions. A confidence score is associated with each instance based on the annotator initial accuracy and agreement of all annotators on that instance. We then split the dataset 75%/15%/10% into train/dev/test partitions, such that the test set has the highest confidence scores. Agreement rate on a random subset of 200 sentences is 75%, which is quite high given the difficulty of the task. Compared with PUBMED-RCT, our dataset exhibits a wider variety of writing styles, since its abstracts are not written with an explicit structural template.

4 Experiments

Training and Implementation We implement our models using AllenNLP (Gardner et al., 2018). We use SCIBERT pretrained weights (Beltagy et al., 2019) in both our model and BERT-based baselines, because our datasets are from the scientific domain. As in prior work (Devlin et al., 2018; Howard and Ruder, 2018), for training, we use dropout of 0.1, the Adam (Kingma and Ba, 2015) optimizer for 2-5 epochs, and learning rates of $5e^6$, $1e^5$, $2e^5$, or $5e^5$. We use the largest batch size that fits in the memory of a Titan V GPU (between 1 to 4 depending on the dataset/model) and use gradient accumulation for effective batch size of 32. We report the average of results from 3 runs with different random seeds for the abstract sentence classification datasets to control potential non-determinism associated with deep neural models (Reimers and Gurevych, 2017). For summarization, we use the best model on the validation set. We choose hyperparameters based on the best performance on the validation set. We release our code and data to facilitate reproducibility.[7]

Baselines We compare our approach with two strong BERT-based baselines, finetuned for the task. The first baseline, BERT+Transformer, uses the `[CLS]` token to encode individual sentences as described in Devlin et al. (2018). We add an additional Transformer layer over the `[CLS]` vectors to contextualize the sentence representations over the entire sequence. The second baseline, BERT+Transformer+CRF, additionally adds a CRF layer. Both baselines split long lists of sentences into splits of length 30 using the method in §2 to fit into the GPU memory.

We also compare with existing SOTA models for each dataset. For the PUBMED-RCT and NICTA datasets, we report the results of Jin and Szolovits (2018), who use a hierarchical LSTM model augmented with attention and CRF. We also apply their model on our dataset, CSABSTRUCT, using the authors' original implementation.[8] For extractive summarization, we compare to Collins et al. (2017)'s model, `SAF+F Ens`, the model with highest reported results on this dataset. This model is an ensemble of an LSTM-based model augmented with global context and abstract similarity features, and a model trained on a set of hand-engineered features.



4.1 Results

Table 3 summarizes results for abstract sentence classification. Our approach achieves state-of-the-art results on all three datasets, outperforming Jin and Szolovits (2018). It also outperforms our BERT-based baselines. The performance gap between our baselines and our best model is large for small datasets (CSABSTRUCT, NICTA), and smaller for the large dataset (PUBMED-RCT). This suggests the importance of pretraining for small datasets.

Table 4 summarizes results on CSPUBSUM. Following Collins et al. (2017) we take the top 10 predicted sentences as the summary and use ROUGE-L scores for evaluation. It is clear that our approach outperforms BERT+TRANSFORMER. The BERT +TRANSFORMER+CRF baseline is not included

(a) Before finetuning (b) After finetuning

Figure 2: Self-attention weights of the top 2 layers of BERT for one abstract. Cell value in row i, column j, is the maximum attention weight of token i attending to token j across all 12 Transformer attention heads.

here because, as mentioned in section 3, we train our model to predict ROUGE, not binary labels as in Collins et al. (2017). As in Collins et al. (2017), we found the ABSTRACT-ROUGE feature to be useful. Our model augmented with this feature slightly outperforms Collins et al. (2017)'s model, which is a relatively complex ensemble model and uses a number of carefully engineered features for the task. Our model is a single model with only one added feature.

Analysis To better understand the advantage of our joint sentence encoding relative to the BERT+Transformer baseline, we qualitatively analyze examples from CSABSTRUCT that our model gets right and the baseline gets wrong. We found that 34/134 of such examples require context to classify correctly.[9]

For example, sentences 2 and 3 from one abstract are as follows: "*We present an improved oracle for the arc-eager transition system, which provides a set of optimal transitions [...].*", "*In such cases, the oracle provides transitions that will lead to the best reachable tree [...].*". In isolation, the label for sentence 3 is ambiguous, but with context from the previous sentence, it clearly falls under the METHOD category.

Figure 2 shows BERT self-attention weights for the above-mentioned abstract before and after finetuning. Before (Figure 2a), attention weights don't exhibit a clear pattern. After (Figure 2b), we observe blocks along the matrix diagonal of sentences attending to themselves, except for the block encompassing sentences 2 and 3. The words in these two sentences attend to each other, enabling the encoding of sentence 3 to capture the information needed from sentence 2 to predict its label (see Appendix A for additional patterns).

[9]Of the 1349 examples in the test set, our model gets 134 correct that the BERT +Transformer baseline gets wrong, and the baseline gets 79 correct that our model gets wrong.

5 Related Work

Prior work on scientific Sequential Sentence Classification datasets (e.g. PUBMED-RCT and NICTA) use hierarchical sequence encoders (e.g. LSTMs) to encode each sentence and contextualize the encodings, and apply CRF on top (Dernoncourt and Lee, 2017; Jin and Szolovits, 2018). Hierarchical models are also used for summarization (Cheng and Lapata, 2016; Nallapati et al., 2016; Narayan et al., 2018), usually trained in a seq2seq fashion (Sutskever et al., 2014) and evaluated on newswire data such as the CNN/Daily mail benchmark (Hermann et al., 2015). Prior work proposed generating summaries of scientific text by leveraging citations (Cohan and Goharian, 2015) and highlights (Collins et al., 2017). The highlights-based summarization dataset introduced by Collins et al. (2017) is among the largest extractive scientific summarization datasets. Prior work focuses on specific architectures designed for each of the tasks described in §3, giving them more power to model each task directly. Our approach is more general, uses minimal architecture augmentation, leverages language model pretraining, and can handle a variety of SSC tasks.

6 Conclusion and Future Work

We demonstrated how we can leverage pretrained language models, in particular BERT, for SSC without additional complex architectures. We showed that jointly encoding sentences in a sequence results in improvements across multiple datasets and tasks in the scientific domain. For future work, we would like to explore methods for better encoding long sequences using pretrained language models.

A Additional analysis

Figures 3 and 4 show attention weights of BERT before and after finetuning. We observe that before finetuning, the attention patterns on `[SEP]` tokens and periods is almost identical between sentences. However, after finetuning, the model attends to sentences differently, likely based on their different role in the sentence that requires different contextual information.

Abstract

We describe a multi-agent communication framework for examining high-level linguistic phenomena at the community-level. We demonstrate that complex linguistic behavior observed in natural language can be reproduced in this simple setting: i) the outcome of contact between communities is a function of inter- and intra-group connectivity; ii) linguistic contact either converges to the majority protocol, or in balanced cases leads to novel creole languages of lower complexity; and iii) a linguistic continuum emerges where neighboring languages are more mutually intelligible than farther removed languages. We conclude that at least some of the intricate properties of language evolution need not depend on complex evolved linguistic capabilities, but can emerge from simple social exchanges between perceptually-enabled agents playing communication games.

1 Introduction

Contact linguistics (Myers-Scotton, 2002) studies what happens when two or more languages or language varieties interact. It poses several pertinent open questions that are difficult to answer: how does symmetric ("mutually intelligible") communication emerge; how do languages behave under contact; how does one language come to dominate another; how and why does extensive language contact tend to lead to simplification (e.g. in creoles); and how does a linguistic continuum come about, where neighboring languages are more intelligible than farther removed ones? In this work, we show that such linguistic phenomena emerge naturally given a few general assumptions about the organizational structure of networks of artificial agents equipped with a minimalistic form of learned communication.

We introduce a multi-agent framework for studying the emergence and evolution of language, where agents are neural networks endowed with the ability to exchange messages about their perceptual input. The advantage of this approach is that one can precisely control linguistic, environmental and algorithmic variables.

First, we investigate linguistic behavior at the agent-level, and examine when symmetric communication emerges within a linguistic community, as well as how the topological organization of communities—i.e., which other agents an agent comes into contact with and how frequently that happens—impacts convergence and learning. We then examine the behavior of communities of such agents when they come into contact, as well as how community-level topology impacts convergence, success rate and mutual intelligibility.

We demonstrate that the following linguistic behaviors emerge, which correspond to known linguistic phenomena in natural languages: 1) the outcome of contact is a function of inter- and intra-group connectivity, i.e. that languages become mutually intelligible through contact, even for agents that have not themselves been exposed to the other language, provided there is sufficient connectivity between communities; 2) linguistic contact over time either converges to the dominant majority protocol, leading to the extinction of the other language, or if the communities are balanced, gives rise to an original "creole" protocol that has lower complexity than the original languages; 3) a linguistic continuum emerges, where neighboring languages are more mutually intelligible than farther removed languages and the topology of the continuum governs its behavior.

To our knowledge, this work constitutes the first attempt at studying contact linguistic phenomena using communities of deep neural agents. Our findings indicate that intricate properties of language evolution need not depend on intrinsic properties of highly complex evolved linguistic capa-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3700–3710, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

bilities, but instead can emerge purely from social exchanges between perceptually-enabled agents with simple communicative capabilities.

2 Related Work

Studying language change *in vivo* is challenging, since it requires simultaneous observation of speaker and community interactions (Brooks and Ragir, 2008; Trudgill, 1974; Joseph, 2017; Christiansen and Kirby, 2003), while carefully controlling for purposes and goals (Winograd, 1971; Flores and Winograd, 1987; Nowak and Krakauer, 1999). Studies of language emergence and evolution must furthermore be conducted over a long period of time, spanning decades or even centuries. Even the Nicaraguan sign language, which emerged remarkably rapidly, took several decades to develop fully (Senghas et al., 2005). Language itself also never ceases to evolve (Fishman, 1964).

Advances in computer science have provided us with opportunities for instead investigating the emergence and evolution of languages *in vitro* using computational and mathematical models (R. Hurford, 1989; Briscoe, 2002; Kirby, 2002; Christiansen and Kirby, 2003; Kirby et al., 2008; Lewis, 2008; Skyrms, 2010). In computational approaches, communities of agents, equipped with the ability to communicate, are deployed in a simulated environment. Their communication protocol is either evolved or learned, in order to maximize some reward provided by the environment. The agents' behavior and communication are observed and used to compare against linguistic phenomena or hypothesized linguistic theories.

Computational multi-agent models are characterized by the complexity of the agents, the choice of learning algorithm, and the design of the environment and reward structure. The complexity of an artificial agent ranges from a set of simple difference equations (Grouchy et al., 2016), to a CPU-like architecture with an instruction set and registers (Knoester et al., 2007), to a co-occurrence matrix between objects and symbols (Nowak and Krakauer, 1999), to a simple single-layer neural network (Trianni and Dorigo, 2006), to a deep neural network (Lazaridou et al., 2016; Foerster et al., 2016; Jorge et al., 2016). The learning algorithm is either a variant of evolutionary algorithms (Nowak and Krakauer, 1999; Kirby, 2002; Grouchy et al., 2016), often used in the framework of Artificial Life (Bedau, 2003), or a gradient-based optimization algorithm, as is often used for training deep neural networks with a supervised or reinforcement learning objective function. The former simulates generations developing complex behavior over time, while the latter enables more sophisticated agents thanks to the recent advances in deep learning (LeCun et al., 2015). Recent years have seen intriguing new results in emergent communication, starting with Lazaridou et al. (2016) and Foerster et al. (2016), using deep neural agents (Lewis et al., 2017; Havrylov and Titov, 2017; Jorge et al., 2016; Evtimova et al., 2018; Das et al., 2018; Cao et al., 2018). Often, these approaches could be framed as special or generalized cases of Lewis's signalling game (Lewis, 2008), in which agents exchange signals to achieve a common goal. In this work, deep neural agents play games within communities of similar agents, where the aim is for agents to communicate about their perceptual input.

3 Multi-agent communication

In order to study emergent linguistic phenomena in a simplified but realistic setting, the communication game needs to have several properties. First, it should be *symmetric*, in that all agents should be able to act as "speaker" and "listener". Second, the agents should communicate about something *external* to themselves, i.e., about the sensory experience of something in their environment. Third, the world should be *partially observable*, implying that communication is required for solving the game successfully. **Fig. 1** shows example training data, the game setup and agent design. See the supplementary material for details.

Reference Game Let $G = \langle A, O, M, W, R \rangle$ be a multi-agent communication game, consisting of communities of agents A communicating across the bidirectional message channel M given environmental observations O, where the community membership of agents is defined as a graph with the agents A as vertices and weighted edges W that determine whether two agents are connected, i.e., W specifies the topology of the network.

Each agent is a deep neural network with perceptual inputs and given a language description, as illustrated in **Fig.1**. All agents have the same network architecture because of the requirement that the game be symmetric, but each agent has its own parameters which are learned during training. Pairs of connected agents learn to play a game

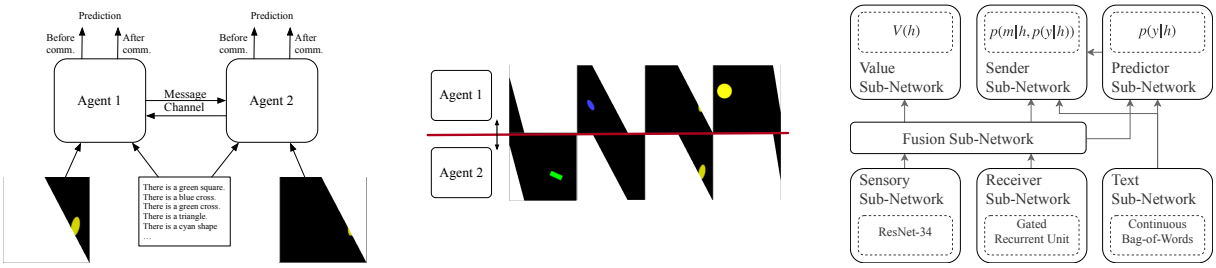

Figure 1: Overview of the communication game and agent structure. **Left**: A graphical illustration of the proposed game. Each of two agents observes a partition of an input image and decides which of ten textual captions best describes the entire image before and after exchanging messages with the other agent. **Middle**: Example training data. Only a random part of each image (dark background) is presented to one agent, necessitating communication in order to solve the game. **Right**: The modular structure of an agent.

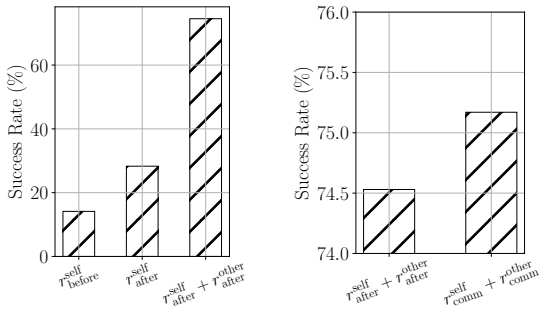

Figure 2: The chance of both agents correctly guessing the answer depends on the reward (averaged over three runs): (**left**) it is important to reward the collective behaviour in order for two agents to collaborate; (**right**) the success rate goes up when we encourage agents to maximize the accuracy *improvement* after communication.

with a reward structure R, designed specifically to require communication-based collaboration. The exchange of information through the communication channel M can take any form. By learning to play the game, agents develop a communication protocol about the observations. This framework allows us to control for proximity constraints, population size and degree of interaction, through the underlying graph structure.

Throughout the game, each agent observes one part of an image that contains an object of a specific shape and color and is given a set of n_{cap} synthetic compositional captions (e.g. "there is a green triangle") of which only one correctly describes the image[1].

The goal is for the agents to identify the correct caption y^* for the image. Since each agent only has partial information, the pair of agents must cooperate via communication to be effective at solving the problem *together*.

At the beginning of the game, each agent makes an initial guess $\hat{y}_0$ of the correct answer, followed by k rounds of communication in which the agents take turns transmitting a binary message to the other agent. In the experiments discussed in this paper, agents communicate using 8-bit binary message vectors. Binary message vectors have been used before for studying the emergence and evolution of language (Kirby and Hurford, 2002). While we selected this type of communication for efficiency reasons, it is straightforward to replace it with sequences of discrete symbols (Jorge et al., 2016; Havrylov and Titov, 2017; Lee et al., 2017; Cao et al., 2018; Lazaridou et al., 2018), continuous vectors or larger binary vectors. After several rounds of communication, each agent makes their final guess $\hat{y}_1$. The game is considered successful if *both* of the agents correctly guessed the answer.

During training, a pair of agents corresponding to adjacent vertices, $a_i \in A$ and $a_j \in A$, is selected at random according to interaction weights $w_{ij} \in W$. One of them is randomly picked as the starting agent. The agents then play one instance of the reference game and their parameters are updated accordingly. The community structure can change during training. For instance, we are able to merge separately trained linguistic communities into a single community and fine-tune the agents from both communities (i.e. bring the communities into contact) to investigate linguistic contact. Once training is done, we can test pairs of distant agents to understand what changed in the protocol.

Reward The reward structure for each agent is designed as follows. First, we reward the agent

[1] ShapeWorld (Kuhnle and Copestake, 2017) was used to derive the data set which includes both the images and captions. See the supplementary material for details.

when it correctly guesses the answer *after* communication $r^{\text{self}}_{\text{after}} = \mathbb{1}_{y^*=\hat{y}_1}$, where $\mathbb{1}$ is an indicator function, in order to encourage it to incorporate information received from the other agent. Second, we reward cooperation by giving each agent a shared reward composed of both its own and the other agent's rewards, i.e., $r_{\text{after}} = r^{\text{self}}_{\text{after}} + r^{\text{other}}_{\text{after}}$. As Fig. 2 shows, we empirically validate the importance of rewarding after-communication behavior and observe that the cooperation reward significantly boosts the success rate. Lastly, we explicitly encourage the agents to rely on communication by rewarding them for *relative improvement from communication*, rather than the success after communication: $r = r^{\text{self}}_{\text{comm}} + r^{\text{other}}_{\text{comm}}$, where $r^{\text{self}}_{\text{comm}} = r^{\text{self}}_{\text{after}} - r^{\text{self}}_{\text{before}}$ and $r^{\text{other}}_{\text{comm}} = r^{\text{other}}_{\text{after}} - r^{\text{other}}_{\text{before}}$. This final reward, which encourages both cooperation and explicit reliance on communication, reaches the highest success rate.

Training Each agent is trained using a hybrid of supervised and reinforcement learning. Each agent computes two predictive distributions before and after message exchange, $p^{\text{before}}(y|h)$ and $p^{\text{after}}(y|h)$, where y refers to one of the n_{cap} image captions and h is the hidden state of the agent network, which fuses perceptual input with the last received message. Since we know the correct caption y^* during training, we use supervised learning to train these two predictive distribution, $\max \log p^{\text{before}}(y^*|h) + \log p^{\text{after}}(y^*|h)$, using backpropagation and stochastic gradient descent (Rumelhart et al., 1986). Since messages are discrete, the message generating process cannot be backpropagated through. Instead, we use REINFORCE (Williams, 1992) to maximize the reward r; $\max \mathbb{E}_{m|h,p(y|h)}[r]$. We add the entropy of the message distribution as a regularization term, encouraging the exploration of various communication strategies in the early stage of learning.

Loss Functions There are four loss functions involved in each game. The first one is a prediction loss function. Given the index y^* of a correct caption, the prediction loss function is

$$\mathcal{L}_{\text{pred}} = -\log p(y = y^*|h).$$

This loss is used twice based on the predictions before and after the message exchange; denoted as $\mathcal{L}^{\text{before}}_{\text{pred}}$ and $\mathcal{L}^{\text{after}}_{\text{pred}}$ respectively.

The second loss is a value loss function. After playing a game, the agent receives a reward r. The agent's value sub-network (see **Fig.1**) learns to predict this reward:

$$\mathcal{L}_{\text{value}} = (r - V(h))^2.$$

The third loss is a message loss function. During training, we sample one message $\tilde{m}$ from the message distribution generated by the agent $p(m|h, p(y|h))$. If this message led to a success, we increase the probability of the sampled message. Otherwise, we decrease it. The success is measured relative to the predicted value. The cost function is then:

$$\mathcal{L}_{\text{msg}} = -(r - \hat{V}(h)) \log p(m = \tilde{m}|h, p(y|h)),$$

where $\hat{V}(h)$ refers to using the predicted value but not updating the value sub-network according to this loss function. The gradient of this message loss function with respect to $p(m = \tilde{m}|h, p(y|h))$ corresponds to REINFORCE (Williams, 1992).

Lastly, we include an entropy penalty. Following (Evtimova et al., 2018), we encourage the entropy of the message distribution to be higher to facilitate exploration:

$$\mathcal{L}_{\text{entropy}} = -\mathcal{H}(p(m|h, p(y|h))).$$

The overall loss function is then the weighted sum of the four loss functions:

$$\mathcal{L} = \alpha_{\text{pred}}\mathcal{L}_{\text{pred}} + \alpha_{\text{value}}\mathcal{L}_{\text{value}} + \alpha_{\text{msg}}\mathcal{L}_{\text{msg}} + \alpha_{\text{entropy}}\mathcal{L}_{\text{entropy}},$$

where we set $\alpha_{\text{pred}} = 1.0$, $\alpha_{\text{value}} = 1.0$, $\alpha_{\text{msg}} = 1.0$ and $\alpha_{\text{entropy}} = 0.01$.

4 Experiments

When Are Protocols Symmetric? We first examine whether it is sufficient to have just two autonomous agents to develop a common communication protocol. That is, we ask whether a *symmetric* language emerges when there are only two agents in a linguistic community, or that they learn to speak distinct idiolects. We formally define "mutual intelligibility" in the communication protocol as the ability for each agent to play the game against itself. This is an elegant solution: if a shared communication protocol has emerged, the agent would not have any trouble playing a game with itself during test time (she "understands" what she "says" and "says" what she "understands"). We run five simulations with

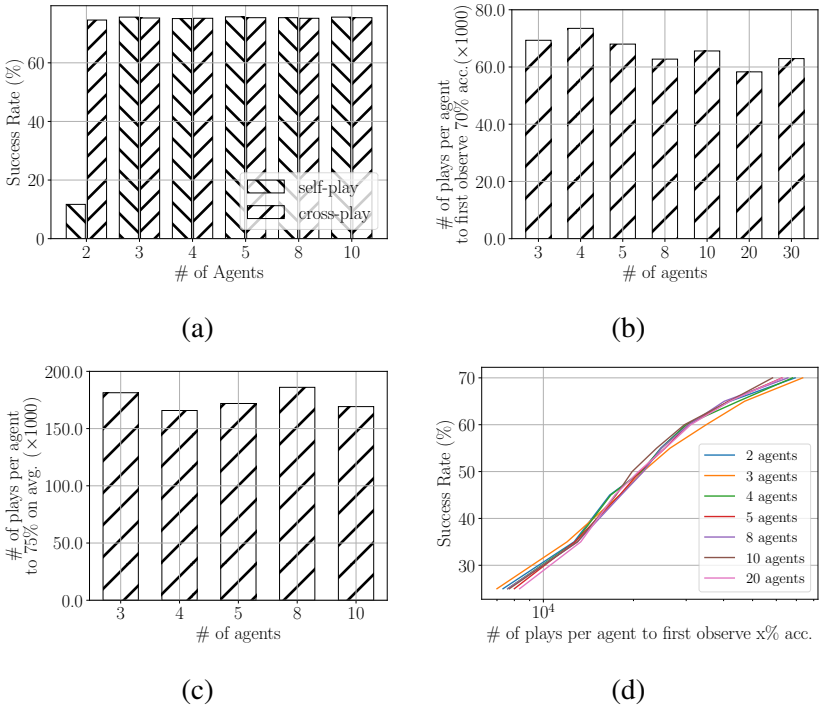

Figure 3: Emergence of symmetric linguistic protocols (averaged over five runs). **(a)** Six communities were trained: we show the success rates under self-play and cross-play. We observe that at least three agents are necessary for the emergent protocol to be symmetric—without any specialized mechanism that enforces the symmetry of emergent protocol. **(b)** The average number of plays per agent to the first observed success rate $\geq 70\%$ between a pair of agents in a linguistic community approximately stays constant with respect to the community size. **(c)** The number of plays required for each agent in a linguistic community to reach the success rate of 75% on average across all agents pairs in the community approximately stays constant with respect to the community size. **(d)** Each agent learns at approximately the same rate regardless of community size, which suggests that the emergent protocol emerges incrementally in a distributed manner rather than in a centralized way.

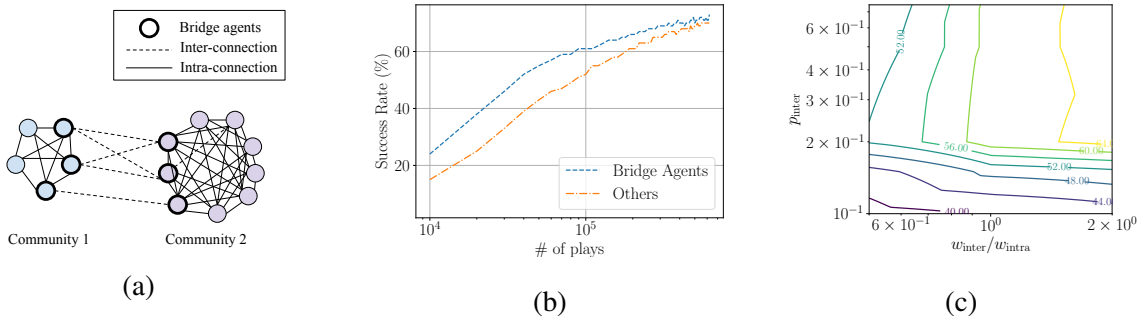
random initialization and examine the success rate between two agents averaged over all the test examples, where the agents succeed on each example if both of them correctly guess the answer after communication.

As shown in **Fig. 3** (a), two agents can play the game with a high success rate when they play with each other (cross-play). However, the success rate drops to random chance (10%) when each agent plays against itself (self-play). This suggests that the emergent communication protocol is not symmetric: each agent has developed its own protocol, to which the other has adapted, leading to two incompatible idiolects, similar to previous observations in both fully (Matignon et al., 2012) and partially observable settings (Lanctot et al., 2017).

We then run additional experiments having more than two agents, where every pair of agents (v_i, v_j) interacts with an equal interaction intensity $w_{ij} = c$ (the success rate is averaged over all possible pairs of agents, unless stated otherwise). We notice that the success rates between self-play and cross-play are indistinguishable, strongly implying that a common, shared language emerges as a social convention if and only if we have more than two language users. This finding demonstrates that it is not strictly necessary to specifically equip an agent with an innate mechanism that ties listening and speaking, such as the obverter technique (Oliphant and Batali, 1997; Choi et al., 2018), nor any explicit community-wide coordination. All that is needed in order for a common language to emerge, at least within this framework, is a minimum number of agents.

We observe no detrimental effect to increasing the number of agents per linguistic community, even though more agents have to come to agree on a single protocol. As shown in **Fig. 3** (b–c), it takes approximately 60–65,000 plays per agent for us to observe the first instance of a pair of agents reaching the success rate of 70% regardless of the community size. Similarly, it takes approximately



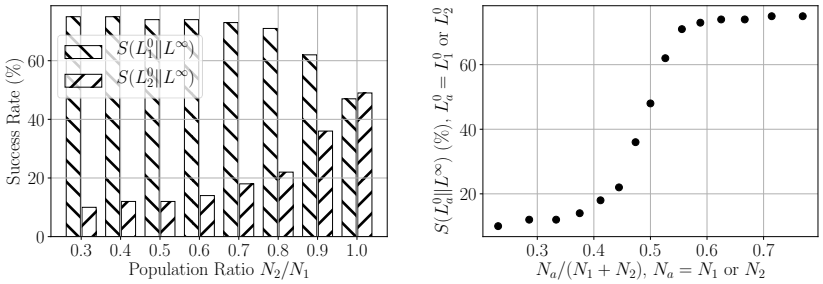


Figure 4: The consequences of contact between two linguistic communities with initially distinct protocols. **(a)** Two linguistic communities come in contact. **(b)** Two communities of population ten each came in contact with the ratio of learning frequencies $(K\ w_{\text{inter}})/(L\ w_{\text{intra}}) = 1$ and the inter-group connectivity $p_{\text{inter}} = 0.2$, after being separately trained in isolation (averaged over five runs). The bridge agents, who interact with the agents from the other community, learn faster and better the new, shared emergent protocol. All the other agents however also rapidly learn to communicate with the agents from the other community, although they never interact directly with them. **(c)** Contour plot visualization of the success rate after 200,000 plays after the contact by two linguistic communities while varying the ratio of learning frequencies $(Kw_{\text{inter}})/(Lw_{\text{intra}})$ and the inter-group connectivity p_{inter} (linearly interpolated from 15 experiments.) We observe that the success rate, which measures the level of convergence of two protocols, requires a certain level of the inter-group connectivity ($p_{\text{inter}} > 0.2$). Even when the inter-group connectivity is high enough, we further see that the bridge agents must interact with the agents from the other community enough ($(Kw_{\text{inter}})/(Lw_{\text{intra}}) \geq 1$) for the converged protocol to be well understood by the agents from both communities.

150-200,000 plays per agent for the success rate averaged over all pairs of agents in a community to reach 75%, again, regardless of the size of the community. Surprisingly, the speed at which each agent learns stays constant with respect to the community size, as in **Fig. 3** (d). That is, we did not observe any correlation between community size and linguistic convergence of the entire community, which would probably only come into play with orders of magnitude more agents or for more complex reference games.

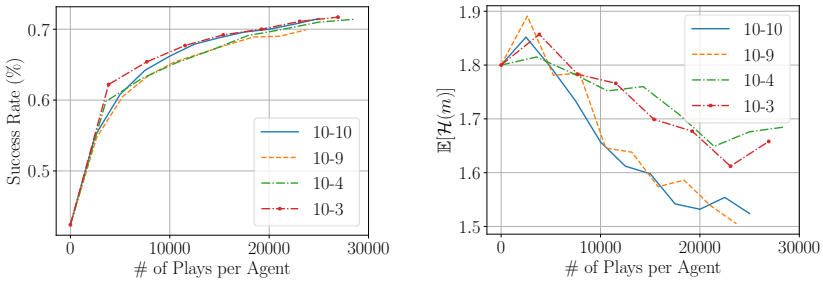
Understanding Convergence We next examine what happens when we expose different linguistic communities *to each other*. Specifically, we consider two linguistic communities of population sizes N_1 and N_2, which are trained independently from each other as fully-connected communities and have developed separate communication protocols. We bring these two communities into contact with each other by introducing a new set of inter-community edges with probability p_{inter} to form a new linguistic community. We assign a weight w_{inter} to all the inter-group edges and another weight w_{intra} to all the intra-group edges. We then examine how "interaction intensity" relates to language shift. See **Fig. 4** (a).

We first investigate two communities of identical population sizes ($N_1 = N_2$) with the ratio of the learning frequencies of the intra-group pairs and inter-group pairs set to $(Kw_{\text{inter}})/(Lw_{\text{intra}}) = 1$, where K is the number of inter-community connections and L is the number of intra-community connections, and the inter-group connectivity chance set to $p_{\text{inter}} = 0.2$. We notice in **Fig. 4** (b) that the bridge agents learn to communicate better more rapidly (evident from the higher success rate among themselves), but the other agents quickly catch up (according to the success rate among themselves excluding the bridge agents), although these other agents never directly interact with agents from the other community. This finding demonstrates the rapid shift toward a common protocol in both groups where all agents learn to speak a shared language, regardless of whether they actually interact with agents from the other group.

Having established that linguistic contact leads to convergence of the communication protocol, we delve deeper into the impact of two major parameters, the ratio $(Kw_{\text{inter}})/(Lw_{\text{intra}})$ and the connectivity probability p_{inter}. We vary the ratio $(Kw_{\text{inter}})/(Lw_{\text{intra}})$ of the learning frequencies of the intra-group pairs and inter-group pairs between $2/1$, $1/1$ and $1/2$, while fixing the inter-group connectivity to $p_{\text{inter}} = 0.2$. After 200,000 plays, the former ($(Kw_{\text{inter}})/(Lw_{\text{intra}}) = 2/1$) converges to a more tightly coupled linguistic community,

(a) (b)

Figure 5: Relationship between the common emergent protocol and the original protocols after linguistic contact between two communities (averaged over five runs). **(a)** Divergence of the common emergent protocol from the original protocols. Agents converge either to the majority protocol or to one in-between the two originals. **(b)** By varying the population ratio, it becomes clear that a near-even balance between two communities is necessary for a novel, contact protocol to emerge rather than the domination by a majority protocol.



achieving 65.6% success rate between agents that never interacted with each other. On the other hand, when the inter-group interaction occurred only half as frequently as the intra-group interaction, the agents from the two groups can play together with a much lower 52.4% success rate. We observed similar patterns over many different combinations of the ratio and inter-group connectivity. For example, we varied the inter-group connectivity p_{inter} between 0.1, 0.15, 0.2, 0.5 and 0.75 while the interaction ratio was fixed to $(Kw_{\text{inter}})/(Lw_{\text{intra}}) = 2/1$. After 200,000 plays, we observed the success rates, averaged over all possible inter-group pairs, reach 42.1%, 51.1%, 65.55%, 66.65% and 66.3%, respectively. This implies that there is a critical level of inter-group connectivity (around 0.2 in this specific case) after which language propagation saturates.

In **Fig. 4** (c), we plot the interplay between the ratio $(Kw_{\text{inter}})/(Lw_{\text{intra}})$ and the inter-group connectivity p_{inter} after interpolating from the fifteen experiments varying these parameters. This demonstrates that both parameters are important in determining the level of linguistic convergence.

Birth of a New Language: Emergence of a Contact Language We investigate the effect of the population size ratio N_1/N_2 between two linguistic communities when they come in contact. We study how population size is a factor in one language coming to "dominate" another language upon contact. We vary the ratio by fixing $N_1 = 10$ and varying $N_2 \in \{3, \ldots, 10\}$. Each community is pretrained in isolation to develop its own protocol before being exposed to the other. We set the interaction ratio $(Kw_{\text{inter}})/(Lw_{\text{intra}})$ to 1 and the inter-group connectivity chance p_{inter} to 0.2.

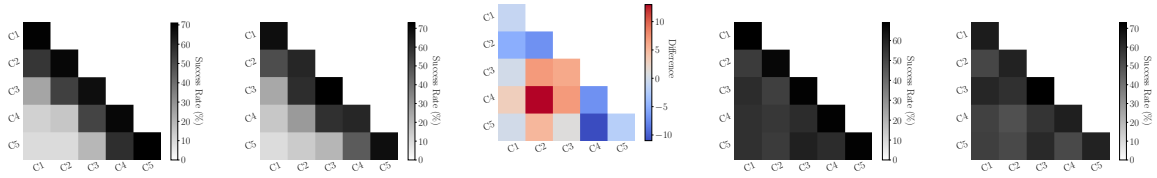
We refer to the original protocols of the communities right after pretraining by L_1^0 and L_2^0. Each of these is then evolved further after these two communities come in contact, resulting in L_1^∞ and L_2^∞. The previous experiment on linguistic contact suggests that $L_1^\infty \approx L_2^\infty$ based on the fact that the agents from both communities can successfully play the game after coming in contact, so we refer to the final protocol as L^∞. We examine how similar L^∞ is to either of the original protocols, L_1^0 or L_2^0. This similarity is measured by letting the agent using L_1^0 or L_2^0 play against the one using L^∞, which is naturally facilitated by the proposed framework. This "historical self-play" accuracy $S(L_\cdot^0\|L^\infty)$ reflects the similarly of the original and final protocols.

When the population ratio deviates from $N_1/N_2 = 1$, we observe that the final protocol rapidly converges to the majority protocol (L_1^0), evident from the near-perfect $S(L_1^0\|L^\infty)$ and the near-chance $S(L_2^0\|L^\infty)$ in **Fig. 5**. This results from the fact that members of both communities are rewarded for cooperating and playing the game well (via the bridge agents). In other words, the agents prefer to integrate or assimilate rather than segregate, similar to how it has been found that minority groups shift toward the use of dominant language (Fase et al., 1992). On the other hand, we observe $S(L_1^0\|L^\infty) \approx S(L_2^1\|L^\infty)$ and that both of these historical self-play accuracies are significantly above chance, when the population ratio is closer to or exactly 1. It is impossible to identify either L_1^0 or L_2^0 as an ancestor of L^∞, but

(a) Success Rate

(b) $\mathbb{E}[\mathcal{H}(p(m|h, p(y|h)))]$

Figure 6: Evolution of success rate and protocol complexity as two communities of varying populations come into contact (averaged over three runs). Agents were finetuned until the average success rate reached at least 70%. The success rate evolves similarly in terms of the number of plays per agent. **(a)** We observe significantly different levels of complexity dependent on the population ratio. **(b)** The complexity is generally lower when the sizes of two communities are more balanced (10-10 and 10-9), while the complexity does not decrease as much when there is a significant imbalance in sizes between two communities (10-4 and 10-3).



L^{∞} is rather a combination of these two original protocols, which is a key characteristic of contact languages (Matras, 2009). Both of these observations suggest the potential of the proposed framework for simulating and understanding the birth and death of new languages via linguistic contact.

We further investigate the complexity of the contact language arising from two linguistic communities coming into contact. We define complexity as the uncertainty of an agent when generating a message, and measure the entropy of the message distribution $\mathcal{H}(p(m|h, p(y|h)))$. Higher entropy indicates that agents can express states in many different ways: in other words, the more complex a language, the higher the degree of freedom. For each linguistic community, we then compute the average of their message distributions in order to characterize the complexity of a learned communication protocol.

We observe in **Fig. 6** (b) that the complexity decreases when two communities come into contact. This observation agrees with a similar phenomenon of structural simplification in creole languages which are understood to arise from the contact of two or more languages (Parkvall, 2008; Bakker et al., 2011). We also observe that the complexity plateaus earlier when there is a larger imbalance between two communities' population (10-3 and 10-4), while it drops further with more balanced communities (10-9 and 10-10). This implies that the new-born contact languages arising from the contact of two similarly-sized communities tend to be substantially simpler.

A Linguistic Continuum of Contact We generalize the previous setting to having $M > 2$ linguistic communities in various topologies. We start by pretraining M linguistic communities of populations $N_1, N_2, \ldots, N_M$ respectively, evolving M distinct communication protocols. We then chain them such that each consecutive pair, C_i and C_{i+1}, comes in contact with a pre-specified intergroup connectivity chance p_{inter} and interaction ratio $(Kw_{\text{inter}})/(Lw_{\text{intra}})$, and begin training all of the communities jointly. We study the emergence of a linguistic continuum, similar to the dialect continuums that can be found in natural languages such as the Nordic Germanic dialects of Scandinavia (Chrystal, 1987). Often, speakers on the border are mutually intelligible, while those from communities geographically separated by many intermediate ones cannot communicate.

We start by considering a chain of five communities of equal population ($M = 5$). As plotted in **Fig. 7** (a), we clearly observe the emergence of a linguistic continuum. The agents from a pair of adjacent communities can communicate with each other almost as well as those within a single community, while communicability rapidly degrades as the distance between a pair of communities grows (off-diagonal). The agents from C_1 and C_5 cannot understand each other at all, achieving the near-chance success rate. A similar continuum is observed when we increased the population of the center community two-fold (5→10). This continuum however exhibits properties different from the original chain of equal-sized communities: the center communities C_2, C_3 and C_4

(a) 5-5-5-5-5 (b) 5-5-10-5-5 (c) Difference (b)-(a) (d) Dense (a) (e) Dense (b)

Figure 7: We plot the protocol similarities among five communities in a chain (averaged over three runs). **(a)** Neighbouring communities exhibit higher protocol similarities, but distant communities are not mutually intelligible. **(b)** With a larger community in the middle of a chain, we observe higher levels of protocol similarities among the communities in the chain. **(c)** Differences between the two, showing that the protocols near the center become more similar to each other when the center community dominates, at the expense of intelligibility between further-removed communities. **(d, e)** We do not observe a continuum when the communities are connected densely.

become more tightly coupled, as evident from the higher success rate among those in **Fig. 7** (b-c). This however happens at the cost of communicability between the agents from furthest-removed communities.

To see if the emergence of such a continuum is due to topological properties of communities, we show similarities $S(L_i^\infty \| L_j^\infty)$ among the five communities when densely connected in **Fig. 7** (d-e). Unlike for chaining, we ensure that every pair of communities comes in contact with each other in a densely connected topology. All communities are uniformly similar, confirming that the linguistic continuum arises from the topology.

5 Discussion and Conclusion

We have described a framework for the large-scale investigation of complex linguistic phenomena via multi-agent communication games. We started by observing that a symmetric communication protocol emerges without any innate, explicit mechanism built in an agent, when there were three or more of them in a community. We then demonstrated the emergence of several complex linguistic phenomena in this simple framework.

First, the result of linguistic contact between communities is determined by inter- and intra-group connectivity patterns. Given sufficient inter-group connectivity, languages become mutually intelligible through contact, even for agents that have not been exposed to the other language. Second, linguistic contact over time either converges to the majority protocol, leading to the extinction of the other language, or gives rise to an original "creole" protocol that has lower complexity than the original languages, if the communities are balanced. Third, a linguistic continuum emerges, where neighboring languages are more mutually intelligible than farther removed languages. The topology of the continuum governs its behavior, and a very dominant central language causes its neighbors to lose mutual intelligibility with communities that are not directly exposed to that central language.

We conclude that intricate properties of language evolution need not depend on complex evolved linguistic capabilities, but can emerge from simple social exchanges between perceptually-enabled agents playing communication games. Language evolution and its properties can be effectively and efficiently investigated in-depth under the proposed framework.

In future work, it would be useful to investigate more complicated environments and more complex agent interactions. The setting in this paper included a very simple vision task, and we suspect emergent linguistic phenomena would be more pronounced and even more interesting to study in more sophisticated settings.

TalkDown: A Corpus for Condescension Detection in Context

Abstract

Condescending language use is caustic; it can bring dialogues to an end and bifurcate communities. Thus, systems for condescension detection could have a large positive impact. A challenge here is that condescension is often impossible to detect from isolated utterances, as it depends on the discourse and social context. To address this, we present TALKDOWN, a new labeled dataset of condescending linguistic acts in context. We show that extending a language-only model with representations of the discourse improves performance, and we motivate techniques for dealing with the low rates of condescension overall. We also use our model to estimate condescension rates in various online communities and relate these differences to differing community norms.

1 Introduction

Condescending language use can derail conversations and, over time, disrupt healthy communities. The caustic nature of this language traces in part to the ways that it keys into differing social roles and levels of power (Fournier et al., 2002). It is common for people to be condescending without realizing it (Wong et al., 2014), but a lack of intent only partly mitigates the damage it can cause. Thus, condescension detection is a potentially high-impact NLP task that could open the door to many applications and future research directions, including, for example, supporting productive interventions in online communities (Spertus, 1997), educating people who use condescending language in writing, helping linguists to understand the implicit linguistic acts associated with condescension, and helping social scientists to study the relationship between condescension and other variables like gender or socioeconomic status.

Progress on this task is currently limited by a lack of high-quality labeled data. A deeper challenge is that condescension is often impossible to detect from isolated utterances. First, a characteristic of condescending language is that it is not overtly negative or critical – it might even include (insincere) praise (Huckin, 2002). Second, condescension tends to rest on a pair of conflicting pragmatic presuppositions: a speaker presumption that the speaker has higher social status than the listener, and a listener presumption that this is incorrect. For example, an utterance that is entirely friendly if said by one friend to another might be perceived as highly condescending if said by a customer to a store clerk. In such cases, the social roles of the participants shape the language in particular ways to yield two very different outcomes.

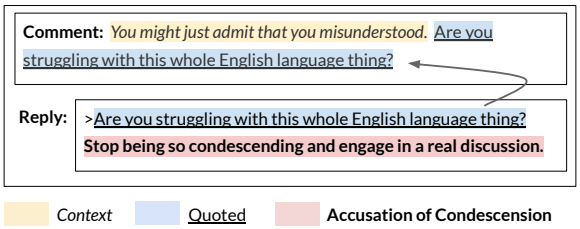

Figure 1: In this example, the REPLY quotes from part of the COMMENT and says that this QUOTED text is condescending.

In this paper, we seek to facilitate the development of models for condescension detection by introducing TALKDOWN, a new labeled dataset of condescending acts in context. The dataset is derived from Reddit, a thriving set of online communities that is diverse in content and tone. We focus on COMMENT and REPLY pairs of the sort given in Figure 1, in which the REPLY targets a specific quoted span (QUOTED) in the COMMENT as being condescending. The examples were multiply-labeled by crowdsourced workers, which ensures high-quality labels and allows us to include nu-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3711–3719,

anced examples that require human judgment.

Our central hypothesis is that context is decisive for condescension detection. To test this, we evaluate models that seek to make this classification based only on the QUOTED span in the COMMENT as well as extensions of those models that include summary representations of the preceding linguistic context, which we treat as an approximation of the discourse context in which the condescension accusation was made. Models with contextual representations are far superior, bolstering the original hypothesis. In addition, we show that these models are robust to highly imbalanced testing scenarios that approximate the true low rate of condescension in the wider world. Such robustness to imbalanced data is an important prerequisite for deploying models like this. Finally, we apply our model to a wide range of subreddits, arguing that our estimated rates of condescension are related to different community norms.

2 The TALKDOWN Corpus

We chose Reddit as the basis for our corpus for a few key reasons. First, it is a large, publicly available dataset from an active set of more than one million user-created online communities (subreddits).[1] Second, it varies in both content and tone. Third, users can develop strong identities on the site, which could facilitate user-level modeling, but these identities are generally pseudonymous, which is useful when studying charged social phenomena (Hamilton et al., 2017; Wang and Jurgens, 2018). Fourth, the subreddit structure of the site creates opportunities to study the impact of condescension on community structure and norms (Buntain and Golbeck, 2014; Lin et al., 2017; Zhang et al., 2017; Chandrasekharan et al., 2018).

The basis for our work is the Reddit data dump 2006–2018.[2] We first extracted COMMENT/REPLY pairs in which the REPLY contains a condescension-related word. After further filtering out self-replies and moderator posts, and normalizing links and references, we obtain 2.62M COMMENT/REPLY pairs.

Not all of these examples truly involve the REPLY saying that the QUOTED span is condescending. Our simple pattern-based extraction method is not sufficiently sensitive. To address this, we conducted an annotation project on Amazon Mechanical Turk. Our own initial assessment of 200 examples using a five-point Likert scale revealed two things that informed this project.

	Median	Mean	Std.	Max
QUOTED	18	22.79	18.40	399
REPLY	67	100.92	112.34	1,921
CONTEXT	47	98.40	154.59	2,136

Table 1: Basic statistics of the length of the examples in the corpus. CONTEXT is everything in the COMMENT before the QUOTED span.

First, we saw a clear split in the positive instances of condescension. In some, specific linguistic acts are labeled as condescending ("This is really condesending"), whereas others involve general user-level accusations that are not tied to specific acts ("You're so condescending"). We chose to focus on the specific linguistic acts. They provide a more objective basis for annotation, and they can presumably be aggregated to provide an empirically grounded picture of user-level behavior (or others' reactions to such behavior). Thus, for positive instances of condescension, we further limited our attention to COMMENT/REPLY pairs in which the REPLY contains a direct quotation from the COMMENT, using fuzzy match based on Levenshtein distance (Navarro, 2001), as illustrated in Figure 1. We extracted 66K such examples. Some statistics on these examples is given in Table 1.

Second, with the above ambiguity addressed, the signal of condescending or not is mostly clear. Thus, we designed the annotation project around a three-way multiple choice question: *condescending*, *not condescending*, and *cannot decide*. Each task began with instructions and two training questions, following by 10 different COMMENT/REPLY pairs to be labeled. Appendix A.2 provides screenshots of the annotation interface.

To process the annotations, we filtered out the work of annotators who did not correctly answer the training questions. The remaining annotators have moderate to substantial agreement (Fleiss $\kappa = 0.593$; Fleiss 1971; Landis and Koch 1977). We then used Expectation–Maximization, as in Dempster et al. 1977, to assign labels. This yields slightly better quality in our hand-inspection than labels by majority vote, presumably because it factors individual worker reliability into the decision making. In the end, we obtained 4,992 valid labeled instances: 65.2% labeled as *conde-*

	Positive	Negative
Balanced (1:1)	3,255	3,255
Imbalanced (1:20)	3,255	65,100

Table 2: Basic statistics of our dataset.

scending (henceforth, *positive*), and 34.8% as *non-condescending* (henceforth, *negative*).[3]

To fully balance the dataset, we pulled out one random month's data for each year in 2011 to 2017. We extracted instances using the same methods as described above, but we filtered out COMMENT/REPLY pairs in which a condescension-related word appeared. Our final dataset thus consists of annotated positive and negative instances, with supplemental randomly-sampled negative instances. For our experiments, we partitioned the data into 80% train, 10% development, and 10% test splits. In addition, to simulate real-world situations, we built a dataset with a 1:20 ratio of positive to negative instances.[4] The basic statistics of the dataset are shown in Table 2.

3 Experiments

We now establish some baselines for the TALKDOWN Corpus and begin to test the hypothesis that contextual representations are valuable for this task. To do this, we use the BERT model of Devlin et al. (2019), which uses a Transformer-based encoder architecture (Vaswani et al., 2017) to learn word representations by training against a masked language modeling task and a next-sentence prediction task. Our models are initialized with the pretrained representations released by the BERT team and a fully connected layer on the top (Figure 4 in Devlin et al. 2019), which is then fine-tuned to our dataset (Peters et al., 2019). We explore both BERT Base ($BERT_B$) and BERT Large ($BERT_L$),[5] to determine whether the added expense of using $BERT_L$ is justified. Appendix B provides details on our process of hyperparameter tuning and optimization.

[3]There was just one case where *cannot decide* was the chosen label; it was in Spanish, so we excluded it and added a language classification step to our preprocessing pipeline.

[4]To the best of our knowledge, there is no prior work on what percentage of conversations on Reddit (or, more broadly, in daily conversations) are condescending. Thus, we chose the ratio based on informal observations on Reddit.

[5]The whole-word masking model was used as it performs better than the original one in multiple benchmarks.

Input 1	Input 2	Model	Imb. F1	Bal. F1
QUOTED ∧ CONTEXT		∧ $BERT_L$	**0.684**	**0.654**
QUOTED ∧ CONTEXT		∧ $BERT_B$	0.657	0.596
QUOTED		∧ $BERT_L$	0.650	0.640
	CONTEXT	∧ $BERT_L$	0.611	0.513
		random	0.371	0.500
		majority	0.488	0.333

Table 3: Performance (macro-F1) for predicting condescension on balanced and imbalanced versions of TALKDOWN. Model selection was done according to the procedure described in Appendix B.

	QUOTED + CONTEXT		QUOTED	
Ratio	Imb. F1	Bal. F1	Imb. F1	Bal. F1
1:1	0.542	**0.708**	0.554	**0.690**
1:20	0.670	0.574	0.620	0.518
2:20	0.682	0.619	0.640	0.554
3:20	**0.684**	0.654	0.646	0.585
4:20	0.678	0.632	**0.650**	0.640
5:20	0.668	0.626	0.645	0.582
10:20	0.672	0.656	0.641	0.640
15:20	0.665	0.641	0.641	0.593
20:20	0.674	0.621	0.645	0.597

Table 4: The impact of different train-set positive:negative ratios. All the models are $BERT_L$. The first row is based on the balanced dataset, and the rest are based on the imbalanced dataset with different oversampling ratios. Model selection again used the procedure in Appendix B.

3.1 Predicting Condescension

Table 3 summarizes the results of our core experiments. Input 1 and Input 2 describe the basis for the feature representations. Thus, for example, QUOTED∧CONTEXT is a model that uses both the quoted span and the preceding linguistic context. We report two testing scenarios: *Balanced* and *Imbalanced*, in which there are 20 negative examples for each positive example.

The results clearly support our hypothesis that context matters; using the QUOTED part and CONTEXT together give us 3–4% boost in macro-F1 using the same model architecture. In addition, we see that increasing the capacity of the model also helps, though more modestly. It's noteworthy that the performance of using the QUOTED part is better than that of using CONTEXT alone, though the QUOTED part is roughly three times shorter. Thus, there is a strong signal in the QUOTED part – the replier chose this span for a reason – but the context contains a signal as well.

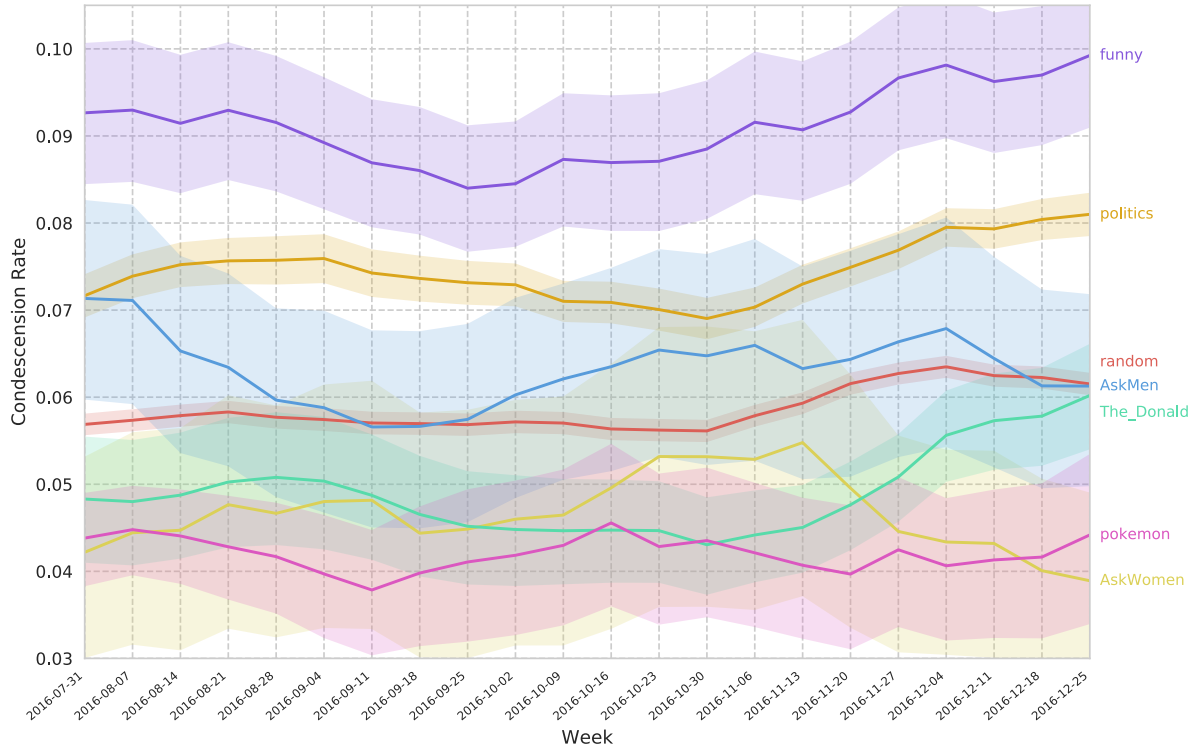

Figure 2: Condescension rates over time in a selection of subreddits, as predicted by our best model. The time window is centered around the 2016 U.S. Presidential Elections. We calculate a rolling mean with a window size of 5 and use July 2016 only for smoothing. We obtain 95% confidence intervals via bootstrapping.

3.2 Imbalanced Testing Scenarios

Imbalanced testing scenarios are more challenging, but they also better reflect usage rates of condescending language in public forums like Reddit. To further understand how best to get traction on this problem, we explored a range of different methods for creating training data. Our results are summarized in Table 4. As expected, the balanced problem is best addressed with a balanced dataset. For the imbalanced problem, we found that an oversampling ratio of 2 to 4 yielded the best performance. Our full QUOTED ∧ CONTEXT model is again clearly superior in these scenarios.

3.3 Condescension Rates Across Subreddits

Our hope for TALKDOWN is that it will play a role in developing systems that can help identify condescending acts on social media. This will depend on models trained on TALKDOWN being able to get an accurate read on condescension at scale. As a first step towards assessing this capability, we ran our models on 14 subreddits, over the time period of July 2016 to December 2016, which covers the 2016 U.S. Presidential Election, an event that we expect to influence condescension rates in various ways across Reddit. Appendix C lists these subreddits along with their post counts and estimated average rates of condescension. Figure 2 highlights a selection of them.

As a baseline, we include a 10% random sample from the top 100 most active subreddits.[6] Consistently above this baseline are 'politics' and 'funny'. It makes sense that an overtly political subreddit would show a high rate of condescension (as do 'news' and 'worldnews'; Appendix C): it's a contentious topic in a contentious time period; see also the rising rate for 'The_Donald' in the post-election period. It is more surprising that 'funny' shows the highest rates. We do not have a deep understanding of why this is, but it could trace to our model confusing irony and sarcasm with condescension.

Below the baseline are 'AskWomen' and 'pokemon'. We expect 'pokemon' to have low rates of condescension, as it strikes us as a supportive community. However, one might be surprised to see 'AskWomen' so low, especially as compared with 'AskMen', which has high rates in general.

[6]This is derived from the 'subscribers' section in http://redditlist.com/all, excluding 'announcements'.

There is wide support for the idea that women experience more condescension than men do (Hall and Braunwald, 1981; Harris, 1993; McKechnie et al., 1998; Cortina et al., 2002; Trix and Psenka, 2003), as reflected in the recent lexical innovation *mansplaining*, which can be roughly paraphrased as 'a man condescending to a woman'.[7] However, community norms on 'AskWomen' and 'AskMen' are likely shaping these outcomes. Whereas the description for 'AskWomen' says it is "curated to promote respectful and on-topic discussions, and not serve as a debate subreddit", the description for 'AskMen' ends with "And don't be an asshole. Also, go away."

4 Conclusion

We introduced TALKDOWN, a new annotated Reddit corpus of condescending linguistic acts in context. Using BERT, we established baseline models that suggest this is a challenging task, and one that benefits from rich contextual representations. Finally, in qualitative analyses on diverse subreddits, we offered initial evidence that models trained on TALKDOWN generalize to new data, a prerequisite for using them to help improve online communities via condescension detection. The full dataset with the pretrained BERT model is available at `http://github.com/zijwang/talkdown`.

Acknowledgements

We would like to thank David Jurgens for his help with the Reddit dataset, Yulia Tsvetkov and Dan Jurafsky for their insightful early-stage suggestions, Lucy Li for detailed comments on an early draft of the paper, and our anonymous EMNLP–IJCNLP reviewers for their helpful feedback. We would also like to thank our Mechanical Turk contributors for their help in annotating the TALKDOWN Corpus. This research is based in part upon work supported by a Google Faculty Research Award and by the NSF under Grant No. BCS-1456077.

A Data

A.1 In-house Annotation Analysis

Figure 3 shows the five-point Likert scale annotations between two in-house annotators. It can be seen that the signal of condescending or not is clear, and the agreement level between the two annotations is substantial: the Fleiss' κ is 0.613 for the five-point scale and 0.732 when normalized to three-point scale used in the paper (Fleiss, 1971; Landis and Koch, 1977).

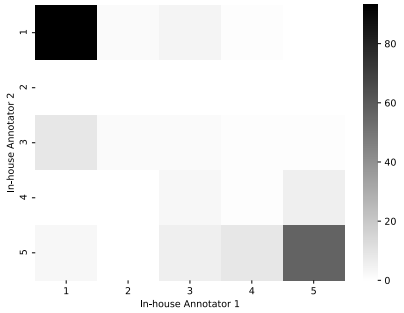

Figure 3: Heatmap for in-house initial assessment with a five-point Likert scale.

A.2 Annotation Interface

In this section, we show examples of the annotation interface we used on Amazon Mechanical Turk: Figure 4 and Figure 5.

Annotators were presented with the task name, the instructions, and two simple training questions, followed by a warning in red saying they needed to pass the training questions to proceed (Figure 4). They had unlimited trials for the training questions, and explanations (for both correct and incorrect answers) were presented directly after each trial. This helped the annotators learn how to approach the task.

After they passed the training questions, they were prompted that they could start to do the test questions (Figure 5). The interface of the test questions was similar to that of the training questions, but without explanations after selections. We explicitly checked that the annotators had made selections on each test question before submission, while this was not forced for training questions. This was to filter out possibly low-quality annotations, where the annotators did not pay attention to the instructions.

B Model Hyperparameters

Our BERT models were trained using a set of hyperparameters based on the recommendations in Devlin et al. 2019. Specifically, we set:

- Model Architecture:
  - $BERT_B$: Bert Base, Cased
  - $BERT_L$: Bert Large, Cased, with whole-word masking
- Learning rate: $\{0.5, 0.8, 1, 2, 3, 5\} \cdot 10^{-5}$
- Epoch: 2, 3
- Batch size: 32
- Max sequence length: 512

When optimizing these models, we set the batch size to 32 in order to ensure there was at least one positive instance per mini-batch. Grid search was performed with different learning rates and oversampling ratios, and best models were selected based on the best performance on the development set under the imbalanced setting. We found that oversampling 2 to 4 times the positive class (i.e., 10%–20% of the number of instances in the negative class) generally yielded good performance in all the experiments we ran. For all experiments, we used the HuggingFace PyTorch implementation of BERT.[8]

C Subreddit Condescension Rates

Table 5 shows basic statistics for all the subreddits we analyzed.

Subreddit	#Pairs	Mean rate	Std. err
4chan	6,099	0.072	0.189
AskMen	19,406	0.064	0.164
AskReddit	256,181	0.049	0.147
AskWomen	9,021	0.046	0.129
The_Donald	57,429	0.051	0.149
aww	8,727	0.059	0.168
funny	71,875	0.092	0.214
gaming	64,881	0.064	0.175

Summary Cloze: A New Task for Content Selection in Topic-Focused Summarization

Daniel Deutsch and Dan Roth
Department of Computer and Information Science
University of Pennsylvania
{ddeutsch,danroth}@seas.upenn.edu

Abstract

A key challenge in topic-focused summarization is determining what information should be included in the summary, a problem known as content selection. In this work, we propose a new method for studying content selection in topic-focused summarization called the *summary cloze* task. The goal of the summary cloze task is to generate the next sentence of a summary conditioned on the beginning of the summary, a topic, and a reference document(s). The main challenge is deciding what information in the references is relevant to the topic and partial summary and should be included in the summary. Although the cloze task does not address all aspects of the traditional summarization problem, the more narrow scope of the task allows us to collect a large-scale datset of nearly 500k summary cloze instances from Wikipedia. We report experimental results on this new dataset using various extractive models and a two-step abstractive model that first extractively selects a small number of sentences and then abstractively summarizes them. Our results show that the topic and partial summary help the models identify relevant content, but the task remains a significant challenge.

1 Introduction

Topic-focused multi-document summarization (MDS) has long been a goal for natural language processing (Dang, 2005, 2006). In contrast to generic summarization, topic-focused summarization systems attempt to summarize a set of reference documents with respect to a specific topic or information need.

Recent research on summarization has mostly focused on generic summarization, in part due to the size of the available datasets. Work on topic-focused summarization (Lin and Bilmes, 2011; Ma et al., 2016; Feigenblat et al., 2017) is largely based on the DUC 2005 and 2006 datasets (Dang, 2005, 2006), which are orders of magnitude smaller than comparable generic summarization datasets (Nallapati et al., 2016; Grusky et al., 2018). Because the available corpora are so small, it is difficult to use them to train recent state-of-the-art summarization systems, which require large amounts of training data.

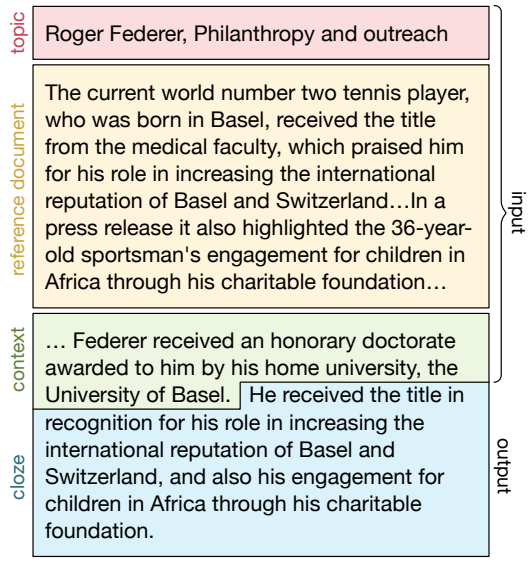

Figure 1: Given a topic, reference document, and a partial summary (the context), the objective of the summary cloze task is to predict the next sentence of the summary, known as the cloze.

Instead of focusing on the full topic-focused MDS problem, we address one aspect of the task known as *content selection*, the problem of deciding what information should be included in the summary (Nenkova, 2006b). Narrowing the scope of the problem makes it easier to collect a large-scale dataset that is tailored to the specific task and thus build upon recent work on summarization.

To that end, we formulate a new task for content selection in topic-focused summarization which

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3720–3729,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

we call the *summary cloze* task (§2). Given a topic, a partial summary, and a reference document(s), the goal of the summary cloze task is to produce the next sentence in the summary (referred to as the *cloze*). The underlying assumption of the task is that the content of the cloze is known to come from the reference document, and thus the primary challenge of the task is to decide what information in the reference document(s) is relevant to the topic and partial summary. An example instance of the summary cloze task is presented in Figure 1.

Then, we collected a new large-scale summary cloze dataset from Wikipedia, called the WIKICITE dataset (§3). Each paragraph in Wikipedia can be viewed as a topic-focused summary of the references cited within the paragraph, where the topic is defined as the article title and section headings. The citations provide supervision at the sentence-level that indicates where the content of the preceding sentence came from. We scraped hundreds of thousands of Wikipedia articles and corresponding references to collect nearly 500k summary cloze instances.[1]

With a new task definition and corresponding large-scale dataset, we then propose an extractive model and a two-step abstractive model, both of which are based on recent successful work on generic summarization (§4). The extractive model combines representations of the topic and partial summary with representations of the document sentences through an attention mechanism to extract one reference sentence. The two-step model first reduces the length of the input data by extractively selecting a small number of sentences, then abstractively summarizes them using a decoder that has an initial hidden state which depends on the partial summary. Our experimental results (§6) show that the topic and context help the models identify relevant information, but the task remains a significant challenge.

The contributions of this work are three-fold: (1) We formalize the summary cloze task as a method to develop content selection models for topic-focused summarization; (2) we release the WIKICITE dataset, which contains nearly 500k summary cloze instances collected from Wikipedia; and (3) we propose sensible baseline extractive and abstractive models for content selection in topic-focused summarization.

2 The Summary Cloze Task

One of the main challenges for a topic-focused MDS system is selecting what content from the reference documents to include in the summary. Intuitively, this decision largely depends on the topic itself and the content of the summary generated thus far. Therefore, being able to predict the next sentence of a summary is an important component of a full topic-focused MDS system and a worthwhile task on its own. With this motivation in mind, we now formally define the summary cloze task.

Task Definition Given a partial summary (the *context*) and a reference document or documents (the *references*), the goal of the summary cloze task is to generate the next sentence of the summary (the cloze). It is assumed that the information in the cloze comes from the provided reference documents. This is the most general definition of the summary cloze task. However, because we are interested in topic-focused summarization, in this work, it is also assumed that a high-level topic is provided as input, such as in Figure 1.

One advantage that the summary cloze task has over the traditional topic-focused MDS problem is the availability of data. Topic-focused MDS requires collecting example summaries of a set of documents about a particular topic. This data is hard to collect from human annotators and is difficult to find occurring naturally. The cloze task requires sentence-level supervision for which we were able to collect a large-scale dataset using Wikipedia (§3). By conditioning the cloze generation on a partial summary and working at the sentence-level, we are able to get around the problem of data scarcity.

Evaluation Evaluating summary cloze models is challenging; The difficulties of evaluating summarization systems (Nenkova, 2006a) still persist for the summary cloze task. We propose for the main evaluation metric to be ROUGE (Lin, 2004), which has been shown to be an effective metric for summarization (Owczarzak et al., 2012). Additionally, for abstractive models we use perplexity to quantify how likely the ground-truth cloze is according to the model.

Because the cloze is only one sentence long, the chance of the ground-truth and model clozes being equally valid but very different to each other is likely higher than for other summarization tasks.

It is desirable to have a good automatic evaluation metric that could capture the coherence of the model's cloze with the context in such situations. However, developing such an automatic metric for measuring summary coherence that correlates well with human judgments is an open problem for summarization in general, and thus we leave it for future work.

3 The WikiCite Dataset

In order to build content selection models, we collected a large-scale dataset of summary cloze instances using Wikipedia.

Wikipedia as a Summary Each paragraph in a Wikipedia article can be viewed as a topic-focused multi-document summary. Many Wikipedia articles have citations to external sources that provide supporting evidence for the information within the article. The articles' paragraphs can be viewed as summarizing the documents cited within the paragraph with respect to the page entity and section headings, which together form the topic of the summary. Since the citations are at the sentence-level, they provide supervision that identifies where the information in the preceding sentence came from, and thus can be used to generate summary cloze instances.

For example, consider a paragraph from the "Family and personal life" section of Barack Obama's Wikipedia page, presented in Figure 2. Nearly all of the sentences in the paragraph are supported with citations, and these citations contain the same information written in the paragraph. Each sentence with a citation can be used to produce a summary cloze instance where the preceding sentences are the context and the topic is "Barack Obama, Family and personal life." Although not all paragraphs on Wikipedia are as well-cited as the example in Figure 2, only one citation is necessary to create a cloze instance.

Dataset Collection To collect a summary cloze dataset, we first parsed the articles and citations from the January 2019 Wikipedia dump. Only articles marked with the category "Living people" were kept because these articles are more likely to have reference documents which can be scraped automatically. The reference document HTMLs were collected from 12 months of Common Crawl data.[2] Then, the text of each document was extracted from the HTML using unfluff.[3]

In June 1989, Obama met Michelle Robinson when he was employed as a summer associate at the Chicago law firm of Sidley Austin.[62] Robinson was assigned for three months as Obama's adviser at the firm, and she joined him at several group social functions but declined his initial requests to date.[63] They began dating later that summer, became engaged in 1991, and were married on October 3, 1992.[64] The couple's first daughter, Malia Ann, was born in 1998,[65] followed by a second daughter, Natasha ("Sasha"), in 2001.[66] The Obama daughters attended the University of Chicago Laboratory Schools. When they moved to Washington, D.C., in January 2009, the girls started at the Sidwell Friends School.[67] The Obamas have two Portuguese Water Dogs; the first, a male named Bo, was a gift from Senator Ted Kennedy.[68] In 2013, Bo was joined by Sunny, a female.[69]
62: [Michelle] Obama was assigned to mentor Barack, who was a summer intern at Sidley & Austin…
67: … Barack Obama and his wife have chosen Sidwell Friends School for their two daughters
68: … the Obamas have chosen a 6-month-old Portuguese water dog — a gift from Senator Edward M. Kennedy… The girls have named the dog Bo…

Figure 2: A paragraph from the "Family and personal life" section of Barack Obama's Wikipedia page and selected excerpts from the cited documents which provide supporting evidence.

In order to filter low-quality instances (e.g., HTML was a 404 page, the body text was incorrectly extracted, etc.), we labeled around 500 instances based on whether or not the reference document provided supporting evidence for the corresponding cloze. We trained a simple linear classifier with length and BM25 features that achieved an F1 score of 85 to filter the data. The remaining data was split between training, 10k validation, and 10k testing instances, ensuring that no reference document or Wikipedia article appears in more than one set.

The dataset statistics compared to those of the DUC 2005 and 2006 datasets are presented in Table 1. Other than the number of instances, the biggest differences between the two datasets are the length of the reference documents and topics. The WIKICITE documents are significantly longer, over double the length DUC documents at one standard deviation above the mean. The DUC topics, which are generally text that describe an information need, are much longer than the WIKICITE topics, which are high-level topic keywords.

Examples from the dataset are provided in Appendix A.

4 Content Selection Models

We propose two sensible extensions to successful single-document summarization systems for the summary cloze task, an extractive model and a two-step abstractive model.

4.1 Extractive Model

The extractive model is based on those presented in Kedzie et al. (2018). The base model works as follows. For every sentence $\mathbf{x}_i$ in the reference document, a sentence-level representation $\mathbf{h}_i$ is created by a sentence encoder (e.g., by averaging word vectors, by using a recurrent neural network, etc.). Then, a sentence extractor creates a document-level representation for each sentence $\mathbf{d}_i$, for example, by running a second RNN over the sentence-level representations. The document-level representation is passed through a multilayer perceptron and a sigmoid unit to calculate the probability of extracting a particular sentence under the model.

Adding Topics and Context We extended the standard extractive model by incorporating the topic and context information through an attention mechanism. First, each of the individual topics is encoded into a vector representation $\mathbf{t}_j$ by averaging the word vectors for each word in topic j. Then, a bidirectional RNN encodes the context tokens into a vector representation $\mathbf{c}_k$ for each token.

The topic and context token representations are combined with the sentence-level sentence representations through an attention mechanism. Specifically, an attention score is computed between each $\mathbf{h}_i$ and the topic and context representations. Then, the subsequent attention scores are used to create a weighted sum of the topic and context representations, $\mathbf{a}_i$.

Finally, the sentence representation $\tilde{\mathbf{h}}_i$ that includes the attention mechanism is computed as

$$\tilde{\mathbf{h}}_i = \mathbf{W}_a[\mathbf{h}_i; \mathbf{a}_i] \quad (1)$$

where $\mathbf{W}_a$ is a matrix of learned parameters.

In this extended version of the model, $\tilde{\mathbf{h}}_i$ is used to compute the extraction probabilities instead of $\mathbf{h}_i$. A graphical representation of the full extractive model is presented in Figure 3.

Training & Inference To convert the abstractive clozes into extractive reference sentence labels, we follow the procedure of Nallapati et al. (2017) and greedily select reference sentences that maximize ROUGE-1 recall until no more sentences improve the score. The training objective is the weighted negative log-likelihood of the labels with the same weighting as Kedzie et al. (2018). At inference, the sentence with the highest probability of extraction is selected.

4.2 Two-Step Abstractive Model

Since the reference documents in the WIKICITE dataset are rather long (see Table 1), we chose to use a two-step approach to build an abstractive system for the summary cloze task.

Extractive Step The first step uses the same extractive model from the previous subsection to significantly reduce the amount of input text. Instead of selecting just one sentence at inference, the extractive model repeatedly selects sentences until a pre-specified number of words has been met. Then, only the sentences which were extracted are passed as input to the abstractive step.

Abstractive Step For the abstractive step, we extended the Pointer-Generator + Coverage network (See et al., 2017) for single-document summarization to include the context.

The Pointer-Generator network is built on a sequence-to-sequence model with attention. The reference document is encoded using an RNN, and the summary is produced using a second RNN. The model is augmented with a copy mechanism by including a soft switch that allows the attention distribution to influence the decoder's probability distribution over the vocabulary, thus making it easier to copy words from the input.

Then, the coverage mechanism discourages the attention weights from repeatedly assigning high values to the same input tokens across decoding time steps. This is accomplished by adding a new

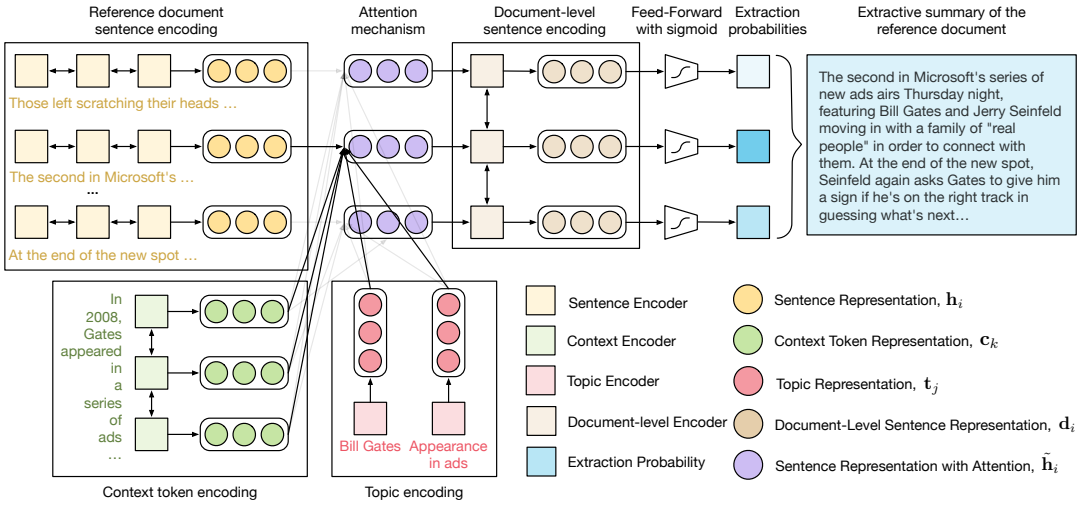

Figure 3: The extractive model uses three separate encoders create representations for the reference document sentences, context tokens, and topics. These are combined through an attention mechanism, encoded at a document-level, and passed through a feed-forward layer to compute an extraction probability for each reference sentence.

term to the loss function which penalizes such behavior and a new term to the attention score calculation that informs the model about the previous steps' attention weights. The coverage mechanism has the effect of decreasing the amount of redundancy in the generated summary.

Conditioning on Context In order to condition the generation of the cloze on the context, we use the context tokens to initialize the decoder's hidden state representation by first forcing the tokens through the decoder.

Concretely, let $\mathbf{s}_t$ be the decoder's hidden state for decoding step t (with $\mathbf{s}_0$ initialized to the final encoder hidden state), $d_\theta(\cdot)$ be the decoder function, and $c_1, \ldots, c_T$ be the context tokens. The context tokens are passed through the decoder to create a new decoder hidden state representation using the following recursive formula

$$\mathbf{s}_t = d_\theta(c_t, \mathbf{s}_{t-1}) \qquad \forall t = 1, \ldots, T \qquad (2)$$

Then, $\mathbf{s}_T$ is used as the initial hidden state that the decoder uses to generate the cloze tokens.

Priming the decoder with the context tokens has the benefit of allowing the model to condition the cloze generation on a representation of the context. Additionally, because the context will impact the decoder's coverage calculation, it will discourage the cloze from repeating information already in the context.

Training & Inference Following See et al. (2017), the training objective is the negative log-likelihood of the ground-truth cloze tokens with the added coverage penalty. Inference is done using beam search.

5 Experimental Setup

Our experiments aim to better understand the WIKICITE dataset, evaluation metric, and performance of the extractive and abstractive models. Numbers in bold indicate statistical significance based on bootstrap resampling with $p = 0.05$.

5.1 Dataset Ablation & Human Performance

In order to better understand the WIKICITE dataset, we estimate how well models can perform without the reference documents and context and establish human performance on the task.

No Reference Document We used the publicly available large-scale language model from Radford et al. (2019) (the 345M parameter version) with the default parameters to generate the cloze. The language model (which we call NO REFERENCE) was conditioned on the context tokens and one full sentence was generated from the model without access to the reference document.

No Context We trained an abstractive model (§4.2) to summarize the first 200 tokens of the reference documents in one sentence, using the cloze as ground-truth, without access to the context. This is equivalent to training a single-document summarization system on the input text. This model is referred to as NO CONTEXT.

Human Performance We manually wrote clozes for 50 different instances with and without access to the topic and context to establish human performance on this task. We also had each cloze judged by 5 crowd workers to rate from 1 to 5 how coherent the topic, context, and cloze are. We report this average quality score alongside ROUGE with the HUMAN label.

5.2 Extractive Models

In addition to an ablation study on the extractive model (referred to as CONTENTSELECTOR; §4.1) where we remove the topic and context, we also evaluate several different extractive models on this task, described below.

Lead & Oracle The LEAD-1 chooses the first sentence from the reference documents as the cloze, a common baseline for summarization.

The ORACLE-1 model selects the one sentence from the reference set which maximizes the ROUGE score using the ground-truth. A different oracle model was created for each individual metric. The performance of the oracle represents the upper-bound ROUGE score that a system which extracts exactly one sentence can achieve.

BM25 BM25 (Robertson et al., 1995) is an information retrieval-based score used to rank documents in search results for an input query. We selected the reference document sentence with the highest BM25 score for the context, treating the context as the query, the sentences as the documents, and computing the document frequency scores over the corpus of reference documents.

SumFocus SumFocus (Vanderwende et al., 2007) is an unsupervised model for topic-focused extractive summarization. The model constructs a unigram distribution over tokens by interpolating the unigram distributions of the documents and topic. Then, the model iteratively selects a sentence that has the highest probability token, discounts the probabilities of tokens in the selected sentence, and repeats. We extend SumFocus by additionally interpolating between the context unigram distribution in addition to the document and topic distributions.

5.3 Abstractive Models

Then, we measured how well the two-step abstractive system performs with and without access to the context and with different extractive models.

Extractive Step Evaluation We use the extractive models above to preprocess the reference set to select the top scoring sentences, up to 200 tokens. The preprocessed documents are evaluated against the ground-truth cloze by calculating the recall variant of ROUGE. This will measure what percent of the cloze n-grams are contained within the text input to the abstractive step.

In addition to the extractive models, we also report lead and extractive oracle scores. The LEAD-200 extractive step selects the first 200 tokens of the reference document. The extractive oracle model preprocesses the reference sentences by selecting only those which were labeled positively in the heuristically-generated extractive labels, limited to 200 tokens. This model, called HEURISTIC LABELS, serves to demonstrate how well the abstractive model would perform with a perfect extractive step.

Abstractive Step Evaluation Using the preprocessed documents from various extractive models, we trained abstractive models (§4.2) to produce the ground-truth cloze, both with and without access to the context. These systems were evaluated with the F1 variant of ROUGE and perplexity.

5.4 Implementation Details

Our models were implemented using PyTorch (Paszke et al., 2017) in the AllenNLP framework (Gardner et al., 2017).[4] We used fixed 200-dimensional GloVe embeddings (Pennington et al., 2014). The RNNs were implemented with LSTMs (Hochreiter and Schmidhuber, 1997) of size 256. The models were trained with Adam (Kingma and Ba, 2014) using a learning rate of 1e-4 and 1e-3 and batch sizes of 32 and 16 for 290k and 62.5k iterations for the extractive and abstractive models, respectively. Following See et al. (2017), we trained the abstractive models without the coverage loss until convergence, then by 3k iterations with a coverage loss weight of 1.

6 Experimental Results

6.1 Human Performance & Evaluation

Table 2 shows the ROUGE and quality scores for the human-written clozes with and without access to the topic and context. For an additional comparison, we included a random human baseline that randomly shuffled the human-written clozes.

[4] All code available at http://cogcomp.org/page/publication_view/880

Model	R1	R2	RL	Qual.
GROUND-TRUTH	100	100	100	4.0
HUMAN	31.78	16.94	28.32	3.9
-TOPIC,-CONTEXT	24.49	7.55	20.11	3.7
RANDOM HUMAN	9.96	0.08	8.24	2.3

Table 2: The ROUGE F1 scores for the human clozes with and without access to the topic and context and crowdsourced quality judgments (on a 1-5 scale) of how well the cloze continues the corresponding text. The standard deviations for the quality judgments (omitted for space) were each around 0.9.

Model	R1	R2	RL
NO REFERENCE	14.47	1.43	11.41
NO CONTEXT	21.79	6.18	17.83

Table 3: The ROUGE F1 results of the baseline models that do not have access to the references or context.

The ROUGE scores for when the human cloze writers had access to the topic and context are higher by 7.3 R1 points, a significant margin. From this observation, we can infer that, when provided with the topic and context, humans do a better job at identifying the same information present in the ground-truth cloze. This is indicative that the topic and context should also be necessary for a system to do the same.

However, the crowd worker quality judgments are roughly equal for the ground-truth and both human-written clozes, and human performance is at 31.78 R1, which is somewhat low on an absolute scale. We believe this reflects the difficulty of evaluating this task and summarization in general. Because there are many possible valid clozes (or valid summaries of documents in the more general case) and only one ground-truth cloze, evaluation with automatic metrics is difficult. Although ROUGE is imperfect, it does positively correlate with the crowd worker quality scores, with a Pearson's coefficient of 0.44.

6.2 Dataset Ablation

The two baseline models that do not have access to the references or context, respectively, are evaluated in Table 3. Although the NO REFERENCE model is a high-quality language model, it performs significantly worse than the NO CONTEXT model. This is likely due to the fact that the NO CONTEXT model was trained for this task.

Model	R1	R2	RL
ORACLE-1	44.32	26.17	37.62
LEAD-1	17.50	4.70	13.45
BM25	21.33	5.76	16.18
SUMFOCUS	17.78	4.61	13.86
CONTENTSELECTOR	**25.13**	**9.48**	**19.65**
-TOPIC	**25.21**	**9.49**	**19.68**
-CONTEXT	22.11	6.53	16.66
-TOPIC,-CONTEXT	21.29	6.01	16.05

Table 4: The ROUGE F1 scores for the extractive models, all of which are significantly lower than the oracle model, indicating there is room for improvement.

6.3 Extractive Models

The performance of the different extractive models on the summary cloze task is presented in Table 4.

The CONTENTSELECTOR model achieves the best score overall with around 25 R1. Providing CONTENTSELECTOR with the topic and context improves the R1 score by nearly 4 points, however, this improvement is mostly due to the context. The topic does not change the model's performance by a statistically significant amount, which is an indication that it is not being properly utilized.

Among the symbolic models, BM25 outperforms SUMFOCUS by 3.55 R1. One reason for this could be that BM25 uses a token weighting to score each sentence based on how frequently the token appears in the entire reference corpora, whereas the standard SUMFOCUS implementation treats all tokens equally.

Although the models perform well, they are still significantly below the oracle model by at least 19 R1 and 16 R2 points. Such a large gap indicates that there is some signal in the data that is not yet captured by the extractive models.

6.4 Abstractive Models

Extractive Step The ROUGE recall scores for the different extractive models used to preprocess the input to the abstractive model are shown in Table 5. The results are largely consistent with the extractive model scores, with CONTENTSELECTOR performing the best, the topic causing no statistically significant difference, and a large gap remaining between current models and a perfect system (the heuristic labels).

Table 5 also contains an ablation study for the SUMFOCUS in which the topic did make a significant difference. This suggests that it may be easier to use the topic in a symbolic model and a model

Model	R1-R	R2-R	RL-R
HEURISTIC LABELS	80.25	35.75	55.11
LEAD-200	60.89	22.31	44.97
BM25	64.19	25.04	56.24
SUMFOCUS	61.79	22.77	54.15
-TOPIC	60.95	22.38	53.61
-CONTEXT	61.03	22.08	53.32
-TOPIC,-CONTEXT	59.11	20.62	51.93
CONTENTSELECTOR	**66.27**	**27.59**	**58.25**
-TOPIC	**66.32**	**27.63**	**58.32**
-CONTEXT	63.86	24.48	55.80
-TOPIC,-CONTEXT	63.11	23.76	55.09

Table 5: An evaluation using the recall variant of ROUGE of the different extractive preprocessing steps.

Ext. Model	Abs.	R1	R2	RL	PPL
HEUR. LAB.	+C	34.30	16.34	28.73	18.08
	–C	33.62	15.80	27.96	18.71
LEAD-200	+C	23.56	7.15	19.3	39.73
	–C	21.79	6.18	17.83	40.90
CONTSEL.	+C	**24.67**	**8.55**	**20.44**	33.22
	–C	22.71	7.33	18.71	32.77

Table 6: The ROUGE F1 and perplexity results for abstractive models with and without the context (+/–C) with heuristic labels, lead, and CONTENTSELECTOR extractive preprocessing steps.

may benefit from combining symbolic and continuous representations.

Abstractive Step The ROUGE scores and perplexities for the abstractive models that use three different extractive steps are presented in Table 6. We observe that the CONTENTSELECTOR extractive step outperforms LEAD-200 in both ROUGE and perplexity. Additionally, including the context improves performance across all models, with nearly a 2 R1 gain with the CONTENTSELECTOR. This result is a clear signal that priming the decoder with the context produces a better cloze.

Example output from the CONTENTSELECTOR model that uses the context can been seen in Figure 4. In general, the model tends to copy long sequences from the reference document, often preferring somewhat formulaic sentences that begin with phrases such as "he became," "she graduated," or "she received" and are similar in style to Wikipedia articles.

Similar to the extractive results, there is a sizable gap between the performance of the abstractive model when it uses the heuristic labels versus the extractive model for preprocessing. This indicates that improving the extractive model will provide large downstream abstractive improvements.

7 Related Work

Summarization Recent work on generic summarization has focused on single-document models on the CNN/DailyMail dataset (Nallapati et al., 2016), focusing on different neural architectures and loss functions for extractive and abstractive summarization (Cheng and Lapata, 2016; Nallapati et al., 2017; Chopra et al., 2016; Nallapati et al., 2016; See et al., 2017, inter alia). Our models were based on the successful approaches of See et al. (2017) and those described in Kedzie et al. (2018).

Most work on topic-focused (also referred to as "query-focused") summarization uses the DUC 2005 and 2006 datasets (Dang, 2005, 2006). Approaches are mostly extractive, with some work selecting sentences based on token frequency/salience (Otterbacher et al., 2005; Vanderwende et al., 2007), diversity with submodular functions (Lin and Bilmes, 2011), or using Bayesian networks (Daumé III and Marcu, 2006). To the best of our knowledge, ours is the first work which builds end-to-end models on a large-scale dataset for topic-focused summarization.

Generating Wikipedia In contrast to our work focusing on content selection for topic-focused summaries, there have been previous work interested in generating Wikipedia articles. Sauper and Barzilay (2009) try to generate articles from a small set of domains by learning to generate templates from similar articles using an integer linear program. Similarly, Banerjee and Mitra (2016) build topic classifiers based on sections on Wikipedia to identify content in search results for topic keywords as part of a pipeline to generate full articles. Like us, Liu et al. (2018) also employ a two-step abstractive approach, but their goal is to generate the lead Wikipedia paragraph from all of the citations and web search results.

8 Conclusion

In this work, we propose the summary cloze task, a new task for studying content selection in topic-focused summarization. By narrowing the scope from the full topic-focused summarization task to one at the sentence-level, we are able to collect a large-scale summary cloze dataset from Wikipedia. Our experimental results demonstrate

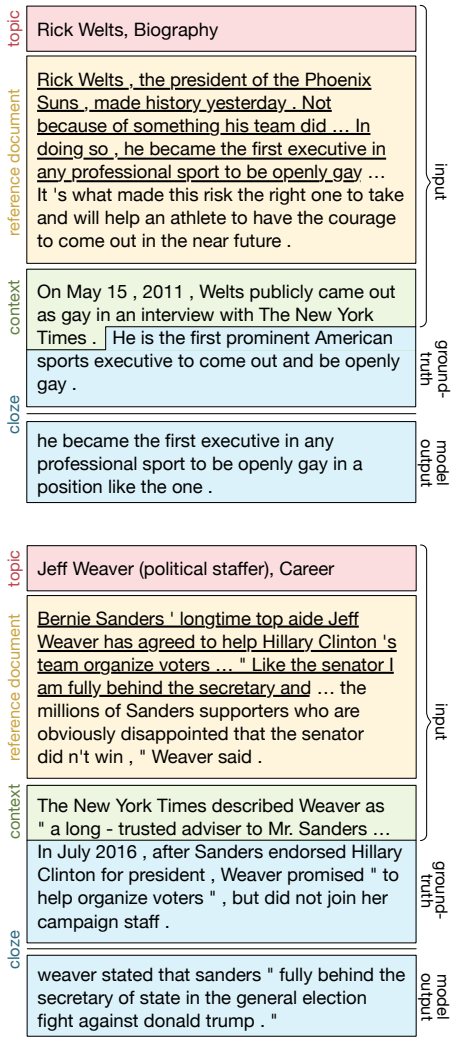

Figure 4: Example outputs from the abstractive model that uses the context. The model often copies sequences from the references which are sometimes correct (top) or incorrect but sensible (bottom), highlighting the difficulty of automatic evaluation. (Documents shortened for space. Sentences which are underlined were selected by the extraction step.)

that the topic and partial summary help the extractive and abstractive models, but the task remains a significant challenge with room for improvement in future work.

Abstract

Bidirectional Encoder Representations from Transformers (BERT; Devlin et al. 2019) represents the latest incarnation of pretrained language models which have recently advanced a wide range of natural language processing tasks. In this paper, we showcase how BERT can be usefully applied in text summarization and propose a general framework for both extractive and abstractive models. We introduce a novel document-level encoder based on BERT which is able to express the semantics of a document and obtain representations for its sentences. Our extractive model is built on top of this encoder by stacking several inter-sentence Transformer layers. For abstractive summarization, we propose a new fine-tuning schedule which adopts different optimizers for the encoder and the decoder as a means of alleviating the mismatch between the two (the former is pretrained while the latter is not). We also demonstrate that a two-staged fine-tuning approach can further boost the quality of the generated summaries. Experiments on three datasets show that our model achieves state-of-the-art results across the board in both extractive and abstractive settings.[1]

1 Introduction

Language model pretraining has advanced the state of the art in many NLP tasks ranging from sentiment analysis, to question answering, natural language inference, named entity recognition, and textual similarity. State-of-the-art pretrained models include ELMo (Peters et al., 2018), GPT (Radford et al., 2018), and more recently Bidirectional Encoder Representations from Transformers (BERT; Devlin et al. 2019). BERT combines both word and sentence representations in a single very large Transformer (Vaswani et al., 2017); it is pretrained on vast amounts of text, with an unsupervised objective of masked language modeling and next-sentence prediction and can be fine-tuned with various task-specific objectives.

In most cases, pretrained language models have been employed as encoders for sentence- and paragraph-level natural language understanding problems (Devlin et al., 2019) involving various classification tasks (e.g., predicting whether any two sentences are in an entailment relationship; or determining the completion of a sentence among four alternative sentences). In this paper, we examine the influence of language model pretraining on text summarization. Different from previous tasks, summarization requires wide-coverage natural language understanding going beyond the meaning of individual words and sentences. The aim is to condense a *document* into a shorter version while preserving most of its meaning. Furthermore, under abstractive modeling formulations, the task requires language generation capabilities in order to create summaries containing novel words and phrases not featured in the source text, while extractive summarization is often defined as a binary classification task with labels indicating whether a text span (typically a sentence) should be included in the summary.

We explore the potential of BERT for text summarization under a general framework encompassing both extractive and abstractive modeling paradigms. We propose a novel document-level encoder based on BERT which is able to encode a document and obtain representations for its sentences. Our extractive model is built on top of this encoder by stacking several inter-sentence Transformer layers to capture document-level features for extracting sentences. Our abstractive model adopts an encoder-decoder architecture, combining the same pretrained BERT encoder with a randomly-initialized Transformer de-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3730–3740, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

coder (Vaswani et al., 2017). We design a new training schedule which separates the optimizers of the encoder and the decoder in order to accommodate the fact that the former is pretrained while the latter must be trained from scratch. Finally, motivated by previous work showing that the combination of extractive and abstractive objectives can help generate better summaries (Gehrmann et al., 2018), we present a two-stage approach where the encoder is fine-tuned twice, first with an extractive objective and subsequently on the abstractive summarization task.

We evaluate the proposed approach on three single-document news summarization datasets representative of different writing conventions (e.g., important information is concentrated at the beginning of the document or distributed more evenly throughout) and summary styles (e.g., verbose vs. more telegraphic; extractive vs. abstractive). Across datasets, we experimentally show that the proposed models achieve state-of-the-art results under both extractive and abstractive settings. Our contributions in this work are threefold: a) we highlight the importance of document encoding for the summarization task; a variety of recently proposed techniques aim to enhance summarization performance via copying mechanisms (Gu et al., 2016; See et al., 2017; Nallapati et al., 2017), reinforcement learning (Narayan et al., 2018b; Paulus et al., 2018; Dong et al., 2018), and multiple communicating encoders (Celikyilmaz et al., 2018). We achieve better results with a minimum-requirement model without using any of these mechanisms; b) we showcase ways to effectively employ pretrained language models in summarization under both extractive and abstractive settings; we would expect any improvements in model pretraining to translate in better summarization in the future; and c) the proposed models can be used as a stepping stone to further improve summarization performance as well as baselines against which new proposals are tested.

2 Background

2.1 Pretrained Language Models

Pretrained language models (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Dong et al., 2019; Zhang et al., 2019) have recently emerged as a key technology for achieving impressive gains in a wide variety of natural language tasks. These models extend the idea of word embeddings by learning contextual representations from large-scale corpora using a language modeling objective. Bidirectional Encoder Representations from Transformers (BERT; Devlin et al. 2019) is a new language representation model which is trained with a masked language modeling and a "next sentence prediction" task on a corpus of 3,300M words.

The general architecture of BERT is shown in the left part of Figure 1. Input text is first preprocessed by inserting two special tokens. [CLS] is appended to the beginning of the text; the output representation of this token is used to aggregate information from the whole sequence (e.g., for classification tasks). And token [SEP] is inserted after each sentence as an indicator of sentence boundaries. The modified text is then represented as a sequence of tokens $X = [w_1, w_2, \cdots, w_n]$. Each token w_i is assigned three kinds of embeddings: *token embeddings* indicate the meaning of each token, *segmentation embeddings* are used to discriminate between two sentences (e.g., during a sentence-pair classification task) and *position embeddings* indicate the position of each token within the text sequence. These three embeddings are summed to a single input vector x_i and fed to a bidirectional Transformer with multiple layers:

$$\tilde{h}^l = \mathrm{LN}(h^{l-1} + \mathrm{MHAtt}(h^{l-1})) \quad (1)$$

$$h^l = \mathrm{LN}(\tilde{h}^l + \mathrm{FFN}(\tilde{h}^l)) \quad (2)$$

where $h^0 = x$ are the input vectors; LN is the layer normalization operation (Ba et al., 2016); MHAtt is the multi-head attention operation (Vaswani et al., 2017); superscript l indicates the depth of the stacked layer. On the top layer, BERT will generate an output vector t_i for each token with rich contextual information.

Pretrained language models are usually used to enhance performance in language understanding tasks. Very recently, there have been attempts to apply pretrained models to various generation problems (Edunov et al., 2019; Rothe et al., 2019). When fine-tuning for a specific task, unlike ELMo whose parameters are usually fixed, parameters in BERT are *jointly* fine-tuned with additional task-specific parameters.

2.2 Extractive Summarization

Extractive summarization systems create a summary by identifying (and subsequently concatenating) the most important sentences in a document. Neural models consider extractive sum-

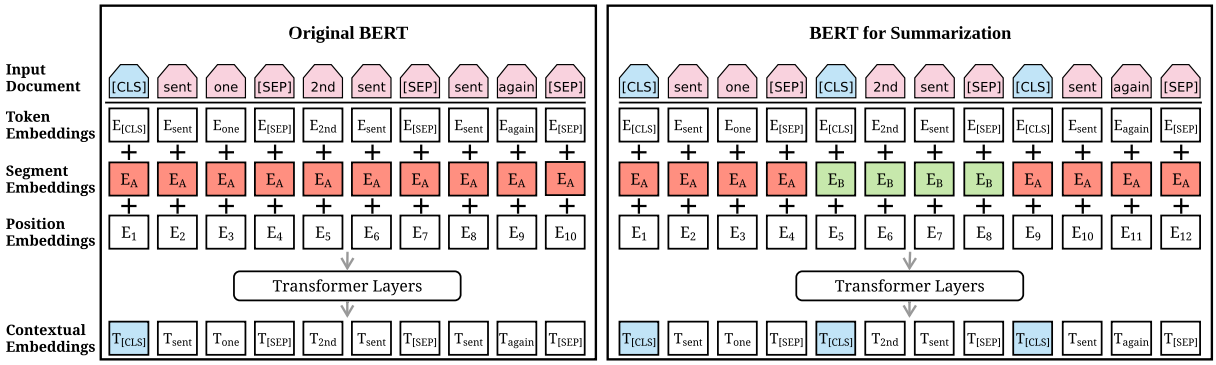

Figure 1: Architecture of the original BERT model (left) and BERTSUM (right). The sequence on top is the input document, followed by the summation of three kinds of embeddings for each token. The summed vectors are used as input embeddings to several bidirectional Transformer layers, generating contextual vectors for each token. BERTSUM extends BERT by inserting multiple [CLS] symbols to learn sentence representations and using interval segmentation embeddings (illustrated in red and green color) to distinguish multiple sentences.

marization as a sentence classification problem: a neural encoder creates sentence representations and a classifier predicts which sentences should be selected as summaries. SUMMARUNNER (Nallapati et al., 2017) is one of the earliest neural approaches adopting an encoder based on Recurrent Neural Networks. REFRESH (Narayan et al., 2018b) is a reinforcement learning-based system trained by globally optimizing the ROUGE metric. More recent work achieves higher performance with more sophisticated model structures. LATENT (Zhang et al., 2018) frames extractive summarization as a latent variable inference problem; instead of maximizing the likelihood of "gold" standard labels, their latent model directly maximizes the likelihood of human summaries given selected sentences. SUMO (Liu et al., 2019) capitalizes on the notion of structured attention to induce a multi-root dependency tree representation of the document while predicting the output summary. NEUSUM (Zhou et al., 2018) scores and selects sentences jointly and represents the state of the art in extractive summarization.

2.3 Abstractive Summarization

Neural approaches to abstractive summarization conceptualize the task as a sequence-to-sequence problem, where an encoder maps a sequence of tokens in the source document $\boldsymbol{x} = [x_1, ..., x_n]$ to a sequence of continuous representations $\boldsymbol{z} = [z_1, ..., z_n]$, and a decoder then generates the target summary $\boldsymbol{y} = [y_1, ..., y_m]$ token-by-token, in an auto-regressive manner, hence modeling the conditional probability: $p(y_1, ..., y_m|x_1, ..., x_n)$.

Rush et al. (2015) and Nallapati et al. (2016) were among the first to apply the neural encoder-decoder architecture to text summarization. See et al. (2017) enhance this model with a pointer-generator network (PTGEN) which allows it to copy words from the source text, and a coverage mechanism (COV) which keeps track of words that have been summarized. Celikyilmaz et al. (2018) propose an abstractive system where multiple agents (encoders) represent the document together with a hierarchical attention mechanism (over the agents) for decoding. Their Deep Communicating Agents (DCA) model is trained end-to-end with reinforcement learning. Paulus et al. (2018) also present a deep reinforced model (DRM) for abstractive summarization which handles the coverage problem with an intra-attention mechanism where the decoder attends over previously generated words. Gehrmann et al. (2018) follow a bottom-up approach (BOTTOMUP); a content selector first determines which phrases in the source document should be part of the summary, and a copy mechanism is applied only to preselected phrases during decoding. Narayan et al. (2018a) propose an abstractive model which is particularly suited to extreme summarization (i.e., single sentence summaries), based on convolutional neural networks and additionally conditioned on topic distributions (TCONVS2S).

3 Fine-tuning BERT for Summarization

3.1 Summarization Encoder

Although BERT has been used to fine-tune various NLP tasks, its application to summarization

is not as straightforward. Since BERT is trained as a masked-language model, the output vectors are grounded to tokens instead of sentences, while in extractive summarization, most models manipulate sentence-level representations. Although segmentation embeddings represent different sentences in BERT, they only apply to sentence-pair inputs, while in summarization we must encode and manipulate multi-sentential inputs. Figure 1 illustrates our proposed BERT architecture for SUMmarization (which we call BERTSUM).

In order to represent *individual* sentences, we insert external [CLS] tokens at the start of each sentence, and each [CLS] symbol collects features for the sentence preceding it. We also use *interval segment* embeddings to distinguish multiple sentences within a document. For $sent_i$ we assign segment embedding E_A or E_B depending on whether i is odd or even. For example, for document $[sent_1, sent_2, sent_3, sent_4, sent_5]$, we would assign embeddings $[E_A, E_B, E_A, E_B, E_A]$. This way, document representations are learned hierarchically where lower Transformer layers represent adjacent sentences, while higher layers, in combination with self-attention, represent multi-sentence discourse.

Position embeddings in the original BERT model have a maximum length of 512; we overcome this limitation by adding more position embeddings that are initialized randomly and fine-tuned with other parameters in the encoder.

3.2 Extractive Summarization

Let d denote a document containing sentences $[sent_1, sent_2, \cdots, sent_m]$, where $sent_i$ is the i-th sentence in the document. Extractive summarization can be defined as the task of assigning a label $y_i \in \{0, 1\}$ to each $sent_i$, indicating whether the sentence should be included in the summary. It is assumed that summary sentences represent the most important content of the document.

With BERTSUM, vector t_i which is the vector of the i-th [CLS] symbol from the top layer can be used as the representation for $sent_i$. Several inter-sentence Transformer layers are then stacked on top of BERT outputs, to capture document-level features for extracting summaries:

$$\tilde{h}^l = \mathrm{LN}(h^{l-1} + \mathrm{MHAtt}(h^{l-1})) \quad (3)$$

$$h^l = \mathrm{LN}(\tilde{h}^l + \mathrm{FFN}(\tilde{h}^l)) \quad (4)$$

where $h^0 = \mathrm{PosEmb}(T)$; T denotes the sentence vectors output by BERTSUM, and function PosEmb adds sinusoid positional embeddings (Vaswani et al., 2017) to T, indicating the position of each sentence.

The final output layer is a sigmoid classifier:

$$\hat{y}_i = \sigma(W_o h_i^L + b_o) \quad (5)$$

where h_i^L is the vector for $sent_i$ from the top layer (the L-th layer) of the Transformer. In experiments, we implemented Transformers with $L = 1, 2, 3$ and found that a Transformer with $L = 2$ performed best. We name this model BERTSUMEXT.

The loss of the model is the binary classification entropy of prediction $\hat{y}_i$ against gold label y_i. Inter-sentence Transformer layers are jointly fine-tuned with BERTSUM. We use the Adam optimizer with $\beta_1 = 0.9$, and $\beta_2 = 0.999$). Our learning rate schedule follows (Vaswani et al., 2017) with warming-up ($\mathrm{warmup} = 10,000$):

$$lr = 2e^{-3} \cdot \min(\mathrm{step}^{-0.5}, \mathrm{step} \cdot \mathrm{warmup}^{-1.5})$$

3.3 Abstractive Summarization

We use a standard encoder-decoder framework for abstractive summarization (See et al., 2017). The encoder is the pretrained BERTSUM and the decoder is a 6-layered Transformer initialized randomly. It is conceivable that there is a mismatch between the encoder and the decoder, since the former is pretrained while the latter must be trained from scratch. This can make fine-tuning unstable; for example, the encoder might overfit the data while the decoder underfits, or vice versa. To circumvent this, we design a new fine-tuning schedule which separates the optimizers of the encoder and the decoder.

We use two Adam optimizers with $\beta_1 = 0.9$ and $\beta_2 = 0.999$ for the encoder and the decoder, respectively, each with different warmup-steps and learning rates:

$$lr_{\mathcal{E}} = \tilde{lr}_{\mathcal{E}} \cdot \min(step^{-0.5}, \mathrm{step} \cdot \mathrm{warmup}_{\mathcal{E}}^{-1.5}) \quad (6)$$

$$lr_{\mathcal{D}} = \tilde{lr}_{\mathcal{D}} \cdot \min(step^{-0.5}, \mathrm{step} \cdot \mathrm{warmup}_{\mathcal{D}}^{-1.5}) \quad (7)$$

where $\tilde{lr}_{\mathcal{E}} = 2e^{-3}$, and $\mathrm{warmup}_{\mathcal{E}} = 20,000$ for the encoder and $\tilde{lr}_{\mathcal{D}} = 0.1$, and $\mathrm{warmup}_{\mathcal{D}} = 10,000$ for the decoder. This is based on the assumption that the pretrained encoder should be fine-tuned with a smaller learning rate and smoother decay (so that the encoder can be trained with more accurate gradients when the decoder is becoming stable).

Datasets	# docs (train/val/test)	avg. doc length		avg. summary length		% novel bi-grams
		words	sentences	words	sentences	in gold summary
CNN	90,266/1,220/1,093	760.50	33.98	45.70	3.59	52.90
DailyMail	196,961/12,148/10,397	653.33	29.33	54.65	3.86	52.16
NYT	96,834/4,000/3,452	800.04	35.55	45.54	2.44	54.70
XSum	204,045/11,332/11,334	431.07	19.77	23.26	1.00	83.31

Table 1: Comparison of summarization datasets: size of training, validation, and test sets and average document and summary length (in terms of words and sentences). The proportion of novel bi-grams that do not appear in source documents but do appear in the gold summaries quantifies corpus bias towards extractive methods.

In addition, we propose a two-stage fine-tuning approach, where we first fine-tune the encoder on the extractive summarization task (Section 3.2) and then fine-tune it on the abstractive summarization task (Section 3.3). Previous work (Gehrmann et al., 2018; Li et al., 2018) suggests that using extractive objectives can boost the performance of abstractive summarization. Also notice that this two-stage approach is conceptually very simple, the model can take advantage of information shared between these two tasks, without fundamentally changing its architecture. We name the default abstractive model BERTSUMABS and the two-stage fine-tuned model BERTSUMEXTABS.

4 Experimental Setup

In this section, we describe the summarization datasets used in our experiments and discuss various implementation details.

4.1 Summarization Datasets

We evaluated our model on three benchmark datasets, namely the CNN/DailyMail news highlights dataset (Hermann et al., 2015), the New York Times Annotated Corpus (NYT; Sandhaus 2008), and XSum (Narayan et al., 2018a). These datasets represent different summary styles ranging from highlights to very brief one sentence summaries. The summaries also vary with respect to the type of rewriting operations they exemplify (e.g., some showcase more cut and paste operations while others are genuinely abstractive). Table 1 presents statistics on these datasets (test set); example (gold-standard) summaries are provided in the supplementary material.

CNN/DailyMail contains news articles and associated highlights, i.e., a few bullet points giving a brief overview of the article. We used the standard splits of Hermann et al. (2015) for training, validation, and testing (90,266/1,220/1,093 CNN documents and 196,961/12,148/10,397 DailyMail documents). We did not anonymize entities. We first split sentences with the Stanford CoreNLP toolkit (Manning et al., 2014) and pre-processed the dataset following See et al. (2017). Input documents were truncated to 512 tokens.

NYT contains 110,540 articles with abstractive summaries. Following Durrett et al. (2016), we split these into 100,834/9,706 training/test examples, based on the date of publication (the test set contains all articles published from January 1, 2007 onward). We used 4,000 examples from the training as validation set. We also followed their filtering procedure, documents with summaries less than 50 words were removed from the dataset. The filtered test set (NYT50) includes 3,452 examples. Sentences were split with the Stanford CoreNLP toolkit (Manning et al., 2014) and pre-processed following Durrett et al. (2016). Input documents were truncated to 800 tokens.

XSum contains 226,711 news articles accompanied with a one-sentence summary, answering the question "What is this article about?". We used the splits of Narayan et al. (2018a) for training, validation, and testing (204,045/11,332/11,334) and followed the pre-processing introduced in their work. Input documents were truncated to 512 tokens.

Aside from various statistics on the three datasets, Table 1 also reports the proportion of novel bi-grams in gold summaries as a measure of their abstractiveness. We would expect models with extractive biases to perform better on datasets with (mostly) extractive summaries, and abstractive models to perform more rewrite operations on datasets with abstractive summaries. CNN/DailyMail and NYT are somewhat extractive, while XSum is highly abstractive.

4.2 Implementation Details

For both extractive and abstractive settings, we used PyTorch, OpenNMT (Klein et al., 2017) and the 'bert-base-uncased'[2] version of BERT to implement BERTSUM. Both source and target texts

[2] https://git.io/fhbJQ

were tokenized with BERT's subwords tokenizer.

Extractive Summarization All extractive models were trained for 50,000 steps on 3 GPUs (GTX 1080 Ti) with gradient accumulation every two steps. Model checkpoints were saved and evaluated on the validation set every 1,000 steps. We selected the top-3 checkpoints based on the evaluation loss on the validation set, and report the averaged results on the test set. We used a greedy algorithm similar to Nallapati et al. (2017) to obtain an oracle summary for each document to train extractive models. The algorithm generates an oracle consisting of multiple sentences which maximize the ROUGE-2 score against the gold summary.

When predicting summaries for a new document, we first use the model to obtain the score for each sentence. We then rank these sentences by their scores from highest to lowest, and select the top-3 sentences as the summary.

During sentence selection we use *Trigram Blocking* to reduce redundancy (Paulus et al., 2018). Given summary S and candidate sentence c, we skip c if there exists a trigram overlapping between c and S. The intuition is similar to Maximal Marginal Relevance (MMR; Carbonell and Goldstein 1998); we wish to minimize the similarity between the sentence being considered and sentences which have been already selected as part of the summary.

Abstractive Summarization In all abstractive models, we applied dropout (with probability 0.1) before all linear layers; label smoothing (Szegedy et al., 2016) with smoothing factor 0.1 was also used. Our Transformer decoder has 768 hidden units and the hidden size for all feed-forward layers is 2,048. All models were trained for 200,000 steps on 4 GPUs (GTX 1080 Ti) with gradient accumulation every five steps. Model checkpoints were saved and evaluated on the validation set every 2,500 steps. We selected the top-3 checkpoints based on their evaluation loss on the validation set, and report the averaged results on the test set.

During decoding we used beam search (size 5), and tuned the α for the length penalty (Wu et al., 2016) between 0.6 and 1 on the validation set; we decode until an end-of-sequence token is emitted and repeated trigrams are blocked (Paulus et al., 2018). It is worth noting that our decoder applies neither a copy nor a coverage mechanism (See et al., 2017), despite their popularity in abstractive summarization. This is mainly because we focus on building a minimum-requirements model and these mechanisms may introduce additional hyper-parameters to tune. Thanks to the subwords tokenizer, we also rarely observe issues with out-of-vocabulary words in the output; moreover, trigram-blocking produces diverse summaries managing to reduce repetitions.

5 Results

5.1 Automatic Evaluation

We evaluated summarization quality automatically using ROUGE (Lin, 2004). We report unigram and bigram overlap (ROUGE-1 and ROUGE-2) as a means of assessing informativeness and the longest common subsequence (ROUGE-L) as a means of assessing fluency.

Table 2 summarizes our results on the CNN/DailyMail dataset. The first block in the table includes the results of an extractive ORACLE system as an upper bound. We also present the LEAD-3 baseline (which simply selects the first three sentences in a document).

The second block in the table includes various extractive models trained on the CNN/DailyMail dataset (see Section 2.2 for an overview). For

Table 4: ROUGE F1 results on the **XSum** test set. Results for comparison systems are taken from the authors' respective papers or obtained on our data by running publicly released software.

comparison to our own model, we also implemented a non-pretrained Transformer baseline (TransformerEXT) which uses the same architecture as BERTSUMEXT, but with fewer parameters. It is randomly initialized and only trained on the summarization task. TransformerEXT has 6 layers, the hidden size is 512, and the feed-forward filter size is 2,048. The model was trained with same settings as in Vaswani et al. (2017).

The third block in Table 2 highlights the performance of several abstractive models on the CNN/DailyMail dataset (see Section 2.3 for an overview). We also include an abstractive Transformer baseline (TransformerABS) which has the same decoder as our abstractive BERTSUM models; the encoder is a 6-layer Transformer with 768 hidden size and 2,048 feed-forward filter size.

The fourth block reports results with fine-tuned BERT models: BERTSUMEXT and its two variants (one without interval embeddings, and one with the large version of BERT), BERTSUMABS, and BERTSUMEXTABS. BERT-based models outperform the LEAD-3 baseline which is not a strawman; on the CNN/DailyMail corpus it is indeed superior to several extractive (Nallapati et al., 2017; Narayan et al., 2018b; Zhou et al., 2018) and abstractive models (See et al., 2017). BERT models collectively outperform all previously proposed extractive and abstractive systems, only falling behind the ORACLE upper bound. Among BERT variants, BERTSUMEXT performs best which is not entirely surprising; CNN/DailyMail summaries are somewhat extractive and even abstractive models are prone to copying sentences from the source document when trained on this dataset (See et al., 2017). Perhaps unsurprisingly we observe that larger versions of BERT lead to performance improvements and that interval embeddings bring only slight gains.

Table 3 presents results on the NYT dataset. Following the evaluation protocol in Durrett et al. (2016), we use limited-length ROUGE Recall, where predicted summaries are truncated to the length of the gold summaries. Again, we report the performance of the ORACLE upper bound and LEAD-3 baseline. The second block in the table contains previously proposed extractive models as well as our own Transformer baseline. COMPRESS (Durrett et al., 2016) is an ILP-based model which combines compression and anaphoricity constraints. The third block includes abstractive models from the literature, and our Transformer baseline. BERT-based models are shown in the fourth block. Again, we observe that they outperform previously proposed approaches. On this dataset, abstractive BERT models generally perform better compared to BERTSUMEXT, almost approaching ORACLE performance.

Table 4 summarizes our results on the XSum dataset. Recall that summaries in this dataset are highly abstractive (see Table 1) consisting of a single sentence conveying the gist of the document. Extractive models here perform poorly as corroborated by the low performance of the LEAD baseline (which simply selects the leading sentence from the document), and the ORACLE (which selects a single-best sentence in each document) in Table 4. As a result, we do not report results for extractive models on this dataset. The second

$\tilde{lr}_{\mathcal{E}}$ \ $\tilde{lr}_{\mathcal{D}}$	1	0.1	0.01	0.001
2e-2	50.69	9.33	10.13	19.26
2e-3	37.21	8.73	9.52	16.88

Table 5: Model perplexity (CNN/DailyMail; validation set) under different combinations of encoder and decoder learning rates.

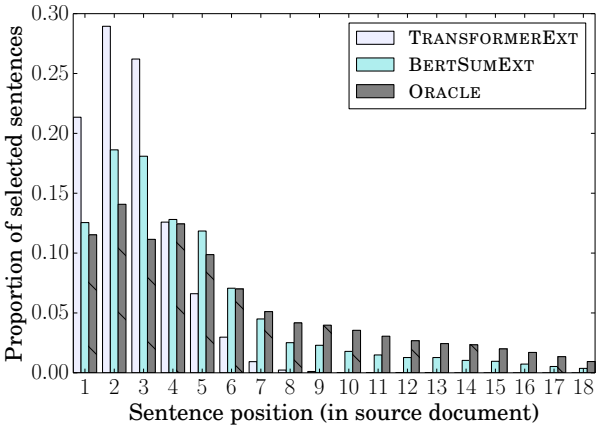
block in Table 4 presents the results of various abstractive models taken from Narayan et al. (2018a) and also includes our own abstractive Transformer baseline. In the third block we show the results of our BERT summarizers which again are superior to all previously reported models (by a wide margin).

5.2 Model Analysis

Learning Rates Recall that our abstractive model uses separate optimizers for the encoder and decoder. In Table 5 we examine whether the combination of different learning rates ($\tilde{lr}_{\mathcal{E}}$ and $\tilde{lr}_{\mathcal{D}}$) is indeed beneficial. Specifically, we report model perplexity on the CNN/DailyMail validation set for varying encoder/decoder learning rates. We can see that the model performs best with $\tilde{lr}_{\mathcal{E}} = 2e-3$ and $\tilde{lr}_{\mathcal{D}} = 0.1$.

Position of Extracted Sentences In addition to the evaluation based on ROUGE, we also analyzed in more detail the summaries produced by our model. For the extractive setting, we looked at the position (in the source document) of the sentences which were selected to appear in the summary. Figure 2 shows the proportion of selected summary sentences which appear in the source document at positions 1, 2, and so on. The analysis was conducted on the CNN/DailyMail dataset for Oracle summaries, and those produced by BERTSUMEXT and the TransformerEXT. We can see that Oracle summary sentences are fairly smoothly distributed across documents, while summaries created by TransformerEXT mostly concentrate on the first document sentences. BERTSUMEXT outputs are more similar to Oracle summaries, indicating that with the pretrained encoder, the model relies less on shallow position features, and learns deeper document representations.

Novel N-grams We also analyzed the output of abstractive systems by calculating the proportion of novel n-grams that appear in the summaries but not in the source texts. The results are shown in Figure 3. In the CNN/DailyMail dataset, the proportion of novel n-grams in automatically generated summaries is much lower compared to reference summaries, but in XSum, this gap is much smaller. We also observe that on CNN/DailyMail, BERTEXTABS produces less novel n-ngrams than BERTABS, which is not surprising. BERTEXTABS is more biased towards selecting sentences from the source document since it is initially trained as an extractive model.



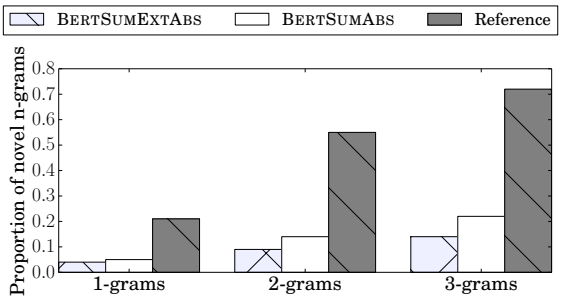


Figure 2: Proportion of extracted sentences according to their position in the original document.

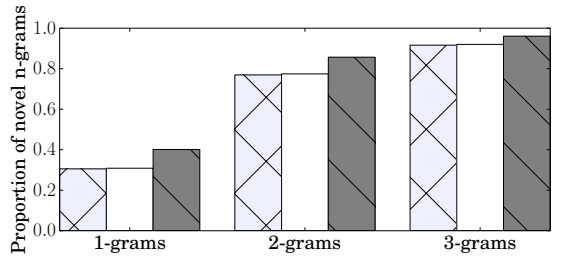
The supplementary material includes examples of system output and additional ablation studies.



5.3 Human Evaluation

In addition to automatic evaluation, we also evaluated system output by eliciting human judgments. We report experiments following a question-answering (QA) paradigm (Clarke and Lapata, 2010; Narayan et al., 2018b) which quantifies the degree to which summarization models retain key information from the document. Under this paradigm, a set of questions is created based on the gold summary under the assumption that it highlights the most important document content. Participants are then asked to answer these questions by reading system summaries alone without access to the article. The more questions a system can answer, the better it is at summarizing the document as a whole.

Moreover, we also assessed the overall quality of the summaries produced by abstractive systems which due to their ability to rewrite content may produce disfluent or ungrammatical output. Specifically, we followed the Best-Worst Scaling (Kiritchenko and Mohammad, 2017) method where participants were presented with the output of two systems (and the original document) and

asked to decide which one was better according to the criteria of *Informativeness*, *Fluency*, and *Succinctness*.

Both types of evaluation were conducted on the Amazon Mechanical Turk platform. For the CNN/DailyMail and NYT datasets we used the same documents (20 in total) and questions from previous work (Narayan et al., 2018b; Liu et al., 2019). For XSum, we randomly selected 20 documents (and their questions) from the release of Narayan et al. (2018a). We elicited 3 responses per HIT. With regard to QA evaluation, we adopted the scoring mechanism from Clarke and Lapata (2010); correct answers were marked with a score of one, partially correct answers with 0.5, and zero otherwise. For quality-based evaluation, the rating of each system was computed as the percentage of times it was chosen as better minus the times it was selected as worse. Ratings thus range from -1 (worst) to 1 (best).

Abstractive	CNN/DM		NYT		XSum	
	QA	Rank	QA	Rank	QA	Rank
LEAD	42.5†	—	36.2†	—	9.20†	—
PTGEN	33.3†	-0.24†	30.5†	-0.27†	23.7†	-0.36†
BOTTOMUP	40.6†	-0.16†	—	—	—	—
TCONVS2S	—	—	—	—	52.1	-0.20†
GOLD	—	0.22†	—	0.33†	—	0.38†
BERTSUM	56.1	0.17	41.8	-0.07	57.5	0.19

Table 7: QA-based and ranking-based evaluation. Models with † are significantly different from BERTSUM (using a paired student t-test; $p < 0.05$). Table cells are filled with — whenever system output is not available. GOLD is not used in QA setting, and LEAD is not used in Rank evaluation.

Results for extractive and abstractive systems are shown in Tables 6 and 7, respectively. We compared the best performing BERTSUM model in each setting (extractive or abstractive) against various state-of-the-art systems (whose output is publicly available), the LEAD baseline, and the GOLD standard as an upper bound. As shown in both tables participants overwhelmingly prefer the output of our model against comparison systems across datasets and evaluation paradigms. All differences between BERTSUM and comparison models are statistically significant ($p < 0.05$), with the exception of TCONVS2S (see Table 7; XSum) in the QA evaluation setting.

6 Conclusions

In this paper, we showcased how pretrained BERT can be usefully applied in text summarization. We introduced a novel document-level encoder and proposed a general framework for both abstractive and extractive summarization. Experimental results across three datasets show that our model achieves state-of-the-art results across the board under automatic and human-based evaluation protocols. Although we mainly focused on document encoding for summarization, in the future, we would like to take advantage the capabilities of BERT for language generation.

Acknowledgments

This research is supported by a Google PhD Fellowship to the first author. We gratefully acknowledge the support of the European Research Council (Lapata, award number 681760, "Translating Multiple Modalities into Text"). We would also like to thank Shashi Narayan for providing us with the XSum dataset.

How to Write Summaries with Patterns? Learning towards Abstractive Summarization through Prototype Editing

Abstract

Under special circumstances, summaries should conform to a particular style with patterns, such as court judgments and abstracts in academic papers. To this end, the prototype document-summary pairs can be utilized to generate better summaries. There are two main challenges in this task: (1) the model needs to incorporate learned patterns from the prototype, but (2) should avoid copying contents other than the patternized words—such as irrelevant facts—into the generated summaries. To tackle these challenges, we design a model named *Prototype Editing based Summary Generator* (PESG). PESG first **learns summary patterns** and prototype facts by analyzing the correlation between a prototype document and its summary. Prototype facts are then utilized to help **extract facts** from the input document. Next, an editing generator generates new summary based on the **summary pattern** or **extracted facts**. Finally, to address the second challenge, a fact checker is used to estimate mutual information between the input document and generated summary, providing an additional signal for the generator. Extensive experiments conducted on a large-scale real-world text summarization dataset[1] show that PESG achieves the state-of-the-art performance in terms of both automatic metrics and human evaluations.

1 Introduction

Abstractive summarization can be regarded as a sequence mapping task that maps the source text to the target summary (Rush et al., 2015; Li et al., 2017; Cao et al., 2018; Gao et al., 2019a). It has drawn significant attention since the introduction of deep neural networks to natural language processing. Under special circumstances, the generated summaries are required to conform to a specific pattern, such as court judgments, diagnosis certificates, abstracts in academic papers, etc. Take the court judgments for example, there is always a statement of the crime committed by the accused, followed by the motives and the results of the judgment. An example case is shown in Table 1, where the summary shares the same writing style and has words in common with the prototype summary (retrieved from the training dataset).

prototype summary	The court held that the defendant Wang had stolen the property of others for the purpose of illegal possession. The amount was large, and his behavior constituted the crime of theft. The accusation of the public prosecution agency was established. The defendant Wang has a criminal record and will be considered when sentencing. Since the defendant Wang did not succeed because of reasons other than his will, he could be punished lightly. After the defendant confessed his crimes to the case, he was given a lighter punishment according to law.
summary	The court held that the accused Zhang and Fan stole property and the amount was large. Their actions constituted the crime of theft. The accusation of the public prosecution agency was established and supported. This crime was committed within two years after the release of the defendants Zhang and Fan. Thus they are recidivists and this situation will be considered when sentencing. The fact that defendants Zhang and Fan surrendered themselves and pleaded guilty in court gives a lighter punishment according to law.

Table 1: An example of patternized summary generation. The text in red denotes patternized words shared in different summaries, and text in blue denotes specific facts.

Existing prototype based generation models such as (Wu et al., 2018) are all applied on short text, thus, cannot handle long documents summarization task. Another series of works focus on template-based methods such as (Oya et al., 2014). However, template-based methods are too rigid for our patternized summary generation task. Hence, in this paper, we propose a summarization framework named *Prototype Editing based Summary Generator* (PESG) that incorporates prototype document-summary pairs to improve summa-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3741–3751, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

rization performance when generating summaries with pattern. First, we calculate the cross dependency between the prototype document-summary pair to obtain a summary pattern and prototype facts (explained in § 4.2). Then, we extract facts from the input document with the help of the prototype facts (explained in § 4.3). Next, a recurrent neural network (RNN) based decoder is used to generate a new summary, incorporating both the summary pattern and extracted facts (explained in § 4.4). Finally, a fact checker is designed to provide mutual information between the generated summary and the input document to prevent the generator from copying irrelevant facts from the prototype (explained in § 4.5). To evaluate PESG, we collect a large-scale court judgment dataset, where each judgment is a summary of the case description with a patternized style. Extensive experiments conducted on this dataset show that PESG outperforms the state-of-the-art summarization baselines in terms of ROUGE metrics and human evaluations by a large margin.

Our contributions can be summarized as follows:

• We propose to use prototype information to help generate better summaries with patterns.

• Specifically, we propose to generate the summary incorporating the prototype summary pattern and extracted facts from input document.

• We provide mutual information signal for the generator to prevent copying irrelevant facts from the prototype.

• We release a large-scale prototype based summarization dataset that is beneficial for the community.

2 Related Work

We detail related work on text summarization and prototype editing.

Text summarization can be classified into extractive and abstractive methods. Extractive methods (Narayan et al., 2018b; Chen et al., 2018) directly select salient sentences from an article to compose a summary. One shortcoming of these models is that they tend to suffer from redundancy. Recently, with the emergence of neural network models for text generation, a vast majority of the literature on summarization (Ma et al., 2018; Zhou et al., 2018; Gao et al., 2019a; Chen et al., 2019) is dedicated to abstractive summarization, which aims to generate new content that concisely paraphrases a document from scratch.

Another line of research focuses on prototype editing. (Guu et al., 2018) proposed the first prototype editing model, which samples a prototype sentence from training data and then edits it into a new sentence. Following this work, (Wu et al., 2018) proposed a new paradigm for response generation, which first retrieves a prototype response from a pre-defined index and then edits the prototype response. (Cao et al., 2018) applied this method on summarization, where they employed existing summaries as soft templates to generate new summary without modeling the dependency between the prototype document, summary and input document. Different from these soft attention methods, (Cai et al., 2018) proposed a hard-editing skeleton-based model to promote the coherence of generated stories. Template-based summarization is also a hard-editing method (Oya et al., 2014), where a multi-sentence fusion algorithm is extended in order to generate summary templates.

Different from all above works, our model focuses on patternized summary generation, which is more challenging than traditional news summarization and short sentence prototype editing.

3 Problem Formulation

For an input document $X = \{x_1, x_2, \ldots, x_{T_m}\}$, we assume there is a ground truth summary $Y = \{y_1, y_2, \ldots, y_{T_n}\}$. In our prototype summarization task, a retrieved prototype document $\hat{X} = \{\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_{T_m}\}$ with a corresponding prototype summary $\hat{Y} = \{\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{T_n}\}$ is also attached according to their similarities with X.

For a given document X, our model extracts salient facts from X guided by a prototype document $\hat{X}$, and then generates the summary $Y^{'}$ by referring to the prototype summary $\hat{Y}$. The goal is to generate a summary $Y^{'}$ that not only follows a patternized style (as defined by prototype summary $\hat{Y}$) but also is consistent with the facts in document X.

4 Model

4.1 Overview

In this section, we propose our *prototype editing based summary generator*, which can be split into two main parts, as shown in Figure 1:

• *Summary Generator.* (1) **Prototype Reader** analyzes the dependency between $\hat{X}$ and $\hat{Y}$ to de-

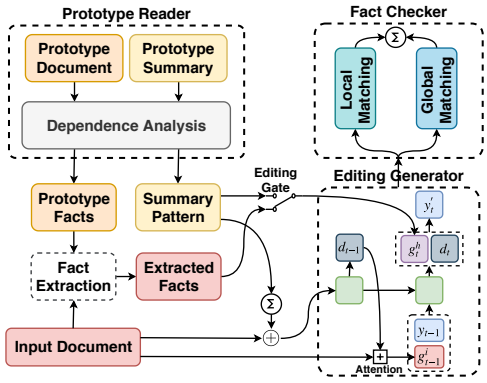

Figure 1: Overview of PESG. We divide our model into four parts: (1) *Prototype Reader*; (2) *Fact Extraction*; (3) *Editing Generator*; (4) *Fact Checker*.

termine the summary pattern and prototype facts. (2) **Fact Extraction** module extracts facts from the input document under the guidance of the prototype facts. (3) **Editing Generator** module generates the summary $Y^{'}$ of document X by incorporating summary pattern and facts.

• *Fact Checker* estimates the mutual information between the generated summary $Y^{'}$ and input document X. This information provides an additional signal for the generation process, preventing irrelevant facts from being copied from the prototype document.

4.2 Prototype Reader

To begin with, we use an embedding matrix e to map a one-hot representation of each word in X, $\hat{X}$, $\hat{Y}$ into a high-dimensional vector space. We then employ a bi-directional recurrent neural network (Bi-RNN) to model the temporal interactions between words:

$$h_t^x = \text{Bi-RNN}_x(e(x_t), h_{t-1}^x), \quad (1)$$

$$\hat{h}_t^x = \text{Bi-RNN}_x(e(\hat{x}_t), \hat{h}_{t-1}^x), \quad (2)$$

$$\hat{h}_t^y = \text{Bi-RNN}_y(e(\hat{y}_t), \hat{h}_{t-1}^y), \quad (3)$$

where h_t^x, $\hat{h}_t^x$ and $\hat{h}_t^y$ denote the hidden state of t-th step in Bi-RNN for X, $\hat{X}$ and $\hat{Y}$, respectively. Following (Tao et al., 2018; Gao et al., 2019b; Hu et al., 2019), we choose long short-term memory (LSTM) as the cell for Bi-RNN.

On one hand, the sections in the prototype summary that are not highly related to the prototype document are the universal patternized words and should be emphasized when generating the new summary. On the other hand, the sections in the prototype document that are highly related to the prototype summary are useful facts that can guide the process of extracting facts from input document. Hence, we employ a bi-directional attention mechanism between a prototype document and summary to analyze the cross-dependency, that is, from document to summary and from summary to document. Both of these attentions are derived from a shared similarity matrix, $S \in \mathbb{R}^{T_m \times T_n}$, calculated by the hidden states of prototype document $\hat{X}$ and prototype summary $\hat{Y}$. S_{ij} indicates the similarity between the i-th document word $\hat{x}_i$ and j-th summary word $\hat{y}_j$ and is computed as:

$$\begin{aligned} S_{ij} &= \alpha(\hat{h}_i^x, \hat{h}_j^y), \\ \alpha(x, y) &= w^\intercal[x \oplus y \oplus (x \otimes y)], \end{aligned} \quad (4)$$

where α is a trainable scalar function that calculates the similarity between two input vectors. $\oplus$ denotes a concatenation operation and $\otimes$ is an element-wise multiplication.

We use $a_t^s = \text{mean}(S_{:t}) \in \mathbb{R}$ to represent the attention weight on the t-th prototype summary word by document words, which will learn to assign high weights to highly related universal patternized words when generating a summary. From a_t^s, we obtain the weighted sum of the hidden states of prototype summary as "**summary pattern**" $l = \{l_1, \ldots, l_{T_n}\}$, where l_i is:

$$l_i = a_i^s \hat{h}_i^y. \quad (5)$$

Similarly, $a_t^d = \text{mean}(S_{t:}) \in \mathbb{R}$ assigns high weights to the words in a prototype document that are relevant to the prototype summary. A convolutional layer is then applied to extract "**prototype facts**" $\hat{r}_t$ from the prototype document:

$$\hat{r}_t = \text{CNN}(a_t^d \hat{h}_t^x). \quad (6)$$

We sum the prototype facts to obtain the overall representation of these facts:

$$q = \textstyle\sum_t^{T_m} \hat{r}_t. \quad (7)$$

4.3 Fact Extraction

In this section, we discuss how to extract useful facts from an input document with the help of prototype facts.

We first extract the facts from an input document by calculating their relevance to prototype facts. The similarity matrix E is then calculated between the weighted prototype document $a_i^d \hat{h}_i^x$ and input document representation h_j^x:

$$E_{ij} = \alpha(a_i^d \hat{h}_i^x, h_j^x), \quad (8)$$

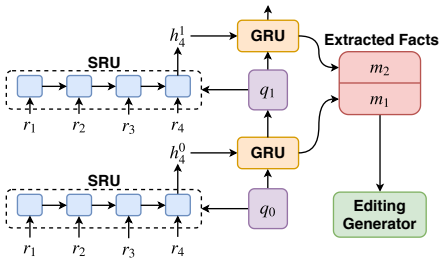

Figure 2: Framework of fact extraction module.

where α is the similarity function introduced in Equation 4. Then, we sum up E_{ij} along the length of the prototype document to obtain the weight $E_j = \sum_{ti}^{T_m} E_{tj}$ for j-th word in the document. Next, similar to Equation 6, a convolutional layer is applied on the weighted hidden states $E_t h_t^x$ to obtain the fact representation r_t from the input document:

$$r_t = \text{CNN}(E_t h_t^x). \tag{9}$$

Inspired by the polishing strategy in extractive summarization (Chen et al., 2018), we propose to use the prototype facts to polish the extracted facts r_t and obtain the final fact representation $m_\cdot$, as shown in Figure 2. Generally, the polishing process consists of two hierarchical recurrent layers. The first recurrent layer is made up of Selective Recurrent Units (SRUs), which take facts $r_\cdot$ and polished fact q_k as input, outputting the hidden state $h_{T_m}^k$. The second recurrent layer consists of regular Gated Recurrent Units (GRUs), which are used to update the polished fact from q_k to q_{k+1} using $h_{T_m}^k$.

SRU is a modified version of the original GRU introduced in (Chen et al., 2018), details of which can be found in Appendix A. Its difference from GRU lies in that the update gate in SRU is decided by both the polished fact q_k and original fact r_t together. The t-th hidden state of SRU is calculated as:

$$h_t^k = \text{SRU}(r_t, q_k). \tag{10}$$

We take $h_{T_m}^k$ as the overall representation of all input facts $r_\cdot$. In this way, SRU can decide to which degree each unit should be updated based on its relationship with the polished fact q_k.

Next, $h_{T_m}^k$ is used to update the polished fact q_k using the second recurrent layer, consisting of GRUs:

$$m_{k+1}, q_{k+1} = \text{GRU}(h_{T_m}^k, q_k), \tag{11}$$

where q_k is the cell state, $h_{T_m}^k$ is the input and m_{k+1} is the output hidden state. q_0 is initialized using q in Equation 7. This iterative process is conducted K times, and each output m_k is stored as **extracted facts** $M = \{m_1, m_2, \ldots, m_K\}$. In this way, M stores facts with different polished levels.

4.4 Editing Generator

The editing generator aims to generate a summary based on the input document, prototype summary and extracted facts. As with the settings of prototype reader, we use LSTM as the RNN cell. We first apply a linear transformation on the summation of the summary pattern $l' = \sum_i^{T_n} l_i$ and input document representations $h_{T_m}^x$, and then employ this vector as the initial state d_0 of the RNN generator as shown in Equation 12. The procedure of t-th generation is shown in Equation 13:

$$d_0 = W_e[h_{T_m}^x \oplus l'] + b_e, \tag{12}$$

$$d_t = \text{LSTM}(d_{t-1}, [g_{t-1}^i \oplus e(y_{t-1})]), \tag{13}$$

where W_e, b_e are trainable parameters, d_t is the hidden state of the t-th generating step, and g_{t-1}^i is the context vector produced by the standard attention mechanism (Bahdanau et al., 2015).

To take advantage of the extracted facts M and prototype summary l, we incorporate them both into summary generation using a dynamic attention. More specifically, we utilize a matching function f to model the relationship between the current decoding state d_t and each v_i (v_i can be a extracted fact m_i or summary pattern l_i):

$$\delta_{it} = \frac{\exp(f(v_i, d_t))}{\sum_j^K \exp(f(v_j, d_t))}, \tag{14}$$

$$g_t^* = \sum_i^K \delta_{it} v_i, \tag{15}$$

where g_t^* can be g_t^m or g_t^s for attending to extracted facts or a summary pattern, respectively. We use a simple but efficient bi-linear layer as the matching function $f = m_i W_f d_t$. As for combining g_t^m and g_t^s, we propose to use an "editing gate" γ, which is determined by the decoder state d_t, to decide the importance of the summary pattern and extracted facts at each decoding step.

$$\gamma = \sigma\left(W_g d_t + b_g\right), \tag{16}$$

where σ denotes the sigmoid function. Using the editing gate, we obtain g_t^h which dynamically

combines information from the extracted facts and summary pattern with the editing gate γ, as:

$$g_t^h = [\gamma g_t^m \oplus (1-\gamma)\, g_t^s]\,. \tag{17}$$

Finally, the context vector g_t^h is concatenated with the decoder state d_t and fed into a linear layer to obtain the generated word distribution P_v:

$$d_t^o = W_o[d_t \oplus g_t^h] + b_o, \tag{18}$$

$$P_v = \text{softmax}\left(W_v d_t^o + b_v\right). \tag{19}$$

The loss is the negative log likelihood of the target word y_t:

$$\mathcal{L}_s = -\sum_{t=1}^{T_n} \log P_v(y_t). \tag{20}$$

In order to handle the out-of-vocabulary (OOV) problem, we equip our decoder with a pointer network (Gu et al., 2016; Vinyals et al., 2015; See et al., 2017). This process is the same as the model described in (See et al., 2017), thus, is omit here due to limited space.

What's more, previous work (Holtzman et al., 2018) has found that using a cross entropy loss alone is not enough for generating coherent text. Similarly, in our task, using $\mathcal{L}_s$ alone is not enough to distinguish a good summary with accurate facts from a bad summary with detailed facts from the prototype document (see § 6.2). Thus, we propose a fact checker to determine whether the generated summary is highly related to the input document.

4.5 Fact Checker

To generate accurate summaries that are consistent with the detailed facts from the input document rather than facts from the prototype document, we add a fact checker to provide additional training signals for the generator. Following (Hjelm et al., 2018), we employ the neural mutual information estimator to estimate the mutual information between the generated summary $Y^{'}$ and its corresponding document X, as well as the prototype document $\hat{X}$. Generally, mutual information is estimated from a local and global level, and we expect the matching degree to be higher between the generated summary and input document than the prototype document. An overview of the fact checker is shown in Figure 3.

To begin, we use a local matching network to calculate the matching degree, for local features, between the generated summary and the input, as well as prototype document. Remember that, in

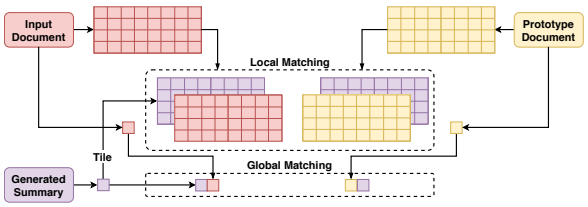

Figure 3: Framework of fact checker module.

§ 4.3, we obtain the fact representation of an input document r_i and prototype facts $\hat{r}_i$. Combining these with the final hidden state d_{T_n} of the generator RNN (in Equation 13), yields the local features of input extracted facts and the prototype facts:

$$C^r = \{d_{T_n} \oplus r_1, \ldots, d_{T_n} \oplus r_{T_m}\}, \tag{21}$$

$$C^f = \{d_{T_n} \oplus \hat{r}_1, \ldots, d_{T_n} \oplus \hat{r}_{T_m}\}. \tag{22}$$

A 1×1 convolutional layer and a fully-connected layer are applied to score these two features:

$$\tau_l^r = \text{CNN}_l(C^r), \quad \tau_l^f = \text{CNN}_l(C^f), \tag{23}$$

where $\tau_l^r \in \mathbb{R}$, $\tau_l^f \in \mathbb{R}$ represent the local matching degree between the generated summary and input document and prototype document, respectively. We want the generated summary to be more similar to the input document than the prototype document. Thus, the optimization objective of the local matching network is to minimize $\mathcal{L}_l$:

$$\mathcal{L}_l = -\left(\log(\tau_l^r) + \log(1-\tau_l^f)\right). \tag{24}$$

We also have a global matching network to measure the matching degree, for global features, between the generated summary and the input document, as well as prototype document. To do so, we concatenate the representation of the generated summary with the final hidden state of the input document $h_{T_m}^x$ and final state of the prototype document $\hat{h}_{T_m}^x$, respectively, and apply a linear layer to these:

$$\tau_g^r = \text{relu}(W_m[d_{T_n} \oplus h_{T_m}^x] + b_m), \tag{25}$$

$$\tau_g^f = \text{relu}(W_m[d_{T_n} \oplus \hat{h}_{T_m}^x] + b_m), \tag{26}$$

where W_m, b_m are trainable parameters and $\tau_g^r \in \mathbb{R}$ and $\tau_g^f \in \mathbb{R}$ represent the matching degree between the generated summary and the input document, and prototype document, respectively. The objective of this global matching network, similar to the local matching network, is to minimize:

$$\mathcal{L}_g = -\left(\log(\tau_g^r) + \log(1-\tau_g^f)\right). \tag{27}$$

Acronym	Gloss
PESG-FC	PESG w/o Fact Checker
PESG-PR	PESG w/o Prototype Reader
PESG-SS	PESG w/o Summary Pattern
PESG-FG	PESG w/o FGRU

Table 2: Ablation models for comparison.

Finally, we combine the local and global loss functions to obtain the final loss $\mathcal{L}$, which we use $\mathcal{L}$ to calculate the gradients for all parameters:

$$\mathcal{L} = \epsilon\mathcal{L}_g + \eta\mathcal{L}_l + \mathcal{L}_s, \tag{28}$$

where ϵ, η are both hyper parameters. To optimize the trainable parameters, we employ the gradient descent method Adagrad (Duchi et al., 2010) to update all parameters.

5 Experimental Setup

5.1 Dataset

We collect a large-scale prototype based summarization dataset[2], which contains 2,003,390 court judgment documents. In this dataset, we use a case description as an input document and the court judgment as the summary. The average lengths of the input documents and summaries are 595.15 words and 273.57 words respectively. The percentage of words common to a prototype summary and the reference summary is 80.66%, which confirms the feasibility and necessity of prototype summarization. Following other summarization datasets (Grusky et al., 2018; Kim et al., 2019; Narayan et al., 2018a), we also count the novel n-grams in a summary compared with the n-grams in the original document, and the percentage of novel n-grams are 51.21%, 84.59%, 91.48%, 94.83% for novel 1-grams to 4-grams respectively. The coverage, compression and density (Grusky et al., 2018) are commonly used as metrics to evaluate the abstractness of a summary. For the summaries in our dataset, the coverage percentage is 48.78%, compression is 2.28 and density is 1.31. We anonymize entity tokens into special tags, such as using "PERS" to replace a person's name.

5.2 Comparisons

In order to prove the effectiveness of each module of PESG, we conduct several ablation studies, shown in Table 2. We also compare our model with the following baselines: (1) `Lead-3` is a commonly used summarization baseline (Nallapati et al., 2017; See et al., 2017), which selects the first three sentences of document as the summary. (2) `S2S` is a sequence-to-sequence framework with a pointer network, proposed by (See et al., 2017). (3) `Proto` is a context-aware prototype editing dialog response generation model proposed by (Wu et al., 2018). (4) `Re`^{3}`Sum`, proposed by (Cao et al., 2018), uses an IR platform to retrieve proper summaries and extends the seq2seq framework to jointly conduct template-aware summary generation. (5) `Uni-model` was proposed by (Hsu et al., 2018), and is the current state-of-the-art abstractive summarization approach on the CNN/DailyMail dataset. (6) We also directly concatenate the prototype summary with the original document as input for S2S and Uni-model, named as `Concat-S2S` and `Concat-Uni`, respectively.

5.3 Evaluation Metrics

For the court judgment dataset, we evaluate standard ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004) on full-length F1 following previous works (Nallapati et al., 2017; See et al., 2017; Paulus et al., 2018), where ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) refer to the matches of unigram, bigrams, and the longest common subsequence respectively.

(Schluter, 2017) notes that only using the ROUGE metric to evaluate summarization quality can be misleading. Therefore, we also evaluate our model by human evaluation. Three highly educated participants are asked to score 100 randomly sampled summaries generated by three models: `Uni-model`, `Re`^{3}`Sum` and PESG. The statistical significance of observed differences between the performance of two runs is tested using a two-tailed paired t-test and is denoted using $^{\blacktriangle}$(or $^{\blacktriangledown}$) for strong (or weak) significance for $\alpha = 0.01$.

5.4 Implementation Details

We implement our experiments in TensorFlow (Abadi et al., 2016) on an NVIDIA GTX 1080 Ti GPU. The word embedding dimension is 256 and the number of hidden units is 256. The batch size is set to 64. We padded or cut input document to contain exactly 250 words, and the decoding length is set to 100. ϵ and η from the Equation 28 are both set to 1.0. We initialize all of the parameters randomly using a Gaussian distribution. We use Adagrad optimizer (Duchi

et al., 2010) as our optimizing algorithm and employ beam search with size 5 to generate more fluency summary sentence. We also apply gradient clipping (Pascanu et al., 2013) with range $[-5, 5]$ during training. We use dropout (Srivastava et al., 2014) as regularization with keep probability $p = 0.7$.

6 Experimental Result

6.1 Overall Performance

We compare our model with the baselines listed in Table 3. Our model performs consistently better than other summarization models including the state-of-the-art model with improvements of 6%, 12% and 6% in terms of ROUGE-1, ROUGE-2 and ROUGE-L. This demonstrates that prototype document-summary pair provides strong guidance for summary generation that cannot be replaced by other complicated baselines without prototype information. Meanwhile, directly concatenating the prototype summary with the original input does not increase performance, instead leading to drops of 9%, 17%, 8% and 1%, 3%, 2% in terms of ROUGE 1,2,L on the S2S and Unified models, respectively. As for the baseline model `Proto`, we found that it directly **copies** from the prototype summary as generated summary, which leads to a totally useless and incorrect summary.

For the human evaluation, we asked annotators to rate each summary according to its consistency and fluency. The rating score ranges from 1 to 3, with 3 being the best. Table 4 lists the average scores of each model, showing that PESG outperforms the other baseline models in both fluency and consistency. The kappa statistics are 0.33 and 0.29 for fluency and consistency respectively, and that indicates the moderate agreement between annotators. To prove the significance of these results, we also conduct the paired student t-test between our model and `Re`^{3}`Sum` (row with shaded background). We obtain a p-value of 2×10^{-7} and 9×10^{-12} for fluency and consistency, respectively.

We also analyze the effectiveness of performance by the two hyper-parameters: η and ϵ. It turns out that our model has a consistently good performance, with ROUGE-1, ROUGE-2, ROUGE-L scores above 39.5, 27.5, 39.4, which demonstrates that our model is very robust.

6.2 Ablation Study

The ROUGE scores of different ablation models are shown in Table 5. All ablation models perform worse than PESG in terms of all metrics, which demonstrates the preeminence of PESG. More importantly, by this controlled experiment, we can verify the contributions of each modules in PESG.

6.3 Analysis of Editing Generator

We visualize the editing gate (illustrated in Equation 16) of two **randomly sampled** examples,

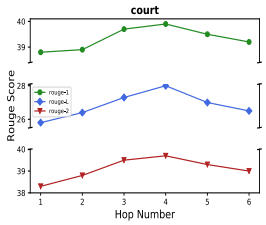

Figure 5: Visualizations of ROUGE score with different hop numbers.

	R1	R2	RL
PESG-FC	38.7	26.2	38.6
PESG-PR	37.3	24.6	37.0
PESG-SS	38.6	25.6	38.3
PESG-FG	38.8	25.9	38.5

Table 5: ROUGE scores of different ablation models of PESG.

shown in Figure 4. A lower weight (lighter color) means that the word is more likely to be copied from the summary pattern; that is to say, this word is a universal patternized word. We can see that the phrase 本院认为 (the court held that) has a lower weight than the name of the defendant (PERS), which is consistent with the fact that (the court held that) is a patternized word and the name of the defendant is closely related to the input document.

We also show a case study in Table 6, which includes the input document and reference summary with the generated summaries. Underlined text denotes a grammar error and a strike-through line denotes a fact contrary to the input document. We only show part of the document and summary due to limited space; the full version is shown in Appendix. As can be seen, the summary generated by `Uni-model` faces an inconsistency problem and the summary generated by `Re`^{3}`Sum` is contrary to the facts described in the input document. However, PESG overcomes both of these problems and generates an accurate summary with good grammar and logic.

6.4 Analysis of Fact Extraction Module

We investigate the influence of the iteration number when facts are extracted. Figure 5 illustrates the relationship between iteration number and the f-value of the ROUGE score. The results show that the ROUGE scores first increases with the number of hops. After reaching an upper limit it then begins to drop. This phenomenon demonstrates that the fact extraction module is effective by polishing the facts representation.

7 Conclusion

In this paper, we propose a framework named *Prototype Editing based Summary Generator* (PESG), which aims to generate summaries in formal writing scenarios, where summaries should conform to a patternized style. Given a prototype document-summary pair, our model first calculates the cross dependency between the prototype document-summary pair. Next, a fact extraction module is employed to extract facts from the document, which are then polished. Finally, we design an editing-based generator to produce a summary by incorporating the polished fact and summary pattern. To ensure that the generated summary is consistent with the input document, we propose a fact checker to estimate the mutual information between the input document and generated summary. Our model outperforms state-of-the-art methods in terms of ROUGE scores and human evaluations by a large margin, which demonstrates the effectiveness of PESG.

	安徽省人民法院作出刑事判决，以斗殴罪判处被告人PERS 有期徒刑YEARS 。合肥市监狱提出减刑意见。执行机关以PERS 在服刑期间确有悔改表现，已获得奖励二个，建议对其减刑。经审理查明，罪犯PERS 在服刑期间，能认罪服法，努力参加技术学习。(Anhui Provincial People's Court made a criminal judgment and sentenced the defendant PERS to YEARS imprisonment for the crime of fighting. Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments. We would also

like to thank Anna Hennig in Inception Institute of Artificial Intelligence for her help on this paper. This work was supported by the National Key Research and Development Program of China (No. 2017YFC0804001), the National Science Foundation of China (NSFC No. 61876196 and NSFC No. 61672058)

A SRU Cell

Gated recurrent unit (GRU) (Cho et al., 2014) is a gating mechanism in recurrent neural networks, which incorporate an update gate in an RNN. We first give the details of the original GRU here.

$$u_i = \sigma(W^{(u)}x_i + U^{(u)}h_{i-1} + b^{(u)}), \quad (29)$$

$$r_i = \sigma(W^{(r)}x_i + U^{(r)}h_{i-1} + b^{(r)}), \quad (30)$$

$$\tilde{h_i} = \tanh(W^{(h)}x_i + r_i \circ Uh_{i-1} + b^{(h)}), \quad (31)$$

$$h_i = u_i \circ \tilde{h_i} + (1 - u_i) \circ h_{i-1}, \quad (32)$$

where σ is the sigmoid activation function, $W^{(u)}, W^{(r)}, W^{(h)} \in \mathbb{R}^{n_H \times n_I}, U^{(u)}, U^{(r)}, U \in \mathbb{R}^{n_H \times n_H}$, n_H is the hidden size, and n_I is the size of input x_i. In the original version of GRU, the update gate u_i in Equation 29 is used to decide how much of the hidden state should be retained and how much should be updated. In our case, we want to decide which facts are salient according to the polished facts q_{k-1} at the k-th hop. To achieve this, we replace the calculation of u_i with the newly computed update gate g_i:

$$f_i = [x_i \circ q_{k-1}; x_i; q_{k-1}], \quad (33)$$

$$z_i = W^{(2)} \tanh(W^{(1)}f_i + b^{(1)}) + b^{(2)}, \quad (34)$$

$$g_i = \frac{\exp(z_i)}{\sum_{j=1}^{n_s} \exp(z_j)}, \quad (35)$$

where $W^{(2)}, W^{(1)}, b^{(1)}, b^{(2)}$ are all trainable parameters and k is the hop number in the multi-hop situation which is a hyper-parameter manually set. The effectiveness of this hyper-parameter is verified in the experimental results shown in § 6.4. Equation 32 now becomes:

$$h_i = g_i \circ \tilde{h_i} + (1 - g_i) \circ h_{i-1}. \quad (36)$$

We use the name "SRU" to denote this modified version of an GRU cell.

B Case Study

	安徽省合肥市包河区人民法院作出刑事判决，以斗殴罪判处被告人PERS 有期徒刑YEARS 。案经本院二审，准许上诉人撤回上诉。判决生效后交付执行。执行机关合肥市义城监狱于DATE 提出减刑意见，报送本院审理。本院依法组成合议庭进行了审理，现已审理终结。执行机关以罪犯PERS 在服刑期间确有悔改表现，已获得奖励二个，建议对其减刑。经审理查明，罪犯PERS 在服刑期间，能认罪服法，努力参加技术学习，积极完成生产任务。(The People's Court of Baohe District, Hefei City, Anhui Province made a criminal judgment and sentenced the defendant PERS to YEARS imprisonment for the crime of fighting. In the second instance of the court, the appellant was allowed to withdraw the appeal. The judgment takes effect after being delivered. The enforcement agency Hefei City Yicheng Prison put forward a commutation opinion on DATE and submitted it to the court for trial. The court had formed a collegiate bench in accordance with the law and had now end the trial. Criminal PERS had repentance during his sentence and received two awards, thus the enforcement agency suggested he should be commuted. Investigation confirmed that the criminal PERS was able to plead guilty while serving his sentence, strived to participate in technical studies, and completed production tasks.)
reference	本院认为，罪犯PERS 在服刑期间确有悔改表现符合法定减刑条件。依据《中华人民共和国刑法》第NUM 款之规定，裁定如下对罪犯PERS 减去自本裁定送达之日起至DATE 止尚未执行完毕的刑罚。本裁定送达后即发生法律效力。(The court held that the criminal PERS did have repentance during the period of serving his sentence in accordance with the statutory commutation conditions. According to the provisions of NUM Section of the Criminal Law of the People's Republic of China, the court decided to exempt PERS from penalty that had not been executed since the date of delivery of this ruling until DATE. Legal effect would occur upon the delivery of this ruling.)
Unified	本院认为，被告人PERS 以非法占有为目的，秘密窃取他人财物，数额较大，其行为已构成盗窃罪，依法应予惩处。公诉机关指控被告人PERS 聚众斗殴罪的事实清楚，证据确实充分，指控罪名成立，本院予以支持。被告人PERS 曾因故意犯罪被判处有期徒刑，在刑罚执行完毕后YEARS 内再犯，应当判处有期徒刑以上刑罚之罪，是累犯，依法应当从重处罚。(The court held that the defendant PERS secretly stole the property of others for the purpose of illegal possession, and the amount was relatively large. His behavior had constituted theft and should be punished according to law. The fact that the defendant PERS commiting the crimes of the fighting was clear, the evidence was indeed sufficient, thus the charges were established and the court supported it. The defendant PERS was sentenced to fixed-term imprisonment for intentional crimes. If he committed another crime in YEARS after the execution of the penalty, he should be sentenced to a fixed-term imprisonment or more. He is a recidivist and should be severely punished according to law.)
Re^{3}Sum	本院认为NUM PERS 在道路上驾驶机动车其行为已构成上诉人服刑确系罪公诉机关指控的犯罪事实清楚证据确实充分指控的罪名成立本院予以支持被告人PERS 归案后如实供述自己的罪行依法予以从轻处罚公诉机关的量刑建议适当本院予以采纳此依照《中华人民共和国刑法》第NUM 款之规定判决如下被告人PERS 犯服刑判处有期徒刑MONTHS并处罚金人民币MONEY (The court held that NUM PERS was driving a motor vehicle on the road, and his behavior constituted that the appellant was guilty of serving a sentence. The criminal facts accused by the public prosecution agency were clear, the evidence was indeed sufficient, and the charges were supported by the court. After confessing his crimes, he should be given a lighter punishment according to law. The public prosecution agency's sentencing recommendations were appropriate and adopted by the court. According to the provisions of Section NUM of the Criminal Law of the People's Republic of China, the judgment was as follows, the defendant PERS was sentenced to imprisonment and sentenced to fixed-term MONTHS imprisonment, and fined the penalty RMB MONEY.)
PESG	本院认为，罪犯PERS 在服刑期间，确有悔改表现。符合法定减刑条件，依照《中华人民共和国刑法》第NUM 条、第NUM 条之规定，裁定如下：对罪犯PERS 减去有期徒刑MONTHS。本裁定送达后即发生法律效力。(The court believed that the criminal PERS did have repentance during his sentence. In accordance with the statutory commutation conditions and NUM and NUM of the Criminal Law of the People's Republic of China, the ruling was as follows: exempted PERS from the MONTHS penalty. Legal effect would occur upon the delivery of this ruling.)

Abstract

The principle of the Information Bottleneck (Tishby et al., 1999) is to produce a summary of information X optimized to predict some other relevant information Y. In this paper, we propose a novel approach to unsupervised sentence summarization by mapping the Information Bottleneck principle to a conditional language modelling objective: given a sentence, our approach seeks a compressed sentence that can best predict the *next* sentence. Our iterative algorithm under the Information Bottleneck objective searches gradually shorter subsequences of the given sentence while maximizing the probability of the next sentence conditioned on the summary. Using only pretrained language models with no direct supervision, our approach can efficiently perform extractive sentence summarization over a large corpus.

Building on our *unsupervised extractive* summarization (*BottleSum*^{Ex}), we then present a new approach to *self-supervised abstractive* summarization (*BottleSum*^{Self}), where a transformer-based language model is trained on the output summaries of our unsupervised method. Empirical results demonstrate that our extractive method outperforms other unsupervised models on multiple automatic metrics. In addition, we find that our self-supervised abstractive model outperforms unsupervised baselines (including our own) by human evaluation along multiple attributes.

1 Introduction

Recent approaches based on neural networks have brought significant advancements for both extractive and abstractive summarization (Rush et al., 2015; Nallapati et al., 2016). However, their success relies on large-scale parallel corpora of input text and output summaries for direct supervision. For example, there are ~280,000 training instances in the CNN/Daily Mail dataset (Nallapati et al., 2016; Hermann et al., 2015), and ~4,000,000 instances in the sentence summarization dataset of Rush et al. (2015). Because it is too costly to have humans write gold summaries at this scale, existing large-scale datasets are based on naturally occurring pairs of summary-like text paired with source text, for instance using news titles or highlights as summaries for news-text. A major drawback to this approach is that these pairs must already exist in-domain, which is often not true.

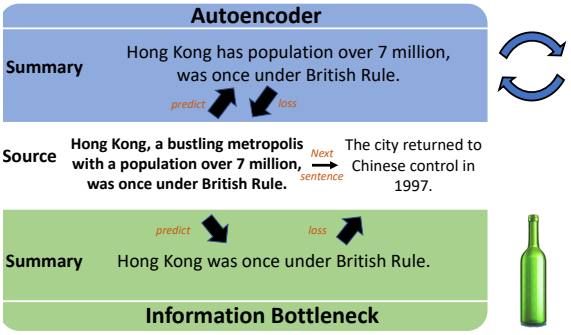

Figure 1: Example contrasting the Autoencoder (AE) and Information Bottleneck (IB) approaches to summarization. While AE (top) preserves any detail that helps to reconstruct the original, such as population size in this example, IB (bottom) uses context to determine which information is relevant, which results in a more appropriate summary.

The sample inefficiency of current neural approaches limits their impact across different tasks and domains, motivating the need for unsupervised or self-supervised alternatives (Artetxe et al., 2017; LeCun, 2018; Schmidhuber, 1990). Further, for summarization in particular, the current paradigm requiring millions of supervision examples is almost counter-intuitive; after all, humans don't need to see a million summaries to know how to summarize, or what information to include.

In this paper, we present *BottleSum*, consisting

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3752–3761, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of a pair of novel approaches, *BottleSum*^{Ex} and *BottleSum*^{Self} for *unsupervised extractive* and *self-supervised abstractive* summarization, respectively. Core to our approach is the principle of the Information Bottleneck (Tishby et al., 1999), producing a summary for information X optimized to predict some other relevant information Y. In particular, we map (conditional) language modeling objectives to the Information Bottleneck principle to guide the unsupervised model on what to keep and what to discard.

The key intuition of our bottleneck-based summarization is that a good sentence summary contains information related to the broader context while discarding less significant details. Figure 1 demonstrates this intuition. Given input sentence "Hong Kong, a bustling metropolis with a population over 7 million, ...", which is followed by the next sentence "The city returned to Chinese control in 1997", the information bottleneck would suggest that minute details such as the city's population being over 7 million are relatively less important to keep. In contrast, the continued discussion of the city's governance in the next sentence suggests its former British rule is important here.

This intuition contrasts with that of autoencoder-based approaches where the goal is to minimize the reconstruction loss of the input sentence when constructing the summary (Miao and Blunsom, 2016; Wang and Lee, 2018; Fevry and Phang, 2018; Baziotis et al., 2019). Under the reconstruction loss, minute but specific details such as the city's population being over 7 million will be difficult to discard from the summary, because they are useful for reconstruction.

Concretely, *BottleSum*^{Ex} is an extractive and unsupervised sentence summarization method using the next sentence, a sample of nearby context, as guidance to *relevance*, or what information to keep. We capture this with a conditional language modelling objective, allowing us to benefit from powerful deep neural language models that are pre-trained over an extremely large-scale corpus. Under the Information Bottleneck objective, we present an iterative algorithm that searches gradually shorter subsequences of the source sentence while maximizing the probability of the next sentence conditioned on the summary. The benefit of this approach is that it requires no domain-specific supervision or fine-turning.

Building on our unsupervised extractive summarization, we then present *BottleSum*^{Self}, a new approach to self-supervised abstractive summarization. This method also uses a pretrained language model, but turns it into an abstractive summarizer by fine-tuning on the output summaries generated by *BottleSum*^{Ex} paired with their original input sentences. The goal is to generalize the summaries generated by an extractive method by training a language model on them, which can then produce abstractive summaries as its generation is not constrained to be extractive.

Together, *BottleSum*^{Ex} and *BottleSum*^{Self} are *BottleSum* methods for unsupervised sentence summarization. Empirical results demonstrate that *BottleSum*^{Ex} outperforms other unsupervised methods on multiple automatic metrics, closely followed by *BottleSum*^{Self}. Furthermore, testing on a large unsupervised corpus, we find *BottleSum*^{Self} outperforms unsupervised baselines (including our own *BottleSum*^{Ex}) on human evaluation along multiple attributes.

2 The Information Bottleneck Principle

Unsupervised summarization requires formulating an appropriate learning objective that can be optimized without supervision (example summaries). Recent work has treated unsupervised summarization as an autoencoding problem with a reconstruction loss (Miao and Blunsom, 2016; Baziotis et al., 2019). The goal is then to produce a compressed summary from which the source sentence can be accurately predicted, i.e. to maximize:

$$\mathbb{E}_{p(\tilde{s}|s)} \ \log p(s|\tilde{s}), \tag{1}$$

where s is the source sentence, $\tilde{s}$ is the generated summary and $p(\tilde{s}|s)$ the learned summarization model. The exact form of this loss may be more elaborate depending on the system, for example including an auxiliary language modeling loss, but the main aim is to produce a summary from which the source can be reconstructed.

The intuitive limitation of this approach is that it will always prefer to retain all informative content from the source. This goes against the fundamental goal of summarization, which crucially needs to forget all but the "relevant" information. It should be detrimental to keep tangential information, as illustrated by the example in Figure 1. As a result, autoencoding systems need to introduce additional loss terms to augment the reconstruction loss (e.g. length penalty, or the topic loss

of Baziotis et al. (2019)).

The premise of our work is that the Information Bottleneck (IB) principle (Tishby et al., 1999) is a more natural fit for summarization. Unlike reconstruction loss, which requires augmentative terms to summarize, IB naturally incorporates a tradeoff between information selection and pruning. These approaches are compared directly in section 5.

At its core, IB is concerned with the problem of maximal compression while defining a formal notion of information relevance. This is introduced with an external variable Y. The key is that $\tilde{S}$, the summary of source S, contains only information useful for predicting Y. This can be posed formally as learning a conditional distribution $p(\tilde{S}|S)$ minimizing:

$$I(\tilde{S};S) - \beta I(\tilde{S};Y), \tag{2}$$

where I denotes mutual information between these variables.

A notion of information relevance comes from the second term, the *relevance term*: with a positive coefficient β, this is encouraging summaries $\tilde{S}$ to contain information shared with Y. The first term, or *pruning term*, ensures that irrelevant information is discarded. By minimizing the mutual information between summary $\tilde{S}$ and source S, any information about the source that is not credited by the *relevance term* is thrown away. The statistical structure of IB makes this compressive by forcing the summary to only contain information shared with the source.[1]

In sum, IB relies on 3 principles:

1. Encouraging relevant information with a *relevance term*.

2. Discouraging extra information with a *pruning term*.

3. Strictly summarizing the source.

To clarify the difference from a reconstructive loss, suppose there is irrelevant information in S (i.e. unrelated to relevance variable Y), call this Z. With the IB objective (eq 3), there is no benefit to keeping any information from Z, which strictly makes the first term worse (more mutual information between source and summary) and does not affect the second (Z is unrelated to Y). In contrast, because Z contains information about S, including it in $\tilde{S}$ could easily benefit the reconstructive loss (eq. 1) despite being irrelevant.

As a relevance variable we will use the sentence following the source in the document in which it occurs. This choice is motivated by linguistic cohesion, in which we expect more broadly relevant information to be common between consecutive sentences, while less relevant information and details are often not carried forward.

We use these principles to derive two methods for sentence summarization. Our first method (§3) enforces strict summarization through being extractive. Additionally, it does not require any training, so can be applied directly without the availability of domain-specific data. The second method (§4) generalizes IB-based summarization to *abstractive* summarization that can be trained on large unsupervised datasets, learning an explicit summarization function $p(\tilde{s}|s)$ over a distribution of inputs.

3 Unsupervised Extractive Summarization

We now use the Information Bottleneck principle to propose *BottleSum*^{Ex}, an unsupervised extractive approach to sentence summarization. Our approach does not require any training; only a pretrained language model is required to satisfy the IB principles of (2), and the stronger the language model, the stronger our approach will be. In section 5 we demonstrate the effectiveness of this method using GPT-2, the pretrained language model of Radford et al. (2019). [2]

3.1 IB for Extractive Summarization

Here, we take advantage of the natural parallel between the Information Bottleneck and summarization developed in section 2. Working from the 3 IB principles stated there, we derive a set of actionable principles for a concrete sentence summarization method.

We approach the task of summarizing a single sentence s using the following sentence s_{next} as the relevance variable. The method will be a deterministic function mapping s to the summary $\tilde{s}$, so instead of learning a distribution over summaries, we take $p(\tilde{s}|s) = 1$ for the summary we arrive at. Our goal is then to optimize the IB equation (Eq 2)

[1] In IB, this is a strict statistical relationship.

[2] We use the originally released "small" 117M parameter version.

for a single example rather a distribution of inputs (as in the original IB method).

In this setting, to minimize equation 2 we can equivalently minimize:

$$-\log p(\tilde{s}) - \beta_1 p(s_{next}|\tilde{s}) p(\tilde{s}) \log p(s_{next}|\tilde{s}), \quad (3)$$

where coefficient $\beta_1 > 0$ controls the trade-off between keeping relevant information and pruning. See appendix A for the derivation of this equation. Similar to eq 2, the first term encourages pruning, while the second encourages information about the relevance variable, s_{next}. Both unique values in eq 3 ($p(\tilde{s})$ and $p(s_{next}|\tilde{s})$) can be estimated directly by a pretrained language model, a result of the summary being natural language as well as our choice of relevance variable. This will give us a direct path to enforcing IB principles 1 and 2 from section 2.

To interpret principle 3 for text, we consider what attributes are important to strict textual summarization. Simply, a strict textual summary should be shorter than the source, while agreeing semantically. The first condition is straightforward but the second is currently infeasible to ensure with automatic systems, and so we instead enforce extractive summarization to ensure the first and encourage the second.

Without a supervised validation set, there is no clear way to select a value for β_1 in Eq 3 and so no way to optimize this directly. Instead, we opt to ensure both terms improve as our method proceeds. Thus, we are not comparing the pruning and relevance terms directly (only ensuring mutual progress), and so we optimize simpler quantities monotonic in the two terms instead: $p(\tilde{s})$ for pruning and $p(y|\tilde{s})$ for relevance.

We perform extractive summarization by iteratively deleting words or phrases, starting with the original sentence. At each elimination step, we only consider candidate deletions which decrease the value of the pruning term, i.e., increase the language model score of the candidate summary. This ensures progress on the pruning term, and also enforces the notion that word deletion should reduce the information content of the summary. The relevance term is optimized through only expanding candidates that have the highest relevance scores at each iteration, and picking the candidate with the highest relevance score as final summary.

Altogether, this gives 3 principles for extractive summarization with IB.

1. Maximize *relevance term* by maximizing $p(s_{next}|\tilde{s})$.
2. Prune information and enforce compression by bounding: $p(\tilde{s}_{i+1}) > p(\tilde{s}_i)$.
3. Enforce strict summarization by extractive word elimination.

3.2 Method

Algorithm 1 *BottleSum*^{Ex} method

Require: sentence s and context s_{next}

1: $C \leftarrow \{s\}$ ▷ set of summary candidates
2: **for** l in $length(s)...1$ **do**
3: $C_l \leftarrow \{s' \in C | len(s') = l\}$
4: sort C_l descending by $p(s_{next}|s')$
5: **for** s' in $C_l[1:k]$ **do**
6: $l' \leftarrow length(s')$
7: **for** j in $1...m$ **do**
8: **for** i in $1...(l'-j)$ **do**
9: $s'' \leftarrow s'[1:i-1] \circ s'[i+j:l']$
10: **if** $p(s'') > p(s')$ **then**
11: $C \leftarrow C + \{s''\}$
12: **return** $\arg\max_{s' \in C} p(s_{next}|s')$

We turn these principles into a concrete method which iteratively produces summaries of decreasing length by deleting consecutive words in candidate summaries (Algorithm 1). The relevance term is optimized in two ways: first, only the top-scoring summaries of each length are used to generate new, shorter summaries (line 5). Second, the final summary is chosen explicitly by this measure (line 12).

In order to satisfy the second condition, each candidate must contain less self-information (i.e., have higher probability) than the candidate that derives it. This ensures that each deletion (line 9) strictly removes information. The third condition, strict extractiveness, is satisfied per definition.

The algorithm has two parameters: m is the max number of consecutive words to delete when producing new summary candidates (line 9), and k is the number of candidates at each length used to generate shorter candidates by deletion (line 5).

4 Abstractive Summarization with Extractive Self-Supervision

Next, we extend the unsupervised summarization of *BottleSum*^{Ex} to abstractive summarization with

BottleSum^{Self}, based on a straightforward technique for self-supervision. Simply, a large corpus of unsupervised summaries is generated with *BottleSum*^{Ex} using a strong language model, then the same language model is tuned to produce summaries from source sentences on that dataset.

The conceptual goal of *BottleSum*^{Self} is to use *BottleSum*^{Ex} as a guide to learn the notion of information relevance as expressed through IB, but in a way that (a) removes the restriction of extractiveness, to produce more natural outputs and (b) learns an explicit compression function not requiring a next sentence for decoding.

4.1 Extractive Dataset

The first step of *BottleSum*^{Self} is to produce a large-scale dataset for self-supervision using the *BottleSum*^{Ex} method set out in §3.2. The only requirement for the input corpus is that next sentences need to be available.

In our experiments, we generate a corpus of 100,000 sentence-summary pairs with *BottleSum*^{Ex}, using the same parameter settings as in section 3. The resulting summaries have an average compression ratio (by character length) of approximately 0.55.

4.2 Abstractive Fine-tuning

The second step of *BottleSum*^{Self} is fine-tuning the language model on its extractive summary dataset. The tuning data is formed by concatenating source sentences with generated summaries, separated by a delimiter and followed by an end token. The model (GPT-2) is fine-tuned with a simple language modeling objective over the full sequence.

As a delimiter, we use `TL;DR:` , following Radford et al. (2019) who found that this induces summarization behavior in GPT-2 even without tuning. We use a tuning procedure closely related to Radford et al. (2018), training for 10 epochs. We take the trained model weights that minimize loss on a held-out set of 7000 extractive summaries.

To generate from this model, we use a standard beam search decoder, keeping the top candidates at each iteration. Unless otherwise specified, assume we use a beam size of 5. We restrict produced summaries to be at least 5 tokens long, and no longer than the source sentence.

5 Experiments

We evaluate our *BottleSum* methods using both automatic metrics and human evaluation. We find our methods dominant over a range of baselines in both categories.

5.1 Setup

We evaluate our methods and baselines using automatic ROUGE metrics (1,2,L) on the DUC-2003 and DUC-2004 datasets (Over et al., 2007), similar to the evaluation used by Baziotis et al. (2019). DUC-2003 and DUC-2004 consist of 624 and 500 sentence-summary pairs respectively. Sentences are taken from newstext, and each summary consists of 4 human-written reference summaries capped at 75 bytes. We recover next-sentences from DUC articles for *BottleSum*^{Ex}.

We also employ human evaluation as a point of comparison between models. This is both to combat known issues with ROUGE metrics (Schluter, 2017) and to experiment beyond limited supervised domains. Studying unsupervised methods allows for comparison over a much wider range of data where training summary pairs are not available, which we take advantage of here by summarizing sentences from the non-anonymized CNN corpus (Hermann et al., 2015; Nallapati et al., 2016; See et al., 2017).

We use Amazon Mechanical Turk (AMT) for human evaluation, summarizing on 100 sentences sampled from a held out set. Evaluation between systems is primarily done as a pairwise comparison between *BottleSum* models and baselines, over 3 attributes: coherence, conciseness, and agreement with the input. AMT workers are then asked to make a final judgement of which summary has higher overall quality. Each comparison is done by 3 different workers. Results are aggregated across workers and examples.

5.2 Models

In both experiments, *BottleSum*^{Ex} is executed as described in section 3.2. In experiments on DUC datasets, next-sentences are recovered from original news sources, while we limit test sentences in the CNN dataset to those with an available next-sentence (this includes over 95% of sentences). We set parameter $k = 1$ (i.e. expand a single candidate at each step) with up to $m = 3$ consecutive words deleted per expansion. GPT-2 (small) is used as the method's pretrained language model,

with no task-specific tuning. To clarify, the only difference between how *BottleSum*^{Ex} runs on the datasets tested here is the input sentences; no data-specific learning is required.

As with *BottleSum*^{Ex}, we use GPT-2 (small) as the base for *BottleSum*^{Self}. To produce source-summary pairs for self supervision, we generate over 100,000 summaries using *BottleSum*^{Ex} with the parameters above, on both the Gigaword sentence dataset (for automatic evaluation) and CNN training set (for human evaluation). *BottleSum*^{Self} is tuned on the respective set for 10 epoch with a procedure similar to Radford et al. (2019). When generating summaries, *BottleSum*^{Self} uses beam-search with beam size of 5, and outputs constrained to be at least 5 tokens long.

We include a related model, Recon^{Ex} as a simple autoencoding baseline comparable in setup to *BottleSum*^{Ex}. Recon^{Ex} follows the procedure of *BottleSum*^{Ex}, but replaces the next-sentence with the source sentence. This aims to take advantage of the tendency of language models to semantically repeat in to substitute the Information Bottleneck objective in *BottleSum*^{Ex} with a reconstruction-inspired loss. While this is not a perfect autoencoder by any means, we include it to probe the role of the next-sentence in the success of *BottleSum*^{Ex}, particularly compared to a reconstructive method. As Recon^{Ex} tends to have a best reconstructive loss by retaining the entire source as its summary, we constrain its length to be as close as possible to the *BottleSum*^{Ex} summary for the same sentence.

As an unsupervised neural baseline, we include SEQ^3 (Baziotis et al., 2019), which is trained with an autoencoding objective paired with a topic loss and language model prior loss. SEQ^3 had the highest comparable unsupervised results on the DUC datasets that we are aware of, which we cite directly. For human evaluation, we retrained the model with released code on the training portion of the CNN corpus.

We use the ABS model of Rush et al. (2015) as a baseline for automatic and human evaluation. For automatic evaluation, this model is the best published supervised result we are aware of on the DUC-2003 dataset, and we include it as a point of reference for the gap between supervised and unsupervised performance. We cite their results directly. For human evaluation, this model demonstrates the performance gap for out-of-domain summarization. Specifically, it requires supervision (unavailable for the CNN dataset), and so we use the model as originally trained on the Gigaword sentence dataset. This constitutes a significant domain-shift from the first-sentences of articles with limited vocabulary to arbitrary article sentences with diverse vocabulary.

Method	R-1	R-2	R-L
Supervised			
ABS	28.18	8.49	23.81
Li et al. (2017)	31.79	10.75	27.48
Unsupervised			
PREFIX	20.91	5.52	18.20
INPUT	22.18	**6.30**	19.33
SEQ^3	22.13	6.18	19.3
Recon^{Ex}	21.97	5.70	18.81
BottleSum^{Ex}	**22.85**	5.71	**19.87**
BottleSum^{Self}	22.30	5.84	19.60

Table 1: Averaged ROUGE scores on the DUC-2004 dataset

We include the result of Li et al. (2017) on DUC-2004, who achieved the best supervised performance we are aware of. This is intended as a point of reference for supervised performance.

Finally, for automatic metrics we include common baseline PREFIX, the first 75 bytes of the source sentence. To take into account lack of strict length constraints and possible bias of ROUGE towards longer sequences, we include INPUT, the full input sentence. Because our model is extractive, we know its outputs will be no longer than the input, but may exceed the length of other methods/baselines.

5.3 Results

In automatic evaluation, we find *BottleSum*^{Ex} achieves the highest R-1 and R-L scores for unsupervised summarization on both datasets. This is promising in terms of the effectiveness of the Information Bottleneck (IB) as a framework. *BottleSum*^{Self} achieves the second highest scores in both of these categories, further suggesting that the tuning process used here is able to capture some of this benefit. The superiority of *BottleSum*^{Ex} suggests possible benefit to having access to a relevance variable (next-sentence) to the effectiveness of IB on these datasets.

The R-2 scores for *BottleSum*^{Ex} on both bench-

Method	R-1	R-2	R-L
Supervised			
ABS	28.48	8.91	23.97
Unsupervised			
PREFIX	21.14	**6.35**	18.74
INPUT	20.83	6.15	18.44
SEQ^3	20.90	6.08	18.55
Recon^{Ex}	21.11	5.77	18.33
BottleSum^{Ex}	**21.80**	5.63	**19.19**
BottleSum^{Self}	21.54	5.93	18.96

Table 2: Averaged ROUGE scores on the DUC-2003 dataset

mark sets were lower than baselines, possibly due to a lack of fluency in the outputs of the extractive approach used. PREFIX and INPUT both copy human text directly and so should be highly fluent, while Rush et al. (2015) and Baziotis et al. (2019) have the benefit of abstractive summarization, which is less restrictive in word order. Further, the fact that *BottleSum*^{Self} is abstractive and surpasses R-2 scores of both new extractive methods tested here (*BottleSum*^{Ex}, Recon^{Ex}) supports this idea. Recon^{Ex}, also extractive, has similar R-2 scores to *BottleSum*^{Ex}.

The performance of Recon^{Ex}, our simple reconstructive baseline, is mixed. It does succeed to some extent (e.g. surpassing R-1 for all other baselines but PREFIX on DUC-2003) but not as consistently as either *BottleSum* method. This suggests that while some benefit may come from the extractive process of *BottleSum*^{Ex} alone (which Recon^{Ex} shares), there is significant benefit to using a strong relevance variable (specifically in contrast to a reconstructive loss).

Next, we consider model results on human evaluation. *BottleSum*^{Self} and *BottleSum*^{Ex} both show reliably stronger performance compared to models from related work (ABS and SEQ^3 in Table 3). While *BottleSum*^{Self} seems superior to Recon^{Ex} other than in conciseness (in accordance with their compression ratios in Table 4), *BottleSum*^{Ex} appears roughly comparable to Recon^{Ex} and slightly inferior to *BottleSum*^{Self}.

The inversion of dominance between *BottleSum*^{Ex} and *BottleSum*^{Self} on automatic and human evaluation may cast light on competing advantages. *BottleSum*^{Ex} captures reference summaries more effectively, while *BottleSum*^{Self}, through a combination of abstractivness and learning a cohesive underlying mechanism of summarization, writes more favorable summaries for a human audience. Further analysis and accounting for known limitations of ROUGE metrics may clarify these competing advantages.

In comparing these models, there are also practical considerations (summarized in table 5). ABS can be quite effective, but requires learning on a large supervised training set (as demonstrated by its poor out-of-domain performance in Table 3). While SEQ^3 is unsupervised, it still needs extensive training on a large corpus of in-domain text. *BottleSum*^{Ex}, whose outputs were preferred over both by humans, requires neither of these. Given a strong pretrained language model (GPT-2 small is used here) it only requires a source and next-sentence to summarize. *BottleSum*^{Self} requires in-domain text for self-supervision, but its superior performance by human evaluation and summarization without next-sentence are clear advantages. Further, its beam-search decoding is more computationally efficient than *BottleSum*^{Ex}, which requires evaluating conditional next-sentence perplexity over a large grid of extractive summary candidates.

Models		Attributes			Overall		
Model	Comparison	coherence	conciseness	agreement	better	equal	worse
BottleSum^{Ex} vs.	ABS	+0.45	+0.48	+0.52	60%	31%	9%
	SEQ^3	+0.61	+0.57	+0.56	61%	34%	5%
	Recon^{Ex}	-0.05	+0.01	-0.05	37%	22%	41%
BottleSum^{Self} vs.	ABS	+0.47	+0.39	+0.48	62%	26%	12%
	SEQ^3	+0.56	+0.45	+0.53	65%	26%	9%
	Recon^{Ex}	+0.11	-0.05	+0.09	47%	14%	39%
	BottleSum^{Ex}	+0.14	+0.06	+0.11	43 %	27%	30%

Table 3: Human evaluation on 100 CNN test sentences (pairwise comparison of model outputs). Attribute scores are averaged over a scale of 1 (better), 0 (equal) and -1 (worse). We also report the overall preferences as percentages.

Another difference from *BottleSum*^{Ex} is the ability of *BottleSum*^{Self} to be abstractivene (Table 4). Other baselines have a higher degree of abstractiveness than *BottleSum*^{Self}, but this can be misleading. Consider the examples in figure 2. While many of the phrases introduced by other models are technically abstractive, they are often off-topic and confusing.

This hints at an advantage of *BottleSum* methods. In only requiring the base model to be a (tunable) language model, they are architecture-agnostic and can incorporate as powerful a language model as is available. Here, incorporating GPT-2 (small) carries benefits like strong pretrained weights and robust vocabulary handling by byte pair encoding, allowing them to process the diverse language of the non-anonymized CNN corpus with ease. The specific benefits of GPT-2 are less central, however; any such language model could be used for *BottleSum*^{Ex} immediately, and *BottleSum*^{Self} with some tuning. This is in contrast architecture-specific models like ABS and SEQ^3, which would require significant restructuring to fully incorporate a new model.

As a first work to study the Information Bottleneck principle for unsupervised summarization, our results suggest this is a promising direction for the field. It yielded two methods with unique performance benefits (Table 1, 2, 3) and practical advantages (table 5). We believe this concept warrants further exploration in future work.

Model	Abstractive Tokens %	Compression Ratio %
BottleSum^{Ex}	-	51
Recon^{Ex}	-	52
BottleSum^{Self}	5.8	56
SEQ^3	12.6	58
ABS	60.4	64

6 Related Work

6.1 Sentence Compression and Summarization

Rush et al. (2015) first proposed abstractive sentence compression with neural sequence to sequence models, trained on a large corpus of headlines with the first sentences of newspaper articles as supervision. This followed early work on approaching headline generation as statistical machine translation (Banko et al., 2000). Subsequently, recurrent neural networks with pointer-generator decoders became the standard model for this task, and focus shifted to document-level summarization (Nallapati et al., 2016; See et al., 2017).

Pointer-based neural models have also been proposed for extractive summarization (Cheng and Lapata, 2016). The main limitations of this approach stem from the fact that the training data is constructed heuristically, covering a very specific type of sentence summarization (headline generation). Thus, these supervised models do not generalize well to other kinds of sentence summarization or domains. In contrast, our method is applicable to any domain for which examples of the inputs to be summarized are available in context.

6.2 Unsupervised Summarization

Miao and Blunsom (2016) framed sentence compression as an autoencoder problem, where the compressed sentence is a latent variable from

Model Name	Model architecture	Data for training	Data for summarizing	When to use
ABS (Rush et al., 2015)	Seq2Seq	Large scale, paired source-summaries (supervised)	source sentence	Large scale supervised training set available
SEQ^3 (Baziotis et al., 2019)	Seq2Seq2Seq	Large scale, unsupervised source sentences	source sentence	Large scale unsupervised (no summaries) data available, *without* next-sentences
BottleSum^{Ex}	Pre-trained LMs	No training data needed	source sentence and next-sentence	No training data available, and next-sentences *are* available for sentences to summarize.
BottleSum^{Self}	Pre-trained LMs (fined-tuned on data from *BottleSum*^{Ex})	Large scale, unsupervised source sentences with next sentences	source sentence	Large scale unsupervised (no summaries) data available, *with* next-sentences and/or no next-sentences available for sentences to summarize

Table 5: Comparison of sentence summarization methods.

which the input sentence can be reconstructed. They proposed extractive and pointer-generator models, regularizing the autoencoder with a language model to encourage compression and optimizing the variational objective with the REINFORCE algorithm. While their extractive model can be trained without supervision, results are only reported for semi-supervised training, which requires less supervised data than purely supervised training. Fevry and Phang (2018) applied denoising autoencoders to fully unsupervised summarization, while Wang and Lee (2018) proposed an autoencoder with a discriminator for distinguising well-formed and ill-formed compressions in a Generative Adversarial Network (GAN) setting, as an alternative to using a language model. However, their discriminator was trained using unpaired summaries, so while they obtain better results than purely unsupervised approaches like ours their results are not directly comparable. Recently Baziotis et al. (2019) proposed a differentiable autoencoder using a gumbel-softmax to represent the distribution over summaries. The model is trained with a straight-through estimator as an alternative to reinforcement learning, obtaining better results on unsupervised summarization. All of these approaches have in common autoencoder-based training, which we argue does not naturally capture an appropriate notion of relevance for summarization.

Recently, Zhou and Rush (2019) introduced a promising method for summarization using contextual matching with pretrained language models. While contextual matching requires pretrained language models to generate contextual vectors, *BottleSum* methods do not have specific architectural constraints. Also, like Wang and Lee (2018) it trains with unpaired summaries and so is not directly comparable to us.

7 Conclusion

We have presented *BottleSum*^{Ex}, an unsupervised extractived approach to sentence summarization, and extended this to *BottleSum*^{Self}, a self-supervised abstractive approach. *BottleSum*^{Ex}, which can be applied without any training, achieves competitive performance on automatic and human evaluations, compared to unsupervised baselines. *BottleSum*^{Self}, trained on a new domain, obtains stronger performance by human evaluation than unsupervised baselines as well as *BottleSum*^{Ex}. Our results show that the Information Bottleneck principle, by encoding a more appropriate notion of relevance than autoencoders, offers a promising direction for progress on unsupervised summarization.

Improving Latent Alignment in Text Summarization by Generalizing the Pointer Generator

Xiaoyu Shen[1,2]*, **Yang Zhao**[3], **Hui Su**[4] **and Dietrich Klakow**[1]

Abstract

Pointer Generators have been the de facto standard for modern summarization systems. However, this architecture faces two major drawbacks: Firstly, the pointer is limited to copying the exact words while ignoring possible inflections or abstractions, which restricts its power of capturing richer latent alignment. Secondly, the copy mechanism results in a strong bias towards extractive generations, where most sentences are produced by simply copying from the source text. In this paper, we address these problems by allowing the model to "edit" pointed tokens instead of always hard copying them. The editing is performed by transforming the pointed word vector into a target space with a learned relation embedding. On three large-scale summarization dataset, we show the model is able to (1) capture more latent alignment relations than exact word matches, (2) improve word alignment accuracy, allowing for better model interpretation and controlling, (3) generate higher-quality summaries validated by both qualitative and quantitative evaluations and (4) bring more abstraction to the generated summaries.[1]

1 Introduction

Modern state-of-the-art (SOTA) summarization models are built upon the pointer generator architecture (See et al., 2017). At each decoding step, the model generates a sentinel to decide whether to sample words based on the neural attention (generation mode), or directly copy from an aligned source context (point mode) (Gu et al., 2016; Merity et al., 2017; Yang et al., 2017). Though outperforming the vanilla attention models, the pointer generator only captures exact word matches. As shown in Fig. 1, for abstractive summarization, there exists a large number of syntactic inflections (escalated → escalates) or semantic transformations (military campaign → war), where the target word also has an explicit grounding in the source context but changes its surface. In standard pointer generators, these words are not covered by the point mode. This largely restricts the application of the pointer generator, especially on highly abstractive dataset where only a few words are exactly copied. Moreover, the hard copy operation biases the model towards extractive summarization, which is undesirable for generating more human-like summaries (Kryściński et al., 2018).

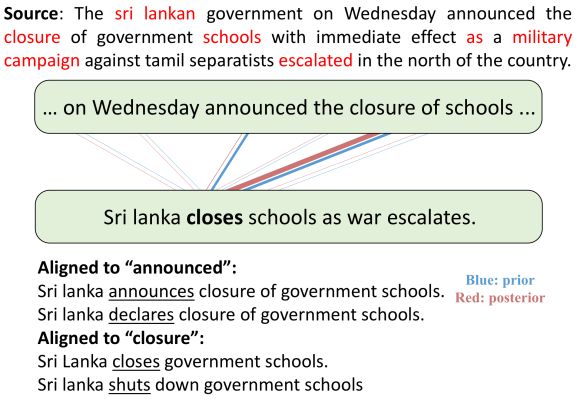

Figure 1: Alignment visualization of our model when decoding "closes". Posterior alignment is more accurate for model interpretation. In contrast, the prior alignment probability is spared to "announced" and "closure", which can be manually controlled to generate desired summaries. Decoded samples are shown when aligned to "announced" and "closure" respectively. Highlighted source words are those that can be directly aligned to a target token in the gold summary.

To solve this problem, we propose **G**eneralized **P**ointer **G**enerator (**GPG**) which replaces the hard copy component with a more general soft "editing" function. We do this by learning a relation embedding to transform the pointed word into a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3762–3773, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

target embedding. For example, when decoding "closes" in Figure 1, the model should first point to "closure" in the source, predict a relation to be applied (noun → third person singular verb), then transform "closure" into "closes" by applying the relation transformation. The generalized point mode is encouraged to capture such latent alignment which cannot be identified by the standard pointer generator.

This improved alignment modelling is intriguing in that (a) people can better control the generation by manipulating the alignment trajectory, (b) posterior alignment can be inferred by Bayes' theorem (Deng et al., 2018; Shankar and Sarawagi, 2019) to provide a better tool for interpretation[2] and finally (c) explicitly capturing the alignment relation should improve generation performance. (Figure 1 shows an example of how latent alignment can improve the controllability and interpretation. Pointer generators fail to model such alignment relations that are not exact copies.) To eliminate the OOV problem, we utilize the byte-pair-encoding (BPE) segmentation (Sennrich et al., 2016) to split rare words into sub-units, which has very few applications in summarization so far (Fan et al., 2018; Kiyono et al., 2018), though being a common technique in machine translation (Wu et al., 2016; Vaswani et al., 2017; Gehring et al., 2017).

Our experiments are conducted on three summarization datasets: CNN/dailymail (Hermann et al., 2015), English Gigaword (Rush et al., 2015) and XSum (Narayan et al., 2018) (a newly collected corpus for extreme summarization). We further perform human evaluation and examine the word alignment accuracy on the manually annotated DUC 2004 dataset. Overall we find our model provides the following benefits:

1. It can capture richer latent alignment and improve the word alignment accuracy, enabling better controllability and interpretation.

2. The generated summaries are more faithful to the source context because of the explicit alignment grounding.

3. It improves the abstraction of generations because our model allows editing the pointed token instead of always copying exactly.

In the next section, we will first go over the background, then introduce our model and finally present the experiment results and conclusion.

2 Background

Let X, Y denote a source-target pair where X corresponds to a sequence of words $x_1, x_2, \ldots, x_n$ and Y is its corresponding summary $y_1, y_2, \ldots, y_m$. In this section, we introduce two baseline models for automatically generating Y from X:

2.1 Seq2seq with Attention

In a seq2seq model, each source token x_i is encoded into a vector h_i. At each decoding step t, the decoder computes an attention distribution a_t over the encoded vectors based on the current hidden state d_t (Bahdanau et al., 2015):

$$a_t = \text{softmax}(f(h_i, d_t)) \tag{1}$$

f is a score function to measure the similarity between h_i and d_t. The context vector c_t and the probability of next token are computed as below.

$$\begin{aligned} c_t &= \sum_i h_i a_{t,i} \\ y_t^* &= [d_t \circ c_t] L \\ p_{vocab} &= \text{softmax}(y_t^* W^T) \end{aligned} \tag{2}$$

$\circ$ means concatenation and L, W are trainable parameters. We tie the parameters of W and the word embedding matrix as in Press and Wolf (2017); Inan et al. (2017). Namely, a target vector y_t^* is predicted, words having a higher inner product with y_t^* will have a higher probability.

2.2 Pointer Generator

The pointer generator extends the seq2seq model to support copying source words (Vinyals et al., 2015). At each time step t, the model first computes a generation probability $p_{gen} \in [0, 1]$ by:

$$p_{gen} = \sigma(\text{MLP}_g([d_t \circ c_t])) \tag{3}$$

σ is a sigmoid function and MLP_g is a learnable multi-layer perceptron. p_{gen} is the probability of enabling the generation mode instead of the point

[2]The induced alignment offers useful annotations for people to identify the source correspondence for each target word. News editors can post-edit machine-generated summaries more efficiently with such annotation. For summary readers, it also helps them track back the source context when they are interested in some specific details. Derivation for inducing the posterior alignment is in the appendix A.1.

mode. In the generation mode, the model computes the probability over the whole vocabulary as in Eq. 2. In the point mode, the model computes which source word to copy based on the attention distribution a_t from Eq.1. The final probability is marginalized over $a_{t,i}$:

$$p(y_t) = p_{gen}p_{vocab}(y_t) + (1 - p_{gen}) \sum_i a_{t,i}\delta(y_t|x_i)$$

$$\delta(y_t|x_i) = \begin{cases} 1, & \text{if } y_t = x_i. \\ 0, & \text{otherwise.} \end{cases} \quad (4)$$

If we know exactly from which mode each word comes from, *e.g.*, by assuming all co-occurred words are copied, then the marginalization can be omitted (Gulcehre et al., 2016; Wiseman et al., 2017), but normally p_{gen} is treated as a latent variable (Gu et al., 2016; See et al., 2017).

3 Generalized Pointer Generator (GPG)

As seen in Eq .4, $\delta(y_t|x_i)$ is a 0-1 event that is only turned on when y_t is exactly the same word as x_i. This restricts the expressiveness of the point mode, preventing it from paying attention to inflections, POS transitions or paraphrases. This section explains how we generalize pointer networks to cover these conditions.

Redefine $\boldsymbol{\delta(y_t|x_i)}$: We extend $\delta(y_t|x_i)$ by defining it as a smooth probability distribution over the whole vocabulary. It allows the pointer to edit x_i to a different word y_t instead of simply copying it. Following Eq. 2, we derive $\delta(y_t|x_i)$ by first predicting a target embedding $y^*_{t,i}$, then applying the softmax. The difference is that we derive $y^*_{t,i}$ as the summation of the pointed word embedding $\overrightarrow{x_i}$ and a relation embedding $r(d_t, h_t)$:

$$\begin{aligned} y^*_{t,i} &= r(d_t, h_i) + \overrightarrow{x_i} \\ \delta(y_t|x_i) &= \text{softmax}(y^*_{t,i}W^T) \end{aligned} \quad (5)$$

$\overrightarrow{x_i}$ denotes the embedding of the word x_i. $r(d_t, h_t)$ can be any function conditioning on d_t and h_t, which we parameterize with a multi-layer-perceptron in our experiments. The computation of $y^*_{t,i}$ is similar to the classical TransE model (Bordes et al., 2013) where an entity vector is added by a relation embedding to translate into the target entity. The intuition is straightforward: After pointing to x_t, humans usually first decide which relation should be applied (inflection, hypernym, synonym, etc) based on the context $[d_t, h_i]$, then transform x_i to the proper target word y_t. Using addition transformation is backed by the observation that vector differences often reflect meaningful word analogies (Mikolov et al., 2013; Pennington et al., 2014) ("man" − "$king$" ≈ "$woman$" − "$queen$") and they are effective at encoding a great amount of word relations like hypernym, meronym and morphological changes (Vylomova et al., 2016; Hakami et al., 2018; Allen and Hospedales, 2019). These word relations reflect most alignment conditions in text summarization. For example, humans often change the source word to its hypernym (boy → child), to make it more specific (person → man) or apply morphological transformations (liked → like). Therefore, we assume $\delta(y_t|x_i)$ can be well modelled by first predicting a relation embedding to be applied, then added to $\overrightarrow{x_i}$. If x_i should be exactly copied like in standard pointer generators, the relation embedding is a zero vector meaning an identity transition. We also tried applying more complex transitions to $\overrightarrow{x_i}$ like diagonal mapping (Trouillon et al., 2016), but did not observe improvements. Another option is to estimate $\delta(y_t|x_i)$ directly from (d_t, h_i) by an MLP regardless of $\overrightarrow{x_i}$. However, this leads to poor alignment and performance drop because y_t is not explicitly grounded on x_i[3]. A comparison of different choices can be found in the appendix A.4. In this paper, we stick to Eq. 5 to compute $\delta(y_t|x_i)$.

Estimate Marginal Likelihood: Putting Eq. 5 back to Eq. 4, the exact marginal likelihood is too expensive for training. The complexity grows linearly with the source text length n and each computation of $\delta(y_t|x_i)$ requires a separate softmax operation. One option is to approximate it by sampling like in hard attention models (Xu et al., 2015; Deng et al., 2017), but the training becomes challenging due to the non-differentiable sampling process. In our work, we take an alternative strategy of marginalizing only over k most likely aligned source words. This top-k approximation is widely adopted when the target distribution is expected to be sparse and only a few modes dominate (Britz et al., 2017; Ke et al., 2018; Shankar et al., 2018). We believe this is a valid assumption in text summarization since most source

[3] h_i can contain context information from surrounding words and thus not necessarily relates to word x_i. It is part of the reason that neural attention has a poor alignment (Koehn and Knowles, 2017). Making it grounded on x_i improves alignment and performance is also observed in machine translation (Nguyen and Chiang, 2018; Kuang et al., 2018)

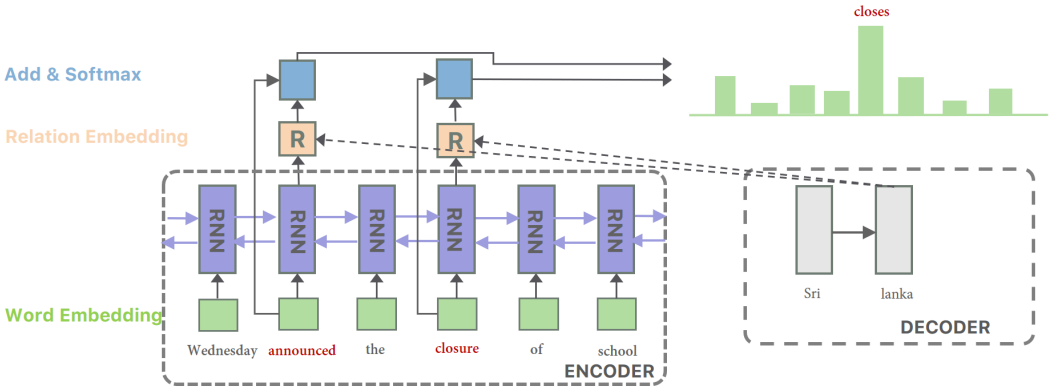

Figure 2: Architecture of the generalized pointer. The same encoder is applied to encode the source and target. When decoding "closes", we first find top-k source positions with the most similar encoded state. For each position, the decoding probability is computed by adding its word embedding and a predicted relation embedding.

tokens have a vanishingly small probability to be transferred into a target word.

For each target word, how to determine the k most likely aligned source words is crucial. An ideal system should always include the gold aligned source word in the top-k selections. We tried several methods and find the best performance is achieved when encoding each source/target token into a vector, then choosing the k source words that are closest to the target word in the encoded vector space. The closeness is measured by the vector inner product[4]. The encoded vector space serves like a contextualized word embedding (McCann et al., 2017; Peters et al., 2018). Intuitively if a target word can be aligned to a source word, they should have similar semantic meaning and surrounding context thus should have similar contextualized word embeddings. The new objective is then defined as in Eq. 6:

$$
\begin{aligned}
p(y_t) &= p_{gen} p_{vocab}(y_t) + (1 - p_{gen}) p_{point}(y_t) \\
p_{point}(y_t) &= \sum_i a_{t,i} \delta(y_t | x_i) \\
&\approx \sum_{i; h_i^T e(y_t) \in \text{TopK}} a_{t,i} \delta(y_t | x_i)
\end{aligned} \tag{6}
$$

$e(y_t)$ is the encoded vector for y_t. The marginalization is performed only over the k chosen source words. Eq. 6 is a lower bound of the data likelihood because it only marginalizes over a subset of X. In general a larger k can tighten the bound to get a more accurate estimation and we analyze the effect of k in Section 5.2. Note that the only extra parameters introduced by our model are the multi-layer-perceptron to compute the relation embedding $r(d_t, h_i)$. The marginalization in Eq. 6 can also be efficiently parallelized. An illustration of the generalized pointer is in Figure 2.

[4]We compared several strategies for choosing the top-k words and report it in Appendix A.5. Note that the top-k approximation is only used for training, so we can spot the whole target text to decide top-k candidates.

4 Related Work

Neural attention models (Bahdanau et al., 2015) with the seq2seq architecture (Sutskever et al., 2014) have achieved impressive results in text summarization tasks. However, the attention vector comes from a weighted sum of source information and does not model the source-target alignment in a probabilistic sense. This makes it difficult to interpret or control model generations through the attention mechanism. In practice, people do find the attention vector is often blurred and suffers from poor alignment (Koehn and Knowles, 2017; Kiyono et al., 2018; Jain and Wallace, 2019). Hard alignment models, on the other hand, explicitly models the alignment relation between each source-target pair. Though theoretically sound, hard alignment models are hard to train. Exact marginalization is only feasible for data with limited length (Yu et al., 2016; Aharoni and Goldberg, 2017; Deng et al., 2018; Backes et al., 2018), or by assuming a simple copy generation process (Vinyals et al., 2015; Gu et al., 2016; See et al., 2017). Our model can be viewed as a combination of soft attention and hard alignment, where a simple top-k approximation is used to train the alignment part (Shankar et al., 2018; Shankar and Sarawagi, 2019). The hard alignment generation probability is designed as a relation summation operation to better fit the sum-

marization task. In this way, the generalized copy mode acts as a hard alignment component to capture the direct word-to-word transitions. On the contrary, the generation mode is a standard soft-attention structure to only model words that are purely functional, or need fusion, high-level inference and can be hardly aligned to any specific source context (Daumé III and Marcu, 2005).

5 Experiments and Results

In the experiment, we compare seq2seq with attention, standard pointer generators and the proposed generalized pointer generator (GPG). To further analyze the effect of the generalized pointer, we implement a GPG model with only the point mode (GPG-ptr) for comparison. We first introduce the general setup, then report the evaluation results and analysis.

5.1 General Setup

Dataset: We perform experiments on the CNN/dailymail (Hermann et al., 2015), English Gigaword (Rush et al., 2015) and XSum (Narayan et al., 2018) dataset. We put statistics of the datasets in Appendix A.2. CNN/DM contains online news with multi-sentence summaries (We use the non-anonymized version from See et al. (2017)). English Gigaword paired the first sentence of news articles with its headline. XSum corpus provides a single-sentence summary for each BBC long story. We pick these three dataset as they have different properties for us to compare models. CNN/DM strongly favors extractive summarization (Kryściński et al., 2018). Gigaword has more one-to-one word direct mapping (with simple paraphrasing) (Napoles et al., 2012) while XSum needs to perform more information fusion and inference since the source is much longer than the target (Narayan et al., 2018).

Model: We use single-layer bi-LSTM encoders for all models. For comparison, hidden layer dimensions are set the same as in Zhou et al. (2017) for Gigaword and See et al. (2017) for CNN/DM and XSum. We train with batch size 256 for gigaword and 32 for the other two. The vocabulary size is set to 30k for all dataset. Word representations are shared between the encoder and decoder. We tokenize words with WordPiece segmentation (Wu et al., 2016) to eliminate the OOV problem. More details are in Appendix A.3

Inference: We decode text using beam search (Graves, 2012) with beam size 10. We apply length normalization to rescale the score. Unlike See et al. (2017); Gehrmann et al. (2018), we do not explicitly impose coverage penalty since it brings extra hyper-parameters. Instead, for CNN/Dailymail, we use a simple tri-gram penalty (Paulus et al., 2018) to prevent repeated generations. GPG models use an exact marginalization for testing and decoding, while for training and validation we use the top-k approximation mentioned above. The decoder will first decode sub-word ids then map them back to the normal sentence. All scores are reported on the word level and thus comparable with previous results. When computing scores for multi-sentence summaries. The generations are split into sentences with the NLTK sentence tokenizer.

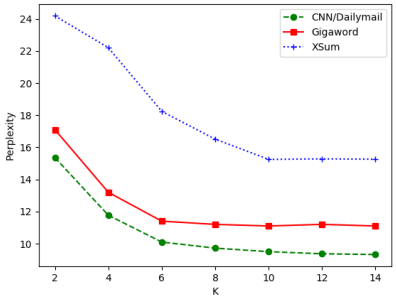

Figure 3: Test perplexity when increasing k

5.2 Results and Analysis

The results are presented in the following order: We first study the effect of the hyperparameter k, then evaluate model generations by automatic metrics and look into the generation's level of abstraction. Finally, we report the human evaluation and word alignment accuracy.

Effect of K: k is the only hyperparameter introduced by our model. Figure 3 visualizes the effect of k on the test perplexity. As mentioned in Sec 3, a larger k is expected to tighten the estimation bound and improve the performance. The figure shows the perplexity generally decreases as increasing k. The effect on Gigaword and XSum saturates at $k = 6$ and 10 respectively, so we fix such k value for later experiments. For the longer dataset CNN/Dailymail, the perplexity might still decrease a bit afterwards, but the improvement is marginal, so we set $k = 14$ for the memory limit.

Automatic Evaluation: The accuracy is evaluated based on the standard metric ROUGE (Lin,

2004) and the word perplexity on the test data. We report the ROUGE-1, ROUGE-2 and ROUGE-L F-score measured by the official script. Table 1, 2 and 3 lists the results for CNN/Dailymail, Gigaword and XSum respectively. Statistically significant results are underlined[5]. On the top two rows of each table, we include two results taken from current state-of-the-art word-based models. They are incomparable with our model because of the different vocabulary, training and decoding process, but we report them for completeness. Lower rows are results from our implemented models. Pointer generators bring only slight improvements over the seq2seq baseline. This suggests that after eliminating the OOV problem, the naive seq2seq with attention model can already implicitly learn most copy operations by itself. GPG models outperform seq2seq and pointer generators on all dataset. The improvement is more significant for more abstractive corpus Gigaword and XSum, indicating our model is effective at identifying more latent alignment relations.

Notably, even the pure pointer model (GPG-ptr) without the generation mode outperforms standard pointer generators in CNN/DM and Gigaword, implying most target tokens can be generated by aligning to a specific source word. The finding is consistent with previous research claiming CNN/DM summaries are largely extractive (Zhang et al., 2018; Kryściński et al., 2018). Though the Gigaword headline dataset is more abstractive, most words are simple paraphrases of some specific source word, so pure pointer GPG-ptr can work well. This is different from the XSum story summarization dataset where many target words require high-level abstraction or inference and cannot be aligned to a single source word, so combining the point and generation mode is necessary for a good performance.

[5]Results on the Gigaword test set is not significant due to the smalle test size (1951 article-summary pairs).

Table 3: ROUGE score on XSum. * marks results from Narayan et al. (2018). Underlined values are significantly better than Point.Gen. with $p = 0.05$.

The word perplexity results are consistent over all dataset (GPG $<$ GPG-ptr $<$ Point.Gen. $<$ seq2seq). The reduction of perplexity does not necessarily indicate an increase for the ROUGE score, especially for pointer generators. This might attribute to the different probability computation of pointer generators, where the probability of copied words are only normalized over the source words. This brings it an inherent advantage over other models where the normalization is over the whole 30k vocabularies.

Level of Abstraction: In Tab. 4, we look into how abstractive the generated summaries are by calculating the proportion of novel unigram, bigram and trigrams that do not exist in the corresponding source text. On CNN/DM, as the generations contain multiple sentences, we further report the proportion of novel sentences (obtained with NLTK sent_tokenize).

Tab. 4 reflects the clear difference in the level of abstraction (seq2seq $>$ GPG $>$ GPG-ptr $>$ Point.Gen.). Though the seq2seq baseline generated most novel words, many of them are hallu-

cinated facts (see Fig 6), as has also been noted in See et al. (2017). The abstraction of GPG model is close to seq2seq and much higher than copy-based pointer generators. We believe it comes from their ability of "editing" pointed tokens rather than simple copying them.

To examine the pointing behavior of the GPG model, we visualize the average pointing ratio on three dataset in Fig. 4. The pointing ratio can be considered as the chance that a word is generated from the point mode instead of the generation mode. We compute it as $(1 - p_{gen}) \sum_i a_{t,i} \delta(y_t | x_i) / p(y_t)$, averaged over all target tokens in the test data. For the GPG model, we further split it into the copy ratio (words that are exactly copied) and the editing ratio (words that are edited). We find the GPG model enables the point mode more frequently than standord pointer generators, especially on the Gigaword dataset (40% more). This also explains why a pure pointer model is more effective for Gigaword and CNN/DM. More than 60% target tokens can be generated from the point mode, while for XSum the ratio is less than 40%. Quite a few pointing operation includes text rewriting (green bar in Fig. 4). This could explain why our model is able to generate more novel words.

A few examples are displayed in Fig 5. We find our model frequently changes the tense (reported → report), singular/plural (death → deaths) or POS tag (jordan → jordanian) of words. Sometimes it also paraphrases (relatives → family) or abstracts a noun to its hypernym (girl → child). The word editing might be wrong though. For example, "death row prisoner" is wrongly changed to "deaths row prisoner" in the second example, possibly because this phrase is rarely seen so that the model made an error by mistaking "death" as the main subject after "thousands more"[6].

Human evaluation: We further perform a human evaluation to assess the model generations. We focus on evaluating the fluency and faithfulness since the ROUGE score often fails to quan-

[6]It also reveals a limit of GPG model in that it only models token-level alignment. For phrases like death row prisoner, it cannot align it based on its compositional meaning.

	Fluency	Faithfulness	0/1

GPG-ptr	0.79	**0.78**	0.67
GPG	0.82	0.74	**0.69**
Gold	0.96	0.92	0.96

Table 5: Human evaluation results on DUC 2004. 0/1 is the score for the 0/1 Turing test.

tify them (Schluter, 2017; Cao et al., 2018). 100 random source-target pairs are sampled from the human-written DUC 2004 data for task 1&2 (Over et al., 2007). Models trained on Gigaword are applied to generate corresponding summaries. The gold targets, together with the model generations are randomly shuffled then assigned to 10 human annotators. Each pair is evaluated by three different people and the most agreed score is adopted. Each pair is assigned a 0-1 score to indicate (1) whether the target is fluent in grammar, (2) whether the target faithfully conveys the source information without hallucination and (3) whether the target is considered human-generated or machine-generated (like a 0/1 Turing test). The averaged score is reported in Table 5. All models generally achieve high scores in fluency, but generations from GPG models are more faithful to the source information thereby have a larger chance of fooling people into believe they're human-generated (over 0.1 higher score on the 0/1 Turing test). This can be explained by GPG's capability at capturing more latent alignments. As shown in Figure 4, GPG generates over half of the target words by its point mode. Words are generated by explicitly grounding on some source context instead of fabricating freely.

Fig. 6 compares some generation snippets. As can be observed, seq2seq models tend to freely synthesize wrong facts not grounded on the source text, especially on the more difficult XSum dataset. In the last example, seq2seq only capture the subject "odom" and some keywords "police", "basketball" then start to freely fabricate random facts. Pointer generators are slightly better as it is trained to directly copy keyword from the source. However, once it starts to enter the generation mode ("of british" in example 2 and "has been arrested" in example 3), the generation also loses control. GPG largely alleviates the problems because it can point to an aligned source word, then transform it by a learned relation embedding. The explicit alignment modelling encourages the model to stay close to the source information.

	seq2seq	Point.Gen.	GPG
Prec	0.361	0.435 (0.512)	0.533 (0.628)

Table 6: Word Alignment Precision on DUC 2004. Number in bracket is the posterior alignment precision.

Alignment Accuracy: We also manually annotate the word alignment on the same 100 DUC 2004 pairs. Following Daumé III and Marcu (2005), words are allowed to be aligned with a specific source word, phrase or a "null" anchor meaning that it cannot be aligned with any source word. The accuracy is only evaluated on the target words with a non-null alignment. For each target token, the most attended source word is considered as alignment (Ghader and Monz, 2017). For the pointer generator and GPG, we also induce the posterior alignment by applying the Bayes' theorem (derivation in appendix A.1). We report the alignment precision (Och and Ney, 2000) in Table 6, i.e., an alignment is considered as valid if it matches one of the human annotated ground truth.

The results show that GPG improves the alignment precision by 0.1 compared with the standard pointer generator. The posterior alignment is more accurate than the prior one (also reflected in Figure 1), enabling better human interpretation.

6 Conclusion

In this work, we propose generalizing the pointer generator to go beyond exact copy operation. At each decoding step, the decoder can either generate from the vocabulary, copy or edit some source words by estimating a relation embedding. Experiments on abstractive summarization show the generalized model generates more abstract summaries yet faithful to the source information. The generalized pointer is able to capture richer latent alignment relationship beyond exact copies. This helps improve the alignment accuracy, allowing better model controllability and interpretation.

We believe the generalized pointer mechanism could have potential applications in many fields where tokens are not exactly copied. By integrating off-the-shelf knowledge bases to clearly model the transition relation embedding, it should further improve the interpretability and might be espe-

Learning Semantic Parsers from Denotations with Latent Structured Alignments and Abstract Programs

Abstract

Semantic parsing aims to map natural language utterances onto machine interpretable meaning representations, aka programs whose execution against a real-world environment produces a denotation. Weakly-supervised semantic parsers are trained on utterance-denotation pairs treating programs as latent. The task is challenging due to the large search space and spuriousness of programs which may execute to the correct answer but do not generalize to unseen examples. Our goal is to instill an inductive bias in the parser to help it distinguish between spurious and correct programs. We capitalize on the intuition that correct programs would likely respect certain structural constraints were they to be aligned to the question (e.g., program fragments are unlikely to align to overlapping text spans) and propose to model alignments as structured latent variables. In order to make the latent-alignment framework tractable, we decompose the parsing task into (1) predicting a partial "abstract program" and (2) refining it while modeling structured alignments with differential dynamic programming. We obtain state-of-the-art performance on the WIKITABLEQUESTIONS and WIKISQL datasets. When compared to a standard attention baseline, we observe that the proposed structured-alignment mechanism is highly beneficial.

1 Introduction

Semantic parsing is the task of translating natural language to machine interpretable meaning representations. Typically, it requires mapping a natural language utterance onto a program, which is executed against a knowledge base to obtain an answer or a denotation. Most previous work (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Lu et al., 2008; Jia and Liang, 2016) has focused on the supervised setting where a model is learned from question-program pairs. Weakly supervised semantic parsing (Berant et al., 2013; Liang et al., 2011) reduces the burden of annotating programs by learning from questions paired with their answers (or denotations).

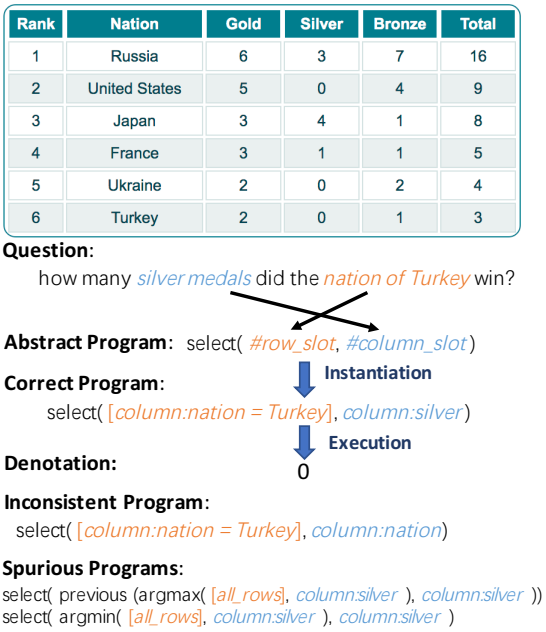

Figure 1: After generating an abstract program for a question, our parser finds alignments between slots (with prefix #) and question spans. Based on the alignment, it instantiates each slot and a complete program is executed against a table to obtain a denotation.

Two major challenges arise when learning from denotations: 1) training of the semantic parser requires exploring a large search space of possible programs to find those which are *consistent*, and execute to correct denotations; 2) the parser should be robust to *spurious* programs which accidentally execute to correct denotations, but do not reflect the semantics of the question. In this paper, we propose a weakly-supervised neural semantic parser that features structured latent alignments to bias learning towards *correct* programs which are consistent but not spurious.

Our intuition is that correct programs should re-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3774–3785, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

spect certain constraints were they to be aligned to the question text, while spurious and inconsistent programs do not. For instance, in Figure 1, the answer to the question ("0") can be obtained by executing the correct program which selects the number of Turkey's silver medals. However, the same answer can be also obtained by the spurious programs shown in the figure.[1] The spurious programs differ from the correct one in that they repeatedly use the column "silver". Whereas, in the question, the word "silver" only refers to the target column containing the answer; it also mistakenly triggers the appearance of the column "silver" in the row selection condition. This constraint, i.e., that a text span within a question cannot trigger two semantically distinct operations (e.g., selecting target rows and target columns) can provide a useful inductive bias. We propose to capture structural constraints by modeling the alignments between programs and questions *explicitly* as structured latent variables.

Considering the large search space of possible programs, an alignment model that takes into account the full range of correspondences between program operations and question spans would be very expensive. To make the process tractable, we introduce a two-stage approach that features *abstract* programs. Specifically, we decompose semantic parsing into two steps: 1) a natural language utterance is first mapped to an abstract program which is a composition of high-level operations; and 2) the abstract program is then instantiated with low-level operations that usually involve relations and entities specific to the knowledge base at hand. This decomposition is motivated by the observation that only a small number of sensible abstract programs can be instantiated into consistent programs. Similar ideas of using abstract meaning representations have been explored with fully-supervised semantic parsers (Dong and Lapata, 2018; Catherine Finegan-Dollak and Radev, 2018) and in other related tasks (Goldman et al., 2018; Herzig and Berant, 2018; Nye et al., 2019).

For a knowledge base in tabular format, we abstract two basic operations of row selection and column selection from programs: these are handled in the second (instantiation) stage. As shown in Figure 1, the question is first mapped to the abstract program "select (#*row_slot*, #*column_slot*)" whose two slots are subsequently instantiated with filter conditions (row slot) and a column name (column slot). During the instantiation of abstract programs, each slot should refer to the question to obtain its specific semantics. In Figure 1, *row_slot* should attend to "nation of Turkey" while *column_slot* needs to attend to "silver medals". The structural constraint discussed above now corresponds to assuming that each span in a question can be aligned to a *unique* row or column slot. Under this assumption, the instantiation of spurious programs will be discouraged. The uniqueness constraint would be violated by both spurious programs in Figure 1, since "column:silver" appears in the program twice but can be only aligned to the span "silver medals" once.

The first stage (i.e., mapping a question onto an abstract program) is handled with a sequence-to-sequence model. The second stage (i.e., program instantation) is approached with local classifiers: one per slot in the abstract program. The classifiers are conditionally independent given the abstract program and a latent alignment. Instead of marginalizing out alignments, which would be intractable, we use structured attention (Kim et al., 2017), i.e., we compute the marginal probabilities for individual span-slot alignment edges and use them to weight the input to the classifiers. As we discuss below, the marginals in our constrained model are computed with dynamic programming.

We perform experiments on two open-domain question answering datasets in the setting of learning from denotations. Our model achieves an execution accuracy of 44.5% in WIKITABLEQUESTIONS and 79.3% in WIKISQL, which both surpass previous state-of-the-art methods in the same weakly-supervised setting. In WIKISQL, our parser is better than recent supervised parsers that are trained on question-program pairs. Our contributions can be summarized as follows:

- we introduce an alignment model as a means of differentiating between correct and spurious programs;
- we propose a neural semantic parser that performs tractable alignments by first mapping questions to abstract programs;
- we achieve state-of-the-art performance on two semantic parsing benchmarks.[2]

[1] The first program can be paraphrased as: find the row with the largest number of silver medals and then select the number of silver medals from the previous row.

[2] Our code is available at https://github.com/berlino/weaksp_em19.

Although we use structured alignments to mostly enforce the uniqueness constraint described above, other types of inductive biases can be useful and could be encoded in our two-stage framework. For example, we could replace the uniqueness constraint with modeling the number of slots aligned to a span, or favor sparse alignment distributions. Crucially, the two-stage framework makes it easier to inject prior knowledge about datasets and formalisms while maintaining efficiency.

2 Background

Given knowledge base t, our task is to map a natural utterance x to program z, which is then executed against a knowledge base to obtain denotation $[[z]]_t = d$. We train our parser only based on d without access to correct programs z^*. Our experiments focus on two benchmarks, namely WIKITABLEQUESTIONS (Pasupat and Liang, 2015) and WIKISQL (Zhong et al., 2017) where each question is paired with a Wikipedia table and a denotation. Figure 1 shows a simplified example taken from WIKITABLEQUESTIONS.

2.1 Grammars

Executable programs z that can query tables are defined according to a language. Specifically, the search space of programs is constrained by grammar rules so that it can be explored efficiently. We adopt the variable-free language of Liang et al. (2018) and define an *abstract* grammar and an *instantiation* grammar which decompose the generation of a program in two stages.[3]

The first stage involves the generation of an abstract version of a program which, in the second stage, gets instantiated. Abstract programs only consider compositions of high-level functions, such as superlatives and aggregation, while low-level functions and arguments, such as filter conditions and entities, are taken into account in the next step. In our table-based datasets, abstract programs do not include two basic operations of querying tables: row selection and column selection. These operations are handled at the instantiation stage. In Figure 1 the abstract program has two slots for row and column selection, which are filled with the conditions "column:nation = Turkey" and "column:silver" at the instantiation stage. The two stages can be easily merged into one step when conducting symbolic combinatorial search. The motivation for the decomposition is to facilitate the learning of our neural semantic parser and the handling of structured alignments.

[3]We also extend their grammar to additionally support operations of conjunction and disjunction. More details are provided in the Appendix.

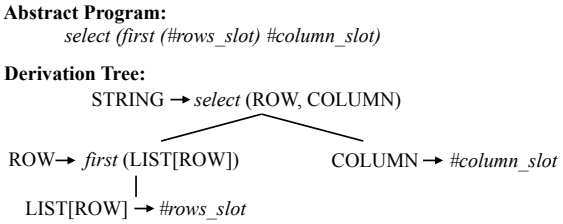

Figure 2: An abstract program and its derivation tree. Capitalized words indicate types of function arguments and their return value.

Abstract Grammar Our abstract grammar has five basic types: ROW, COLUMN, STRING, NUMBER, and DATE; COLUMN is further sub-typed into STRING_COLUMN, NUMBER_COLUMN, and DATE_COLUMN; other basic types are augmented with LIST to represent a list of elements like LIST[ROW]. Arguments and return values of functions are typed using these basic types.

Function composition can be defined recursively based on a set of production rules, each corresponding to a function type. For instance, function ROW → *first*(LIST[ROW]) selects the first row from a list of rows and corresponds to production rule "ROW → *first*".

The abstract grammar has two additional types for slots (aka terminal rules) which correspond to row and column selection:

$$\text{LIST[ROW]} \rightarrow \textit{\#row_slot}$$
$$\text{COLUMN} \rightarrow \textit{\#column_slot}$$

An example of an abstract program and its derivation tree is shown in Figure 2. We linearize the derivation by traversing it in a left-to-right depth-first manner. We represent the tree in Figure 2 as a sequence of production rules: "ROOT → STRING, STRING → *select*, ROW → *first*", LIST[ROW] → *#row_slot*, COLUMN → *#column_slot*". The first action is always to select the return type for the root node.

Given a specific table t, the abstract grammar $\mathcal{H}_t$ will depend on its column types. For example, if the table does not have number cells, "max/min" operations will not be executable.

Instantiation Grammar A column slot is directly instantiated by selecting a column; a row

slot is filled with one or multiple conditions (COND) which are joined together with conjunction (*OR*) and disjunction (*AND*) operators:

COND → COLUMN OPERATOR VALUE
#row_slot → COND (*AND* COND)*
#row_slot → COND (*OR* COND)*

where OPERATOR $\in [>, <, =, \geq, \leq]$ and VALUE is a string, a number, or a date. A special condition *#row_slot* → all_rows is defined to signify that a program queries all rows.

2.2 Search for Consistent Programs

A problematic aspect of learning from denotations is that, since annotated programs are not available (e.g., for WIKITABLEQUESTIONS), we have no means to directly evaluate a proposed grammar. As an evaluation proxy, we measure the coverage of our grammar in terms of consistent programs. Specifically, we exhaustively search for all consistent programs for each question in the training set. While the space of programs is exponential, we observed that abstract programs which are instantiated into correct programs are not very complex in terms of the number of production rules used to generate them. As a result, we impose restrictions on the number of production rules which can abstract programs, and in this way the search process becomes tractable.[4]

We find that 83.6% of questions in WIKITABLEQUESTIONS are covered by at least one consistent program. However, each question eventually has 200 consistent programs on average and most of them are spurious. Treating them as ground truth poses a great challenge for learning a semantic parser. The coverage for WIKISQL is 96.6% and each question generates 84 consistent programs.

Another important observation is that there is only a limited number of abstract programs that can be instantiated into consistent programs. The number of such abstract programs is 23 for WIKITABLEQUESTIONS and 6 for WIKISQL, suggesting that there are a few patterns underlying several utterances. This motivates us to design a semantic parser that first maps utterances to abstract programs. For the sake of generality, we do not restrict our parser to abstract programs in the training set. We elaborate on this below.

[4]Details are provided in the Appendix.

3 Model

After obtaining consistent programs z for each question via offline search, we next show how to learn a parser that can generalize to unseen questions and tables.

3.1 Training and Inference

Our learning objective $\mathcal{J}$ is to maximize the log-likelihood of the marginal probability of all consistent programs, which are generated by mapping an utterance x to an interim abstract program h:

$$\mathcal{J} = \log\{\sum_{h \in \mathcal{H}_t} p(h|x,t) \sum_{[[z]]=d} p(z|x,t,h)\}. \quad (1)$$

During training, our model only needs to focus on abstract programs that have successful instantiations of consistent programs and it does not have to explore the whole space of possible programs.

At test time, the parser chooses the program $\hat{z}$ with the highest probability:

$$\hat{h}, \hat{z} = \arg\max_{h \in \mathcal{H}_t,\ z} p(h|x,t)p(z|x,t,h). \quad (2)$$

For efficiency, we only choose the top-k abstract programs to instantiate through beam search. $\hat{z}$ is then executed to obtain its denotation as the final prediction.

Next, we will explain the basic components of our neural parser. Basically, our model first encodes a question and a table with an input encoder; it then generates abstract programs with a seq2seq model; and finally, these abstract programs are instantiated based on a structured alignment model.

3.2 Input Encoder

Each word in an utterance is mapped to a distributed representation through an embedding layer. Following previous work (Neelakantan et al., 2017; Liang et al., 2018), we also add an indicator feature specifying whether the word appears in the table. This feature is mapped to a learnable vector. Additionally, in WIKITABLEQUESTIONS, we use POS tags from the CoreNLP annotations released with the dataset and map them to vector representations. The final representation for a word is the concatenation of the vectors above. A bidirectional LSTM (Hochreiter and Schmidhuber, 1997) is then used to obtain a contextual representation $\boldsymbol{l}_i$ for the i_{th} word.

A table is represented by a set of columns. Each column is encoded by averaging the embeddings

of words under its column name. We also have a column type feature (i.e., number, date, or string) and an indicator feature signaling whether at least one entity in the column appears in the utterance.

3.3 Generating Abstract Programs

Instead of extracting abstract programs as templates, similarly to Xu et al. (2017) and Catherine Finegan-Dollak and Radev (2018), we generate them with a seq2seq model. Although template-based approaches would be more efficient in practice, a seq2seq model is more general since it could generate unseen abstract programs which fixed templates could not otherwise handle.

Our goal here is to generate a sequence of production rules that lead to abstract programs. During decoding, the hidden state $\boldsymbol{g}_j$ of the j-th timestep is computed based on the previous production rule, which is mapped to an embedding $\boldsymbol{a}_{j-1}$. We also incorporate an attention mechanism (Luong et al., 2015) to compute a contextual vector $\boldsymbol{b}_j$. Finally, a score vector $\boldsymbol{s}_j$ is computed by feeding the concatenation of the hidden state and context vector to a multilayer perceptron (MLP):

$$\begin{aligned} \boldsymbol{g}_j &= \text{LSTM}(\boldsymbol{g}_{j-1}, \boldsymbol{a}_{j-1}) \\ \boldsymbol{b}_j &= \text{Attention}(\boldsymbol{g}_j, \boldsymbol{l}) \\ \boldsymbol{s}_j &= \text{MLP}_1([\boldsymbol{g}_j; \boldsymbol{b}_j]) \\ p(a_j|x,t,a_{<j}) &= \text{softmax}_{a_j}(\boldsymbol{s}_j) \end{aligned} \tag{3}$$

where the probability of production rule a_j is computed by the softmax function. According to our abstract grammar, only a subset of production rules will be valid at the j-th time step. For instance, in Figure 2, production rule "STRING $\rightarrow$ *select*" will only expand to rules whose left-hand side is ROW, which is the type of the first argument of *select*. In this case, the next production rule is "ROW $\rightarrow$ *first*". We thus restrict the normalization of softmax to only focus on these valid production rules. The probability of generating an abstract program $p(h|x,t)$ is simply the product of the probability of predicting each production rule $\prod_j p(a_j|x,t,a_{<j})$.

After an abstract program is generated, we need to instantiate slots in abstract programs. Our model first encodes the abstract program using a bi-directional LSTM. As a result, the representation of a slot is contextually aware of the entire abstract program (Dong and Lapata, 2018).

3.4 Instantiating Abstract Programs

To instantiate an abstract program, each slot must obtain its specific semantics from the question. We model this process by an alignment model which learns the correspondence between slots and question spans. Formally, we use a binary alignment matrix $\boldsymbol{A}$ with size $m \times n \times n$, where m is the number of slots and n is the number of tokens. In Figure 1, the alignment matrix will only have $\boldsymbol{A}_{0,6,8} = 1$ and $\boldsymbol{A}_{1,2,3} = 1$ which indicates that the first slot is aligned with "nation of Turkey", and the second slot is aligned with "silver medals". The second and third dimension of the matrix represent the start and end position of a span.

We model alignments as discrete latent variables and condition the instantiation process on the alignments as follows:

$$\begin{aligned} &\sum_{[z]=d} p(z|x,t,h) = \\ &\quad \sum_{\boldsymbol{A}} p(\boldsymbol{A}|x,t,h) \sum_{[z]=d} p(z|x,t,h,\boldsymbol{A}). \end{aligned} \tag{4}$$

We will first discuss the instantiation model $p(z|x,t,h,\boldsymbol{A})$ and then elaborate on how to avoid marginalization in the next section. Each slot in an abstract program can be instantiated by a set of candidates following the instantiation grammar. For efficiency, we use local classifiers to model the instantiation of each slot independently:

$$p(z|x,t,h,\boldsymbol{A}) = \prod_{s \in S} p(s \rightarrow c|x,t,h,\boldsymbol{A}), \tag{5}$$

where S is the set of slots and c is a candidate following our instantiation grammar. "$s \rightarrow c$" represents the instantiation of slot s into candidate c.

Recall that there are two types of slots, one for rows and one for columns. All column names in the table are potential instantiations of column slots. We represent each column slot candidate by the average of the embeddings of words in the column name. Based on our instantiation grammar in Section 2.1, candidates for row slots are represented as follows: 1) each condition is represented with the concatenation of the representations of a column, an operator, and a value. For instance, condition "string_column:nation = Turkey" in Figure 1 is represented by vector representations of the column 'nation', the operator '=', and the entity 'Turkey'; 2) multiple conditions are encoded by averaging the representations of all conditions and adding a vector representation of *AND*/*OR* to indicate the relation between them.

For each slot, the probability of generating a candidate is computed with softmax normalization on a score function:

$$p(s \to c|x,t,h,\boldsymbol{A}) \propto \exp\{\text{MLP}([\boldsymbol{s};\boldsymbol{c}])\}, \quad (6)$$

where $\boldsymbol{s}$ is the representation of the span that slot s is aligned with, and $\boldsymbol{c}$ is the representation of candidate c. The representations $\boldsymbol{s}$ and $\boldsymbol{c}$ are concatenated and fed to a MLP. We use the same MLP architecture but different parameters for column and row slots.

3.5 Structured Attention

We first formally define a few structural constraints over alignments and then explain how to incorporate them efficiently into our parser.

The intuition behind our alignment model is that row and column selection operations represent distinct semantics, and should therefore be expressed by distinct natural language expressions. Hence, we propose the following constraints:

Unique Span In most cases, the semantics of a row selection or a column selection is expressed uniquely with a single contiguous span:

$$\forall k \in [1, |S|], \quad \sum_{i,j} \boldsymbol{A}_{k,i,j} = 1, \quad (7)$$

where $|S|$ is the number of slots.

No Overlap Spans aligned to different slots should not overlap. Formally, at most one span that contains word i can be aligned to a slot:

$$\forall i \in [1, n], \quad \sum_{k,j} \boldsymbol{A}_{k,i,j} \leq 1. \quad (8)$$

As an example, the alignments in Figure 1 follow the above constraints. Intuitively, the one-to-one mapping constraint aims to assign distinct and non-overlapping spans to slots of abstract programs. To further bias the alignments and improve efficiency, we impose additional restrictions: (1) a row slot must be aligned to a span that contains an entity since conditions that instantiate the slot would require entities for filtering; (2) a column slot must be aligned to a span with length 1 since most column names only have one word.

Marginalizing out all $\boldsymbol{A}$ in Equation (4) would be very expensive considering the exponential number of possible alignments. We approximate the marginalization by moving the outside expectation directly inside over $\boldsymbol{A}$. As a result, we instead optimize the following objective:

$$\mathcal{J} \approx \log\Big\{ \sum_{h \in \mathcal{H}_t} p(h|x,t) \sum_{[[z]]=d} p(z|x,t,h,\mathbb{E}[\boldsymbol{A}]) \Big\}, \quad (9)$$

where $\mathbb{E}[\boldsymbol{A}]$ are the marginals of $\boldsymbol{A}$ with respect to $p(\boldsymbol{A}|x,t,h)$.

The idea of using differentiable surrogates for discrete latent variables has been used in many other works like differentiable data structures (Grefenstette et al., 2015; Graves et al., 2014) and attention-based networks (Bahdanau et al., 2015; Kim et al., 2017). Using marginals $\mathbb{E}[\boldsymbol{A}]$ can be viewed as *structured attention* between slots and question spans.

The marginal probability of the alignment matrix $\boldsymbol{A}$ can be computed efficiently using dynamic programming (see Täckström et al. 2015 for details). An alignment is encoded into a path in a weighted lattice where each vertex has $2^{|S|}$ states to keep track of the set of covered slots. The marginal probability of edges in this lattice can be computed by the forward-backward algorithm (Wainwright et al., 2008). The lattice weights, represented by a scoring matrix $\boldsymbol{M} \in \mathbb{R}^{m \times n \times n}$ for all possible slot-span pairs, are computed using the following scoring function:

$$\boldsymbol{M}_{k,i,j} = \text{MLP}_2([\boldsymbol{r}(k); \mathbf{span}[i:j]]), \quad (10)$$

where $\boldsymbol{r}(k)$ represents the k_{th} slot and $\mathbf{span}[i:j]$ represents the span from word i to j. Recall that we obtain $\boldsymbol{r}(k)$ by encoding a generated abstract program. A span is represented by averaging the representations of the words therein. These two representations are concatenated and fed to a MLP to obtain a score. Since $\mathbb{E}[\boldsymbol{A}]$ is not discrete anymore, the aligned representation of slot $\boldsymbol{s}$ in Equation (6) becomes the weighted average of representations of all spans in the set.

4 Experiments

We evaluated our model on two semantic parsing benchmarks, WIKITABLEQUESTIONS and WIKISQL. We compare against two common baselines to demonstrate the effectiveness of using abstract programs and alignment. We also conduct detailed analysis which shows that structured attention is highly beneficial, enabling our parser to differentiate between correct and spurious programs. Finally, we break down the errors of our parser so as

to examine whether structured attention is better at instantiating abstract programs.

4.1 Experimental Setup

Datasets WIKITABLEQUESTIONS contains 2,018 tables and 18,496 utterance-denotation pairs. The dataset is challenging as 1) the tables cover a wide range of domains and unseen tables appear at test time; and 2) the questions involve a variety of operations such as superlatives, comparisons, and aggregation (Pasupat and Liang, 2015). WIKISQL has 24,241 tables and 80,654 utterance-denotation pairs. The questions are logically simpler and only involve aggregation, column selection, and conditions. The original dataset is annotated with SQL queries, but we only use the execution result for training. In both datasets, tables are extracted from Wikipedia and cover a wide range of domains.

Entity extraction is important during parsing since entities are used as values in filter conditions during instantiation. String entities are extracted by string matching utterance spans and table cells. In WIKITABLEQUESTIONS, numbers and dates are extracted from the CoreNLP annotations released with the dataset. WIKISQL does not have entities for dates, and we use string-based normalization to deal with numbers.

Implementation We obtained word embeddings by a linear projection of GloVe pre-trained embeddings (Pennington et al., 2014) which were fixed during training. Attention scores were computed based on the dot product between two vectors. Each MLP is a one-hidden-layer perceptron with ReLU as the activation function. Dropout (Srivastava et al., 2014) was applied to prevent overfitting. All models were trained with Adam (Kingma and Ba, 2015). Implementations of abstract and instantiation grammars were based on AllenNLP (Gardner et al., 2017).[5]

4.2 Baselines

Aside from comparing our model against previously published approaches, we also implemented the following baselines:

Typed Seq2Seq Programs were generated using a sequence-to-sequence model with attention (Dong and Lapata, 2016). Similarly to Krishnamurthy et al. (2017), we constrained the decoding process so that only well-formed programs are predicted. This baseline can be viewed as merging the two stages of our model into one stage where generation of abstract programs and their instantiations are performed with a shared decoder.

[5]Please refer to the Appendix for the full list of hyperparameters used in our experiments.

f.w. structured attention	**43.7**	**44.5**

Table 1: Results on WIKITABLEQUESTIONS. *f.w.* stands for slots filled with.

Standard Attention The aligned representation of slot s in Equation (6) is computed by a standard attention mechanism: $\boldsymbol{s} = \text{Attention}(\boldsymbol{r}(s), \boldsymbol{l})$ where $\boldsymbol{r}(s)$ is the representation of slot s from abstract programs. Each slot is aligned independently with attention, and there are no global structural constraints on alignments.

4.3 Main Results

For all experiments, we report the mean accuracy of 5 runs. Results on WIKITABLEQUESTIONS are shown in Table 1. The structured-attention model achieves the best performance, compared against the two baselines and previous approaches. The standard attention baseline with abstract programs is superior to the typed Seq2Seq model, demonstrating the effectiveness of decomposing semantic parsing into two stages. Results on WIKISQL are shown in Table 2. The structured-attention model is again superior to our two baseline models. Interestingly, its performance surpasses previously reported weakly-supervised models (Liang et al., 2018; Agarwal et al., 2019) and is on par even with fully supervised ones (Dong and Lapata, 2018).

The gap between the standard attention baseline and the typed Seq2Seq model is not very large on WIKISQL, compared to WIKITABLEQUESTIONS. Recall from Section 2.2 that WIK-

Models	WTQ	WIKISQL
Liang et al. (2018)	46.3 (10)	74.2 (5)
Agarwal et al. (2019)	46.9 (10)	76.9 (5)
Our model	**47.3** (10)	**81.7** (5)

Table 3: Results of ensembled models on the test set; ensemble sizes are shown within parentheses.

Error Types	standard	structured
Abstraction Error	19.2	20.0
Instantiation Error	41.5	36.2
Coverage Error	39.2	43.8

Table 4: Proportion of errors on the development set in WIKITABLEQUESTIONS.

ISQL only has 6 abstract programs that can be successfully instantiated. For this reason, our decomposition alone may not be very beneficial if coupled with standard attention. In contrast, our structured-attention model consistently performs much better than both baselines.

We report scores of ensemble systems in Table 3. We use the best model which relies on abstract programs and structured attention as a base model in our ensemble. Our ensemble system achieves better performance than Liang et al. (2018) and Agarwal et al. (2019), while using the same ensemble size.

4.4 Analysis of Spuriousness

To understand how well structured attention can help a parser differentiate between correct and spurious programs, we analyzed the posterior distribution of consistent programs given a denotation: $p(z|x,t,d)$ where $[[z]] = d$.

WIKISQL includes gold-standard SQL annotations, which we do not use in our experiments but exploit here for analysis. Specifically, we converted the annotations released with WIKISQL to programs licensed by our grammar. We then computed the log-probability of these programs according to the posterior distribution as a measure of how well a parser can identify them amongst all consistent programs $\log \sum_{z^*} p(z^*|x,t,d)$, where z^* denotes correct programs. The average log-probability assigned to correct programs by structured and standard attention is -0.37 and -0.85, respectively. This gap confirms that structured attention can bias our parser towards correct programs during learning.

4.5 Error Analysis

We further manually inspected the output of our structured-attention model and the standard attention baseline in WIKITABLEQUESTIONS. Specifically, we randomly sampled 130 error cases independently from both models and classified them into three categories.

Abstraction Errors If a parser fails to generate an abstract program, then it is impossible for it to instantiate a consistent complete program.

Instantiation Errors These errors arise when abstract programs are correctly generated, but are mistakenly instantiated either by incorrect column names or filter conditions.

Coverage Errors These errors arise from implicit assumptions made by our parser: a) there is a long tail of unsupported operations that are not covered by our abstract programs; b) if entities are not correctly identified and linked, abstract programs cannot be correctly instantiated.

Table 4 shows the proportion of errors attested by the two attention models. We observe that structured attention suffers less from instantiation errors compared against the standard attention baseline, which points to the benefits of the structured alignment model.

5 Related Work

Neural Semantic Parsing We follow the line of work that applies sequence-to-sequence models (Sutskever et al., 2014) to semantic parsing (Jia and Liang, 2016; Dong and Lapata, 2016). Our work also relates to models which enforce type constraints (Yin and Neubig, 2017; Rabinovich et al., 2017; Krishnamurthy et al., 2017) so as to restrict the vast search space of potential programs. We use both methods as baselines to show that the structured bias introduced by our model can help our parser handle spurious programs in the setting of learning from denotations. Note that our alignment model can also be applied in the supervised case in order to help the parser rule out incorrect programs.

Earlier work has used lexicon mappings (Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Lu et al., 2008; Kwiatkowski et al., 2010) to model correspondences between programs and natural language. However, these methods cannot generalize to unseen tables where new relations and entities appear. To address this issue, Pasupat and Liang (2015) propose a floating parser which allows partial programs to be generated without being anchored to question tokens. In the same spirit, we use a sequence-to-sequence model to generate abstract programs while relying on explicit alignments to instantiate them. Besides semantic parsing, treating alignments as discrete latent variables has proved effective in other tasks like sequence transduction (Yu et al., 2016) and AMR parsing (Lyu and Titov, 2018).

Learning from Denotations To improve the efficiency of searching for consistent programs, Zhang et al. (2017) use a macro grammar induced from cached consistent programs. Unlike Zhang et al. (2017) who abstract entities and relations from logical forms, we take a step further and abstract the computation of row and column selection. Our work also differs from Pasupat and Liang (2016) who resort to manual annotations to alleviate spuriousness. Instead, we equip our parser with an inductive bias to rule out spurious programs during training. Recently, reinforcement learning based methods address the computational challenge by using a memory buffer (Liang et al., 2018) which stores consistent programs and an auxiliary reward function (Agarwal et al., 2019) which provides feedback to deal with spurious programs. Guu et al. (2017) employ various strategies to encourage even distributions over consistent programs in cases where the parser has been misled by spurious programs. Dasigi et al. (2019) use coverage of lexicon-like rules to guide the search of consistent programs.

6 Conclusions

In this paper, we proposed a neural semantic parser that learns from denotations using abstract programs and latent structured alignments. Our parser achieves state-of-the-art performance on two benchmarks, WIKITABLEQUESTIONS and WIKISQL. Empirical analysis shows that the inductive bias introduced by the alignment model helps our parser differentiate between correct and spurious programs. Alignments can exhibit different properties (e.g., monotonicity or bijectivity), depending on the meaning representation language (e.g., logical forms or SQL), the definition of abstract programs, and the domain at hand. We believe that these properties can be often captured within a probabilistic alignment model and hence provide a useful inductive bias to the parser.

A Grammars

We created our grammars following Zhang et al. (2017) and Liang et al. (2018). Compared with Liang et al. (2018), we additionally support disjunction(*OR*) and conjunction(*AND*). Some functions are pruned based on their effect on coverage, which is the proportion of questions that obtain at least one consistent program. "same_as" function (Liang et al., 2018) is excluded since it introduces too many spurious programs while contributing little to the coverage. For the same reason, conjunction(*AND*) is not used in WIKITABLEQUESTIONS and disjunction(*OR*) is not used in WIKISQL.

We also include non-terminals of function types in production rules (Krishnamurthy et al., 2017). For instance, function "ROW → *first*(LIST[ROW])" selects the first row from a list of rows and will lead to the production rule "ROW → *first*". In the paper, we eliminate the function type for simplicity. Practically, we use two production rules to represent the function: ROW → <ROW: LIST[ROW] > and <ROW:LIST[ROW]> → *first* , where < ROW: LIST[ROW] > is an abstract function type.

B Search for Consistent Programs

We enumerate all possible programs in two stages using the abstract and instantiation grammars. To constrain the space and make the search process tractable, we restrict the maximal number of production rules for generating abstract programs during the first stage. It is based on the observation that the abstract programs which can be successfully instantiated into *correct* programs are usually not very complex. In other words, the *consistent* programs that are instantiated by long abstract programs are very likely to be spurious. For instance, programs like "select(previous(next(previous(argmax [all_rows], column:silver) column:bronze)" are unlikely to have a corresponding question. Specifically, we set the maximal number of production rules for generating abstract programs to 6 and 9, which leads to search time of around 7 and 10 hours for WIKISQL and WIKITABLEQUESTIONS respectively, using a single CPU. Note that this needs to be done only once.

C Hyperparameters

Models used in WIKITABLEQUESTIONS and WIKISQL share similar hyperparameters which are listed in Table 5. Our input embeddings are obtained by a linear projection from the fixed pre-trained embedding (Pennington et al., 2014). Word Indicator refers to the indicator feature of whether a word appears in the table; Column Indicator refers to the indicator feature of whether at least one entity in a column appears in the question. All MLPs mentioned in the paper have the

Hyperparameters	WTQ	WIKISQL

MLP Dropout	0.25	0.2

Table 5: Hyperparameters for WTQ (WIKITABLEQUESTIONS) and WIKISQL. AP Encoder is the encoder representing the abstract programs we generate.

.

same hidden size and dropout rate. During decoding, we choose the top-6 abstract programs to instantiate via beam search.

D Alignments

If a row slot is instantiated with the special condition 'all_rows', then it is possible that the semantics of this slot is implicit. For instance, the question "which driver completed the least number of laps? " should first be mapped to the abstract program "select (argmin (#*row_slot*, #*column_slot*), #*column_slot*)" which is then instantiated to the correct program "select (argmin (all_rows, column:laps) column:driver)". The row slot in the abstract program is instantiated with 'all_rows', but this is not explicitly expressed in the question.

To make it compatible with our constraints in Equation (6) and (7), we add a special token "ALL_ROW" at the end of each question. If a row slot is aligned with this token, then it is expected to be instantiated with the special condition 'all_rows'. Specifically, this special token is mapped to a learnable vector during instantiations. Our alignment needs to learn to align this special token with a row slot if this row slot should be instantiated with the condition 'all_rows'.

Broad-Coverage Semantic Parsing as Transduction

{kevinduh, vandurme}@cs.jhu.edu

Abstract

We unify different broad-coverage semantic parsing tasks under a transduction paradigm, and propose an attention-based neural framework that *incrementally* builds a meaning representation via a sequence of semantic relations. By leveraging multiple attention mechanisms, the transducer can be effectively trained without relying on a pre-trained aligner. Experiments conducted on three separate broad-coverage semantic parsing tasks – AMR, SDP and UCCA – demonstrate that our attention-based neural transducer improves the state of the art on both AMR and UCCA, and is competitive with the state of the art on SDP.

1 Introduction

Broad-coverage semantic parsing aims at mapping *any* natural language text, regardless of its domain, genre, or even the language itself, into a general-purpose meaning representation. As a long-standing topic of interest in computational linguistics, broad-coverage semantic parsing has targeted a number of meaning representation frameworks, including CCG (Steedman, 1996, 2001), DRS (Kamp and Reyle, 1993; Bos, 2008), AMR (Banarescu et al., 2013), UCCA (Abend and Rappoport, 2013), SDP (Oepen et al., 2014, 2015), and UDS (White et al., 2016).[1] Each of these frameworks has their specific formal and linguistic assumptions. Such framework-specific "*balkanization*" results in a variety of framework-specific parsing approaches, and the state-of-the-art semantic parser for one framework is not always applicable to another. For instance, the state-of-the-art approaches to SDP parsing (Dozat and Manning, 2018; Peng et al., 2017a) are not directly transferable to AMR and UCCA because of the lack of explicit alignments between tokens in the sentence and nodes in the semantic graph.

While transition-based approaches are adaptable to different broad-coverage semantic parsing tasks (Wang et al., 2018; Hershcovich et al., 2018; Damonte et al., 2017), when it comes to representations such as AMR whose nodes are *unanchored* to tokens in the sentence, a pre-trained aligner has to be used to produce the reference transition sequences (Wang et al., 2015; Damonte et al., 2017; Peng et al., 2017b). In contrast, there are attempts to develop attention-based approaches in a graph-based parsing paradigm (Dozat and Manning, 2018; Zhang et al., 2019), but they lack parsing incrementality, which is advocated in terms of computational efficiency and cognitive modeling (Nivre, 2004; Huang and Sagae, 2010).

In this paper, we approach different broad-coverage semantic parsing tasks under a unified framework of transduction. We propose an attention-based neural transducer that extends the two-stage semantic parser of Zhang et al. (2019) to directly transduce input text into a meaning representation in *one* stage. This transducer has properties of both transition-based approaches and graph-based approaches: on the one hand, it builds a meaning representation incrementally via a sequence of semantic relations, similar to a transition-based parser; on the other hand, it leverages multiple attention mechanisms used in recent graph-based parsers, thereby removing the need for pre-trained aligners.

Requiring only minor task-specific adaptations, we apply this framework to three separate broad-coverage semantic parsing tasks: AMR, SDP, and UCCA. Experimental results show that our neural transducer outperforms the state-of-the-art parsers on AMR (77.0% F1 on LDC2017T10 and 71.3%

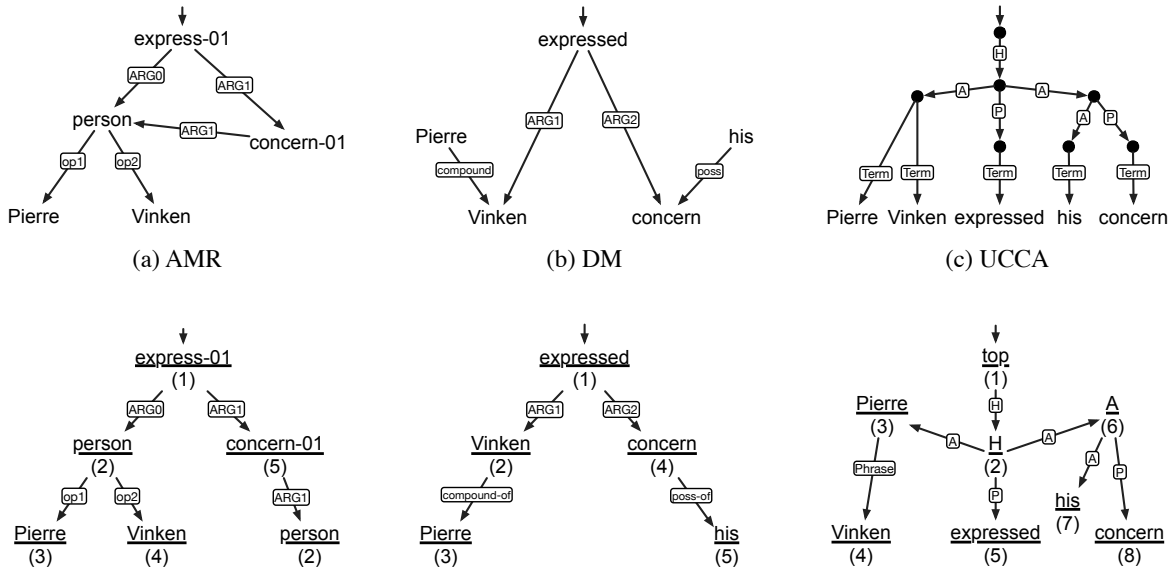
F1 on LDC2014T12) and UCCA (76.6% F1 on the English-Wiki dataset v1.2), and is competitive with the state of the art on SDP (92.2% F1 on the English DELPH-IN MRS dataset).

2 Background and Related Work

We provide summary background on the meaning representations we target, and review related work on parsing for each.

Abstract Meaning Representation (AMR; Banarescu et al., 2013) encodes sentence-level semantics, such as predicate-argument information, reentrancies, named entities, negation and modality, into a rooted, directed, and usually acyclic graph with node and edge labels. AMR graphs abstract away from syntactic realizations, i.e., there is no explicit correspondence between elements of the graph and the surface utterance. Fig. 1(a) shows an example AMR graph.



Since its first general release in 2014, AMR has been a popular target of data-driven semantic parsing, notably in two SemEval shared tasks (May, 2016; May and Priyadarshi, 2017). Graph-based parsers build AMRs by identifying concepts and scoring edges between them, either in a pipeline (Flanigan et al., 2014), or jointly (Zhou et al., 2016; Lyu and Titov, 2018; Zhang et al., 2019). This two-stage parsing process limits the parser incrementality. Transition-based parsers either transform dependency trees into AMRs (Wang et al., 2015, 2016; Goodman et al., 2016), or employ transition systems specifically tailored to AMR parsing (Damonte et al., 2017; Ballesteros and Al-Onaizan, 2017). Transition-based parsers rely on pre-trained aligner produce the reference transitions. Grammar-based parsers leverage external semantic resources to derive AMRs compositionally based on CCG rules (Artzi et al., 2015), or SHRG rules (Peng et al., 2015). Another line of work uses neural model translation models to convert sentences into *linearized* AMRs (Barzdins and Gosko, 2016; Peng et al., 2017b), but has relied on data augmentation to produce effective parsers (van Noord and Bos, 2017; Konstas et al., 2017). Our parser differs from the previous ones in that it has incrementality without relying on pre-trained aligners, and can be effectively trained without data augmentation.

Semantic Dependency Parsing (SDP) was introduced in 2014 and 2015 SemEval shared tasks (Oepen et al., 2014, 2015). It is centered around three semantic formalisms – DM (DELPH-IN MRS; Flickinger et al., 2012; Oepen and Lønning, 2006), PAS (Predicate-Argument Structures; Miyao and Tsujii, 2004), and PSD (Prague Semantic Dependencies; Hajič et al., 2012) – representing predicate-argument relations between content words in a sentence. Their annotations have been converted into bi-lexical dependencies, forming directed graphs whose nodes injectively correspond to surface lexical units, and edges represent semantic relations between nodes. In this work, we focus on only the DM formalism. Fig. 1(b) shows an example DM graph.

Most recent parsers for SDP are graph-based: Peng et al. (2017a, 2018) use a max-margin classifier on top of a BiLSTM, with the factored score for each graph over predicates, unlabeled arcs, and arc labels. Multi-task learning approaches and disjoint data have been used to improve the parser performance. Dozat and Manning (2018) extend an LSTM-based syntactic dependency parser to produce graph-structured dependencies, and carefully tune it to state of the art performance. Wang et al. (2018) extend the transition system of Choi and McCallum (2013) to produce non-projective trees, and use improved versions of stack-LSTMs (Dyer et al., 2015) to learn representation for key components. All of these are specialized for bi-lexical dependency parsing, whereas our parser can effectively produce both bi-lexical semantics graphs, and graphs that are less anchored to the surface utterance.

Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013) targets a level of semantic granularity that abstracts away from syntactic paraphrases in a typologically-motivated, cross-linguistic fashion. Sentence representations in UCCA are directed acyclic graphs (DAG), where terminal nodes correspond to surface lexical tokens, and non-terminal nodes to semantic units that participate in super-ordinate relations. Edges are labeled, indicating the role of a child in the relation the parent represents. Fig. 1(c) shows an example UCCA DAG.

The first UCCA parser is proposed by Hershcovich et al. (2017), where they extend a transition system to produce DAGs. To leverage other semantic resources, Hershcovich et al. (2018) is one of the few attempts to present (lossy) conversion from AMR, SDP and Universal Dependencies (UD; Nivre et al., 2016) to a unified UCCA-

(a) AMR (b) DM (c) UCCA

(d) AMR arborescence (e) DM arborescence (f) UCCA arborescence

Figure 1: Meaning representation in the task-specific format – (a) AMR, (b) DM, and (c) UCCA – for an example sentence "*Pierre Vinken expressed his concern*". Meaning representation (d), (e) and (f) are in the unified arborescence format, which are converted from (a), (b) and (c) respectively.

based DAG format. They explore multi-task learning under the unified format. While multi-task learning improves UCCA parsing results, it shows poor performance on AMR, SDP and UD parsing. In contrast, different semantic parsing tasks are formalized in our unified transduction paradigm with no loss, and our approach achieves state-of-the-art or competitive performance on each task, using only single-task data.

3 Unified Transduction Problem

3.1 Unified Arborescence Format

We first introduce a unified target format for different broad-coverage semantic parsing tasks. Meaning representation in the unified format is an arborescence (aka, a directed rooted tree), which is converted from its corresponding task-specific semantic graph via the following *reversible* steps:

AMR Reentrancy is what can make an AMR graph not an arborescence (it introduces cycles). Following Zhang et al. (2019), we convert an AMR graph into an arborescence by duplicating nodes that have reentrant relations; that is, whenever a node has a reentrant relation, we make a copy of that node and use the copy to participate in the relation, thereby resulting in an arborescence. Next, in order to preserve the reentrancy information, we assign a node index to each node. Duplicated nodes are assigned the same index as the original node. Fig. 1(d) shows an AMR arborescence converted from Fig. 1(a): two "*person*" nodes have the same node index 2. The original AMR graph can be recovered by merging identically indexed nodes.

DM We first break the DM graph into a set of *weakly* connected subgraphs. For each subgraph, if it has the *top* node, we treat *top* as root; otherwise, we treat the node with the max outdegree as root. We then run depth-first traversal over each subgraph from its root to yield an arborescence, and repeat the following three steps until no more edges can be added to the arborescence: (1) we run breadth-first traversal over the arborescence from the root until we find a node that has an incoming edge not belonging to the arborescence; (2) we reverse the edge and add a `-of` suffix to the edge label; (3) we run depth-first search from that node to include more edges to the arborescence. During the whole process, we add node indices and duplicate reentrant nodes in the same way as AMR conversion. Finally, we connect arborescences by adding a `null` edge from *top* to other arborescence roots. Fig. 1(e) shows a DM arborescence converted from Fig. 1(b). The original DM graph can be recovered by removing `null` edges, merging identically indexed nodes, and reversing edges with `-of` suffix.

UCCA To date, official UCCA evaluation only considers UCCA's *foundational* layer, which is al-

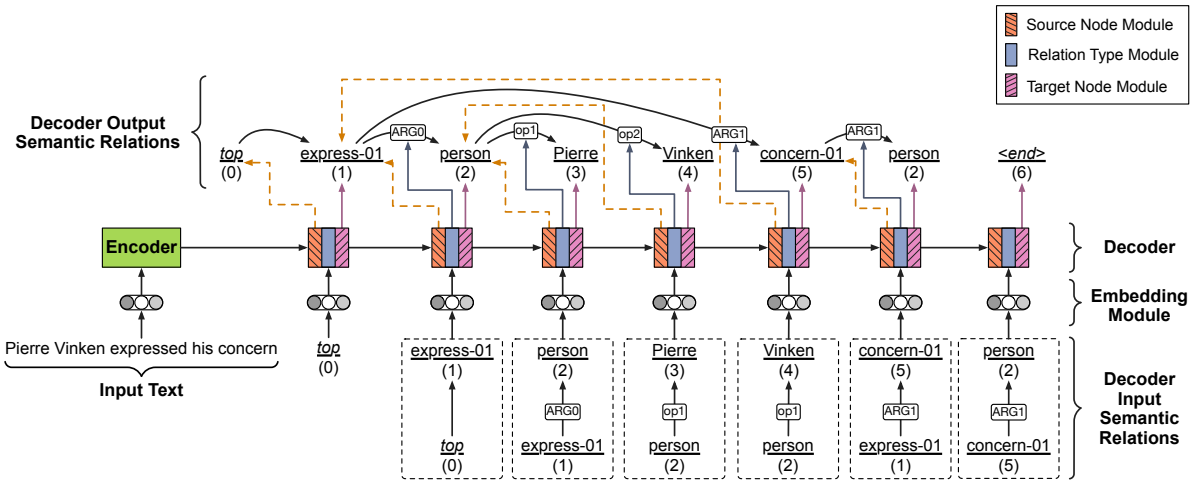


Figure 2: The encoder-decoder architecture of our attention-based neural transducer. An encoder encodes the input text into hidden states. A decoder is composed by three modules: a target node module, a relation type module, and a source node module. At each decoding time step, the decoder takes the previous semantic relation as input, and outputs a new semantic relation in a *factorized* way: firstly, the target node module produces a new target node; secondly, the source node module *points* to a preceding node as a new source node; finally, the relation type module predicts the relation type between source and target nodes.

ready an arborescence. We convert it to the unified arborescence format by first collapsing subgraphs of pre-terminal nodes: we replace each pre-terminal node with its first terminal node; if the pre-terminal node has other terminals, we add a special `phrase` edge from the first terminal node to other terminal nodes. The collapsing step largely reduces the number of terminal nodes in UCCA. We then add labels to the remaining non-terminal nodes. Each node label is simply the same as its incoming edge label. We find that adding node labels improves performance of our neural transducer (See Section 6.2 for the experimental results). Lastly, we add node indices in the same way as AMR conversion. Fig. 1(f) shows a DM arborescence converted from Fig. 1(c). The original UCCA DAG can be recovered by expanding pre-terminal subgraphs, and removing non-terminal node labels.

3.2 Problem Formalization

For any broad-coverage semantic parsing task, we denote the input text by X, and the output meaning representation in the unified arborescence format by Y, where X is a sequence of tokens $\langle x_1, x_2, ..., x_n \rangle$ and Y can be decomposed as a sequence of semantic relations $\langle y_1, y_2, ..., y_m \rangle$. A relation y is a tuple $\langle u, d^u, r, v, d^v \rangle$, consisting of a source node label u, a source node index d^u, a relation type r, a target node label v, and a target node index d^v.

Let $\mathcal{Y}$ be the *output space*. The unified transduction problem is to seek the most-likely sequence of semantic relations $\hat{Y}$ given X:

$$\begin{aligned}\hat{Y} &= \arg\max_{Y \in \mathcal{Y}} \mathrm{P}(Y \mid X) \\ &= \arg\max_{Y \in \mathcal{Y}} \prod_{i}^{m} \mathrm{P}(y_i \mid y_{<i}, X)\end{aligned}$$

4 Transducer

To tackle the unified transduction problem, we introduce an attention-based neural transducer that extends Zhang et al. (2019)'s attention-based parser. Their attention-based parser addresses semantic parsing in a two-stage process: it first employs an extended variant of pointer-generator network (See et al., 2017) to convert the input text into a list of nodes, and then uses a deep biaffine graph-based parser (Dozat and Manning, 2016) with a maximum spanning tree (MST) algorithm to create edges. In contrast, our attention-based neural transducer directly transduces the input text into a meaning representation in *one* stage via a sequence of semantic relations. A high-level model architecture of our transducer is depicted in Fig. 2: an *encoder* first encodes the input text into hidden states; and then conditioned on the hidden states, at each decoding time step, a *decoder* takes the previous semantic relation as input, and outputs a new semantic relation, which includes a target node, a relation type, and a source node.

Specifically, there a significant difference between Zhang et al. (2019) and our model: Zhang et al. (2019) first predicts nodes, and then edges. These two stages are done *separately* (except that a shared encoder is used). At the node prediction stage, their model has no knowledge of edges, and therefore node prediction is performed purely based previous nodes. At the edge prediction stage, their model predicts the head of each node in parallel. Head prediction of one node has no constrains or impact on another. As a result, MST algorithms have to be used to search for a valid prediction. In comparison, our model does not have two separate stages for node and edge prediction. At each decoding step, our model predicts not only a node, but also the incoming edge to the node, which includes a source and a relation type. See Fig. 2 for an example. The predicted node and incoming edge together with previous predictions form a partial semantic graph, which is used as input of the next decoding step for the next node and incoming edge prediction. Our model therefore makes predictions based on the partial semantic graph, which helps prune the output space for both nodes and edges. Since at each decoding step, we assume the incoming edge is always from a preceding node (see Section 4.3 for the details), the predicted semantic graph is guaranteed to be a valid arborescence, and a MST algorithm is no longer needed.

4.1 Encoder

At the encoding stage, we employ an encoder embedding module to convert the input text into vector representations, and a BiLSTM is used to encode vector representations into hidden states.

Encoder Embedding Module concatenates word-level embeddings from GloVe (Pennington et al., 2014) and BERT[2] (Devlin et al., 2018), char-level embeddings from CharCNN (Kim et al., 2016), and randomly initialized embeddings for POS tags.

For AMR, it includes extra randomly initialized embeddings for anonymization indicators that tell the encoder whether a token is an anonymized token from preprocessing.

For UCCA, it includes extra randomly initialized embeddings for NER tags, syntactic dependency labels, punctuation indicators, and shapes that are provided in the UCCA official dataset.

Multi-layer BiLSTM (Hochreiter and Schmidhuber, 1997) is defined as:

$$\mathbf{s}_t^l = \begin{bmatrix} \overrightarrow{\mathbf{s}}_t^l \\ \overleftarrow{\mathbf{s}}_t^l \end{bmatrix} = \begin{bmatrix} \overrightarrow{\text{LSTM}}(\mathbf{s}_t^{l-1}, \mathbf{s}_{t-1}^l) \\ \overleftarrow{\text{LSTM}}(\mathbf{s}_t^{l-1}, \mathbf{s}_{t+1}^l) \end{bmatrix}, \quad (1)$$

where $\mathbf{s}_t^l$ is the l-th layer hidden state at time step t; $\mathbf{s}_i^t$ is the embedding module output for token x_t.

4.2 Decoder

Decoder Embedding Module at decoding time step i converts elements in the input semantic relation $\langle u_i, d_i^u, r_i, v_i, d_i^v \rangle$ into vector representations $\langle \mathbf{u}_i, \mathbf{d}_i^u, \mathbf{r}_i, \mathbf{v}_i, \mathbf{d}_i^v \rangle$:[3]

$\mathbf{u}_i$ and $\mathbf{v}_i$ are concatenations of word-level embeddings from GloVe, char-level embeddings from CharCNN, and randomly initialized embeddings for POS tags. POS tags for source and target nodes are inferred at runtime: if a node is copied from input text, the POS tag of the corresponding token is used; if it is copied from a preceding node, the POS tag of the preceding node is used; otherwise, an `UNK` tag is used.

$\mathbf{d}_i^u, \mathbf{d}_i^v$ and $\mathbf{r}_i$ are randomly initialized embeddings for source node index, target node index, and relation type.

Next, the decoder outputs a new semantic relation in a *factorized* way depicted in Fig. 2: First, a target node module takes vector representations of the previous semantic relation, and predicts a target node label as well as its index. Then, a source node module predicts a source node via *pointing* to a preceding node. Lastly, a relation type module takes the predicted source and target nodes, and predicts the relation type between them.

Target Node Module converts vector representations of the input semantic relation into a hidden state $\mathbf{z}_i$ in the following way:

$$\mathbf{z}_i = \text{FFN}^{(\text{relation})}([\mathbf{h}_i^l; \mathbf{c}_i; \mathbf{r}_i; \mathbf{u}_i; \mathbf{d}_i^u]) \quad (2)$$

$$\mathbf{h}_i^l = \text{LSTM}(\mathbf{h}_i^{l-1}, \mathbf{h}_{i-1}^l) \quad (3)$$

$$\text{FFN}(\mathbf{x}) = \mathbf{W}\mathbf{x} + \mathbf{b} \quad (4)$$

where an l-layer LSTM generates contextual representation $\mathbf{h}_i^l$ for *target* node v_i (for initialization, $\mathbf{h}_i^0 = [\mathbf{v}_i; \mathbf{d}_i^v]$, $\mathbf{h}_0^l = [\overleftarrow{\mathbf{s}}_1^l; \overrightarrow{\mathbf{s}}_n^l]$). A feed-forward neural network $\text{FFN}^{(\text{relation})}$ generates the hidden

[2] We use average pooling in the same way as Zhang et al. (2019) to get word-level embeddings from BERT.

[3] While training, the input semantic relation is from the reference sequence of relations; at test time, it is the previous decoder output semantic relation.

state $\mathbf{z}_i$ of the input semantic relation by combining contextual representation $\mathbf{h}_i^l$ for target node v_i, encoder context vector $\mathbf{c}_i$, and vector representations $\mathbf{r}_i, \mathbf{u}_i, \mathbf{d}_i^u$ for relation type r_i, source node label u_i and source node index d_i^u.

Encoder context vector $\mathbf{c}_i$ is a weighted-sum of encoder hidden states $\mathbf{s}_{1:n}^l$. The weight is attention $\mathbf{a}_i^{(\text{enc})}$ from the decoder at decoding step i to encoder hidden states:

$$\mathbf{a}_i^{(\text{enc})} = \text{softmax}\big(\text{MLP}^{(\text{enc})}([\mathbf{h}_i^l; \mathbf{s}_{1:n}^l])\big) \quad (5)$$

$$\text{MLP}(\mathbf{x}) = \text{ELU}(\mathbf{W}\mathbf{x} + \mathbf{b}) \quad (6)$$

Given the hidden state $\mathbf{z}_i$ for input semantic relation, we use an extended variant of pointer-generator network to compute the probability distribution of next target node label v_{i+1}:

$$\text{P}(v_{i+1}) = p_{\text{gen}}\mathbf{p}_i^{(\text{vocab})} \oplus p_{\text{enc}}\mathbf{a}_i^{(\text{enc})} \oplus p_{\text{dec}}\mathbf{a}_i^{(\text{dec})} \quad (7)$$

$$\mathbf{p}_i^{(\text{vocab})} = \text{softmax}\big(\text{FFN}^{(\text{vocab})}(\mathbf{z}_i)\big) \quad (8)$$

$$\mathbf{a}_i^{(\text{dec})} = \text{softmax}\big(\text{MLP}^{(\text{dec})}([\mathbf{z}_i; \mathbf{z}_{1:i-1}])\big) \quad (9)$$

$$[p_{\text{gen}}, p_{\text{enc}}, p_{\text{dec}}] = \text{softmax}\big(\text{FFN}^{(\text{switch})}(\mathbf{z}_i)\big) \quad (10)$$

$\text{P}(v_{i+1})$ is a hybrid of three parts: (1) emitting a new node label from a pre-defined vocabulary via probability distribution $\mathbf{p}_i^{(\text{vocab})}$; (2) copying a token from the encoder input text as node label via encoder-side attention $\mathbf{a}_i^{(\text{enc})}$; and (3) copying a node label from preceding target nodes via decoder-side attention $\mathbf{a}_i^{(\text{dec})}$. Scalars $p_{\text{gen}}, p_{\text{enc}}$ and p_{dec} act as a soft switch to control the production of target node label from different sources.

The next target node index d_{i+1}^v is assigned based on the following rule:

$$d_{i+1}^v = \begin{cases} d_j^v, \text{ if } v_{i+1} \text{ copies its antecedent } v_j. \\ i+1, \text{ otherwise.} \end{cases}$$

Source Node Module produces the next source node label u_{i+1} via *pointing* to a node label among preceding *target* node labels (the dotted arrows shown in Fig. 2). The probability distribution of next source node label u_{i+1} is defined as

$$\text{P}(u_{i+1}) = \text{softmax}\big(\text{BIAFFINE}(\mathbf{h}_{i+1}^{(\text{start})}, \mathbf{h}_{1:i}^{(\text{end})})\big) \quad (11)$$

where BIAFFINE is a biaffine function (Dozat and Manning, 2016). $\mathbf{h}_{i+1}^{(\text{start})}$ is the vector representation for the *start* of the pointer. $\mathbf{h}_{1:i}^{(\text{end})}$ are vector representations for possible *ends* of the pointer. They are computed by two multi-layer perceptrons:

$$\mathbf{h}_{i+1}^{(\text{start})} = \text{MLP}^{(\text{start})}(\mathbf{h}_{i+1}^l) \quad (12)$$

$$\mathbf{h}_{1:i}^{(\text{end})} = \text{MLP}^{(\text{end})}(\mathbf{h}_{1:i}^l) \quad (13)$$

Note that $\mathbf{h}_{i+1}^l$ is the LSTM hidden state for target node v_{i+1}, generated by Equation (3) in the target node module. We reuse LSTM hidden states from the target node module such that we can train the decoder modules jointly.

Then, the next source node index d_{i+1}^u is the same as the target node the module points to.

Relation Type Module also reuses LSTM hidden states from the target node module to compute the probability distribution of next relation type r_{i+1}. Assuming that the source node module points to target node label v_j as the next source node label, The next relation type probability distribution is computed by:

$$\text{P}(r_{i+1}) = \text{softmax}\big(\text{BILINEAR}(\mathbf{h}_{i+1}^{(\text{rel-src})}, \mathbf{h}_{i+1}^{(\text{rel-tgt})})\big) \quad (14)$$

$$\mathbf{h}_{i+1}^{(\text{rel-src})} = \text{MLP}^{(\text{rel-src})}(\mathbf{h}_j^l) \quad (15)$$

$$\mathbf{h}_{i+1}^{(\text{rel-tgt})} = \text{MLP}^{(\text{rel-tgt})}(\mathbf{h}_{i+1}^l) \quad (16)$$

4.3 Training

To ensure that at each decoding step, the source node can be found in the preceding nodes, we create the reference sequence of semantic relations by running a *pre-order* traversal over the reference arborescence. The pre-order traversal only determines the order between a node and its children. As for the order of its children, we sort them in alphanumerical order in the case of AMR, following Zhang et al. (2019). In the case of SDP, we sort the children based on their order in the input text. In the case of UCCA, we sort the children based on their UCCA node ID.

Given a training pair $\langle X, Y \rangle$, the optimization objective is to maximize the decomposed conditional log likelihood $\sum_i \log\big(\text{P}(y_i \mid y_{<i}, X)\big)$, which is approximated by:

$$\sum_i \log\big(\text{P}(u_i)\big) + \log\big(\text{P}(r_i)\big) + \log\big(\text{P}(v_i)\big) \quad (17)$$

We also employ label smoothing (Szegedy et al., 2016) to prevent overfitting, and include a coverage loss (See et al., 2017) to penalize repetitive nodes: $\text{covloss}_i = \sum_t \min(\mathbf{a}_i^{(\text{enc})}[t], \mathbf{cov}_i[t])$, where $\mathbf{cov}^i = \sum_{j=0}^{i-1} \mathbf{a}_j^{(\text{enc})}$.

4.4 Prediction

Our transducer at each decoding time step looks for the source node from the preceding nodes, which ensures that the output of a greedy search is already a valid arborescence $\hat{Y}$:

$$\mathrm{P}(\hat{Y} \mid X) = \prod_i \max_{u_i} \mathrm{P}(u_i) \max_{r_i} \mathrm{P}(r_i) \max_{v_i} \mathrm{P}(v_i)$$

Therefore, a MST algorithm such as the Chu-Liu-Edmonds algorithm at $\mathcal{O}(EV)$ used in Zhang et al. (2019) is no longer needed,[4] and the decoding speed of our transducer is $\mathcal{O}(V)$. Moreover, since our transducer builds the meaning representation via a sequence of semantic relations, we implement a beam search over relation in Algo. 1. Compared to the beam search of Zhang et al. (2019) that only returns top-k nodes, our beam search finds the top-k relation scores, which includes source nodes, relation types and target nodes.

Algorithm 1: Beam Search over Semantic Relations.

Input : The input text X.
Output: A sequence of relations $Y = \{y_1, ...y_m\}$.

```
// Initialization.
i, score ← 0, 0;
Y, finished ← {}, {};
beam← {{Y, score}};
// Encoding.
encode(X);
// Decoding.
for i ← 1 to MaxLength do
    new_beam ← {};
    {Y, score} = beam.pop();
    for v_i in topK(P(v_i)) do
        if v_i = EOS then
            finished.push({Y, score});
        else
            for u_i ← v_0 to v_{i-1} do
                for r_i in RelationTypeSet do
                    Y ← Y ∪ {⟨u_i, r_i, v_i⟩};
                    score ← score + log(P(u_i)) +
                      log(P(r_i)) + log(P(v_i));
                    new_beam.push({Y, score});
                end
            end
        end
    end
    beam ← new_beam.topK();
end
// Finishing.
while beam.not_empty() do
    {Y, score} ← beam.pop();
    finished.push({Y, score});
end
{Y, score} ← finished.topK(k=1);
return Y;
```

[4] E denotes the number of edges. V the number of nodes.

5 Data Pre- and Post-processing

AMR Pre- and post-processing steps are similar to those of Zhang et al. (2019): in preprocessing, we anonymize subgraphs of entities, remove senses, and convert resultant AMR graphs into the unified format; in post-processing, we assign the most frequent sense for nodes, restore Wikipedia links using the DBpedia Spotlight API (Daiber et al., 2013), add polarity attributes based on rules observed from training data, and recover the original AMR format from the unified format.

DM No pre- or post-processing is done to DM except converting them into the unified format, and recovering them from predictions.

UCCA During training, multi-sentence input text and its corresponding DAG are split into single-sentence training pairs based on rules observed from training data. At test time, we split multi-sentence input text, and join the predicted graphs into one. We also convert the original format to the unified format in preprocessing, and recover the original DAG format in post-processing.

Table 1: Hyperparameter settings

6 Experiments

6.1 Data and Setup

We evaluate our approach on three separate broad-coverage semantic parsing tasks: (1) AMR 2.0 (LDC2017T10) and 1.0 (LDC2014T12); (2) the English DM dataset from SemEval 2015 Task 18 (LDC2016T10); (3) the UCCA English Wikipedia Corpus v1.2 (Abend and Rappoport, 2013). The train/dev/test split follows the official setup. Our model is trained on two GeForce GTX TITAN X GPUs with early stop based on the dev set. We fix BERT parameters similar to Zhang et al. (2019) due to the limited GPU memory. Hyperparameter setting for each task is provided in Table 1.

6.2 Results

Data	Parser	F1(%)
AMR 2.0	Cai and Lam (2019)	73.2
	Lyu and Titov (2018)	74.4±0.2
	Lindemann et al. (2019)	75.3±0.1
	Naseem et al. (2019)	75.5
	Zhang et al. (2019)	76.3±0.1
	- w/o beam search	75.3±0.1
	Ours	**77.0**±0.1
	- w/o beam search	76.4±0.1
AMR 1.0	Flanigan et al. (2016)	66.0
	Pust et al. (2015)	67.1
	Wang and Xue (2017)	68.1
	Guo and Lu (2018)	68.3±0.4
	Zhang et al. (2019)	70.2±0.1
	- w/o beam search	69.2±0.1
	Ours	**71.3**±0.1
	- w/o beam search	70.4±0.1

Table 2: SMATCH F1 on AMR 2.0 and 1.0 test sets. Standard deviation is computed over 3 runs.

AMR Table 2 compares our neural transducer to the previous best results (SMATCH F1, Cai and Knight, 2013) on AMR test sets. The transducer improves the state of the art on AMR 2.0 by 0.7% F1. On AMR 1.0 where training data is much smaller than AMR 2.0, it shows a larger improvement (1.1% F1) over the state of the art.

In Table 2, we also conduct ablation study on beam search to investigate contributions from the model architecture itself and the beam search algorithm. The transducer model without beam search is already better than the previous best parser that is equipped with beam search. When compared with the previous best parser without beam search, our model still has around 1.0% F1 improvement.

Metric	L'18	N'19	Z'19	Ours
SMATCH	74	75	76	**77**
Unlabeled	77	**80**	79	**80**
No WSD	76	76	77	**78**
Reentrancies	52	56	60	**61**
Concepts	**86**	**86**	85	**86**
Named Ent.	**86**	83	78	79
Wikification	76	80	**86**	**86**
Negation	58	67	75	**77**
SRL	70	**72**	70	71

Table 3: Fine-grained F1 scores on the AMR 2.0 test set. L'18 is Lyu and Titov (2018); N'19 is Naseem et al. (2019); Z'19 is Zhang et al. (2019).

Table 3 summarizes the parser performance on each subtask using Damonte et al. (2017) evaluation tool. Our transducer outperforms Zhang et al. (2019) on all subtasks, but is still not close to Lyu and Titov (2018) on named entities due to the different preprocessing methods for anonymization.

Parser	ID	OOD
Du et al. (2015)	89.1	81.8
Almeida and Martins (2015)$^{(open)}$	89.4	83.8
Wang et al. (2018)	90.3	84.9
Peng et al. (2017a): BASIC	89.4	84.5
Peng et al. (2017a): FREDA3	90.4	85.3
Peng et al. (2018)	91.2	86.6
Dozat and Manning (2018)	**93.7**	**88.9**
Ours	92.2	87.1

Table 4: Labeled F1 (%) scores on the English DM in-domain (WSJ) and out-of-domain (Brown corpus) test sets. $^{(open)}$ denotes results from the open track.

DM Table 4 compares our neural transducer to the state of the art (labeled F1) on the English DM in-domain (ID) and out-of-domain (OOD) data. Except Dozat and Manning (2018), our transducer outperforms all other baselines, including FREDA3 of Peng et al. (2017a) and Peng et al. (2018), which leverage multi-task learning from different datasets. The best parser (Dozat and Manning, 2018) is specifically designed for bi-lexical dependencies, and is not directly applicable to other se-

mantic parsing tasks such as AMR and UCCA. In contrast, our transducer is more general, and is competitive to the best SDP parser.

Parser	F1 (%)
Hershcovich et al. (2017)	71.1
Hershcovich et al. (2018): single	71.2
Hershcovich et al. (2018): MTL	74.3
Ours	**76.6**±0.1
- w/o non-terminal node labels	75.7±0.1

Table 5: Labeled F1 (%) scores for all edges including primary edges and remote edges. Standard deviation is computed over 3 runs.

UCCA Table 5 compares our results to the previous best published results (labeled F1 for all edges) on the English Wiki test set. Hershcovich et al. (2018) explore multi-task learning (MTL) to improve UCCA parsing, using AMR, DM and UD parsing as auxiliaries. While improvement is achieved UCCA parsing, their MTL model shows poor results on the auxiliary tasks: 64.7% unlabeled F1 on AMR, 27.2% unlabeled F1 on DM, and 4.9% UAS on UD. In comparison, our transducer improves the state of the art on AMR, and shows competitive results on DM. At the same time, it also outperforms the best published UCCA results by 2.3% F1. When converting UCCA DAGs to the unified format, we adopt a simple rule (Section 3.1) to add node labels to non-terminals. Table 5 shows that these node labels do improve the parsing performance from 75.7% to 76.6%.

6.3 Analysis

Validity Graph-based parsers like Dozat and Manning (2018); Zhang et al. (2019) make independent decisions on edge types. As a result, the same outgoing edge type can appear multiple times to a node. For instance, a node can have more than one `ARG1` outgoing edge. Although F1 scores can be computed for graphs with such kind of nodes, these graphs are in fact invalid mean representations. Our neural transducer incrementally builds meaning representations: at each decoding step, it takes a semantic relation as input, and has memory of preceding edge type information, which implicitly places constraints on edge type prediction. We compute the number of invalid graphs predicted by the parser of Zhang et al. (2019) and our neural transducer on the AMR 2.0 test set, and find that our neural transducer reduces the number of invalid graphs by 8%.

Speed Besides the improvement on parsing accuracy, we also significantly speed up parsing. Table 6 compares the parsing speed of our transducer and Zhang et al. (2019) on the AMR 2.0 test set, under the same environment setup. Without relying on MST algorithms to produce a valid arborescence, our transducer is able to parse at 1.7x speed.

	Speed (tokens/sec)
Zhang et al. (2019)	617
Ours	**1076**

Table 6: Parsing speed on the AMR 2.0 test set.

7 Conclusion

We cast three broad-coverage semantic parsing tasks into a unified transduction framework, and propose a neural transducer to tackle the problem. Given the input text, the transducer incrementally builds a meaning representation via a sequence of semantic relations. Experiments conducted on three tasks show that our approach improves the state of the art in both AMR and UCCA, and is competitive to the best parser in SDP.

This work can be viewed as a starting point for cross-framework semantic parsing. Also, compared with transition-based parsers (e.g. Damonte et al., 2017) and graph-based parsers (e.g. Dozat and Manning, 2018), our transductive framework does not require a pre-trained aligner, and it is capable of building a meaning representation that is less anchored to the input text. These advantages make it well suited to semantic parsing in cross-lingual settings (Zhang et al., 2018). In the future, we hope to explore its potential in cross-framework and cross-lingual semantic parsing.

Core Semantic First: A Top-down Approach for AMR Parsing*

Abstract

We introduce a novel scheme for parsing a piece of text into its Abstract Meaning Representation (AMR): Graph Spanning based Parsing (GSP). One novel characteristic of GSP is that it constructs a parse graph incrementally in a top-down fashion. Starting from the root, at each step, a new node and its connections to existing nodes will be jointly predicted. The output graph spans the nodes by the distance to the root, following the intuition of first grasping the main ideas then digging into more details. The *core semantic first* principle emphasizes capturing the main ideas of a sentence, which is of great interest. We evaluate our model on the latest AMR sembank and achieve the state-of-the-art performance in the sense that no heuristic graph re-categorization is adopted. More importantly, the experiments show that our parser is especially good at obtaining the core semantics.

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic formalism that encodes the meaning of a sentence as a rooted labeled directed graph. As illustrated by an example in Figure 1, AMR abstracts away from the surface forms in text, where the root serves as a rudimentary representation of the overall focus while the details are elaborated as the depth of the graph increases. AMR has been proved useful for many downstream NLP tasks, including text summarization (Liu et al., 2015; Hardy and Vlachos, 2018) and question answering (Mitra and Baral, 2016).

The task of AMR parsing is to map natural language strings to AMR semantic graphs automatically. Compared to constituent parsing (Zhang and Clark, 2009) and dependency parsing (Kübler et al., 2009), AMR parsing is considered more challenging due to the following characteristics: (1) The nodes in AMR have no explicit alignment to text tokens; (2) The graph structure is more complicated because of frequent reentrancies and non-projective arcs; (3) There is a large and sparse vocabulary of possible node types (concepts).

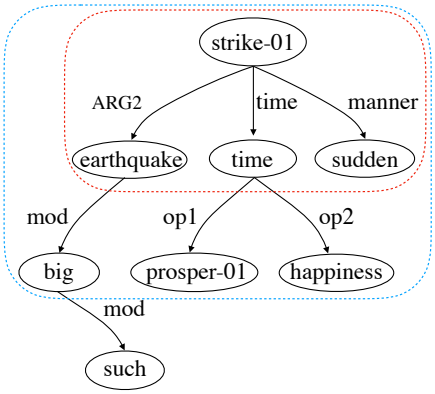

Figure 1: AMR for the sentence "*During a time of prosperity and happiness, such a big earthquake suddenly struck.*", where the subgraphs close to the root represent the core semantics.

Many methods for AMR parsing have been developed in the past years, which can be categorized into three main classes: Graph-based parsing (Flanigan et al., 2014; Lyu and Titov, 2018) uses a pipeline design for concept identification and relation prediction. Transition-based parsing (Wang et al., 2016; Damonte et al., 2017; Ballesteros and Al-Onaizan, 2017; Guo and Lu, 2018; Liu et al., 2018; Wang and Xue, 2017) processes a sentence from left-to-right and constructs the graph incrementally. The third class is seq2seq-based parsing (Barzdins and Gosko, 2016; Konstas et al., 2017; van Noord and Bos, 2017), which views parsing as sequence-to-sequence transduction by a linearization (depth-first traversal) of the AMR graph.

While existing graph-based models cannot sufficiently model the interactions between individual decisions, the autoregressive nature of transition-based and seq2seq-based models makes them suffer from error propagation, where later decisions can easily go awry, especially given the complexity of AMR. Since capturing the core semantics of a sentence is arguably more important and useful in practice, it is desirable for a parser to have a global view and a priority for capturing the main ideas first. In fact, AMR graphs are organized in a hierarchy that the core semantics stay closely to the root, for which a top-down parsing scheme can fulfill the desiderata. For example, in Figure 1, the subgraph in the red box already conveys the core meaning "*an earthquake suddenly struck at a particular time*", and the subgraph in the blue box further informs that "*the earthquake was big*" and "*the time was of prosperity and happiness*".

We propose a novel framework for AMR parsing known as Graph Spanning based Parsing (GSP). One novel characteristic of GSP is that, to our knowledge, it is the first top-down AMR parser.[1] GSP performs parsing in an incremental, root-to-leaf fashion, but still maintains a global view of the sentence and the previously derived graph. At each step, it generates the connecting arcs between the existing nodes and the coming new node, upon which the type of the new node (concept) is jointly decided. The output graph spans the nodes by the distance to the root, following the intuition of first grasping the main ideas then digging into more details. Compared to previous graph-based methods, our model is capable of capturing more complicated intra-graph interactions, while reducing the number of parsing steps to be linear in the sentence length.[2] Compared to transition-based methods, our model removes the left-to-right restriction and avoids sophisticated oracle design for handling the complexity of AMR graphs.

Notably, most existing methods including the state-the-of-art parsers often rely on heavy graph re-categorization for reducing the complexity of the original AMR graphs. For graph re-categorization, specific subgraphs of AMR are grouped together and assigned to a single node with a new compound category (Werling et al., 2015; Wang and Xue, 2017; Foland and Martin, 2017; Lyu and Titov, 2018; Groschwitz et al., 2018; Guo and Lu, 2018). The hand-crafted rules for re-categorization are often non-trivial, requiring exhaustive screening and expert-level manual efforts. For instance, in the re-categorization system of Lyu and Titov (2018), the graph fragment "`temporal-quantity` $\xrightarrow{:ARG3-of}$ `rate-entity-91` $\xrightarrow{:unit}$ `year` $\xrightarrow{:quant}$ `1`" will be replaced by one single nested node "`rate-entity-3(annual-01)`". There are hundreds of such manual heuristic rules. This kind of re-categorization has been shown to have considerable effects on the performance (Wang and Xue, 2017; Guo and Lu, 2018). However, one issue is that the precise set of re-categorization rules differs among different models, making it difficult to distinguish the performance improvement from model optimization or carefully designed rules. In fact, some work will become totally infeasible when removing this re-categorization step. For example, the parser of Lyu and Titov (2018) requires tight integration with this step as it is built on the assumption that an injective alignment exists between sentence tokens and graph nodes.

We evaluate our parser on the latest AMR sembank and achieve competitive results to the state-of-the-art models. The result is remarkable since our parser directly operates on the original AMR graphs and requires no manual efforts for graph re-categorization. The contributions of our work are summarized as follows:

- We propose a new method for learning AMR parsing that produces high-quality core semantics.
- Without the help of heuristic graph re-categorization which requires expensive expert-level manual efforts for designing re-categorization rules, our method achieves state-of-the-art performance.

2 Related Work

Currently, most AMR parsers can be categorized into three classes: (1) *Graph-based* methods (Flanigan et al., 2014, 2016; Werling et al., 2015; Foland and Martin, 2017; Lyu and Titov, 2018; Zhang et al., 2019) adopt a pipeline approach for graph construction. It first maps continuous text spans into AMR concepts, then calculates the scores of possible edges and uses a max-

[1] Depth-first traversal in seq2seq models does not produce a strictly top-down order due to the reentrancies in AMR.

[2] Since the size of AMR graph is approximately linear in the length of sentence.

imum spanning connected subgraph algorithm to select the final graph. The major deficiency is that the concept identification and relation prediction are strictly performed in order, yet the interactions between them should benefit both sides (Zhou et al., 2016). In addition, for computational efficacy, usually only first-order information is considered for edge scoring. (2) *Transition-based* methods (Wang et al., 2016; Damonte et al., 2017; Wang and Xue, 2017; Ballesteros and Al-Onaizan, 2017; Liu et al., 2018; Peng et al., 2018; Guo and Lu, 2018; Naseem et al., 2019) borrow techniques from shift-reduce dependency parsing. Yet the non-trivial nature of AMR graphs (e.g., reentrancies and non-projective arcs) makes the transition system even more complicated and difficult to train (Guo and Lu, 2018). (3) *Seq2seq-based* methods (Barzdins and Gosko, 2016; Peng et al., 2017; Konstas et al., 2017; van Noord and Bos, 2017) treat AMR parsing as sequence-to-sequence problem by linearizing AMR graphs, thus existing seq2seq models (Bahdanau et al., 2014; Luong et al., 2015) can be readily utilized. Despite its simplicity, the performance of the current seq2seq models lag behind when the training data is limited. The first reason is that seq2seq models are often not as effective on smaller datasets. The second reason is that the linearized AMRs add the challenges of making use of the graph structure information.

There are also some notable exceptions. Peng et al. (2015) introduce a synchronous hyperedge replacement grammar solution. Pust et al. (2015) regard the task as a machine translation problem, while Artzi et al. (2015) adapt combinatory categorical grammar. Groschwitz et al. (2018); Lindemann et al. (2019) view AMR graphs as the structure AM algebra.

Most AMR parsers require an explicit alignment between tokens in the sentences and nodes in the AMR graph during training. Since such information is not annotated, a pre-trained aligner (Flanigan et al., 2014; Pourdamghani et al., 2014; Liu et al., 2018) is often required. More recently, Lyu and Titov (2018) demonstrate that the alignments can be treated as latent variables in a joint probabilistic model.

3 Background and Overview

3.1 Background of Multi-head Attention

The multi-head attention mechanism introduced by Vaswani et al. (2017) is used as a basic building block in our framework. The multi-head attention consists of H attention heads, and each of which learns a distinct attention function. Given a query vector x and a set of vectors $\{y_1, y_2, \ldots, y_m\}$ or in short $y_{1:m}$, for each attention head, we project x and $y_{1:m}$ into distinct query, key, and value representations $q \in \mathbb{R}^d$, $K \in \mathbb{R}^{m \times d}$ and $V \in \mathbb{R}^{m \times d}$ respectively, where d is the dimension of the vector space. Then we perform scaled dot-product attention (Vaswani et al., 2017):

$$a = \text{softmax}\frac{(Kq)}{\sqrt{d}}$$
$$attn = aV$$

where $a \in \mathbb{R}^m$ is the attention vector (a distribution over all input $y_{1:m}$) and $attn$ is the weighted sum of the value vectors. Finally, the outputs of all attention heads are concatenated and projected to the original dimension of x. For brevity, we will denote the whole attention procedure described above as a function $T(x, y_{1:m})$.

Based on the multi-head attention, the Transformer encoder (Vaswani et al., 2017) uses self-attention for context information aggregation when given a set of vectors (e.g., word embeddings in a sentence or node embeddings in a graph).

3.2 Overview

Figure 2 depicts the major neural components in our proposed framework: The Sentence Encoder component and the Graph Encoder component are designed for token-level sentence representation and node-level graph representation respectively. Given an input sentence $\mathbf{w} = (w_1, w_2, \ldots, w_n)$, where n is the sentence length, the Sentence Encoder component will first read the whole sentence and encode each word w_i into the hidden state s_i. The initial graph G_0 is always initialized with one dummy node d^* and a previously generated concept c_j is encoded into the hidden state v_j by the Graph Encoder component.

At each time step t, the Focus Selection component reads both the sentence representation $s_{1:n}$ and the graph representation $v_{0:t-1}$ of G_{t-1} repeatedly, generates the initial parser state h_t. The

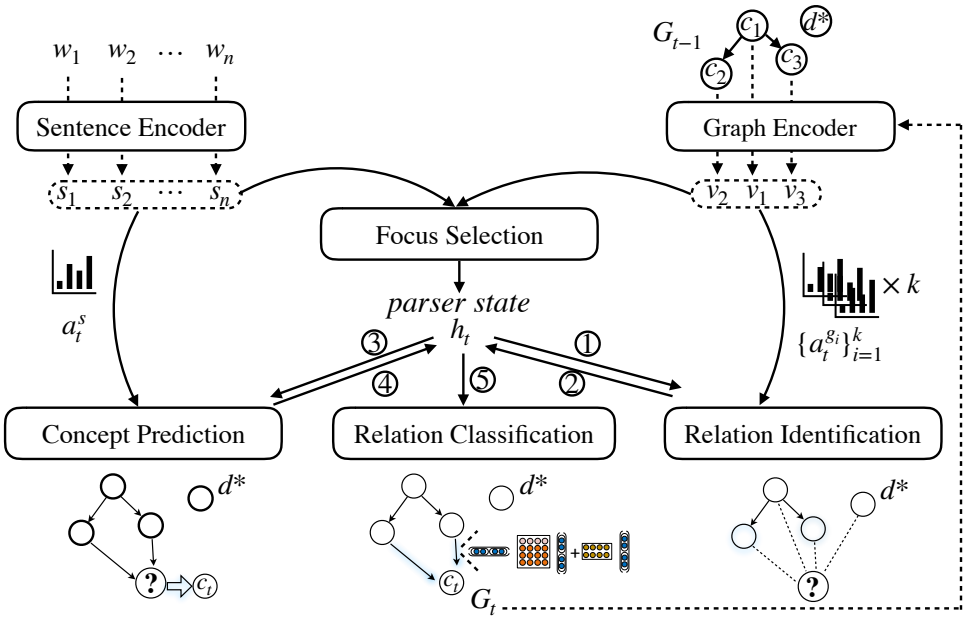

Figure 2: Model architecture of GSP, together with the decoding procedure at the time step t, where the read and write operations around the parser state h_t follow the order ① → ② → ③ → ④ → ⑤.

parser state carries the most useful information and serves as a writable memory during the expansion step. Next, the Relation Identification component decides which specific head nodes to expand by computing the multiple attention scores $\{a_t^{g_i}\}_{i=1}^k$ over the existing nodes. New arcs are generated according to the attention scores. Then the Concept Prediction component updates the parser state h_t with arc information, computes the attention vector a_t^s over the sentence and accordingly chooses a specific part to generate the new concept c_t. Finally, the Relation Classification component is used to predict the relation labels between the newly generated concept and its predecessors. Consequently an updated graph G_t is produced and G_t will be processed for the next time step. The whole decoding procedure is terminated if the newly generated concept is the special stop concept $\oslash$.

Our method expands the graph in a root-to-leaf fashion, nodes with shorter distances to the root will be introduced first. It follows a similar way that humans grasp the meaning: first seeking the main concepts then proceeding to the substructures governed by certain head concepts (Banarescu et al., 2013).

During training, we use breadth-first search to decide the order of nodes. However, for nodes with multiple children, there still exist multiple valid selections. In order to define a deterministic decoding process, we sort sibling nodes by their relations to the head node. We will present more discussions on the choice of sibling order in § 5.3.

4 Framework Description

4.1 Sentence & Graph Representation

Transformer encoder architecture is employed for both the Sentence Encoder and the Graph encoder components. For sentence encoding, a special token ($\triangleright$) is prepended to the input word sequence, whose final hidden state s_0 is regarded as an aggregated summary of the whole sentence and used as the initial state in parsing steps.

The Graph Encoder component takes previously generated concept sequence $(c_0, c_1, \ldots, c_{t-1})$ (c_0 is the dummy node d^*) as input. For computation efficiency and reducing error propagation, instead of encoding the edge information explicitly, we use the Transformer encoder to capture the interactions between nodes. Finally, the encoder outputs a sequence of node representations $(v_0, v_1, \ldots, v_{t-1})$.

4.2 Focus Selection

At each time step t, the Focus Selection component will read the sentence and the partially constructed graph repeatedly for gradually locating and collecting the most relevant information for the next expansion. We simulate the repeated reading by multiple levels of attention. Formally,

the following recurrence is applied by L times:

$$x_{t,1}^{l+1} = \text{LN}(h_t^l + T_1^{l+1}(h_t^l, s_{1:n}))$$
$$x_{t,2}^{l+1} = \text{LN}(x_{t,1}^{l+1} + T_2^{l+1}(x_{t,1}^{l+1}, v_{0:t-1}))$$
$$h_t^{l+1} = \max(x_{t,2}^{l+1} W_1^{l+1} + b_1^{l+1}) W_2^{l+1} + b_2^{l+1}$$

where $T(\cdot,\cdot)$ is the multi-head attention function. LN is the layer normalization (Ba et al., 2016) and h_t^0 is always initialized with s_0. For clarity, we denote the last hidden state h_t^L as h_t, as the parser state at the time step t. We now proceed to present the details of each decision stage of one parsing step, which is also illustrated in Figure 2.

4.3 Relation Identification

Our Relation Identification component is inspired by a recent attempt of exposing auxiliary supervision on attention mechanism (Strubell et al., 2018). It can be considered as another attention layer over the existing graph, yet the attention weights explicitly indicate the likelihood of the new node being attached to a specific node. In other words, its aim is to answer the question of where to expand. Since a node can be attached to multiple nodes by playing different semantic roles, we utilize multi-head attention and take the maximum over different heads as the final arc probabilities.

Formally, through a multi-head attention mechanism taking h_t and $v_{0:t-1}$ as input, we obtain a set of attention weights $\{a_t^{g_i}\}_{i=1}^k$, where k is the number of attention heads and $a_t^{g_i}$ is the i-th probability vector. The probability of the arc between the new node and the node v_j is then computed by $a_{t,j}^g = max_i(a_{t,j}^{g_i})$. Intuitively, each head is in charge of a set of possible relations (though not explicitly specified). If certain relations do not exist between the new node and any existing node, the probability mass will be assigned to the dummy node d^*. The maximum pooling reflects that the arc should be built once one relation is activated.[3]

The attention mechanism passes the arc decisions to later layers by the update of the parser state as follows:

$$h_t = LN(h_t + W^{\text{arc}} \sum_{j=0}^{t-1} a_{t,j}^g v_j)$$

[3]We also found that there may exist more than one relation between two distinct nodes, however, it rarely happens.

4.4 Concept Prediction

Our Concept Prediction component uses a soft alignment between words and the new concept. Concretely, a single-head attention a_t^s is computed based on the parser state h_t and the sentence representation $s_{1:n}$, where $a_{t,i}^s$ denotes the attention weight of the word w_i in the current time step. This component then updates the parser state with the alignment information via the following equation:

$$h_t = LN(h_t + W^{\text{conc}} \sum_{i=1}^{n} a_{t,i}^s s_i)$$

The probability of generating a specific concept c from the concept vocabulary $\mathcal{V}$ is calculated as $gen(c|h_t) = \exp({x_c}^T h_t)/\sum_{c' \in \mathcal{V}} \exp({x_{c'}}^T h_t)$, where x_c (for $c \in \mathcal{V}$) denotes the model parameters. To address the data sparsity issue in concept prediction, we introduce a copy mechanism in similar spirit to Gu et al. (2016). Besides generation, our model can either directly copy an input token w_i (e.g, for entity names) or map w_i to one concept $m(w_i)$ according to the alignment statistics[4] in the training data (e.g., for "went", it would propose *go*). Formally, the prediction probability of a concept c is given by:

$$\begin{aligned} P(c|h_t) =& P(copy|h_t) \sum_{i=1}^{n} a_{t,i}^s [[w_i = c]] \\ &+ P(map|h_t) \sum_{i=1}^{n} a_{t,i}^s [[m(w_i) = c]] \\ &+ P(gen|h_t) gen(c|h_t) \end{aligned}$$

where $[[\ldots]]$ is the indicator function. $P(copy|h_t)$, $P(map|h_t)$ and $P(gen|h_t)$ are the probabilities of three prediction modes respectively, computed by a single layer neural network with softmax activation.

4.5 Relation Classification

Lastly, the Relation Classification component employs a multi-class classifier for labeling the arcs detected in the Relation Identification component. The classifier uses a biaffine function to score each label, given the head concept representation v_i and the child vector h_t as input:

$$e_t^i = h_t^T W v_i + U^T h_t + V^T v_i + b$$

[4]Based on the alignments provided by Liu et al. (2018), for each word, the most frequently aligned concept (or its lemma if it has empty alignment) is used for direct mapping.

where W, U, V, b are model parameters. As suggested by Dozat and Manning (2016), we project v_i and h_t to a lower dimension for reducing the computation cost and avoiding the overfitting of the model. The label probabilities are computed by a softmax function over all label scores.

4.6 Reentrancies

AMR reentrancy is employed when a node participates in multiple semantic relations (with multiple parent nodes), and that is why AMRs are graphs, rather than trees. The reentrancies are often hard to treat. While previous work often either remove them (Guo and Lu, 2018) or relies on rule-based restoration in the postprocessing stage (Lyu and Titov, 2018; van Noord and Bos, 2017), our model provides a new and principled way to deal with reentrancies. In our approach, when a new node is generated, all its connections to already existing nodes are determined by the multi-head attention. For example, for a node with k parent nodes, k different heads will point to the those parent nodes respectively. For a better understanding of our model, a pseudocode is presented in Algorithm 1.

4.7 Training and Inference

Our model is trained to maximize the log likelihood of the gold AMR graphs given sentences, i.e. $\log P(G|\mathbf{w})$, which can be factorized as:

$$\log P(G|\mathbf{w}) = \sum_{t=1}^{m} \Bigg(\log P(c_t|G_{t-1}, \mathbf{w}) + \sum_{i \in pred(t)} \log P(arc_{it}|G_{t-1}, \mathbf{w}) + \sum_{i \in pred(t)} \log P(rel_{arc_{it}}|G_{t-1}, \mathbf{w}) \Bigg)$$

where m is the total number of vertices. The set of predecessor nodes of c_t is denoted as $pred(t)$. arc_{it} denotes the arc between c_i and c_t, and $rel_{arc_{it}}$ indicates the arc label (relation type).

As mentioned, GSP is an autoregressive model, such as seq2seq models and transition models, but it factors the distribution according to a top-down graph structure rather than a depth-first traversal or a left-to-right chain. Meanwhile, GSP has a clear separation of node, arc and relation label probabilities, interacting in a more interpretable and tighten manner.

Algorithm 1 Graph Spanning based Parsing

Input: the input sentence $\mathbf{w} = (w_1, w_2, \ldots, w_n)$
Output: the AMR graph G corresponds to $\mathbf{w}$.

◇ Learning Sentence Representation
$\mathbf{w} = (w_0 = \triangleright) + (w_1, w_2, \ldots, w_n)$
$s_0, s_1, s_2, \ldots, s_n =$ Transformer($\mathbf{w}$)
◇ Initialization
initialize the graph G_0 ($c_0 = d^*$)
initialize time step $t = 1$
◇ Entering Main Spanning Loop
while True **do**
  $h_0, \ldots, v_{t-1}$ = Transformer($c_{0:t-1}$)
  h_t = Focus_Selection $(s_0, v_{0:t-1}, s_{1:n})$
  h_t = Relation_Identification $(h_t, v_{0:t-1})$
  decide the parents nodes $pred(t)$ *of* c_t
  h_t = Concept_Prediction $(h_t, s_{1:n})$
  decide the node type of c_t
  if $c_t == \oslash$ **then**
    break
  end if
  for $i \in pred(t)$ **do**
    Relation_Classification (h_t, v_i)
    decide the edge type between c_t *and* c_i
  end for
  update G_{t-1} to G_t
end while
return G_{t-1}

At the operational or testing time, the prediction for the input $\mathbf{w}$ is obtained via $\hat{G} = \arg\max_{G'} P(G'|\mathbf{w})$. Rather than iterating over all possible graphs, we adopt a beam search to approximate the best graph. Specifically, for each partially constructed graph, we only consider the top-K concepts obtaining the best single-step probability (a product of the corresponding concept, arc, and relation label probability), where K is the beam size. Only the best K graphs at each time step are kept for the next expansion.

5 Experiments

5.1 Setup

We focus on the most recent LDC2017T10 dataset, as it is the largest AMR corpus. It consists of 36521, 1368, and 1371 sentences in the training, development, and testing sets respectively.

We use Stanford CoreNLP (Manning et al., 2014) for text preprocessing, including tokenization, lemmatization, part-of-speech, and named-entity tagging. The input for sentence encoder

consists of the randomly initialized lemma, part-of-speech tag, and named-entity tag embeddings, as well as the output from a learnable CNN with character embeddings as inputs. The graph encoder uses randomly initialized concept embeddings and another char-level CNN. Model hyper-parameters are chosen by experiments on the development set. The details of the hyper-parameter settings are provided in the Appendix. During testing, we use a beam size of 8 for generating graphs.[5]

Conventionally, the quality of AMR parsing results is evaluated using the Smatch tool (Cai and Knight, 2013), which seeks for the maximum number of overlaps between two AMR annotations after decomposing AMR graphs into triples. However, the ordinary Smatch metric treats all triples equally regardless of their roles in the composition of the whole sentence meaning. We refine the ordinary Smatch metric to take into consideration the notion of core semantics. Specifically, we compute:

- Smatch-weighted: This metric weights different triples by their importance of composing the core ideas. The root distance d of a triple is defined as the minimum root distance of its involving nodes, the weight of the triple is then computed as:

$$w = \min(-d + d_{thr}, 1)$$

  In other words, the weight has a linear decay in root distance until d_{thr}. If two triples are matched, the minimum importance score of them is obtained. In our experiments, d_{thr} is set to 5.

- Smatch-core: This metric only compares the subgraphs representing the main meaning. Precisely, we cut down AMR graphs by setting a maximum root distance d_{max} and only keep the nodes and edges within the threshold. d_{max} is set to 4 in our experiments, of which the remaining subgraphs still have a broad coverage of the original meaning, as illustrated by the distribution of root distance in Figure 3.

Besides, we also evaluate the quality by computing the following metrics.

[5]Our code can be found at https://github.com/jcyk/AMR-parser.

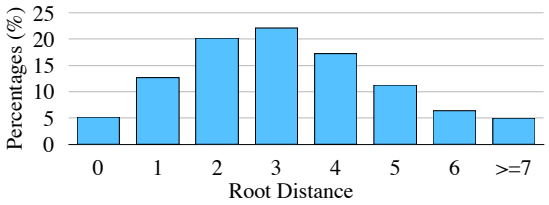

Figure 3: The distribution of root distance of concepts in the test set.

- complete-match (CM): This metric counts the number of parsing results that are completely correct.

- root-accuracy (RA): This metric measures the accuracy of the root concept identification.

5.2 Main Results and Case Study

The main result is presented in Table 1. We compare our method with the best-performing models in each category as discussed in § 2.

Concretely, van Noord and Bos (2017) is a character-level seq2seq model that achieves very competitive result. However, their model is very data demanding as it requires to train on additional 100K sentence-AMR pairs generated by other parsers. Guo and Lu (2018) is a transition-based parser with refined search space for AMR. Certain concepts and relations (e.g., reentrancies) are removed to reduce the burdens during training. Lyu and Titov (2018) is a graph-based method that achieves the best-reported result evaluated by the ordinary Smatch metric. Their parser uses different LSTMs for concept prediction, relation identification, and root identification sequentially. Also, the relation identification stage has the time complexity of $O(m^2 \log m)$ where m is the number of concepts. Groschwitz et al. (2018) views AMR as terms of the AM algebra (Groschwitz et al., 2017), which allows standard tree-based parsing techniques to be applicable. The complexity of their projective decoder is $O(m^5)$. Last but not least, all these models except for that of van Noord and Bos (2017) require hand-crafted heuristics for graph re-categorization.

We consider the Smatch-weighted metric as the most suitable metric for measuring the parser's quality on capturing core semantics. The comparison shows that our method significantly outperforms all other methods. The Smatch-core metric also demonstrates the advantage of our

Model	Graph Re-ca.	Smatch(%)			RA(%)	CM(%)
		weighted	core	ordinary		
Buys and Blunsom (2017)	No	-	-	61.9	-	-
