Sub-graph Matching via Path Finding. We define a schema graph as a sub-graph g of the whole knowledge graph G, which represents the related knowledge for reasoning a given question-answer pair with minimal additional concepts and edges. One may want to find a minimal spanning sub-graph covering all the question and answer concepts, which is actually the NP-complete "Steiner tree problem" in graphs (Garey and Johnson, 1977). Due to the incompleteness and tremendous size of ConceptNet, we find that it is impractical to retrieve a comprehensive but helpful set of knowledge facts this way. Therefore, we propose a straightforward yet effective graph construction algorithm via path finding among mentioned concepts ($\mathcal{C}_q \cup \mathcal{C}_a$).

Specifically, for each question concept $c_i \in \mathcal{C}_q$ and answer concept $c_j \in \mathcal{C}_a$, we can efficiently find paths between them that are shorter than k concepts[4]. Then, we add edges, if any, between the concept pairs within $\mathcal{C}_q$ or $\mathcal{C}_a$.

3.3 Path Pruning via KG Embedding

To prune irrelevant paths from potentially noisy schema graphs, we first utilize knowledge graph embedding (KGE) techniques, like TransE (Wang et al., 2014), to pre-train concept embeddings $\mathbf{V}$ and relation type embeddings $\mathbf{R}$, which are also used as initialization for KagNet (§4). In order to measure the quality of a path, we decompose it into a set of triples, the confidence of which can be directly measured by the scoring function of the KGE method (i.e. the confidence of triple classification). Thus, we score a path with the multiplication product of the scores of each triple in the path, and then we empirically set a threshold for pruning (§5.3).

4 Knowledge-Aware Graph Network

The core component of our reasoning framework is the knowledge-aware graph network module KagNet. The KagNet first encodes plain structures of schema graphs with graph convolutional networks (§4.1) to accommodate pre-trained con-

[3] The full mapping list is in the appendix.

[4] We set $k = 4$ in experiments to gather three-hop paths.

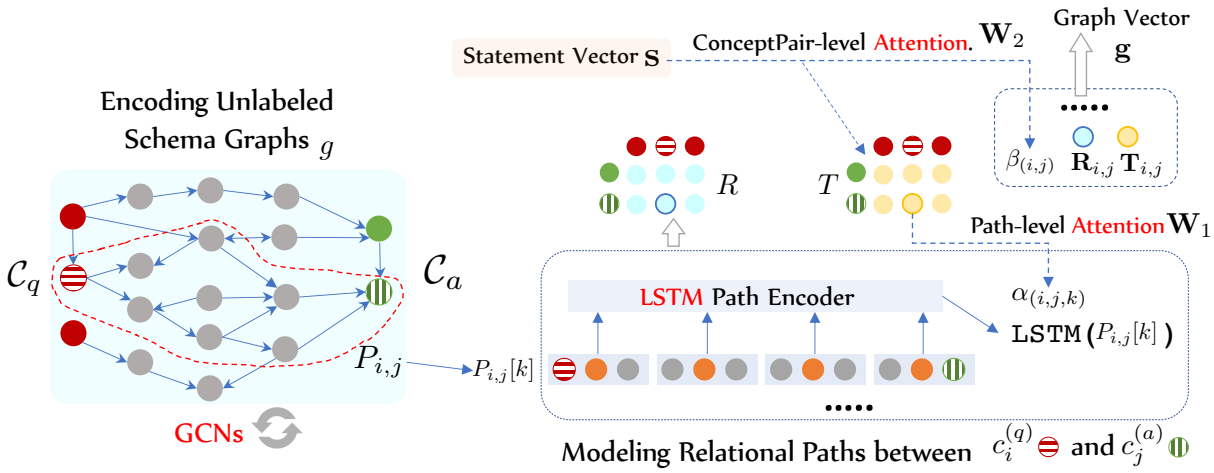

Figure 3: Illustration of the GCN−LSTM−HPA architecture for the proposed KAGNET module.

cept embeddings in their particular context within schema graphs. It then utilizes LSTMs to encode the paths between $\mathcal{C}_q$ and $\mathcal{C}_a$, capturing multi-hop relational information (§4.2). Finally, we apply a hierarchical path-based attention mechanism (§4.3) to complete the GCN−LSTM−HPA architecture, which models relational schema graphs with respect to the paths between question and answer concepts.

4.1 Graph Convolutional Networks

Graph convolutional networks (GCNs) encode graph-structured data by updating node vectors via pooling features of their adjacent nodes (Kipf and Welling, 2017). Our intuition for applying GCNs to schema graphs is to 1) contextually refine the concept vectors and 2) capture structural patterns of schema graphs for generalization.

Although we have obtained concept vectors by pre-training (§3.3), the representations of concepts still need to be further accommodated to their specific schema graphs context. Think of polysemous concepts such as "close" (§3.1), which can either be a verb concept like in "close the door" or an adjective concept meaning "a short distance apart". Using GCNs to update the concept vector with their neighbors is thus helpful for disambiguation and contextualized concept embedding. Also, the pattern of schema graph structures provides potentially valuable information for reasoning. For instance, shorter and denser connections between question and answer concepts could mean higher plausibility under specific contexts.

As many works show (Marcheggiani and Titov, 2017; Zhang et al., 2018), relational GCNs (Schlichtkrull et al., 2018) usually over-parameterize the model and cannot effectively utilize multi-hop relational information. We thus apply GCNs on the plain version (unlabeled, non-directional) of schema graphs, ignoring relation types on the edges. Specifically, the vector for concept $c_i \in \mathcal{V}_g$ in the schema graph g is initialized by their pre-trained embeddings at first ($h_i^{(0)} = \mathbf{V}_i$). Then, we update them at the $(l+1)$-th layer by pooling features of their neighboring nodes (N_i) and their own at the l-th layer with an non-linear activation function σ:

$$h_i^{(l+1)} = \sigma(W_{self}^{(l)} h_i^{(l)} + \sum_{j \in N_i} \frac{1}{|N_i|} W^{(l)} h_j^{(l)})$$

4.2 Relational Path Encoding

In order to capture the relational information in schema graphs, we propose an LSTM-based path encoder on top of the outputs of GCNs. Recall that our graph representation has a special purpose: "*to measure the plausibility of a candidate answer to a given question*". Thus, we propose to represent graphs with respect to the paths between question concepts $\mathcal{C}_q$ and answer concepts $\mathcal{C}_a$.

We denote the k-th path between i-th question concept $c_i^{(q)} \in \mathcal{C}_q$ and j-th answer concept $c_j^{(a)} \in \mathcal{C}_a$ as $P_{i,j}[k]$, which is a sequence of triples:

$$P_{i,j}[k] = [(c_i^{(q)}, r_0, t_0), ..., (t_{n-1}, r_n, c_j^{(a)})]$$

Note that the relations are represented with trainable relation vectors (initialized with pre-trained relation embeddings), and concept vectors are the GCNs' outputs ($h^{(l)}$). Thus, each triple can be represented by the concatenation of the three

corresponding vectors. We employ LSTM networks to encode these paths as sequences of triple vectors, taking the concatenation of the first and the last hidden states:

$$\mathbf{R}_{i,j} = \frac{1}{|P_{i,j}|} \sum_k \texttt{LSTM}(P_{i,j}[k])$$

The above $\mathbf{R}_{i,j}$ can be viewed as the latent relation between the question concept $c_i^{(q)}$ and the answer concept $c_j^{(a)}$, for which we aggregate the representations of all the paths between them in the schema graph. Now we can finalize the vector representation of a schema graph $\mathbf{g}$ by aggregating all vectors in the matrix $\mathbf{R}$ using mean pooling:

$$\mathbf{T}_{i,j} = \texttt{MLP}([\mathbf{s}\ ;\ \mathbf{c_q^{(i)}}\ ;\ \mathbf{c_a^{(j)}}])$$
$$\mathbf{g} = \frac{\sum_{i,j}[\mathbf{R}_{i,j}\ ;\ \mathbf{T}_{i,j}]}{|\mathcal{C}_q| \times |\mathcal{C}_a|}$$

, where $[\cdot\ ;\ \cdot]$ means concatenation of two vectors.

The statement vector $\mathbf{s}$ in the above equation is obtained from a certain language encoder, which can either be a trainable sequence encoder like LSTM or features extracted from pre-trained universal language encoders like GPT/BERT). To encode a question-answer pair with universal language encoders, we simply create a sentence combining the question and the answer with a special token ("`question`+ [sep] + `answer`"), and then use the vector of '[cls]' as suggested by prior works (Talmor et al., 2019)..

We concatenate $\mathbf{R}_{i,j}$ with an additional vector $\mathbf{T}_{i,j}$ before doing average pooling. The $\mathbf{T}_{i,j}$ is inspired from the `Relation Network` (Santoro et al., 2017), which also encodes the latent relational information yet from the context in the statement s instead of the schema graph g. Simply put, we want to combine the relational representations of a pair of question/answer concepts from both the schema graph side (symbolic space) and the language side (semantic space).

Finally, the plausibility score of the answer candidate a to the question q can be computed as $\texttt{score}(q, a) = \texttt{sigmoid}(\texttt{MLP}(\mathbf{g}))$.

4.3 Hierarchical Attention Mechanism

A natural argument against the above `GCN-LSTM-mean` architecture is that mean pooling over the path vectors does not always make sense, since some paths are more important than others for reasoning. Also, it is usually not the case that all pairs of question and answer concepts equally contribute to the reasoning. Therefore, we propose a hierarchical path-based attention mechanism to selectively aggregate important path vectors and then more important question-answer concept pairs. This core idea is similar to the work of Yang et al. (2016), which proposes a document encoder that has two levels of attention mechanisms applied at the word- and sentence-level. In our case, we have path-level and concept-pair-level attention for learning to contextually model graph representations. We learn a parameter matrix $\mathbf{W}_1$ for path-level attention scores, and the importance of the path $P_{i,j}[k]$ is denoted as $\hat{\alpha}_{(i,j,\cdot)}$.

$$\alpha_{(i,j,k)} = \mathbf{T}_{i,j}\ \mathbf{W}_1\ \texttt{LSTM}(P_{i,j}[k]),$$
$$\hat{\alpha}_{(i,j,\cdot)} = \texttt{SoftMax}(\alpha_{(i,j,\cdot)}),$$
$$\hat{\mathbf{R}}_{i,j} = \sum_k \hat{\alpha}_{(i,j,k)} \cdot \texttt{LSTM}(P_{i,j}[k]).$$

Afterwards, we similarly obtain the attention over concept-pairs.

$$\beta_{(i,j)} = \mathbf{s}\ \mathbf{W}_2\ \mathbf{T}_{i,j}$$
$$\hat{\beta}_{(\cdot,\cdot)} = \texttt{SoftMax}(\beta_{(\cdot,\cdot)})$$
$$\hat{\mathbf{g}} = \sum_{i,j} \hat{\beta}_{(i,j)}[\hat{\mathbf{R}}_{i,j}\ ;\ \mathbf{T}_{i,j}]$$

The whole `GCN-LSTM-HPA` architecture is illustrated in Figure 3. To sum up, we claim that the KAGNET is a graph neural network module with the `GCN-LSTM-HPA` architecture that models relational graphs for relational reasoning under the context of both knowledge symbolic space and language semantic space.

5 Experiments

We introduce our setups of the `CommonsenseQA` dataset (Talmor et al., 2019), present the baseline methods, and finally analyze experimental results.

5.1 Dataset and Experiment Setup

The `CommonsenseQA` dataset consists of 12,102 (v1.11) natural language questions in total that require human commonsense reasoning ability to answer, where each question has five candidate answers (hard mode). The authors also release an easy version of the dataset by picking two random terms/phrases for sanity check. `CommonsenseQA` is directly gathered from real human annotators and covers a broad range of

types of commonsense, including spatial, social, causal, physical, temporal, etc. To the best of our knowledge, CommonsenseQA may be the most suitable choice for us to evaluate supervised learning models for question answering.

For the comparisons with the reported results in the CommonsenseQA's paper and leaderboard, we use the official split (9,741/1,221/1,140) named (OFtrain/OFdev/OFtest). Note that the performance on OFtest can only be tested by submitting predictions to the organizers. To efficiently test other baseline methods and ablation studies, we choose to use randomly selected 1,241 examples from the training data as our in-house data, forming an (8,500/1,221/1,241) split denoted as (IHtrain/IHdev/IHtest). All experiments are using the random-split setting as the authors suggested, and three or more random states are tested on development sets to pick the best-performing one.

5.2 Compared Methods

We consider two different kinds of baseline methods as follows:

• *Knowledge-agnostic Methods.* These methods either use no external resources or only use unstructured textual corpora as additional information, including gathering textual snippets from search engine or large pre-trained language models like BERT-LARGE. QABILINEAR, QACOMPARE, ESIM are three supervised learning models for natural language inference that can be equipped with different word embeddings including GloVe and ELMO. BIDAF++ utilizes Google web snippets as context and is further augmented with a self-attention layer while using ELMO as input features. GPT/BERT-LARGE are fine-tuning methods with an additional linear layer for classification as the authors suggested. They both add a special token '[sep]' to the input and use the hidden state of the '[cls]' as the input to the linear layer. More details about them can be found in the dataset paper (Talmor et al., 2019).

• *Knowledge-aware Methods.* We also *adopt* some recently proposed methods of incorporating knowledge graphs for question answering. KV-MEM (Mihaylov and Frank, 2018) is a method that incorporates retrieved triples from ConceptNet at the word-level, which uses a key-valued memory module to improve the representation of each token individually by learning an attentive aggregation of related triple vectors. CBPT (Zhong et al., 2018) is a plug-in method of assembling the predictions of any models with a straightforward method of utilizing pre-trained concept embeddings from ConceptNet. TEXTGRAPHCAT (Wang et al., 2019c) concatenates the graph-based and text-based representations of the statement and then feed it into a classifier. We create sentence template for generating sentences and then feed retrieved triples as additional text inputs as a baseline method TRIPLESTRING. Rajani et al. (2019) propose to collect human explanations for commonsense reasoning from annotators as additional knowledge (COS-E), and then train a language model based on such human annotations for improving the model performance.

5.3 Implementation Details of KagNet

Our best (tested on OFdev) settings of KAGNET have two GCN layers (100 dim, 50dim respectively), and one bidirectional LSTMs (128dim) . We pre-train KGE using TransE (100 dimension) initialized with GloVe embeddings. The statement encoder in use is BERT-LARGE, which works as a pre-trained sentence encoder to obtain fixed features for each pair of question and answer candidate. The paths are pruned with path-score threshold set to *0.15*, keeping *67.21%* of the original

paths. We did not conduct pruning on concept pairs with less than three paths. For very few pairs with none path, $\hat{\mathbf{R}}_{(i,j)}$ will be a randomly sampled vector. We learn our KAGNET models with Adam optimizers (Kingma and Ba, 2015). In our experiments, we found that the recall of ConceptNet on commonsense questions and answers is very high (over 98% of QA-pairs have more than one grounded concepts).

5.4 Performance Comparisons and Analysis

Comparison with standard baselines.
As shown in Table 2, we first use the official split to compare our model with the baseline methods reported on the paper and leaderboard. BERT and GPT-based pre-training methods are much higher than other baseline methods, demonstrating the ability of language models to store commonsense knowledge in an implicit way. This presumption is also investigated by Trinh and Le (2019) and Wang et al. (2019). Our proposed framework achieves an absolute increment of 2.2% in accuracy on the test data, a state-of-the-art performance.

We conduct the experiments with our in-house splits to investigate whether our KAGNET can also work well on other universal language encoders (GPT and BERT-BASE), particularly with different fractions of the dataset (say 10%, 50%, 100% of the training data). Table 1 shows that our KAGNET-based methods using fixed pre-trained language encoders outperform fine-tuning themselves in all settings. Furthermore, we find that the improvements in a small data situation (10%) is relatively limited, and we believe an important future research direction is thus few-shot learning for commonsense reasoning.

Comparison with knowledge-aware baselines.
To compare our model with other adopted baseline methods that also incorporate ConceptNet, we set up a bidirectional LSTM networks-based model for our in-house dataset. Then, we add baseline methods and KAGNET onto the BLSTMs to compare their abilities to utilize external knowledge[5]. Table 3 shows the comparisons under both easy mode and hard mode, and our methods outperform all knowledge-aware baseline methods by a large margin in terms of accuracy. Note that we compare our model and the CoS-E in Table 2. Although CoS-E also achieves better result than only fine-tuning BERT by training with human-generated explanations, we argue that our proposed KagNet does not utilize any additional human efforts to provide more supervision.

Ablation study on model components.
To better understand the effectiveness of each component of our method, we have done ablation study as shown in Table 4. We find that replacing our GCN-LSTM-HPA architecture with traditional relational GCNs, which uses separate weight matrices for different relation types, results in worse performance, due to its over-parameterization. The attention mechanisms matters almost equally in two levels, and pruning also effectively filters noisy paths.

Error analysis.
In the failed cases, there are three kinds of hard problems that KAGNET is still not good at.

- **negative reasoning:** the grounding stage is not sensitive to the negation words, and thus can choose exactly opposite answers.
- **comparative reasoning strategy:** For the

[5]We do LSTM-based setup because it is non-trivial to apply token-level knowledge-aware baseline methods for complicated pre-trained encoders like BERT.

Model	IHdev.(%)	IHtest.(%)
KAGNET (STANDARD)	62.35	57.16
: replace GCN-HPA-LSTM w/ R-GCN	60.01	55.08
: w/o GCN	61.84	56.11
: #GCN Layers = 1	62.05	57.03
: w/o Path-level Attention	60.12	56.05
: w/o QAPair-level Attention	60.39	56.13
: using all paths (w/o pruning)	59.96	55.27

Table 4: Ablation study on the KAGNET framework.

questions with more than one highly plausible answers, the commonsense reasoner should benefit from explicitly investigating the difference between different answer candidates, while KAGNET training method is not capable of doing so.

- **subjective reasoning:** Many answers actually depend on the "personality" of the reasoner. For instance, "*Traveling from new place to new place is likely to be what?*" The dataset gives the answer as "exhilarating" instead of "exhausting", which we think is more like a personalized subjective inference instead of common sense.

5.5 Case Study on Interpretibility

Our framework enjoys the merit of being more transparent, and thus provides more interpretable inference process. We can understand our model behaviors by analyzing the hierarchical attention scores on the question-answer concept pairs and path between them.

Figure 4 shows an example how we can analyze our KAGNET framework through both pair-level and path-level attention scores. We first select the concept-pairs with highest attention scores and then look at the (one or two) top-ranked paths for each selected pair. We find that paths located in this way are highly related to the inference process and also shows that noisy concepts like 'fountain' will be diminished while modeling.

5.6 Model Transferability.

We study the transferability of a model that is trained on CommonsenseQA (CSQA) by directly testing it with another task while fixing its parameters. Recall that we have obtained a BERT-LARGE model and a KAGNET model trained on CSQA. Now we denoted them as CSQA-BL and CSQA-KN to suggest that they are not trainable anymore.

In order to investigate their transferability, we separately test them on SWAG (Zellers et al., 2018)

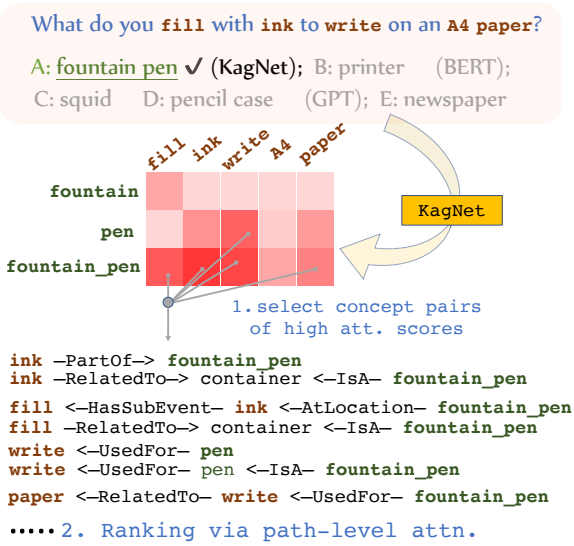

Figure 4: An example of interpreting model behaviors by hierarchical attention scores.

and WSC (Levesque, 2011) datasets. We first test them the 20k validation examples in SWAG. CSQA-BL has an accuracy of 56.53%, while our fixed CSQA-KN model achieves 59.01%. Similarly, we also test both models on the WSC-QA, which is converted from the WSC pronoun resolution to a multi-choice QA task.

The CSQA-BL achieves an accuracy of 51.23%, while our model CSQA-KN scores 53.51%. These two comparisons further support our assumption that KAGNET, as a knowledge-centric model, is more extensible in commonsense reasoning. As we expect for a good knowledge-aware frameworks to behave, our KAGNET indeed enjoys better transferablity than only fine-tuning large language encoders like BERT.

5.7 Recent methods on the leaderboard.

We argue that the KAGNET utilizes the ConceptNet as the only external resource and other methods are improving their performance in orthogonal directions: 1) we find that most of the other recent submissions (as of Aug. 2019) with public information on the leaderboard utilize larger additional textual corpora (e.g. top 10 matched sentences in full Wikipedia via information retrieval tools), and fine-tuning on larger pre-trained encoders, such as XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019). 2) there are also models using multi-task learning to transfer knowledge from other reading comprehension datasets, such as RACE (Lai et al., 2017) and

OpenBookQA (Mihaylov et al., 2018).

An interesting fact is that the best performance on the OFtest set is still achieved the original fine-tuned RoBERTa model, which is pre-trained with copora much larger than BERT. All other RoBERTa-extended methods have negative improvements. We also use statement vectors from RoBERTa as the input vectors for KagNet, and find that the performance on OFdev marginally improves from 77.47% to 77.56%. Based on our above-mentioned failed cases in error analysis, we believe fine-tuning RoBERTa has achieved the limit due to the annotator biases of the dataset and the lack of comparative reasoning strategies.

6 Related Work

Commonsense knowledge and reasoning. There is a recent surge of novel large-scale datasets for testing machine commonsense with various focuses, such as situation prediction (SWAG) (Zellers et al., 2018), social behavior understanding (Sap et al., 2019a,b), visual scene comprehension (Zellers et al., 2019), and general commonsense reasoning (Talmor et al., 2019), which encourages the study of supervised learning methods for commonsense reasoning. Trinh and Le (2018) find that large language models show promising results in WSC resolution task (Levesque, 2011), but this approach can hardly be applied in a more general question answering setting and also not provide explicit knowledge used in inference. A unique merit of our KagNet method is that it provides grounded explicit knowledge triples and paths with scores, such that users can better understand and put trust in the behaviors and inferences of the model.

Injecting external knowledge for NLU. Our work also lies in the general context of using external knowledge to encode sentences or answer questions. Yang and Mitchell (2017) are the among first ones to propose to encode sentences by keeping retrieving related entities from knowledge bases and then merging their embeddings into LSTM networks computations, to achieve a better performance on entity/event extraction tasks. Weissenborn et al. (2017), Mihaylov and Frank (2018), and Annervaz et al. (2018) follow this line of works to incorporate the embeddings of related knowledge triples at the word-level and improve the performance of natural language understanding tasks. In contrast to our work, they do not explicitly impose graph-structured knowledge into models , but limit its potential within transforming word embeddings to concept embeddings.

Some other recent attempts (Zhong et al., 2018; Wang et al., 2019c) to use ConceptNet graph embeddings are adopted and compared in our experiments (§5). Rajani et al. (2019) propose to manually collect more human explanations for correct answers as additional supervision for auxiliary training. KagNet-based framework focuses on injecting external knowledge as an explicit graph structure, and enjoys the relational reasoning capacity over the graphs.

Relational reasoning. KagNet can be seen as a knowledge-augmented Relation Network module (RN) (Santoro et al., 2017), which is proposed for the visual question answering task requiring relational reasoning (i.e. questions about the relations between multiple 3D-objects in an image). We view the concepts in the questions and answers as objects and effectively utilize external knowledge graphs to model their relations from both semantic and symbolic spaces (§4.2), while prior methods mainly work on the semantic one.

7 Conclusion

We propose a knowledge-aware framework for learning to answer commonsense questions. The framework first constructs schema graphs to represent relevant commonsense knowledge, and then model the graphs with our KagNet module. The module is based on a GCN-LSTM-HPA architecture, which effectively represent graphs for relational reasoning purpose in a transparent, interpretable way, yielding a new state-of-the-art results on a large-scale general dataset for testing machine commonsense. Future directions include better question parsing methods to deal with negation and comparative question answering, as well as incorporating knowledge to visual reasoning.

Abstract

This paper studies the problem of supporting question answering in a new language with limited training resources. As an extreme scenario, when no such resource exists, one can (1) transfer labels from another language, and (2) generate labels from unlabeled data, using translator and automatic labeling function respectively. However, these approaches inevitably introduce noises to the training data, due to translation or generation errors, which require a judicious use of data with varying confidence. To address this challenge, we propose a weakly-supervised framework that quantifies such noises from automatically generated labels, to deemphasize or fix noisy data in training. On reading comprehension task, we demonstrate the effectiveness of our model on low-resource languages with varying similarity to English, namely, Korean and French.

1 Introduction

Reading comprehension question answering (RCQA) is one of many well-known NLP tasks, to answer questions based on text understanding. For RCQA, a well-known resource is SQuAD (Rajpurkar et al., 2016) with 100K QA data created by human, followed by NarrativeQA (Kočiskỳ et al., 2018), SQuAD 2.0 (Rajpurkar et al., 2018), and CoQA (Reddy et al., 2018). However, as these datasets support only English, supporting other languages requires either annotation efforts in a comparable scale (Lim et al., 2018), or modeling efforts to overcome the limitation of training resources in terms of **quantity** or **quality**. Our work pursues the latter goal.

To illustrate, consider an extreme scenario of bootstrapping a RCQA model for a new language with no labelled resource. We can overcome the limitation in **quantity** by generating alternative low-quality resources. First, neural machine translation (NMT) can convert existing English annotations into a target language (Faruqui and Kumar, 2015; Ture and Boschee, 2016). For example, (passage p, question q, answer a) in SQuAD can be translated into (p', q', a') in a target language (Asai et al., 2018; Lee et al., 2018). Second, automatic labeling function (Du and Cardie, 2018; Serban et al., 2016) can be adopted to generate synthetic labels in a target language. For example, Du and Cardie (2018) leverages Question Generator (QG) and Answer Extractor (AE) as labeling function for RCQA, to create training resources of a virtually infinite amount from unlabeled corpora.

However, overcoming the quantity limitation using the above methods, leads to **quality** problems. As a consequence, some of the following assumptions on quality may cease to hold, after errors introduced from generation. (1) **Answerability**: the semantic of the translated passage or generated question may shift, so that a question gets unanswerable after generation, or (2) **Answer alignment**: the answer span in a target language may become incorrect. Our goal is estimating the quality of resources and even improving the quality, to overcome the limited quality of training resources.

For the goal, we exploit noisy data from the above two sources, translator and labeling function, considered as **weak labels**, and pursue robust learning overcoming noises: Our key contribution is ***Refinery*** network that predict confidence – quality of (p, q, a) instance into a score in the range of 0 to 1. While most existing weakly supervision approach focuses on generating positive examples, we leverage synthetic negative examples for training *Refinery*, optimized to distinguish positive from negative one.

As shown in Figure 1, a training procedure of

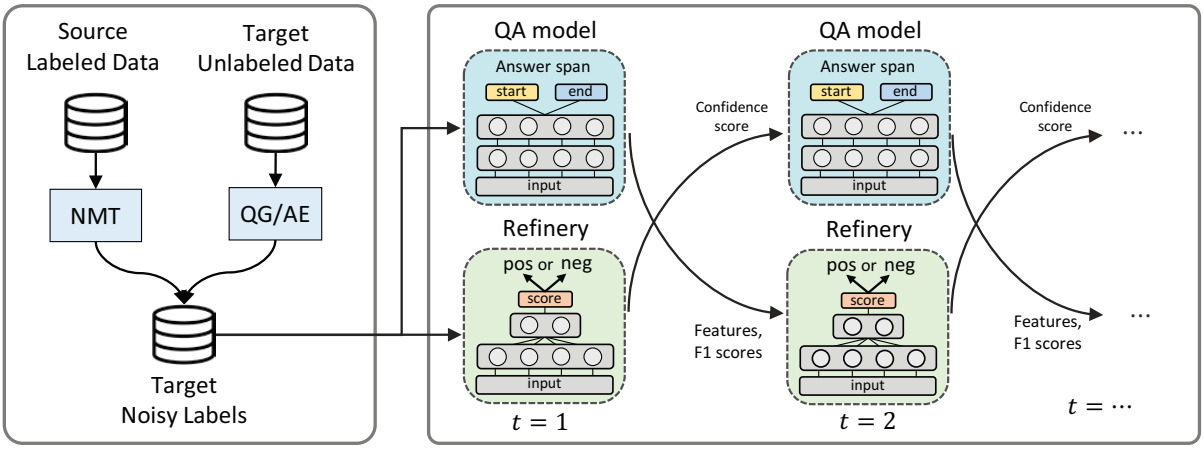

Figure 1: Overview of our approach

QA and *Refinery* is iterative: QA model is used for confidence estimation and *Refinery* is used to determine which noisy instances should be deemphasized in training, or whether to modify wrong labels, towards the direction of improving QA model. As our framework does not re-train or access data generation models, our approach is agnostic to generation model, such that it can extend to generation models not discussed here.

For experiments on RCQA in a new language, our model is evaluated on three human-annotated sets. Our experiments show that our method with *Refinery* augments training data and outperforms all state-of-the-arts. This observation can be generalized over similar and distant language pairs (English with French and Korean respectively), and with and without significant topic overlaps: To validate this claim, we evaluate over widely adopted human generated evaluation sets on Korean and French Wikipedia documents. In addition, our reported gains are orthogonal to a pre-trained model, such that we can easily leverage the strength of the latest BERT model (Devlin et al., 2018), and contribute additional gains. Our implementation is available at: https://github.com/lkj0509/multilingual_MRC.

2 Preliminaries

RCQA problem is defined based on SQuAD dataset (Rajpurkar et al., 2016) in English, which consists of 23,215 passages and 100k+ question-answer pairs requiring the understanding of corresponding passages to answer correctly. Let p be a passage with m words, *i.e.*, $p = \{w_1^p, w_2^p, ..., w_m^p\}$, and q be a question with n words, *i.e.*, $q = \{w_1^q, w_2^q, ..., w_n^q\}$. Then, given a pair of passage p and question q, the objective of RCQA is to estimate a consecutive answer span a, *i.e.*, $a = \{w_i^p, w_{i+1}^p, ..., w_j^p\}$ where $a \subseteq p$. For task evaluation, the estimated answer span a is compared with the ground truth answer span a^* in terms of F1 score at word-level.

The majority of RCQA models (Seo et al., 2016; Yu et al., 2018; Devlin et al., 2018) consist of (a) encoding the passage and question into a fixed-size vector, then (b) decoding to predict the probability of each position in the passage being the start or end of an answer span. As a basic QA model, we start from BiDAF model (Seo et al., 2016), which is a widely known open-source code.[1] BiDAF model uses bi-directional LSTM networks with attention mechanism to align question with passage and vice-versa. More specifically, the probabilities of the starting and ending position are modeled as:

$$\begin{aligned} \mathbf{P}^1 &= softmax(h_1 \cdot [M^0 ; M^1]) \\ \mathbf{P}^2 &= softmax(h_2 \cdot [M^0 ; M^2]) \end{aligned} \quad (1)$$

where h_1, h_2 are trainable weights, and M^0, M^1, M^2 are the hidden states at each LSTM layer to represent the passage words according to the given question. The probability of s-to-e span of the passage is defined as follows:

$$P(a = \{w_s^p, ..., w_e^p\} | p, q) = \mathbf{P}_s^1 \times \mathbf{P}_e^2 \quad (2)$$

In test, the model selects the answer span with the highest probability (Eq. (2)) during post-processing.

3 Data Generation for New Language

This section introduces how we generate weak supervisions, from machine translation and synthetic label generation.

3.1 Method I: Neural Machine Translation

SQuAD is a set of (p, q, a) triple, where answer a to question q can be found as a consecutive substring match in the passage p (*i.e.*, $a \subseteq p$). Due to this property of SQuAD, translating the triple (p, q, a) is non-trivial: when p and a are translated into target language, p_t and a_t, $a_t \subseteq p_t$ may no longer hold. Therefore, we need to find the answer span a_t in the target language, by matching with a_s in the source language s. We overviewed a high-precision baseline (Lee et al., 2018) where a_s and p_s are independently translated, and a_t is found only when the translation of a_s is exactly and consecutively found in that of p_s. However, this suffers low-recall, considering we found only 53.6% spans among whole translated Q-A pairs by the high-precision method.

To complement, we propose a perfect-recall alignment to find 46.4% spans that cannot be extracted by the above method. Our method is extensible to any language with an existing open-source NMT, leveraging only its attention scores (Bahdanau et al., 2014).

(1) One-to-one alignment: A widely adopted simplifying assumption for machine translation is that each target word is aligned to one source language word (Brown et al., 1993). Based on attention score in NMT, each word in a_s can be aligned with word in the target language, by selecting highest score. After 1-to-1 matching, we select the longest sub-sequence as answer span a_t.

(2) Span-to-span alignment: One-to-one assumption is simplifying, by treating values in the alignment matrix as binary and excluding a possibility that a word can be aligned with multiple target words. Instead, we align span-to-span, to calculate a "soft" score between a_s and a_t, and change the span boundary dynamically. To illustrate, assume $a_t = \{i, ..., j\}$ is the answer span found from the one-to-one alignment. Before finalizing this answer, we may ask whether changing the boundary i and j improves the match[2]. Formally, when $S_{m,n}$ denotes (m, n)-th element in the alignment matrix, we can evaluate the match score of between a_s and a_t by averaging all pairwise combinations in the two spans: $\boldsymbol{S} = average(S_{m,n})$ for $\forall m \in a_s$, $\forall n \in a_t$. If changing the target boundary $a'_t = \{i', ..., j'\}$ improves this score, we will make a modification. Specifically, we consider updating the end position to j' in the range of $j \pm N$, within a pre-defined window size N, and enqueue a possible update j' if the average score of $\boldsymbol{S}$ for a_s and a'_t is higher than that of a_s and a_t. Similarly, we compare the scores of start position in the range of $i \pm N$ to enqueue a possible update i'. After this, highest-scoring update pair (i', j') in the queue (Hwang and Chang, 2005) can be aligned.

[2]We notice that 16% spans from 1-to-1 alignment can be changed to gain F1 score of 1% point on Korean test set.

3.2 Method II: Synthetic Label Generation

This section introduces an automatic labeler which can generate question-answer pairs from unlabeled text crawled for the target language. Training data collected via NMT is inherently skewed to specific domains answerable for English-speaking area (*e.g.*, United States), which causes the domain gap with test data on a new language. Automatic labeler can complement by collecting unlabeled text on the domains not covered, and generating synthetic labels.

For generating synthetic training data, we leverage Question Generator (QG) and Answer Extractor (AE) as labeler, following (Du and Cardie, 2018). Given a passage in a target language, our goal is to generate question-answer pairs, related to the given passage. In (Du and Cardie, 2018), BiLSTM-CRF model (Huang et al., 2015) is used for AE, classifying whether the word belongs to the answer span. For QG, sequence-to-sequence model (Bahdanau et al., 2014) is adopted, by setting a passage and answer candidates as input and question words as output. To train QG and AE, we use weak labels obtained from Method I. At inference time of QG and AE, we insert human-written passages, crawled from web documents in a target language (*e.g.*, Wikipedia), and obtain pairs of question and answer as the output of QG and AE, respectively.

4 Weakly-supervised QA model

In this section, we illustrate how we score confidence for noisy training data obtained from the above two generation methods. We propose a new *Refinery* network, of not only estimating confi-

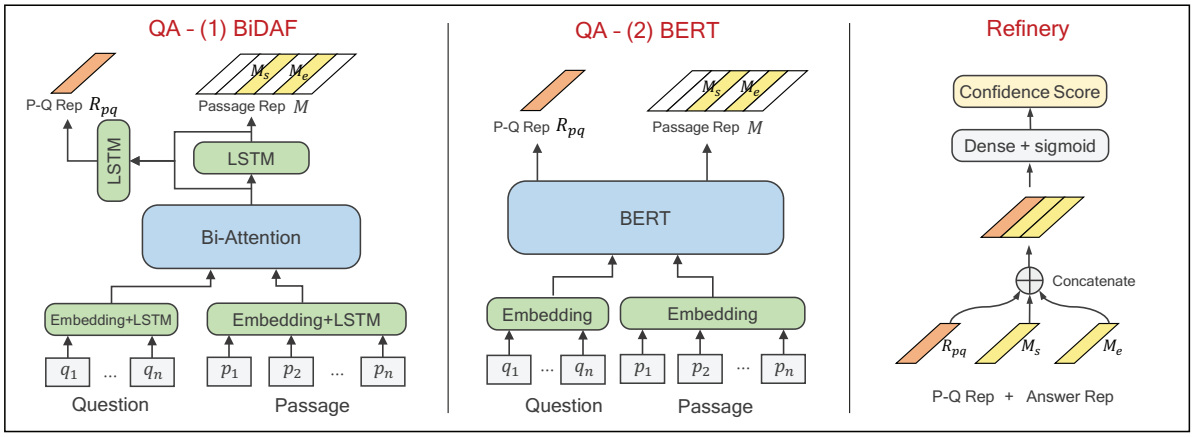

Figure 2: Architecture of our QA model and *Refinery*. Our approach of *Refinery* (Right) can be applicable to various RCQA models, illustrated with BiDAF (Left) and BERT (Center) here.

dence of noisy input from multiple generators but also improving labels and QA model. Existing work (Bach et al., 2011) estimates translation error that can be used as a confidence proxy. However, it requires large labels through human-correction, and cannot apply to other generators such as QG. Our goal is confidence estimation regardless of whether it is generated from NMT or QG methods (generator-agnostic).

4.1 Refinery Network

Our *Refinery* aims to score the quality of the generated (p, q, a) labels, depending on whether the example is positive or negative. It is known that RCQA models trained solely on positive examples fail on unanswerable cases, assuming that a correct answer is guaranteed to exist in the passage (Rajpurkar et al., 2018). A simple remedy is to manually augment training resources with negative examples, to teach how to distinguish them from positive examples. Our key contribution is automatic collection of both positive and negative training examples for training **confidence** prediction, which we will discuss in details below.

Our research question now is then: how do we obtain positive and negative examples? For positive examples, we treat weak labels from the generation methods as "pseudo-positive", since it would be positive, when the translation/generation is perfect. For negative examples, we generate synthetic noises, similarly to translation/generation errors, by adopting a naive but effective method to change words or sentences in a positive example (Levy et al., 2017; Zhang et al., 2019; Yang et al., 2019).

Specifically, we modify pseudo-positive labels to generate synthetic negative examples of unanswerable or wrong answer. For unanswerable cases, (1) we first replace a question with its semantic neighbor derived from other documents (*e.g.*, "who first discovered america?" into "who first discovered canada?"). For this, we use the average of word embedding and the cosine distance. Second, (2) we modify a passage by removing a sentence containing the answer span, so that the modified passage is the subset of original one, but unanswerable. Lastly, for wrong answers, (3) we perturb an answer span into a random span in the same passage, which is answerable but with an incorrect label. We generate negative examples from the above (1)-(3) methods (33.3% each). As we will show later in Section 5, these negative examples are empirically effective for training *Refinery*.

The training objective is that CS of pseudo-positive example should be greater than that of negative one, with at least margin δ. To deal with pseudo-positive examples unequally, we set the margin δ dynamically, which is derived from F1 score of QA model. That is, we relatively assign a larger margin to a higher confidence instance, and smaller otherwise. The magnitude of margin depends on the F1 score of the predicted answer from QA model. Considering the margin δ, the final objective function is computed as follows:

$$\delta_i = \alpha \cdot F1\ score(p_i^+, q_i^+, a_i^+)$$
$$L_{cs} = \sum_i max(0, \delta_i - \{CS_i^+ - CS_i^-\}) \quad (3)$$

where α is a hyper-parameter, CS_i^+ indicates the confidence of positive example, and CS_i^- is that of negative example.

Now, to obtain the confidence score, we use BiDAF (Seo et al., 2016) as QA model, as shown in Figure 2 (Left). First, to model answerability of (p, q), we extract the feature of (p, q) from QA model. For this, we concatenate the two hidden states M^1 and M^2 from BiDAF, as mentioned in Section 2.1. Then, the representations are aggregated by LSTM and attention layer, as follows:

$$\begin{aligned} G &= \sigma(W_1[M^1 ; M^2] + b_1) \\ \overline{G} &= \overleftrightarrow{LSTM}(G) \\ a &= softmax(v_1 \cdot \sigma(W_2\overline{G} + b_2)) \\ R_{pq} &= \sum_i a_i \cdot \overline{G_i} \end{aligned} \tag{4}$$

where W_1, W_2, v_1, b_1, b_2 are trainable weights, and σ is tanh function. The vector R_{pq} containing the information of both passage and question will be used for confidence score.

Second, to model the confidence of answer labels, we represent answer spans in the labels. For this, we concatenate two hidden states M_s^1 and M_e^2 of s-th start and e-th end words in the answer. The final confidence score CS is obtained from R_{pq} and the answer feature, as follows:

$$\begin{aligned} R_{span} &= [\ M_s^1 ; M_e^2\ ] \\ CS &= sigmoid(v_2 \cdot [\ R_{pq} ; R_{span}\ ] + b_3) \end{aligned} \tag{5}$$

where v_2 and b_3 are trainable weights, and $[\ ;\ ]$ indicates concatenation.

An extension to the above model is to replace BiDAF with BERT (Devlin et al., 2018), a pre-trained model on a masked language model task. Due to the commonality of BiDAF and BERT, taking question and passage as input and generating passage representations for answer span prediction, we can apply BERT to our approach, as shown in Figure 2 (Center), by modifying *Refinery* module of modeling confidence score. Meanwhile, architectural differences of the two, such as BiDAF using bi-attention layers and BERT using self-attention layers, require some minor changes: In BERT, as the output of CLS token can represent the input sequence of passage and question, we use the output vector of CLS as R_{pq}. For R_{span}, we use the hidden states at the layer of BERT, instead of M in Eq. (5). We will show the effectiveness of our approach on both BiDAF and BERT model in Section 5.

4.2 Improving QA and Weak Labels

During an iterative procedure of QA and *Refinery*, our approach improves both QA model and weak labels. Using confidence, *Refinery* acts as two functions: (1) **down-weighting** instances with low-quality, and (2) **answer modification** with low-quality for higher quality.

The objective of original QA model minimizes the sum of the negative log probabilities:

$$\begin{aligned} L_{qa} &= -\sum_i^N log(\mathbf{P}^1_{s_i}) + log(\mathbf{P}^2_{e_i}) \\ &= -\sum_i^N log(P(a_i|p_i, q_i)) \end{aligned} \tag{6}$$

where N is the number of examples in training set, s_i and e_i are the start and end indices of the i-th example, respectively. For down-weighting noise, we combine this QA loss function with weighted confidence score, based on function $f(CS(p, q))$:

$$L_{qa'} = -\sum_i^N f(CS_i) \cdot log(P(a_i|p_i, q_i)) \tag{7}$$

However, in initial steps of training, the confidence score is not reliable, and may cause unstable training. To avoid the problem, we apply an annealing technique, adjusting the contribution of the confidence score. We set the initial function f to be uniform constant, and then gradually increase the contribution of instance weighting as learning steps. That is, we design the function f as follows:

$$f(CS_i) = \frac{c \cdot e^{-\lambda t} + CS_i}{c \cdot e^{-\lambda t} + 1} \tag{8}$$

where t is the number of current iteration step, c and λ are hyper-parameters.

Besides down-weighting noisy instances, we could change some answers in weak labels to higher-quality one, while unanswerable passages-question pairs are difficult to modify. To improve such labels, we compare confidence scores between the answer a^* predicted by QA model and a in the weak label. If the confidence increase is greater than threshold γ, we change the answer a to the model-generated answer a^* when each epoch ends. Finally, we train the QA and *Refinery* modules jointly, as Eq. (3) and (7), which are updated in turns[3], until convergence. Algorithm 1 describes this procedure in detail.

[3]When updating *Refinery*, we freeze parameters in QA model, because negative examples could be harmful in QA

5 Experiment

In this section, we address the following research questions:

- RQ1: Does our proposed work outperform existing approaches? Does it generalize for languages with diverse distance or topics?
- RQ2: Does our model generally work on more noisy environment?
- RQ3: Is our *Refinery* effective in distinguishing positive and negative set? How does QA/*Refinery* contribute to each other?

5.1 Dataset

For evaluation, we conduct experiments on three datasets for French and Korean RCQA. First is the public datasets, built on French (327 pairs) (Asai et al., 2018) and Korean (2K pairs) (Lee et al., 2018) Wikipedia, denoted as **Wiki_Fr** and **Wiki_Kr** respectively. Supposing zero-annotation at training, we use their training set (2K) in **Wiki_Kr** as our dev set, and evaluate our model on the test set. Third dataset is a history RC dataset (7K), which we collect on Korean-specific topics to show the robustness of our model with respect to domain gap: Specifically, dealing with Korean history documents, as denoted as **History_Kr**. For annotation, we follow the convention of SQuAD (Rajpurkar et al., 2016). Lastly, for generating synthetic labels, we crawled about 400 articles in each French and Korean, with general and (Korean) history topic from Wikipedia and Doopedia[4], respectively. Through automatic labeler (QG/AE) as mentioned in Section 3.2, we generated totally 100K QA pairs from passages in Wikipedia and Doopedia.

5.2 Experimental Setting

Our implementation settings for QA model follow original BiDAF (Seo et al., 2016) and BERT (Multilingual-Base version) (Devlin et al., 2018). For machine translation, we use pre-trained and open-sourced NMT models for French[5] and Korean[6]. As hyper-parameters, α, c, λ and γ, are set to 1/10, 10, 1/4000, and 0.5 respectively, optimized by dev set. For QG and AE implementations, we follow the setting of NQG model (Zhou et al., 2017). In BiDAF model, we used Natural Language Toolkit (NLTK) and KoNLPY[7] for French/Korean tokenizer, and FastText (Mikolov et al., 2017) for word embedding.

5.3 Evaluation of Full QA Model

We compare our QA model with the following baselines:

Base1&2: Asai et al. (2018) translate (p, q, a) in target language into English, then test on pre-trained English QA model. The answer from model is translated back to target language. We present their reported F1 scores for French with and without ELMo (Peters et al., 2018), and leave unreported results blank.

Base3: Lee et al. (2018) proposed semi-supervised method, to train the weak model on a small human-labeled set, and evaluate translated QA pairs by the output probabilities (in Eq. (2)) of the weak QA model. For training QA, the translated data over threshold is used together with a human-labeled data. We present their reported F1 scores and leave unreported results blank.

Ours: Our proposed models are trained on BiDAF and BERT, and with/without Refinery (for ablation purposes described below).

[5] https://github.com/pytorch/fairseq/blob/master/examples/translation
[6] https://developers.naver.com/products/nmt/
[7] https://konlpy-ko.readthedocs.io/

Table 1: The results of QA models. Compared to version w/o Refinery, our models outperform with statistical significance (* indicates $p < 0.05$).

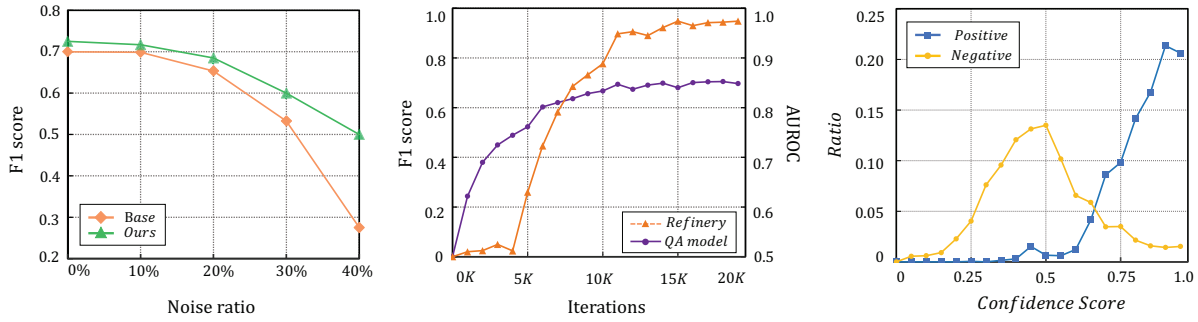
	Method	QA model	F1 score		
			Wiki_Fr	Wiki_Kr	History_Kr
Base1	Test on source (Asai et al., 2018)	BiDAF+ELMo	61.9	-	-
Base2	Test on source (Asai et al., 2018)	BiDAF	57.6	-	-
Base3	Semi-supervision (Lee et al., 2018)	BiDAF	-	71.5	-
Ours	No weighting (w/o *Refinery*)	BiDAF	60.8	70.1	61.5
	Full model with *Refinery*	BiDAF	63.5*	73.4*	64.1*
	No weighting (w/o *Refinery*)	BERT	74.3	77.1	67.7
	Full model with *Refinery*	BERT	**76.6***	**79.7***	**70.4***

Results on QA datasets Table 1 shows the comparison on En-Kr (distant) and En-Fr (close) language pairs. Similarly, we contrast in diverse topic-similarity scenarios: History (distant) and Wiki (close). When compared with Base1&2 (Test on source), our model outperforms the two models, even when Base1 is boosted by ELMo (Peters et al., 2018). When compared with Base3, semi-supervision (Lee et al., 2018) using 2K human labels outperforms our BiDAF model (without *Refinery*), on Wiki_Kr set. However, ours with *Refinery* outperforms the Base3 model, which means that large and noisy labels refined by our method have comparable quality to small but strong labels.

To show that the effectiveness of our approach is orthogonal to QA model, we construct two QA models, BiDAF and BERT, as in Table 1. When compared with *No weighting*, our full model on BiDAF improved 2.7%, 3.3% and 2.6% of F1 scores, and that on BERT improved 2.3%, 2.6% and 2.7% of F1 score, on Wiki_Fr, Wiki_Kr and History_Kr, respectively. BERT model with our *Refinery* performs the best among all models, by adding the power of pre-trained representations.

Ablation Study As shown in Table 2, we conduct an ablation study on both BiDAF and BERT models, by examining the effects, from removing each component. In (A), we replace our confidence score (CS) with the probabilities in Eq. (2), which is similar to the use of confidence in (Lee et al., 2018). We normalize the probabilities in mini-batch by softmax function, then apply to *down-weighting*. On the QA model using the replaced confidence, the performance decreased significantly, suggesting the importance of CS. In (B), we remove a dynamic margin in Eq. (3), by setting the margin as a constant value instead (*i.e.*, $\delta = 1$). Using static margin lowered the performance of both QA models, suggesting that QA feedback (dynamic margin) is effective for refining noises. In (C), we remove *answer modification* in Section 4.2, while preserving *down-weighting* module. Compared with our full model, adding *answer modification* improved the performance on both QA models. We can also observe the effect of *down-weighting*, as the model without *answer modification* still outperforms that with *No weighting* in Table 1.

Table 2: The ablation study on three datasets. The number inside the parenthesis indicates the decrease from our full model.



(a) On BiDAF

		F1 score		
		Wiki_Fr	Wiki_Kr	History_Kr
	Our full model	63.5	73.4	64.1
(A)	Replace CS with Prob	61.1 (-2.4)	70.3 (-3.1)	61.8 (-2.3)
(B)	Remove dynamic margin	62.0 (-1.5)	72.3 (-1.1)	62.4 (-1.7)
(C)	Remove answer modification	62.3 (-1.2)	71.9 (-1.5)	62.8 (-1.3)

(b) On BERT

		F1 score		
		Wiki_Fr	Wiki_Kr	History_Kr
	Our full model	76.6	79.7	70.4
(A)	Replace CS with Prob	74.3 (-2.3)	77.3 (-2.4)	67.8 (-2.6)
(B)	Remove dynamic margin	75.1 (-1.5)	77.8 (-1.9)	68.4 (-2.0)
(C)	Remove answer modification	75.2 (-1.4)	78.6 (-1.1)	69.2 (-1.2)

For RQ2, we design scenarios with noisier training data to demonstrate the robustness. When training QA, we replace positive examples with negative examples, perturbing an input to fool a machine model. Figure 3(a) shows the robustness of our BiDAF model over varying noise ratios. As

(a) QA performance as noise ratio (b) Iterative QA and *Refinery* (c) Distribution of confidence score

Figure 3: Experimental results of our model on dev set. (a) Comparison of robustness between Base (w/o *Refinery*) and Ours in noisy environments. (b) The performances of QA (F1 score) and *Refinery* (AUROC) over iterations. (c) Distribution of confidence scores for positive and negative examples.

Table 3: The results of confidence score evaluation

	TNR (95% TPR)	AUROC	AUPR
	(Wiki_Kr / History_Kr)		
(A) Base1	47.4 / 39.0	82.9 / 85.8	78.2 / 85.4
(B) Base2	44.9 / 69.5	71.2 / 83.5	63.3 / 75.7
Ours	**88.4 / 90.9**	**97.7 / 98.5**	**98.2 / 98.8**

noises increase, Base BiDAF model sharply drops its F1 score, while that of our full model degrades gracefully.

5.4 Evaluation of Confidence Score

This section addresses RQ3, aiming at directly observing whether our confidence score effectively distinguishes the positive from negative. As baselines, we conduct (A) and (B) in the above ablation study. (A) Base1 uses the probability in Eq. (2) as confidence score. (B) Base2 is *Refinery* without a dynamic margin ($\delta = 1$). In this experiment, we use BiDAF model on Wiki_Kr and History_Kr, and generate negative examples from positive test set as 1:1 ratio.

As a quantitative evaluation, we measure three metrics of detecting negative examples, comparing confidence of positive and negative one.

- True Negative Rate (TNR) at 95% True Positive Rate (TPR).
- Area under the Receiver Operating Characteristic Curve (AUROC).
- Area under the Precision – Recall Curve (AUPR).

As shown in Table 3, our *Refinery* outperforms other baselines with statistical significance of $p <$ 0.01 and by a large margin on all measures, showing *Refinery* is effective in distinguishing positive-negative pairs. We also compare our work with and without a dynamic margin from QA feedback, to show that such strategy improves the performance.

To show performance of QA/*Refinery* over iterations, we check their performance as iterations continue on dev set, in Figure 3(b). In early iterations, *Refinery* cannot contribute to QA, because F1 score of all instance is zero. After the training stabilizes, the performance of *Refinery* increases rapidly. Figure 3(c) contrasts the distribution of confidence from positive and negative samples: Unlike negative examples of varying confidence, positive examples are clearly skewed to high-ends.

Table 4 compares the examples in Baseline and our model, where the first two are high-quality data and the third and forth are not. In the first example, both models show high score, while Baseline underestimates the quality and *Refinery* works correctly for the second example. The third example is unanswerable on (p, q) pair, since the words about the subject disappeared during translation, which is assigned to lower scores by two models. The last example has also translation error where the given question was mistranslated from 'when' to 'how'. In this case, our *Refinery* network successfully assigned low confidence score, as the question is no longer answerable after a bad translation, but Baseline gives a high confidence.

ply English-based models, then translate the answer back (Asai et al., 2018). Not only for question answering, such method has been successful in sentiment classication (Zhou et al., 2016), relation extraction (Faruqui and Kumar, 2015), and causal commonsense (Yeo et al., 2018). However, these approaches are dependent on quality of translation.

RCQA for Resource-Poor Language To overcome the lack of RCQA resources on other language, in (Lee et al., 2018), they proposed a semi-supervised strategy to remove the noise instances. They hand-annotated a small seed set of QA pairs to train a weak QA. Then, the weak QA indirectly judges the quality of machine-translated SQuAD pairs, by considering the output probability as confidence score. As confidence score, they selectively remove translated pairs below a fixed threshold. Meanwhile, we eliminate the needs for human annotation, by leveraging positive and negative sets from translated and generated data.

Combining models of QG and QA: Several works (Wang et al., 2017; Tang et al., 2017; Tang et al.) propose a framework jointly optimizing QG and QA model as dual. These approaches share commonality with our approach for generating training data with another model, but with the following crucial difference: Existing work can use a reliable training set annotated by human, which can be strong hint to decide the quality of generated data. For example, in (Tang et al.), QG generates questions on the given answer sentence, then the generated question is compared with the original question in training set. Meanwhile, we do not require human annotation, and rather leverage automatically generated from NMT and QG models, judiciously guided by our Refinery network.

7 Conclusion

This paper studies a zero-resource training data generation for supporting RCQA to a new target language. Inspired by limited resources, we generate RCQA data, by using existing NMT and QG techniques. To explore the noisy generated data, we proposed an integrated QA model with *Refinery* to control the generated data as confidence score. Our results showed that our strategies using *Refinery* and generated data enhance the performance of existing QA model, and *Refinery* has effectiveness to distinguish positive-negative pairs.

Abstract

Many question answering (QA) tasks only provide weak supervision for how the answer should be computed. For example, TRIVIAQA answers are entities that can be mentioned multiple times in supporting documents, while DROP answers can be computed by deriving many different equations from numbers in the reference text. In this paper, we show it is possible to convert such tasks into discrete latent variable learning problems with a precomputed, task-specific set of possible *solutions* (e.g. different mentions or equations) that contains one correct option. We then develop a hard EM learning scheme that computes gradients relative to the most likely solution at each update. Despite its simplicity, we show that this approach significantly outperforms previous methods on six QA tasks, including absolute gains of 2–10%, and achieves the state-of-the-art on five of them. Using hard updates instead of maximizing marginal likelihood is key to these results as it encourages the model to find the one correct answer, which we show through detailed qualitative analysis.[1]

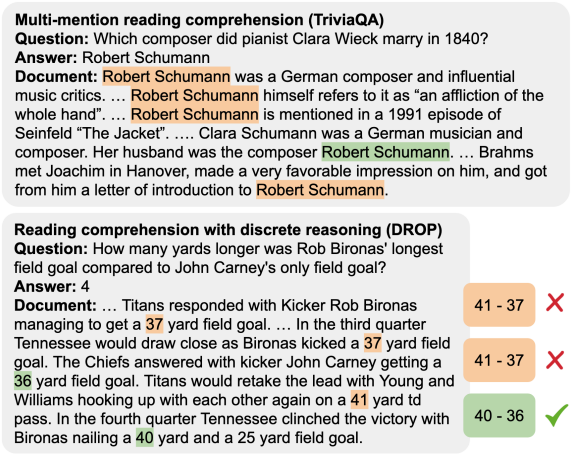

Figure 1: Examples from two different question answering tasks. **(Top) Multi-mention reading comprehension.** The answer text is mentioned five times in the given document, however, only the fourth span actually answers the question. **(Bottom) Reading comprehension with discrete reasoning.** There are many potential equations which execute the answer ('4'), but only one of them is the correct equation ('40-36') and the others are false positives.

1 Introduction

A natural setting in many question answering (QA) tasks is to provide weak supervision to determine how the question should be answered given the evidence text. For example, as seen in Figure 1, TRIVIAQA answers are entities that can be mentioned multiple times in supporting documents, while DROP answers can be computed by deriving many different equations from numbers in the reference text. Such weak supervision is attractive because it is relatively easy to gather, allowing for large datasets, but complicates learning because there are many different spurious ways to derive the correct answer. It is natural to model such ambiguities with a latent variable during learning, but most prior work on reading comprehension has rather focused on the model architecture and used heuristics to map the weak signal to full supervision (e.g. by selecting the first answer span in TRIVIAQA (Joshi et al., 2017; Tay et al., 2018; Talmor and Berant, 2019)). Some models are trained with maximum marginal likelihood (MML) (Kadlec et al., 2016; Swayamdipta et al., 2018; Clark and Gardner, 2018; Lee et al., 2019), but it is unclear if it gives a meaningful improvement over the heuristics.

In this paper, we show it is possible to formulate a wide range of weakly supervised QA tasks as discrete latent-variable learning problems. First, we define a *solution* to be a particular derivation of a model to predict the answer (e.g. a span in

Table 1: Six QA datasets in three different categories used in this paper (detailed in Section 5) along with the size of each dataset. An average and median of the size of precomputed solution sets (denoted by Z) are also reported. Details on how to obtain Z are given in Section 4.

the document or an equation to compute the answer). We demonstrate that for many recently introduced tasks, which we group into three categories as given in Table 1, it is relatively easy to precompute a discrete, task-specific set of possible solutions that contains the correct solution along with a modest number of spurious options. The learning challenge is then to determine which solution in the set is the correct one, while estimating a complete QA model.

We model the set of possible solutions as a discrete latent variable, and develop a learning strategy that uses hard-EM-style parameter updates. This algorithm repeatedly (i) predicts the most likely solution according to the current model from the precomputed set, and (ii) updates the model parameters to further encourage its own prediction. Intuitively, these hard updates more strongly enforce our prior beliefs that there is a single correct solution. This method can be applied to any problem that fits our weak supervision assumptions and can be used with any model architecture.

We experiment on six different datasets (Table 1) using strong task-specific model architectures (Devlin et al., 2019; Dua et al., 2019; Hwang et al., 2019). Our learning approach significantly outperforms previous methods which use heuristic supervision and MML updates, including absolute gains of 2–10%, and achives the state-of-the-art on five datasets. It outperforms recent state-of-the-art reward-based semantic parsing algorithms (Liang et al., 2018; Agarwal et al., 2019) by 13% absolute percentage on WIKISQL, strongly suggesting that having a small precomputed set of possible solutions is a key ingredient. Finally, we present a detailed analysis showing that, in practice, the introduction of hard updates encourages models to assign much higher probability to the correct solution.

2 Related Work

Reading Comprehension. Large-scale reading comprehension (RC) tasks that provide full supervision for answer spans (Rajpurkar et al., 2016) have seen significant progress recently (Seo et al., 2017; Xiong et al., 2018; Yu et al., 2018a; Devlin et al., 2019). More recently, the community has moved towards more challenging tasks such as distantly supervised RC (Joshi et al., 2017), RC with free-form human generated answers (Kočiskỳ et al., 2018) and RC requiring discrete or multi-hop reasoning (Dua et al., 2019; Yang et al., 2018). These tasks introduce new learning challenges since the gold solution that is required to answer the question (e.g. a span or an equation) is not given.

Nevertheless, not much work has been done for this particular learning challenge. Most work on RC focuses on the model architecture and simply chooses the first span or a random span from the document (Joshi et al., 2017; Tay et al., 2018; Talmor and Berant, 2019), rather than modeling this uncertainty as a latent choice. Others maximize the sum of the likelihood of multiple spans (Kadlec et al., 2016; Swayamdipta et al., 2018; Clark and Gardner, 2018; Lee et al., 2019), but it is unclear if it gives a meaningful improvement. In this paper, we highlight the learning challenge and show that our learning method, independent of the model architecture, can give a significant gain. Specifically, we assume that one of

mentions are related to the question and others are false positives because (i) this happens for most cases, as the first example in Table 2, and (ii) even in the case where multiple mentions contribute to the answer, there is often a single span which fits the question the best.

Semantic Parsing. Latent-variable learning has been extensively studied in the literature of semantic parsing (Zettlemoyer and Collins, 2005; Clarke et al., 2010; Liang et al., 2013; Berant et al., 2013; Artzi and Zettlemoyer, 2013). For example, a question and an answer pair (x, y) is given but the logical form that is used to compute the answer is not. Two common learning paradigms are maximum marginal likelihood (MML) and reward-based methods. In MML, the objective maximizes $\sum_{z \in \hat{Z}} \mathbb{P}(z|x)$, where $\hat{Z}$ is an approximation of a set of logical forms executing y (Liang et al., 2013; Berant et al., 2013; Krishnamurthy et al., 2017). In reward-based methods, a reward function is defined as a prior, and the model parameters are updated with respect to it (Iyyer et al., 2017; Liang et al., 2017, 2018). Since it is computationally expensive to obtain a precomputed set in semantic parsing, these methods typically recompute the set of logical forms with respect to the beam at every parameter update. In contrast, our learning method targets tasks that a set of solutions can be precomputed, which include many recent QA tasks such as reading comprehension, open-domain QA and a recent SQL-based semantic parsing task (Zhong et al., 2017).

3 Method

In this section, we first formally define our general setup, which we will instantiate for specific tasks in Section 4 and then we describe our learning approach.

3.1 Setup

Let x be the input of a QA system (e.g. a question and a document) and y be the answer text (e.g. 'Robert Schumann' or '4'). We define a *solution* as a particular derivation that a model is supposed to produce for the answer prediction (e.g. a span in the document or an equation to compute the answer, see Table 2). Let f denote a task-specific, deterministic function which maps a solution to the textual form of the answer (e.g. by simply returning the string associated with a particular selected mention or solving an equation to get the final number, see Table 2). Our goal is to learn a model (with parameters θ) which takes an input x and outputs a solution z such that $f(z) = y$.

In a fully supervised scenario, a true solution $\bar{z}$ is given, and θ is estimated based on a collection of $(x, \bar{z})$ pairs. In this work, we focus on a weakly supervised scenario in which $\bar{z}$ is not given. For this setup, we define Z_{tot} as a finite set of all the possible solutions. In the case that the search space is very large or infinite, we can usually approximate Z_{tot} with a high coverage in practice. Then, we obtain $Z = \{z \in Z_{\text{tot}} : f(z) = y\}$ by enumerating all $z \in Z_{\text{tot}}$. This results a set of all the possible solutions that lead to the correct answer. We assume it contains one solution that we want to learn to produce, and potentially many other spurious ones. In practice, Z is defined in a task-specific manner, as we will see in Section 4.

At inference time, the model produces a solution $\tilde{z} \in Z_{\text{tot}}$ from an input x with respect to θ and predicts the final answer as $f(\tilde{z})$. Note that we cannot compute Z at inference time because the groundtruth y is not given.[2]

3.2 Learning Method

In a fully-supervised setting where $\bar{z}$ is given, we can learn θ by optimizing the negative log likelihood of $\bar{z}$ given the input x with respect to θ.

$$J_{\text{Sup}}(\theta|x, \bar{z}) = -\log \mathbb{P}(\bar{z}|x; \theta)$$

In our setup, the model has access to x and $Z = \{z_1, z_2, \ldots, z_n\}$. In this scenario, the selection of the best solution in Z can be modeled as a latent variable. We can compute the maximum marginal likelihood (MML) estimate, which marginalizes the likelihood of each $z_i \in Z$ given the input x with respect to θ. Formally,

$$\begin{aligned}\mathbb{P}(y|x; \theta) &= \sum_{z_i \in Z_{\text{tot}}} \mathbb{P}(y|z_i)\mathbb{P}(z_i|x; \theta) \\ &= \sum_{z_i \in Z} \mathbb{P}(z_i|x; \theta)\end{aligned}$$

is used to compute the objective as follows:

$$J_{\text{MML}}(\theta|x, Z) = -\log \sum_{z_i \in Z} \mathbb{P}(z_i|x; \theta)$$

However, there are two major problems in the MML objective in our settings. First, MML can be

[2] This is a main difference from multi-instance learning (MIL) (Zhou et al., 2009), since a bag of input instances is given at inference time in MIL.

maximized by assigning high probabilities to any subset of $z_i \in Z$; whereas in our problems, instances in Z other than one correct z are spurious solutions which the model should ideally assign very low probability. Second, in MML we optimize the sum over probabilities of Z during training but typically predict the maximum probability solution during inference, creating a discrepancy between training and testing.

We introduce a learning strategy with a hard-EM approach. First, the model computes the likelihood of each z_i given the input x with respect to θ, $\mathbb{P}(z_i|x;\theta)$, and picks one of Z with the largest likelihood:

$$\tilde{z} = \text{argmax}_{z_i \in Z} \mathbb{P}(z_i|x;\theta)$$

Then, the model optimizes on a standard negative log likelihood objective, assuming $\tilde{z}$ is a true solution. The objective can be re-written as follows:

$$\begin{aligned} J_{\text{Hard}}(\theta|x,Z) &= -\log \mathbb{P}(\tilde{z}|x;\theta) \\ &= -\log \max_{z_i \in Z} \mathbb{P}(z_i|x;\theta) \\ &= -\max_{z_i \in Z} \log \mathbb{P}(z_i|x;\theta) \\ &= \min_{z_i \in Z} J_{\text{Sup}}(\theta|x,z_i) \end{aligned}$$

This loss can be seen as a variant of MML, where the sum is replaced with a max.

4 Task Setup

We apply our approach to three different types of QA tasks: multi-mention reading comprehension, RC with discrete reasoning and a semantic parsing task. In this section, we describe each task in detail: how we define a solution z and pre-compute a set Z based on input x and answer y. The statistics of $|Z|$ and examples on each task are shown in Table 1 and Table 2 respectively.

4.1 Multi-Mention Reading Comprehension

Multi-mention reading comprehension naturally occurs in several QA tasks such as (i) distantly-supervised reading comprehension where a question and answer are collected first before the evidence document is gathered (e.g. TRIVIAQA), (ii) abstractive reading comprehension which requires a free-form text to answer the question (e.g. NARRATIVEQA), and (iii) open-domain QA where only question-answer pairs are provided.

Given a question $Q = [q_1, \ldots, q_l]$ and a document $D = [d_1, \ldots, d_L]$, where q_i and d_j denote the tokens in the question and document, the output y is an answer text, which is usually mentioned multiple times in the document.

Previous work has dealt with this setting by detecting spans in the document through text matching (Joshi et al., 2017; Clark and Gardner, 2018). Following previous approaches, we define a solution z as a span in the document. We obtain a set of possible solutions $Z = \{z_1, \ldots, z_n\}$ by finding exact match or similar mentions of y, where $z_i = (s_i, e_i)$ is a span of text with start and end token indices s_i and e_i. Specifically,

$$\begin{aligned} g_{\text{max}} &= \max_{1 \le s_i \le e_i \le L} g([d_{s_i}, \ldots, d_{e_i}], y) \\ Z &= \{z_i = (s_i, e_i) \text{ s.t. } g(s_i, e_i) = g_{\text{max}}\}, \end{aligned}$$

where g is a string matching function. If the answer is guaranteed to be a span in the document D, g is a binary function which returns 1 if two strings are the same, and 0 otherwise. If the answer is free-form text, we choose g as the ROUGE-L metric (Lin, 2004).

This complicates the learning because the given document contains many spans matching to the text, while most of them are not related to answering the question. As an example shown in Table 2, only the fourth span out of six is relevant to the question.

4.2 Reading Comprehension with Discrete Reasoning

Some reading comprehension tasks require reasoning in several discrete steps by finding clues from the document and aggregating them. One such example is mathematical reasoning, where the model must pick numbers from a document and compute an answer through arithmetic operations (Dua et al., 2019).

In this task, the input is also a question Q and a document D, and the output y is given as a numeric value. We define a solution z to be an executable arithmetic equation. Since there is an infinite set of potential equations, we approximate Z_{tot} as a finite set of arithmetic equations with two numeric values and one operation, following Dua et al. (2019).[3] Specifically,

$$\begin{aligned} Z_{\text{tot}} = \big\{ & z_i = (o_1, n_1, o_2, n_2) \text{ s.t.} \\ & o_1, o_2 \in \{+, -, \%\}, \\ & n_1, n_2 \in N_D \cup N_Q \cup S \big\}, \end{aligned}$$

[3]This approximation covers 93% of the examples in the development set.

1. Multi-Mention Reading Comprehension (TRIVIAQA, NARRATIVEQA, TRIVIAQA-OPEN & NATURALQUESTIONS-OPEN)

Question: Which composer did pianist Clara Wieck marry in 1840?
Document: Robert Schumann was a German composer and influential music critic. He is widely regarded as one of the greatest composers of the Romantic era. (...) Robert Schumann himself refers to it as "an affliction of the whole hand". (...) Robert Schumann is mentioned in a 1991 episode of Seinfeld "The Jacket". (...) Clara Schumann was a German musician and composer, considered one of the most distinguished pianists of the Romantic era. Her husband was the composer Robert Schumann . <Childhood> (...) At the age of eight, the young Clara Wieck performed at the Leipzig home of Dr. Ernst Carus. There she met another gifted young pianist who had been invited to the musical evening, named Robert Schumann , who was nine years older. Schumann admired Clara' s playing so much that he asked permission from his mother to discontinue his law studies. (...) In the spring of 1853, the then unknown 20-year-old Brahms met Joachim in Hanover, made a very favorable impression on him, and got from him a letter of introduction to Robert Schumann .
Answer (y): Robert Schumann
f: Text match
Z_{tot}: All spans in the document
Z: Spans which match 'Robert schumann' (red text)

2. Reading Comprehension with Discrete Reasoning (DROP_{num})

Question: How many yards longer was Rob Bironas' longest field goal compared to John Carney's only field goal?
Document: (...) The Chiefs tied the game with QB Brodie Croyle completing a `10` yard td pass to WR Samie Parker. Afterwards the Titans responded with Kicker Rob Bironas managing to get a `37` yard field goal. Kansas city would take the lead prior to halftime with croyle completing a `9` yard td pass to FB Kris Wilson. In the third quarter Tennessee would draw close as Bironas kicked a `37` yard field goal. The Chiefs answered with kicker John Carney getting a `36` yard field goal. Afterwards the Titans would retake the lead with Young and Williams hooking up with each other again on a `41` yard td pass. (...) Tennessee clinched the victory with Bironas nailing a `40` yard and a `25` yard field goal. With the win the Titans kept their playoff hopes alive at `8 6` .
Answer (y): 4
f: Equation executor
Z_{tot}: Equations with two numeric values and one arithmetic operation
Z: { 41-37, 40-36, 10-6, ... }

3. SQL Generation (WIKISQL)

Question: What player played guard for Toronto in 1996-1997?
Table Header: `player, year, position, ...`
Answer (y): John Long
f: SQL executor
Z_{tot}: Non-nested SQL queries with up to 3 conditions
Z:
```
Select player where position=guard and year in toronto=1996-97
Select max(player) where position=guard and year in toronto=1996-97
Select min(player) where position=guard
Select min(player) where year in toronto=1996-97
Select min(player) where position=guard and year in toronto=1996-97
```

Table 2: Examples of the input, answer text (y), f, Z_{tot} and Z. First, in multi-mention reading comprehension, the answer text 'Robert Schumann' is mentioned six times but only the fourth span is related to the question. Second, in reading comprehension with discrete reasoning, many equations yield to the answer 4, but only '40-37' answers the question. Lastly, in SQL query generation, five SQL queries lead to the answer but only the first one is the correct query. See Section 4 for more details.

where N_D and N_Q are all numeric values appearing in D and Q, respectively, and S are a set of predefined special numbers. Then

$$Z = \{z_i \in Z_{\text{tot}} \text{ s.t. } f(z_i) = y\}$$

where f is an execution function of equations.

Figure 1 shows an example Z given a question and a document. We can see that one equation is correct, while the others are false positives which coincidentally lead to the correct answer.

4.3 SQL Query Generation

To evaluate if our training strategy generalizes to other weak supervision problems, we also study a semantic parsing task where a question and an answer are given but the logical form to execute the answer is not. In particular, we consider a task of answering questions about a given table by generating SQL queries.

The input is a question $Q = [q_1, \ldots, q_l]$ and a table header $H = [h_1, \ldots, h_{n_L}]$, where q_i is a token, h_i is a multi-token title of each column, and n_L is the number of headers. The supervision is given as the SQL query result y, which is always a text string.

We define a solution to be an SQL query. Since the set of potential queries is infinite, we approximate Z_{tot} as a set of non-nested SQL queries with at most three conditions.[4] Specifically, given A as a set of aggregating operators $\{\text{sum}, \text{mean}, \text{max}, \text{min}, \text{count}\}$ and C as a set of possible conditions $\{(h, o, t) \text{ s.t. } h \in [1, n_L], o \in \{=, <, >\}, t \in \text{spans in } Q\}$, we define Z_{tot}:

$$\begin{aligned} Z_{\text{tot}} = \{z_i &= (z_i^{\text{sel}}, z_i^{\text{agg}}, \{z_{i,j}^{\text{cond}}\}_{j=1}^{3}\} \text{ s.t.} \\ z_i^{\text{sel}} &\in [1, n_L] \\ z_i^{\text{agg}} &\in \{\text{none}\} \cup A \\ z_{i,j}^{\text{cond}} &\in \{\text{none}\} \cup C \text{ for } j \in [1, 3]\}, \end{aligned}$$

then,

$$Z = \{z_i \in Z_{\text{tot}} \text{ s.t. } f(z_i) = y\},$$

[4] This approximation covers 99% of the examples in the development set.

where f is an SQL executor. The third example in Table 2 shows Z may contain many spurious SQL querie, e.g. the third query in Z coincidentally executes the answer because 'John Long' is ranked first among all the guards in alphabetical order.

5 Experiments

We experiment on a range of question answering tasks with varied model architectures to demonstrate the effectiveness of our approach. Built on top of strong base models, our learning method is able to achieve state-of-the-art on NARRATIVEQA, TRIVIAQA-OPEN, NATURALQUESTIONS-OPEN, DROP_{num} and WIKISQL.

5.1 Multi-mention Reading Comprehension

We experiment on two reading comprehension datasets and two open-domain QA datasets. For reading comprehension, we evaluate on TRIVIAQA (Wikipedia) (Joshi et al., 2017) and NARRATIVEQA (summary) (Kočiskỳ et al., 2018).

For open-domain QA, we follow the settings in Lee et al. (2019) and use the QA pairs from TRIVIAQA-unfiltered (Joshi et al., 2017) and NATURAL QUESTIONS (Kwiatkowski et al., 2019) with short answers and discard the given evidence documents. We refer to these two datasets as TRIVIAQA-OPEN and NATURALQUESTIONS-OPEN.[5]

We experiment with three learning methods as follows.

- First Only: $J(\theta) = -\log\mathbb{P}(z_1|x;\theta)$, where z_1 appears first in the given document among all $z_i \in Z$.
- MML: $J(\theta) = -\log\Sigma_{i=1}^{n}\mathbb{P}(z_i|x;\theta)$.
- Ours: $J(\theta) = -\log\max_{1\le i\le n}\mathbb{P}(z_i|x;\theta)$.

$\mathbb{P}(z_i|Q,D)$ can be obtained by any model which outputs the start and end positions of the input document. In this work, we use a modified version of BERT (Devlin et al., 2019) for multi-paragraph reading comprehension (Min et al., 2019).

Training details. We use uncased version of $\text{BERT}_{\text{base}}$. For all datasets, we split documents into a set of segments up to 300 tokens because BERT limits the size of the input. We use batch size of 20 for two reading comprehension tasks and 192 for two open-domain QA tasks. Following Clark and Gardner (2018), we filter a subset of segments in TRIVIAQA through TF-IDF similarity between a segment and a question to maintain a reasonable length. For open-domain QA tasks, we retrieve 50 Wikipedia articles through TF-IDF (Chen et al., 2017) and further run BM25 (Robertson et al., 2009) to retrieve 20 (for train) or 80 (for development and test) paragraphs. We try 10, 20, 40 and 80 paragraphs on the development set to choose the number of paragraphs to use on the test set.

To avoid local optima, we perform annealing: at training step t, the model optimizes on MML objective with a probability of $\min(t/\tau, 1)$ and otherwise use our objective, where τ is a hyperparameter. We observe that the performance is improved by annealing while not being overly sensitive to the hyperparameter τ. We include full hyperparameters and detailed ablations in Appendix B.

Results. Table 3 compares the results of baselines, our method and the state-of-the-art on four datasets.[6] First of all, we observe that First-Only is a strong baseline across all the datasets. We hypothesize that this is due to the bias in the dataset that answers are likely to appear earlier in the paragraph. Second, while MML achieves comparable result to the First-Only baseline, our learning method outperforms others by 2+ F1/ROUGE-L/EM consistently on all datasets. Lastly, our method achieves the new state-of-the-art on NARRATIVEQA, TRIVIAQA-OPEN and NATURALQUESTIONS-OPEN, and is comparable to the state-of-the-art on TRIVIAQA, despite our aggressive truncation of documents.

5.2 Reading Comprehension with Discrete Reasoning

We experiment on a subset of DROP (Dua et al., 2019) with numeric answers (67% of the entire dataset) focusing on mathematical reasoning. We refer to this subset as DROP_{num}. The current state-of-the-art model is an augmented version of QANET (Yu et al., 2018a) which selects two numeric values from the document or the question and performs addition or subtraction to get the answer. The equation to derive the answer is not

[5] Datasets and their split can be downloaded from https://bit.ly/2HK1Fqn.

[6] For NARRATIVEQA, we compare with models trained on NARRATIVEQA only. For open-domain QA, we only compare with models using pipeline approach.

	TriviaQA (F1)		NarrativeQA (ROUGE-L)		TriviaQA -open (EM)		NaturalQ -open (EM)		DROP_{num} w/ BERT (EM)	DROP_{num} w/ QANet (EM)
	dev	test	dev	test	dev	test	dev	test	dev	dev
First Only	64.4	64.9	55.3	57.4	48.6	48.1	23.6	23.6	42.9	36.1
MML	64.8	65.5	55.8	56.1	47.0	47.4	26.6	25.8	39.7	43.8
Ours	66.9	67.1	**58.1**	**58.8**	**50.7**	**50.9**	**28.8**	**28.1**	**52.8**	**45.0**
SOTA	-	**71.4**	-	54.7	47.2	47.1	24.8	26.5	43.8	

Table 3: **Results on multi-mention reading comprehension & discrete reasoning tasks.** We report performance on five datasets with different base models. Note that we are not able to obtain the test result on the subset DROP_{num}. Previous state-of-the-art are from Wang et al. (2018), Nishida et al. (2019), Lee et al. (2019), Lee et al. (2019) and Dua et al. (2019), respectively. Our training method consistently outperforms the First-Only and MML by a large margin in all the scenarios.

Model	Accuracy dev	Accuracy test
Weakly-supervised setting		
REINFORCE (Williams, 1992)	< 10	
Iterative ML (Liang et al., 2017)	70.1	
Hard EM (Liang et al., 2018)	70.2	
Beam-based MML (Liang et al., 2018)	70.7	
MAPO (Liang et al., 2018)	71.8	72.4
MAPOX (Agarwal et al., 2019)	74.5	74.2
MAPOX+MeRL (Agarwal et al., 2019)	74.9	74.8
MML	70.6	70.5
Ours	**84.4**	**83.9**
Fully-supervised setting		
SQLNet (Xu et al., 2018)	69.8	68.0
TypeSQL (Yu et al., 2018b)	74.5	73.5
Coarse2Fine (Dong and Lapata, 2018)	79.0	78.5
SQLova (Hwang et al., 2019)	87.2	86.2
X-SQL (He et al., 2019)	**89.5**	**88.7**

Table 4: **Results on WikiSQL.** We compare accuracy with weakly-supervised or fully-supervised settings. Our method outperforms previous weakly-supervised methods and most of published fully-supervised methods.

given and Dua et al. (2019) adopted the MML objective.

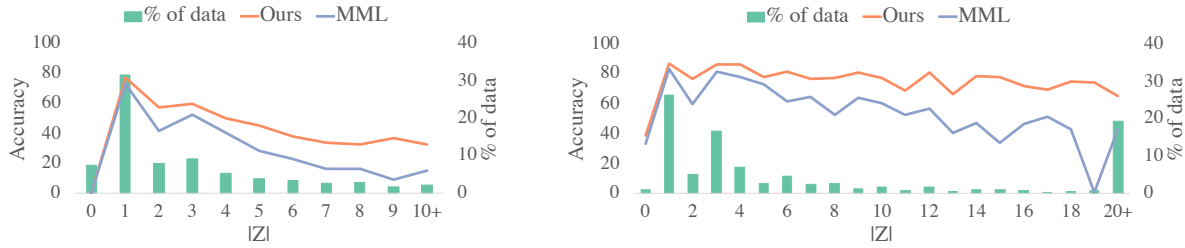
$\mathbb{P}(z_i|Q, D)$ can take as any model which generates equations based on the question and document. Inspired by Dua et al. (2019), we take a sequence tagging approach on top of two competitive models: (i) augmented QANet, the same model as Dua et al. (2019) but only supporting addition, subtraction and counting, and (ii) augmented BERT, which supports addition, subtraction and percentiles.[7]

Training details. We truncate the document to be up to 400 words. We use the batch size of 14 and 10 for QANet and BERT, respectively.

Results. Table 3 shows the results on DROP_{num}. Our training strategy outperforms the First-Only baseline and MML by a large margin, consistently across two base models. In particular, with BERT, we achieve an absolute gain of 10%.

5.3 SQL Query Generation

Finally, we experiment on the weakly-supervised setting of WikiSQL (Zhong et al., 2017), in which only the question & answer pair is used and the SQL query (z) is treated as a latent variable.



$\mathbb{P}(z_i|Q, H)$ can be computed by any query generation or semantic parsing models. We choose SQLova (Hwang et al., 2019), a competitive model on WikiSQL (designed for fully supervised setting), as our base model. We modify the model to incorporate either the MML objective or our hard-EM learning approach for the weakly-supervised setting.

We compare with both traditional and recently-developed reward-based algorithms for weak supervision, including beam-based MML (MML which keeps a beam during training), conventional hard EM[8], REINFORCE (Williams, 1992), iterative ML (Liang et al., 2017; Abolafia et al., 2018) and a family of MAPO (Memory-augmented policy optimization) (Liang et al., 2018; Agarwal et al., 2019). For a fair comparison, we only consider single models without execution-guided decoding.

Training details. We adopt the same set of hyperparameters as in Hwang et al. (2019), except that we change the batch size to 10 and truncate the input to be up to 180 words for memory efficiency.

[7] As we use a different set of operations for the two models, they are not directly comparable. Details of the model architecture are shown in Appendix A.

[8] This method differs from ours in that it does not have a precomputed set, and uses a beam of candidate predictions to execute for each update.

(a) DROP_{num} (b) WikiSQL

Figure 2: **Varying the size of solution set ($|Z|$) at test time.** We compare the model trained on MML objective (blue) and our training strategy (orange). Our approach consistently outperforms MML on DROP_{num} and WIKISQL, especially when $|Z|$ is large.

Group	Avg $\lvert Z\rvert$	Median $\lvert Z\rvert$	# train
3	3.0	3	10k
10	10.2	9	10k
30	30.0	22	10k
100	100.6	42	10k
300	300.0	66	10k

Figure 3: **Varying the size of solution set ($|Z|$) at training.** (Left) Subsets of the train set on WIKISQL varying in the size of solution set ($|Z|$). All subsets contain 10k training examples (total in the original train set is 55k). All subsets are evaluated on the same, original development set for a fair comparison. (Right) Performance across subsets of the training set with varying $|Z|$. Our method achieves substantial gains over MML.

Results. Table 4 shows that our training method significantly outperforms all the weakly-supervised learning algorithms, including 10% gain over the previous state of the art. These results indicate that precomputing a solution set and training a model through hard updates play a significant role to the performance. Given that our method does not require SQL executions at training time (unlike MAPO), it provides a simpler, more effective and time-efficient strategy. Comparing to previous models with full supervision, our results are still on par and outperform most of the published results.

6 Analysis

In this section, we will conduct thorough analyses and ablation studies, to better understand how our model learns to find a solution from a precomputed set of possible solutions. We also provide more examples and analyses in Appendix C.

Varying the size of solution set at inference time. Figure 2 shows a breakdown of the model accuracy with respect to the size of a solution set ($|Z|$) at test time. We observe that the model with our training method outperforms the model with MML objective consistently across different values of $|Z|$. The gap between MML and our method is marginal when $|Z| = 0$ or 1, and gradually increases as $|Z|$ grows.

Varying the size of solution set at training. To see how our learning method works with respect to the size of a solution set ($|Z|$) of the training data, particularly with large $|Z|$, we take 5 subsets of the training set on WIKISQL with $|Z| = 3, 10, 30, 100, 300$. We train a model with those subsets and evaluate it on the original development set, both with our training method and MML objective. Figure 3 shows statistics of each subset and results. We observe that (i) our learning method outperforms MML consistently over different values of $|Z|$, and (ii) the gain is particularly large when $|Z| > 3$.

Model predictions over training. We analyze the top 1 prediction and the likelihood of $z \in Z$ assigned by the model on DROP_{num} with different number of training iterations (steps from 1k to 32k). Table 5 shows one example on DROP_{num} with the answer text '4', along with the model's top 1 prediction and a subset of Z. We observe that

Q: How many yards longer was Rob Bironas' longest field goal compared to John Carney's only field goal? (**Answer:** 4)
P: ... The Titans responded with Kicker Rob Bironas managing to get a 37 yard field goal. ...Tennessee would draw close as Bironas kicked a 37 yard field goal. The Chiefs answered with kicker John Carney getting a 36 yard field goal. The Titans would retake the lead with Young and Williams hooking up with each other again on a 41 yard td pass. ...Tennessee clinched the victory with Bironas nailing a 40 yard and a 25 yard field goal.

t	Pred	Z (ordered by $\mathbb{P}(z\|x;\theta_t)$)			
1k	10-9	10-6	41-37	40-36	41-37‡
2k	37-36	40-36	41-37	41-37‡	10-6
4k	40-36	40-36	41-37‡	41-37	10-6
8k	40-36	40-36	41-37‡	41-37	10-6
16k	37-36	40-36	41-37	41-37‡	10-6
32k	40-36	40-36	41-37	41-37‡	10-6

Table 5: An example from DROP_{num} (same as Figure 1 and Table 2), with its answer text '4' and a subset of the solution set (Z), containing two of '41-38' (which '41' come from different mentions; one denoted by ‡ for distinction), '40-36' and '10-4'. For each training step t, the top 1 prediction and Z ordered by $P(z|x;\theta_t)$, a probability of $z \in Z$ with respect to the model at t through training procedure are shown. Note that at inference time Z is not given, so top 1 prediction is not necessarily an element of Z.

the model first begins by assigning a small, uniform probability distribution to Z, but gradually learns to favor the true solution. The model sometimes gives the wrong prediction—for example, at $t = 16$k, and changes its prediction from the true solution to the wrong solution, '37-36'—but again changes its prediction to be a true solution afterward. In addition, its intermediate wrong solution, '37-36' indicates the model was confused with distinguishing the longest field goal of Rob Bironas (40 vs. 37), which is an understandable mistake.

We also compare the predictions from the model with our method to those from the model with MML, which is shown in Appendix C.

Quality of the predicted solution. We analyze if the model outputs the correct solution, since the solution executing the correct answer could be spurious. First, on NARRATIVEQA and DROP_{num}, we manually analyze 50 samples from the development set and find that 98% and 92% of correct cases produce the correct solution respectively. Next, on WIKISQL, we compare the predictions from the model to the annotated SQL queries on the development set. This is possible because gold SQL queries are available in the dataset for the full supervision. Out of 8,421 examples, 7,110 predictions execute the correct answers. Among those, 88.5% of the predictions are exactly same as the annotated queries. Others are the cases where (i) both queries are correct, (ii) the model prediction is correct but the annotated query is incorrect, and (iii) the annotated query is correct and the model prediction is spurious. We show a full analysis in Appendix C.

Robustness to the noise in $|Z|$. Sometimes noise arises during the construction of $|Z|$, such as $|Z|$ constructed based on ROUGE-L for NARRATIVEQA. To explore the effect of noise in Z, we experiment with more noisy solution set by picking all the spans with scores that is equal to or larger than the 5th highest. The new construction method increases $|Z|$ from 4.3 to 7.1 on NARRATIVEQA. The result by MML objective drops significantly (56.07→ 51.14) while the result by ours drops marginally (58.77→ 57.97), suggesting that MML suffers more with a noisier Z while ours is more robust.

7 Conclusion

In this paper, we demonstrated that, for many QA tasks which only provide the answer text as supervision, it is possible to precompute a discrete set of possible solutions that contains one correct option. Then, we introduced a discrete latent variable learning algorithm which iterates a procedure of predicting the most likely solution in the precomputed set and further increasing the likelihood of that solution. We showed that this approach significantly outperforms previous approaches on six QA tasks including reading comprehension, open-domain QA, discrete reasoning task and semantic parsing, achieving absolute gains of 2–10% and setting the new state-of-the-art on five well-studied datasets.

A Model details

We describe the detailed model architecture used as a base model. In other words, we describe how we obtain $\mathbb{P}(z|x;\theta)$.

The following paragraphs describe (i) BERT extractive model used for multi-mention RC (Section 5.1) and (ii) BERT sequence tagging model for discrete reasoning task (Section 5.2), respectively. For QANET for discrete reasoning and the model for SQL generation (Section 5.3), we use the open-sourced code of the original implementation[9] of Dua et al. (2019) and Hwang et al. (2019) and do not make any modification except the objective function, so we refer to original papers.

All implementations are done in Pytorch (Paszke et al., 2017). For BERT, we modify the open-sourced implementation in PyTorch[10] and use the uncased version of $\text{BERT}_{\text{base}}$.

Extractive QA model for multi-mention RC The model architecture is closed to that of Min et al. (2019) and Alberti et al. (2019), where the model operates independently on each paragraph, and selects the best matching paragraph and its associated answer span.

The input is a question Q and a set of paragraphs $\{P_1, \ldots, P_N\}$, and the desired output is a span from one of paragraphs. Since our goal is to compute a probability of a specific span, z, let's say z is s-th through e-th word in k-th paragraph.

The model receives a question Q and a single paragraph P_i in parallel. Then, $S_i = Q : [\texttt{SEP}] : P$, a list of $m + n_i + 1$ words, where : indicates a concatenation, [SEP] is a special token, m is the length of Q, and n_i is the length of P_i. This S_i is fed into BERT:

$$\bar{S}_i = \text{BERT}(S) \in \mathbb{R}^{h\times(m+n_i+1)}$$

where h is the hidden dimension of BERT. Then,

$$\begin{aligned} p_{i,\text{start}} &= \text{Softmax}\big(\bar{S}_i^T W_1\big) \in \mathbb{R}^{m+n_i+1} \\ p_{i,\text{end}} &= \text{Softmax}\big(\bar{S}_i^T W_2\big) \in \mathbb{R}^{m+n_i+1} \end{aligned}$$

where $W_1, W_2 \in \mathbb{R}^h$ are learnable vectors.

Finally, the probability of z, s-th through e-th word in i-th paragraph, is obtained by:

$$\mathbb{P}(z|Q,P_i) = p^s_{i,\text{start}} \times p^e_{i,\text{end}}$$

where p^d denotes d-th element of the vector p.

Separately, a paragraph selector is trained through $p_{i,\text{exit}} = \text{Softmax}\big(W_3 \text{maxpool}(\bar{S}_i)\big) \in \mathbb{R}^2$ where $W_3 \in \mathbb{R}^{h\times 2}$ is learnable vector. At inference time, $k = \text{argmax}_i p^1_{i,\text{exit}}$ is computed and $\mathbb{P}(z|Q,P_k)$ is only considered to output a span.

Sequence Tagging model for discrete reasoning The basic idea of the model is closed to that of Dua et al. (2019). The input is a question Q and a paragraph P. Our goal is to compute a probability of an equation, $z = (o_1, n_1, o_2, n_2)$, where $o_1, o_2 \in \{+, -, *0.01\}$ and $n_1, n_2 \in N_P \cup N_Q \cup S$, N_P and N_Q are all numeric values appearing in P and Q, and S are a set of predefined special numbers.[11].

First, BERT encodings of the question and the paragraph is obtained via

$$\bar{S} = \text{BERT}(Q : [\texttt{SEP}] : P) \in \mathbb{R}^{h\times(m+n+1)}$$

where : indicates a concatenation, [SEP] is a special token, m is the length of Q, n is the length of P, and h is the hidden dimension of BERT. Then,

$$\begin{aligned} p_{\text{input}} &= \text{Softmax}\big(\bar{S}^T W_1\big) \in \mathbb{R}^{(m+n+1)\times 4} \\ p_{\text{special}} &= \text{Softmax}\big(\text{maxpool}(\bar{S}) W_2\big) \in \mathbb{R}^{|S|\times 4} \end{aligned}$$

where $W_1 \in \mathbb{R}^{h\times 4}$ and $W_2 \in \mathbb{R}^{h\times|S|\times 4}$ are learnable matrices. Then,

$$\mathbb{P}(z|x) = \Pi_{i=1}^{m+n+1} p^{g(i)}_{\text{input}} \Pi_{j=1}^{|S|} p^{h(j)}_{\text{special}}$$

where

$$g(i) = \begin{cases} \alpha(o_1) & \text{if } [Q : [\texttt{SEP}] : P]^i = n_1 \\ \alpha(o_2) & \text{if } [Q : [\texttt{SEP}] : P]^i = n_2 \\ 0 & \text{o.w.} \end{cases}$$

$$h(j) = \begin{cases} \alpha(o_1) & \text{if } S^j = n_1 \\ \alpha(o_2) & \text{if } S^j = n_2 \\ 0 & \text{o.w.} \end{cases}$$

$$\alpha(o) = \begin{cases} 1 & \text{if } o = \text{`+'} \\ 2 & \text{if } o = \text{`-'} \\ 3 & \text{if } o = \text{`*0.01'} \end{cases}$$

Here, subscript i of the vector or the sequence indicate i-th dimension of the vector or i-th element of the sequence, respectively.

τ	TRIVIAQA F1
None	55.83
20k	58.05
30k	57.99
40k	56.66

τ	DROP_{num} EM
None	52.31
5k	51.98
10k	52.82
20k	51.74

Dataset	batch size	τ
TRIVIAQA	20	15K
NARRATIVEQA	20	20K
TRIVIAQA-OPEN	192	4K
NATURALQUESTIONS-OPEN	192	8K
DROP_{num} with BERT	14	10K
DROP_{num} with QANET	14	None
WIKISQL	10	None

Table 6: **(Left)** Ablations with varying values of τ on TRIVIAQA. **(Middle)** Ablations with varying values of τ on DROP_{num} with BERT. **(Right)** Final τ chosen for the main results on each dataset. Note that for DROP_{num} with QANET and WIKISQL, we just report the number without annealing.

B Annealing

To prevent the model to be optimized on early decision of the model, we perform annealing: at training step t, the model optimizes on MML objective with a probability of $\min(t/\tau, 1)$ and otherwise use our objective, where τ is a hyperparameter. We observe that the performance is improved by annealing while not being sensitive to the hyperparameter τ. Ablations and chosen τ for each dataset are shown in Table 6. Note that for DROP_{num} with QANET and WIKISQL, we do not ablate with varying τ and just report the number without annealing.

C Examples

To see if the prediction from the model is the correct solution to derive the answer, we analyze outputs from the model.

TRIVIAQA. Table 7 shows one example from TRIVIAQA where the answer text (Montgomery) is mentioned in the paragraph multiple times. Predictions from the model with our training method and that with MML objective are shown in the red text and the blue text, respectively. The span predicted by the model with our method actually answers to the question, while other spans with the answer text is not related to the question.

DROP_{num}. Table 8 shows predictions from the model with our method and that with MML objective over training procedure. We observe that the model with our method learns to assign a high probability to the best solution ('34-24'), while the model with MML objective fails to do so. Another notable observation is that the model with our method assign sparse distribution of likelihood over Z, compared to the model with MML objective. We quantitatively define sparsity as

$$\frac{|\{z \in Z \text{ s.t. } \mathbb{P}(z|x;\theta) < \epsilon\}|}{|Z|}$$

(Hurley and Rickard, 2009) and show that the model with our method gives higher sparsity than the model with MML (59 vs. 36 with $\epsilon = 10^{-3}$, 54 vs. 17 with $\epsilon = 10^{-4}$ on DROP).

WIKISQL. WIKISQL provides the annotated SQL queries, makes it easy to compare the predictions from the model to the annotated queries. Out of 8421 examples from the development set, 7110 predictions execute the correct answers. Among those, 6296 predictions are exactly same as the annotated queries. For cases where the predictions execute the correct answers but are not exactly same as the groundtruth queries, we show four examples in Table 9. In the first example, both the annotated query and the prediction are correct, because the selected column does not matter for counting. Similarly in the second example, both queries are correct because `Capital (exonym)` and `Capital (endonym)` both indicate the capital city. In the third example, the prediction makes more sense than the annotated query because the question does not imply anything about `min`. In the last example, the annotated query makes more sense than the prediction because the prediction misses `Ship Type = battleship`. We conjecture that the model might learn to ignore some information in the question if the table header implies the table is specific about that information, hence does not need to condition on that information.

Question & Document
Q: What is the state capital of Alabama? (Groundtruth: Montgomery) **D:** Alabama is nicknamed the Yellowhammer State, after the state bird. Alabama is also known as the "Heart of Dixie" and the "Cotton State". The state tree is the longleaf pine, and the state flower is the camellia. Alabama's capital is Montgomery. (...) From 1826 to 1846, Tuscaloosa served as Alabama's capital. On January 30, 1846, the Alabama legislature announced it had voted to move the capital city from Tuscaloosa to Montgomery. The first legislative session in the new capital met in December 1847. A new capitol building was erected under the direction of Stephen Decatur Button of Philadelphia. The first structure burned down in 1849, but was rebuilt on the same site in 1851. This second capitol building in Montgomery remains to the present day.

Table 7: An example from TRIVIAQA with multiple spans of the answer text (underlined). The model trained with self-training technique outputs the correct answer (red) and the model trained on MML objective does not (blue).

Question & Passage
Q: How many sports are not olympic sports but are featured in the asian games ? (A: 10) **P:** The first 30 sports were announced by the singapore national olympic council on 10 december 2013 on the sidelines of the 27th sea games in myanmar. It announced then that there was room for as many as eight more sports. On 29 april 2014 the final six sports namely boxing equestrian floorball petanque rowing and volleyball were added to the programme. Floorball will feature in the event for the first time after being a demonstration sport in the 2013 edition. In its selection of events the organising committee indicated their desire to set a model for subsequent games in trimming the number of 'traditional' sports to refocus on the seag' s initial intent to increase the level of sporting excellence in key sports. Hence despite room for up to eight traditional sports only two floorball and netball were included in the programme. Amongst the other 34 sports 24 are olympic sports and all remaining sports are featured in the asian games.

Ours

t	Pred	Z (ordered by $\mathbb{P}(z\|x;\theta_t)$)			
1k	10+two	eight+two	eight+two‡	34-24	10
2k	30-24	34-24	eight+two	eight+two‡	10
4k	34+24	34-24	eight+two	eight+two‡	10
8k	34+24	34-24	eight+two	10	eight+two‡
16k	34-24	34-24	eight+two	eight+two‡	10
32k	34-24	34-24	eight+two	eight+two‡	10

MML

t	Pred	Z (ordered by $\mathbb{P}(z\|x;\theta_t)$)			
1K	10+two	eight+two	eight+two‡	10	34-24
2k	eight+two	eight+two	eight+two‡	34-24	10
4k	24+5	eight+two	eight+two‡	34-24	10
8k	24+5	eight+two	eight+two‡	34-24	10
16k	34-24	34-24	eight+two	eight+two‡	10
32k	24+5	34-24	eight+two	eight+two‡	10

Table 8: An example from DROP_{num}, with its answer text '10' and a subset of Z, containing '10', two of 'eight+two' (which 'eight' come from different mentions; one denoted by '‡' for distinction) and '34-24'. The below tables are predictions from the model with our training strategy (left) and MML (right). For each training step t, the top 1 prediction and Z ordered by $P(z|x;\theta_t)$, a probability of $z \in Z$ with respect to the model at t are shown. Note that at inference time Z cannot be obtained, so top 1 prediction is not necessarily in Z.

Q	How many times was the # of total votes 2582322?
H	Election, # of candidates nominated, # of seats won, # of total votes, % of popular vote
A	`Select count(# of seats won) where # of total votes = 2582322`

P	`Select No.in series where Production code = 8abx15`
Q	what is the name of the battleship with the battle listed on May 13, 1915?
H	Estimate, Name, Nat., Ship Type, Principal victims, Date
A	`Select Name where Ship Type = battleship and Date = may 13, 1915`
P	`Select Name where Date = may 13, 1915`

Table 9: Four examples from WIKISQL where the prediction from the model is different from annotated SQL query, although the executed answers are the same. **Q**, **H**, **A** and **P** indicate the given question, the given table header, annotated SQL query and predicted SQL query. First two example shows the case where both queries are correct. Next example shows the case that the model prediction makes more sense than the annotated query. The last example shows the cases that the annotated query makes more sense than the model prediction.

Is the *Red Square* Big?
MALeViC: Modeling Adjectives Leveraging Visual Contexts

Sandro Pezzelle and **Raquel Fernández**
Institute for Logic, Language, and Computation
University of Amsterdam
{s.pezzelle|raquel.fernandez}@uva.nl

Abstract

This work aims at modeling how the meaning of gradable adjectives of *size* ('big', 'small') can be learned from visually-grounded contexts. Inspired by cognitive and linguistic evidence showing that the use of these expressions relies on setting a threshold that is dependent on a specific *context*, we investigate the ability of multi-modal models in assessing whether an object is 'big' or 'small' in a given visual scene. In contrast with the standard computational approach that simplistically treats gradable adjectives as 'fixed' attributes, we pose the problem as *relational*: to be successful, a model has to consider the full visual context. By means of four main tasks, we show that state-of-the-art models (but not a relatively strong baseline) can learn the function subtending the meaning of size adjectives, though their performance is found to decrease while moving from simple to more complex tasks. Crucially, models fail in developing abstract representations of gradable adjectives that can be used compositionally.

1 Introduction

There is no doubt that planets are *big* things. Among the planets of our Solar System, however, Mars is unquestionably a *small* planet (though not the smallest), while Saturn is definitely a *big* one (though not the biggest). This example highlights some crucial properties of gradable adjectives (hence, GAs). First, what counts as 'big' or 'small' is *relative*, i.e., determined by the context: Phobos is both a *big* moon of Mars and a *small* celestial body of the Solar System. This makes GAs different from non-gradable or *absolute* adjectives like 'open', 'empty', 'red': Mars, for example, is *red* and *rocky* in any circumstance. More formally, the compositional semantic properties of GAs are *subsective* since they select a subset of entities denoted by the noun they modify, which acts as a *reference set* ($\|\text{big}\| \subseteq \|\text{moon}\|$), while non-GAs are *intersective* ($\|\text{Galilean}\| \cap \|\text{moon}\|$). This has consequences for the inferences they license: if Ganymede is both a *Galilean* moon and a celestial body, we can infer that Ganymede is a Galilean celestial body. In contrast, if it is a *big* moon and a celestial body, the inference that Ganymede is a big celestial body is not valid (Partee, 1995).

Second, besides depending on a contextually-given reference set, GAs rely on orderings, i.e, they denote functions that map entities onto scales of degrees (Cresswell, 1976; Kennedy, 1999). Using 'big' or 'small', thus, implies mapping a target object onto a size scale, which allows us to use degree morphology to express that Saturn is *bigger* than Mars (comparative form) or that Mercury is the *smallest* planet (superlative form). As for the non-inflected, so-called positive form of GAs (e.g., Saturn is a *big* planet), its interpretation involves applying a *statistical function* that makes use of a standard threshold degree (Kamp, 1975; Pinkal, 1979; Barker, 2002; Kennedy, 2007).

Third, GAs are considered to be *vague*, because whether they apply or not to a given entity can be a matter of debate among speakers (Van Deemter, 2012; Lassiter and Goodman, 2017). Since people might rely on slightly different functions involving probabilistic thresholds, there are often *borderline cases*: e.g., Neptune (i.e., the fourth planet out of eight in terms of size) could be considered as a *big* planet by most but not all speakers in all situations.

Our aim in this work is to computationally learn the meaning of size GAs ('big', 'small') from visually-grounded contexts. Based on the semantic properties of such expressions (context-dependence, statistically-defined interpretation, vagueness), we tackle the task as a *relational* problem in the domain of visual reasoning (similarly, e.g., to spatial problems like assessing whether 'X is on the left of Y'). Simply put, a model needs

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2865–2876,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

to consider the entire visual context (not just the queried object) in order to solve the task. Such setup resembles experimental paradigms in developmental psychology which test how children interpret GAs when applied to objects grounded in visual scenes (Barner and Snedeker, 2008). Evidence shows that children learn to use GAs compositionally early on: when asked to assess whether an object is 'tall' or 'short' in a visual context, 4-year-old children are able to (a) restrict the reference set by means of linguistic cues and (b) derive a tall/short threshold relative to that set. That is, 4-year-olds do not interpret GAs categorically but *compositionally*. This is radically different from how adjectives are treated in current visual reasoning approaches, which consider them static labels standing for attributes (size, color, material) whose value is fixed across contexts (Johnson et al., 2017a; Santoro et al., 2017): i.e., for current models, Saturn is always *big* and Mars is always *small*.

To model GAs in a relational fashion, we rely on a statistical function that is found to be best predictive of human interpretations (Schmidt et al., 2009) and build **MALeViC**,[1] a battery of datasets for **M**odeling **A**djectives **Le**veraging **Vi**sual **C**ontexts (see Figure 1). Each dataset, including 20K synthetic visual scenes and automatically-generated language descriptions (e.g., 'the red square is a *big* square'), is used to test different abilities. We experiment with several models and show that FiLM (Perez et al., 2018) and, to a lesser extent, Stacked Attention Networks (Yang et al., 2016) can learn the function subtending the meaning of size adjectives, though their performance is found to decrease while moving from simple to more complex tasks. Crucially, all models fail in developing abstract representations of gradable adjectives that can be used compositionally.

2 Related Work

Computational Linguistics Computational approaches to GAs have mostly focused on automatically ordering elements with respect to their intensity (e.g., *good*<*great*<*excellent*, de Marneffe et al., 2010) to overcome a problem with lexical resources like WordNet (Fellbaum, 1998), which

[1]The name is inspired by that of the Russian 20th-century artist Kazimir Malevič (or Malevich), famous for his paintings of geometric shapes, such as the *Red Square*. Datasets, code, and trained models can be found here: https://github.com/sandropezzelle/malevic

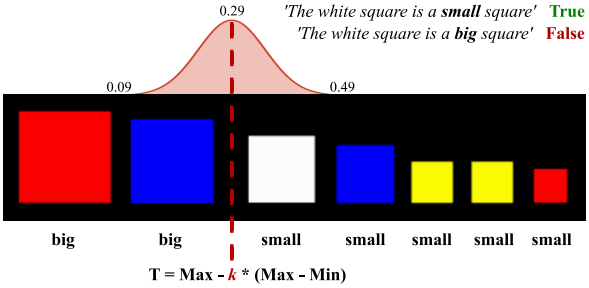

Figure 1: Our approach: given a visual **context** depicting several objects and a **sentence** about one object size, models have to assess whether the sentence is true or false. Ground-truth answers are *context*-specific and depend on a threshold T (Schmidt et al., 2009) which counts objects as 'big' based on: (1) the area of the biggest (Max) and smallest (Min) object in the context; (2) the value of a 'vague' k determining the top k% of sizes which count as 'big'. In our approach, all objects that are *not* 'big' count as 'small'. Best viewed in color.

consider words like 'small' and 'minuscule' as synonyms. These efforts showed the potential of using techniques based on word embeddings (Kim and de Marneffe, 2013), web-scale data (Sheinman et al., 2013; De Melo and Bansal, 2013), or their combination (Shivade et al., 2015; Kim et al., 2016) to determine the relative intensity of different words on a scale. By focusing on the *ordering* between adjectives, however, these works do not shed light on how the *meaning* of such expressions is determined by contextual information. This goal, in contrast, has been pursued by work on automatic Generation of Referring Expressions (GRE), where GAs have represented an interesting test case precisely due to their context-dependent status (van Deemter, 2006). Several small datasets of simple visual scenes and corresponding descriptions have been proposed (van Deemter et al., 2006; Viethen and Dale, 2008, 2011; Mitchell et al., 2010, 2013a), and forerunner GRE algorithms have been tested to refer to visible objects using attributes like *size* (Mitchell et al., 2011, 2013b). Due to their extremely small size, however, these datasets are not suitable for large-scale deep learning investigations.

Language & Vision Recent work in language and vision has dealt with (gradable) adjectives from at least three perspectives. First, multi-modal information has been used to order real-world entities with respect to an attribute described by a GA. Bagherinezhad et al. (2016), for example, assess whether elephants are *bigger* than butterflies.

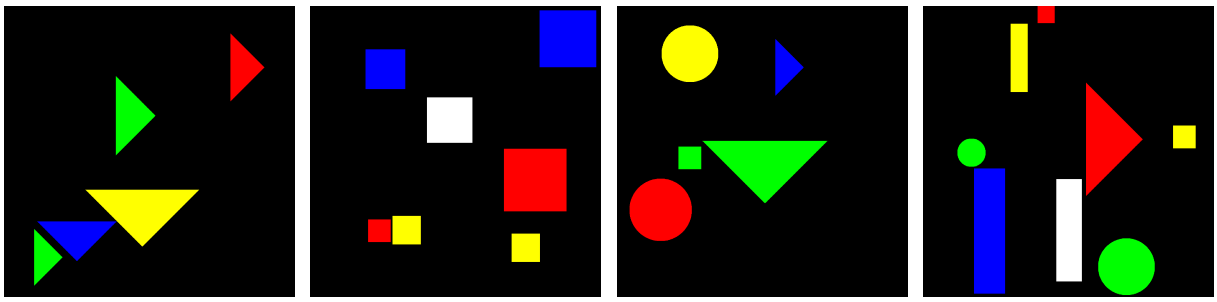

Figure 2: One scene and one corresponding generated true sentence for each of the 4 tasks. From left to right, **SUP$_1$:** The yellow triangle is the *biggest* triangle; **POS$_1$:** The white square is a *small* square; **POS:** The red circle is a *big* object; **SET+POS:** The white rectangle is a *big* rectangle. Best viewed in color.

Thus, rather than modeling the meaning of GAs, this work focuses on the relative size of object types, which is crucially different from our goal. Second, visual gradable attributes have been used as fine-grained features to answer questions about entities in natural scenes (Antol et al., 2015; Hudson and Manning, 2019), to perform discriminative and pragmatically-informative image captioning (Vedantam et al., 2017; Cohn-Gordon et al., 2018), and to discriminate between similar images in reference games (Su et al., 2017). In these works, however, GAs are labels standing for *fixed* attributes: e.g., an airplane is annotated as 'large' or 'small' with no or little relation to the visual context. Third, gradable attributes are explored in work on visual reasoning (Johnson et al., 2017a; Yi et al., 2018), where multi-modal models are challenged to answer complex, high-level questions about objects and their relations in synthetic scenes. Surprisingly, however, questions involving GAs are treated as *non-relational*: e.g., a given size *always* corresponds to either 'big' or 'small', regardless of the objects in the visual context. One exception is Kuhnle et al. (2018), whose investigation of superlative ('biggest') and comparative ('darker') GAs represents a first step toward a *relational* account of these expressions. To our knowledge, we are the first to tackle the modeling of *positive* GAs as a linguistically- and cognitively-inspired relational problem in language and vision.

3 Tasks

To test model abilities in learning size GAs, we propose 4 main tasks (see Figure 2). All tasks are framed as a sentence-verification problem: given an image depicting colored, geometric shapes and a sentence about one object's relative size, systems are asked to verify whether the given sentence is true or false in that context. These tasks are aimed at assessing one ability at a time, and are specifically designed to form a pipeline of increasingly difficult operations. Tasks differ with respect to:

- the **statistical function** at play: a max/min function (SUP) or a threshold function (POS);
- the number of geometric **shape types**: one (SUP$_1$/POS$_1$) or several;
- the scope of the **reference set**: the entire visual scene or a subset of objects (SET; only applicable with several shape types per scene).

SUP$_1$ This task tests whether a model is able to interpret size GAs in their **superlative** form: e.g., 'The yellow triangle is the *biggest* triangle' (only triangles in the scene). To solve this task, a model is required to (1) identify the queried object, (2) measure object size, and (3) determine whether the target object has the largest or smallest size in the entire visual scene.

POS$_1$ This task evaluates the ability of models to interpret **positive**-form size GAs: e.g., 'The white square is a *small* square' (only squares in the scene). To adequately solve this task, a model is not only required to (1) identify the queried object and (2) measure object size, but also (3) to learn the threshold function that makes an object count as 'big' or 'small' depending on the size of the other objects in the entire visual scene, and (4) to assess whether the target object counts as 'big'/'small' in this context. In contrast to the superlative form, which is precise, the positive form is *vague*: there may be borderline cases (see Figure 1 and *Threshold Function* in Section 4).

POS This task is an extension of POS$_1$ where the restriction to one single geometric shape type

per scene is lifted: e.g., 'The red circle is a *big* object' (any shape in the scene) – see Figure 2. As before, and in contrast to the next task, the reference set is the entire visual scene.

SET+POS Finally, this task assesses the ability of models to interpret **positive**-form GAs with respect to a restricted context: e.g., 'The white rectangle is a *big* rectangle' (any shape in the scene). To solve this task, in addition to the skills required to address the POS task, a model needs to determine the relevant **reference set** (e.g., the set of rectangles in the scene) and to apply all POS operations to this set. This task, thus, brings together all the key components that make up the semantics of size adjectives, as described in Section 1.

4 Datasets

Visual Data For each task, we build a dataset of synthetic scenes (1478 x 1478 pixels) depicting 5 to 9 colored objects[2] on a black background. Each object is randomly assigned one shape among circle, rectangle, square, triangle; one color among red, blue, white, yellow, green; one area among 10 predefined ones (based on number of pixels) that we label using tens ranging from 30 to 120 (i.e. 30, 40, 50, ... 120); and a given spatial position in the scene which avoids overlapping with other objects. In tasks SUP_1 and POS_1 only one shape type is present in a given scene, while in tasks POS and SET+POS several shape types are present.

Linguistic Data While generating the visual data, ground-truth labels ('biggest', 'smallest', 'big', 'small') are automatically assigned to each object based on the area of the objects present in the reference set. For tasks POS_1, POS and SET+POS, for each object in the scene the generation algorithm generates a sentence based on the template: *The* <color> <shape> *is a* <size> <shape>. For task SUP_1, for objects that are biggest/smallest in the scene the algorithm generates a sentence using the template *The* <color> <shape> *is the* <sup_size> <shape>. In order for a sentence to be licensed, the following constraints have to be met: (1) The queried object is uniquely identifiable within the scene, either by <color> in tasks SUP_1 and POS_1 or by <color, shape> in tasks POS and SET+POS (this ensures there is no ambiguity regarding the target); (2) the area of the queried object must be in the 40-110 range, so to avoid querying objects whose size would always be small/smallest or big/biggest in any scene irrespective of the area of the other objects (see Figure 3, which shows the distribution of queried objects' areas per question type in the train set of POS; as can be seen, no objects with an area equal to either 30 or 120 are present). In task SET+POS, we include two additional constraints: (3) the queried object is neither the biggest nor the smallest object in the entire scene (i.e., the max/min function is not effective without identifying the reference subset); and (4) there are at least three objects in the scene with the same shape as the target (i.e., the reference set includes at least three objects), so to make the computation of the threshold function required to solve the task. Only sentences meeting these constraints are generated and the corresponding scene retained. For each true sentence, a false sentence is automatically generated by replacing the true adjective (e.g., 'big') with the false one (e.g., 'small').

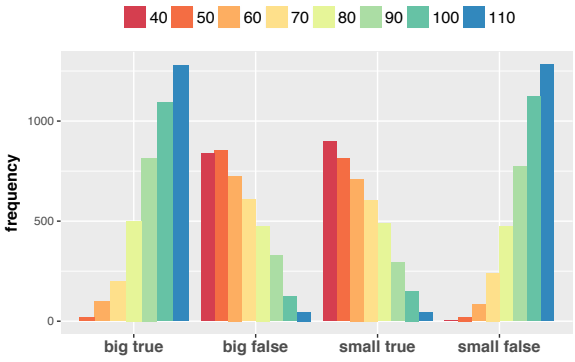

Figure 3: **POS.** Distribution of queried objects' areas per question type in train. This plot highlights an important feature of MALeViC, namely that objects with any area from 40 to 110 can be either 'big' or 'small' depending on the visual context. Best viewed in color.

Threshold Function To assign ground-truth labels to objects in tasks POS_1, POS and SET+POS, we make use of a *threshold function* experimentally determined by Schmidt et al. (2009), who explore a number of statistical functions to describe speakers' use of the adjective 'tall' (following the authors, we assume these functions to be valid for any GAs, including 'big').[3] In particular, we use their *Relative Height by Range* (RH-R) function,

[2]This resembles the setup used by Barner and Snedeker (2008) in their first experiment, which involves 9 objects.

[3]Note also that, while size may be argued to be two-dimensional, in our approach we treat it as one-dimensional (i.e., based on number of pixels), similarly to tallness.

according to which any item within the top $k\%$ of the range of sizes in the reference set is 'tall' ('big'). According to this function, the threshold T for a given context C is defined as follows: T(C) = Max - k * (Max – Min), where $k \in [0, 1]$, Max is the maximum size in C, and Min the minimum size (see Figure 1). In our data, we make the simplifying assumption to consider 'small' any object that is *not* 'big'. This way, we also avoid dealing with negative statements. Since Schmidt et al. (2009) experimentally show k = 0.29 to best fit their human data, we use this value as our reference k. To account for *vagueness*, for each scene we randomly sample a k from the normal distribution of values centered on 0.29 (μ = 0.29, σ = 0.066),[4] as illustrated in Figure 1. This introduces some perturbation in the definition of T, which mimics the fact that speakers may rely on slightly different definitions of GAs (i.e., what counts as 'big' for one person might not *always* count as 'big' for another one; Raffman, 1996; Shapiro, 2006; Sharp et al., 2018), with communication still being successful in most of the cases.

Datasets The four final datasets, including 20K datapoints each, are perfectly balanced with respect to the number of cases for each combination of variables used. In particular, 250 <scene, sentence> datapoints are included for each of the 80 classes (4 shapes * 5 colors * 2 sizes * 2 ground truths), where one class is e.g.: <red> <circle> <big> <true>. Such balancing is kept when randomly splitting the datasets into train (16K cases), validation (2K) and test (2K) sets.

5 Models

We test 3 models that have proved effective in visual reasoning tasks (Johnson et al., 2017a; Suhr et al., 2018; Yi et al., 2018). All models are *multi-modal*, i.e., they use both a visual representation of the scene and a linguistic representation of the sentence. Unless otherwise specified, visual features representing the scenes are extracted via a *fixed* Convolutional Neural Network (CNN) fed with images resized to 224 x 224 pixels. In particular, features from the *conv4* layer of a ResNet-101 (He et al., 2016) pre-trained on ImageNet (Russakovsky et al., 2015) are used.

CNN+LSTM This model simply concatenates the CNN visual features with a representation of the sentence encoded using the final hidden state of an LSTM (Hochreiter and Schmidhuber, 1997). These concatenated features are passed to a Multi-Layer Perceptron (MLP) that predicts the answer.

Stacked Attention (CNN+LSTM+SA) This model combines the CNN visual features and the LSTM final state by means of two rounds of soft spatial attention. An MLP over the combined representation predicts the answer (Yang et al., 2016).

CNN+GRU+Feature-wise Linear Modulation (FiLM) This model (∼100% on CLEVR; Johnson et al., 2017a) processes the image features by means of 4 residual blocks where the visual representation is linearly transformed by the sentence embedding (i.e., the final hidden state of a GRU; Chung et al., 2014). After a global max-pooling, a two-layer MLP classifier outputs a softmax distribution over the answers (Perez et al., 2018).[5]

Experimental Setup For each model in each task, we experiment with 16 configurations of hyper-parameters, i.e., 4 learning rates (5e-5, 3e-4, 5e-4, 5e-3) * 2 dropout values (0, 0.5) * 2 batch normalization options (yes, no). Each model configuration is trained 3 times with randomly initialized weights for 10K iterations (40 epochs), and the best configuration is chosen based on average validation accuracy. In total, 576 models (3 architectures * 4 tasks * 48 runs) are tested. For comparison with previous work (Perez et al., 2018; Kuhnle et al., 2018), we also test FiLM end-to-end (i.e., trained from raw pixels) with the same hyper-parameters as above, for a total of 192 models (4 tasks * 48 runs). Since no substantial differences are observed between the two versions (in line with Perez et al., 2018), we focus on the results by the less tailored and less computationally-expensive models using *pre-trained* features.

6 Results

Overall, we observe the expected pattern of results, in line with the conjectured, increasing difficulty of the tasks: accuracy declines from SUP_1 to POS_1 and from POS to SET+POS. There are, however, clear differences across models.

[4] By setting σ = 0.066, we expect 99.7% k values to be $\pm$ 3 standard deviations from 0.29, i.e. ranging from 0.09 to 0.49; 95% k within $\pm$ 2 SD (0.16-0.42); 68% within $\pm$ 1 SD (0.22-0.36). σ value was set experimentally to keep $k < 0.5$.

[5] For CNN+LSTM and CNN+LSTM+SA, we use the implementations by Johnson et al. (2017b). For FiLM, we use the implementation by Perez et al. (2018). All models are trained using Python 3.5.2 and PyTorch v1.0.1.

task	model	accuracy			hyper-parameters		
		max val (pixels)	avg val ± sd	avg test ± sd	lr	drop	b norm
SUP$_1$	CNN-LSTM	0.841	0.8153 ± 0.033	0.8066 ± 0.033	5e-4	0.5	no

all	*chance*	0.5	0.5	0.5			

Table 1: Results by each **model** (column 2) in each **task** (1). Note that **max val** (3) refers to the highest accuracy obtained in the task by a given architecture across 192 runs (in brackets, highest accuracy obtained across 192 runs by FiLM trained from raw **pixels**), while **avg val** ± **sd** (4) and **avg test** ± **sd** (5) refer to the average accuracy (and relative standard deviation) obtained across 3 runs by the best configuration of hyper-parameters of a given architecture on, respectively, val and test set. As for the **hyper-parameters** (6), we report value of learning rate (**lr**), dropout (**drop**), and use/not use of batch normalization (**b norm**). Values in bold are the highest in the column.

CNN+LSTM does well on SUP (the simplest task) but performs around chance on all other tasks (which require a threshold function). Both CNN+LSTM+SA and FiLM obtain high accuracy on POS$_1$/POS, while FiLM neatly outperforms CNN+LSTM+SA in the most challenging SET+POS task, proving its higher ability to reason over complex, context-dependent linguistic expressions. Accuracy scores are reported in Table 1. In the following, we describe the results per task in more detail.

SUP$_1$ Both CNN+LSTM+SA and FiLM obtain perfect accuracy (∼100%), with CNN+LSTM performing well above chance (∼80%). These results indicate that assessing whether an object is the 'biggest'/'smallest' in the scene is a relatively simple task even for basic models. This is encouraging since mastering *superlatives* requires several core skills that also underlie the use of *positive* GAs, namely (1) object identification, (2) object size estimation, and (3) object size ordering.

POS$_1$ / POS CNN+LSTM+SA and FiLM obtain similar, very high max accuracy (∼94%) in these two tasks, with CNN+LSTM being only slightly above chance level (∼57%). Note that in this case we should not expect models to obtain 100% accuracy: while the min/max function in SUP is precise, the POS threshold function is vague (giving rise to borderline cases). The performance to be expected with sharp $k = 0.29$ is 97% for these two tasks (i.e, only in 3% of cases k is assigned a value that makes the truth/falsity of a sentence different from what it would be with $k = 0.29$). The performance of the two top models is thus 3% below average ceiling accuracy (94% vs. 97%). These results, thus, indicate that CNN+LSTM+SA and FiLM are able to learn the *threshold function* that makes an object count as 'big'/'small' in a given visual scene, while CNN+LSTM is not.[6]

SET+POS As before, CNN+LSTM performs only slightly above chance. Both FiLM and CNN+LSTM+SA experience a drop in performance compared to POS$_1$/POS, confirming that computing the threshold function over a subset of objects is the most challenging task. Applying the threshold function to the entire visual scene would yield ∼65% accuracy in this dataset. This indicates that none of the two top models uses this strategy simplistically, as their performance is well above this result (max 81% for CNN+LSTM+SA and 92% for FiLM).[7] FiLM neatly outperforms CNN+LSTM+SA (+11% in both max and average accuracy), thus showing a more robust pattern of results across tasks and a higher ability to handle complex reasoning problems.

[6] FiLM's performance in POS$_1$ (where each scene contains only one shape type, but all shape types are seen across images) is rather unstable across runs (high SD). Since this is not so in POS, we conjecture that it may be due to the model learning shape-specific strategies in some runs of POS$_1$.

[7] As in POS$_1$/POS, ceiling performance with fixed $k = 0.29$ is 97% in this dataset.

hard test (train)	model	avg acc ± sd
POS-hard (POS)	CNN+LSTM	0.5325 ± 0.01
	CNN+LSTM+SA	0.8653 ± 0.005
	FiLM	**0.8693 ± 0.003**
SET+POS-hard (SET+POS)	CNN+LSTM	0.4623 ± 0.004
	CNN+LSTM+SA	0.478 ± 0.015
	FiLM	**0.6513 ± 0.059**
all	*chance*	0.5

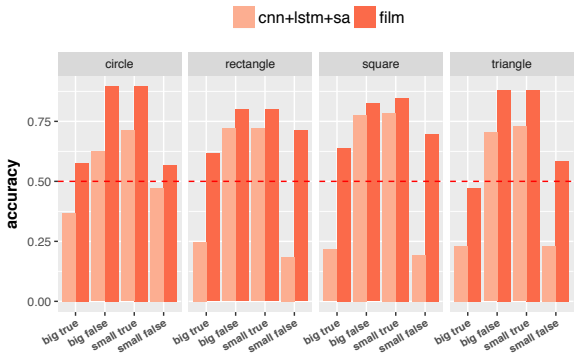

Figure 4: **SET+POS-hard.** Accuracy per sentence type (big true, big false, small true, small false) obtained by the best run of CNN+LSTM+SA (49% acc.) and FiLM (73% acc.) for each shape type. The dashed line signals *chance* level. Best viewed in color.

While these results are very encouraging, they might be the outcome of exploiting biases in the data rather than learning the semantic components that make up the meaning of GAs according to linguistic theory and psycholinguistic evidence. For example, identifying the reference subset but applying the max/min function (rather than a threshold function) to this set would yield a remarkable 92% accuracy, which is on a par with the top result by FiLM. In what follows, we investigate the abilities of the trained models in more depth by testing them on a number of diagnostic test sets.

7 Analysis

In this section, we aim at better understanding what the models learn (or do not learn) when performing the different tasks. To do so, we carry out a *stress-test* and a *compositionality* analysis.

7.1 Stress-Test: Hard Contexts

To test to what extent models master the core abilities that are arguably needed to perform POS and SET+POS, we build two *hard* diagnostic test sets which make the use of other strategies not effective. Similarly to the main datasets, these hard test sets include 2K perfectly-balanced datapoints.

POS-hard We explore whether models trained on POS properly learn to compute the threshold function rather than using a simplistic strategy such as applying the min/max function over the visual context. Indeed, it has been proposed that young children might use positive-form GAs as superlatives in early stages of language acquisition (Clark, 1970). To test whether this explains (part of) the results on POS, we build a *hard* test set identical to POS except for the fact that objects that are either the biggest or the smallest in the entire visual scene are never queried. Thus, in POS-hard systematically using the superlative strategy would result in chance level scores. As reported in Table 2, the accuracy obtained by CNN+LSTM+SA and FiLM does not dramatically decrease compared to POS (∼94% vs. ∼87%). The drop can be explained by the fact that in POS-hard we query objects that are overall *closer* to the threshold, thus increasing the number of more difficult, borderline cases.[8] This test thus confirms that CNN+LSTM+SA and FiLM do learn to generally compute and apply the threshold function over an entire visual scene.

SET+POS-hard To investigate whether models trained on SET+POS learn to identify the reference subset and to apply the threshold function to it, we build a hard test set identical to SET+POS except for the fact that objects that are the biggest or the smallest *in the reference set* are never queried. Thus, in SET+POS-hard applying the min/max function to the reference set would lead to chance level. As shown in Table 2, only FiLM is above chance level in this test set, with 65% accuracy. Both CNN+LSTM and CNN+LSTM+SA obtain scores slightly below chance (–30% for CNN+LSTM+SA compared to SET+POS). This is a striking result, which reveals that the accuracy scores achieved by CNN+LSTM+SA in SET+POS must be due to shortcut strategies.

While we do not have full understanding of what is being exploited by the CNN+LSTM+SA model, we do observe a bias towards predicting that an object counts as 'small'. As shown in Figure 4, the model obtains high accuracy on sentences involving small objects (small true, big

[8] This also leads to slightly lower average ceiling accuracy in POS-hard: performance with fixed $k = 0.29$ is now ∼92% in contrast to ∼97% in POS.

Figure 5: **SET+POS-hard.** Distribution of k against sentence type (clockwise from top-left: big true, big false, small false, small true). Cases labelled as *different* are those for which the ground truth adjective (e.g. 'big') would change with $k = 0.29$ (e.g., 'small'); in *same* cases, it would be the same. Best viewed in color.

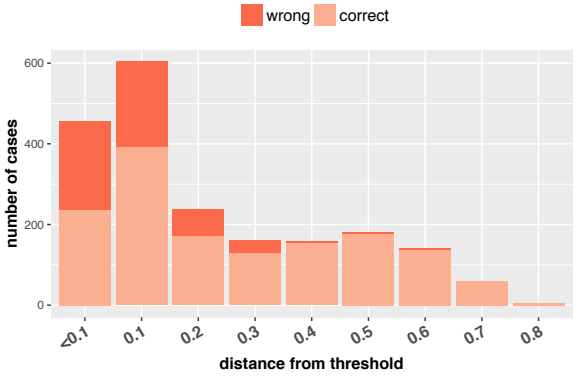

Figure 6: **SET+POS-hard.** Correct and wrong predictions by best run of FiLM (73% acc.) against distance from the threshold. Best viewed in color.

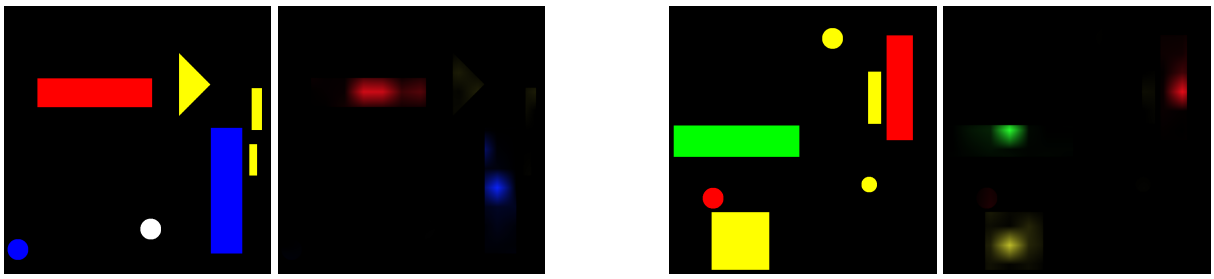

false), while its accuracy on sentences targeting big objects (big true, small false) is below chance level. Indeed, the model predicts *false* for big objects and *true* for small objects in 73% of cases.

As for FiLM, its pattern of accuracy is overall more stable across sentence types, though big objects (big true, small false) are still significantly harder than small ones (small true, big false). Bigger objects are more challenging because by definition they are closer to the threshold (as can clearly be seen in Figure 1), which in turn means that they are more likely to be borderline cases. The plots in Figure 5 illustrate this effect, showing that objects that count as 'big' are more likely to flip the truth value of a sentence due to the fuzziness of the threshold. FiLM's results are thus to be expected, and in fact encouraging: if a model is correctly learning to apply the threshold function to the reference set, most of the errors should involve borderline objects. This is confirmed: see Figure 6, where correct and wrong predictions by the best FiLM model are plotted against the (normalized) distance of the queried object from the threshold (83% of the errors within the 2 leftmost columns correspond to objects that count as 'big'). In Figure 7, we report two *borderline* cases randomly sampled from the test set where distance from the threshold is 0.09 (a) and 0.04 (b), respectively. For both scenes, the sentence 'The red rectangle is a *big* rectangle' is *true*. However, FiLM's best run predicts the correct answer only in (a). By visualizing the distribution of locations responsible for FiLM's globally-pooled features fed to the classifier, we notice that, in both cases, features related to the queried object (the red rectangle) and objects in the reference set (rectangles) are highly activated (though with a bias toward larger objects), confirming the ability of FiLM to focus on language-relevant features. However, (high) activations are also assigned to *unrelated* objects' features, particularly in (b). Though no conclusions can be drawn from these examples, they suggest that FiLM uses features related to several objects, in line with the *relational* nature of the task.

Finally, the evidence that models obtain slightly different results across shapes (see Figure 4) could suggest that models learn different, shape-specific representations of 'big' and 'small'. The following analysis precisely aims at exploring this issue.

7.2 Compositionality: Unseen Combinations

In our last analysis, we investigate whether the models learn an *abstract* representation of GAs that can be compositionally applied to unseen adjective-noun combinations. We focus on the SET+POS task and extract a subset of the corresponding dataset in which each size adjective appears only with two nouns denoting two distinct shape types: 'big (circle|rectangle)', 'small (square|triangle)'. This subset of the data amounts to half of SET+POS and thus contains 10K datapoints, that we split into train (8K), val (1K), and test (1K). We refer to this test set as *seen* (its adjective-noun combinations are seen in training). We then create a second, *unseen* test set with 1K datapoints, where the adjectives appear with different nouns: 'big (square|triangle)', 'small (circle|rectangle)'. We train all models three times using their best hyper-parameter configurations and evaluate them on both *seen* and *unseen*. If

(a) (b)

Figure 7: **SET+POS-hard.** Two *borderline* cases from the test set where FiLM's best run makes a correct (a) or wrong (b) prediction to 'The red rectangle is a *big* rectangle', which is *true* in both scenes. The rightmost panels show the distribution of locations used by FiLM for its globally max-pooled features. Best viewed in color.

models learn an abstract representation of GAs that includes a variable for the noun they modify, we should observe no difference in performance between the two test sets.

As reported in Table 3, this turns out not to be the case. While in the *seen* test set all models obtain similar accuracies to those obtained in SET+POS, in *unseen* their performance is not only well below chance level, but it is in fact the inverse of their results on *seen*: all instances which are predicted correctly in *seen* are incorrectly predicted in *unseen* (e.g, FiLM obtains ∼85% on *seen* and ∼15% on *unseen*). This suggests that the models learn a default strategy per noun rather than an abstract adjective representation that generalizes to unseen combinations. For example, the models predict *true* any time the size of a circle or a rectangle exceeds a certain threshold, regardless of whether the noun is modified by 'big' (*seen* combinations) or 'small' (*unseen* combinations).

model	avg *seen* ± sd	avg *unseen* ± sd
CNN+LSTM	0.608 ± 0.01	0.4036 ± 0.003
CNN+LSTM+SA	0.7813 ± 0.009	0.235 ± 0.006
FiLM	0.8489 ± 0.014	0.153 ± 0.02
chance	0.5	0.5

Table 3: **Compositional task.** Results by the models.

8 Discussion

We tackle the modeling of size GAs as a *relational* problem in the domain of visual reasoning, and show (in contrast with Kuhnle et al., 2018) that FiLM is able to learn the function underlying the meaning of these expressions. However, none of the models develop an *abstract* representation of GAs that can be applied *compositionally*, an ability that even 4-year-olds master (Barner and Snedeker, 2008). This is in line with recent evidence showing that deep learning models do not rely on systematic compositional rules (Baroni, 2019; Bahdanau et al., 2019).

An interesting open question, which we plan to explore in future work, is whether training models to jointly learn superlative, comparative, and positive GAs (similarly to how Pezzelle et al. (2018) did for quantities), or framing the task in a dialogue setting (as Monroe et al. (2017) did for colors) could lead to more compositional models. Moreover, it might be worth exploring whether equipping models with similar inductive biases as those leading speakers of any language to develop abstract, compositional representations of size adjectives is needed to properly handle these expressions. In parallel, the present work could be extended to other GAs and threshold functions.

In the long term, we aim to move to natural images. This requires world knowledge, a confounding factor intentionally abstracted away in synthetic data. Since children learn to exploit world knowledge after mastering the perceptual context (Tribushinina, 2013), adopting an incremental approach might be promising.

Acknowledgments

We kindly thank Raffaella Bernardi and Elia Bruni for insightful discussions and their comments on an early draft of this paper, Alexander Kuhnle for sharing opinions and details regarding the models, and the audience at talks given at the ILLC and at the Blackbox@NL Workshop held at the Jheronimus Academy of Data Science. We are very grateful to the anonymous reviewers of EMNLP-IJCNLP for their valuable feedback. This work was funded by the Netherlands Organisation for Scientific Research (NWO) under VIDI grant no. 276-89-008, *Asymmetry in Conversation*.

Abstract

Though state-of-the-art sentence representation models can perform tasks requiring significant knowledge of grammar, it is an open question how best to evaluate their grammatical knowledge. We explore five experimental methods inspired by prior work evaluating pretrained sentence representation models. We use a single linguistic phenomenon, negative polarity item (NPI) licensing in English, as a case study for our experiments. NPIs like *any* are grammatical only if they appear in a *licensing environment* like negation (*Sue doesn't have any cats vs. *Sue has any cats*). This phenomenon is challenging because of the variety of NPI licensing environments that exist. We introduce an artificially generated dataset that manipulates key features of NPI licensing for the experiments. We find that BERT has significant knowledge of these features, but its success varies widely across different experimental methods. We conclude that a variety of methods is necessary to reveal all relevant aspects of a model's grammatical knowledge in a given domain.

1 Introduction

Recent sentence representation models have attained state-of-the-art results on language understanding tasks, but standard methodology for evaluating their knowledge of grammar has been slower to emerge. Recent work evaluating grammatical knowledge of sentence encoders like BERT (Devlin et al., 2018) has employed a variety of methods. For example, Shi et al. (2016), Ettinger et al. (2016), and Tenney et al. (2019) use probing tasks to target a model's knowledge of particular grammatical features. Marvin and Linzen (2018) and Wilcox et al. (2019) compare language models' probabilities for pairs of minimally different sentences differing in grammatical acceptability. Linzen et al. (2016), Warstadt et al. (2018), and Kann et al. (2019) use Boolean acceptability judgments inspired by methodologies in generative linguistics. However, we have not yet seen any substantial direct comparison between these methods, and it is not yet clear whether they tend to yield similar conclusions about what a given model knows.

We aim to better understand the trade-offs in task choice by comparing different methods inspired by previous work to evaluate sentence understanding models in a single empirical domain. We choose as our case study negative polarity item (*NPI*) licensing in English, an empirically rich phenomenon widely discussed in the theoretical linguistics literature (Kadmon and Landman, 1993; Giannakidou, 1998; Chierchia, 2013, a.o.). NPIs are words or expressions that can only appear in environments that are, in some sense, *negative* (Fauconnier, 1975; Ladusaw, 1979; Linebarger, 1980). For example, *any* is an NPI because it is acceptable in negative sentences (1) but not positive sentences (2); negation thus serves as an NPI *licensor*. NPIs furthermore cannot be outside the syntactic *scope* of a licensor (3). Intuitively, a licensor's scope is the syntactic domain in which an NPI is licensed, and it varies from licensor to licensor. A sentence with an NPI present is only acceptable in cases where (i) there is a licensor—as in (1) but not (2)—and (ii) the NPI is within the scope of that licensor—as in (1) but not (3).

(1) Mary has**n't** eaten *any* cookies.

(2) *Mary has eaten *any* cookies.

(3) **Any* cookies have**n't** been eaten.

We compare five experimental methods to test BERT's knowledge of NPI licensing. We consider: (i) a *Boolean acceptability classification* task to test BERT's knowledge of sentences in

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2877–2887, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

isolation, (ii) an *absolute minimal pair* task evaluating whether the absolute Boolean outputs of acceptability classifiers distinguish between pairs of minimally different sentences that differ in acceptability and each isolate a single key property of NPI licensing, (iii) a *gradient minimal pair* task evaluating whether the gradient outputs of acceptability classifiers distinguish between minimal pairs, (iv) a *cloze test* evaluating the grammatical preferences of BERT's masked language modeling head, and (v) a *probing task* directly evaluating BERT's representations for knowledge of specific grammatical features relevant to NPI licensing.

We find that BERT does have knowledge of all the key features necessary to predict the acceptability of NPI sentences in our experiments. However, our five methods give meaningfully different results. While the gradient minimal pair experiment and, to a lesser extent, the acceptability classification and cloze tests indicate that BERT has systematic knowledge of all NPI licensing environments and relevant grammatical features, the absolute minimal pair and probing experiments show that BERT's knowledge is in fact not equal across these domains. We conclude that each method depicts different relevant aspects of a model's grammatical knowledge; comparing both gradient and absolute measures of performance of models gives a more complete picture. We recommend that future studies use multiple complementary methods to evaluate model performance.

2 Related Work

Evaluating Sentence Encoders The success of sentence encoders and broader neural network methods in NLP has prompted significant interest in understanding the linguistic knowledge encapsulated in these models.

A portion of related work focuses on Boolean classification tasks of English sentences to evaluate the grammatical knowledge encoded in these models. The objective of this task is to predict whether a single input sentence is acceptable or not, abstracting away from gradience in acceptability judgments. Linzen et al. (2016) train classifiers on this task using data with manipulated verbal inflection to investigate whether LSTMs can identify subject-verb agreement violations, and therefore a (potentially long distance) syntactic dependency. Warstadt et al. (2018) train models on this task using the CoLA corpus of acceptability judgments as a method for evaluating domain general grammatical knowledge, and Warstadt and Bowman (2019) analyze how these domain general classifiers perform on specific linguistic phenomena. Kann et al. (2019) use this task to evaluate whether sentence encoders represent information about verbal argument structure classes.

A related method employs minimal pairs, consisting of two sentences that differ minimally in their content and differ in linguistic acceptability, to judge whether a model is sensitive to a single grammatical feature. Marvin and Linzen (2018) and Wilcox et al. (2019) apply this method to phenomena such as subject-verb agreement, NPI licensing, and reflexive licensing.

Another branch of work uses probing tasks in which the objective is to predict the value of a particular linguistic feature given an input sentence. Probing tasks have been used to investigate whether sentence embeddings encode syntactic and surface features such as tense and voice (Shi et al., 2016), sentence length and word content (Adi et al., 2016), or syntactic depth and morphological number (Conneau et al., 2018). Giulianelli et al. (2018) use diagnostic classifiers to track the propagation of information in RNN-based language models. Ettinger et al. (2018) and Dasgupta et al. (2018) use automatic data generation to evaluate compositional reasoning. Tenney et al. (2019) introduce sub-sentence level probing tasks derived from common NLP tasks.

Negative Polarity Items In the theoretical literature on NPIs, proposals have been made to unify the properties of the diverse NPI licensing environments. For example, a popular view states that NPIs are licensed if and only if they occur in downward entailing (DE) environments (Fauconnier, 1975; Ladusaw, 1979), i.e. an environment that licences inferences from sets to subsets.[1]

For instance, (4) shows that the environment under the scope of negation is DE. The property *been to Paris* is a subset of *been to France*, because those who have been to Paris are a subset of those who have been to France. While the inference from set to subset is normally invalid (4-b), it is valid if the property is embedded under negation (4-a). According to the DE theory of NPI licens-

[1]Other prominent theories of NPI licensing are based on notions of non-veridicality (Giannakidou, 1994, 1998; Zwarts, 1998), domain widening and emphasis (Kadmon and Landman, 1993; Krifka, 1995; Chierchia, 2013), a.o.

ing, this explains the contrast between (1) and (2).

(4) a. I haven't been to France.
$\rightarrow$ I haven't been to Paris. (DE)
b. I have been to France.
$\not\rightarrow$ I have been to Paris. (not DE)

This view does not capture licensing in some environments, for example questions. No theory is yet accepted as identifying the unifying properties of all NPI licensing environments.

Within computational linguistics, NPIs are used as a testing ground for neural network models' grammatical knowledge. Marvin and Linzen (2018) find that LSTM LMs do not systematically prefer sentences with licensed NPIs (1) over sentencew with unlicensed NPIs (2). Jumelet and Hupkes (2018) shows LSTM LMs find a relation between the licensing context and the negative polarity item, and appears to be aware of the scope of this context. Wilcox et al. (2019) use NPIs and filler-gap dependencies, as instances of non-local grammatical dependencies, to probe the effect of supervision with hierarchical structure. They find that structurally-supervised models outperform state-of-the-art sequential LSTM models, showing the importance of structure in learning non-local dependencies like NPI licensing.

CoLA We use the Corpus of Linguistic Acceptability (CoLA; Warstadt et al., 2018) in our experiments to train supervised acceptability classifiers. CoLA is a dataset of over 10k syntactically diverse example sentences from the linguistics literature with Boolean acceptability labels. As is conventional in theoretical linguistics, sentences are taken to be *acceptable* if native speakers judge them to be possible sentences in their language. Such sentences are widely used in linguistics publications to illustrate phenomena of interest. The examples in CoLA are gathered from diverse sources and represent a wide array of syntactic, semantic, and morphological phenomena. As measured by the GLUE benchmark (Wang et al., 2018), acceptability classifiers trained on top of BERT and related models reach near-human performance on CoLA.

3 Methods

We experiment with five approaches to the evaluation of grammatical knowledge of sentence representation models like BERT using our generated NPI acceptability judgment dataset (§4). Each data sample in the dataset contains a sentence, a Boolean label which indicates whether the sentence is grammatically acceptable or not, and three Boolean meta-data variables (licensor, NPI, and scope; Table 2). We evaluate four model types: BERT-large, BERT with fine-tuning on one of two tasks, and a simple bag-of-words baseline using GloVe word embeddings (Pennington et al., 2014).

Boolean Acceptability We test the model's ability to judge the grammatical acceptability of the sentences in the NPI dataset. Following standards in linguistics, sentences for this task are assumed to be either totally acceptable or totally unacceptable. We fine-tune the sentence representation models to perform these Boolean judgments. For BERT-based sentence representation models, we add a classifier on top of the `[CLS]` embedding of the last layer. For BoW, we use a max pooling layer followed by an MLP classifier. The performance of the models is measured as Matthews Correlation Coefficient (MCC; Matthews, 1975)[2] between the predicted label and the gold label.

Absolute Minimal Pair We conduct a minimal pair experiment to analyze Boolean acceptability classifiers on minimally different sentences. Two sentences within paradigm form a minimal pair if they differ in one feature (licensor, NPI, or scope), but have different acceptability. For example, the sentences in (1) and (2) differ in whether an NPI licensor (negation) is present. We evaluate the models trained on acceptability judgments with the minimal pairs. In *absolute minimal pair* evaluation, the models needs to correctly classify both sentences in the pair to be counted as correct.

Gradient Minimal Pair The *gradient minimal pair* evaluation is a more lenient version of *absolute minimal pair* evaluation: Here, we count a pair as correctly classified as long as the Boolean classifier's output for the acceptable class is higher for the acceptable sentence than for the unacceptable sentence. In other words, the classifier need only predict the acceptable sentence has the higher likelihood of being acceptable, but need not correctly predict that it is acceptable.

Cloze Test In the cloze test, a standard sentence-completion task, we use the masked language modeling (MLM) component in BERT (Devlin et al., 2018) and evaluate whether it assigns a

[2]MCC gives the correlation of two Boolean distributions between -1 and 1. A score of 0 is given to any two unrelated distributions, without requiring balanced class sizes.

higher probability to the acceptable sentence in a minimal pair, following Linzen et al. (2016). An MLM predicts the probability of a single masked token based on the rest of the sentence. The minimal pairs tested are a subset of those in the absolute and gradient minimal pair experiments, where both sentences must be equal in length and differ in only one token. This differing token is replaced with `[MASK]`, and the minimal pair is taken to be classified correctly if the MLM assigns a higher probability to the token from the acceptable sentence. In contrast with the other minimal pair experiments, this experiment is entirely unsupervised, using BERT's native MLM functionality.

Feature Probing We use probing classifiers as a more fine-grained approach to the identification of grammatical variables. We freeze the sentence encoders both with and without fine-tuning from the acceptability judgment experiments and train lightweight classifiers on top of them to predict meta-data labels corresponding to the key properties a model must learn in order to judge the acceptability of NPI sentences. These properties are whether a licensor is present, whether an NPI is present, and whether the NPI (or a similar item) is in the syntactic scope of the licensor (or a similar item). Crucially, each individual meta-data label by itself does not decide acceptability (i.e., these probing experiments test a different but related set of knowledge from acceptability experiments).

4 Data

In order to probe BERT's performance on sentences involving NPIs, we generate a set of sentences and acceptability labels for the experiments in this paper. We use generated data so that we can assess minimal pairs, and so that there are sufficient unacceptable sentences. We release all our data[3] and our generation code and vocabulary.[4]

Licensing Features We create a controlled set of 136,000 English sentences using an automated sentence generation procedure, inspired in large part by previous work by Ettinger et al. (2016, 2018), Marvin and Linzen (2018), Dasgupta et al. (2018), and Kann et al. (2019). The set contains nine NPI licensing environments (Table 1), and two NPIs (*any*, *ever*). All but one licensor-NPI pair follows a 2×2×2 paradigm, which manipulates three boolean NPI licensing features: licensor presence, NPI presence, and the occurrence of an NPI within a licensor's scope. Each 2×2×2 paradigm forms 5 minimal pairs. Table 2 shows an example paradigm.

The *Licensor* feature indicates whether an NPI licensor is present in the sentence. For many environments, there are multiple lexical items that serve as a licensor (e.g., the adverbs environment contains *rarely*, *hardly*, *seldom*, *barely*, and *scarcely* as NPI licensors). When the licensor is not present, we substitute it with a *licensor replacement* that has a similar syntactic distribution but does not license NPIs, again using multiple appropriate lexical items as replacements. For example, licensor replacements for quantifier licensors like *every* include quantifiers like *some*, *many*, and *more than three* that do not license NPIs.

The *NPI* feature indicates whether an NPI is in the sentence or if it is substituted by an *NPI replacement* with similar structural distribution. For example, NPI replacements for *ever* include other adverbs such as *often*, *sometimes*, and *certainly*.

The *Scope* feature indicates whether the NPI/NPI replacement is within the scope of the licensor/licensor replacement. As illustrated earlier in (3), a sentence containing an NPI is only acceptable when the NPI falls within the scope of the licensor. What constitutes the scope of a licensor is highly dependent on the type of licensor.

The exception to the 2×2×2 paradigm is the Simple Questions licensing condition, with a reduced 2×2 paradigm. It lacks a scope manipulation because the question takes scope over the entire clause, and in Simple Questions the clause is the whole sentence. The paradigm for Simple Questions is given in Table 3 in the Appendix; it forms only 2 minimal pairs.

Data Generation To generate sentences, we create sentence templates for each condition. Templates follow the general structure illustrated in example (5), in which the part-of-speech (auxiliary verb, determiner, noun, verb), as well as the instance number is specified. For example, N2 is the second instance of a noun in the template. We use these labels here for illustrative purposes; in reality, the templates include more fine-grained properties, such as verb tense and noun number.

Environment	Abbrev.	Example
Adverbs	ADV	The guests who **rarely** love *any* actors had left libraries.
Conditionals	COND	**If** the pedestrian passes *any* schools, the senator will talk to the adults.
Determiner negation	D-NEG	Just as the waitress said, **no** customers thought that *any* dancers bought the dish.
Sentential negation	S-NEG	These drivers have **not** thought that *any* customers have lied.
Only	ONLY	From what the cashier heard, **only** the children have known *any* dancers.
Quantifiers	QNT	**Every** actress who was talking about *any* high schools criticizes the children.
Questions	QUES	The boys wonder **whether** the doctors went to *any* art galleries.
Simple questions	SMP-Q	**Has** the guy worked with *any* teenagers**?**
Superlatives	SUP	The teenagers approach the **nicest** actress that *any* customers had criticized.

Table 1: Examples of each of the NPI licensing environments generated. The licensor is in bold, and the NPI (here *any*) is in italics. All examples show cases where the NPI is present (NPI=1), the licensor is present (Licensor=1), and the NPI is in the scope of the licensor (Scope=1); all are acceptable to native speakers of English.

Licensor	NPI	Scope	Sentence
1	1	1	Those boys wonder **whether** [the doctors *ever* went to an art gallery.]
1	1	0	*Those boys *ever* wonder **whether** [the doctors went to an art gallery.]
1	0	1	Those boys wonder **whether** [the doctors *often* went to an art gallery.]
1	0	0	Those boys *often* wonder **whether** [the doctors went to an art gallery.]
0	1	1	*Those boys say **that** [the doctors *ever* went to an art gallery.]
0	1	0	*Those boys *ever* say **that** [the doctors went to an art gallery.]
0	0	1	Those boys say **that** [the doctors *often* went to an art gallery.]
0	0	0	Those boys *often* say **that** [the doctors went to an art gallery.]

Table 2: Example 2×2×2 paradigm using the Questions environment. The licensor (*whether*) or licensor replacement (*that*) is in bold. The NPI (*ever*) or NPI replacement (*often*) is in italics. When licensor=1, the licensor is present rather than its replacement word. When NPI=1, the NPI is present rather than its replacement. The scope of the licensor/licensor replacement is shown in square brackets (brackets, italicization, and boldface are not present in the actual data). When scope=1, the NPI/NPI replacement is within the scope of the licensor/licensor replacement. Unacceptable sentences are marked with *. The five minimal pairs are connected by arrows that point from the unacceptable to the acceptable sentence.

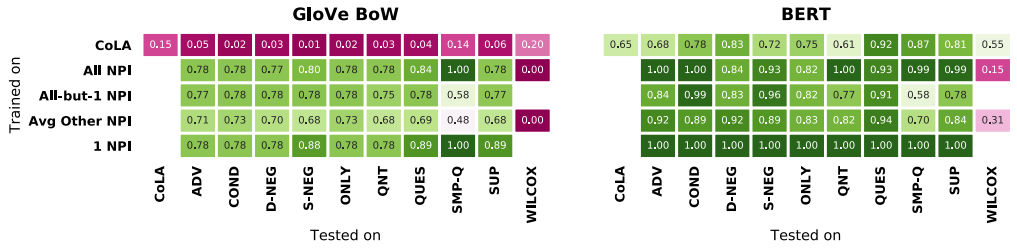

Figure 1: Results from the acceptability judgment experiment in MCC. The columns indicate evaluation tests, and the rows fine-tuning settings.

(5) Aux1 D1 N1 V1 any N2 ?
Has the guy seen any waitresses ?

Given the specifications encoded in the sentence templates, words were sampled from a vocabulary of over 1000 lexical items annotated with 30 syntactic, morphological, and semantic features. The annotated features allow us to encode selectional requirements of lexical items, e.g., what types of nouns a verb can combine with. This avoids blatantly implausible sentences.

For each environment, the training set contains 10K sentences, and the dev and test sets contain 1K sentences each. Sentences from the same paradigm are always in the same set.

In addition to our data set, we also test BERT on a set of 104 handcrafted sentences from the NPI sub-experiment in Wilcox et al. (2019), who use a paradigm that partially overlaps with ours, but has an additional condition where the NPI linearly follows its licensor while not being in the scope of the licensor. This is included as an additional test set for evaluating acceptability classifiers in (6).

Data validation We use Amazon Mechanical Turk (MTurk) to validate a subset of our data to assure that the generated sentences contrast in acceptability as intended. We randomly sample 500 sentences in approximately equal amounts from each environment, NPI and paradigm. Each sentence is rated on a Likert scale of 1-6, with 1 being "the sentence is not possible in English" and 6 being "the sentence is possible in English" by 20 unique participants in the US who self-identified as native English speakers. Participants are compensated $0.25 per HIT and are often able to complete a HIT of 5 sentences in just under 1 minute.

Table 4 in the Appendix shows the participants' scores transformed into a Boolean judgment of 0 (unacceptable, score ≤ 3) or 1 (acceptable, score ≥ 4) and presented as the percentage of 'acceptable' ratings assigned to the sentences in each of the NPI-licensing environments. Across all NPI-licensing environments, 81.3% of the sentences labelled acceptable are assigned an acceptable rating by the MTurk raters, and 85.2% of sentences labeled unacceptable are assigned an unacceptable rating. This gives an overall agreement rating of 82.8%[5]. A Wilcoxon signed-rank test (Wilcoxon, 1945) shows that within each environment and for each NPI, the acceptable sentences are more often rated as acceptable by our MTurk validators than the unacceptable sentences (all p-values < 0.001). This contrast holds considering both the raw Likert-scale responses and the responses transformed to a Boolean judgment.

5 Experimental Settings

We conduct our experiments with the jiant 0.9 [6] (Wang et al., 2019) multitask learning and transfer learning toolkit, the AllenNLP platform (Gardner et al., 2018), and the BERT implementation from HuggingFace.[7]

Models We study the following sentence understanding models: (i) *GloVe BoW*: a bag-of-words baseline obtained by max-pooling of 840B tokens 300-dimensional GloVe word embeddings (Pennington et al., 2014) and (ii) *BERT* (Devlin et al., 2018): we use the cased version of BERT-large model, which works the best for our tasks in pilot experiments. In addition, since recent work (Liu et al., 2019; Stickland and Murray, 2019) has shown that intermediate training on related tasks can meaningfully impact BERT's performance on downstream tasks, we also explore two additional BERT-based models—(iii) *BERT→MNLI*: BERT fine-tuned on the Multi-Genre Natural Language Inference corpus (Williams et al., 2018), motivated both by prior work on pretraining sentence encoders on MNLI (Conneau et al., 2017) as well as work showing significant improvements to BERT on downstream semantic tasks (Phang et al., 2018; Bowman et al., 2018) (iv) *BERT→CCG*: BERT fine-tuned on Combinatory Categorial Grammar Bank corpus (Hockenmaier and Steedman, 2007), motivated by Wilcox et al.'s (2019) finding that structural supervision may improve a LSTM-based sentence encoders knowledge on non-local syntactic dependencies.

Training-Evaluation Configurations We are interested in whether sentence representation models learn NPI licensing as a unified property. Can the models generalize from trained environments to previously unseen environments? To answer these questions, for each NPI environment, we extensively test the performance of the models in the following configurations: (i) *CoLA*: training on CoLA, evaluating on the environment. (ii) *1 NPI*: training and evaluating on the same NPI environment. (iii) *Avg Other NPI*: training independently on every NPI environment except one, averaged over the evaluation results on that environment. (iv) *All-but-1 NPI*: training on all environments except for one environment, evaluating on that environment. (v) *All NPI*: training on all environments, evaluating on the environment.

6 Results

Acceptability Judgments The results in Fig. 1 show that BERT outperforms the BoW baseline on all test data with all fine-tuning settings. Within each BERT variant, MCC reaches 1.0 on all test data in the *1 NPI* setting. In the *All-but-1 NPI* training-evaluation configuration, the performance on all NPI environments for BERT drops. While the MCC value on environments like conditionals and sentential negation remains above 0.9, on the simple question environment it drops to 0.58.

[5] We observe that sentences with 'any' get over-accepted. Overall agreement for sentences with 'ever' is 87.3%, while agreement for those with 'any' is 78.3%. We believe this is due to a free-choice interpretation of 'any' occurring more easily than is often reported in the semantics literature.

Figure 2: Results from the minimal pair test. The top section shows the average accuracy for detecting the presence of the NPI, the middle section shows average accuracy for detecting the presence of the licensor, and the bottom shows average accuracy of minimal pair contrasts that differ in whether the NPI is in scope of the licensor. Within each section, we show performance of GloVe BoW and BERT models under both absolute preference and gradient preference evaluation methods. The rows represent the training-evaluation configuration, while the columns represent different licensing environments.

Compared with NPI data fine-tuning, CoLA fine-tuning results in BERT's lower performance on most of the NPI environments but better performance on data from Wilcox et al. (2019).

In comparing the three BERT variants (see full results in Figure 5 in the Appendix), the *Avg Other NPI* shows that on 7 out of 9 NPI environments, plain BERT outperforms BERT→MNLI and BERT→CCG. Even in the remaining two environments, plain BERT yields about as good performance as BERT→MNLI and BERT→CCG, indicating that MNLI and CCG fine-tuning brings no obvious gain to acceptability judgments.

Absolute and Gradient Minimal Pairs The results (Fig. 2) show that models' performance hinges on how minimal pairs differ. When tested on minimal pairs differing by the presence of an NPI, BoW and plain BERT obtain (nearly) perfect accuracy on both absolute and gradient measures across all settings. For minimal pairs differing by licensor and scope, BERT again achieves near perfect performance on the gradient measure, while BoW does not. On the absolute measure, both BERT and BoW perform worse. Overall, it

shows that absolute judgment is more challenging when targeting licensor, which involves a larger pool of lexical items and syntactic configurations than NPIs; and scope, which requires nontrivial syntactic knowledge about NPI licensing.

As in the acceptability experiment, we find that intermediate fine-tuning on MNLI and CCG does not improve performance (see full results in Figures 6-8 in Appendix).

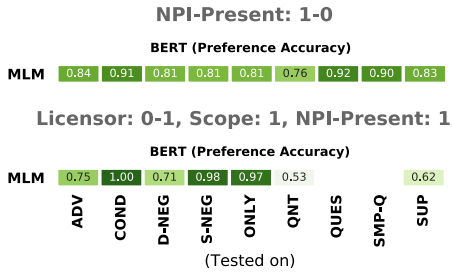

Figure 3: Results of BERT MLM performance in the cloze test. The top section shows the average accuracy for detecting the presence of the NPI; the bottom section show the accuracy for detecting the presence of the licensor. The columns represent different licensing environments

Cloze Test The results (Fig. 3) show that even without supervision on NPI data, the BERT MLM can distinguish between acceptable and unacceptable sentences in the NPI domain. Performance is highly dependent on the NPI-licensing environment and type of minimal pair. Accuracy for detecting NPI presence falls between 0.76 and 0.93 for all environments. Accuracy for detecting licensor presence is much more variable, with the BERT MLM achieving especially high performance in conditional, sentential negation, and *only* environments; and low performance in quantifier and superlative environments.

Feature Probing Results (Fig. 4) show that plain BERT outperforms the BoW baseline in detecting whether NPI is in the scope of the licensor (henceforth 'scope detection'). As expected, BoW is nearly perfect in detecting presence of NPI and licensor, as these tasks do not require knowledge of syntax or word order. Consistent with results from previous experiments, detecting the presence of a licensor is slightly more challenging for models fine-tuned with CoLA or NPI data. However, the overall lower performances in scope detection compared with detecting the presence of the licensor is not found in the minimal-pair experiments.

CoLA fine-tuning improves the performance for BERT, especially for detecting NPI presence. Fine-tuning on NPI data improves scope detection. Inspection of environment-specific results shows that models struggle when the superlative, quantifiers, and adverb environments are the held-out test sets in the All-but-1 NPI fine-tuning setting.

Different from other experiments, BERT and BERT→MNLI have comparable performance across many settings and tasks, beating BERT→CCG especially in scope detection (see full results in Figure 9 in the Appendix).

7 Discussion

We find that BERT systematically represents all features relevant to NPI licensing across most individual licensing environments, according to certain evaluation methods. However, these results vary widely across the different methods we compare. In particular, BERT performs nearly perfectly on the gradient minimal pairs task across all of minimal pair configurations and nearly all licensing environments. Based on this method alone, we might conclude that BERT's knowledge of this domain is near perfect. However, the other methods show a more nuanced picture.

BERT's knowledge of which expressions are NPIs and NPI licensors is generally stronger than its knowledge of the licensors' scope. This is especially apparent from the probing results (Fig. 4). BERT without acceptability fine-tuning performs close to ceiling on detecting the presence of a licensor, but is inconsistent at scope detection. Tellingly, the BoW baseline is also able to perform at ceiling on telling whether a licensor is present. For BoW to succeed at this task, the GloVe embeddings for NPI-licensors must share some common property, most likely the fact that licensors co-occur with NPIs. It is possible that BERT is able to succeed using a similar strategy. By contrast, identifying whether an NPI is in the scope of a licensor requires at the very least word order information and not just co-occurrences.

The contrast in BERT's performance on the gradient and absolute tasks tells us that these evaluations reveal different aspects of BERT's knowledge. The gradient task is strictly easier than the absolute task. On the one hand, BERT's high performance on the gradient task reveals the presence of systematic knowledge in the NPI domain. On the other hand, due to ceiling effects, the gradi-

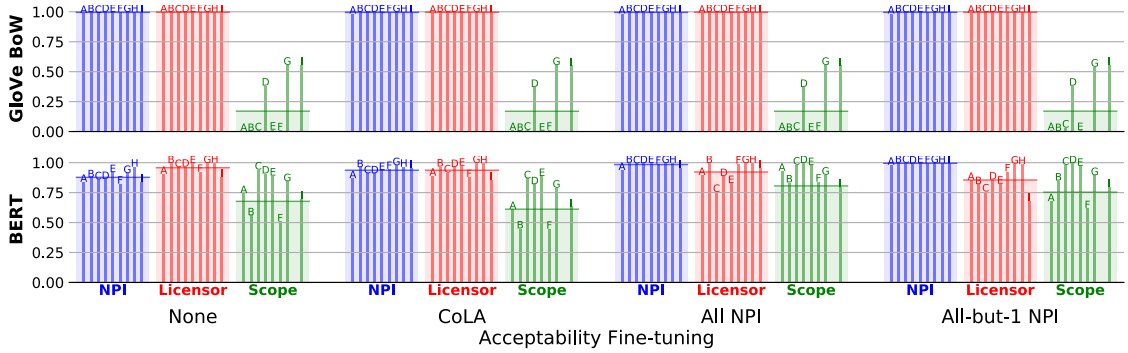

Figure 4: Results of probing classification on NPI presence, licensor presence, and whether the NPI is in the scope of the licensor (scope detection), shown in MCC. Letters on top of bars refer to NPI environments: A=ADV, B=COND, C=D-NEG, D=S-NEG, E=ONLY, F=QNT, G=QUES, H=SMP-Q, I=SUP.

ent task fails to reveal actual differences between NPI-licensing environments that we clearly observe based on absolute, cloze, and probing tasks.

While BERT has systematic knowledge of acceptability contrasts, this knowledge varies across different licensing environments and is not categorical. Generative models of syntax (Chomsky, 1965, 1981, 1995) model human knowledge of natural language as categorical: In that sense BERT fails at attaining human performance. However, some have argued that acceptability is inherently gradient (Lau et al., 2017), and results from the human validation study on our generated dataset show evidence of gradience in the acceptability of sentences in our dataset.

Supplementing BERT with additional pretraining on CCG and MNLI does not improve performance, and even lowers performance in some cases. While results from Phang et al. (2018) lead us to hypothesize that intermediate pretraining might help, this is not what we observe on our data. This result is in direct contrast with the results from Wilcox et al. (2019), who find that syntactic pretraining does improve performance in the NPI domain. This difference in findings is likely due to differences in models and training procedure, as their model is an RNN jointly trained on language modeling and parsing over the much smaller Penn Treebank (Marcus et al., 1993).

Future studies would benefit from employing a variety of different methodologies for assessing model performance withing a specified domain. In particular, a result showing generally good performance for a model should be regarded as possibly hiding actual differences in performance that a different task would reveal. Similarly, generally poor performance for a model does not necessarily mean that the model does not have systematic knowledge in a given domain; it may be that an easier task would reveal systematicity.

8 Conclusion

We have shown that within a well-defined domain of English grammar, evaluation of sentence encoders using different tasks will reveal different aspects of the encoder's knowledge in that domain. By considering results from several evaluation methods, we demonstrate that BERT has systematic knowledge of NPI licensing. However, this knowledge is unequal across the different features relevant to this phenomenon, and does not reflect the Boolean effect that these features have on acceptability.

Representation of Constituents in Neural Language Models: Coordination Phrase as a Case Study

Abstract

Neural language models have achieved state-of-the-art performances on many NLP tasks, and recently have been shown to learn a number of hierarchically-sensitive syntactic dependencies between individual words. However, equally important for language processing is the ability to combine words into phrasal constituents, and use constituent-level features to drive downstream expectations. Here we investigate neural models' ability to represent constituent-level features, using coordinated noun phrases as a case study. We assess whether different neural language models trained on English and French represent phrase-level number and gender features, and use those features to drive downstream expectations. Our results suggest that models use a linear combination of NP constituent number to drive CoordNP/verb number agreement. This behavior is highly regular and even sensitive to local syntactic context, however it differs crucially from observed human behavior. Models have less success with gender agreement. Models trained on large corpora perform best, and there is no obvious advantage for models trained using explicit syntactic supervision.

1 Introduction

Humans deploy structure-sensitive expectations to guide processing during natural language comprehension (Levy, 2008). While it has been shown that neural language models show similar structure-sensitivity in their predictions about upcoming material (Linzen et al., 2016; Futrell et al., 2018), previous work has focused on dependencies that are conditioned by features attached to a single word, such as subject number (Gulordava et al., 2018; Marvin and Linzen, 2018) or wh-question words (Wilcox et al., 2018). There has been no systematic investigation into models' ability to compute phrase-level features—features that are attached to a set of words—and whether models can deploy these more abstract properties to drive downstream expectations.

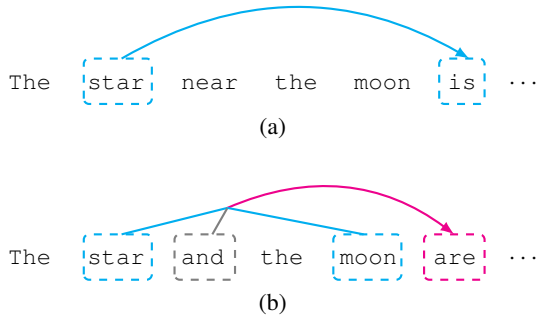

Figure 1: Subject-verb agreement with (a) the head of a noun phrase structure, and (b) the coordination structure.

In this work, we assess whether state-of-the-art neural models can compute and employ phrase-level gender and number features of coordinated subject Noun Phrases (CoordNPs) with two nouns. Typical syntactic phrases are ENDOCENTRIC: they are HEADED by a single child, whose features determine the agreement requirements for the entire phrase. In Figure 1a, for example, the word *star* heads the subject NP *The star*; since *star* is singular, the verb must be singular. CoordNPs lack endocentricity: neither conjunct NP solely determines the features of the NP as a whole. Instead, these feature values are determined by compositional rules sensitive to the features of the conjuncts and the identity of the coordinator. In Figure 1b, because the coordinator is *and*, the subject NP number is plural even though both conjuncts (*the star* and *the moon*) are singular. As this case demonstrates, the agreement behavior for CoordNPs must be driven by more abstract, constituent-level representations, and cannot be reduced to features hosted on a single lexical item.

We use four suites of experiments to assess

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2888–2899, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

whether neural models are able to build up phrase-level representations of CoordNPs on the fly and deploy them to drive humanlike behavior. First, we present a simple control experiment to show that models can represent number and gender features of non-coordinate NPs **(Non-coordination Agreement)**. Second, we show that models modulate their expectations for downstream verb number based on the CoordNP's coordinating conjunction combined with the features of the coordinated nouns **(Simple Coordination)**. We rule out the possibility that models are using simple heuristics by designing a set of stimuli where a simple heuristic would fail due to structural ambiguity **(Complex Coordination)**. The striking success for all models in this experiment indicates that even neural models with no explicit hierarchical bias, trained on a relatively small amount of text are able to learn fine-grained and robust generalizations about the interaction between CoordNPs and local syntactic context. Finally, we use subject–auxiliary inversion to test whether an upstream lexical item modulates model expectation for the phrasal-level features of a downstream CoordNP **(Inverted Coordination)**. Here, we find that all models are insensitive to the fine-grained features of this particular syntactic context. Overall, our results indicate that neural models can learn fine-grained information about the interaction of Coordinated NPs and local syntactic context, but their behavior remains unhumanlike in many key respects.

2 Methods

2.1 Psycholinguistics Paradigm

To determine whether state-of-the-art neural architectures are capable of learning humanlike CoordNP/verb agreement properties, we adopt the psycholinguistics paradigm for model assessment. In this paradigm the models are tested using handcrafted sentences designed to test underlying network knowledge. The assumption here is that if a model implicitly learns humanlike linguistic knowledge during training, its expectations for upcoming words should qualitatively match human expectations in novel contexts. For example, Linzen et al. (2016) and Kuncoro et al. (2016) assessed how well neural models had learned the subject/verb number agreement by feeding them with the prefix *The keys to the cabinet ....* If the models predicted the grammatical continuation *are* over the ungrammatical continuation *is*, they can be said to have learned the number agreement insofar as the number of the head noun and not the number of the distractor noun, *cabinet*, drives expectations about the number of the matrix verb.

	Model	Training data	# tokens
English	LSTM (PTB)	Penn Treebank	$\sim$ 1M
	ActionLSTM (PTB)	Penn Treebank	$\sim$ 1M
	RNNG (PTB)	Penn Treebank	$\sim$ 1M
	LSTM (enWiki)	English Wikipedia	$\sim$ 90M
	LSTM (1B)	1 Billion Word	$\sim$ 800M
French	LSTM (FTB)	French Teebank	$\sim$ 0.5M
	ActionLSTM (FTB)	French Teebank	$\sim$ 0.5M
	RNNG (FTB)	French Teebank	$\sim$ 0.5M
	LSTM (frWaC)	Subset of frWaC	$\sim$ 138M

Table 1: A summary of models tested.

If models are able to robustly modulate their expectations based on the internal components of the CoordNP, this will provide evidence that the networks are building up a context-sensitive phrase-level representation. We quantify model expectations as SURPRISAL VALUES. Surprisal is the negative log-conditional probability $S(x_i) = -\log_2 p(x_i|x_1 \dots x_{i-1})$ of a sentence's i^{th} word x_i given the previous words. Surprisal tells us how strongly x_i is expected in context and is known to correlate with human processing difficulty (Hale, 2001; Levy, 2008; Smith and Levy, 2013). In the CoordNP/Verb agreement studies presented here, cases where the proceeding context sets high expectation for a number-inflected verb form w_i, (e.g. singular 'is') we would expect $S(w_i)$ to be lower than its number-mismatched counterpart (e.g. plural 'are').

2.2 Models Tested

Recurrent Neural Network (RNN) Language Models are trained to output the probability distribution of the upcoming word given a context, without explicitly representing the structure of the context (Sundermeyer et al., 2012; Elman, 1990). We trained two two-layer recurrent neural language models with long short-term memory architecture (Hochreiter and Schmidhuber, 1997) on a relatively small corpus. The first model, referred as '**LSTM (PTB)**' in the following sections, was trained on the sentences from Penn Treebank (Marcus and Marcinkiewicz). The second model, referred as '**LSTM (FTB)**', was trained on the sentences from French Treebank (Abeillé et al., 2003). We set the size of input word embedding and LSTM hidden layer of both models as 256.

We also compare LSTM language models

trained on large corpora. We incorporate two pre-trained English language models: one trained on the Billion Word benchmark (referred as '**LSTM (1B)**') from Jozefowicz et al. (2016), and the other trained on English Wikipedia (referred as '**LSTM (enWiki)**') from Gulordava et al. (2018). For French, we trained a large LSTM language model (referred as '**LSTM (frWaC)**') on a random subset (about 4 million sentences, 138 million word tokens) of the frWaC dataset (Baroni et al., 2009). We set the size of the input embeddings and hidden layers to 400 for the LSTM (frWaC) model since it is trained on a large dataset.

ActionLSTM models the linearized bracketed tree structure of a sentence by learning to predict the next action required to construct a phrase-structure parse (Choe and Charniak, 2016). The action space consists of three possibilities: open a new non-terminal node and opening bracket; generate a terminal node; and close a bracket. To compute surprisal values for a given token, we approximate $P(w_i|w_{1\cdots i-1})$ by marginalizing over the most-likely partial parses found by word-synchronous beam search (Stern et al., 2017).

Generative Recurrent Neural Network Grammars (RNNG) jointly model the word sequence as well as the underlying syntactic structure (Dyer et al., 2016). Following Hale et al. (2018), we estimate surprisal using word-synchronous beam search (Stern et al., 2017). We use the same hyper-parameter settings as Dyer et al. (2016).

The annotation schemes used to train the syntactically-supervised models differ slightly between French and English. In the PTB (English) CoordNPs are flat structures bearing an 'NP' label. In FTB (French), CoordNPs are binary-branching, labeled as NPs, except for the phrasal node dominating the coordinating conjunction, which is labeled 'COORD'. We examine the effects of annotation schemes on model performance in Appendix A. [1]

3 Experiment 1: Non-coordination Agreement

In order to provide a baseline for following experiments, here we assess whether the models tested have learned basic representations of number and gender features for non-coordinated Noun Phrases. We test number agreement in English and French as well as gender agreement in French. Both English and French have two grammatical number feature: SINGULAR (sg) and PLURAL (pl). French has two grammatical gender features: MASCULINE (m) and FEMININE (f).

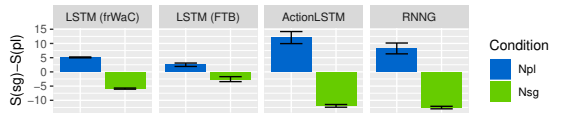
Table 3: Conditions of gender agreement in Non-coordination Agreement experiment.



The experimental materials include sentences where the subject NPs contain a single noun which can either match with the matrix verb (in the case of number agreement) or a following predicative adjective (in the case of gender agreement). Conditions are given in Table 2 and Table 3. We measure model behavior by computing the *plural expectation*, or the surprisal of the singular continuation minus the surprisal of the plural continuation for each condition and took the average for each condition. We expect a positive *plural expectation* in the *Npl* conditions and a negative *plural expectation* in the *Nsg* conditions. For gender expectation we compute a *gender expectation*, which is S(feminine continuation) − S(masculine continuation). We measure surprisal at the verbs and predicative adjectives themselves.

The results for this experiment are in Figure 2, with the *plural expectation* and *gender expectation* on the y-axis and conditions on the x-axis. For this and subsequent experiments error bars represent 95% confidence intervals for across-item means. For number agreement, all the models in English and French show positive plural expectation when the head noun is plural and negative plural expectation when it is singular. For gender agreement, however, only the LSTM (frWaC) shows modulation of gender expectation based on the gender of the head noun. This is most likely due to the lower

frequency of predicative adjectives compared to matrix verbs in the corpus.

4 Experiment 2: Simple Coordination

In this section, we test whether neural language models can use grammatical features hosted on multiple components of a coordination phrase—the coordinated nouns as well as the coordinating conjunction—to drive downstream expectations. We test number agreement in both English and French and gender agreement in French.

4.1 Number Agreement

In simple subject/verb number agreement, the number features of the CoordNP are determined by the coordinating conjunction and the number features of the two coordinated NPs. CoordNPs formed by *and* are plural and thus require plural verbs; CoordNPs formed by *or* allow either plural or singular verbs, often with the number features of the noun linearly closest to the verb playing a more important role, although this varies cross-linguistically (Fowler et al., 1992). Forced-choice preference experiments in Keung and Staub (2018) reveal that English native speakers prefer singular agreement when the closest conjunct in an *or*-CoordNP is singular and plural agreement when the closest conjunct is plural. In French, both singular and plural verbs are possible when two singular NPs are joined via disjunction (Goosse and Grevisse, 2016).

In order to assess whether the neural models learn the basic CoordNP licensing for English, we

Table 4: Conditions of number agreement in Simple Coordination experiment.

adapted 37 items from Keung and Staub (2018), along the 16 conditions outlined in Table 4. Test items consist of the sentence preamble, followed by either the singular or plural *BE* verb, half the time in present tense (*is/are*) and half the time in past tense *(was/were)*. We measured the plural expectation, following the procedure in Section 3. We created 24 items using the same conditions as the English experiment to test the models trained in French, using the 3^{rd} person singular and plural form of verb *aller*, 'to go' (*va, vont*). Within each item, nouns match in gender; across all conditions half the nouns are masculine, half feminine.

The results for this experiment can be seen in Figure 3, with the results for English on the left and French on the right. The results for *and* are on the top row, *or* on the bottom row. For all figures the y-axis shows the plural expectation, or the difference in surprisal between the *singular* condition and the *plural* condition. Turning first to **English-*and*** (Figure 3a), all models show plural expectation (the bars are significantly greater than zero) in the *pl_and_pl* and *sg_and_pl* conditions, as expected. For the *pl_and_sg* condition, only the LSTM (enWiki) and ActionLSTM are greater than zero, indicating humanlike behavior. For the *sg_and_sg* condition, only the LSTM (enWiki) model shows the correct plural expectation. For the **French-*and*** (Figure 3b), all models show positive plural expectation in all conditions, as expected, except for the LSTM (FTB) in the *sg_and_sg* condition.

Examining the results for **English-*or***, we find that all models demonstrate humanlike expectation in the *pl_or_pl* and *sg_or_pl* conditions. The LSTM (1B), LSTM (PTB), and RNNG models show zero or negative singular expectation for the *pl_or_sg* conditions, as expected. However the LSTM (enWiki) and ActionLSTM models show positive plural expectation in this condition, indi-

(b) French and-coordination

(c) English or-coordination

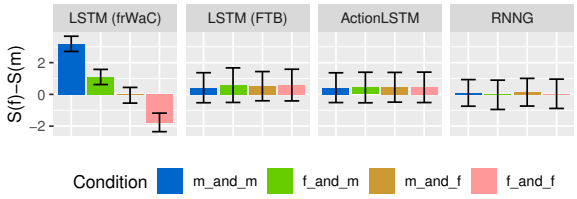
(d) French or-coordination

Figure 3: Comparison of models' expectation preferences for singular vs. plural predicate in English and French Simple Coordination experiments.

cating that they have not learned the humanlike generalizations. All models show significantly negative plural expectation in the *sg_or_sg* condition, as expected. In the **French-*or*** cases, models show almost identical behavior to the *and* conditions, except the LSTM (frWaC) shows smaller plural expectation when singular nouns are linearly proximal to the verb.

These results indicate moderate success at learning coordinate NP agreement, however this success may be the result of an overly simple heuristic. It appears that expectation for both plural and masculine continuations are driven by a linear combination of the two nominal number/gender features transferred into log-probability space, with the earlier noun mattering less than the later noun. A model that optimally captures human grammatical preferences should show no or only slight difference across conditions in the surprisal differential for the *and* conditions, and be greater than zero in all cases. Yet, all the models tested show gradient performance based on the number of plural conjuncts.

4.2 Gender Agreement



In French, if two nouns are coordinated with *et* (*and*-coordination), agreement must be masculine if there is one masculine element in the coordinate structure. If the nouns are coordinated with *ou* (*or*-coordination), both masculine and feminine agreement is acceptable (Corbett, 1991; Wechsler and Zlatić, 2003). Although linear proximity effects have been tested for a number of languages that employ grammatical gender, as in e.g. Slavic languages (Willer et al., 2018), there is no systematic study for French.

Table 5: Conditions for the and-coordination experiment. (Items for or-coordination are the same except that we change the coordinator to *ou*.)

To assess whether the French neural models learned humanlike gender agreement, we created 24 test items, following the examples in Table 5, and measured the masculine expectation. In our test items, the coordinated subject NP is followed by a predicative adjective, which either takes on masculine or feminine gender morphology.

Results from the experiment can be seen in Figure 4. No models shows qualitative difference based on the coordinator, and only the LSTM (frWaC) shows significant behavior difference between conditions. Here, we find positive masculine expectation in the *m_and_m* and *f_and_m* conditions, and negative masculine expectation in the *f_and_f* condition, as expected. However, in the *m_and_f* condition, the masculine expectation is not significantly different from zero, where we would expect it to be positive. In the *or-*

(a) French and-coordination

(b) French or-coordination

Figure 4: Comparison of models' expectation preferences for Feminine v.s. Masculine predicative adjectives in French.

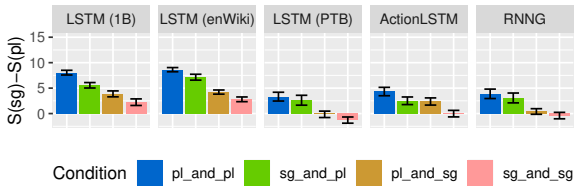
coordination conditions, following our expectation, masculine expectation is positive when both conjuncts are masculine and negative when both are feminine. For the LSTM (FTB) and ActionLSTM models, the masculine expectation is positive (although not significantly so) in all conditions, consistent with results in Section 3.

5 Experiment 3: Complex Coordination

One possible explanation for the results presented in the previous section is that the models are using a 'bag of features' approach to plural and masculine licensing that is opaque to syntactic context: Following a coordinating conjunction surrounded by nouns, models simply expect the following verb to be plural, proportionally to the number of plural nouns.

In this section, we control for this potential confound by conducting two experiments: In the *Complex Coordination Control* experiments we assess models' ability to extend basic CoordNP licensing into sententially-embedded environments, where the CoordNP can serve as an embedded subject. In the *Complex Coordination Critical* experiments, we leverage the sentential embedding environment to demonstrate that when the CoordNPs cannot plausibly serve as the subject of the embedded phrase, models are able to suppress the previously-demonstrated expectations set up by these phrases. These results demonstrate that models are not following a simple strategy for predicting downstream number and gender features, but are building up CoordNP representations on the fly, conditioned on the local syntactic context.

5.1 Complex Coordination Control



Following certain sentential-embedding verbs, CoordNPs serve unambiguously as the subject of the verb's sentence complement and should trigger number agreement behavior in the main verb of the embedded clause, similar to the behavior presented in 4.1. To assess this, we use the 37 test items in English and 24 items in French in section 4.1, following the conditions in Table 6 (for number agreement), testing only *and* coordination. For gender agreement, we use the same test items and conditions for *and* coordination in Section 4.2, but with the Coordinated NPs embedded in a context similar to (1). As before, we derived the plural expectation by measuring the difference in surprisal between the singular and plural continuations and the gender expectation by computing the difference in surprisal between the masculine and feminine predicates.

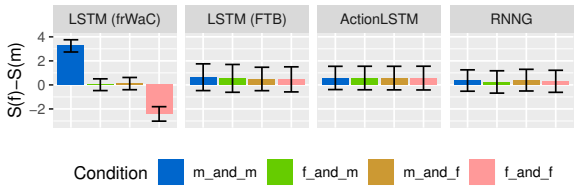
Table 6: Conditions of number agreement in Complex Coordination Control experiment.



The results for the control experiments can be seen in Figure 5, with English number agreement on the top row, French number agreement in the middle row and French gender agreement on the bottom. The y-axis shows either plural or masculine expectation, with the various conditions along the x-axis. For English number agreement, we find that the models behave similarly as they do for simple coordination contexts. All models show significant plural expectation when the closest noun is plural, with only two models demonstrating plural expectation in the *sg_and_sg* case. The French number agreement tests show simi-

lar results, with all models except LSTM (FTB) demonstrating significant plural prediction in all cases. Turning to French gender agreement, only the LSTM (frWaC) shows sensitivity to the various conditions, with positive masculine expectation in the *m_and_m* condition and negative expectation in the *f_and_f* condition, as expected. These results indicate that the behavior shown in Section 4.1 extends to more complex syntactic environments—in this case to sentential embeddings. Interestingly, for some models, such as the LSTM (1B), behavior is *more humanlike* when the CoordNP serves as the subject of an embedded sentence. This may be because the model, which has a large number of hidden states and may be extra sensitive to fine-grained syntactic information carried on lexical items (Futrell et al., 2018), is using the complementizer, *that*, to drive more robust expectations.

5.2 Complex Coordination Critical

In order to assess whether the models' strategy for CoordNP/verb number agreement is sensitive to syntactic context, we contrast the results presented above to those from a second, critical experiment. Here, two coordinated nouns follow a verb that cannot take a sentential complement, as in the examples given in Table 7. Of the two possible continuations—*are* or *is*—the plural is only grammatically licensed when the second of the two conjuncts is plural. In these cases, the plural continuation may lead to a final sentence where the first noun serves as the verb's object and the second introduces a second main clause coordinated with the first, as in *I fixed the doors and the windows are still broken.* For the same reason, the singular-verb continuation is only licensed when the noun immediately following *and* is singular.

We created 37 test items in both English and French, and calculated the plural expectation. If the models were following a simple strategy to drive CoordNP/verb number agreement, then we should see either no difference in plural expectation across the four conditions or behavior no different from the control experiment. If, however, the models are sensitive to the licensing context, we should see a contrast based solely on the number features of the second conjunct, where plural expectation is positive when the second conjunct is plural, and negative otherwise.

Vpl_Npl	What are the doors and
Vpl_Nsg	What are the door and
Vsg_Nsg	What is the door and

Table 8: Conditions in Inverted Coordination experiment.

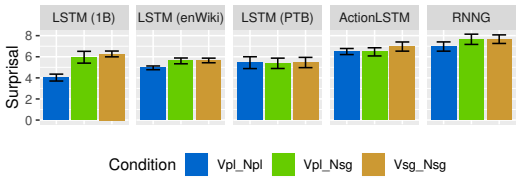
Experimental items for a critical gender test were created similarly, as in Example (2). As with plural agreement, gender expectation should be driven solely by the second conjunct: For the *f_and_m* and *m_and_m* conditions, the only grammatical continuation is one where the adjectival predicate bears masculine gender morphology. Conversely, for the *m_and_f* or *f_and_f* conditions, the only grammatical continuation is one where the adjectival predicate bears feminine morphology. As in 4.1, we created 24 test items and measured the gender expectation by calculating the difference in surprisal between the masculine and feminine continuations.

(2) Nous avons accepté les prix et les
we have accepted the.PL price.MPL and the
dépenses étaient importants/importantes.
expense.FPL were important.MPL/FPL
We have accepted the prices and the expenses were important.

The results from the critical experiments are in Figure 6, with the English number agreement on the top row, French number agreement in the middle and gender expectation on the bottom row. Here the y-axis shows either plural expectation or masculine expectation, with the various conditions are on the x-axis. The results here are strikingly different from those in the control experiments. For number agreement, all models in both languages show strong plural expectation in conditions where the second noun is plural (blue and green bars), as they do in the control experiments. Crucially, when the second noun is singular, the plural expectation is significantly negative for all models (save for the French LSTM (FTB) *pl_and_sg* condition). Turning to gender agreement, only the LSTM (frWaC) model shows differentiation between the four conditions tested. However, whereas the *f_and_m* and *m_and_f* gender expectations are not significantly different from zero in the control condition, in the critical condition they pattern with the purely masculine and purely feminine conditions, indicating that, in this syntactic context, the model has successfully learned to base gender expectation solely off of the second noun.

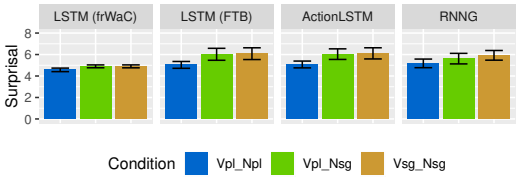
These results are inconsistent with a simple 'bag of features' strategy that is insensitive to local syntactic context. They indicate that both models can interpret the same string as either a coordinated noun phrase, or as an NP object and the start of a coordinated VP with the second NP as its subject.

6 Experiment 4: Inverted Coordination



In addition to using phrase-level features to drive expectation about downstream lexical items, human processors can do the inverse—use lexical features to drive expectations about upcoming syntactic chunks. In this experiment, we assess whether neural models use number features hosted on a verb to modulate their expectations for upcoming CoordNPs.

To assess whether neural language models learn inverted coordination rules, we adapted items from Section 4.1 in both English (37 items) and French (24 items), following the paradigm in Table 8. The first part of the phrase contains either a plural or singular verb and a plural or singular noun. In this case, we sample the surprisal for the continuations *and* (*or* is grammatical in all conditions, so it is omitted from this study). Our expectation is that 'and' is less surprising in the *Vpl_Nsg* condition than in the *Vsg_Nsg* condition, where a CoordNP is not licensed by the grammar in either French or English (as in **What is the pig and the cat eating?*). We also expect lower surprisal for *and* in the *Vpl_Nsg* condition, where it is obligatory for a grammatical continuation, than in the *Vpl_Npl* condition, where it is optional.



For French experimental items, the question is embedded into a sentential-complement taking verb, following Example (3), due to the fact that unembedded subject-verb inverted questions sound very formal and might be relatively rare in the training data.

(3) Je me demande où vont le
I myself ask where go.3PL the.MSG
maire et
mayor.MSG and

The results for both languages are shown in Figure 7, with the surprisal at the coordinator on the y-axis and the various conditions on the x-axis. No model in either language shows a signficant difference in surprisal between the *Vpl_Nsg* and *Vpl_Npl* conditions or between the *Vpl_Nsg* and *Vsg_Nsg* conditions. The LSTM (1B) shows significant difference between the *Vpl_Nsg* and *Vpl_Npl* conditions, but in the opposite direction than expected, with the coordinator less surprising in the latter condition. These results indicate that the models are unable to use the fine-grained context sensitivity to drive expectations for CoordNPs, at least in the inversion setting.

(a) English

(b) French

Figure 7: Comparison of models' surprisals of *and*-coordination in Inverted Coordination experiment.

7 Discussion

The experiments presented here extend and refine a line of research investigating what linguistic knowledge is acquired by neural language models. Previous studies have demonstrated that sequential models trained on a simple regime of optimizing the next word can learn long-distance syntactic dependencies in impressive detail. Our results provide complimentary insights, demonstrating that a range of model architectures trained on a variety of datasets can learn fine-grained information about the interaction of CoordNPs and local syntactic context, but their behavior remains unhumanlike in many key ways. Furthermore, to our best knowledge, this work presents the first psycholinguistic analysis of neural language models trained on French, a high-resource language that has so far been under-investigated in this line of research.

In the **simple coordination** experiment, we demonstrated that models were able to capture some of the agreement behaviors of humans, although their performance deviated in crucial aspects. Whereas human behavior is best modeled as a 'percolation' process, the neural models appear to be using a linear combination of NP constituent number to drive CoordNP/verb number agreement, with the second noun weighted more heavily than the first. In these experiments, supervision afforded by the RNNG and ActionLSTM models did not translate into more robust or humanlike learning outcomes. The **complex coordination** experiments provided evidence that the neural models tested were not using a simple 'bag of features' strategy, but were sensitive to syntactic context. All models tested were able to interpret material that had similar surface form in ways that corresponded to two different tree-structural descriptions, based on local context. The **inverted coordination** experiment provided a contrasting example, in which models were unable to modulate expectations based on subtleties in the syntactic environment.

Across all our experiments, the French models performed consistently better on subject/verb number agreement than on subject/predicate gender agreement. Although there are likely more examples of subject/verb number agreement in the French training data, gender agreement is syntactically mandated and widespread in French. It remains an open question why all but one of the models tested were unable to leverage the numerous examples of gender agreement seen in various contexts during training to drive correct subject/predicate expectations.

(a) PTB-control

(b) PTB-coord

Figure 8: Comparison of annotation schemes of coordination structure.

A The Effect of Annotation Schemes

This section further investigates the effects of CoordNP annotation schemes on the behaviors of structurally-supervised models. We test whether an explicit COORD phrasal tag improves model performance. We trained two additional RNNG models on 38,546 sentences from the Penn Treebank annotated with two different schemes: The first, **RNNG (PTB-control)** was trained with the original Penn Treebank annotation. The second, **RNNG (PTB-coord)**, was trained on the same sentences, but with an extended coordination annotation scheme, meant to employ the scheme employed in the FTB, adapted from Ficler and Goldberg (2016). We stripped empty categories from their scheme and only kept the NP-COORD label for constituents inside a coordination structure. Figure 8 illustrates the detailed annotation differences between two datasets. We tested both models on all the experiments presented in Sections 3-6 above.

Turning to the results of these six experiments: We see little difference between the two models in the *Non-coordination agreement* experiment. For the *Complex coordination control* and *Complex coordination critical* experiments, both models are largely the same as well. However, in the *Simple and-coordination* and *Simple or-coordination* experiments the values for all conditions are shifted upwards for the RNNG PTB-coord model, indicating higher over-all preference for the plural continuation. Furthermore, the range of values is reduced in the RNNG PTB-coord model, compared to the RNNG PTB-control model. These results indicate that adding an explicit COORD phrasal label does not drastically change model performance: Both models still appear to be using a linear combination of number features to drive plural vs. singular expectation. However, the explicit representation has made the interior of the coordination phrase more opaque to the model (each feature matters less) and has slightly shifted model preference towards plural continuations. In this sense, the PTB-coord model may have learned a generalization about CoordNPs, but this generalization remains unlike the ones learned by humans.

Abstract

Can we construct a neural language model which is inductively biased towards learning *human* language? Motivated by this question, we aim at constructing an informative prior for held-out languages on the task of character-level, open-vocabulary language modeling. We obtain this prior as the posterior over network weights conditioned on the data from a sample of training languages. This prior is approximated through Laplace's method. Based on a large and diverse sample of languages, the use of our prior outperforms baseline models with an uninformative prior in both zero-shot and few-shot settings, showing that the prior is imbued with universal linguistic knowledge. Moreover, we harness broad language-specific information available for most languages of the world, i.e., features from typological databases, as distant supervision for held-out languages. We explore several language modeling conditioning techniques, which appear beneficial in the few-shot setting, but ineffective in the zero-shot setting. Since the paucity of even plain digital text affects the majority of the world's languages, we hope that these insights will broaden the scope of applications for language technology.

1 Introduction

With the success of recurrent neural networks and other black-box models on core NLP tasks, such as language modelling, researchers have turned their attention to the study of the inductive bias such neural models exhibit (Linzen et al., 2016; Marvin and Linzen, 2018; Ravfogel et al., 2018). A number of natural questions have been asked. For example, do recurrent neural language models learn syntax (Marvin and Linzen, 2018)? Do they map onto grammaticality judgements (Warstadt et al., 2018)? However, as Ravfogel et al. (2019) note, "[m]ost of the work so far has focused on English." Moreover, these studies have almost always focused on training scenarios where a large number of in-language sentences are available.

In this work, we aim to find a prior distribution over network parameters that generalize well for human language. The recent vein of research on the inductive biases of neural nets implicitly assumes a uniform (unnormalizable) prior over the space of neural network parameters (Ravfogel et al., 2019, *inter alia*). In contrast, we take a Bayesian-updating approach and construct a suitable prior by approximating the posterior distribution over the network parameters conditioned on the data from a sample of *seen* training languages using the Laplace method (Azevedo-Filho and Shachter, 1994). The posterior distribution serves as a prior for maximum-a-posteriori (MAP) estimation of network parameters for the held-out unseen languages.

The search for a universal prior for linguistic knowledge is motivated by the notion of Universal Grammar (UG), originally proposed by Chomsky (1959). The presence of innate biological properties of the brain that constrain possible human languages was posited to explain why human children learn human languages so quickly despite the poverty of the stimulus (Chomsky, 1978; Legate and Yang, 2002). In turn, UG has been connected with Greenberg (1963)'s typological universals by Graffi (1980) and Gilligan (1989): this way, the patterns observed in cross-lingual variation could be explained by the language-specific configuration of an innate set of parameters.

Our study explores the task of character-level, open-vocabulary language modeling to allow for intercomparability between the performance of different models across different languages (Gerz et al., 2018a,b; Cotterell et al., 2018; Mielke et al., 2019). We run experiments under several regimes of data scarcity for the held-out languages (zero-shot, few-shot, and joint multilingual learning) over a sample

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2900–2910, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of 77 typologically diverse languages.

Realistically, a model should not be completely in the dark about held-out languages, as coarse-grained features about general linguistic properties are documented for most world's languages and available in typological databases such as URIEL (Littell et al., 2017). Hence, we also explore a regime where we condition the universal prior over the weights on typological side information. In particular, we consider concatenating typological features to hidden states (Östling and Tiedemann, 2017) and generating the network parameters based on the typological features (Platanios et al., 2018).

Empirically, given the results of our study, we offer two findings. The first is that neural recurrent models with a universal prior significantly outperform baselines with uninformative priors both in zero-shot and few-shot training settings. Secondly, conditioning on typological features further reduces bytes per character in the few-shot setting, but we report negative results for the zero-shot setting, possibly due to some inherent limitations of typological databases (Ponti et al., 2018a).

The study of low-resource language modelling also has a practical impact. According to Simons (2017), 45.71% of the world's languages do not have written texts available. The situation is even more dire for their *digital* footprint. As of March 2015, just 40 out of the 188 languages documented on the Internet accounted for 99.99% of the web pages.[1] And as of April 2019, Wikipedia is translated only in 304 out of the 7097 existing languages. What is more, Kornai (2013) prognosticates that the digital divide will act as a catalyst for the extinction of many of the world's languages. The transfer of language technology may help reverse this course and give space to unrepresented communities.

2 LSTM Language Models

In this work, we address the task of *character-level* language modeling. Whereas word lexicalization is mostly arbitrary across languages, phonemes allow for transfer of universal constraints on phonotactics[2] and language-specific sequences that may be shared across languages, such as borrowings and genetically related words (Brown et al., 2008). Since languages are mostly recorded in text rather than phonemic symbols (IPA), however, we focus on characters as a substitute of phonemes.

Let Σ^ℓ be the set of characters for language ℓ. For a collection of languages $\mathcal{D}$, let $\Sigma = \cup^{\ell \in \mathcal{D}} \Sigma^\ell$ be the union of characters in all languages. A universal, character-level language model is then a probability distribution over Σ^*.[3] Let $\mathbf{x} \in \Sigma^*$ be a sequence of characters. We write:

$$p(\mathbf{x} \mid \mathbf{w}) = \prod_{t=1}^{n} p(x_t \mid \mathbf{x}_{<t}, \mathbf{w}) \quad (1)$$

where x_0 is a distinguished beginning-of-sentence symbol and t is a time step.

We implement character-level language models with Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997). These encode the entire history $\mathbf{x}_{<t}$ as a fixed-length vector by manipulating a memory cell $\mathbf{c}_t$ through a set of gates. Then we define

$$p(x_t \mid \mathbf{h}_t, \mathbf{w}) = \mathit{softmax}(\mathbf{W}\,\mathbf{h}_t + \mathbf{b}). \quad (2)$$

Since we tie $\mathbf{W}$ to the character embeddings $\mathbf{X}$, $\mathbf{W} = \mathbf{X}^\top$. The parameters $\mathbf{w}$ are typically optimized to maximize the likelihood of token input sequences. LSTMs have an advantage over other recurrent architectures as memory gating mitigates the problem of vanishing gradients and captures long-distance dependencies (Pascanu et al., 2013).

3 Neural Language Modelling with a Universal Prior

The fundamental hypothesis of this work is that there exists a prior $p(\mathbf{w})$ over the weights of a neural language model that places high probability on networks that describe human-like languages. The inductive bias in such a prior will facilitate the training of language models for *unseen* languages. Our goal is to estimate the prior as the posterior distribution over the weights of a language model of *seen* languages. Taking a Bayesian approach, with $\mathcal{D}_t$ as the set of training languages, the posterior over weights is given by the Bayes' rule:

$$\underbrace{p(\mathbf{w} \mid \mathcal{D}_t)}_{\textit{posterior}} \propto \underbrace{\prod^{\ell \in \mathcal{D}_t} p(\mathbf{x}^\ell \mid \mathbf{w})}_{\textit{likelihood}} \times \underbrace{p(\mathbf{w})}_{\textit{prior}} \quad (3)$$

[1] https://w3techs.com/technologies/overview/content_language/all

[2] E.g. with few exceptions (Evans and Levinson, 2009, sec. 2.2.2), the basic syllabic structure is vowel–consonant.

[3] Note that Σ is also augmented with punctuation and white space, and distinguished beginning-of-sequence and end-of-sequence symbols, respectively.

Computation of the posterior $p(\mathbf{w} \mid \mathcal{D})$ is woefully intractable: recall that each $p(\mathbf{x} \mid \mathbf{w})$ is in our setting an LSTM language model, like the one defined in eq. (2). We take the prior to be a Gaussian, i.e.

$$p(\mathbf{w}) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{1}{2\sigma^2}||\mathbf{w}||_2^2\right) \quad (4)$$

with zero mean and covariance matrix $\sigma^2 I$. Here, we opt for a simple approximation to the posterior, using the classic Laplace method (Azevedo-Filho and Shachter, 1994). This method has recently been applied to other transfer learning tasks in the neural network literature (Kirkpatrick et al., 2017; Kochurov et al., 2018; Ritter et al., 2018).

In §3.1, we first introduce the Laplace method, which approximates the posterior with a Gaussian.[4] The mean and covariance matrix are chosen through an optimization-based procedure, so it is amenable to computation with backpropagation, as detailed in §3.2. Finally, we describe how to use this distribution as a prior to perform maximum-a-posteriori inference over new data in §3.3.

3.1 Laplace Method

First, we (locally) maximize the log-likelihood of the data in all the training languages plus the prior:[5]

$$\mathcal{L}(\mathbf{w}) = \sum^{\ell \in \mathcal{D}_t} \log p(\mathbf{x}^\ell \mid \mathbf{w}) + \log p(\mathbf{w}) \quad (5)$$

We note that this is equivalent to the log-posterior up to an additive constant, i.e.,

$$\log p(\mathbf{w} \mid \mathcal{D}_t) = \mathcal{L}(\mathbf{w}) - \log p(\mathbf{x}^\ell) \quad (6)$$

where the constant $\log p(\mathbf{x}^\ell)$ is the log-normalizer for the posterior by the Bayes' rule. Let $\mathbf{w}^\star$ be a local maximizer of $\mathcal{L}$. We now approximate the log-posterior with a second-order Taylor expansion around the local maximizer $\mathbf{w}^\star$:

$$\log p(\mathbf{w} \mid \mathcal{D}_t) \quad (7)$$
$$\approx \mathcal{L}(\mathbf{w}^\star) + \frac{1}{2}(\mathbf{w} - \mathbf{w}^\star)^\top \mathbf{H} (\mathbf{w} - \mathbf{w}^\star)$$

where we have omitted the first-order term, since the gradient $\nabla_{\mathcal{L}}$ at the local maximizer $\mathbf{w}^\star$ is zero. Note that we have defined $\mathbf{H}$ as the Hessian. This quadratic approximation to the log-posterior implies that the approximate posterior is Gaussian. This can be seen by exponentiating both sides in eq. (7):

$$p(\mathbf{w} \mid \mathcal{D}_t) \propto \exp\left(\frac{1}{2}(\mathbf{w} - \mathbf{w}^\star)^\top \mathbf{H} (\mathbf{w} - \mathbf{w}^\star)\right) \quad (8)$$

where $\mathcal{L}(\mathbf{w}^\star)$ and $\log p(\mathbf{x}^\ell)$ are absorbed into the Gaussian's normalization constant, which may be computed analytically. Because $\mathbf{w}^\star$ is a local maximizer, $\mathbf{H}$ is a negative-definite matrix. In principle, computing the Hessian is possible through running backpropagation twice: This yields a matrix with d^2 entries. However, in practice, this is not possible. First, running backpropagation twice is tedious. Second, we can not easily store a matrix with d^2 entries since d is the number of parameter in the neural language model.

3.2 Approximating the Hessian

To cut the computation down to one pass, we exploit a property from theoretical statistics: Namely, that the Hessian of the log-likelihood bears a close resemblance to a quantity known as the Fisher information matrix. This connection allows us to develop a more efficient algorithm that approximates the Hessian with one pass of backpropagation.

We derive this approximation to the Hessian of $\mathcal{L}(\mathbf{w})$ here. First, we note that due to the linearity of ∇^2, we have

$$\mathbf{H} = \nabla^2 \mathcal{L}(\mathbf{w}) \quad (9)$$
$$= \nabla^2 \left(\sum^{\ell \in \mathcal{D}} \log p(\mathbf{x}^\ell \mid \mathbf{w}) + \log p(\mathbf{w})\right) \quad (10)$$
$$= \underbrace{\sum^{\ell \in \mathcal{D}} \nabla^2 \log p(\mathbf{x}^\ell \mid \mathbf{w})}_{\textit{likelihood}} + \underbrace{\nabla^2 \log p(\mathbf{w})}_{\textit{prior}} \quad (11)$$

We discuss each term individually. First, to approximate the likelihood term, we draw on the relation between the Hessian and the Fisher information matrix. A basic fact from information theory (Cover and Thomas, 2006) gives us that the Fisher information matrix may be written in two equivalent ways:

$$-\mathbb{E}_{\mathbf{x}^\ell}\left[\nabla^2 \log p(\mathbf{x}^\ell \mid \mathbf{w})\right] \quad (12)$$
$$= \underbrace{\mathbb{E}_{\mathbf{x}^\ell}\left[\nabla \log p(\mathbf{x}^\ell \mid \mathbf{w}) \nabla \log p(\mathbf{x}^\ell \mid \mathbf{w})^\top\right]}_{\textit{expected Fisher information matrix}}$$

[4] Note that, in general, the true posterior is multi-modal. The Laplace method instead approximates it with a unimodal distribution.

[5] In this case, we provide an uninformative prior $\mathcal{N}(0, 1)$.

Note that the integral over all possible languages $\mathbf{x}^\ell$ is a discrete summation, so we may exchange summands and derivatives such as is required for the proof. This equality suggests a natural approximation of the expected Fisher information matrix, the *observed* Fisher information matrix $\mathbf{F}$

$$-\frac{1}{|\mathcal{D}|}\sum^{\ell\in\mathcal{D}}\nabla^2\log p(\mathbf{x}^\ell \mid \mathbf{w}) \tag{13}$$
$$\approx \underbrace{\frac{1}{|\mathcal{D}|}\sum^{\ell\in\mathcal{D}}\nabla\log p(\mathbf{x}^\ell \mid \mathbf{w})\,\nabla\log p(\mathbf{x}^\ell \mid \mathbf{w})^\top}_{\textit{observed Fisher information matrix}}$$

which is tight in the limit as $|\mathcal{D}| \to \infty$ due to the law of large numbers. Indeed, when we have a large number of training exemplars, the average of the outer products of the gradients will be a good approximation to the Hessian. However, even $\mathbf{F}$ still has d^2 entries, which is far too many to be practical. Thus, we further use a diagonal approximation. We denote the diagonal of the observed Fisher information matrix as the vector $\mathbf{f} \in \mathbb{R}^d$ where we define

$$f_i = \sum^{\ell\in\mathcal{D}}\Big(\nabla\log p(\mathbf{x}^\ell \mid \mathbf{w})\Big)_i^2 \tag{14}$$

which yields the $\mathit{diag}(\mathbf{F})$.

Computation of the Hessian of the prior term is more straight-forward and does not require approximation. Indeed, in the general case it is the inverse covariance matrix, which means in our case we have

$$\nabla^2\log p(\mathbf{w}) = \frac{1}{\sigma^2}I \tag{15}$$

This yields the final diagonal approximation to the Hessian

$$\tilde{\mathbf{H}} = -\mathit{diag}(\mathbf{f}) + \frac{1}{\sigma^2}I \tag{16}$$

In practice, computing the Laplace approximation may be achieved through backpropagation with a few tricks:[6] A gradient-based optimization method is used to locally optimize $\mathcal{L}$.[7] Then, since a neural network typically has millions of parameters and $\mathbf{H}$ would be intractable to even store, we approximate it with the Hessian's diagonal matrix.

[6]While it is intractable to compute the normalizing constant, and hence the posterior, the gradient of this constant with respect to the neural network's weights is zero and, thus, irrelevant for optimization.

[7]In practice, non-convex optimization is only guaranteed to reach a critical (saddle) point. However, the derivation of Laplace's method assumes we do reach a local maximizer.

3.3 MAP Inference

Finally, we use the posterior $p(\mathbf{w} \mid \mathcal{D}_t)$ as the prior over model parameters for training a language model on new held-out languages. We incorporate this prior through MAP estimation, by augmenting the optimization of the likelihood of the new data with a regularization term. This is only an approximation to full Bayes estimators, because it does not characterize the entire distribution of the posterior, but rather just the mode (Gelman et al., 2013).

In the zero-shot setting, this boils down to using the mean of the prior as network parameters. In the few-shot setting instead, we assume that some data for the target language $\mathcal{D}_e$ is available, so we treat the posterior as a prior over the weights and update the weights accordingly. In particular, we maximize the log-likelihood of the target language data and the regularizer derived through the Laplace Approximation scaled by a factor λ:

$$\mathcal{L}(\mathbf{w}) = \sum^{\ell\in\mathcal{D}_e}\log p(\mathbf{x}^\ell \mid \mathbf{w}) + \frac{\lambda}{2}(\mathbf{w}-\mathbf{w}^\star)^\top\tilde{\mathbf{H}}\,(\mathbf{w}-\mathbf{w}^\star) \tag{17}$$

As a baseline for the UNIV prior, we perform Maximum A Posteriori inference with an uninformative prior $\mathcal{N}(0,1)$. We label this model NINF. In the zero-shot setting, this means that the parameters are sampled from the uninformative prior. In the few-shot setting, we maximize the likelihood of the data for the held-out language while minimizing a regularizer that reduces to $\frac{\lambda}{2}||1\odot(\mathbf{w}-0)||_2^2 = \frac{\lambda}{2}\mathbf{w}^2$. Note that, owing to the uninformative prior, the uninformed NINF models do not have access to the posterior of the weights given the data from the training languages.

Moreover, we consider a common approach for neural transfer learning (Ruder, 2017), which lies outside the Bayesian framework, as an additional baseline. Namely, after optimizing the weights on the training data, those are simply fine-tuned on the held-out data, until finding a new local maximizer. We label this method FITU.

4 Language Modeling Conditioned on Typological Features

Realistically, the prior over network weights should also be augmented with side information about the general properties of the held-out language to be

learnt, if such information is available. In fact, linguists have documented such information even for languages without plain digital texts available, and stored it in publicly accessible databases (Croft, 2002; Dryer and Haspelmath, 2013). This information usually takes the form of features that express either: i) the formal strategies each language employs to express a specific semantic / functional construction (Croft et al., 2017). For instance, English expresses the construction of nominal predication with a copula strategy; or ii) the presence or absence of specific phenomena. For instance, English possesses a grammatical category for tense.

The usage of such features to inform neural NLP models is still scarce, partly because the evidence in their favour is mixed (Ponti et al., 2018b,a). In this work, we propose a way to distantly supervise the model with this *side information* effectively. We extend our non-conditional language model with a universal prior (BARE) to a series of architectures *conditioned* on language-specific properties that have been proposed in previous work (Östling and Tiedemann, 2017; Platanios et al., 2018). A fundamental difference, however, is that these learn such properties in an end-to-end fashion from the data in a joint multilingual learning setting. Obviously, this is not feasible for the zero-shot setting and unreliable for the few-shot setting. Rather, we represent languages with their typological feature vector, which we assume readily available both for training and for held-out languages.

Let $\mathbf{t}^\ell \in [0,1]^d$ be a vector of typological features for language $\ell \in \mathcal{D}_t \cup \mathcal{D}_e$. We reinterpret the conditional language models within the Bayesian framework as estimating the posterior probability

$$\prod^{\ell \in \mathcal{D}} p(\mathbf{x}^\ell \mid \mathbf{w}, \mathbf{t}^\ell) \times p(\mathbf{w} \mid \mathbf{t}^\ell). \quad (18)$$

We now outline several candidate methods to estimate $p(\mathbf{w} \mid \mathbf{t}^\ell)$. We first encode the features through a non-linear transformation $f(\mathbf{t}) = \text{ReLU}(\mathbf{W}\,\mathbf{t} + b)$. A first variant, labeled OEST, is inspired by Östling and Tiedemann (2017). Assuming the standard LSTM architecture where $\mathbf{o}_t$ is the output gate and $\mathbf{c}_t$ is the memory cell, we modify the equation for the hidden state $\mathbf{h}_t$ as follows:

$$\mathbf{h}_t = o_t \odot \tanh(\mathbf{c}_t) \oplus f(\mathbf{t}^\ell) \quad (19)$$

In other words, we concatenate the typological features to all the hidden states.

Moreover, we experiment with a second variant where the parameters of the LSTM are generated by a meta-network (i.e., a simple linear layer with weight $W^{d \times |\mathbf{w}|}$) that transforms $\mathbf{t}^\ell$ into $\mathbf{w}$. This approach, labeled PLAT, is inspired by Platanios et al. (2018), with the additional difference that they generate parameters for an encoder-decoder.

On the other hand, we do not consider the conditional model proposed by Sutskever et al. (2014), where $f(\mathbf{t})$ would be used to initialize the values for $\mathbf{h}_0$ and $\mathbf{c}_0$. During evaluation, $\mathbf{h}$ and $\mathbf{c}$ are never reset on sentence boundaries, so this model would find itself at disadvantage because it would require to erase the sequential history cyclically.

5 Experimental Setup

Data Our text data source is the Bible corpus[8] (Christodouloupoulos and Steedman, 2015).[9] We exclude languages that are not written in the Latin script and duplicate languages, resulting in a subsample of 77 languages.[10] Since not all translations cover the entire Bible, they vary in size. The text from each language is split into training, development, and evaluation sets with a ratio of 80/10/10%. Moreover, for the MAP inference in the few-shot setting, we randomly sample 100 sentences from each training set.

We obtain the typological feature vectors from URIEL (Littell et al., 2017).[11] We include the features related to 3 levels of linguistic structure, for a total of 245 features: i) syntax, e.g. whether the subject tends to precede the object. These originate from the World Atlas of Language Structures (Dryer and Haspelmath, 2013) and the Syntactic Structures of the World's Languages (Collins and Kayne, 2009); ii) phonology, e.g. whether a language has distinctive tones; iii) phonological inventories, e.g. whether a language possesses the retroflex approximant /ɻ/. Both ii) and iii) were originally collected in PHOIBLE (Moran et al., 2014). Missing values were inferred as a weighted average of the 10 nearest neighbour languages in terms of family, geography, and typology.

[8] http://christos-c.com/bible/

[9] This corpus is arguably representative of the variety of the world's languages: it covers 28 genealogical families, several geographic areas (16 languages from Africa, 23 from Americas, 26 from Asia, 33 from Europe, 1 from Oceania), and endangered or poorly documented languages (39 with less than a million speakers).

[10] These are identified with their 3-letter ISO 639-3 codes throughout the paper. Consult the Appendix in the supplemental material for the full list of language names mapped to ISO 639-3 codes.

Table 3: BPC scores (lower is better) for the FEW-SHOT learning setting, with NINF, FITU and UNIV priors. Colors define the split in which each language (rows) has been held out.

Language Model We implement the LSTM following the best practices and hyper-parameter settings indicated for language modelling by Merity et al. (2017, 2018). In particular, we optimize the weights with Adam (Kingma and Ba, 2014) and a non-monotonically decayed learning rate: its value is initialized as 10^{-4} and decreases by a factor of 10 every $1/3$rd of the total epochs. The maximum number of epochs amounts to 6 for $\mathcal{D}_t$, with early stopping based on development set performance, and the maximum number of epochs is 25 for $\mathcal{D}_e$.

Moreover, we extend the model to multilingual joint training. In each iteration, we sample a language proportionally to the amount of its data: $p(\ell) \propto |\mathcal{D}_t|$, in order not to exhaust examples from resource-lean languages in the early phase of training. Then, we sample without replacement from $\mathcal{D}_t$ a mini-batch of 128 sequences with a variable maximum sequence length.[12] This length is sampled from a distribution $m \sim \mathcal{N}(\mu = 125, \sigma = 5)$.[13] Each epoch comes to an end when all the data sequences have been sampled.

We apply several techniques of dropout for regu-

[12] This avoids creating insurmountable boundaries to back-propagation though time (Tallec and Ollivier, 2017).

[13] The learning rate is therefore scaled by $\frac{m}{\mu}$ and $\frac{\mathcal{D}}{L \cdot \mathcal{D}^\ell}$.

larization, including variational dropout (Gal and Ghahramani, 2016), which applies an identical mask to all time steps, with $p = 0.1$ for character embeddings and intermediate hidden states and $p = 0.4$ for the output hidden states. DropConnect (Wan et al., 2013) is applied to the model parameters U of the first hidden layer with $p = 0.2$.

Following Merity et al. (2017), the underlying language model architecture consists of 3 hidden layers with 1,840 hidden units each. The dimensionality of the character embeddings is 400. For conditional language models, the dimensionality of $f(\mathbf{t})$ is set to 115 with the OEST method based on concatenation (Östling and Tiedemann, 2017), and 4 (due to memory limitations) in the PLAT method based on meta-networks (Platanios et al., 2018). For the regularizer in eq. (17), we perform grid search over the hyperparameter λ: we finally select a value of 10^5 for UNIV and 10^{-5} for NINF.

Regimes of Data Paucity We explore different regimes of data paucity for the held-out languages:
• ZERO-SHOT transfer setting: we split the sample of 77 languages into 4 subsets. The languages in each subset are held out in turn, and we use their test set for evaluation.[14] For each subset, we further randomly choose 5 languages whose development set is used for validation. The training set of the rest of the languages is used to estimate a prior over network parameters via the Laplace approximation.
• FEW-SHOT transfer setting: on top of the zero-shot setting, we use the prior to perform MAP inference over a small sample (100 sentences) from the training set of each held-out language.
• JOINT multilingual setting: $\mathcal{D}_e$ includes the full training set for all 77 languages, including held-out languages. This works as a ceiling for the expected performance of language transfer models.

6 Results and Analysis

The results for our experiments are grouped in Table 1 for the ZERO-SHOT regime, Table 3 for the FEW-SHOT regime, and in Table 2 for the JOINT multilingual regime. The scores represent Bits Per Character (BPC) (Graves, 2013): this metric is simply defined as the average negative log-likelihood of test data divided by $\log 2$. We compare the results along the following dimensions:

[14]Holding out each language individually would not increase the sample of training languages significantly, while inflating the number of experimental runs needed.

Informativeness of Prior Our main result is that the UNIV prior consistently outperforms the NINF prior across the board and by a large margin in both ZERO-SHOT and FEW-SHOT settings. The scores for the naïvest baseline, ZERO-SHOT NINF BARE, are considerably worse than with both ZERO-SHOT UNIV models: this suggests that the transfer of information on character sequences is meaningful. The lowest BPC reductions are observed for languages like Vietnamese (15.94% error reduction) or Highland Chinantec (19.28%) where character inventories or distributions are unmatched in other languages. Moreover, the ZERO-SHOT UNIV models are on a par or better than even the FEW-SHOT NINF models. In other words, the most helpful supervision comes from a universal prior rather than from a small in-language sample of sentences. This demonstrates that the UNIV prior is truly imbued with universal linguistic knowledge that facilitates learning of previously unseen languages.

The averaged BPC score for the other baseline without a prior, FINE-TUNE is 3.007 for FEW-SHOT OEST, to be compared with 2.731 BPC of UNIV. Note that fine-tuning is an extremely competitive baseline, as it lies at the core of most state-of-the-art NLP models (Peters et al., 2019). Hence, this result demonstrates the usefulness of a Bayesian treatment of transfer learning.

Conditioning on Typological Information Another important result regards the fact that conditioning language models on typological features yield opposite effects in the ZERO-SHOT and FEW-SHOT settings. By comparing the BARE and OEST models' columns in Table 1, the non-conditional baseline BARE is superior for 71 / 77 languages (the exceptions being Chamorro, Croatian, Italian, Swazi, Swedish, and Tuareg). On the other hand, the same columns in Table 3 and Table 2 reveal an opposite pattern: OEST outperforms the BARE baseline in 70 / 77 languages. Finally, OEST surpasses the BARE baseline in the JOINT setting for 76 / 77 languages (save Q'eqchi').

We also also take into consideration an alternative conditioning method, namely PLAT. For clarity's sake, we exclude this batch of results from Table 1 and Table 3, as this method proves to be consistently worse than OEST. In fact, the average BPC of PLAT amounts to 5.479 in the ZERO-SHOT setting and 3.251 in the FEW-SHOT setting. These scores have to be compared with 4.691 and 2.731 for OEST, respectively.

The possible explanation behind the mixed evidence on the success of typological features points to some intrinsic flaws of typological databases. Ponti et al. (2018a) has shown how their feature granularity may be too coarse to be reconciled with data-driven probabilistic models, and their limited coverage of features introduces noise as missing values have to be inferred. As a result, language models seem to be damaged by typological features in absence of data, whereas they find a way to follow their guidance when at least a small sample of sentences is available in the FEW-SHOT setting.

Data Paucity Different regimes of data paucity display uneven levels of performance. The best models for each setting (ZERO-SHOT UNIV BARE, FEW-SHOT UNIV OEST, and JOINT OEST) reveal large gaps between their average scores. Hence, in-language supervision should be still considered unsubstitutable, and transferred language models still lag behind their resource-rich equivalents.

7 Related Work

LSTMs have been probed for an inductive bias in capturing syntactic dependencies (Linzen et al., 2016) and grammaticality judgements (Marvin and Linzen, 2018; Warstadt et al., 2018). Ravfogel et al. (2019) have extended the scope of this analysis to typologically different languages through *synthetic* variations of English. In this work, we aim to model the inductive bias explicitly by constructing a prior over the space of neural network parameters.

Few-shot word-level language modelling for truly under-resourced languages such as Yongning Na has been investigated by Adams et al. (2017) with the aid of a bilingual lexicon. Vinyals et al. (2016) and Munkhdalai and Trischler (2018) proposed novel architectures (Matching Networks and LSTMs augmented with Hebbian Fast Weights, respectively) for rapid associative learning in English, and evaluated them in few-shot cloze tests. In this respect, our work is novel in pushing the problem to its most complex formulation, zero-shot inference, and in taking into account the largest sample of languages for language modelling to date.

In addition to the set of standard architectures considered in our work, there are also alternatives to conditional language modelling. Kalchbrenner and Blunsom (2013) used encoded features as additional biases in recurrent layers. Kiros et al. (2014) put forth a log-bilinear model that allows for a "multiplicative interaction" between hidden representations and input features (such as images). With a similar device, but a different gating method, Tsvetkov et al. (2016) trained a phoneme-level joint multilingual model of words conditioned on typological features from Moran et al. (2014).

The use of the Laplace method for neural transfer learning has been proposed by Kirkpatrick et al. (2017), inspired by synaptic consolidation in neuroscience to avoid catastrophic forgetting. Kochurov et al. (2018) tackled the problem of continuous learning from independent data portions for a single fixed task by approximating the posterior probabilities through stochastic variational inference. Ritter et al. (2018) substitute diagonal Laplace approximation with a Kronecker factored method, leading to better uncertainty estimates. Finally, the regularizer proposed by Duong et al. (2015) for cross-lingual dependency parsing can be interpreted as a prior for Maximum A Posteriori estimation where the covariance is an identity matrix.

8 Conclusions

In this work, we proposed a Bayesian approach to cross-lingual language modeling transfer. We created a universal prior over neural network weights that is capable of generalizing well to new languages riddled by data paucity, by Laplace-approximating the posterior of the weights conditioned on the data from a sample of training languages. Based on the results of character-level language modelling on a sample of 77 languages, we demonstrated the superiority of the universal prior over uninformative priors and uniform priors (i.e., the widespread fine-tuning approach) in both zero-shot and few-shot settings. Moreover, we showed that adding language-specific side information drawn from typological databases to the universal prior further increases the levels of performance in the few-shot regime. While we also showed that language transfer still lags behind multilingual joint learning when sufficient in-language data are available, our work is the first step towards bridging this gap in the future.

What Gets Echoed? Understanding the "Pointers" in Explanations of Persuasive Arguments

Abstract

Explanations are central to everyday life, and are a topic of growing interest in the AI community. To investigate the process of providing natural language explanations, we leverage the dynamics of the `/r/ChangeMyView` subreddit to build a dataset with 36K naturally occurring explanations of why an argument is persuasive. We propose a novel word-level prediction task to investigate how explanations selectively reuse, or *echo*, information from what is being explained (henceforth, *explanandum*). We develop features to capture the properties of a word in the explanandum, and show that our proposed features not only have relatively strong predictive power on the echoing of a word in an explanation, but also enhance neural methods of generating explanations. In particular, while the non-contextual properties of a word itself are more valuable for stopwords, the interaction between the constituent parts of an explanandum is crucial in predicting the echoing of content words. We also find intriguing patterns of a word being echoed. For example, although nouns are generally less likely to be echoed, subjects and objects can, depending on their source, be more likely to be echoed in the explanations.

1 Introduction

Explanations are essential for understanding and learning (Keil, 2006). They can take many forms, ranging from everyday explanations for questions such as why one likes Star Wars, to sophisticated formalization in the philosophy of science (Salmon, 2006), to simply highlighting features in recent work on interpretable machine learning (Ribeiro et al., 2016).

Although everyday explanations are mostly encoded in natural language, natural language explanations remain understudied in NLP, partly due to a lack of appropriate datasets and problem formulations. To address these challenges, we leverage `/r/ChangeMyView`, a community dedicated to sharing counterarguments to controversial views on Reddit, to build a sizable dataset of naturally-occurring explanations. Specifically, in `/r/ChangeMyView`, an original poster (OP) first delineates the rationales for a (controversial) opinion (e.g., in Table 1, "most hit music artists today are bad musicians"). Members of `/r/ChangeMyView` are invited to provide counterarguments. If a counterargument changes the OP's view, the OP awards a Δ to indicate the change and is required to *explain why the counterargument is persuasive*. In this work, we refer to what is being explained, including both the original post and the persuasive comment, as the *explanandum*.[1]

An important advantage of explanations in `/r/ChangeMyView` is that the explanandum contains most of the required information to provide its explanation. These explanations often select key counterarguments in the persuasive comment and connect them with the original post. As shown in Table 1, the explanation naturally points to, or *echoes*, part of the explanandum (including both the persuasive comment and the original post) and in this case highlights the argument of "music serving different purposes."

These naturally-occurring explanations thus enable us to computationally investigate the selective nature of explanations: "people rarely, if ever, expect an explanation that consists of an actual and complete cause of an event. Humans are adept at selecting one or two causes from a sometimes infinite number of causes to be the explanation" (Miller, 2018). To understand the selective process of providing explanations, we formulate a word-level task to predict whether a word in an

[1]The plural of *explanandum* is explananda.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2911–2921,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Original post (OP): CMV: most hit music artists today are bad musicians Now I know, music is art and art has no rules, but this is only so true. Movies are art too but I think most of us can agree the emoji movie was objectively bad. That aside: I really feel like once you remove the persona and performances of the artists from the "top 40" songs and listen to them as just a song, most are objectively bad. They're super repetitive, the lyrics and painfully generic, and there's hardly ever anything new or challenging. And from what I understand most of these artists don't even write their own songs. Of course there are exceptions but I find them to be extremely rare. It seems to me they're only popular become of who they are and how they look/perform. I realize this is probably a very snobbish view which is why I want to be enlightened, so can anyone convince me otherwise? Are they actually good musicians or just good performers? [one more paragraph ...]
Persuasive comment (PC): Music appreciation is a skill, and it's all about pattern recognition. When we're children, we need songs that are really simple, repetitive and with easy to recognize patterns. The younger we are, the simpler the songs. Toddlers like nursery rhymes, lullabies, jingles. Teens like pop music. And teens spend more on music than anyone else. [four more paragraphs ...] Lastly, you have to consider that music can be listened to in different ways and for different purposes. You can listen to it alone on headphones, and think about what it means and how it makes you feel. Or you can dance to it with your friends. Or maybe you need something on in the background during a dinner party, or a house party, or while you study, or are trying to fall asleep, or work out. Pop music is really good in some of these situations, really bad in others. But it serves a definite purpose and isn't bad in any essential way.
Explanation: Δ I guess I never *really looked* at it as *music serving different purposes*. I can *see* how *pop music* fills a certain *purpose*, and I guess the *artist* does *n't* necessarily have to be the *one* to *write* the *song* (although I *appreciate* it when they do).

Table 1: An illustration of the pointers in an example explanation of `/r/ChangeMyView`. We color the words in the explanation based on whether it is used in the original post (e.g., *artist*), in the persuasive comment (e.g., *purpose*), or both (e.g., *music*). We stem all the words before matching and do not color stopwords for readability.

explanandum will be echoed in its explanation.

Inspired by the observation that words that are likely to be echoed are either frequent or rare, we propose a variety of features to capture how a word is used in the explanandum as well as its non-contextual properties in Section 4. We find that a word's usage in the original post and in the persuasive argument are similarly related to being echoed, except in part-of-speech tags and grammatical relations. For instance, verbs in the original post are less likely to be echoed, while the relationship is reversed in the persuasive argument.

We further demonstrate that these features can significantly outperform a random baseline and even a neural model with significantly more knowledge of a word's context. The difficulty of predicting whether content words (i.e., non-stopwords) are echoed is much greater than that of stopwords,[2] among which adjectives are the most difficult and nouns are relatively the easiest. This observation highlights the important role of nouns in explanations. We also find that the relationship between a word's usage in the original post and in the persuasive comment is crucial for predicting the echoing of content words. Our proposed features can also improve the performance of pointer generator networks with coverage in generating explanations (See et al., 2017).

[2]We use the stopword list in NLTK.

To summarize, our main contributions are:

- We highlight the importance of computationally characterizing human explanations and formulate a concrete problem of predicting how information is selected from explananda to form explanations, including building a novel dataset of naturally-occurring explanations.
- We provide a computational characterization of natural language explanations and demonstrate the U-shape in which words get echoed.
- We identify interesting patterns in what gets echoed through a novel word-level classification task, including the importance of nouns in shaping explanations and the importance of contextual properties of both the original post and persuasive comment in predicting the echoing of content words.
- We show that vanilla LSTMs fail to learn some of the features we develop and that the proposed features can even improve performance in generating explanations with pointer networks.

Our code and dataset is available at `https://chenhaot.com/papers/explanation-pointers.html`.

2 Related Work

To provide background for our study, we first present a brief overview of explanations for the NLP community, and then discuss the connection

of our study with pointer networks, linguistic accommodation, and argumentation mining.

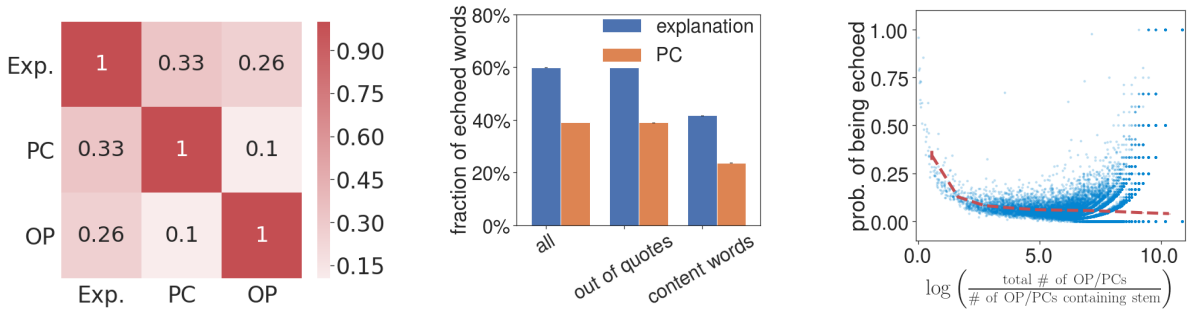
The most developed discussion of explanations is in the philosophy of science. Extensive studies aim to develop formal models of explanations (e.g., the deductive-nomological model in Hempel and Oppenheim (1948), see Salmon (2006) and Woodward (2005) for a review). In this view, explanations are like proofs in logic. On the other hand, psychology and cognitive sciences examine "everyday explanations" (Keil, 2006; Lombrozo, 2006). These explanations tend to be selective, are typically encoded in natural language, and shape our understanding and learning in life despite the absence of "axioms." Please refer to Wilson and Keil (1998) for a detailed comparison of these two modes of explanation.

Although explanations have attracted significant interest from the AI community thanks to the growing interest on interpretable machine learning (Doshi-Velez and Kim, 2017; Lipton, 2016; Guidotti et al., 2019), such studies seldom refer to prior work in social sciences (Miller, 2018). Recent studies also show that explanations such as highlighting important features induce limited improvement on human performance in detecting deceptive reviews and media biases (Lai and Tan, 2019; Horne et al., 2019). Therefore, we believe that developing a computational understanding of everyday explanations is crucial for explainable AI. Here we provide a data-driven study of everyday explanations in the context of persuasion.

In particular, we investigate the "pointers" in explanations, inspired by recent work on pointer networks (Vinyals et al., 2015). Copying mechanisms allow a decoder to generate a token by copying from the source, and have been shown to be effective in generation tasks ranging from summarization to program synthesis (See et al., 2017; Ling et al., 2016; Gu et al., 2016). To the best of our knowledge, our work is the first to investigate the phenomenon of pointers in explanations.

Linguistic accommodation and studies on quotations also examine the phenomenon of reusing words (Danescu-Niculescu-Mizil et al., 2011; Giles and Ogay, 2007; Leskovec et al., 2009; Simmons et al., 2011). For instance, Danescu-Niculescu-Mizil et al. show that power differences are reflected in the echoing of function words; Tan et al. (2018) find that news media prefer to quote locally distinct sentences in political debates. In comparison, our word-level formulation presents a fine-grained view of echoing words, and puts a stronger emphasis on content words than work on linguistic accommodation.

Finally, our work is concerned with an especially challenging problem in social interaction: persuasion. A battery of studies have done work to enhance our understanding of persuasive arguments (Wang et al., 2017; Zhang et al., 2016; Habernal and Gurevych, 2016; Lukin et al., 2017; Durmus and Cardie, 2018), and the area of argumentation mining specifically investigates the structure of arguments (Lippi and Torroni, 2016; Walker et al., 2012; Somasundaran and Wiebe, 2009). We build on previous work by Tan et al. (2016) and leverage the dynamics of `/r/ChangeMyView`. Although our findings are certainly related to the persuasion process, we focus on understanding the self-described reasons for persuasion, instead of the structure of arguments or the factors that drive effective persuasion.



3 Dataset

Our dataset is derived from the `/r/ChangeMyView` subreddit, which has more than 720K subscribers (Tan et al., 2016). `/r/ChangeMyView` hosts conversations where someone expresses a view and others then try to change that person's mind. Despite being fundamentally based on argument, `/r/ChangeMyView` has a reputation for being remarkably civil and productive (CMV moderators, 2019a), e.g., a journalist wrote "In a culture of brittle talking points that we guard with our lives, Change My View is a source of motion and surprise" (Heffernan, 2018).

The delta mechanism in `/r/ChangeMyView` allows members to acknowledge opinion changes and enables us to identify *explanations* for opinion changes (CMV moderators, 2019b). Specifically, it requires "Any user, whether they're the OP or not, should reply to a comment that changed their view with a delta symbol and *an explanation of the change*." As a result, we have access to tens of thousands of naturally-occurring explanations and associated explananda. In this work, we focus on the opinion changes of the original posters.

Throughout this paper, we use the following terminology:

- An **original post (OP)** is an initial post where the original poster justifies his or her opinion. We also use OP to refer to the original poster.

(a) Length correlations.

(b) Fraction of words that are echoed from the explanandum.

(c) Word-level echoing probability vs. document frequency.

Figure 1: Figure 1a shows the pairwise Pearson correlation coefficient between lengths of OP, PC, and explanation (all values are statistically significant with $p < 1e{-}10$). Figure 1b shows the average fraction of words in an explanation that are in its OP or PC, and the fraction of words in a PC that are in its OP. In Figure 1c, the y-axis represents the probability of a word in an OP or PC being echoed in the explanation, while the x-axis shows the inverse document frequency of that word in training data. For each document frequency decile, we calculate the probability of a word in that decile being echoed, and plot those probabilities with the red line. In Figure 1b and Figure 1c, the (small) error bars represent standard errors.

- A **persuasive comment (PC)** is a comment that directly leads to an opinion change on the part of the OP (i.e., winning a Δ).
- A **top-level comment** is a comment that directly replies to an OP, and `/r/ChangeMyView` requires the top-level comment to "challenge at least one aspect of OPs stated view (however minor), unless they are asking a clarifying question."
- An **explanation** is a comment where an OP acknowledges a change in his or her view and provides an explanation of the change. As shown in Table 1, the explanation not only provides a rationale, it can also include other discourse acts, such as expressing gratitude.

Using `https://pushshift.io`, we collect the posts and comments in `/r/ChangeMyView` from January 17th, 2013 to January 31st, 2019, and extract tuples of (OP, PC, explanation). We use the tuples from the final six months of our dataset as the test set, those from the six months before that as the validation set, and the remaining tuples as the training set. The sets contain 5,270, 5,831, and 26,617 tuples respectively. Note that there is no overlap in time between the three sets and the test set can therefore be used to assess generalization including potential changes in community norms and world events.

Preprocessing. We perform a number of preprocessing steps, such as converting blockquotes in Markdown to quotes, filtering explicit edits made by authors, mapping all URLs to a special `@url@` token, and replacing hyperlinks with the link text. We ignore all triples that contain any deleted comments or posts. We use spaCy for tokenization and tagging (Honnibal and Montani, 2017). We also use the NLTK implementation of the Porter stemming algorithm to store the stemmed version of each word, for later use in our prediction task (Loper and Bird, 2002; Porter, 1980). Refer to the supplementary material for more information on preprocessing.

Data statistics. Table 2 provides basic statistics of the training tuples and how they compare to other comments. We highlight the fact that PCs are on average longer than top-level comments, suggesting that PCs contain substantial counterarguments that directly contribute to opinion change. Therefore, we simplify the problem by focusing on the (OP, PC, explanation) tuples and ignore any other exchanges between an OP and a commenter.

Below, we highlight some notable features of explanations as they appear in our dataset.

The length of explanations shows stronger correlation with that of OPs and PCs than between OPs and PCs (Figure 1a). This observation indicates that explanations are somehow better related with OPs and PCs than PCs are with OPs in terms of language use. A possible reason is that the explainer combines their natural tendency towards length with accommodating the PC.

Explanations have a greater fraction of "pointers" than do persuasive comments (Figure 1b). We measure the likelihood of a word in an explanation being copied from either its OP or PC and provide a similar probability for a PC for copying from its OP. As we discussed in Section

	count	#sentences	#words
Tuples of (OP, PC, Explanations)			
Original Posts	26.3K	16.8	298.8
Persuasive comments	26.3K	12.6	218.3
Explanations	26.3K	5.3	79.8
All of `/r/ChangeMyView` during the training period			
Original posts	93.4k	13.2	172.6
Top-level comments	681.6k	9.1	147.4
All comments	3.6M	6.5	98.9

Table 2: Basic statistics of the training dataset.

1, the words in an explanation are much more likely to come from the existing discussion than are the words in a PC (59.8% vs 39.0%). This phenomenon holds even if we restrict ourselves to considering words outside quotations, which removes the effect of quoting other parts of the discussion, and if we focus only on content words, which removes the effect of "reusing" stopwords.

Relation between a word being echoed and its document frequency (Figure 1c). Finally, as a preview of our main results, the document frequency of a word from the explanandum is related to the probability of being echoed in the explanation. Although the average likelihood declines as the document frequency gets lower, we observe an intriguing U-shape in the scatter plot.[3] In other words, the words that are most likely to be echoed are either unusually frequent or unusually rare, while most words in the middle show a moderate likelihood of being echoed.

4 Understanding the Pointers in Explanations

To further investigate how explanations select words from the explanandum, we formulate a word-level prediction task to predict whether words in an OP or PC are echoed in its explanation. Formally, given a tuple of (OP, PC, explanation), we extract the unique stemmed words as $\mathcal{V}_{\text{OP}}, \mathcal{V}_{\text{PC}}, \mathcal{V}_{\text{EXP}}$. We then define the label for each word in the OP or PC, $w \in \mathcal{V}_{\text{OP}} \cup \mathcal{V}_{\text{PC}}$, based on the explanation as follows:

$$y_w = \begin{cases} 1 & \text{if } w \in \mathcal{V}_{\text{EXP}}, \\ 0 & \text{otherwise.} \end{cases}$$

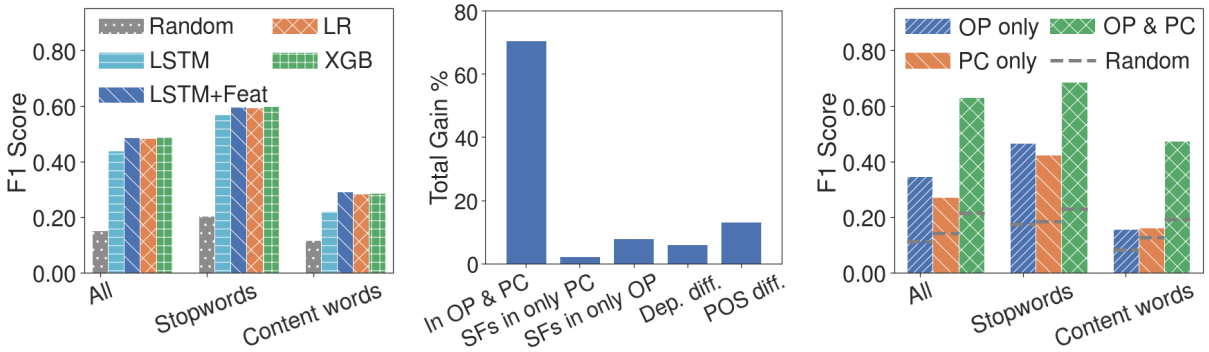
Our prediction task is thus a straightforward binary classification task at the word level. We develop the following five groups of features to capture properties of how a word is used in the explanandum (see Table 3 for the full list):

- Non-contextual properties of a word. These features are derived directly from the word and capture the general tendency of a word being echoed in explanations.
- Word usage in an OP or PC (two groups). These features capture *how* a word is used in an OP or PC. As a result, for each feature, we have two values for the OP and PC respectively.
- How a word connects an OP and PC. These features look at the difference between word usage in the OP and PC. We expect this group to be the most important in our task.
- General OP/PC properties. These features capture the general properties of a conversation. They can be used to characterize the background distribution of echoing.

Table 3 further shows the intuition for including each feature, and condensed t-test results after Bonferroni correction. Specifically, we test whether the words that were echoed in explanations have different feature values from those that were not echoed. In addition to considering all words, we also separately consider stopwords and content words in light of Figure 1c. Here, we highlight a few observations:

- Although we expect more complicated words (*#characters*) to be echoed more often, this is not the case on average. We also observe an interesting example of Simpson's paradox in the results for Wordnet depth (Blyth, 1972): shallower words are more likely to be echoed across all words, but deeper words are more likely to be echoed in content words and stopwords.
- OPs and PCs generally exhibit similar behavior for most features, except for part-of-speech and grammatical relation (subject, object, and other.) For instance, verbs in an OP are less likely to be echoed, while verbs in a PC are more likely to be echoed.

[3] A similar U-shape exists if we examine the probability of a PC echoing its OP, but does not show up if we compare an OP echoing a different, randomly chosen OP. It is worth noting that PCs can also be viewed as explaining why the OP is problematic. However, constructing a PC involves selecting from a large number of possible counter perspectives (all of which are unobservable). See the supplementary material for a detailed discussion.



Feature group	Features and intuitions	Echoed?
Non-contextual properties	Inverse document frequency. As shown in Figure 1c, although document frequency can have non-linear relationships with being copied, the average echoing probability is greater for more common words.	$\downarrow\downarrow\downarrow\downarrow$
	Number of characters. Longer words tend to be more complicated, and may be more likely to be echoed as part of the core argument.	$\downarrow\downarrow\downarrow\downarrow$
	Wordnet depth. Similar to number of characters, the depth in wordnet can indicate the complexity of a word and we expect words with greater depth to be echoed.	$\downarrow\downarrow\downarrow\downarrow^{RC,RS}$
	Echoing likelihood. We also compute the general tendency of a word being echoed in the training data. We expect the feature to be positively correlated with the label.	$\uparrow\uparrow\uparrow\uparrow$
How a word is used in an OP or PC (OP/PC usage)	Part-of-speech (POS) tags. We compute the percentage of times that the surface forms of a stemmed word appear as different part-of-speech tags. We expect nouns and verbs more likely to be echoed. Results: verb in an OP $\downarrow\downarrow\downarrow\downarrow^{RS}$, noun in an OP ($\downarrow\downarrow\downarrow\downarrow$), verb in a PC ($\uparrow\uparrow\uparrow\uparrow$), noun in a PC: $\downarrow\downarrow\downarrow\downarrow^{RC}$.	
	Subjects and objects from dependency labels. We compute the percentage of times that the word appears as subjects, objects, and others. We expect subjects and objects more likely to be echoed. Results: subjects in an OP: $\uparrow\uparrow\uparrow\uparrow$, objects in an OP: $\downarrow\downarrow\downarrow\downarrow^{RC}$, others in an OP: $\uparrow\uparrow\uparrow\uparrow^{RC}$, subjects in a PC: $\downarrow\downarrow\downarrow\downarrow$, objects in a PC: $\downarrow\downarrow\downarrow\downarrow$; others in a PC: $\uparrow\uparrow\uparrow\uparrow$.	
	(Normalized) term frequency. We expect frequent terms to be echoed.	$\uparrow\uparrow\uparrow\uparrow$
	#surface forms. We expect words that have diverse surface forms to be echoed.	$\uparrow\uparrow\uparrow\uparrow$
	Location. For words that never show up in an OP or PC, the default value is 0.5. We expect later words to be echoed. Results: location in an OP: $\uparrow\uparrow\uparrow\uparrow$ (not significant in stopwords); location in a PC: $\uparrow^{RS}$.	
	In quotes. We expect words in quotes to be echoed as they are already emphasized.	$\uparrow\uparrow\uparrow\uparrow$
	Entity. We expect entities to be echoed.	$\uparrow\uparrow\uparrow\uparrow$
How a word connects an OP and PC (OP-PC relation)	Occurs both in an OP and PC.	$\uparrow\uparrow\uparrow\uparrow$
	#Surface forms in an OP but not in the PC.	$\downarrow\downarrow\downarrow\downarrow$
	#Surface forms in a PC but not in the OP.	$\uparrow\uparrow\uparrow\uparrow^{RS}$
	Jensen-Shannon (JS) distance between the OP and PC POS tag distributions of the word.	$\downarrow\downarrow\downarrow\downarrow$
	JS distance between subjects/objects distributions of the word in an OP and PC.	$\downarrow\downarrow\downarrow\downarrow$
General OP/PC properties	OP length.	$\downarrow\downarrow\downarrow\downarrow^{RS}$
	PC length.	$\uparrow\uparrow\uparrow\uparrow$
	Difference in #words.	$\downarrow\downarrow\downarrow\downarrow^{RS}$
	Difference in average #characters in words.	$\downarrow\downarrow\downarrow\downarrow$
	Part-of-speech tags distributional differences between an OP and PC.	$\downarrow\downarrow\downarrow\downarrow$
	Depth of the PC in the thread.	$\uparrow\uparrow\uparrow\uparrow$

Table 3: Features to capture the properties of a word in the context of an explanandum. The last column shows $t-$test results after Bonferroni correction. $\uparrow$ indicates that words that are echoed have a greater value in the feature, while $\downarrow$ indicates the reverse. The number of arrows indicates the level of p-value: $\uparrow\uparrow\uparrow\uparrow$: $p < 0.0001$, $\uparrow\uparrow\uparrow$: $p < 0.001$, $\uparrow\uparrow$: $p < 0.01$, $\uparrow$: $p < 0.05$. ^{RC} and ^{RS} indicate that the direction is flipped in content words and stopwords respectively. We show significance testing results in a condensed format for space reasons. Refer to the supplementary material for the complete testing results.

- Although nouns from both OPs and PCs are less likely to be echoed, within content words, subjects and objects from an OP are more likely to be echoed. Surprisingly, subjects and objects in a PC are less likely to be echoed, which suggests that the original poster tends to refer back to their own subjects and objects, or introduce new ones, when providing explanations.
- Later words in OPs and PCs are more likely to be echoed, especially in OPs. This could relate to OPs summarizing their rationales at the end of their post and PCs putting their strongest points last.
- Although the number of surface forms in an OP or PC is positively correlated with being echoed, the differences in surface forms show reverse trends: the more surface forms of a word that show up only in the PC (i.e., not in the OP), the more likely a word is to be echoed. However, the reverse is true for the number of surface forms in only the OP. Such contrast echoes Tan et al. (2016), in which dissimilarity in word usage between the OP and PC was a predictive feature of successful persuasion.

5 Predicting Pointers

We further examine the effectiveness of our proposed features in a predictive setting. These features achieve strong performance in the word-level classification task, and can enhance neural models in both the word-level task and generating explanations. However, the word-level task remains challenging, especially for content words.

(a) Overall Performance comparison between models.

(b) Feature importance of an ablated model with OP-PC relation.

(c) Performance vs. word source.

Figure 2: Figure 2a presents the performance of different models. We evaluate the performance of each model on the subset of stopwords and content words. Our features with XGBoost and logistic regression outperform the vanilla LSTM model, and adding our features to the vanilla LSTM model achieves similar performance as XGBoost. Figure 2b shows the normalized total gain of the classifier only based on features in OP-PC relation, while Figure 2c further breaks down the performance based on where the words come from.

5.1 Experiment setup

We consider two classifiers for our word-level classification task: logistic regression and gradient boosting tree (XGBoost) (Chen and Guestrin, 2016). We hypothesized that XGBoost would outperform logistic regression because our problem is non-linear, as shown in Figure 1c.

To examine the utility of our features in a neural framework, we further adapt our word-level task as a tagging task, and use LSTM as a baseline. Specifically, we concatenate an OP and PC with a special token as the separator so that an LSTM model can potentially distinguish the OP from PC, and then tag each word based on the label of its stemmed version. We use GloVe embeddings to initialize the word embeddings (Pennington et al., 2014). We concatenate our proposed features of the corresponding stemmed word to the word embedding; the resulting difference in performance between a vanilla LSTM demonstrates the utility of our proposed features. We scale all features to $[0, 1]$ before fitting the models. As introduced in Section 3, we split our tuples of (OP, PC, explanation) into training, validation, and test sets, and use the validation set for hyperparameter tuning. Refer to the supplementary material for additional details in the experiment.

Evaluation metric. Since our problem is imbalanced, we use the F1 score as our evaluation metric. For the tagging approach, we average the labels of words with the same stemmed version to obtain a single prediction for the stemmed word. To establish a baseline, we consider a random method that predicts the positive label with 0.15 probability (the base rate of positive instances).

5.2 Prediction Performance

Overall performance (Figure 2a). Although our word-level task is heavily imbalanced, all of our models outperform the random baseline by a wide margin. As expected, content words are much more difficult to predict than stopwords, but the best F1 score in content words more than doubles that of the random baseline (0.286 vs. 0.116). Notably, although we strongly improve on our random baseline, even our best F1 scores are relatively low, and this holds true regardless of the model used. Despite involving more tokens than standard tagging tasks (e.g., Marcus et al. (1994) and Plank et al. (2016)), predicting whether a word is going to be echoed in explanations remains a challenging problem.

Although the vanilla LSTM model incorporates additional knowledge (in the form of word embeddings), the feature-based XGBoost and logistic regression models both outperform the vanilla LSTM model. Concatenating our proposed features with word embeddings leads to improved performance from the LSTM model, which becomes comparable to XGBoost. This suggests that our proposed features can be difficult to learn with an LSTM alone.

Despite the non-linearity observed in Figure 1c, XGBoost only outperforms logistic regression by a small margin. In the rest of this section, we use XGBoost to further examine the effectiveness

	content	stop
all features	0.286	0.600
random	0.116	0.205

	forward		backward	
	content	stop	content	stop
Non-contextual prop.	0.177	**0.582**	0.285	**0.561**
OP usage	0.191	0.527	0.281	0.599
PC usage	0.233	0.520	**0.275**	0.598
OP-PC relation	**0.280**	0.542	0.289	0.600
General OP/PC prop.	0.153	0.266	0.285	0.598

Table 4: Ablation performance with XGBoost on content words and stopwords (each ablated model is tuned based on performance on all words). "forward" refers to only using a group of features, while "backward" refers to only removing a group of features.

of different groups of features, and model performance in different conditions.

Ablation performance (Table 4). First, if we only consider a single group of features, as we hypothesized, the relation between OP and PC is crucial and leads to almost as strong performance in content words as using all features. To further understand the strong performance of OP-PC relation, Figure 2b shows the feature importance in the ablated model, measured by the normalized total gain (see the supplementary material for feature importance in the full model). A word's occurrence in both the OP and PC is clearly the most important feature, with distance between its POS tag distributions as the second most important. Recall that in Table 3 we show that words that have similar POS behavior between the OP and PC are more likely to be echoed in the explanation.

Overall, it seems that word-level properties contribute the most valuable signals for predicting stopwords. If we restrict ourselves to only information in either an OP or PC, how a word is used in a PC is much more predictive of content word echoing (0.233 vs 0.191). This observation suggests that, for content words, the PC captures more valuable information than the OP. This finding is somewhat surprising given that the OP sets the topic of discussion and writes the explanation.

As for the effects of removing a group of features, we can see that there is little change in the performance on content words. This can be explained by the strong performance of the OP-PC relation on its own, and the possibility of the OP-PC relation being approximated by OP and PC usage. Again, word-level properties are valuable for strong performance in stopwords.

Performance vs. word source (Figure 2c). We further break down the performance by where a word is from. We can group a word based on whether it shows up only in an OP, a PC, or both OP and PC, as shown in Table 1. There is a striking difference between the performance in the three categories (e.g., for all words, 0.63 in OP & PC vs. 0.271 in PC only). The strong performance on words in both the OP and PC applies to stopwords and content words, even accounting for the shift in the random baseline, and recalls the importance of occurring both in OP and PC as a feature.

Furthermore, the echoing of words from the PC is harder to predict (0.271) than from the OP (0.347) despite the fact that words only in PCs are more likely to be echoed than words only in OPs (13.5% vs. 8.6%). The performance difference is driven by stopwords, suggesting that our overall model is better at capturing signals for stopwords used in OPs. This might relate to the fact that the OP and the explanation are written by the same author; prior studies have demonstrated the important role of stopwords for authorship attribution (Raghavan et al., 2010).

Nouns are the most reliably predicted part-of-speech tag within content words (Table 5). Next, we break down the performance by part-of-speech tags. We focus on the part-of-speech tags that are semantically important, namely, nouns, proper nouns, verbs, adverbs, and adjectives.

Prediction performance can be seen as a proxy for how reliably a part-of-speech tag is reused when providing explanations. Consistent with our expectations for the importance of nouns and verbs, our models achieve the best performance on nouns within content words. Verbs are more challenging, but become the least difficult tag to predict when we consider all words, likely due to stopwords such as "have." Adjectives turn out to be the most challenging category, suggesting that adjectival choice is perhaps more arbitrary than other parts of speech, and therefore less central to the process of constructing an explanation. The important role of nouns in shaping explanations resonates with the high recall rate of nouns in memory tasks (Reynolds and Flagg, 1976).

5.3 The Effect on Generating Explanations

One way to measure the ultimate success of understanding pointers in explanations is to be able to generate explanations. We use the pointer gen-

	content	all	random
noun	0.354	0.361	0.130
adverb	0.342	0.411	0.127
verb	0.306	0.466	0.122
proper noun	0.280	0.336	0.109
adjective	0.237	0.289	0.111

Table 5: Performance on five non-function part-of-speech tags (sorted by performance within content words). As a comparison, we also show the performance of the random baseline on content words, which is relatively stable across part-of-speech tags.

	ROUGE-1	ROUGE-2	ROUGE-L
w/o features	18.91	4.12	17.05
with features	22.01	3.93	19.02

Table 6: ROUGE scores (F1) on the test dataset (Lin, 2004). The differences in ROUGE-1 and ROUGE-L are statistically significant with $p < 1e{-}10$.

erator network with coverage as our starting point (See et al., 2017; Klein et al., 2017) (see the supplementary material for details). We investigate whether concatenating our proposed features with word embeddings can improve generation performance, as measured by ROUGE scores.

Consistent with results in sequence tagging for word-level echoing prediction, our proposed features can enhance a neural model with copying mechanisms (see Table 6). Specifically, their use leads to statistically significant improvement in ROUGE-1 and ROUGE-L, while slightly hurting the performance in ROUGE-2 (the difference is not statistically significant). We also find that our features can increase the likelihood of copying: an average of 17.59 unique words get copied to the generated explanation with our features, compared to 14.17 unique words without our features. For comparison, target explanations have an average of 34.81 unique words. We emphasize that generating explanations is a very challenging task (evidenced by the low ROUGE scores and examples in the supplementary material), and that fully solving the generation task requires more work.

6 Concluding Discussions

In this work, we conduct the first large-scale empirical study of everyday explanations in the context of persuasion. We assemble a novel dataset and formulate a word-level prediction task to understand the selective nature of explanations. Our results suggest that the relation between an OP and PC plays an important role in predicting the echoing of content words, while a word's non-contextual properties matter for stopwords. We show that vanilla LSTMs fail to learn some of the features we develop and that our proposed features can improve the performance in generating explanations using pointer networks. We also demonstrate the important role of nouns in shaping explanations.

Although our approach strongly outperforms random baselines, the relatively low F1 scores indicate that predicting which word is echoed in explanations is a very challenging task. It follows that we are only able to derive a limited understanding of how people choose to echo words in explanations. The extent to which explanation construction is fundamentally random (Nisbett and Wilson, 1977), or whether there exist other unidentified patterns, is of course an open question. We hope that our study and the resources that we release encourage further work in understanding the pragmatics of explanations.

There are many promising research directions for future work in advancing the computational understanding of explanations. First, although `/r/ChangeMyView` has the useful property that its explanations are closely connected to its explananda, it is important to further investigate the extent to which our findings generalize beyond `/r/ChangeMyView` and Reddit and establish universal properties of explanations. Second, it is important to connect the words in explanations that we investigate here to the structure of explanations in pyschology (Lombrozo, 2006). Third, in addition to understanding what goes into an explanation, we need to understand what makes an explanation effective. A better understanding of explanations not only helps develop explainable AI, but also informs the process of collecting explanations that machine learning systems learn from (Hancock et al., 2018; Rajani et al., 2019; Camburu et al., 2018).

Abstract

In argumentation, framing is used to emphasize a specific aspect of a controversial topic while concealing others. When discussing the legalization of drugs, for instance, its economical aspect may be emphasized. In general, we call a set of arguments that focus on the same aspect a *frame*. An argumentative text has to serve the "right" frame(s) to convince the audience to adopt the author's stance (e.g., being pro or con legalizing drugs). More specifically, an author has to choose frames that fit the audience's interests and cultural background. This paper introduces *frame identification*, which is the task of splitting a set of arguments into a set of non-overlapping frames. We present a fully unsupervised approach to this task, which first removes topical information from the arguments and then identifies frames using clustering. For evaluation purposes, we provide a corpus with 12 326 debate-portal arguments, organized along the frames of the debates' topics. On this corpus, our approach outperforms different strong baselines, achieving an F_1-score of 0.28.

1 Introduction

Different interests, cultural backgrounds, and socializations make people disagree on taking a certain course of action. A *debate* is a means for the involved parties to resolve their disagreement. A debate is characterized by a *topic*, e.g., "Should one legalize abortion?". Upon the topic, the disagreeing parties have a pro or con *stance* respectively, say, "Abortion should be legalized" or "Abortion should not be legalized". A stance is supported by *arguments*; a pro argument could be "Abortion is good for a free society because it gives women their basic right of controlling their bodies." while a con argument could be "Abortion is against human rights because it is a systematic murder of innocent life." One part of an argument (here: the part before the word "because") is called a *conclusion*, the other part consists of one or more *premises*. A debate can be considered as set of pro and con arguments.

Typically, numerous arguments exist for a topic. The parties involved in a debate have to choose among the arguments, thereby *framing* the topic by emphasizing a specific aspect while concealing others. We call the set of the arguments which share an aspect a *frame*. More specifically, a frame F is subset of a set of arguments A, $F \subseteq A$. Likewise, a set of frames, $\{F_1, \ldots, F_k\}$ covers a set of arguments iff. $A \subseteq \bigcup_j^k F_j$.

For instance, the following arguments target different topics but concentrate on the same frame, namely, the *economical* aspect.

Argument 1 *"I support legalization of marijuana since it can be taxed for revenue gain."*
Topic: Marijuana

Argument 2 *"Legalizing prostitution would increase government revenue. A tax on the fee charged by a prostitute, and the imposition of income tax on the earnings of prostitutes would generate revenue."*
Topic: Prostitution

Framing is a decisive step in the construction of arguments, which affects the outcome of a debate (Eemeren and Houtlosser, 1999). To achieve persuasion, an author of an argumentative text should choose frames that resonate with the target audience. As a simple example, an argument appealing to Christianity might not be acceptable to an atheist. Knowing the arguments for a topic along with their frames enables authors to choose those arguments that best address their audience.

The constellation of pro and con arguments for a topic is an urgent need for authors of argumentative texts. Argument search is a new research area that aims at assessing users in forming an opinion and debating. Current approaches use clas-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2922–2932,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

sifiers to mine arguments for a given topic from a relevant document (Levy et al., 2014; Stab et al., 2018; Wachsmuth et al., 2017a). The mentioned approaches ignore identifying the frames of arguments during mining and retrieval, this way omitting extremely valuable information.

The paper in hand starts by reviewing related work to framing (Section 2). In Section 3, we introduce the first argument dataset that has been annotated with frames and topics, and we provide statistical insights into the dataset. Section 4 presents a new unsupervised approach to identify frames in a set of arguments. Our approach first removes topical features from the arguments and then clusters the arguments into frames. In Section 5, we describe the experiments that we conducted to evaluate our approach. We apply the approach to all arguments from *debatepedia.org* and evaluate the returned frames against the ground-truth frames in our dataset. Section 6 shows and discusses the effectiveness of our approach. In Section 7, we analyze the errors made by the approach in the experiments.

The main contributions of this paper are:

- A formal view of frames in argumentation.
- An unsupervised approach to identifying frames in a set of argumentative texts.
- An argument framing dataset with 465 topics, 1 623 frames, and 12 326 arguments.

We freely provide the complete dataset to the research community.[1]

2 Related Work

Research on framing is scattered across different fields such as media, social, and cognitive studies. Entman (1993) was the first to introduce a formal definition of framing as a way to select and make specific aspects of a topic salient. Subsequent research on framing is concentrated on the effect of using frames in news on a specific audience. One of the open questions is whether frames are topic-specific or generic concepts, or both. Vreese (2005) studied framing in news articles and considered frames to be both of the two. Johnson et al. (2017) and Card et al. (2015), on the other hand, defined frames to be independent of the topic and investigated their usage across different topics.

Recently, framing caught some attention in the NLP community. Different computational models have been developed for modeling frames in natural language text. Tsur et al. (2015) used topic models on statements released by congress members of the two major parties in the US, Republicans and Democrats. The learned topics were then aggregated into clusters, such as health and economy, and interpreted as being generic frames. On this basis, the authors studied the frequency of the frames in the released statements for the two parties as well as their distribution over time. A related work was conducted by Menini et al. (2017) to model frames in political manifestos released by the parties (texts declaring a stance) as clusters of key phrases. The developed method was shown to outperform standard topic models in capturing frames.

Card et al. (2015) annotated around 16k news articles on three topics (same-sex marriage, immigration, and smoking), along with a list of 15 generic frames. While the annotations had to cover continuous spans of text, their granularity was left unspecified. The inter-annotator agreement on frames for the different frames ranged between 0.08 and 0.23 in terms of Krippendorff's α. By comparison, our dataset covers both generic and topic-specific frames and are annotated on the argument level. Naderi and Hirst (2017) extended this line of work by training a neural network to classify the frames in the constructed corpus. The authors modeled frames on the sentence level and reached an accuracy of 53.7% in multi-class classification and 89.3% for one-against-others classification. Using the same corpus, (Field et al., 2018) created a lexicon for each one of the 15 frames and analyzed which frames are used mainly to talk about the United States in Russian news.

A related line of research is the mining of arguments from natural language text (Al-Khatib et al., 2016). Most approaches uses supervised classifiers to extract the structure of arguments (*conclusion* and *premise*) (Stab and Gurevych, 2014). (Lawerence and Reed, 2017) showed that topic models helps identifying the relevance of a premise to a conclusion when they are trained on topically relevant documents. The stance of the mined arguments is classified as pro or con towards a given topic (Somasundaran and Wiebe, 2010; Bar-Haim et al., 2017). The arguments are then used for applications such as argument search (Wachsmuth et al.,

[1] Argument framing dataset: https://webis.de/data/webis-argument-framing-19.html or https://doi.org/10.5281/zenodo.3373355

2017a; Levy et al., 2018; Stab et al., 2018) with the goal of retrieving relevant arguments for an input claim. Use cases for argument search include writing and debating support. In comparison to user queries in conventional search that can often be satisfied by one or a few retrieved documents, these use cases require a broader consideration of the retrieved arguments. Hence, the user of an argument search engine will often investigate both stances and multiple frames on a given topic. While several studies tackled the task of ranking arguments according to their quality (Habernal and Gurevych, 2016; Wachsmuth et al., 2017b), how to aggregate arguments into frames is largely unstudied.

The relation between arguments and frames was introduced briefly in some works (Boydstun et al., 2013; Gabrielsen et al., 2011). Still, recent research on computational argumentation largely ignores frames, and a model for aggregating arguments into frames is still missing. Naderi (2016) considered a frame to be an argument and classified sentences in parliamentary speeches into one of seven frames. (Reimers et al., 2019) created a dataset of argument pairs that are labeled according to their similarity. Based on the dataset, they introduced the task of argument clustering which aims at classifying an argument pair with the same topic into similar or dissimilar. The main difference to this work is that no explicit aspect are assigned to the arguments during annotation.

3 Data

Debate portals are websites where people debate or collect arguments for or against controversial topics. Some debate portals are dialogical, such as *debate.org*, allowing two opponents to debate one topic in rounds. Other debate portals such as *debatepedia.org* are wiki-like where arguments are listed according to their stance on the topic. Debate portals keep a canonical structure of the arguments considered for each topic (usually a conclusion and a premise). The structure and the wide topic coverage offered by debate portals has made them a suitable resource for research on computational argumentation (Cabrio and Villata; Al-Khatib et al., 2016; Wachsmuth et al., 2017a).

3.1 Argument Frames from Debatepedia.org

For the given work, we crawled all arguments from debatepedia.org in order to construct a dataset for the evaluation of frame identification. Debatepedia.org organizes a debate into sets of arguments that address a topical aspect of the debate. A label that describes the topical aspect is attached to some of the sets, such as *economics*. An argument on debatepedia.org is listed as a conclusion on the topic along with a premise that supports it.

# Topics	# Frames	# Merged Frames	# Arguments
465	1 645	1 623	12 326

Table 1: Counts of topics, frames, merged frames, and arguments in the webis-argument-framing-19 dataset.

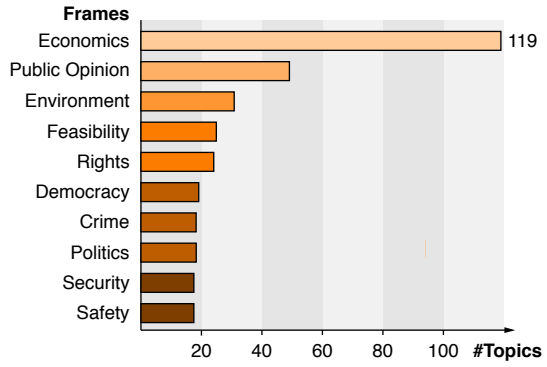

Figure 1: The number of topics in which each of the 10 most frequent frame labels in our dataset occurs.

Arguments which are not labeled might introduce noise to the dataset, since the true knowledge regarding their frames is unavailable. To exclude possible noise in the planned experiments, we filtered out all arguments without labels (about 1800). Next, we analyzed the extracted labels and found that some labels have a similar meaning but are worded differently. In particular, we noticed the presence of the following cases:

1. Labels with hierarchical relations, such as *business* and *US business*.
2. Opposite labels, such as *health* and *unhealthy*, or, *protecting smokers* and *protecting non-smokers*.
3. Labels that are equal when being lemmatized, such as *economics* and *economic*, *democratizing* and *democratic*, etc.

Labels with the same lemmas are likely to carry the same meaning, which is why we merged them into the same label. The count of such merged label pairs was 22, each containing 42 arguments on average. Since the labels in the first and second cases might constitute different frames in some context, we kept them as they are.

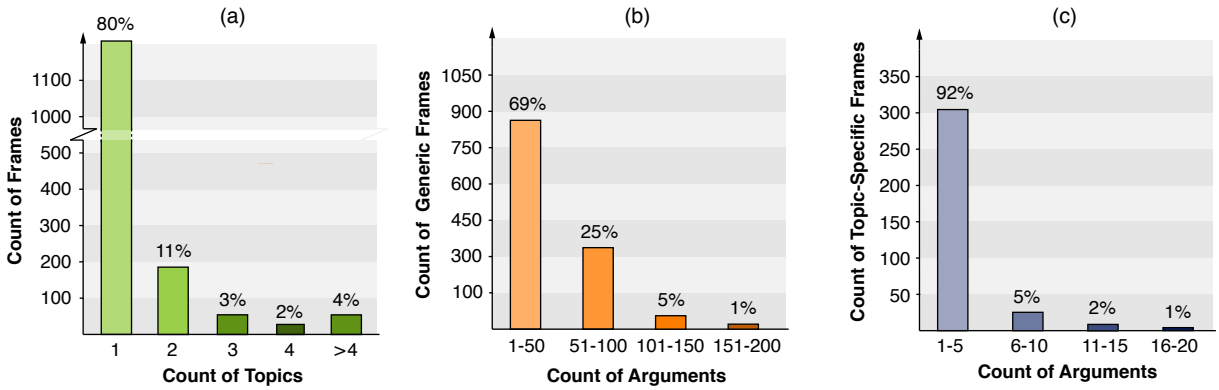

Figure 2: General statistics of frames from debatepedia.org in the webis-argument-framing-19 dataset. (a): Histogram of frames over the count of topics in which they are used. (b): Histogram of generic frames over the count of arguments they contain. (c): Histogram of topic-specific frames over the count of arguments they contain.

3.2 Webis-Argument-Framing-19 Dataset

Table 1 shows general statistics of the final dataset after crawling and preprocessing, called *webis-argument-framing-19*. As visualized in Figure 1, the ten most frequent labels in our dataset are: *economics*, *public opinion*, *environment*, *feasibility*, *rights*, *democracy*, *crime*, *politics*, *security* and, *safety*. These labels largely overlap with those introduced by Card et al. (2015); hence, we considered each set of arguments to be a frame.

The count of topics in which a frame occurs indicates whether a frame is generic or topic-specific. To distinguish between these two types of frames, we grouped all frame labels in our dataset according to how many topics they occur in. Figure 2 (a) shows a histogram of the frames in our dataset over the count of topics in which they are used. As depicted, 80% (1293) of the frames are used in one topic and, hence, we labeled them as *topic-specific*. Frames that are used in more than one topic add up to 20% (330) frames and are labeled as *generic*. Generic frames in the dataset cover 7052 arguments while topic specific frames cover 5274 arguments. Figure 2 (b) and (c) show a histogram of generic and of topic-specific frames over the count of arguments they contain respectively. The histograms reveal that generic frames cover an order of magnitude more as many arguments as topic-specific frames.

4 Approach

In this section, we introduce our unsupervised approach to modeling frames formally. We assume frames to be exclusive and non-overlapping. Given a set of arguments $A = \{a_1, a_2, \ldots, a_n\}$, our goal is to find a set of frames, which constitutes a cover of A. A cover of A is a set of sets $\{F_1, F_2, \ldots, F_k\}$ whose union contains A, i.e., $A \subseteq \bigcup_j^k F_j$. Table 2 lists the symbols used in this section along with their meaning.

The main idea of our approach is to first remove topical features from arguments and then to cluster the arguments into frames. Following known topic modeling approaches, we represent the content of an argument a as a bag of words and propose two models to find topic-specific words. Both models utilize the frequency of the words in an argument and the argument's structure. The structure of a is represented by its conclusion c and its premise(s) p. Our approach includes three main steps:

(a) **Topic clustering.** Cluster the arguments in A into m topics $\bar{\mathcal{A}} = \{\bar{A}_0, \bar{A}_1, \ldots, \bar{A}_m\}$.

(b) **Topic removal.** Given the produced clusters, develop an extraction model E that extracts topical features from an argument a_i and its cluster. E is applied to each $\bar{A}_j \in \bar{\mathcal{A}}$ to remove topic-specific features. As a result, we obtain "topic-free" arguments $a'_i = a_i - E(a, \bar{A}_j)$. We denote the set of all "topic-free" arguments with A' where $A' = \{a'_1, a'_2, \ldots, a'_n\}$.

(c) **Frame clustering.** Cluster the arguments A' into k clusters, each respresenting one frame.

Figure 3 sketches the general idea of the three steps of our approach. We detail our concrete realization of each step in the following.

4.1 Topic Clustering

To cluster the given set of arguments into topics, we first map each argument into a vector space that

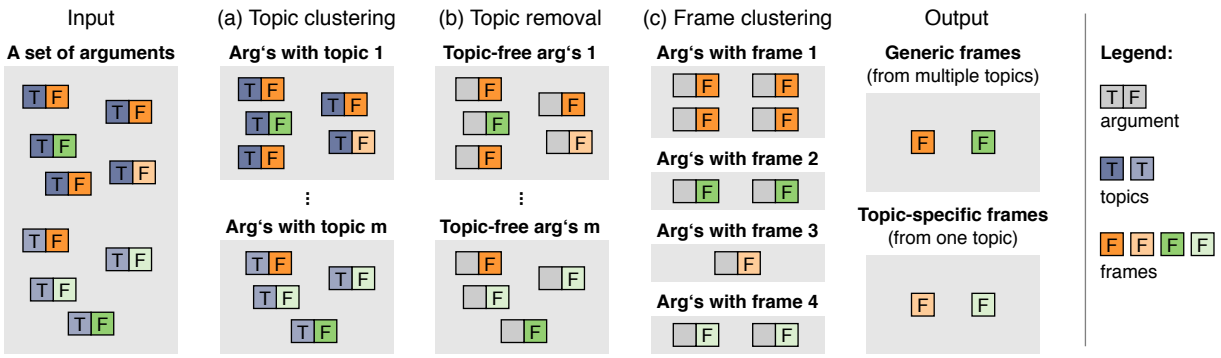

Figure 3: Sketch of the proposed unsupervised approach to argument frame identification. An argument is modeled as a topic and a frame. The input is a sets of arguments. The output is representations of two types of found frames.

Symbol	Meaning
a	An argument
c	The conclusion of an argument
A	A set of arguments
$\bar{A}$	A set of arguments on the same topic
$\mathcal{A}$	A set of sets of arguments
F	A frame
v	A word
V	A vocabulary
E	A topic extraction model

Table 2: Notation of the symbols used in the approach

represents its semantics. We use k-means (Hartigan and Wong, 1979) with Euclidean distance as a clustering algorithm. For semantic spaces, we consider two alternatives: *Term Frequency-Inverse Document Frequency* (TF-IDF), and *Latent Semantic Analysis* (LSA).

TF-IDF TF-IDF defines a vector space whose dimensions are words in the dataset. An argument is mapped to this space according to the frequency of each of its words, normalized by the word's frequency in all considered arguments. TF-IDF is a sparse vector space since all words in a set of arguments are considered. To reduce sparsity, we construct a vocabulary V which comprises the 5000 most frequent words in the arguments after stopword removal. Words that occur in more than half of the arguments are ignored as well. The main reason for reducing the vocabulary is to increase the computational efficiency of the approach.

LSA Latent Semantic analysis (Deerwester et al., 1990) infers from a term-document frequency matrix a linear transformation that project documents into a topic space. We construct two different semantic spaces using LSA. The first, simply called *LSA*, considers each argument to be a document. The second, *LSA Debate*, considers a whole debate to be a document. Since LSA Debate works on the debate level, it can better capture the topic context of an argument. The reason is that arguments capture the topic differently and may have few words in common. Using all arguments in a debate ensures a broader context of the topic. To compare both LSA models systematically, we use the same number of dimension for both models: 1000.

4.2 Topic Removal

The goal of this step is to remove topic-specific features in the topic clusters $\bar{\mathcal{A}} = \{\bar{A}_0, \bar{A}_2, \ldots, \bar{A}_m\}$. To achieve this goal, we develop two models to extract topic-specific features, E_1^q and and E_2. E_1^q utilizes the content of the arguments in one cluster, whereas E_2 utilizes the argument structure, i.e., conclusion and premise information.

E_1^q utilizes the term-frequency inverse document frequency measure TF-IDF for every word v in each cluster. We calculate idf as follows:

$$idf(v) = \frac{\left|\bar{\mathcal{A}}\right|}{\left|\bar{A}_j \in \bar{\mathcal{A}} : v \in \bar{A}_j\right|}$$

Then, $E_1^q(a)$ returns those words that best discriminates a specific topic as follows based on a threshold q, which can be understood as the aggressiveness of the model:[2]

$$E_1^q(a, \bar{A}_j) = \{v \in \bar{A}_j : tf.idf(v) > q\}$$

E_2 utilizes the structure of an argument on a local level. The hypothesis here is that the conclusion of an argument contains more words that target the topic than its premise. Hence, we remove the conclusion in an argument. Formally:

$$E_2(a, \bar{A}_j) = \{v \in c\}$$

[2]In our experiments, we chose the threshold q empirically.

4.3 Frame clustering

This step aims at grouping arguments that share a common aspect after removing topical features. For clustering, we use k-means again and experiment with different values of k. Below, we choose k based on an experiment that evaluates the output of the cluster against the ground-truth. We also use Euclidean distance to estimate the similarity between the arguments in the two semantic spaces.

5 Experiments

Based on the dataset we introduced in Section 3, we conduct experiments to evaluate and analyze our approach to modeling frames in argumentation. As discussed above, the approach consists of three steps: topic clustering, topic removal, and frame clustering. We evaluate the three steps and their interaction with each other in different experiments.

Topic Clustering Experiment The goal of this experiment is to find the best method to group arguments into topics. The produced clusters for each semantic space are evaluated against the arguments' topics in the ground-truth dataset. An external measure is then used to evaluate the output of the clustering algorithm for each semantic space. In particular, we use *Bcubed F_1-score* (Bagga and Baldwin, 1998) to evaluate the effectiveness of our approach in modeling topics in the dataset. Bcubed F_1-score rewards only the instance pairs that exist in the output of the clustering algorithm and in the ground-truth together in the same cluster. The reason for choosing Bcubed F_1-score is that it is proven to satisfy desired constraints in the output of clustering algorithms (Amigó et al., 2009).

Topic Removal Experiment This experiment aims at evaluating our models E_1^q and E_2 at removing topical features from the arguments in $\bar{A}$. The evaluation criterion here is the effectiveness drop of the topic clustering algorithm after removing the topical features in $\bar{A}$. We rerun the topic clustering algorithm with the same k after removing the output of both models E_1^q and E_2. To have a consistent comparison, we set k to the best count of topics we found in the previous experiment.

Frame Clustering Experiment The last experiment evaluates clustering arguments into frames after topic removal. To test our hypothesis that topic removal benefits frame identification, we also cluster arguments in the same semantic space without topic removal. For both semantic spaces, we conduct three experiments: main experiment, generic frame experiment, and topic-specific frame experiment. In the topic-specific and generic frame experiment, we use the frames in our dataset that are labeled as topic specific and generic frame separately. In the main experiment, we test our approach on the whole dataset without distinguishing the type of frames. The different experiments should show us the performance of our approach at identifying generic and topic-specific frames. Similar to topic clustering, we use Bcubed F_1-score (Bagga and Baldwin, 1998) to evaluate the frame clustering algorithm in the three experiment. Since our dataset contains 1623 frames, we evaluate the output of the clustering algorithm for each $k \in \{1000, \ldots, 1600\}$.

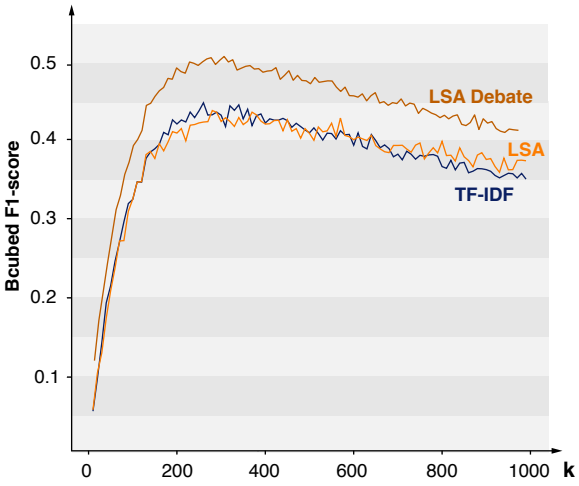

Figure 4: Bcubed F_1-score of the topic clustering algorithms for the semantic spaces TF-IDF, LSA and LSA Debate for each k.

6 Results and Discussion

In the following, we report on the results of the three experiments explained above separately. At the end, we discuss the findings of the experiments and draw final conclusions on the performance of our approach at identifying frames.

6.1 Topic Clustering

Figure 4 shows the effectiveness of topic clustering using the different semantic spaces. We visualize for each k the Bcubed F_1-score of the clustering algorithms for the three semantic spaces. As shown, TF-IDF and LSA perform similarly for all k. The clustering algorithm performs better using the semantic space LSA Debate than LSA and

Semantic Space	# Topics	F_1
LSA Debate	310	**0.52**
TF-IDF	260	0.45
LSA	280	0.44

Table 3: Bcubed F_1-score of the topic clustering algorithm for each semantic space and the corresponding count of topics found.

TF-IDF. This shows the importance of considering the context of an argument for modeling their topics. All the three depicted plots, however, show a clear elbow between topic counts 200 and 400. Table 3 shows the highest corresponding F_1-score and the count of topic clusters for each semantic space. The best topic clustering achieved by the algorithms comprises 310 clusters. Given its high effectiveness in modeling topics, we decided to proceed with the topic clusters produced by the LSA Debate in the next experiment.

6.2 Topic Removal

Table 4 shows the results of the topic removal experiment and frame clustering experiment. For both semantic spaces, the effectiveness of topic clustering algorithm is reported after using the models E_1^q and E_2 to remove topic-specific words. To evaluate the topic extraction models, we re-list the effectiveness achieved by the topic clustering algorithm for both spaces. We show the results of E_1^q only for $q = 0.005$ since higher values of q showed similar or lower results in all experiments.

As shown, E_2 decreases the effectiveness of topic clustering algorithm to around the half. The model $E_1^{0.005}$ achieves a smaller drop of 0.03-0.04 in the two semantic spaces. Despite its simplicity, E_2 is more effective at removing topic-specific features than $E_1^{0.005}$.

6.3 Frame Clustering

Table 4 shows the results of the frame clustering algorithm in the experiments: generic, topic-specific, and main. In each experiment, the clustering algorithm is run after using the two topic extraction models to remove topic-specific features and without applying them (baseline). In the main and the generic experiment, using the topic extraction models outperforms not using them in both semantic spaces. In the topic-specific experiment, our approach's effectiveness outperformed the baseline only in LSA space. The comparison between the results in the generic and topic-specific experiments shows that identifying generic frames is harder. The reason can also be the small size of topic-specific frames in the ground-truth. Our approach, however, is only effective at identifying generic frames and fails at outperforming the baseline in the topic-specific experiments. A reason to justify this is that removing topic-specific features negatively affects identifying topic-specific frames.

To better analyze our approach, we plot the achieved Bcubed F_1-score for each semantic space and each experiment for different values of k. Figure 5 (a,b,c) shows the effectiveness achieved in the three experiments main, topic-specific and generic respectively in TF-IDF space. As shown, both models $E_1^{0.005}$ and E_2 start to outperform the baseline at $k = 1200$ in the main experiment. All the approaches converge starting from this value and not much effectiveness is achieved for higher values of k. In the generic experiment, both models achieve their first peaks at $k = 800$. The performance of both models oscillates but keeps at the same rate of for larger values of k. In the topic-specific experiments, the performance of our approach increases significantly while approaching the value of $k = 400$. The gain achieved by for more clusters decreases slowly for larger values of k.

Figure 6 (a,b,c) shows the effectiveness achieved in the three experiments main, topic-specific and generic respectively in LSA space. As depicted in the three figures, the model $E_1^{0.005}$ outperforms E_2 in all cases which shows that content-based topic-removal of arguments is more effective than using its structure. In the generic experiment, all models in LSA space shows subpar effectiveness to their counterpart in TF-IDF space and lack clear peaks. In the topic-specific experiment, our approach outperforms the LSA baseline and their counterpart in TF-IDF space. Nevertheless, like in the generic experiment, no clear peak is reached by any model.

6.4 Discussion

The results show the merit of removing the topic-specific of an argument for identifying its frame. According to the reported results, our approach is effective at identifying generic frames and does not suit identifying topic-specific frames. An interesting finding is that the premise of an argument carries more information about its frame than the conclusion. This is shown in the higher effectiveness achieved after applying E_2 compared to the

Semantic Space	Topic Removal		Frame Clustering								
	Model	Topic F_1	Generic Frames			Topic-specific Frames			Frames		
			F_1	P	R	F_1	P	R	F_1	P	R
TF-IDF	Baseline	**0.45**	0.19	0.25	0.15	**0.48**	0.53	0.44	0.26	0.27	0.25
	$E_1^{0.005}$	0.42	**0.28**	0.26	0.30	0.45	0.50	0.40	**0.28**	0.24	0.33
	E^2	0.17	0.26	0.25	0.28	0.45	0.48	0.42	0.27	0.25	0.29
LSA	Baseline	0.44	0.16	0.20	0.13	0.39	0.44	0.35	0.21	0.22	0.22
	$E_1^{0.005}$	0.4	0.21	0.15	0.33	0.47	0.44	0.48	0.26	0.25	0.27
	E^2	0.25	0.2	0.18	0.22	0.46	0.41	0.50	0.24	0.24	0.24

Table 4: Best bcubed F_1-score, precision, and recall for the topic extraction models E_1^q, E_2 and without topic removal (baseline) in the generic, topic-specific and main frame experiments together with the corresponding bcubed F_1-score in topic clustering.

baseline. A justification can be that a conclusion is more likely to carry stance-taking words toward the topic. In general, $E_1^{0.005}$ achieved higher results than E_2, which shows that using the content of an argument is more effective than using its structure to model frames. A possible justification for this can be that E_2 is more aggressive than needed at removing topic-specific features.

7 Error Analysis

We analyze the topic and frame clusters produced by our approach to convey to the reader a sense of its performance. For topic clusters, we focus on the semantic space LSA Debate since our approach performed the best in this semantic space. For Frame clusters, we analyze the output of our approach in the semantic space TF-IDF after applying $E_2^{0.005}$ since our approach performed the best in this semantic space. Our goal is to identify the topics and frames in the dataset which our approach completely confused or correctly identified. To identify these cases, we sort the topics and frames in the ground-truth dataset according to the maximum F_1-score achieved in the aforementioned semantic spaces respectively. We manually analyze the topic and frames labels and the count of arguments they comprise and report the most interesting cases.

For topic clustering, examples of topics that our approach correctly identified (with an F_1-score of 1) are: *Zoos* and *Compulsory vaccination*. On the other hand, our approach struggled at identifying topics like *Is Pluto a planet?* and *Immunity from prosecution for politicians* (with an F_1-score lower than 0.1). A reason for this might be that these topics are too specific and not covered well in our dataset.

In frame clustering, the hardest cases for our approach in TF-IDF space were topic-specific frames that contain few arguments, e.g., *child disability*. Generic frames such as *rights* and *feasibility* were also hard to identify (with an F_1-score lower than 0.1). A possible explanation is that these frames can be confused with generic frames like *human rights* and *economics*. Examples of generic frames that were effectively identified are *freedom of speech* and *public health* (with an F_1-score equals to 0.5).

8 Conclusion

A disagreement between people on a topic can lead to a lively debate where the opposing parties exchange arguments on the topic to enforce their stance. In favor of a particular stance, an argument emphasizes a certain aspect of the topic, thereby hiding other aspects. This phenomenon is called framing and has been introduced in social science (Entman, 1993). Knowing the frame of an argument helps users to choose arguments that better address the audience's cultural background.

Research on framing in natural languages is still lacking. In this paper, we tried to close this gap by introducing a formal view on framing that defines a frame as a set of arguments that share an aspect. Starting from this view, we introduced an approach to remove the topic's features from the arguments and then to cluster them. We operationalized our approach by using two different models. While the first removes an argument's topic features using its content, the second utilizes its structure (conclusion and premise).

For evaluation purposes, we constructed a new dataset that comprises 12 326 arguments grouped along 1 623 frames based on debatepedia.org. The experiments show that we can outperform sensi-

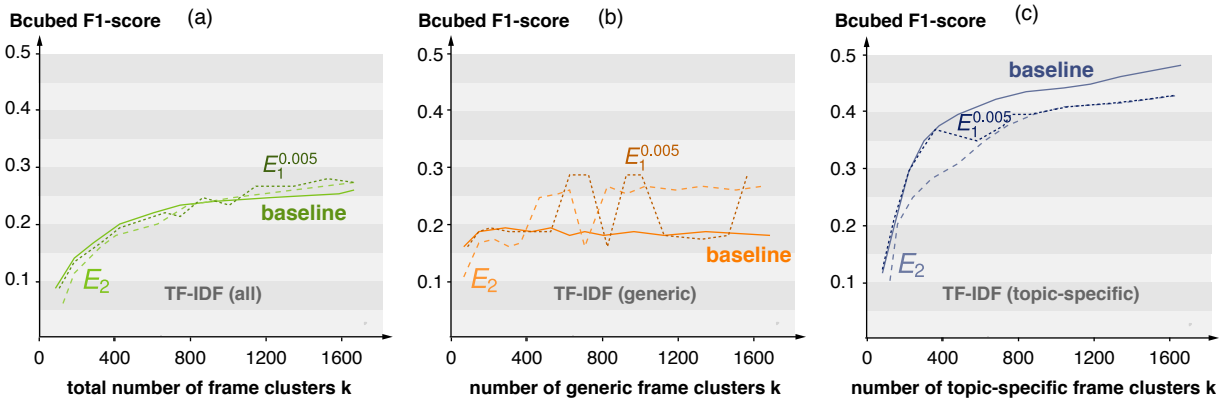

Figure 5: Effectiveness of frame clustering with TF-IDF without topic removal (baseline) and after applying $E_1^{0.005}$ and E_2 in (a) the main frame experiment, (b) the generic frame experiment, and (c) the topic-specific experiment.

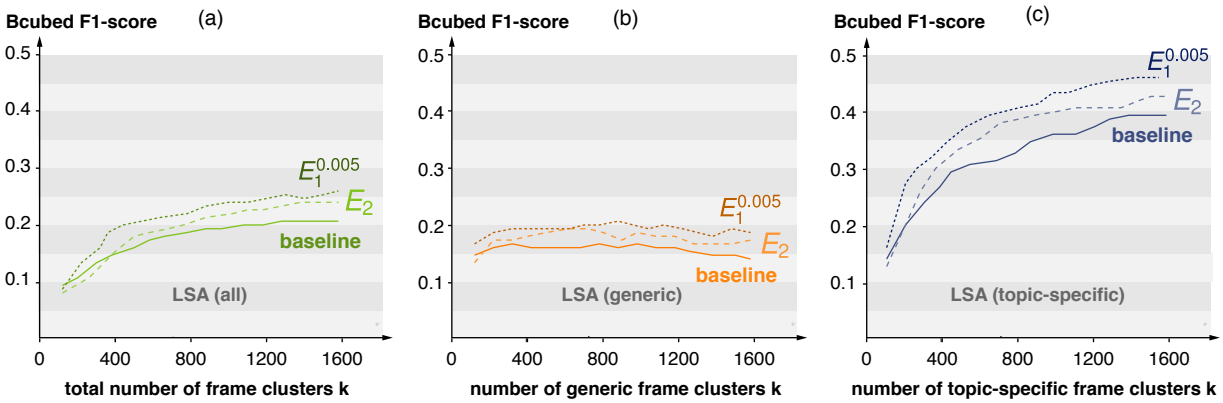

Figure 6: Effectiveness of frame clustering with LSA without topic removal (baseline) and after applying $E_1^{0.005}$ and E_2 in (a) the main frame experiment, (b) the generic frame experiment, and (c) the topic-specific experiment.

ble baselines that utilize the same semantic spaces without deleting topic information. We conducted three types of experiments that evaluate our approach in identifying generic (those which are used in multiple topics), topic-specific and both.

Our experiments clearly show the benefit of removing topic's features for identifying an argument's frame. In particular, we find that identifying generic frames benefits from removing topic features, which are actually the hardest case. On the other hand, removing topic features cannot help in identifying topic-specific frames. We also observed that removing an argument's conclusion helps identifying its frame, although it is more likely to carry the stance and the topic of an argument.

Having set a lacking methodology for modeling frames in argumentation, our next step is to develop better approaches for modeling and removing the topic of an argument. Neural networks such as auto-encoders and attention-based models are likely to perform better at modeling frames in argumentation than LSA and TF-IDF. Regarding topic removal, potential research directions will investigate using external knowledge such as Wikipedia to find topic-specific features.

Future work on framing will focus on its application to down-stream argument mining tasks such as analyzing argument quality. Especially interesting is whether specific frames are expected to persuade an audience. A follow-up question will be whether frames in an argumentative text should be delivered in a specific sequence to achieve the persuasion of an audience.

The simplicity of our model allows its application in domains such as news, laws, or student essays. A promising application of our model is argument search since a frame of an argument sheds a light on its acceptability for a specific audience. A clear problem here is how to label a frame given its arguments in order to deliver short labels for the user. We also expect framing to play a major role in generating arguments since a specific frame might resonate with an audience.

Abstract

Argumentation is a type of discourse where speakers try to persuade their audience about the reasonableness of a claim by presenting supportive arguments. Most work in argument mining has focused on modeling arguments in monologues. We propose a computational model for argument mining in online persuasive discussion forums that brings together the micro-level (argument as product) and macro-level (argument as process) models of argumentation. Fundamentally, this approach relies on identifying relations between components of arguments in a discussion thread. Our approach for relation prediction uses contextual information in terms of fine-tuning a pre-trained language model and leveraging discourse relations based on Rhetorical Structure Theory. We additionally propose a candidate selection method to automatically predict what parts of one's argument will be targeted by other participants in the discussion. Our models obtain significant improvements compared to recent state-of-the-art approaches using pointer networks and a pre-trained language model.

1 Introduction

Argument mining is a field of corpus-based discourse analysis that involves the automatic identification of argumentative structures in text. Most current studies have focused on monologues or *micro-level* models of argument that aim to identify the structure of a single argument by identifying the argument components (classes such as "claim" and "premise") and relations between them ("support" or "attack") (Somasundaran et al., 2007; Stab and Gurevych, 2014; Swanson et al., 2015; Feng and Hirst, 2011; Habernal and Gurevych, 2017; Peldszus and Stede, 2015). *Macro-level* models (or dialogical models) and rhetorical models which focus on the *process* of argument in a dialogue (Bentahar et al., 2010) have received less attention.

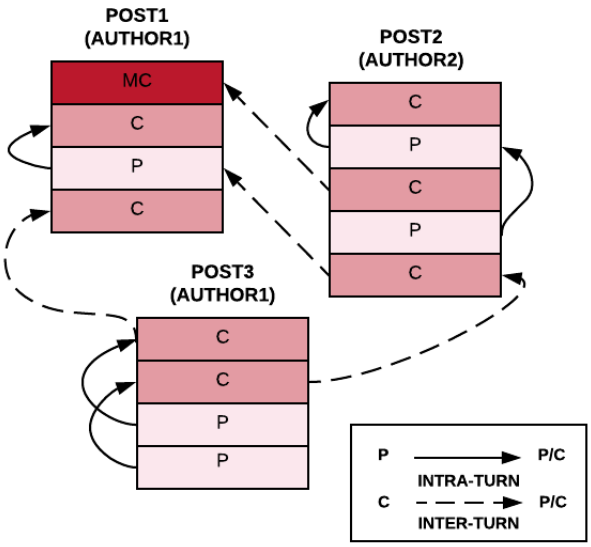

Figure 1: Annotated Discussion Thread (C: Claim, P: Premise, MC: Main Claim)

We propose a novel approach to automatically identify the argument structure in persuasive dialogues that brings together the micro-level and the macro-level models of argumentation. Our approach identifies argument components in a full discussion thread and two kinds of argument relations: *inter-turn relations* (argumentative relations to support or attack the other person's argument) and *intra-turn* relations (to support one's claim). Figure 1 shows a thread structure consisting of multiple posts with argumentative components (main claims, claims or premises) and both intra- and inter-turn relations. We focus here on the relation identification task (i.e, predicting the existence of a relation between two argument components).

To learn to predict relations, we **annotate argumentative relations** in threads from the Change

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2933–2943,

My View (CMV) subreddit. In addition to the CMV dataset we also **introduce two novel distantly-labeled data-sets** that incorporate the macro- and micro-level context (further described in Section 3). We also **propose a new transfer learning approach** to fine-tune a pre-trained language model (Devlin et al., 2019) on the distant-labeled data (Section 4) and demonstrate improvement on both argument component classification and relation prediction (Section 5). We further show that **using discourse relations** based on Rhetorical Structure Theory (Mann and Thompson, 1988) improves the results for relation identification both for inter-turn and intra-turn relations. Overall, our approach for argument mining **obtains statistically significant improvement** over a state-of-the-art model based on pointer networks (Morio and Fujita, 2018) and a strong baseline using a pre-trained language model (Devlin et al., 2019). We make our data,[1] code, and trained models publicly available.[2]

2 Related Work

Argument mining on monologues Most prior work in argument mining (AM) has focused on monologues or essays. Stab and Gurevych (2017) and Persing and Ng (2016) used pipeline approaches for AM, combining parts of the pipeline using integer linear programming (ILP) to classify argumentative components. Stab and Gurevych (2017) represented relations of argument components in essays as tree structures. Both Stab and Gurevych (2017) and Persing and Ng (2016) propose joint inference models using ILP to detect argumentative relations. They however rely on handcrafted (structural, lexical, indicator, and discourse) features. We on the other hand use a transfer learning approach for argument mining in discussion forums.

Recent work has examined neural models for argument mining. Potash et al. (2017) use pointer networks (Vinyals et al., 2015) to predict both argumentative components and relations in a joint model. For our work, we focus primarily on relation prediction but conduct experiments with predicting argumentative components in a pipeline. A full end-to-end neural sequence tagging model was developed by Eger et al. (2017) that predicts argumentative discourse units (ADUs), components, and relations at the token level. In contrast, we assume we have ADUs and predict components and relations at that level.

Argument mining on discussion forums (online discussion) Most computational work related to argumentation as a process has focused on the detection of agreement and disagreement in online interactions (Abbott et al., 2011; Sridhar et al., 2015; Rosenthal and McKeown, 2015; Walker et al., 2012). However, these approaches do not identify the argument components that the (dis)agreement has scope over (i.e., what has been targeted by a disagreement or agreement move). Also in these approaches, researchers predict the type of relation (e.g. agreement) given that a relationship exists. On the contrary, we predict both argument components as well as the existence of a relation between them. Boltužić and Šnajder (2014) and Murakami and Raymond (2010) address relations between complete arguments but without the micro-structure of arguments as in Stab and Gurevych (2017). Ghosh et al. (2014) introduce a scheme to annotate inter-turn relations between two posts as "target-callout", and intra-turn relations as "stance-rationale". However, their empirical study is reduced to predicting the type of inter-turn relations as agree/disagree/other. Our computational model on the other hand handles both macro- and micro- level structures of arguments (argument components and relations).

Budzynska et al. (2014) focused on building foundations for extracting argument structure from dialogical exchanges (radio-debates) in which that structure may be implicit in the dynamics of the dialogue itself. By combining recent advances in theoretical understanding of inferential anchors in dialogue with grammatical techniques for automatic recognition of pragmatic features, they produced results for illocutionary structure parsing which are comparable with existing techniques acting at a similar level such as rhetorical structure parsing. Furthermore, Visser et al. (2019) presented US2016, the largest publicly available set of corpora of annotated dialogical argumentation. Their annotation covers argumentative relations, dialogue acts and pragmatic features.

Although Niculae et al. (2017) tried relation prediction between arguments in user comments on web discussion forums using structured SVM

[1] https://github.com/chridey/change-my-view-modes
[2] https://github.com/tuhinjubcse/AMPERSAND-EMNLP2019

and RNN the work closest to our task is that of Morio and Fujita (2018). They propose a pointer network model that takes into consideration the constraints of thread structure. Their model discriminates between types of arguments (e.g., claims or premises) and both intra-turn and inter-turn relations, simultaneously. Their dataset, which is not publically available, is three times larger than ours, so instead we focus on transfer learning approaches that take advantage of discourse and dialogue context and use their model as our baseline.

3 Data

3.1 Labeled Persuasive Forum Data

To learn to predict relations, we use a corpus of 78 threads from the CMV subreddit annotated with argumentative components (Hidey et al., 2017). The authors annotate *claims* ("propositions that express the speakers stance on a certain matter"), and *premises* ("propositions that express a justification provided by the speaker in support of a claim"). In this data, the *main claim*, or the central position of the original poster, is always the title of the original post.

We expand this corpus by annotating the argumentative relations among these propositions (both inter-turn and intra-turn) and extend the corpus by annotating additional argument components (using the guidelines of the authors) for a total of 112 threads. It is to be noted that the claims, premises, and relations have been annotated jointly. Our annotation results on the argumentative components for the additional threads were similar to Hidey et al. (2017) (IAA using Kripendorff alpha is 0.63 for claims and 0.65 for premises). The annotation guidelines for relations are available in the aforementioned Github repository.

Intra-turn Argumentative Relations As in previous work (Morio and Fujita, 2018), we restrict intra-turn relations to be between a premise and another claim or premise, where the premise either supports or attacks the claim or other premise. Evidence in the form of a premise is either support or attack. Consider the following example:

> [Living and studying overseas is an irreplaceable experience.]$_{0:\text{CLAIM}}$ [One will struggle with loneliness]$_{1:\text{PREMISE:ATTACK:0}}$ [but those difficulties will turn into valuable experiences.]$_{2:\text{PREMISE:ATTACK:1}}$ [Moreover, one will learn to live without depending on anyone.]$_{3:\text{PREMISE:SUPPORT:0}}$

The example illustrates that the argumentative component at index 0 is a claim, and is followed by attacking one's own claim, and in turn attacking that premise (an example of the rhetorical move known as prolepsis or prebuttal). They conclude the argument by providing supporting evidence for their initial claim.

Inter-turn Argumentative Relations Inter-turn relations connect the arguments of two participants in the discussion (agreement or disagreement). The argumentative components involved in inter-turn relations are claims, as the nature of dialogic argumentation is a difference in stance. An *agreement* relation expresses an agreement or positive evaluation of another user's claim whereas a *disagreement/attack* relation expresses disagreement. We further divide disagreement/attack relations into *rebuttal* and *undercutter* types to distinguish when a claim directly challenges the truth of the other claim or challenges the reasoning connecting the other claim to the premise that supports it, respectively. We also allowed annotators to label claims as *partial* agreement or disagreement/attack if the response concedes part of the claim, depending on the order of the concession.

In the following example, User A makes a claim and supports it with a premise. User B agrees with the claim but User C disputes the idea that there even is global stability. Meanwhile, User D disagrees with the reasoning that the past is always a good predictor of current events.

> A: [I think the biggest threat to global stability comes from the political fringes.]$_{0:\text{CLAIM}}$ [It has been like that in the past.]$_{1:\text{PREMISE}}$
>
> B: [Good arguments.]$_{2:\text{AGREEMENT:0}}$
>
> C: [The only constant is change.]$_{3:\text{REBUTTAL:0}}$
>
> D: [What happened in the past has nothing to do with the present.]$_{4:\text{UNDERCUTTER:1}}$

We obtain moderate agreement for relation annotations, similar to other argumentative tasks

(Morio and Fujita, 2018). The Inter-Annotator Agreement (IAA) with Kripendorff's α is 0.61 for relation presence and 0.63 for relation types.

In total, the dataset contains 380 turns of dialogue for 2756 sentences. There were 2741 argumentative propositions out of which 1205 are claims and 1536 are premises, with an additional 799 non-argumentative propositions. 66% of relations were in support, 26% attacking, and 8% partial. As we found that most intra-turn relations were in support and inter-turn relations were attacking, due to the dialogic nature of the data, for our experiments we only predicted whether a relation was present and not the relation type.

Overall, there are 7.06 sentences per post for our dataset, compared to 4.19 for Morio and Fujita (2018). This results in a large number of possible relations, as all pairs of argumentative components are candidates. The resulting dataset is very unbalanced (only 4.6% of 27254 possible pairs have a relation in the intra-turn case with only 3.2% of 26695 for inter-turn), adding an extra challenge to modeling this task.

3.2 Distant-Labeled Data

As the size of this dataset is small for modern deep learning approaches, we leverage distant-labeled data from Reddit and use transfer learning techniques to fine-tune a model on the appropriate context — micro-level for intra-turn relations and macro-level (dialogue) for inter-turn relations.

Micro-level Context Data In order to leverage transfer learning methods, we need a large dataset with distant-labeled relation pairs. In previous work, Chakrabarty et al. (2019) collected a distant-labeled corpus of opinionated claims using sentences containing the internet acronyms IMO (in my opinion) or IMHO (in my humble opinion) from Reddit. We leverage their data to model relation pairs by considering the following sentence (i.e., a premise) as well (when it was present), resulting in a total of 4.6 million comments. We denote this dataset as **IMHO+context**. The following example shows an opinionated claim (in bold) backed by a supporting premise (in italics).

> **IMHO, Calorie-counting is a crock what you have to look at is how wholesome are the foods you are eating.** *Refined sugar is worse than just empty calories - I believe your body uses a lot of nutrients up just processing and digesting it.*

We assume in this data that a relation exists between the sentence containing IMHO and the following one. While a premise does not always directly follow a claim, it does so frequently enough that this noisy data should be helpful.

Macro-level Context Data While the IMHO data is useful for modeling context from consecutive sentences from the same author, inter-turn relations are of a dialogic nature and would benefit from models that consider that macro-level context. We take advantage of a feature of Reddit: when responding to a post, users can easily *quote* another user's response, which shows up in the metadata. Particularly in CMV, this feature is used to highlight exactly what part of someone's argument a particular user is targeting. In the example in Table 1, the response contains an exact quote of a claim in the original post. We collect 95,406 threads from the full CMV subreddit between 2013-02-16 and 2018-09-05 and find pairs of posts where the quoted text in the response is an exact match for the original post (removing threads that overlap with the labeled data). This phenomenon occurs a minority of the time, but we obtain 19,413 threads. When the quote feature is used, posters often respond to multiple points in the original text, so for the 19,413 threads we obtain 97,636 pairs. As most language model fine-tuning is performed at the sentence level, we take the quoted text and the following sentence as our distant-labeled inter-post pairs. We refer to this dataset as **QR**, for quote-response pairs.

4 Methods

Identifying argumentative components is a necessary precursor to predicting an argumentative relation. In our data, we require the "source" of an intra-turn relation to be a premise that supports or attacks a "target" (a premise or another claim). For inter-turn relations, the source is always a claim that agrees or disagrees with a target. Thus, we model this process as a pipeline: perform three-way classification on claims, premises, and non-arguments and then predict if an outgoing relation exists from the source premise/claim to a target premise/claim. In predicting these relations, we consider all possible source-target pairs of premises and argumentative components within

CMV: A rise in female representation in elected government isn't a good or bad thing. According to this new story, a record number of women are seeking office in this year's US midterm elections. While some observers hail this phenomenon as a step in the right direction, I don't think it's good thing one way or the other: a politician's sex has zero bearing on their ability to govern or craft effective legislation. As such...
"I don't think it's good thing one way or the other: a politician's sex has zero bearing on their ability to govern or craft effective legislation" Nobody is saying that women are better politicians than men, and thus, more female representation is inherently better for our political system. Rather, the argument is that...

Table 1: Two posts from the CMV sub-reddit where a claim is targeted by the response

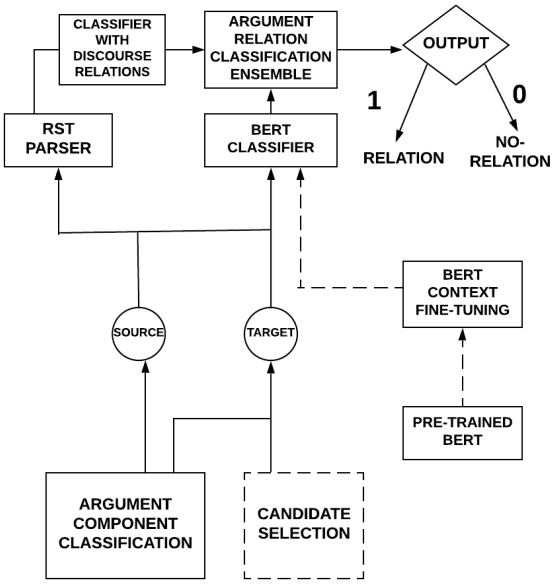

Figure 2: Schematic of our pipeline involving various components. The Candidate Selection Component is only used for Inter-turn relation identification

a single post (for intra-turn) and claims from one post and argumentative components from another post (for inter-turn).

As our data set is relatively small, we leverage recent advances in transfer learning for natural language processing. BERT (Devlin et al., 2019) has shown excellent performance on many semantic tasks, both for single sentences and pairs of sentences, making this model an ideal fit for both argument component classification and relation prediction. The BERT model is initially trained with a multi-task objective (masked language modeling and next-sentence prediction) over a 3.3 billion word English corpus. In the standard use, given a pre-trained BERT model, the model can be used for transfer learning by fine-tuning on a domain-specific corpus using a supervised learning objective.

We take an additional step of fine-tuning on the relevant distant-labeled data from Section 3.2 before again fine-tuning on our data from Section 3.1. We hypothesize that this novel use of BERT will help because the data is structured such that the sentence and next sentence pair (for intra-turn) or quote and response pair (for inter-turn) will encourage the model to learn features that improve performance on detecting argumentative components and relations. For argumentative components, we use this fine-tuned BERT model to classify a single proposition (as BERT can be used for both single inputs and input pairs). For relations (both intra-turn and inter-turn), we predict the relation between a pair of propositions. In the relation case, we postulate that additional components besides BERT can help: adding features derived from RST structure and pruning the space of possible pairs by selecting candidate target components. The pipeline is illustrated in Figure 2.

Argument Component Classification We fine-tune a BERT model on the **IMHO+context** dataset described in Section 3.2 using both the masked language modeling and next sentence prediction objectives. We then again fine-tune BERT to predict the argument components for both sources and targets, as indicated in Figure 2. Given the predicted argumentative components, we consider all possible valid pairs either within a post (for intra-turn) or across (inter-turn) and make a binary prediction of whether a relation is present.

Context Fine-Tuning For intra-turn relation prediction we use the same fine-tuned BERT model on **IMHO+context** that we used for argument component classification, as premises often immediately follow claims so this task is a noisy analogue to the task of interest. We then fine-tune on the relation prediction task on all possible pairs, using the labeled relations in the CMV data. For inter-turn relation prediction, we fine-tune first on the **QR** dataset, where the dialogue context more closely represents our labeled inter-post relations. Then, we fine-tune on inter-turn relation predic-

tion using all possible pairs as training. This process is indicated in Figure 2, where we use the appropriate context fine-tuning to obtain a relation classifier.

Discourse Relations Rhetorical Structure Theory was originally developed to offer an explanation of the coherence of texts. Musi et al. (2018) and, more recently Hewett et al. (2019), showed that discourse relations from RST often correlate with argumentative relations. We thus derive features from RST trees and train a classifier using these features to predict an argumentative relation. To extract features from a pair of argumentative components, we first concatenate the two components so that they form a single text input. We then use a state-of-the-art RST discourse parser (Ji and Eisenstein, 2014)[3] to create parse trees and take the predicted discourse relation at the root of the parse tree as a categorical feature in a classifier. There are 28 unique discourse relations predicted in the data, including *Circumstance*, *Purpose*, and *Antithesis*. We use a one-hot encoding of these relations as features and train an XGBoost Classifier (Chen and Guestrin, 2016) to predict whether an argument relation exists. This classifier with discourse relations, as indicated in Figure 2, is then ensembled with our predictions from the BERT classifier by predicting a relation if either one of the classifiers predicts a relation.

Candidate Target Selection For inter-turn relations, we take additional steps to reduce the number of invalid relation pairs. Predicting an argumentative relation is made more difficult by the fact that we need to consider all possible relation pairs. However, some argumentative components may contain linguistic properties that allow us to predict when they are targets even without the full relation pair. Thus, if we can predict the targets with high recall, we are likely to increase precision as we can reduce the number of false positives. Our candidate selection component, which identifies potential targets (as shown in Figure 2), consists of two sub-components: an extractive summarizer and a source-target constraint.

First, we use the **QR** data to train a model to identify candidate targets using techniques from extractive summarization, with the idea that targets may be salient sentences or propositions. We treat the quoted sentences as gold labels, resulting in 19,413 pairs of document (post) and summary (quoted sentences). For the example provided in Table 1, this would result in one sentence included in the summary. Thus, for a candidate argument pair A $\rightarrow$ B, where B is the quoted sentence in Table 1, if B is not extracted by the summarization model we predict that there is no relation between A and B. An example of target selection via extractive summarization is shown in Figure 3.

We use a state-of-the-art extractive summarization approach (Liu, 2019) for extracting the targets. The authors obtain sentence representations from BERT (Devlin et al., 2019), and build several summarization specific layers stacked on top of the BERT outputs, to capture document-level features for extracting summaries. We refer the reader to (Liu, 2019) for further details. We select the best summarization model on a held out subset using recall at the top K sentences.

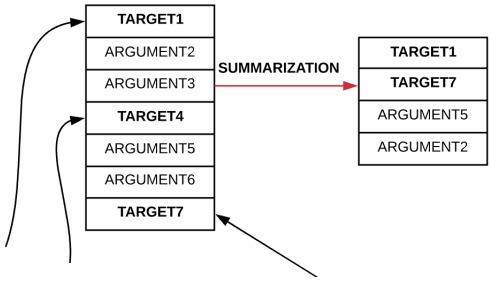

Figure 3: Schematic of our Target Extraction Approach

Second, in addition to summarization, we take advantage of a dataset-specific constraint: a target cannot also be a source unless it is related to the main claim. In other words, if B is a predicted target in A $\rightarrow$ B, we predict that there is no relation for B $\rightarrow$ A except when A is a main claim. In the CMV data, the main claim is always the title of the original Reddit post, so it is trivial to identify.

Method	C	P	NA
Stab and Gurevych (2017) + EWE	56.0	65.9	69.6

Table 3: Results for Intra-turn Relation Prediction with Gold and Predicted Premises

Hyper-parameters are discussed in Appendix A.

5.1 Argumentative Component Classification

For baseline experiments on argumentative component classification we rely on the handcrafted features used by Stab and Gurevych (2017): lexical (unigrams), structural (token statistics and position), indicator (*I, me, my*), syntactic (POS, modal verbs), discourse relation (PDTB), and word embedding features. Hidey et al. (2017) show that emotional appeal or pathos is strongly correlated with persuasion and appears in premises. This motivated us to augment the work of Stab and Gurevych (2017) with emotion embeddings (Agrawal et al., 2018) which capture emotion-enriched word representations and show improved performance over generic embeddings (denoted in the table as EWE).

We also compare our results to several neural models - a joint model using pointer networks (Morio and Fujita, 2018), a model that leverages context fine-tuning (Chakrabarty et al., 2019), and a BERT baseline (Devlin et al., 2019) using only the pre-trained model without our additional fine-tuning step.

Table 2 shows that our best model gains statistically significant improvement over all the other models ($p < 0.001$ with a Chi-squared test). To compare directly to the work of Chakrabarty et al. (2019), we also test our model on the binary claim detection task and obtain a Claim F-Score of 70.0 with fine-tuned BERT, which is a 5-point improvement in F-score over pre-trained BERT and a 12-point improvement over Chakrabarty et al. (2019). These results show that fine-tuning on the appropriate context is key.

5.2 Relation Prediction

For baseline experiments on relation prediction, we consider prior work in macro-level argument mining. Menini et al. (2018) predict argumentative relations between entire political speeches from different speakers, which is similar to our dialogues. We re-implement their model using their features (lexical overlap, negation, argument entailment, and argument sentiment, among others). As with component classification, we also compare to neural models for relation prediction - the joint pointer network architecture (Morio and Fujita, 2018) and the pre-trained BERT (Devlin et al., 2019) baseline.

As the majority of component pairs contain no relation, we could obtain high accuracy by predicting that all pairs have no relation. Instead, we want to measure our performance on relations, so we also include an "all-relation" baseline, where we always predict that there is a relation between two components, to indicate the difficulty of modeling such an imbalanced data set. In the test data, for intra-turn relations there are 2264 relation pairs, of which only 174 have a relation, and for inter-turn relations there are 120 relation pairs, compared to 2381 pairs with no relation.

As described in Section 3.1, for intra-turn relations, the source is constrained to be a premise whereas for intra-turn, it is constrained to be a claim. We thus provide experiments using both gold claims/premises and predicted ones.

Intra-turn Relations We report the results of our binary classification task in Table 3 in terms of Precision, Recall and F-score for the "true" class, i.e., when a relation is present. We report results given both gold premises and predicted premises (using our best model from 5.1). Our best re-

Method	Precision		Recall		F-Score	
	Gold	Pred	Gold	Pred	Gold	Pred
All relations	5.0	-	100.0	-	9.0	-
Menini et al. (2018)	5.9	4.8	82.0	80.0	11.0	9.0
Menini et al. (2018) + RST Features	6.4	4.9	83.0	80.0	11.8	9.3

+ Source $\neq$ Target Constraint	**18.9**	**17.5**	79.0	74.0	**30.5**	**28.3**

Table 4: Results for Inter-Turn Relation Prediction with Gold and Predicted Claims

sults are obtained from ensembling the RST classifier with BERT fine-tuned on **IMHO+context**, for statistically significant ($p < 0.001$) improvement over all other models. We obtain comparable performance to previous work on relation prediction in other argumentative datasets (Niculae et al., 2017; Morio and Fujita, 2018).

Inter-turn Relations As with intra-turn relations, we report F-score on the "true" class in Table 4 for both gold and predicted claims. Our best results are obtained by fine-tuning the BERT model on the appropriate context (in this case the **QR** data) and ensembling the predictions with the RST classifier. We again obtain statistically significant ($p < 0.001$) improvement over all baselines.

Our methods for candidate target selection obtain further improvement. Using our extractive summarizer, we found that we obtained the best target recall of 62.7 at $K = 5$ (the number of targets to select). This component improves performance by approximately 5 points in F-score by reducing the search space of relation pairs. By further constraining targets to only be a source when targeting a main claim, we obtain another 4 point gain.

Window Clipping We also conduct experiments showing the performance for intra-turn relation prediction when constraining the relations to be within a certain distance in terms of the number of sentences apart. Often, in persuasive essays or within a single post the authors use premises to back/justify claims they immediately made. As shown in Figure 4, this behavior is also reflected in our dataset where the distance between the two arguments in the majority of the relations is +1.

We thus limit the model's prediction of a relation to be within a certain window and predict "no relation" for any pairs outside of that window. Table 5 shows that this window clipping on top of our best model improves F-score by only limiting the context where we make predictions. As our models are largely trained on discourse context and the next sentence usually has a discourse relation, we obtain improved performance as we narrow the window size. While we see a drop in recall the precision improves compared to our previous results in Table 3. It is also important to note that window clipping is only beneficial once we have a high recall, low precision scenario because when we predict everything at a distance of +1 as a relation we obtain low F-scores.

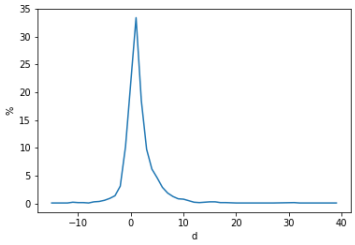

Figure 4: Distances d between Intra-Turn Relations

6 Qualitative Analysis

Role of Context We retrieve examples from the **IMHO+context** and **QR** data using TF-IDF similarity to pairs of argument components from our data that were predicted incorrectly by pre-trained BERT but correctly by the respective fine-tuned model. The first two rows in Table 6 show a relation between a claim and premise in the IMHO+Context and the CMV data respectively

Method	Window	Precision		Recall		F-Score	
		Gold	Pred	Gold	Pred	Gold	Pred
All relations	0 TO +1	5.0	4.0	31.0	25.0	8.7	6.9
Best Model	0 TO +5	19.5	17.1	**70.0**	**67.0**	30.5	27.2
	0 TO +4	21.4	19.5	67.0	65.0	32.2	30.0
	0 TO +3	25.2	23.3	61.1	58.0	35.6	33.2
	0 TO +2	32.5	29.8	50.0	48.0	39.3	36.8
	0 TO +1	**41.5**	**39.1**	47.0	42.0	**44.1**	**40.3**

Table 5: Intra-Turn Relation Prediction with Varying Window Settings

while the last four rows show a relation between a claim and premise in the QR data and the CMV data. The model learns discriminative discourse relations from the **IMHO+context** data and correctly identifies this pair. The last four rows show rebuttal from the QR and the CMV data respectively, where the model learns discriminative dialogic phrases (highlighted in bold).

Context	Pair
IMHO	IMHO, you should not **quantify** it as good or bad. **Tons of people** have monogamous relationships without issue.
CMV	[how would you even **quantify** that] [there are **many people** who want close relationships without romance]
QR	[It might be that egalitarians,anti-feminists, MRAs & redpillers, groups that I associate with opposing feminism - might be in fact very **distinct** & **different** groups, but I don't know that] [**I do see** all four of these as **distinct** groups].
CMV	[I may have a different stance on seeing no **difference** between companion animals and farm animals.] [**I do see distinction** between a pet and livestock]
QR	[Of course you **intend to kill** the person if you draw your **weapon**, if you can reasonably assume that they have a **weapon**] [**I don't think** some of them would **start killing**].
CMV	[So i thought, why would a police officer even use **firearms** if he/she doesn't **intend to kill**?] [**I dont think**, police are allowed to **start killing** someone with their gun if they don't intend to .]

Table 6: CMV and Context Examples

Role of Discourse We also provide examples that are predicted incorrectly by BERT but correctly by our classifier trained with RST features. For the first example in Table 7 the RST parser predicts an *Evaluation* relation, which is an indicator of an argumentative relation according to our model. For the second example the RST parser predicts *Antithesis*, which is correlated with attack relations (Musi et al., 2018), and is predicted correctly by our model.

Discourse	Argument1	Argument2
Evaluation	The only way your life lacks meaning is if you give it none to begin with	Life is ultimately meaningless and pointless.
Antithesis	Joseph was just a regular Jew without the same kind of holiness as the other two	Aren't Mary and Joseph, two holy people especially perfect virgin Mary, both Jews? Wasn't Jesus a Jew?

Table 7: Predicted Discourse Relations in CMV

7 Conclusion

We show how fine-tuning on data-sets similar to the task of interest is often beneficial. As our data set is small we demonstrated how to use transfer learning by leveraging discourse and dialogue context. We show how the structure of the fine-tuning corpus is essential for improved performance on pre-trained language models. We also showed that predictions that take advantage of RST discourse cues are complementary to BERT predictions. Finally, we demonstrated methods to reduce the search space and improve precision.

In the future, we plan to experiment further with language model fine-tuning on other sources of data. We also plan to investigate additional RST features. As the RST parser is not perfect, we want to incorporate other features from these trees that allow us to better recover from errors.

Abstract

Automated fact verification has been progressing owing to advancements in modeling and availability of large datasets. Due to the nature of the task, it is critical to understand the vulnerabilities of these systems against adversarial instances designed to make them predict incorrectly. We introduce two novel scoring metrics, attack *potency* and system *resilience* which take into account the correctness of the adversarial instances, an aspect often ignored in adversarial evaluations. We consider six fact verification systems from the recent Fact Extraction and VERification (FEVER) challenge: the four best-scoring ones and two baselines. We evaluate adversarial instances generated by a recently proposed state-of-the-art method, a paraphrasing method, and rule-based attacks devised for fact verification. We find that our rule-based attacks have higher potency, and that while the rankings among the top systems changed, they exhibited higher resilience than the baselines.

1 Introduction

Fact verification is the task of predicting whether claims can be supported or refuted by evidence. Advances in this task have been achieved through improved modelling and the availability of resources to train and validate systems (e.g. Wang (2017); Baly et al. (2018b); Thorne et al. (2018)). As this is a task with potentially sensitive applications like propaganda (Baly et al., 2018a) or biased news detection (Potthast et al., 2018), it is critical to understand how systems and models behave when exposed to real-world data and how deficiencies in their training data may contribute to this. It has been observed in related NLP tasks that as models become more complex, it is difficult to fully understand and characterize their behaviour (Samek et al., 2017). And from an NLP perspective, there has been an ongoing discussion as to what extent these models understand language (Jia and Liang, 2017) or they are exploiting unintentional biases and cues that are present in the datasets they are trained on (Poliak et al., 2018; Gururangan et al., 2018).

Adversarial REFUTED Instance:
There is a movie directed by Phillip D'Antoni called Bullitt.
Adversarial SUPPORTED Instance:
Bullitt is not a movie directed by Phillip D'Antoni
Evidence:
Bullitt is a 1968 American action thriller film directed by Peter Yates and produced by Philip D'Antoni

Figure 1: Adversarial instances generated through rule-based transformations of existing claims

One of the diagnostic tools for understanding how models behave is *adversarial evaluation*, where data that is deliberately designed to induce classification errors is used to expose "blind spots" of a system. While there are many recently proposed techniques for generating adversarial instances for NLP tasks (surveyed in Section 2), they vary in the degree to which newly generated instances are correct, i.e. grammatical and appropriately labelled.

In this paper, we introduce two scoring metrics, (adversarial) attack *potency* and system *resilience*, that enable comparison of both adversarial instance generators and the systems that they are executed on respectively. We argue for manual evaluation of instances generated and the incorporation of their correctness for scoring. We con-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2944–2953, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

duct our experiments in the context of the FEVER Shared Task (Thorne et al., 2018) (example in Figure 1), which incorporates both information retrieval and natural language inference to predict whether short factoid claims are SUPPORTED or REFUTED by evidence from Wikipedia. Systems must return not only the correct label but also the sentences providing the evidence for it. In the case where there is not enough evidence in Wikipedia for either label, the label NOTENOUGHINFO (NEI) is applied and no evidence needs to be returned.

We evaluate three adversarial attacks against four state-of-the-art systems and two baselines and apply our proposed scoring metrics that incorporate instance correctness. The first attack, informed by model behaviour, uses Semantically Equivalent Adversarial Rules (SEARs) (Ribeiro et al., 2018), a state-of-the-art method for generating rules that perform meaning-preserving transformations to instances that induce classification errors. The second attack is informed by dataset biases: we identify common patterns and constructions in the claims of the FEVER dataset and exploit them with hand-crafted rules to generate a number of new dataset instances. The final attack is a lexically-informed approach which makes use of a paraphrase model to generate new instances.

Our findings indicate that the instances generated by hand-crafted dataset-informed rules reduced all systems' classification accuracy more than the other approaches we tested. This was because the instances were not only more challenging to the systems under test, they were also more frequently correct – both of these characteristics factor into our *potency* score. While the lexically-informed approach induced a comparable number of misclassifications to the SEARs model, the instances were often incorrect, resulting in a *potency* score that was worse than sampling unmodified instances at random from the test set. Considering the *resilience* of the systems under adversarial evaluation, the 4^{th}-ranked model from the FEVER challenge performed better than the top system, but otherwise, the rankings of the systems were unchanged, and all top-ranked systems outperformed the baselines.

2 Methods for adversarial evaluation

Adversarial examples were initially studied in the field of computer vision (Szegedy et al., 2014) where model deficiencies such as over-sensitivity to perturbed inputs (by altering pixel intensities in a way which is imperceptible to humans) resulted in changes to the predictions. Making similar perturbations to text for adversarial evaluation is more challenging due to the discrete symbol space: modifying a single token may change an instance's semantics or make it ungrammatical. Various methods for attacks have been proposed ranging from manual construction and rule-based perturbation to automated paraphrasing and distractor information. Each of these methods can be informed by observations on the datasets for the task, model predictions and behaviour, and external knowledge and lexical resources. There is also a trade-off between the level of automation (which allows both scale and diversity of new claims) and to what extent the new instances are correct (i.e. grammatical and appropriately labelled). We survey a range of methods for generating adversarial instances and consider the suitability of the methods with respect to the FEVER task and generating correct instances.

Manual construction informed by expert knowledge: Instances that exploit world knowledge, semantics, pragmatics, morphology and syntactic variation have been written and compiled into challenge datasets for Machine Translation (Isabelle et al., 2017), Sentiment Analysis (Mahler et al., 2017; Staliūnaite and Bonfil, 2017) and Natural Language Understanding (Levesque, 2013). While these instances are expensive to construct, the attacker would have a high degree of confidence that the instances are correct and therefore correctness is not incorporated into the scoring metrics of any of these works. In FEVER, generating instances is more complex due to the need for annotators to highlight appropriate evidence: scaling up annotation to create new instances from scratch is non-trivial.

Noise introduced by character-level perturbations: Character-level attacks highlight the brittleness of systems by making letter swaps or insertions. Belinkov and Bisk (2018), Naik et al. (2018) and Ebrahimi et al. (2018) generate distorted examples which cause misclassifications or translation errors. An evaluation is performed comparing the performance of human crowdworkers for a classification task which only indicated minimal losses in classification accuracy between the orig-

inal and modified instances. While it is unlikely that a single character can unintentionally change the semantics of a sentence, requiring relabelling, this method is still *intentionally* introducing typographical errors meaning that by the definition of the FEVER task, the instances would be incorrect.

Adding distractor information: Jia and Liang (2017) evaluated the addition of distractor sentences to instances and their effect on systems trained on the SQuAD question answering task (Rajpurkar et al., 2016). In their study, they compared appending a nonsensical string of words to the instance against appending sensible distractors generated by an automated method with the use of human annotators for a final filtering step. This approach cannot be ported to generate adversarial instances for the FEVER task as the claims are single sentences and the Wikipedia database which is used as evidence is considered immutable. Naik et al. (2018) concatenate manually-written logical tautologies (such as 'and true is true') to instances for a natural language inference task and this approach could be used to modify the claim portion of instances.

Paraphrasing existing instances: Iyyer et al. (2018) and Ribeiro et al. (2018) generate adversarial instances through paraphrasing existing ones. The method proposed by Ribeiro et al. (2018) is informed by both the predictions from a model as well as the external resource of a neural translation model whereas the approach taken by Iyyer et al. (2018) make use of a translation model only.

Zhao et al. (2018) use an autoencoder architecture to generate new instances that are semantically equivalent. Paraphrasing introduces the risk of meaning-altering changes to the sentence which would require relabelling, or producing sentences which are ungrammatical. Iyyer et al. (2018) identified that in at least 17.7% of cases, the generated examples were not paraphrases and in at least 14.0% of cases, the paraphrases were ungrammatical. In a pilot study, Zhao et al. (2018) find that 19% of generated examples were not 'semantically similar to the original input'[1] and ungrammatical in 14% of cases.

Ribeiro et al. (2018) generate textual replacement rules that are applied to dataset instances, modifying them in order to generate new semantically equivalent adversarial instances. In a crowdworker evaluation, not all rules are accepted as some induced higher high rates of incorrect instances: for the simpler task of sentiment analysis, 86.6% of rules were retained whereas, for visual question answering, only 43.5% of rules were retained. Paraphrasing approaches are applicable to FEVER, but their success depends on constructing instances that are both correctly labeled and grammatical. As FEVER consists of both information retrieval and natural language inference, the risk of generation of incorrect instances by paraphrasing can be quite high as subtle semantic changes may change the label of the instance.

[1]The authors do not state whether the newly generated adversarial instances retained the original label.

3 Potency and resilience

Consider a method for generating adversarial instances (hereafter referred to as an adversary), a, that generates a set of instances $X_a = \{x_{a,i}\}_{i=1}^{N}$ with accompanying labels $Y_a = \{y_{a,i}\}_{i=1}^{N}$. To evaluate such adversaries, we must consider both their correctness and their effect on a system under test.

We measure the effectiveness of an adversary (a) through a system's (s) evaluation measure f (such as F_1 or FEVER Score), on a set of predictions made by the system $\hat{Y}_{s,a}$. Intuitively, better adversarial instances induce more misclassifications, resulting in a lower evaluation measure. Assuming the evaluation measure outputs a real value in the range $[0, 1]$, we define *potency* by the average reduction in score (from a perfect score) across all systems, $s \in S$ weighted by the correctness rate of the adversary, c_a.

$$\text{Potency}(a) \stackrel{\text{def}}{=} c_a \frac{1}{|S|} \sum_{s \in S} \big(1 - f(\hat{Y}_{s,a}, Y_a)\big) \quad (1)$$

Instances are correct if they are grammatical, appropriately labeled and meet the task requirements. To illustrate the need to incorporate correctness into evaluation, we will compare against *raw potency* where the correctness rate of the system c_a is set to 1. In our experiments, we will be using an estimate of the correctness rate for each adversary through annotating a sample of instances as it is not cost-effective with adversaries generating a large number of instances to perform a complete annotation.

A system that is resilient will have fewer errors induced by the adversarial instances, reflected in

higher scores at evaluation. We wish to penalize systems for making mistakes on instances from adversaries with higher correctness rate. We define *resilience* as the average score scaled by the correctness rate for each adversary, $a \in A$:

$$\text{Resilience}(s) \stackrel{\text{def}}{=} \frac{\sum_{a \in A} c_a \times f(\hat{Y}_{s,a}, Y_a)}{\sum_{a \in A} c_a} \quad (2)$$

4 Adversarial attacks against fact verification systems

A FEVER dataset instance (example in Figure 1) consists of a claim accompanied by a label and evidence sentences unless the label is NOTENOUGHINFO (NEI) and no evidence needs to be provided. The adversaries we explore in this paper generate new instances by altering the claim sentence of existing instances and applying a new label if appropriate, without modifying the evidence. We chose this approach over generating completely novel instances as this obviates the need to search for new evidence, a process that is rather error-prone if done automatically. We explore three methods for generating adversarial instances by modifying existing dataset instances: manually crafted rule-based transformation informed by the training data; a recently proposed state-of-the-art method for automatically generating Semantically Equivalent Adversarial Rules (Ribeiro et al., 2018, SEARs) that is model targeted; and a lexically-informed method for paraphrasing model.

4.1 Training data-targeted adversary

This adversary assumes access to the dataset used to train the models and it identifies lexico-syntactic patterns in the claims that are highly frequent. The claims following these patterns undergo rule-based transformations to generate new instances with patterns not encountered in the training data. We evaluate three different types of transformations: entailment preserving rewrites, simple negations and complex negations (see examples in Table 1).

The entailment-preserving transformations we use include straightforward rules such as switching from active to passive voice while retaining the original label. For transformations that reverse the labels from SUPPORTED label to REFUTED and vice versa, negations were applied to a claim's verb phrase. More complex negations were introduced by combining the above two techniques.

We constructed 61 rules that matched the most common claim patterns identified in the training portion of the FEVER dataset, for example: X is a Y, X was directed by Y, X died on Y. 23 of our rules were entailment preserving, 19 were simple changes to negate claims and 23 were complex changes that also negated the claims. We release all of the rules on GitHub[2].

4.2 Lexically-informed adversary

Our adversary generates paraphrases of the claim without altering the evidence or label in a two-step process. The first step is to generate candidate claims x' by substituting nouns and adjectives with lemmas from all matching synsets from WordNet (Miller, 1995). The second step is to realize the surface forms for each of the lemmas. This is performed using a neural translation model, translating the candidate sentence into a foreign pivot language and back-translating into English yielding x'' using the model from Ribeiro et al. (2018). Instances are scored using the ratio of translation probabilities between the paraphrased and the original sentences $\frac{P(x''|x)}{P(x|x)}$ as given by the translation model. For instances where this ratio is low, the translated sentence is not representative of the semantics from the original claim. Where the ratio is high, we observed that the generated instances x'' were sometimes nonsensical: $P(x''|x)$ was extremely high in cases where sentences contained a high number of repeated words. To mitigate this, all claims were ranked using this measure and the upper and lower quartiles were excluded.

4.3 Model-targeting adversary

We also consider an adversary which exploits model predictions by generating Semantically Equivalent Adversarial Rules (Ribeiro et al., 2018, SEARs). The rules are generated by identifying transformations between paraphrased instances that alter the label predicted by a model while maintaining semantic equivalence. From all the rules generated from the dataset, a submodular selection is performed yielding a subset of non-redundant rules which induce misclassifications that apply to a large proportion of instances.

We applied three sets of adversarial rules to the FEVER dataset to generate new claims. The first set of adversarial rules induced classification er-

[2] https://github.com/j6mes/fever-attacks-emlnp-2019

Transformation	Pattern	Template
Entailment Preserving	(.+) is a (.+)	There exists a $2 called $1
	(.+) (?:was | is)? directed by (.+)	$2 is the director of $1
Simple Negation	(.+) was an (.+)	$1 was not an $2
	(.+) was born in (.+)	$1 was never born
Complex Negation	(.+) (?:was | is)? directed by (.+)	There is a movie called $1 which wasn't directed by $2
	(.+) an American (.+)	$1 $2 that originated from outside the United States.

Table 1: Example rule-based attacks that preserve the entailment relation of the original claim (within the definition of the FEVER shared task), perform simple negation and more complex negations. The output new claims that are sufficiently different to confuse the classifier. The matching groups within the regular expression are copied into the template (variables begin with $).

rors in classifier for a sentiment analysis task (as reported in Ribeiro et al. (2018)) and the second and third sets of rules were generated using predictions made by the highest scoring model from the shared task (Nie et al., 2019).

Because SEARs requires $\mathcal{O}(n^2)$ model queries, generating rules using the full dataset may be prohibitively expensive for some users. In our evaluation, we compare the rules generated using model predictions on a sample of 1000 instances from the development set against rules generated from the full development set containing 9999 instances.

5 Experimental setup

We evaluate the potency of the adversarial instances generated by the approaches described in the previous section against four state-of-the-art models from the FEVER shared task and two baseline models. The models we evaluate were the Neuro-Semantic Matching Network (NSMN) (Nie et al., 2019), HexaF (Yoneda et al., 2018) Enhanced ESIM (Hanselowski et al., 2018) and the Transformer Model (Malon, 2018) as trained by the authors. For the baseline systems, we adopt the architecture from Thorne et al. (2018), using both a Decomposable Attention model and ESIM+ELMo model for natural language inference from AllenNLP (Gardner et al., 2017) and a Term Frequency - Inverse Document Frequency (TF-IDF) model for document retrieval and sentence selection.

Adversarial instances are generated by applying each adversary to existing FEVER instances and making modifications to the claim and label where appropriate. We apply each adversary to the development and test split of the dataset of Thorne et al. (2018)[3] to generate datasets of novel claims. We tune parameters using the development data and report results using a balanced uniform random sample of instances generated from the test data.

We measure instance correctness through blind annotation of a random sample of approximately 100 instances generated by each of the adversaries. We annotate each instance for grammaticality and whether the labelled claim is supported by the evidence from the original instance, following the manual error coding process described in Appendix B of the FEVER dataset description (Thorne et al., 2018).

6 Results

Applying each adversary to the 9999 instances in the FEVER test set generated a large number of new adversarial instances. From the training data targeted rule-based adversary, 21348 new claims were created, from the lexically-informed adversary using WordNet substitutions and a paraphrase model, 14046 instances were created, and using SEARs, 3668, 4144 and 7386 instances were generated depending on whether the rules were generated using the model of Nie et al. (2019) on the full dataset, sampled dataset or using the model of the sentiment analysis classifier respectively. For

[3]Note: This is the test split from the paper containing 9999 examples each that later formed part of a development set for the FEVER shared task. The reserved blind test instances from the shared task were not used.

Rank	Method	Raw Potency (%)	Correct Rate (%)	Potency (%)
1	Rule-based adversary	63.16	89.5	56.53
2	*Baseline (Unmodified Instances)*	44.79	97.0	43.46
3	SEARs (FEVER Full)	57.84	62.5	36.15
4	SEARs (FEVER Sample)	53.90	55.0	29.65
5	SEARs (Sentiment)	47.36	50.0	23.68
6	Paraphrase + WordNet	65.64	34.0	22.32

Table 2: Potency of adversaries where correctness rate is estimated using inspection of the generated instances. The baseline method of sampled instances is not used for scoring resilience. Raw potency is potency score without the considering the correctness of instances.

Rank	System	FEVER Score (%)	Resilience (%)
1	Transformer	57.04	58.66
2	NSMN	63.98	51.09
3	HexaF	62.34	50.06
4	Enhanced ESIM	61.32	43.98
5	TF-IDF + ESIM	36.87	26.86
6	TF-IDF + DA	27.71	22.28

Table 3: Systems ranked by the resilience to adversarial attacks. The FEVER Score column uses reported scores from the shared task.

each adversary we create a balanced dataset for evaluation through a stratified sample of 1000 instances where we report the *potency* of each adversary and *resilience* of each system, considering instance correctness. Our summary results are presented in two tables: Table 2 describes the potency of each adversary against the systems tested and Table 3 describes the resilience of each system to the adversaries.

Considering potency, the highest scoring adversary was the rule-based method – where the rules were manually written informed by observations on the training set. While the raw potency (not considering the correctness of instances) of the instances generated by the lexically-informed paraphrase adversary was higher than the rule-based adversary, a large number of instances generated from this method failed to meet the guidelines for the task, resulting in the lowest potency in our evaluation. We the adversarial instances that were generated by SEARs – which is informed by model behaviour – also had a higher raw potency than instances sampled from the dataset (baseline), the errors introduced when automatically generating adversarial instances resulted in a lower potency once the correctness of instances was taken into account. However, this method generated a higher rate of correct instances than the paraphrase based method.

For the rule-based method, the largest proportion of incorrect instances were generated by rules that inadvertently matched sentences that encountered in the observations used to design the rules. For example, the rule that transforms the pattern: 'X is a Y' to 'There is a Y called X' correctly generates instances in most cases, but for the sentence "Chinatown's producer is a Gemini" which contains a compound noun, the adversary "There is a Gemini called Chinatown's producer" was generated. Similar errors were produced when the patterns also matched determiners and included these in the new sentence in a position which altered the semantics or were ungrammatical.

The potency of SEARs is dependent on the model and dataset used for generating the Semantically Equivalent Adversarial Rules. When the rules were generated using the full FEVER development split, they not only resulted in a lower FEVER Score (contributing to higher potency) of the models but were also correct more often.

System	FEVER Score (%)				
	Rules	SEARS (FEVER Full)	SEARS (FEVER Sample)	SEARS (Sentiment)	Paraphrase
Transformer	56.36	58.26	62.66	68.67	44.24
NSMN	48.85	47.85	53.35	64.56	39.44
HexaF	45.25	50.15	55.06	62.86	35.64
Enhanced ESIM	31.53	46.75	48.05	62.26	38.24
TF-IDF + ESIM	20.72	28.13	31.03	31.03	27.83
TF-IDF + DA	18.32	21.82	26.43	26.43	20.72

Table 4: Breakdown of FEVER Scores of each system to each adversarial attack prior used for calculating resilience and potency. Lower scores indicates stronger attack (contributing to potency). Higher scores indicate stronger systems (contributing to resilience). Scores in this table do not account for correctness of instances.

Using only 10% of the FEVER development set instances when generating the adversarial rules was orders magnitude faster than the full dataset (generation took about a day instead of over two months), but this had a negative impact on the potency score in two ways: the systems made correct predictions on approximately 4% more of these instances and the instances were less correct about 7% of the time. SEARs generated on the out-of-domain movie sentiment dataset had the lowest potency of the three variants we evaluated. Some of these rules (such as replacement of 'movie' with 'film') worked well when applied to FEVER.

A common failure mode from all variants of SEARs was the replacement of a large number of indefinite articles (such as *a*) with definite articles (such as *the*) making claims nonsensical or altering the semantics to the point where a label change was required. The SEARs also often made changes to determiners and quantifiers or deleted terms such as *only*, which altered the semantics of a claim, making it incorrectly labelled. A higher proportion of this behaviour was observed with SEARs generated from the sentiment analysis task.

The paraphrasing model exhibited a great degree of variance in the quality of the generated claims – resulting in a low correctness score. While all the claims generated were intelligible, there were a large number of grammatical errors present and some nonsensical paraphrases which altered the semantics by substituting synonyms for the wrong word senses. Some of the paraphrases resulted in proper nouns and named entities being replaced by third-person pronouns meaning that these claims failed to meet the FEVER guideline as all entities must be referenced directly to facilitate evidence retrieval.

The most resilient system was the transformer-based model (Malon, 2018) with a score of 58.66%. The instances generated by SEARs had a positive impact on the performance as both recall and FEVER Score were higher than the values reported from the shared task and the instances generated by manually constructed rules only negatively affected the model by a marginal amount. Meanwhile, the highest performing system from the shared task (NSMN) (Nie et al., 2019) had a lower resilience: 51.09%. Using the breakdown of FEVER Scores by system and adversary (reported in Table 4)), we observe that the NSMN was affected by the rule-based adversary and SEARS (FEVER Full) adversaries much more than transformer model.

With the exception of the transformer model, the resilience of the systems is well correlated with the performance on the original FEVER task. This demonstrates that the top-scoring systems in the shared task were able to better capture the semantic space of the task as the resilience of the baseline TF-IDF models and that evaluation was adequate in assessing their generalization abilities.

6.1 Effect of rule-based transformations

All the evaluated systems were pipelines of information retrieval and natural language inference components. We perform an analysis of the models under test considering the effect of rule-based adversarial instances and their impact on each pipeline stage. We compare the performance of the models using the new instances generated by applying transformations to existing instances (re-

Model	Precision (%)			Recall (%)		
	Original	Modified	Delta	Original	Modified	Delta
Transformer	95.42	97.93	+2.51	71.47	50.00	-21.47
NSMN	41.14	44.18	+3.04	78.07	71.62	-6.45
HexaF	65.23	59.76	-5.47	80.78	75.98	-4.80
Enhanced ESIM	24.36	22.30	-2.06	86.04	80.93	-5.11
TF-IDF	10.49	9.10	-1.39	45.50	39.20	-6.30

Table 5: Effect of rule-based adversarial attacks on the evidence retrieval component of the pipelines considering sentence-level accuracy of the evidence.

Model	Accuracy (%)			FEVER Score (%)		
	Original	Modified	Delta	Original	Modified	Delta
Oracle + DA	82.38	62.56	-19.82	=	=	=
Oracle + ESIM	83.58	60.66	-22.92	=	=	=
TF-IDF + DA	46.49	37.44	-9.05	27.73	18.32	-9.41
TF-IDF + ESIM	49.75	37.34	-12.41	32.83	20.72	-12.11
Transformer	75.58	57.26	-18.32	73.87	56.36	-17.51
NSMN	70.27	50.35	-19.92	68.77	48.85	-19.92
HexaF	74.67	51.35	-23.32	67.37	45.25	-22.12
Enhanced ESIM	67.56	36.84	-30.72	62.76	31.53	-31.23

Table 6: Summary of label accuracy and FEVER Scores for instances used in rule-based adversarial attacks. For the case of the oracle evidence retrieval component, FEVER Score is equal to accuracy.

ported in *modified* columns) and compare this to the instances that were used to generate them (reported in *original* columns).

Considering the evidence retrieval component (refer to Table 5), we find that the adversarial instances did not affect the information retrieval component of some systems to the same extent as the NLI component. Most systems incorporated either TF-IDF of keyword matching in their information retrieval component and thus they are little affected by the rule-based transformations (which were mostly adding stop words and reordering the words within the sentence). The only exception is the Transformer Model; even though it uses TF-IDF to retrieve documents, it makes use of an entailment classifier for sentence retrieval from the documents. While this approach maintained very high precision with the newly generated instances, the recall decreased indicating a brittleness for instances that differed from the distribution of the training set.

Considering the NLI stage of the systems (refer to Table 6), we observe that in an oracle environment (using manually labelled evidence – assuming perfect evidence retrieval), both the ESIM and Decomposable Attention models for natural language inference suffer a stark decrease in accuracy when making predictions on the adversarial examples. The decrease is less pronounced when considering the full pipeline (i.e. with an actual imperfect evidence retrieval component), which reduces the upper bound for the FEVER Score and accuracy. This is due to the noise introduced by the evidence retrieval pipeline stage.

The Enhanced ESIM system had the highest reduction in accuracy for the rule-based adversarial instances. Even though the model had an evidence recall of 80.93% (a reduction of 5.11%), the FEVER score reduced by 30.72%. On inspection, this model is mostly predicting SUPPORTED for most adversarial instances. In contrast, the Transformer Model had the lowest reduction in FEVER score (-17.51%) despite a reduction in evidence recall of 23.17%. This model also exhibited similar behaviour to the Enhanced ESIM model: while a large number of supported claims were cor-

rectly classified, this model predominantly predicted NOTENOUGHINFO for the adversarial instances. As this class does not require evidence to be correctly scored, 'falling back' to it resulted in a higher FEVER Score when no suitable evidence was found.

The rule-based adversary applies both entailment-preserving and label-altering (through negation) transformations to claims to generate new adversarial instances. We observe in all models (with the exception of the Enhanced ESIM (Hanselowski et al., 2018)) that the reduction in accuracy for the claims generated through entailment-preserving transformations was lower than the claims generated by the negating transformations. This may be revealing an inherent bias in the models similar to the one discussed by Naik et al. (2018), where models perform poorly for antonymous examples due to a dependence on word-overlap as a feature.

7 Conclusions

As automated means for generating adversarial instances do not always produce grammatical or correctly labelled instances, we developed a method for evaluation which incorporates instance correctness. We introduced two metrics that enable evaluation of adversarial attacks against systems: the *potency* of attack, and the *resilience* of systems to these attacks.

In this paper, we evaluated four state-of-the-art systems and two baselines against instances generated from three methods for adversarial attack: manually written rules that were informed by observations of the training data, an automated lexically-informed paraphrasing model and an automated state-of-the-art model-targeted approach. While the manually-written rules exhibited high correctness rate, the automated methods often made grammatical errors or label-altering changes which lowered the correctness rate. Our metrics captured this trade-off between correctness and impact on system scores – despite the paraphrasing automated method having the greatest impact on systems under test, it was not the most potent, owing to the low correctness rate.

We hope that the findings and metrics that we present in this paper help continue the discussion on improving the robustness of models and enable better comparisons between adversarial attacks to be made that consider instance correctness.

Nonsense!: Quality Control via Two-Step Reason Selection for Annotating Local Acceptability and Related Attributes in News Editorials

Abstract

Annotation quality control is a critical aspect for building reliable corpora through linguistic annotation. In this study, we present a simple but powerful quality control method using two-step reason selection. We gathered sentential annotations of local acceptability and three related attributes through a crowdsourcing platform. For each attribute, the reason for the choice of the attribute value is selected in a two-step manner. The options given for reason selection were designed to facilitate the detection of a nonsensical reason selection. We assume that a reliable annotation may not contain a nonsensical reason selected for the choice of the attribute value, and an annotation that contains a nonsensical reason is less reliable than the one without such reason. Our method, based solely on this assumption, is found to retain the annotations with remarkable quality out of the entire annotations mixed with those of low quality.

1 Introduction

Crowdsourcing has recently enabled the collection of large amounts of data quickly. However, crowdsourced annotations require more quality control than traditional in-house annotations. This is because it is difficult to assure the expertise of the participating crowdsource workers in the linguistic annotation.

To ensure the quality of the annotations obtained through crowdsourcing, a frequently utilized approach is to request several workers annotate the same data, aggregate the annotations, and infer the ground truth based on the assumption that the consensus of the workers would lead to the ground truth (Lease, 2011). Various statistical methods have also been proposed to filter out the mistakes or (spamming) random responses of the crowdsource workers (Liu et al., 2012; Hovy et al., 2013; Nguyen et al., 2017). However, the way to filter out the mistakes or the random responses through statistical means is difficult to utilize for a fundamentally subjective annotation task. This is because statistical methods make it hard to differentiate the annotator's mistakes from their subjective annotations, as the individual subjectivity of views on different topics can make the gathered data apparently random.

Local acceptability, which is for how much the given text is rationally worthy of being believed to be true (Wachsmuth et al., 2017; Yang et al., 2019), is a fundamentally subjective measure. It is thus hard to utilize only statistical methods for the annotation quality control. Yet, local acceptability is also understood as a strong factor influencing the argumentation quality in writing, which is of great importance for computer-assisted writing. In this work, we present a simple but powerful method for annotation quality control of local acceptability using two-step reason selection, where the options given for reason selection were designed to facilitate the detection of a nonsensical reason selection. In order to show the effectiveness of the method, we performed the sentential annotation of local acceptability and three possibly related attributes through crowdsourcing.

Using our method, we were able to filter out the annotation results with Krippendorff's alpha of 0.3 for local acceptability, which is comparable to our sentence-level in-house annotation of local acceptability (Yang et al., 2019) and the document-level annotation of local acceptability by Wachsmuth et al. (2017). The overall, non-filtered annotation results were with the alpha of 0.01. Our analysis on argumentation strategy indicates that the filtered annotation results match good linguistic intuition whereas those non-filtered do not. The filtered annotation results also show distinctive cor-

[†] Corresponding author

relation patterns whereas those non-filtered do not.

The contributions of this paper are as follows. (1) We present a new method of using reason selection for the quality control of the annotation of local acceptability and three (possibly related) attributes. (2) We provide a statistical analysis of the annotation results and detailed statistics on the filtering and show that our method has a good potential for future research into annotation quality control. (3) We make all the related data and the code for filtering publicly available.

To the best of our knowledge, our method is the first in utilizing nonsensical reason selection for the quality control of the linguistic annotation.

2 Related Work

2.1 Argument mining and the annotation of the reasons

Hasan and Ng (2014) annotated the reasons for ideological debate posts and built the classifiers for such reasons. They set out four target domains, and categorized possible reasons into several groups for each of the two stances of support and opposition. Habernal and Gurevych (2016) annotated the convincingness of arguments through crowdsourcing, with a specified reason for the annotated convincingness. They presented a decision tree that restricts the scope of the possible reasons and enables a structured analysis of the reasons selected by workers. Ding et al. (2018) annotated the reasons for an event being affective, based on seven categories of common human needs. They formalized a classification task for such seven categories by assigning a gold label on the reason for each event. They also showed that baseline classifiers could achieve moderate performance on the task. On the other hand, we focus on local acceptability of arguments with restricted options for reason selection. We choose the reasons not only for a deeper understanding of the reasons for local acceptability judgment itself, but also for an automated identification of the random responses by the workers.

2.2 Quality control of crowdsourced annotation

Raykar et al. (2010) proposed a nonlinear statistical method to infer the actual, hidden label among the multiple and possibly noisy labels provided by multiple annotators, and showed that their method is superior to that of majority voting. Liu et al. (2012) addressed the problem of aggregating the labels from unreliable annotators via crowdsourcing as a standard inference problem in graphical models and showed that the belief propagation model and the mean field model can be effective. Hovy et al. (2013) proposed MACE (Multi-Annotator Competence Estimation) system that can identify the adversary (spamming) annotators utilizing a latent variable that can encode the information of whether or not an annotator is spamming and when the annotator is spamming. Nguyen et al. (2017) utilized Hidden Markov Model to aggregate the sequential labels obtained through a crowdsourcing platform,

	Score	Description
Local Acceptability	7	I **strongly accept** the information given by the sentence to be true. I have sound and cogent arguments to justify my acceptance.
	6	I **accept** the information given by the sentence to be true. I have some arguments to justify my acceptance.
	5	I **weakly accept** the information given by the sentence to be true. I do not have arguments justifying my acceptance. Still, I will accept it rather than reject it.
	4	It is **hard to judge** whether I should accept or reject the information given by the sentence to be true.
	3	I **weakly reject** the information given by the sentence to be true. I do not have arguments for the rejection. Still, I will reject it rather than accept it.
	2	I **reject** the information given by the sentence to be true, and I have arguments for the rejection.
	1	I **strongly reject** the information given by the sentence to be true. I have sound and cogent arguments for the rejection.
Knowledge Awareness	3	I **already knew** the information before I read this document.
	2	I **did not know** the information before I read this document, **but came to know** it by reading the previous sentences in this document.
	1	I **did not know** the information.
Verifiability	5	I can verify it **using my knowledge**. I do not need to google it to verify.
	4	I can verify it by **short-time googling**.
	3	I can verify it by **long-time googling**. I could verify it using deduction if I google it for some time for deeper understanding.
	2	I might find an **off-line way** to verify it, but it will be very hard.
	1	There is **no way to verify** it.
Disputability	4	Whether or not it is reasonable to accept the information given by the sentence as true, it is **highly disputable**.
	3	Whether ... true, it is **disputable**.
	2	Whether ... true, it is **weakly disputable**.
	1	Whether true, it is **not disputable**.

Table 1: Description of Local Acceptability and related attributes.

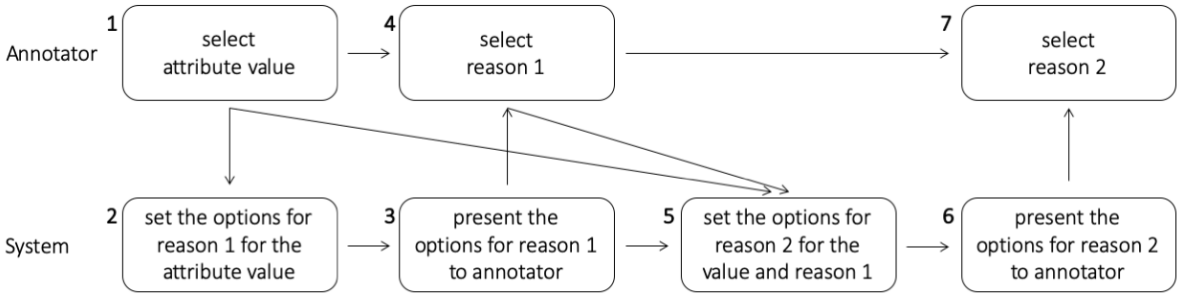

Figure 1: The process of the annotation for an attribute value. For a sentence, the annotator iterates the process four times for the four attributes to annotate. The number at the upper left side of each box indicates the order of the process. The arrow indicates the passing of the information.

and showed that their method works satisfactorily on the sequential labeling tasks of Named Entity Recognition and Information Extraction.

Guillaume et al. (2016) presented ZombiLingo, which is a 'Game with a Purpose' (GWAP) for dependency syntax annotation. Even though the annotation of dependency syntax is expected to require moderate linguistic expertise, they gathered more than 100,000 annotations in 9 months for French dependency syntax with 0.93 precision by decomposing the task into sub-tasks and by including the annotator training as a part of the game. Abad et al. (2017) presented a method for crowdsourced annotation, in which an automatic classifier is used for self-training. For some data with which the classifier shows high confidence for the predicted label, their self-training system guides the annotators to the (highly likely) correct labels predicted by the classifier. For the task of assessing the quality of the machine translated results, Mathur et al. (2018) estimated the reliability of the workers by presenting multiple translations as an assignment. For the translations in an assignment, some were already scored by human experts, and some were presented twice in the assignment. They assessed the reliability of each annotator by seeing how close their annotations were to the expert-annotated results, and whether they annotated the same translations with the same score.

In this study, unlike the previous researches, we use the reason selection method for an automated identification of the random responses by the workers. To the best of our knowledge, there has been no method utilizing reason selection for automated identification, even though incoherence between the selected reason and the attribute value can be a strong indicator for random responses. Our experiment shows that the reason selection method is simple, but very powerful.

3 Data

We used the Webis-Editorials-16 corpus provided by Al-Khatib et al. (2016). For 300 news editorials, they annotated discourse units in each news editorial with the labels that are related to an argumentation strategy, such as (1) *Common Ground*, (2) *Assumption*, (3) *Testimony*, (4) *Statistics*, (5) *Anecdote*, and (6) *Other*. We randomly selected 105 news editorials among the original 300 news editorials in the corpus and annotated local acceptability and the related attributes for each sentence in the 105 news editorials. The news editorials are somewhat out-dated, but we have chosen to use the data with two reasons: (1) Their annotation of argumentation strategy has high and reliabile quality. (2) Our previous sentential annotation of local acceptability (Yang et al., 2019) is based on the news editorial corpus.

4 Annotation

4.1 Definition

Local acceptability is defined, for the premises of an argument, as "rationally worthy of being believed to be true" (Wachsmuth et al., 2017). A premise gives the reason for justifying (or refuting) a claim, where the claim is a possibly controversial statement and the central argument component. A claim and one or more premises compose an argument (Stab and Gurevych, 2017). Following the definition of local acceptability by Wachsmuth et al. (2017), we define the local acceptability *of a sentence*, based on the truth-value of the sentence defined in the *truth-conditional*

Attribute Value	Reason 1	Reason 2
I did not know the information	I am not familiar with the topic	I am an expert on the subject
I did not know the information before, but came to know it by reading the previous sentences	It is not directly stated so far, but I can infer it from the previous sentences	The same information was stated in one of the previous sentences
I can verify it using my knowledge	I can logically verify the information	It is a transition sentence that is meaningless
strong accept	It is not a factual information, but I agree with the statement	It is a fact

Table 2: Examples for nonsensical reason

Attribute Value	Reason 1	Reason 2
weakly disputable	Some may think different on some details	It is a famous conflict
I already knew the information before I read this document	I know it from my personal experience	I am not familiar with the topic
I can verify it by short-time googling	I would find a direct reference to verify it	I can interview the people related to it
accept	It is a subjective statement, but I agree with the statement	It can easily be verified

Table 3: Examples for unnatural reason

theory (Lewis, 1970), as: A sentence is locally acceptable if the truth-value of the sentence is rationally worthy of being believed to be true (Yang et al., 2019).

4.2 Attributes

Table 1 shows the rubrics for local acceptability and the other three attributes that we annotated through crowdsourcing. We introduced the three attributes (and the rubrics) in Yang et al. (2019) for a more in-depth understanding of local acceptability, focusing on the aspects of computational journalism (Cheruiyot and Ferrer-Conill, 2018; Aharoni and Tenenboim-Weinblatt, 2019).

Local Acceptability (LA) is an indicator of whether the truth-value of the sentence is rationally worthy of being believed to be true. We divide each of the *accept* and *reject* judgments into three subcategories. For *accept*, we divided it into *strong accept*, *accept*, and *weak accept*, and the same goes for *reject*. We did so as the judgment on the truth-value can be unclear (Hamblin, 1970).

Knowledge Awareness (KA) is an indicator of whether or not an annotator already knew the information given by the sentence before reading a document.

Verifiability (V) is an indicator of how easy it is to verify the information given by the sentence. We include this attribute because we anticipate that the information recognized as easily verifiable by a reader would be more likely to be accepted by the reader.

Disputability (D) is an indicator of how controversial the information given by the sentence is. We anticipate that the personal acceptance of information by a reader would be different from the reader's expectation of the public acceptance of the information by others.

5 Method

5.1 Two-step reasons for each attribute

For each attribute of a sentence, after the annotator chose its value according to the rubrics, they were asked also to choose the reasons for the value, in a two-step manner. At the first step, the annotator was asked to select one of the possible options as a reason (reason 1). Then, they were asked to select another reason (reason 2), where the options for the second step were determined by the attribute value and the reason selected in the first step. Figure 1 illustrates the process of the attribute value and reason selection.

The options for a reason were designed manually, based on our previous sentence-level in-house annotation result (Yang et al., 2019), mainly because the automatic categorization of reasons is a fundamentally challenging problem (Skorupski, 2002). The in-house annotation was performed by three of the authors and seven undergraduate students with native competence in English, where three of them were student journalists responsible for the school newspaper. The in-house annotation was for the same attributes but the students wrote down the reasons by themselves without any given

Attribute	Attribute Value	Reason 1	Reason 2	label
Local Acceptability	strong accept	It is a subjective statement, but I agree with the statement	It is a fact	Nonsensical
Knowledge Awareness	I did not know the information	I am not familiar with the topic	I am an expert on the subject	Nonsensical
Verifiability	I might find an off-line way to verify it, but it will be very hard	I could visit related places to obtain the information	I can interview the people related to it	Natural
Disputability	weakly disputable	Some may think different on some details	It is a famous conflict	Unnatural

Table 4: An example for the two-step reason selection for a sentence

option. The in-house annotation gathered 4,623 sentential annotations for the 105 news editorials with specific reasons written without any given option. One of the authors thoroughly read all of the 4,623 sentential annotations, and two other authors inspected part of the annotations. Based on the in-house annotation result, three of the authors discussed and designed the options so that they can cover all the responses on the in-house annotation result. Yet, anticipating that there may be a case where the options for the reasons were not enough for a sentence, we allowed the workers to choose *n/a* at each of the three steps to select (1) attribute value, (2) reason 1, and (3) reason 2. When a worker chose *n/a* for an attribute value, we asked the annotator to select the reasons in a two-step manner, and if a worker chose *n/a* for either reason 1 or reason 2, we did not ask the worker for further details. We expect that the selections of *n/a* would enable us to estimate the range of sentences that the option design may not cover.

5.2 Nonsensical/Unnatural Reason

For each attribute, we intentionally added nonsensical/unnatural options for a reason at the second step. Those were designed to identify the mistakes or the (spamming) random responses by the workers. We deemed the selection of the nonsensical/unnatural reason as an indicator for the unreliability of the annotation. The definition of the nonsensical/unnatural reason is as follows.

Nonsensical reason is the reason that a reliable annotator would not select for the annotation and is the reason that works as an indicator for a (spamming) random response. For example, if the reason 'I am not familiar with the topic' for knowledge awareness is selected with the reason 'I am an expert on the subject,' we find that it does not make any sense. Table 2 shows examples for nonsensical reason.

Unnatural reason is the reason that a reliable annotator is less likely select than the other given options, but it is the reason behind which the annotator might have a sophisticated rationale. For example, if an attribute value of *weakly disputable* for disputability is selected with the reason of 'It is a famous conflict,' it makes some sense, but it is deemed as unnatural. This is because if a sentence is about a famous conflict, the attribute values of *disputable* or *highly disputable* would have been more suitable. Table 3 shows examples for unnatural reason.

For each of the triples of (attribute value, reason 1, reason 2) that can be selected by the worker, we assigned one of the following labels: (1) natural, (2) unnatural, and (3) nonsensical. The assignment was also conducted manually by three of the authors. The reader is referred to Appendix A for the entire set of options and the corresponding labels for the two-step reason selection. Table 4 shows an example of the possible selection for a sentence. It should be noted that a sentential annotation can contain more than one nonsensical/unnatural reason. If an annotator chose the options in Table 4 for a sentence, the sentential annotation contains two nonsensical reasons and an unnatural reason.

5.3 Unreliability Score

For sentential annotation, we compute the unreliability score of the annotation as follows:

$$u(x) = 0.5 \times N_u(x) + N_n(x) \quad (1)$$

where x is a sentential annotation, $u(x)$ is the unreliability score of x, $N_u(x)$ is the number of the unnatural reasons over the four attributes within x, and $N_n(x)$ is the number of nonsensical reasons within x. For example, $u(x)$ is 2.5 for the selection in Table 4. Regarding the coefficient 0.5, another value can also be chosen in its place. The unreliability score can be defined as a function that takes $N_u(x)$ and $N_n(x)$ as arguments. In this paper, we are using the linear function with an ad-hoc coefficient of 0.5 to demonstrate the effectiveness of our method as we believe that it is the simplest form of the equation.

For a worker, we compute his or her unreliability score as follows:

$$U(w) = Average(u(x)) \quad (2)$$

for x in $X(w)$ where w is a worker, $U(w)$ is the unreliability score of w, $X(w)$ is the set of annotations annotated by w (possibly over multiple news editorials), and $Average(u(x))$ for x in $X(w)$ indicates the average of the unreliability scores of all the annotations conducted by the worker w.

6 Experiment

6.1 Setting

In this study, the annotators were asked to proceed with the annotation in one direction. In other words, they were asked to read a sentence, to annotate the sentence, then to read the next sentence, and so on. Therefore, before proceeding with the annotation, we built an annotation tool in order to provide an environment that helps unidirectional reading. The annotation tool shows only a single sentence at a time on the screen, and the annotator could proceed to the next sentence by a keystroke. We allowed the annotators to go back to the previous sentence, and modify the previous annotation. The tool also recorded the time of each keystroke.

We conducted the annotation through the Amazon Mechanical Turk (AMT) crowdsourcing platform. In each assignment, the workers were presented with the annotation guideline and URL for a news editorial. For each sentence, workers were asked to select an attribute value for each attribute and to select the reasons for the attribute value in a two-step manner. The workers were asked to proceed to the annotation using the annotation tool. Although we used the corpus of argument strategies as the basis for our annotation, we provided the annotators only with plain sentences, without any extra information hinting at the argument strategies. Moreover, we paid attention not to inform the workers of the fact that we could assess the annotation quality based on the nonsensical/unnatural reason selection during the entire communication with the workers. We also did not reject any worker for the nonsensical/unnatural reason selection.

We made an additional request for the annotations from annotators who completed them too quickly, for instance in less than 20 seconds for all the 12 values for a sentence. If the annotators did not agree to re-do the annotation for the second time, we rejected the first annotation. We made this additional request on 29% of the initially requested assignments. Among these, 90% were re-annotated, and 10% were rejected. For the re-requested annotations, we dismissed the first annotations and took only the re-annotated results for our experiment. As a result, counting only the approved (and not rejected) annotations, 218 workers (with the lifetime approval rate $> 95\%$) participated in our annotation, over about two weeks including the time for the re-request. One annotator was allowed to annotate multiple news editorials, but not the same news editorials multiple times.

Using our method, we ranked the workers based on his or her unreliability score, and divided the workers into three groups as follows: (1) the group of top 1/3 workers with the *lowest* unreliability score per worker, (2) the group of bottom 1/3 workers with the *highest* unreliability score per worker, and (3) the group of the other workers. Among the 218 workers who participated in our annotation, the size of each group was (1) 72, (2) 73, and (3) 73, respectively, as 218 is not a multiple of three.

Then, we grouped the annotations conducted by the annotators in each of the (1)-(3) groups and named the groups of annotations as (1) *good*, (2) *bad*, and (3) *moderate* annotations, respectively. Among the *good* annotations, we filtered out some of the annotations again with the lowest unreliability score per annotation so that the number of retaining annotations in the group would be 10% of the total annotations gathered from our experiment, and named the group as *good squared* annotations. In short, the *good*, *bad*, and *moderate* annotations were filtered based on the unreliability of the annotators, and the *good squared* annotations were those filtered again from the *good* annotations based on the unreliability score of each annotation. It should be noted that the four groups are those of annotations, not those of workers.

6.2 Results

6.2.1 Statistics

We annotated 3,591 sentences in 105 news editorials and gathered 17,414 sentence level annotations. For each of the documents, the average of the number of annotators per news editorial was 4.85. We initially set the number of annotators as five annotators per news editorial, and 3% of the assignments were rejected. For the unrelia-

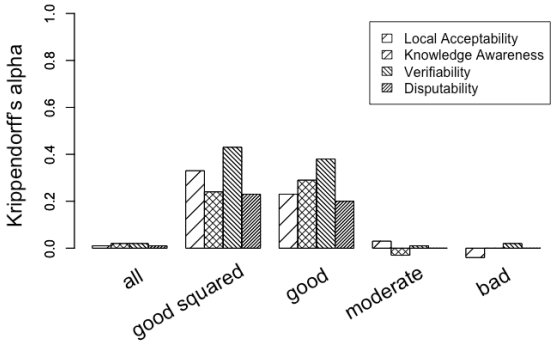

Figure 2: Inter-annotator agreement

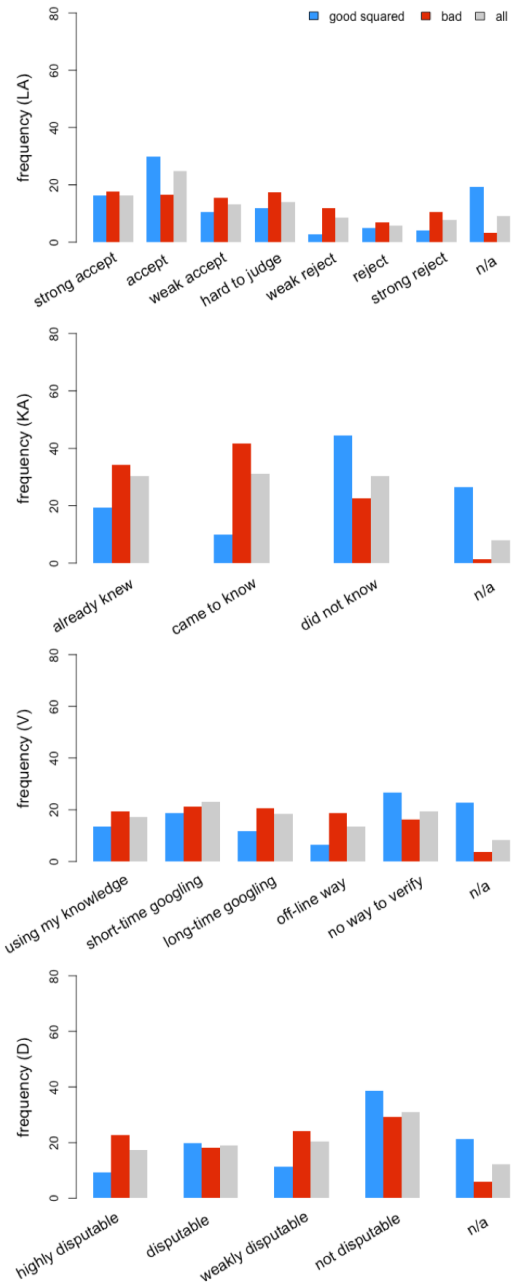

Figure 3: Relative occurrence frequency (unit: %)

bility score of annotation, the average of the unreliability score, over the annotations in the *good squared*, *good*, *moderate*, *bad* annotations, is zero, 0.05, 0.48, and 0.84, respectively. The number of annotations within the *good squared*, *good*, *moderate*, and *bad* group is 1,741 (10%), 3,024 (17%), 6,304 (36%), and 8,086 (46%), respectively.

We speculate that the imbalance on the number of annotations for each of the *good*, *moderate*, *bad* annotations might have been due to the difference in the time that took for the annotation per annotator. The average time that took for a news editorial [1] was 54 minutes per assignment (per document, *i.e.*, per news editorial) for overall annotators. For the *good*, *moderate*, and *bad* annotations, it was 122, 66, and 19 minutes, respectively. For the *good squared* annotations, it was the same as the *good* annotations, as the filtering from the *good* annotations to *good squared* annotations is conducted only on an annotation-level filtering within an assignment, not affecting the calculation. As the workers could be assigned to another news editorial until the study ends, the workers who completed an assignment faster could be given another assignment, hence the different number of annotations.

6.2.2 Inter-annotator Agreement

In order to check for the effectiveness of the quality control method using the two-step reason selection, for each of the four groups, we retained only the annotations by the annotators in the group and measured the inter-annotator agreement (IAA) of the annotations that were retained, dismissing all the other annotations in the other groups. For example, for the *good squared* annotations, we retained only the 1,741 *good squared* annotations among the 17,414 crowdsourced annotations, dismissing all the other 15,673 (=17,414−1,741) annotations and measured the IAA for the 1,741 annotations that were retained. The IAA for *good*, *moderate*, and *bad* annotations was calculated in the same way. Figure 1 shows the inter-annotator agreement for each group. We measured the IAA based on the Krippendorffs alpha, as the attribute values are ordinal. For local acceptability, alpha was 0.33 for *good squared* annotations and 0.23 for *good* annotations. On the other hand, for all of *moderate*, *bad*, and *all* annotations, the IAA for each attribute was less than 0.03, which is very

[1] We dismissed 18 outliers taking time longer than 10 hours for annotating a news editorial.

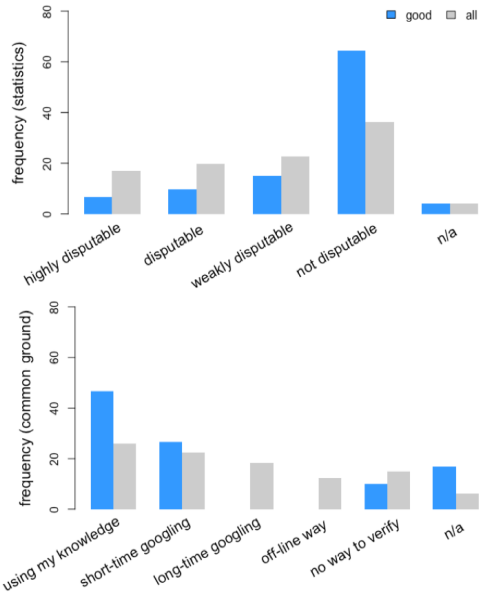

Figure 4: Relative occurrence frequency (unit: %)

low. The alphas of *good squared* annotations and *good* annotations are comparable to those of in-house annotations by Yang et al. (2019), which is the basis for the design of the reason options (see Section 5.1), showed IAA of 0.24 alpha. Wachsmuth et al. (2017) reported that the IAA of the document-level local acceptability annotations was measured between the most agreeing annotator pair among the three annotators and that the result was 0.46. Besides, seven experts who participated in their pilot study are found to show the IAA lower than 0.22 on pilot data, which is comparable to the alpha of our *good squared* and *good* annotations.

We also note that the sample size (the number of annotations) of each of the *good squared*, *good*, *moderate*, and *bad* annotations is different. To make sure that the IAA of *good squared* and *good* annotations is not the result of a different sample size, we randomly sampled 10%, 20%, ..., and 90% of all the annotations. In other words, we adopted random sampling as a baseline method to compare with our proposed method of the two-step reason selection, and checked the effect of the sample size on IAA. For each of the groups of randomly selected annotations with a different sample size, the IAA was less than 0.03 alpha for all the attributes. This confirms that the IAA of *good squared* and *good* annotations is not due to a different sample size of the annotations.

6.2.3 Occurrence Frequency

Figure 2 shows the occurrence frequency of the attribute values for each attribute. It is notable that for local acceptability, the imbalance of the data was quite significant. The occurrence frequencies of *accept* and *strong accept* were much higher than those of the other labels. The *bad* annotations contain fewer *n/a*'s than *all* annotations, or the entire crowdsourced dataset. We find that the *bad* annotations have a more balanced distribution of the attribute values selected for each attribute. We believe that this is an indicator for more randomized selections in the *bad* annotations.

We also looked into the relative frequency of the attribute values for the sentences that contain a discourse unit with a strategy label. We report two cases of *Common Ground* and *Statistics* for the attributes of verifiability and disputability, respectively. Figure 4 shows the relative frequency of the attribute values for the two strategy labels. For *Common Ground*, the distribution of the attribute values for disputability of *good* annotations shows a higher bias to *not disputable* than those of *all* annotations. For *Statistics*, the distribution for verifiability for *good* annotations shows a higher bias to *using my knowledge* than those for *all* annotations. We believe that these biases match good linguistic intuition and that the higher biases of *good* annotations than *all* show the effectiveness of our method.

6.2.4 Correlation Analysis

In Yang et al. (2019), we report that our in-house annotation results show a positive correlation between local acceptability and verifiability, and a negative correlation between local acceptability and disputability. Moreover, knowledge awareness and verifiability show a positive correlation. We see that the correlation pattern is an expected result, based on the definitions of the attributes. Figure 5 shows the Pearson's Correlation Coefficient (PC) between the four attributes for our annotation results using the two-step reason selection. *Good squared* and *good* annotations show the distinctive correlation pattern that is similar to that reported in Yang et al. (2019). *Moderate* and *all* annotations on the other hand show an opaque correlation pattern, and *bad* annotations show no correlation pattern except for a small negative correlation between local acceptability and disputability. We believe that the correlation patterns of the *good squared* and *good* annotations

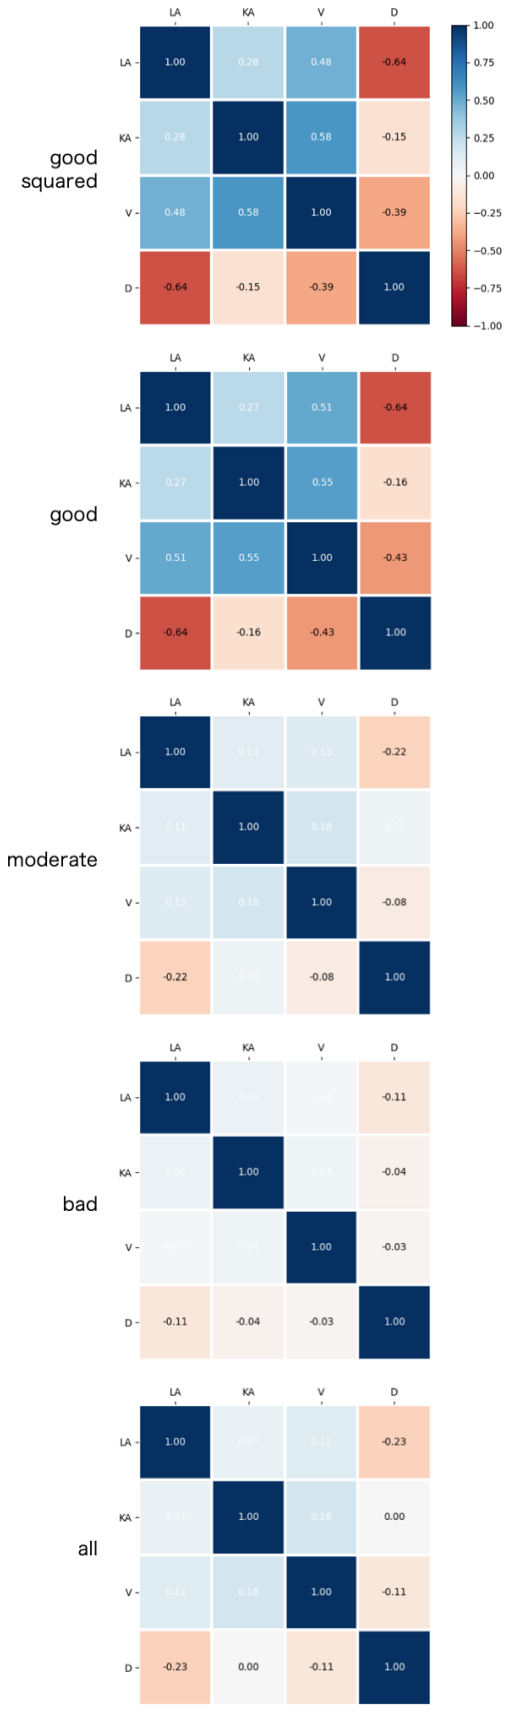

Figure 5: Pearson's Correlation Coefficient between local acceptability and the related attributes.

match good linguistic intuition, and that those of the other annotation groups do not. We also believe that the difference in the correlation pattern between the annotation groups shows the effectiveness of our quality control method using the two-step reason selection.

7 Conclusion and Future Work

In this study, we presented a simple but powerful method of quality control for annotating local acceptability and the related attributes using two-step reason selection. We designed a system in which a nonsensical reason can be selected within a sentential annotation and regarded it as an indicator for the unreliability of the annotation. The analysis of inter-annotator agreement shows that the method is effective at retaining only the annotations with remarkable quality. We conducted our annotation through crowdsourcing *without* the assurance of the expertise of the participating workers in the linguistic annotation, and *without* a separate training phase. Yet, the *good squared* and *good* annotations identified by our method show comparable quality to our previous in-house annotation results which were performed *with* the required expertise and *with* the training for linguistic annotation (Yang et al., 2019). Therefore, we believe that our results show a great potential for the crowdsourced annotation, especially when it is followed by a working quality control method.

One limitation of this study is that the annotators should not know about our use of the nonsensical reason selection as the indicator for unreliability during the annotation. As such, we paid attention not to inform the workers of this and did not reject workers for their selections of the nonsensical reasons. Therefore, we leave it as future work to develop a method that is effective even when workers are aware of quality control methods that employ nonsensical reasons, possibly by making the nonsensical reasons change automatically between annotations.

Abstract

The neural revolution in machine translation has made it easier to model larger contexts beyond the sentence-level, which can potentially help resolve some discourse-level ambiguities such as pronominal anaphora, thus enabling better translations. Unfortunately, even when the resulting improvements are seen as substantial by humans, they remain virtually unnoticed by traditional automatic evaluation measures such as BLEU, as only a few words end up being affected. Thus, specialized evaluation measures are needed. With this aim in mind, we contribute an extensive, targeted dataset that can be used as a test suite for pronoun translation, covering multiple source languages and different pronoun errors drawn from real system translations, for English. We further propose an evaluation measure to differentiate good and bad pronoun translations. Finally, we conduct a user study and we report correlation with human judgments.

1 Introduction

Traditionally, machine translation (MT) has been performed at the level of individual sentences, i.e., in isolation from the rest of the document. This was due to the nature of the underlying frameworks: word-based (Brown et al., 1993), then phrase-based (Koehn et al., 2003), syntactic (Galley et al., 2004), and hierarchical (Chiang, 2005). While there have been attempts to model the context beyond the sentence level, e.g., looking at neighboring sentences (Carpuat and Wu, 2007; Chan et al., 2007) or even at the entire document (Hardmeier et al., 2012), these approaches were still limited by the underlying framework.

Then, along came the neural revolution. Thanks to the attention mechanism, neural translation models such as sequence-to-sequence (Bahdanau et al., 2015) and the Transformer (Vaswani et al., 2017) could model much broader context. While initially translation was still done in a sentence-by-sentence fashion, researchers soon realized that going beyond that has become easier, and recent work has successfully exploited this (Bawden et al., 2018; Voita et al., 2018). This is an exciting research direction as it can help address inter-sentential phenomena such as anaphora, gender agreement, lexical consistency, and text coherence, to mention just a few.

Unfortunately, going beyond the sentence level typically yields very few changes in the translation output, and even when these changes are seen as substantial by humans, they remain virtually unnoticed by typical MT evaluation measures such as BLEU (Papineni et al., 2002), which are known to be notoriously problematic for the evaluation of discourse-level aspects in MT (Hardmeier, 2014).

The limitations of BLEU are well-known and have been discussed in detail in a recent study (Reiter, 2018). It has long been argued that as the quality of machine translation improves, there will be a singularity moment when existing evaluation measures would be unable to tell whether a given output was produced by a human or by a machine. Indeed, there have been recent claims that human parity has already been achieved (Hassan et al., 2018), but it has also been shown that it is easy to tell apart a human translation from a machine output when going beyond the sentence level (Läubli et al., 2018). Overall, it is clear that there is a need for machine translation evaluation measures that look beyond the sentence level, and thus can better appreciate the improvements that a discourse-aware MT system could potentially bring.

Alternatively, one could use diagnostic test sets that are designed to evaluate how an MT system handles specific discourse phenomena (Bawden et al., 2018; Rios et al., 2018). There have also been proposals to use semi-automatic measures and test suites (Guillou and Hardmeier, 2018).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2964–2975, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Here we propose a targeted dataset for machine translation evaluation with a focus on anaphora. We further present a specialized evaluation measure trained on this dataset. The measure performs pairwise evaluations: it learns to distinguish good vs. bad translations of pronouns, without being given specific signals of the errors. It has been argued that pairwise evaluation is useful and sufficient for machine translation evaluation (Guzmán et al., 2015, 2017). In particular, Duh (2008) has shown that ranking-based evaluation measures can achieve higher correlations with human judgments, as ranking judgments are easier to obtain from human judges and are also easy to use in training, while also directly achieving the purpose of comparing two systems.

Note that while it may be possible to rank translations using strong pre-trained conditional language models such as GPT (Radford et al., 2018), all kinds of errors would influence the score, and it would not be targeted towards a specific source of error, such as anaphora here. Our model provides a way to do this, and we demonstrate that it indeed focuses on the translation of pronouns.

Although our pronoun test suite naturally consists of the source text paired with a reference human translation, our pronoun evaluation measure is generally independent of the source language. Moreover, we use real machine translation output, which may contain various types of errors. Our contributions are as follows:

- We create a dataset for pronoun translation that covers multiple source languages and various target English pronouns.
- We propose a novel evaluation measure that differentiates good pronoun translations from bad ones irrespective of the source language they were translated from.
- Unlike previous work, both the dataset and the model are based on actual system outputs.
- Our evaluation measure achieves high agreement with human judgments.

We make both the dataset and the evaluation measure publicly available at https://ntunlpsg.github.io/project/discomt/eval-anaphora/.

2 Related Work

Previous work on discourse-aware machine translation and MT evaluation has targeted a number of phenomena such as anaphora, gender agreement, lexical consistency, and coherence. In this work, we focus on pronoun translation.

Pronoun translation has been the target of a shared task at the DiscoMT and WMT workshops in 2015-2017 (Hardmeier et al., 2015; Guillou et al., 2016; Loáiciga et al., 2017). However, the focus was on cross-lingual pronoun prediction, which required choosing the correct pronouns in the context of an existing translation, i.e., this was not a realistic translation task. The 2015 edition of the task also featured a pronoun-focused translation task, which was like a normal MT task except that the evaluation focused on the pronouns only, and was performed manually. In contrast, we have a real MT evaluation setup, and we develop and use a fully automatic evaluation measure.

More recently, there has been a move towards using specialized test suites specifically designed to assess system quality for some fine-grained problematic categories, including pronoun translation. For example, the PROTEST test suite (Guillou and Hardmeier, 2016) comprises 250 pronoun tokens, used in a semi-automatic evaluation: the pronouns in the MT output and in the reference are compared automatically, but in case of no matches, manual evaluation was required. Moreover, no final aggregate score over all pronouns was produced. In contrast, we have a much larger test suite with a fully automatic measure.

Another semi-automatic system is described in (Guillou et al., 2018). It focused on just two pronouns, *it* and *they*, and was applied to a single language pair. In contrast, we have a fully automated evaluation measure, we handle many English pronouns, and we cover multiple source languages.

Bawden et al. (2018) presented hand-crafted discourse test sets to test a model's ability to exploit previous source and target sentences, based on 200 contrastive pairs, one with a correct and one with a wrong pronoun translation. This alleviates the need for an automatic evaluation measure as one can just count how many times the MT system has generated the correct pronoun. In contrast, we use texts from pre-existing MT evaluation datasets, we do not require them to be in contrastive pairs, and we have a fully automated evaluation measure; we also use larger datasets.

Müller et al. (2018) also used contrastive translation pairs, mined from a parallel corpus using automatic coreference-based mining of context, thus minimizing the risk of producing wrong contrastive examples that are both valid translations. Yet, they did not propose an evaluation measure.

Finally, there have been pronoun-focused automatic machine translation evaluation measures. Two important examples include APT (Miculicich Werlen and Popescu-Belis, 2017) and AutoPRF (Hardmeier and Federico, 2010). Both measures require alignments between the source, the reference and the system output texts for evaluating the pronoun translations. However, automatic alignments are noisy; Guillou and Hardmeier (2018) have shown that improvements using heuristics are not statistically significant. They also found low agreement between these measures and human judgments, primarily due to the possibility of many translation choices per pronoun. APT also uses a predetermined list of 'equivalent pronouns', obtained for specific pronouns based on a French grammar book and verified through probability counts. This list is used to weigh pronouns that are not exact matches, and the accuracy of the pronoun translations is calculated accordingly. Miculicich Werlen and Popescu-Belis (2017) collect such a list for English-French for the pronouns *it* and *they*. This limits the evaluation measure both in terms of the language and also of the pronouns it is applicable to. In contrast, our framework requires only two candidate translations of the same text as input for comparison: this could be a reference vs. a system translation, or a comparison between two candidate translations (see Section 5.5).

3 Dataset Generation

We automatically generated our dataset, which we used to build a pronoun test suite and to train a pronoun evaluation model. In order to avoid generating synthetic data that may not necessarily represent a difficult context (for an MT system to correctly translate the pronouns), we used data from actual system outputs submitted for the WMT translation tasks in 2011–2015 and 2017 (Callison-Burch et al., 2011, 2012; Bojar et al., 2013, 2014, 2015, 2017). Using such data means that what is essentially a conditional language model solution, such as the one used by Bawden et al. (2018), has already failed on these examples.

Original French input: ***Il*** *était créatif, généreux, drôle, affectueux et talentueux, et il va beaucoup* ***me*** *manquer.*

Reference translation: ***He*** *was creative, generous, funny, loving and talented, and* ***I*** *will miss him dearly.*

MT system translation: ***It*** *was creative, generous, funny, affectionate and talented, and* ***we*** *will greatly miss.*

Generated noisy example 1: ***It*** *was creative, generous, funny, loving and talented, and I will miss him dearly.*

Generated noisy example 2: *He was creative, generous, funny, loving and talented, and* ***we*** *will miss him dearly.*

Figure 1: Noisy examples generated by substituting an MT-generated pronoun in the reference translation.

In particular, we aligned the system outputs with the reference translation using an automatic alignment tool (Dyer et al., 2013), and we found examples in which the pronouns did not match the reference translation. This process yielded potentially noisy data, as the alignments are automatic and thus not always perfect.

3.1 User Study

In order to ensure that the mismatched pronouns are not equally good translations in the given context, we conducted a user study on a subset of the data. To focus the study on pronouns and to remove the influence of other MT errors, we generated a noisy candidate by replacing the correct pronoun in the reference with the aligned (potentially) incorrect pronoun from the system output. We did this for each differing pronoun, so that the difference between the reference and the noisy version is one pronoun only (see Figure 1).

Our goal was to find pronoun pairs, e.g., *he-it* in Figure 1, where there is high agreement that the reference is the correct translation, so that we can automatically classify it as a positive example and the MT output as a negative one. The study participants were fluent in English and were native speakers of Chinese, Russian, French, or German. They were shown the source and two candidate translations (the reference and its noisy version) in random order. The relevant sentence was shown in bold, with the pronoun highlighted. Two previous sentences were given as a context; see Figure 2.

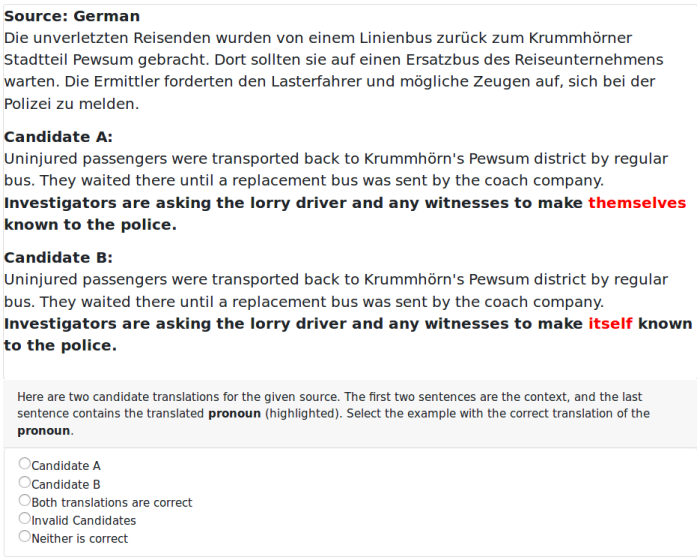

Figure 2: Our annotation framework.

Language Pair	Nb. of Ann.	Avg% Ref	AC1 (Incl. Ties)	AC1 (Excl. Ties)
Russian→English	3	80.2	0.82	0.92
French→English	2	83.9	0.86	0.96
German→English	2	84.3	0.89	0.97
Chinese→English	3	86.0	0.86	0.91
- - Only English	3	85.3	0.84	0.92

Table 1: Inter-annotator agreement.

We asked the study participants to choose the text with the better pronoun. They were allowed to choose (*a*) candidate A, (*b*) candidate B, (*c*) equivalent translations (tie), (*d*) "neither is correct", and (*e*) "invalid candidates", i.e., the highlighted words are not pronouns or are the wrong pronouns due to misalignment. We excluded from further consideration all examples marked as (*d*) or (*e*). Each participant annotated a total of **500 examples** per language pair. Statistics[1] about the annotation process are given in Table 1. We also report the proportion of cases where the participants preferred the reference translation over the noisy version (see **Avg%Ref**).[2] We can see that there is high agreement for all language pairs, ranging from 0.82 to 0.89. The ties seem to be the major source of disagreement: excluding them yields agreements in the range of 0.91–0.97.

[1]Due to the nature of the dataset, the human annotators are always more likely to choose the reference as the better candidate, which yields a skewed distribution of the annotations; traditional correlation measures such as Cohen's kappa are not robust to this, and thus we report the more appropriate Gwet's AC1/gamma coefficient.(Gwet, 2008).

[2]High agreement could also mean that the participants consistently picked the noisy version as the better choice.

In order to measure the effect, if any, that the source text might have on the annotator's choices, we also conducted a study without providing them the source text. We did this for the texts from the Chinese→English study. The participants were only shown the English texts: the reference vs. the noisy sentence, with the context as before. The results for this study are shown on the last line of Table 1. We can see that the agreement for this English-only setup is also fairly high (0.84); the overall agreement between all six participants (three from Chinese→English and three from only English) is 0.85. We observe very similar agreement of 0.91 (Chinese→English) and 0.92 (Only English) when the ties were excluded, with the overall agreement being 0.90 between the six participants. However, further analysis showed that although the two groups disagreed on about 10% of the examples, only 2% of the examples were common to both groups, showing that the sources of disagreement between the two groups are different. It can be that having the source context helps disambiguate the other 8% of the cases, while also introducing ambiguity that does not seem to be an issue for the participants who saw the English texts only. See Figure 1 for an example where the source is helpful; here, noisy example 2 would be acceptable, except that the original French text uses a singular pronoun. However, the disagreements form a small part of the dataset; we also filtered out all pronoun pairs with low agreements from further use. Figure 3 shows one such low-agreement example.

Source Text: 不过现在，她只想享受当下。我不想说这是我的最后一场比赛。这会给我带来太大的压力。

Reference translation: *For now she just wants to enjoy the moment. I didn't want to say **this** was my last race. That would have meant too much pressure.*

Noisy candidate: *For now she just wants to enjoy the moment. I didn't want to say **that** was my last race. That would have meant too much pressure.*

Figure 3: Low-agreement example: Chinese-English.

3.2 Pronoun Test Suite for MT Systems

The source sentences can also be used as a **test suite** for MT systems to check their pronoun translations: it can be considered to be a challenging, diagnostic test set for pronoun translation, covering a range of errors such as gender (he/she→it), number (they→it), animacy (who→which), syntactic role (e.g., subject/object: he→him), and others; see the Appendix for a complete list.

The WMT test sets come from news articles; the context is available, and thus the test suite is particularly suitable for discourse-level MT systems. It is available for each source language for which English translations are generated in the WMT tasks, e.g., Czech, French, German, etc. (Table 2).

The corresponding noisy versions of the reference are also generated, but are somewhat noisy. However, the subset used in our study is curated in some sense as human judgments are available. This data can serve as a more refined test suite: not only useful for checking the agreement with human judgments, but also for identifying equivalent pronoun translations in context, as the data is also annotated for ties.

Source Language	Test Data from WMT Years	Unique Source Contexts
German	2011-2015,17	7,823
Czech	2011-2015,2017	6,713
French	2011-2015	4,659
Russian	2013,2014,2017	4,513
Spanish	2011-2013	4,417
Finnish	2015,2017	1,551
Turkish	2017	1,372
Hindi	2014	921
Chinese	2017	696
Latvian	2017	652

Table 2: Pronoun test suite for MT systems: English as a target and various languages as a source.

4 The Evaluation Measure

While *diagnostic datasets* allow us to evaluate MT systems with respect to specific discourse-level phenomena, an automatic discourse-aware *evaluation measure* is useful not only for evaluation but also for tuning MT systems. Moreover, an evaluation measure that only looks at the target language (which is computationally feasible, even if not ideal, as our study above has shown) offers additional benefits; we can train it for a specific target language without requiring a separate dataset for each source-target language pair. Below, we propose such a measure for pronoun translation.

Let $R = (C_r; r)$ and $S = (C_s; s)$ denote a *reference* and a *system* tuple pair containing a reference and a system translation, r and s, along with a context of previous sentences, C_r and C_s, respectively. Note that C_r and C_s can contain the same sentences or different sentences, or be empty in case no context is provided. Given a training set $\mathcal{D} = \{(R_i, S_i)\}_{i=1}^{N}$ containing N such tuple pairs, our aim is to learn an evaluation measure that can rank any unseen translation pair (R, S) with respect to the correct use of pronouns.[3] In Section 3, we described how such datasets can be collected opportunistically without recourse to expensive manual annotation.

Figure 4 shows our proposed framework to evaluate MT outputs with respect to pronouns. The inputs to the model are sentences (with or without context C_r and C_s): R and S. Each input sentence is first mapped into a set of word embedding vectors of dimensionality d by performing a lookup in the shared embedding matrix $E \in \mathbb{R}^{v \times d}$ with vocabulary size v. E can be initialized randomly or with any pre-trained embeddings such as GloVe (Pennington et al., 2014), or contextualized word vectors such as ELMo (Peters et al., 2018a).

In case of initialization with GloVe vectors, we use a BiLSTM (Hochreiter and Schmidhuber, 1997) layer to get a representation of the words that is encoded with contextual information. Let $X = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ denote an input sequence, where $\mathbf{x}_t$ is the t^{th} word embedding vector of the sequence. The LSTM recurrent layer computes a compositional representation $\mathbf{k}_t$ at every time step t by performing nonlinear transformations of the current input $\mathbf{x}_t$ and the output of the previous time step $\mathbf{k}_{t-1}$.

[3] Here R (or S) can be a reference or a system translation.

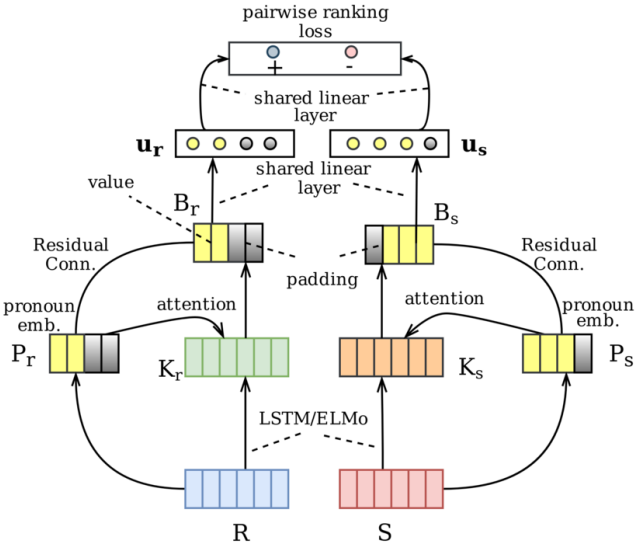

Figure 4: Our proposed framework to differentiate good pronoun translations from bad ones in context.

In a BiLSTM, we get the representation $\overrightarrow{\mathbf{k}_t}$ by processing the sequence in the forward direction, and the representation $\overleftarrow{\mathbf{k}_t}$ by processing the sequence in the backward direction. The final representation $\mathbf{k}_t$ of a word is the concatenation of these two representations, i.e., $\mathbf{k}_t = [\overrightarrow{\mathbf{k}_t}; \overleftarrow{\mathbf{k}_t}]$.

With ELMo initialization, the word vectors obtained are used directly. ELMo uses stacked biLSTM encoder and gives very powerful contextualized word representations learned from large corpora by optimizing a bi-directional language modeling loss. The ELMo representations already capture morphological, syntactic and contextual semantic features (Peters et al., 2018b).[4]

Let K_r and K_s be the matrices whose rows represent the word representations of R and S, respectively (obtained either from Bi-LSTM or directly from ELMo). From these representations, we extract the representations of the pronouns in the target sentence (from r and s; not from the contexts). Let P_r and P_s be the matrices whose rows represent the contextualized word representations of the pronouns in r and s, respectively. We use zero-padding (shown as shaded boxes) to make P_r and P_s fixed-length. We then use *scaled multiplicative attention* (Vaswani et al., 2017) to compute a contextual representation for the pronouns in r and s. Specifically, we consider the rows of P_r (*resp.* P_s) as *query* vectors, the rows of K_r (*resp.* K_s) as *key* and *value* vectors, and the matrix P_r (*resp.* P_s) to attend over K_r (*resp.* K_s).

[4]We also tried an ELMo-initialized BiLSTM, but it did not perform well while increasing model complexity.

We use residual connection and layer normalization to get pronoun representations B_r and B_s:

$$B'_r = \mathcal{S}(\frac{P_r K_r^T}{\sqrt[2]{d}})K_r; \quad B'_s = \mathcal{S}(\frac{P_s K_s^T}{\sqrt[2]{d}})K_s \quad (1)$$

$$B_r = \text{LayerNor}(P_r + B'_r); \; B_s = \text{LayerNor}(P_s + B'_s) \quad (2)$$

Note that B_r and B_s contain a d-dimensional vector for each query (pronoun) vector (and *zero* vectors due to padding). We pass these vectors through a **shared** linear layer parameterized by $\mathbf{z} \in \mathbb{R}^d$ to obtain a score for each pronoun. This yields vectors $\mathbf{u}_r$ and $\mathbf{u}_s$ for the reference and for the system translations:

$$\mathbf{u}_r = B_r\mathbf{z}; \quad \mathbf{u}_s = B_s\mathbf{z}; \quad (3)$$

A final **shared** linear layer parameterized by $\mathbf{w}$ converts these vectors to contrastive scores, yielding a (positive) score y_r for the reference and a (negative) score y_s for the system translation:

$$y_r = \mathbf{u}_r^T\mathbf{w}; \quad y_s = \mathbf{u}_s^T\mathbf{w}; \quad (4)$$

We then use the scores in a pairwise ranking loss (Collobert et al., 2011) to find model parameters that assign a higher score to y_r than to y_s. We minimize the following ranking objective:

$$\mathcal{L}(\theta) = \max\{0, 0.1 - y_r + y_s\} \quad (5)$$

Note that the network shares all of its parameters (θ) to obtain y_r and y_s from a pair of inputs $R_i = (C_r, r)$ and $S_i = (C_s, s)$. Once trained, it can be used to score any input independently.

5 Experiments

Below, we describe our data, the experimental setup, and the evaluation results.

5.1 Data

We first created a set of commonly confused pronoun pairs. Using the data from the study, we calculated the inter-annotator agreement for each pair of a reference/correct pronoun and a system translation/incorrect pronoun. We excluded the pairs with low agreement (<0.8) or for which the system output was chosen as the correct translation more often. Pairs with low agreement are essentially cases where the annotators cannot agree that the reference translation is better. The source of ambiguity in this case is that the system translation is not absolutely wrong (see Figure 3); therefore, these cases may not be so critical to correct. The remaining pairs are, with a fairly high confidence, positive–negative (correct–incorrect) pairs.

Next, we filtered the WMT data, only keeping sentences with these pronoun pairs. This yielded 97,461 reference translation (positive text) — unique system output (negative text) pairs for training, taken from WMT11,12,13,15 (Table 3).

The development data collected from WMT14 system outputs has 5,727 unique system translations and 6,635 unique noisy candidate pairs.[5]

For testing, we used the annotated data from the user study, generated from a subset of WMT17 system translations (except for French, which is from the discussion forum test set from WMT15, not overlapping with the training data). There are 500 unique noisy-reference pairs per source language, a total of 2,000.

Data	Source	#Unique Pairs
Training	WMT11-13,15	97,461
Development	WMT14	5,727
Development (noisy)	WMT14	6,635
Test (noisy)	WMT15,17	2,000

Table 3: Statistics about our dataset.

[5]The number of unique noisy candidates exceeds that of unique system translations because a separate noisy candidate was generated for each error in a system translation.

5.2 Experimental Setup

We evaluated the models in terms of accuracy, i.e., the proportion of times the model scored the reference translation higher than the system/noisy output, and we report results using either GloVe (Pennington et al., 2014) or ELMo (Peters et al., 2018a). We conducted a number of experiments, training and testing under different conditions:

No Context (NC). The reference (R) (or the noisy reference R') and the system (S) translations go through ELMo or BiLSTM, without contextual information C_r/C_s (i.e., query = P_r/P_s, key, value = $R = r/S = s$);

With Context: The reference (R) (or the noisy reference R') and the system (S) translation representations include two previous sentences as a context. The context can be further categorized as

(i) **Respective Context (RC)**: R includes its own reference context $C_r = r_{-2}r_{-1}$, and S includes its own respective system context $C_s = s_{-2}s_{-1}$ (query = P_r/P_s, key, value = $R = r_{-2}r_{-1}r/S = s_{-2}s_{-1}s$);

(ii) **Common Reference Context (CRC)**: The context for R and S includes the same reference context $C_r = C_s = r_{-2}r_{-1}$ for both (query = P_r/P_s, key, value = $R = r_{-2}r_{-1}r/S = r_{-2}r_{-1}s$);

We perform the evaluation in two ways:

(a) $\mathbf{R}$ vs. $\mathbf{S}$: Testing over pairs of reference (R) and system translation (S) texts;

(b) $\mathbf{R}$ vs. $\mathbf{R}'$: Testing over pairs of reference (R) and noisy candidate (R') texts.

Baseline. For a baseline performance, we simply take the average of the extracted pronoun representations in P_r and P_s, and we convert them to pairwise scores through linear layers. The baseline is also evaluated with and without context.

Exp	Context Setting	Test	Acc. (Glove)	Acc. (ELMo)
1	NC-Baseline	$\mathbf{R}$ vs. $\mathbf{R}'$	69.12	85.80
2	NC	$\mathbf{R}$ vs. $\mathbf{R}'$	68.97	88.04
3	NC	$\mathbf{R}$ vs. $\mathbf{S}$	79.67	89.09
4	RC-Baseline	$\mathbf{R}$ vs. $\mathbf{R}'$	69.07	85.80
5	RC	$\mathbf{R}$ vs. $\mathbf{R}'$	67.88	87.90
6	CRC-Baseline	$\mathbf{R}$ vs. $\mathbf{R}'$	69.16	86.66
7	CRC	$\mathbf{R}$ vs. $\mathbf{R}'$	68.93	89.11
8	CRC	$\mathbf{R}$ vs. $\mathbf{S}$	77.87	90.69

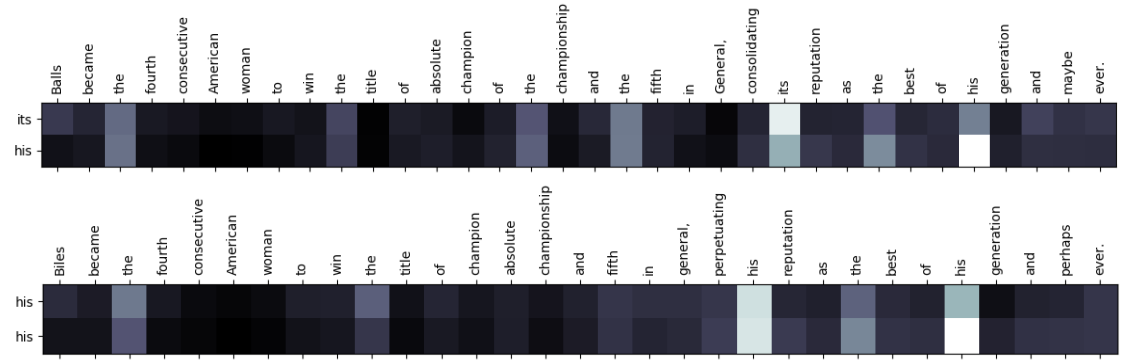

Figure 6: Attention maps for two candidate system translations of the same text (best viewed in color)

5.3 Results and Analysis

The first three experiments in Table 4 show results for the 'No Context' setting. These are on the noisy data (Exp. 1-2) and are indicative of how sensitive our model is to pronouns, since R and R' differ in a single pronoun. The results on the reference/system translation pair R and S (Exp. 3) is indicative of the performance in a real use case. In the case of the GloVe-BiLSTM model, using attention instead of averaging pronouns does not help. However, using ELMo greatly improves the accuracy of the baseline and also yields an improvement when using attention. ELMo can model syntactic and semantic information and can thus improve co-reference resolution (Peters et al., 2018a), which could be a contributing factor.

The second part of our experiments (Exp. 4-5) concerns the addition of contextual information. When the respective contexts are added, there is no improvement (even a drop in case of GloVe-BiLSTM); quite possibly, other differences in the text make it harder for the model to focus on the pronoun errors.

To offset this issue, we use a common context for both the reference and the system sentences, taken from the reference (Exp. 6-8). Training the model with a common reference context (CRC) yields marginal difference in the GloVe-BiLSTM model, but the ELMo model improves with the addition of context. Our experiments[6] show that ELMo is quite powerful at capturing contextual information, even as the context size grows.

Finally, we test our *ELMo - common reference context* model on the held-out dataset used for the user study. Table 5 shows the results. The accuracy of the system is lower on the study dataset. Note that since the training data was filtered based on the pronoun pairs with high agreement from the study, the study dataset contains pronoun pairs with low agreement that were not seen during training. We also calculate the agreement with human judgments excluding ties since our model does not handle ties. The overall agreement with the human judgments remains high.

[6]We also ran experiments with BERT (Devlin et al., 2019) and found that it performed on par with ELMo.

Language	Acc.(ELMo)	AC1 Agr.
Russian→English	79.4	0.80
French→English	82.0	0.84
German→English	81.6	0.83
Chinese→English	82.4	0.83
- - Only English	—-	0.83
Overall (average)	81.35	—-

Table 5: **Acc**uracy and AC1 **Agr**eement for the ELMo-based model predictions on the study dataset.

5.4 Pronoun-wise Analysis

We performed a pronoun-wise analysis of the results in Table 5. The model scored the noisy version higher than the reference in about 19% of the cases. Of these, 46% were pronoun pairs that were not seen during training.

Of the remaining pronoun pairs that were seen during training, the main source of errors (over 11%) were cases when ***that*** in the reference was replaced by ***it*** in the noisy version (*"We always tell victims not to pay up;* ***that/it*** *simply exacerbates the problem", explains Kleczynski*). The noisy candidate was scored higher about 28% of the time, out of 79 samples. The next highest source of errors was the reference–noisy pair of ***it–she*** at 10%.

In contrast, the best-performing pair was when a ***he*** in the reference was replaced with an ***it*** in the noisy version (***He/It*** *risked everything to save other people's lives.*). The reference was scored higher than the noisy candidate 95% of the time, out of 135 samples. The next highest performer was the reference–noisy pair of ***his–its***, which was correctly scored 86% of the time.

This performance follows the distribution of the pronoun pairs seen during training. The ***he–it*** and ***his–its*** pairs together account for over 12% of the training data, while the ***that–it*** and ***it–she*** pairs together form only 3.7%. Since the distribution of the pronoun pairs in the training data is itself based on the distribution of errors in the system translations, the model performs best over error cases that occur most often in system translations.

5.5 Discussion

As systems participating in WMT improve over the years, our test data is closer to state-of-the-art neural MT, while most of the training data is from statistical systems. This setting allows us to capture a wider range of errors while showing that our model is sensitive to small errors in a fluent output. Note that since the model was trained on the full system output and also on all pronouns in that output, it has not received any signal about which pronoun is wrong. Yet, we can see from the attention maps in Figure 5 that the model can correctly identify the incorrect pronoun. In Figure 5 (top), the model distinguishes the wrong pronoun *it* (the correct one is *she*), while in Figure 5 (bottom) it correctly finds *herself* as the wrong translation (the correct one is *she*).

We further compare the scores of two system translations for the same sentence from WMT17 Russian-English system outputs (see Figure 6). Here, the correct pronoun to be found is *her*. While one system translates it alternately as *its* and *his* (see Figure 6, top), the other system translates both cases as *his* (see Figure 6, bottom). Our model scores the translation in Figure 6 (bottom) higher than the translation in Figure 6 (top); even though the model highlights both occurrences of *his* as wrong, it ends up believing that having *its* as a translation is worse. We could argue that the translation in Figure 6 (bottom) is better since it maintains the animacy/human aspect, even if the grammatical gender is wrong; moreover, this translation is also consistent.

One could further argue that pronoun-focused automatic machine translation evaluation measures such as APT and AutoPRF are likely to yield the same accuracy/precision-recall for both cases above.

6 Conclusions and Future Work

We have presented a new, extensive, targeted dataset for pronoun translation that covers multiple source languages and a wide range of target English pronouns. We have also proposed a novel evaluation measure for differentiating good vs. bad pronoun translations, irrespective of the source language, which achieved high correlation with human judgments.

In future work, we want to handle cases where multiple pronouns are equally suitable in a given context. We would also like to extend the work to other discourse phenomena.

Acknowledgments

We would like to thank the anonymous reviewers for their comments. Shafiq Joty would also like to thank the funding support from his Start-up Grant (M4082038.020).

A Regularization Approach for Incorporating Event Knowledge and Coreference Relations into Neural Discourse Parsing

Zeyu Dai, Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
{jzdaizeyu, huangrh}@tamu.edu

Abstract

We argue that external commonsense knowledge and linguistic constraints need to be incorporated into neural network models for mitigating data sparsity issues and further improving the performance of discourse parsing. Realizing that external knowledge and linguistic constraints may not always apply in understanding a particular context, we propose a regularization approach that *tightly* integrates these constraints with contexts for deriving word representations. Meanwhile, it *balances* attentions over contexts and constraints through adding a regularization term into the objective function. Experiments show that our knowledge regularization approach outperforms all previous systems on the benchmark dataset PDTB for discourse parsing.

1 Introduction

Discourse parsing and identifying rhetorical discourse relations between two text spans (i.e., discourse units, either clauses or sentences) is crucial and beneficial for a wide variety of downstream tasks and applications such as machine translation (Webber et al., 2017), text generation (Mann, 1984; Bosselut et al., 2018) and text summarization (Gerani et al., 2014).

In the PDTB-style discourse parsing (Prasad et al., 2008), we commonly distinguish implicit discourse relations from explicit relations, depending on whether a discourse connective (e.g., "because", "however") appears between two discourse units. In general, recognizing implicit discourse relations is more challenging due to the lack of connective, which has recently drawn significant attention from the NLP researchers.

Recent research for implicit discourse relation classification has mostly focused on applying powerful neural network models (Qin et al., 2016a,b; Liu and Li, 2016; Lei et al., 2017; Bai and Zhao, 2018) for modeling compositional meanings and word-level interactions of two discourse units. More recent research has also exploited utilizing broader contexts (Dai and Huang, 2018) as well as leveraging external training data (Xu et al., 2018). Although progress has been made, the performance of implicit discourse relation identification remains low (macro F1 $< 50\%$).

We believe that the low performance is mainly due to the data sparsity issue (Braud and Denis, 2015), which hinders data-thirsty neural network models from making further improvements. Considering the following example from PDTB with two discourse units (DUs):

***DU1*:** The editorial of the WHO notes that tobacco consumption and **lung-cancer** mortality rates are rising in developing countries.

***DU2*:** "No **smoking** should be established as the norm of social behavior" around the world, the editorial says, through the enactment of laws that limit advertising and promote anti-smoking education.

***Discourse Relation*:** Implicit Contingency.**Cause**

Humans can easily recognize this discourse relation as "Cause" because we know that "smoking" is the key causal factor for "lung-cancer", but it is extremely difficult for neural network models trained with limited amount of data to detect it considering the keyword "lung-cancer" only appears few times in the whole PDTB data.

We further argue that external knowledge and linguistic constraints need to be considered for improving implicit discourse relation classification since human annotators also rely on these commonsense knowledge (e.g., smoking causes the lung-cancer) to label the discourse relations. *First*, we consider external event knowledge, because discourse relations (e.g., cause and temporal relations) are often defined as the relation between two

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2976–2987,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

events (situations in general) as described in two discourse units. As shown in the above example, the "Cause" discourse relation between the two DUs depends on the relation between two events *"smoking"* and *"lung-cancer"* with one event in each DU. *Second*, we consider entity coreference relations as a useful form of linguistic constraints in inferring discourse relations. This is motivated by prior work (Rutherford and Xue, 2014; Ji and Eisenstein, 2015) showing that coreference based features can improve entity mention representations within a DU, which facilitates recognizing coherence and discourse relations between DUs.

In this paper, we investigate how to incorporate external event knowledge and entity coreference relation based linguistic constraints into neural network models for discourse parsing. One key difficulty we want to address is that external knowledge derived event relations or hard linguistic constraints may not always apply for interpreting a particular context, and may hurt performance if used blindly (Kishimoto et al., 2018). Therefore, we propose to *tightly* integrate these constraints into the discourse relation inference process by manipulating hidden word representations to reflect relations between words, and meanwhile *balance* attentions to contexts and constraints through adding a knowledge regularization term in the final objective function.

Specifically, we choose the paragraph-level model we proposed (Dai and Huang, 2018) as the base model, which exploits wider paragraph-level contexts and has been shown effective for PDTB-style discourse parsing. The model mainly consists of a two-level hierarchical BiLSTMs (Schuster and Paliwal, 1997) for modeling both word-level and DU-level inter-dependencies (with a brief description in section 3.1). To implement the knowledge guided regularization for discourse parsing, we *first* insert a new knowledge layer between the word-level BiLSTM and DU-level BiLSTM layer. This knowledge layer modifies hidden representations of words that participate in an event or coreference relation, by applying a relation type specific feedforward neural network. *Then*, we compose a knowledge regularizer based on word representation outputs of the knowledge layer, by adapting a classic knowledge embedding method TransE (Bordes et al., 2013). The regularization term is added to the overall objective function and minimized during model training.

The experiments on PDTB v2.0 demonstrate that our proposed knowledge regularization approach can effectively utilize several types of externally obtained event knowledge and entity coreference relations[1], and improves the performance of both implicit and explicit discourse relation recognition compared to all previous work.

2 Related Work

2.1 Discourse Parsing on PDTB

With the release of Penn Discourse Treebank (PDTB) (Prasad et al., 2008), the task of discourse parsing, especially implicit discourse relation recognition, has received a lot of attention from the NLP community and researchers (Pitler and Nenkova, 2009; Lin et al., 2014; Xue et al., 2015; Rutherford and Xue, 2016). A large number of previous work attempted to model the semantic meanings of two discourse units using latest and advanced neural network models (Chen et al., 2016; Ji et al., 2016; Rutherford et al., 2017; Qin et al., 2017; Guo et al., 2018; Bai and Zhao, 2018). Paragraph-wide contexts were considered for building better discourse unit representations in Dai and Huang (2018). Another research direction for improving implicit discourse relation classification is to expand the training data by leveraging explicit relations (Liu et al., 2016; Lan et al., 2017) or discourse connective informed unlabeled data (Rutherford and Xue, 2015; Xu et al., 2018).

2.2 Incorporate Knowledge into Discourse Parsing

Only a few previous work (Park and Cardie, 2012; Biran and McKeown, 2013; Lei et al., 2018) has exploited external knowledge, including WordNet features (e.g., Antonyms and Hypernyms) and Verb Class (Levin, 1993), in discourse parsing by deriving discrete indicator features and then feed them into feature-based classifiers. Incorporating knowledge as additional features into neural network models often generalize poorly due to the sparsity of features, as also shown in our experiments. Recently, Kishimoto et al. (2018) incorporated the whole of ConceptNet into a MAGE-GRU (Dhingra et al., 2017) based neural networks, but their experiments show that it did not work well for improving implicit discourse relation identification compared with their own base-

[1]Entity coreference relations were generated using an existing coreference resolver from Standford CoreNLP toolkit.

line. We interpret this negative result as the consequence of using irrelevant (noisy) knowledge types blindly without proper regularization.

There are also recent work (Yang and Mitchell, 2017; Xu et al., 2017; Zhou et al., 2018) that incorporate external knowledge into neural network models for improving several other NLP tasks, including information extraction and conversation generation, which mostly followed the *two-step* approach that first obtained representations of knowledge (with triplet format) from knowledge base using knowledge graph embedding methods such as TransE (Bordes et al., 2013), and then utilized attention mechanism (or added gates in a RNN cell (Ma et al., 2018)) to integrate knowledge representations with hidden word vectors. This approach has two main drawbacks: (1) Knowledge representations learned from the first step are fixed without considering the influences of contexts, which may be suboptimal when used for understanding a particular context. (2) With no filtering or regularization, it is difficult for attention mechanisms to explicitly select and attend to the relevant knowledge. In contrast, our proposed regularization approach can be regarded as an end-to-end *joint-learning* framework for discourse parsing and knowledge representation learning, which not only considers both knowledge and contexts in knowledge-aware word representation learning, but also naturally balances attentions on both contexts and knowledge through regularization.

3 Model

Figure 1 illustrates the overall architecture of our model, which implements our knowledge regularization approach (the right part) on top of an existing model as the base model (the left part). There are only two modifications we made to the base model: (1) we insert a novel knowledge layer between the two BiLSTM layers of the base mode; (2) we add a regularizer into the overall objective function. We will first briefly describe the base model, a replication[2] of our recently proposed paragraph-level discourse parsing model (Dai and Huang, 2018). We will then explain the knowledge layer and knowledge regularizer we added.

3.1 Base Model

The base model processes a paragraph containing a sequence of discourse units each time, and predicts a sequence of discourse relations (both implicit and explicit relations) with one relation between each pair of adjacent discourse units (DU). The base model utilizes a hierarchical BiLSTM to calculate both word-level and DU-level representations, followed by a prediction layer and Conditional Random Field (CRF) layer (Lafferty et al., 2001) for jointly predicting a sequence of discourse relations within a paragraph. The base model consists of the following layers:

Character-level CNN Layer: The character-level features, such as the prefix or suffix of a word, can help alleviate the out-of-vocabulary (OOV) problem and improve the word representation in neural nets (Santos and Zadrozny, 2014). In our base model, we use one layer of CNN[3] with max-pooling to extract character-level representation $\boldsymbol{w}_i^{char}$ for the i-th word of the input paragraph.

Word-level BiLSTM Layer: Given a words sequence $X = (x_1, x_2, ..., x_L)$ as the input paragraph, for each word x_i, we construct the expanded word vector by concatenating its word embedding $\boldsymbol{w}_i^{word}$ with its character-level representation and extra word-level features[4] as:

$$\boldsymbol{w}_i = [\boldsymbol{w}_i^{word}; \boldsymbol{w}_i^{char}; \boldsymbol{w}_i^{features}]$$

The word-level BiLSTM layer will process the sequence of expanded word vectors $(\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_L)$ and compute the word x_i's hidden representation at each word index i:

$$\boldsymbol{h}_{x_i} = BiLSTM(\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_L)$$

DU-level BiLSTM Layer: Given the output of word-level BiLSTM $(\boldsymbol{h}_{x_1}, \boldsymbol{h}_{x_2}, ..., \boldsymbol{h}_{x_L})$, we calculate the raw DU representation by applying max-pooling operation (Conneau et al., 2017) over the sequence of word representations for all words within a discourse unit: $\boldsymbol{h}'_{DU_j} = \max_{x_i \in DU_j} \boldsymbol{h}_{x_i}$

Then, the DU-level BiLSTM will process the sequence of raw DU representations and obtain the refined DU representation $\boldsymbol{h}_{DU_j}$ for the j-th discourse unit in a paragraph:

$$\boldsymbol{h}_{DU_j} = BiLSTM(\boldsymbol{h}'_{DU_1}, \boldsymbol{h}'_{DU_2}, ..., \boldsymbol{h}'_{DU_{T+1}})$$

[2] In our re-implementation, we made several minor modifications to the original base model by using character-level features as well as supporting both traditional fixed word embeddings (300D GloVe (Pennington et al., 2014)) and latest context-dependent word embeddings (1024D ELMo (Peters et al., 2018)) for word embedding initialization.

[3] Both character embedding and CNN hidden size is 50.

[4] In this work, we used capitalization (Cap) flag, Part-of-speech (POS) tag and named entity (NER) tag of each word as extra word-level features. The embedding size for Cap/POS/NER is 5/35/20. We used Standford CoreNLP toolkit (Manning et al., 2014) to generate POS and NER tags.

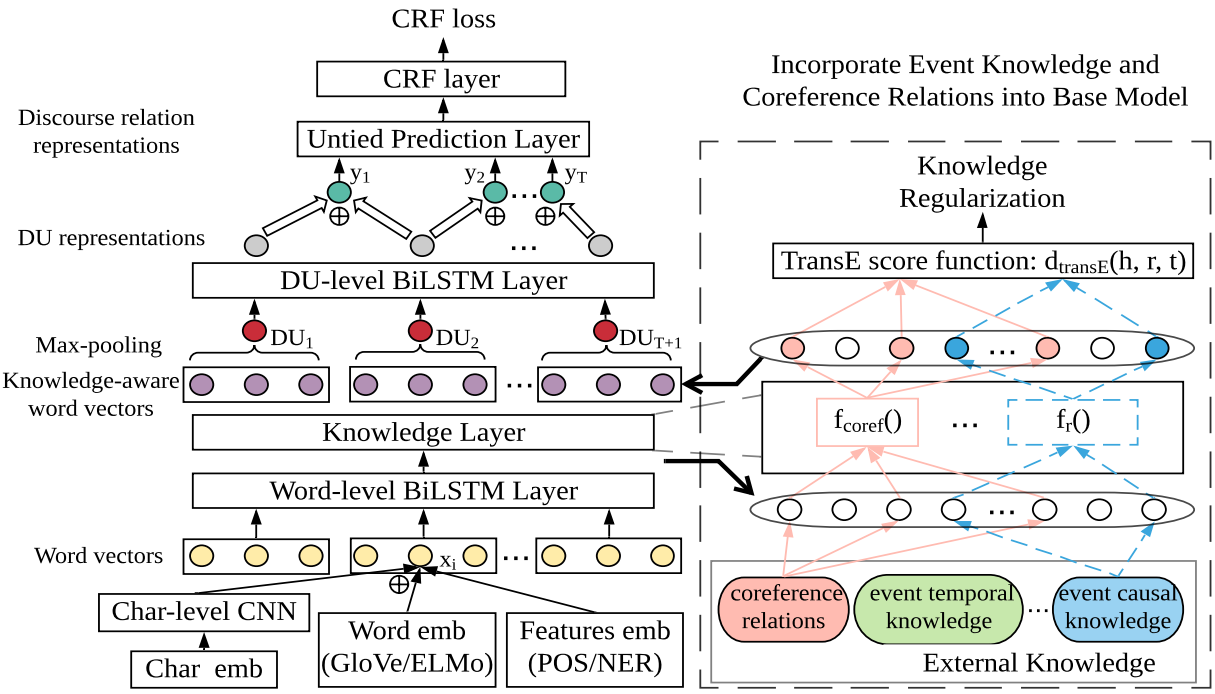

Figure 1: Model Architecture for Paragraph-level Discourse Parsing. The left part is the base model. The right part with colored arrows and neurons show how to incorporate coreference and event knowledge into base model.

Untied (Explicit vs. Implicit) Prediction Layer: Considering the different natures of explicit and implicit discourse relations (Pitler et al., 2009; Lin et al., 2009), the base model trains two independent linear layers with untied parameters for predicting explicit or implicit discourse relations between each two adjacent DUs respectively:

$$\boldsymbol{h}_{y_t} = \begin{cases} W_{exp}[\boldsymbol{h}_{DU_t}; \boldsymbol{h}_{DU_{t+1}}] + b_{exp}, & \text{if } y_t \in exp \\ W_{imp}[\boldsymbol{h}_{DU_t}; \boldsymbol{h}_{DU_{t+1}}] + b_{imp}, & \text{if } y_t \in imp \end{cases}$$

CRF Layer for Discourse Relation Sequence Labeling: A CRF layer (Biran and McKeown, 2015) is added on top of the prediction layer to fine-tune the predicted sequence of discourse relations by capturing continuity and transition patterns (e.g., a temporal relation is likely to follow another temporal relation).

Given the hidden discourse relation representations $\boldsymbol{H}^{(i)} = (\boldsymbol{h}^{(i)}_{y_1}, \boldsymbol{h}^{(i)}_{y_2}, ..., \boldsymbol{h}^{(i)}_{y_T})$ and the target discourse relation label sequence $\boldsymbol{y}^{(i)} = (y^{(i)}_1, y^{(i)}_2, ..., y^{(i)}_T)$ for the i-th training instance, we minimize the following CRF loss function during model training:

$$L_{CRF} = -\sum_i \log p(\boldsymbol{y}^{(i)}|\boldsymbol{H}^{(i)})$$

During testing, the Viterbi algorithm is used to search for the optimal label sequence $\boldsymbol{y}^*$ that maximizes the conditional probability $p(\boldsymbol{y}|\boldsymbol{H})$.

3.2 Knowledge Layer

We simply insert a knowledge layer between the word-level and DU-level BiLSTM layers of the base model, as shown in Figure 1, for incorporating external knowledge and linguistic constraints. Although the knowledge layer can be easily extended to support other types of knowledge, we only consider event knowledge and coreference relations in this paper and leave the exploration of other knowledge types in the future work.

Since there are some notable differences between event relations and entity coreference relations, we model event and coreference constraints in different ways considering their specificities. For example, (1) an event relation can be represented as the triple format $((h, r, t)$ or $(head, relation, tail)$ where $head$ and $tail$ are two event words, $relation$ indicates the relationship between two events $head$ and $tail$.) while a coreference relation can have more than two coreferential entity mentions; (2) event relations are directed while coreference relations are undirected.

Event Knowledge: As the input of our knowledge layer, $\mathbb{E} = (\mathbb{E}_1, \mathbb{E}_2, ..., \mathbb{E}_M)$ denotes the collection of event knowledge triplets generated by matching the paragraph contexts with external event knowledge base (we will give more details in the following section 4.1.), where each triplet has the form of (h, r, t) meaning that there is an event

relation r (either *temporal*, *causal* or *subevent* in this work) between the head event x_h at the position h and tail event x_t at the position t.

For each triplet $\mathbb{E}_m = (h, r, t)$, we use a feedforward neural network[5] $f_r()$ to update the hidden word representations of head and tail events:

$$f_r(\boldsymbol{h}_{x_h}); f_r(\boldsymbol{h}_{x_t}) = \tanh(\boldsymbol{W}_r[\boldsymbol{h}_{x_h}; \boldsymbol{h}_{x_t}] + \boldsymbol{b}_r)$$

where $\boldsymbol{W}_r$ and $\boldsymbol{b}_r$ are relation-specific weights and bias learned for each type of event relation r *only*.

Coreference Relations: Our system assumes that coreference relations in each paragraph are given in the form of coreference clusters, which are generated by running an existing coreference resolver (Clark and Manning, 2016) from the latest version (3.9.2) of Stanford CoreNLP toolkit.

Let $\mathbb{C} = (\mathbb{C}_1, \mathbb{C}_2, ..., \mathbb{C}_K)$ denote coreference clusters in one paragraph, where $\mathbb{C}_k$ contains the word indices with corresponding words referring to the same entity. Similar as above, we use one feedforward neural network $f_{coref}()$ to update the hidden word representation $\boldsymbol{h}_{x_i}$ for words within each coreference cluster. Specifically, the output word vector has the following form:

$$f_{coref}(\boldsymbol{h}_{x_i}) = \begin{cases} \tanh(\boldsymbol{W}_{coref}[\boldsymbol{h}_{x_i}; \boldsymbol{h}_{\mathbb{C}_k}] + \boldsymbol{b}_{coref}), & \text{if } x_i \in \mathbb{C}_k \\ \boldsymbol{h}_{x_i}, & otherwise \end{cases}$$

where $\boldsymbol{W}_{coref}$ and $\boldsymbol{b}_{coref}$ are the weights and bias, $\boldsymbol{h}_{\mathbb{C}_k}$ is a coreference vector calculated by applying max-pooling to all word representations in one cluster: $\boldsymbol{h}_{\mathbb{C}_k} = \max_{x_i \in \mathbb{C}_k} \boldsymbol{h}_{x_i}$. The role of coreference vector is similar to "context vector" utilized in soft attention mechanism (Bahdanau et al., 2015), but we use simple max-pooling instead of computing weights[6] for different word vectors.

3.3 Knowledge Regularization

Inspired by the success of TransE (Bordes et al., 2013) approach in knowledge representation learning, we adapt the key assumption of TransE (i.e., we want $\boldsymbol{h} + \boldsymbol{r} \approx \boldsymbol{t}$ when (h, r, t) holds.) to our framework and hypothesize that the hidden representation of tail t should be close to the hidden representation of head h plus the relation-specific vector $\boldsymbol{h}_r$ in vector space if (h, r, t) holds.

To guide the knowledge-aware word representation learning of the knowledge layer, we propose a knowledge regularizer based on TransE[7] score function $d_{transE}()$ and apply it to the output word vectors of the knowledge layer. The resulting regularization term is also minimized as a part of the objective function during model training. In other words, the knowledge regularization will smoothly penalize constraint depending on whether this constraint can be applied for interpreting relevant relation in a particular context.

Specifically, we use cosine similarity[8] to measure the similarity of two vectors, so the score function for triplet (h, r, t) has the following form:

$$d_{transE}(h, r, t) = 1 - cos(f_r(\boldsymbol{h}_{x_h}) + \boldsymbol{h}_r, f_r(\boldsymbol{h}_{x_t}))$$

where $\boldsymbol{h}_r$ is the relation-specific vector which will be updated as parameters during model training. The event knowledge regularization term is:

$$R_{event} = \sum_{\mathbb{E}_m = (h,r,t) \in \mathbb{E}} d_{transE}(h, r, t)$$

For coreference relations, we create a special triplet $(h, coref, t)$ for each two entity mentions h and t in one coreference cluster, and fix the relation-specific vector $\boldsymbol{h}_{coref}$ to be a zero vector representing the relation of being "identical". The coreference relation regularization term is:

$$R_{coref} = \sum_{\mathbb{C}_k \in \mathbb{C}} \sum_{(h,t) \in \mathbb{C}_k} d_{transE}(h, coref, t)$$

Hence, the overall loss function for our model is:

$$L = L_{CRF} + \lambda_{event} * R_{event} + \lambda_{coref} * R_{coref}$$

4 Experiments

4.1 Dataset and Preprocessing

Dataset: We evaluate our model on PDTB v2.0 (Prasad et al., 2008), which is the largest annotated dataset containing 19K explicit discourse relations and 17K implicit discourse relations. To make our experimental results directly comparable with previous work, we adopted the most-used dataset splitting "PDTB-Ji" (Ji and Eisenstein, 2015) that uses sections 2-20, 0-1, and 21-22

[5] We also tried to use more complicated neural nets including neural tensor networks (Socher et al., 2013) and self-attentions mechanism (Vaswani et al., 2017), but none of them performed better than straightforward feedforward neural network. We even tried to not update (identical function) hidden word vectors, but it performed significantly worse.

[6] We tried to employ weights with soft-attention mechanism, but it did not show improvement in our experiments.

[7] We also tried TransD (Ji et al., 2015) and TransR (Lin et al., 2015) for knowledge regularization, but none of them showed clear improvement over TransE in our experiments.

[8] Note that cosine similarity performed better than L1 or L2 distance in our experiments.

Relation Type	Source	#	Discourse
Coreference	CoreNLP	19,819	Exp & Cont
Event Temporal	Yao et al.	18,515	Temp
Event Causal	ConceptNet	947	Cont
Event Subevent	ConceptNet	626	Exp & Temp

Table 1: Overview of relation types. # is the number of matched triplets (clusters for coreference). The last column summarizes relevant discourse relation classes each knowledge type may potentially help identify.

as train, dev and test sets respectively. To recover the paragraph contexts and gold discourse units, we directly ran the source code[9] of Dai and Huang (2018), and obtained 12,037/1222/1050 paragraph instances in train/dev/test sets respectively.

Knowledge Preprocessing: Table 1 gives an overview of the relation types used in our experiments and the number of triplets (clusters) identified in the PDTB dataset. Specifically, for coreference relations, we utilized the Stanford CoreNLP coreference resolver to identify coreference clusters in each paragraph. For event knowledge, we considered three major event relation types including temporal, causal and subevent. We obtained event temporal knowledge from a previous work (Yao and Huang, 2018)[10] and we retrieved the latter two types of event knowledge from ConceptNet[11] (Speer and Havasi, 2012), which is a widely-used commonsense knowledge base.

4.2 Experiment Setting

Evaluation Setting: Annotated discourse relation labels in PDTB v2.0 are organized in a three-level hierarchy. The top-level coarse-grained discourse relation classes include Comparison (Comp), Contingency (Cont), Expansion (Exp) and Temporal (Temp), which are further split into 16 fine-grained classes at the second-level. To compare with previous work, we report the macro-average F1-score and accuracy[12] on the top-level multi-class classification setting. Note that the macro-average F1-score is normally treated as the main evaluation metric in most previous work considering the imbalanced distribution of discourse relations. In addition, we report class-wise F1-scores for the top-level implicit discourse relations. But different from many previous work that report class-wise F1-scores obtained by using the one-versus-all binary classification setting, we instead report class-wise F1-scores using the 4-way multi-class classification setting, following Dai and Huang (2018) which pointed out that compared to the one-versus-all binary classification setting where all binary classifiers may predict a positive label for one instance, the multi-class classification setting is more appropriate in evaluating a practical end-to-end discourse parser without the need of prediction conflict resolution. We additionally evaluate our models at the second-level using the 11-way[13] multi-class classification.

Training Setting: To make it easy for model tuning, we only chose λ_{coref} and λ_{event} from [0.1, 0.5, 1.0] and tuned them based on the best performance on the dev set. All the BiLSTM layers and our knowledge layer used the hidden state size of 512, so the dimension of all hidden vectors ($\boldsymbol{h}_*$, $f_{coref}(\boldsymbol{h}_*)$ and $f_r(\boldsymbol{h}_*)$) is 512. To prevent gradient exploding problem of LSTMs, we clipped the gradient L2-norm with threshold 5.0 and used L2 regularization with coefficient 10^{-8}. We applied dropout with probability 0.5 on the input/output of BiLSTMs to alleviate overfitting. For the optimizer, we used the SGD with momentum 0.9 and batch size of 64, and we set the initial learning rate as 0.015 which will decay by 5% after each epoch.

To diminish the effects of randomness in neural network model training, we ran all our proposed model, its variants as well as our own base model 3 times using different random seeds and reported the average performance over 3 runs. For fair comparison, we implemented all our models with Pytorch and tested them on a Nvidia 1080Ti GPU.

4.3 Models for Comparison

We compare our proposed regularization models with the following base model, our own baselines and recent published discourse parsing systems:

- (Dai and Huang, 2018): the original model for paragraph-level discourse parsing.

[9] Available at https://github.com/ZeyuDai/paragraph_implicit_discourse_relations. Relations (0.5%) between non-adjacent DUs were discarded.

[10] We also tried to use VerbOcean (Chklovski and Pantel, 2004) which performed worse than our choices.

[11] Available at http://conceptnet.io. To extract event causal knowledge, we merged the relations ['Causes', 'CausesDesire', 'Entails'] defined in ConceptNet. To extract subevent knowledge, we merged the relations ['HasSubevent', 'HasFirstSubevent', 'HasLastSubevent']. For simplicity, we removed relations containing multi-word events or non-event words (e.g., function words).

[12] Note that 3% discourse relations in PDTB were annotated with more than one label. Following previous work (Dai and Huang, 2018; Bai and Zhao, 2018), we considered a prediction as correct if it matches one of the gold labels.

[13] We followed Ji and Eisenstein (2015) to exclude 5 minor second-level classes in our experiments because none of these classes appear in the test or dev sets.

Table 2: Top-level Multi-class Classification Results on PDTB. We report macro-average F1-score (Macro), accuracy (Acc) and F1-score on each class (Comparison, Contingency, Expansion and Temporal). Note that Bai and Zhao (2018) used ELMo word embeddings, so this result is only comparable with the last section.

- Base Model: our replicated model of (Dai and Huang, 2018) for paragraph-level discourse parsing.
- Base Model + Word Features: our own baseline that creates discrete features for each word. We create one feature for each type of relations, including three types of event relations and coreference relations, which counts the number of relation triplets that contain a word. We concatenate these word features with the input word vector $\boldsymbol{w}_i$.
- Base Model + DU Features: our own baseline that creates discrete features for each DU DU_j. We create two features for each type of relations: one counts relation triplets that have both nodes within DU_j; and the other counts relation triplets that have one node in DU_j and the other node in an adjacent DU. We concatenate these DU features with the hidden DU representation $\boldsymbol{h}_{DU_j}$. Adding either word features or DU features is to imitate traditional feature-based approaches and incorporate event knowledge and coreference relation constraints as features.
- Base Model + two-step approach: our own baseline that follows the two-step approach for incorporating relational constraints, including both event relations and coreference relations. We re-implement the inference model proposed by Chen et al. (2018)[14], which first employs TransE to obtain relation representations, and then uses attention mechanism to incorporate relations and build knowledge-enhanced DU representations.
- (Rutherford and Xue, 2015): a feature-based classifier that utilizes explicit discourse connectives for creating more implicit relations.
- (Liu et al., 2016): CNN based multi-task joint learning model that leverages both PDTB and RST (Carlson et al., 2003) datasets.
- (Liu and Li, 2016): a hierarchical attention-over-attention neural network model for implicit discourse relation recognition.
- (Lan et al., 2017): multi-task attention-based model for predicting implicit discourse relations that leverages both explicit discourse relations of PDTB and unlabeled data.
- (Bai and Zhao, 2018): a complex deep residual bi-attention based neural network model for implicit discourse relation classification which improves the hidden representations at character, subword, word and DU levels.

4.4 Experiment Results

Table 2 shows the comparisons. The first section lists the results of previous models that were evaluated on PDTB using top-level multi-class classification. Note that many cells are empty, it is be-

[14]We followed Chen et al. (2018) to tune the hyper-parameter λ for each relation type in the range [0.1, 0.5, 1, 5, 10, 20, 50, 100], and we found that the best result was achieved when λ is set to 0.1 for each type of relations.

Table 3: Second-level Multi-class Classification Results on PDTB. We report macro-average F1-score (Macro) and accuracy (Acc).

cause that many previous publications chose to report the class-wise implicit relation prediction performance using the one-versus-all binary classification setting, which are not directly comparable with our class-wise results using the multi-class classification setting following our previous work Dai and Huang (2018). In addition, we also report the explicit relation results.

In the second section, the replicated model (Base Model) achieves an overall similar performance[15] compared to the original model of Dai and Huang (2018). By incorporating coreference relations (+ Coreference) into the base model using our regularization approach, implicit discourse relation prediction performance was improved for two classes, Contingency and Expansion. Adding event temporal knowledge (+ Event Temporal) into the base model significantly boosts the performance of Temporal discourse relation identification. Furthermore, adding the additional two types of event knowledge (+ Event), causal and subevent relations, yields clear performance gains in predicting another two classes of implicit discourse relations: Contingency and Expansion. These performance gains meet our expectations that event relations are correlated with discourse relations and event relational knowledge facilitates predicting corresponding discourse relations, with correspondences listed in Table 1. The full model considering both event knowledge and coreference relations (+ C&E) achieves further improvements on implicit relation prediction, and outperforms the base model by 1.5 and 1.9 points on macro-average F1-score and accuracy respectively. Meanwhile, our full model obtains the best results for explicit relation prediction as well.

Shown in the third section, our own baselines which incorporate relational constraints either as features or via the two-step approach only perform slightly better than the base model, but clearly worse than the full model using the regularization approach. The first two baselines incorporate constraints as additional discrete features and may suffer from feature sparsity issues, while the two-step approach may fail to balance attentions to contexts and knowledge constraints.

The last section presents the performance when using ELMo word embeddings. Our full model outperforms the base model on three out of four (except Comp) implicit discourse relations and improves both macro-average F1-score and accuracy by 2.1 and 3.2 points respectively. Furthermore, our full model outperforms the previous best system (Bai and Zhao, 2018) using ELMo by over 1.8 points of macro-average F1-score.

[16]We downloaded the pretrained ELMo embedding (5.5B version) from AllenAI's website (https://allennlp.org/elmo) and froze its parameters during model training.

[15]The performance changes on individual categories are due to minor modifications we made in replication, such as adding char-level CNN and replacing word2vec with GloVe.

	Implicit		Explicit

w/o Reg	48.55	56.45	93.77	94.65

Table 4: Impact of the Knowledge Regularization. We report the top-level performance when knowledge regularizer was removed (w/o Reg) from full model.

5 Analysis

5.1 Second-level Multi-class Classification

Table 3 reports the performance of our models for predicting second-level fine-grained discourse relations. Same as top-level, our full model consistently outperforms the base model and its variants using either word-level or DU-level features.

5.2 Impact of the Knowledge Regularization

To study the necessity of the knowledge regularization in our full model, we removed the regularization terms from the objective function by setting λ_{coref} and λ_{event} to be 0, which essentially means that we did not restrict or regulate the hidden knowledge-aware word vectors at all. From Table 4, we can see that the model without knowledge regularizer performs significantly worse than the full model and even worse than the base model, which supports our hypothesis that using external knowledge or linguistic constraints

Model	# of errors
Base Model	217
Full Model	193

Table 5: Number of errors made by both models for predicting implicit discourse relations with constraints.

blindly can hurt the performance. We conclude that the knowledge regularizer plays a key role in achieving the state-of-the-art performance and the knowledge layer must be used together with knowledge regularization in our framework.

5.3 Qualitative Analysis

To better understand the strengths and weaknesses of the regularization approach, we analyzed implicit discourse relation predictions made by our base model and full model on the dev set. In total, there are 507 implicit discourse relations that match with at least one event or coreference constraint across two DUs, while the remaining 717 instances do not involve those constraints. It turns out that both the full model and base model performed comparably on recognizing implicit discourse relations without event or coreference constraints, with 407 vs. 402 discourse relations correctly predicted by the full model and the base model respectively. Therefore, the overall performance gains achieved by the full model are mainly from better resolving implicit discourse relations with constraints, and as shown in Table 5, the full model made 24 less errors than base model for predicting such implicit discourse relations.

We further compared predictions made by the two models for implicit discourse relations with constraints. We found that 96 predictions in total have been changed by the full model, with clearly more corrections (60, i.e., the full model corrected predictions that were made wrongly by the base model.) than false reversions (36, i.e., the correct predictions made by the base model were wrongly reverted by the full model.). Here is one example from the 60 corrections made by the full model:

***DU1*:** Steve and his firm still **worth** a lot of money.

***DU2*:** A package of credit **support** was put together including the assets of Steve and his firm.

***Gold Discourse Relation*:** Implicit Contingency

***Base Model's prediction*:** Implicit Expansion

***Full Model's prediction*:** Implicit Contingency

The event causal relation between "worth" and "support" identified using external event knowledge has enabled the full model to correctly recognize this Contingency discourse relation.

We further examined the 36 wrong reversions of decisions. Around one third of these errors were due to either noise of event relation knowledge or incorrect coreference relations produced by the external CoreNLP coreference resolver we used. The remaining errors came from over-reliance of the full model on constraints in general. Considering the following example from the 36 reversions:

***DU1*:** Another analyst thought that India may have **pulled back** because of the concern over the stock market.

***DU2*:** India may have felt that if there was a severe **drop** in the stock market and it affected sugar, it could buy at lower prices.

***Gold Discourse Relation*:** Implicit Expansion

***Base Model's prediction*:** Implicit Expansion

***Full Model's prediction*:** Implicit Temporal

The full model could have relied on the event temporal relation between "pulled back" and "drop" and made the wrong discourse relation prediction.

6 Conclusion and Future Work

We have presented an effective regularization approach for incorporating external event knowledge and system predicted coreference relations into an existing paragraph-level neural network model for discourse parsing. Our approach tightly integrates knowledge and linguistic constraints with contexts for deriving knowledge-aware word vectors and meanwhile balances attentions over context and constraints through regularization, which robustly improves both implicit and explicit discourse relation classification performance on the benchmark PDTB corpus. In the future, we will identify new types of commonsense knowledge for further improving the performance of discourse parsing. For example, antonyms (e.g., *warm vs. cold*) can directly indicate a contrast relation between two situations, and this type of knowledge has potential to further improve the performance on *Comparison* discourse relations.

Abstract

We present a method for extracting causality knowledge from Wikipedia, such as *Protectionism* → *Trade war*, where the cause and effect entities correspond to Wikipedia articles. Such causality knowledge is easy to verify by reading corresponding Wikipedia articles, to translate to multiple languages through Wikidata, and to connect to knowledge bases derived from Wikipedia. Our method exploits Wikipedia article sections that describe causality and the redundancy stemming from the multilinguality of Wikipedia. Experiments showed that our method achieved precision and recall above 98% and 64%, respectively. In particular, it could extract causalities whose cause and effect were written distantly in a Wikipedia article. We have released the code and data for further research.

1 Introduction

Much of the world consists of entities that causally depend on each other. Therefore, causality knowledge, e.g., *Protectionism* → *Trade war*,[1] is useful for many tasks such as why-QA (Oh et al., 2017), reading comprehension (Berant et al., 2014), and event prediction (Radinsky et al., 2012).

Although many methods have been proposed for causality extraction from text (Ning et al., 2018; Gao et al., 2018; Kruengkrai et al., 2017; Rehbein and Ruppenhofer, 2017; Dunietz et al., 2017; Hidey and McKeown, 2016; Zhao et al., 2016; Hashimoto et al., 2014, 2012; Do et al., 2011; Riaz and Girju, 2010; Abe et al., 2008), they have rarely addressed three issues that are important for constructing a causality knowledge base (CKB). First, we should be able to *verify* extracted causalities, so that the CKB can sustain the credibility of its information.[2] Second, it would be desirable to easily *translate* the CKB to multiple languages, to avoid duplicating the construction effort for different languages. Third, it would also be desirable to automatically *connect* the CKB to other knowledge bases (KBs), to bring together KB construction efforts in various communities and thus maximize their synergistic effect.

Therefore, we propose a method for extracting causalities from Wikipedia by using cause and effect entities that correspond to Wikipedia articles; for example, for *Tobacco* → *Lung cancer*, English Wikipedia has articles titled *Tobacco* and *Lung cancer*. Such causalities satisfy the above three desiderata. First, we can easily *verify* such causalities, because Wikipedia articles tend to credibly attest them; for example, the *Tobacco* article states that inhaling its smoke can cause *Lung cancer*.[3] In contrast, knowledge from other sources such as the web text tends to be difficult to verify, owing to a deluge of false information. Second, causalities extracted from Wikipedia can be *translated* trivially to multiple languages, because Wikidata (Vrandečić and Krötzsch, 2014), a free, multilingual KB, provides links among Wikipedia articles on the same subject in different languages. Third, it is easy to *connect* causalities whose cause and effect are the topics of Wikipedia articles to other KBs derived from Wikipedia, e.g., Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2009), Knowledge Graph (Singhal, 2012), YAGO2 (Hoffart et al., 2013), and Wikidata. In addition, Wikidata also provides links to external KBs, which connect the causalities to those KBs.

Because our task is to identify causal relations between entities that are the topics of Wikipedia articles, a simple solution would be to use relation extraction (RE) methods (Vashishth et al., 2018; Zhang et al., 2018, 2017; Zhou et al., 2016;

[1] In this paper, $A \rightarrow B$ denotes that A causes B.

[2] The verifiability in this paper means that one can verify extracted causalities with credible sources of information.

[3] Most of the Wikipedia contents mentioned in this paper were downloaded on January 7th, 2019.

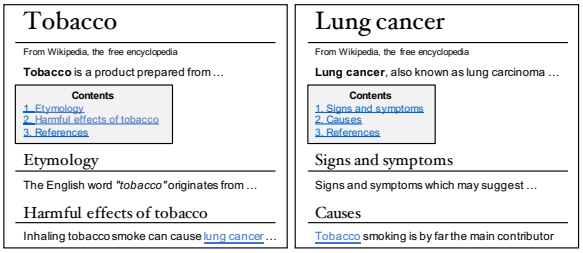

Figure 1: Sections that describe causality in Wikipedia: *Harmful effects of tobacco* and *Causes*. We can extract *Tobacco* → *Lung cancer* from these sections.

Lin et al., 2016; Wang et al., 2016; Cai et al., 2016; Shen and Huang, 2016). Most RE methods, however, identify relations between entities co-occurring in a sentence (with exceptions such as Quirk and Poon, 2017; Peng et al., 2017) and cannot deal with a large portion of our test data (67.3%, as we detail in §3.2), because the cause and effect entities in the data tend to appear distantly in a Wikipedia article. This is reasonable given that the subject of an encyclopedia article would not typically be repeated throughout the article, as the author may expect readers to know that the whole article is about the subject.

We aim to extract causalities from Wikipedia regardless of whether their cause and effect co-occur in a sentence by training a causality classifier from causality instances whose cause and effect may appear distantly. Here, we face two problems:

Lack of labeled data: For the learning of the causality classifier, there is no data marking causes and effects in Wikipedia articles, and manually creating such data would be laborious. A possible solution would be distant supervision (Mintz et al., 2009) using external KBs to mark relevant entities in articles. Because Wikipedia evolves rapidly, however, relying on such KBs would make the resulting CKB obsolete. Therefore, how can we instantly acquire such data directly from Wikipedia?

Lack of redundancy: An encyclopedia tends to avoid redundancy in text, which many knowledge extraction methods rely on to reliably estimate the probability of extracted knowledge (Christensen et al., 2011; Downey et al., 2005). Therefore, how can we reliably estimate the probability of a causality extracted from Wikipedia?

For the lack of labeled data, we can accurately extract hundreds of causalities by harnessing the property of Wikipedia that some articles have sections describing relevant causalities. For example, as shown in Fig. 1, the *Lung cancer* article has a section named *Causes* that mentions *Tobacco*, and the *Tobacco* article has a section named *Harmful effects of tobacco* that mentions *Lung cancer*. Accordingly, we can extract *Tobacco* → *Lung cancer* and then use it for the learning of the classifier. All the supervision we need is a handful of keywords for such sections, e.g., *causes* and *effects*.

For the lack of redundancy, we exploit another kind of redundancy stemming from the *multilinguality* of Wikipedia: the same subject may be described by articles in different languages; for example, *Tobacco* is described in 112 languages. We thus use a data source consisting of Wikipedia articles in nine languages: English (en), German (de), French (fr), Spanish (es), Italian (it), Portuguese (pt), Swedish (sv), Dutch (nl), and Polish (pl). This requires our method to be language independent. For these nine languages, however, the only required linguistic analysis is detection of word boundaries, i.e., white space. This simplicity has an advantage of allowing our method to parse Wikipedia quickly to keep the CKB up to date.

We evaluated our method by using the relation triples in Wikidata, which represents a causality by either a has cause or a has effect relation (§3). Our method achieved precision and recall above 98% and 64%, respectively, rivaling an *oracle* relation extractor that perfectly detected the causality between entities co-occurring in a sentence. We also confirmed that the multilingual redundancy of Wikipedia was effective: using more languages led to significantly better performances.

Our contributions are five-fold. (1) We proposed the three desiderata for CKBs: *verifiability*, *translatability*, and *connectivity*. (2) We presented the ideas of exploiting the *causality-describing sections* and *multilingual redundancy* of Wikipedia. (3) Based on these ideas, we proposed a weakly-supervised, multilingual causality extraction method. (4) We evaluated our method in relatively large-scale settings. (5) We have released the code and data from this study (§6).[4]

In this paper we focus on causality extraction. We will present how to construct the CKB from causalities extracted by our method in future.

In this study, we define a causality $A \rightarrow B$ according to Wikipedia and Wikidata. Specifically,

[4]The code and data from this study will be available at https://research-lab.yahoo.co.jp/people/chikara_hashimoto.html.

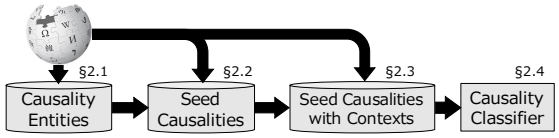

Figure 2: Overview of our method. Numbers indicate sections that describe corresponding components.

$A \rightarrow B$ if Wikipedia describes A as causing B either explicitly or implicitly, or if A (B) has the has effect (has cause) relation to B (A) in Wikidata.

2 Proposed Method

Our method learns a causality classifier that, given an entity pair (e_1, e_2), determines if $e_1 \rightarrow e_2$ holds. The entities are Wikidata identifiers (IDs) having at least one corresponding Wikipedia article. For example, Q1566 is the Wikidata ID for *Tobacco*, which is described in Wikipedia in 112 languages.

Figure 2 shows the learning process; the method identified entities that tend to participate in causality (§2.1), extracted seed causalities between such entities from causality-describing sections as illustrated in Fig. 1 (§2.2), extracted the contexts of the seed causalities from articles in multiple languages (§2.3), and finally learned the classifier from the multilingual contexts of the seeds (§2.4).

The resulting classifier thus takes (e_1, e_2) as input, examines the multilingual contexts of e_1 and e_2, and determines if $e_1 \rightarrow e_2$ holds.

The Python code that accompanies this paper is an implementation of our method (§6).

2.1 Causality Entity Extraction

Some entities, e.g., *Tobacco*, are more likely to participate in causality than others, e.g., *A (the alphabet letter)*. We call them *causality entities*. To accurately extract seed causalities in the next step, we first extracted causality entities by identifying articles that had causality-describing sections: *Tobacco* and *Lung cancer* in Fig. 1 were thus regarded as causality entities.

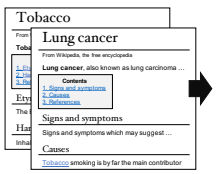
To identify causality-describing sections, we manually prepared a handful of keywords that tended to appear in the titles of such sections for the nine languages: en, de, fr, es, it, pt, sv, nl, and pl. This was the only supervision of our method. Specifically, we chose *Cause*, *Causes*, *Effect*, and *Effects* as such keywords for en and translated them to the other languages by reference to Wiktionary.[5] We have released these keywords (§6).

We then extracted causality entities from the Wikipedia dump of each language and kept only those entities that appeared in more than one language. The identify of an entity across languages could be confirmed by Wikidata IDs; e.g., *Tobacco* (en) and *Tabaco* (es) both correspond to Q1566.

2.2 Seed Causality Extraction

A seed causality is an entity pair (e_1, e_2) such that e_1 appears in a causality-describing section, whose title contains *Cause* or *Causes* (in the case of en), in the article corresponding to e_2; and such that e_2 appears in a causality-describing section, whose title contains *Effect* or *Effects*, in the article corresponding to e_1. For instance, *Tobacco* $\rightarrow$ *Lung cancer* in Fig. 1 is a seed causality, as it satisfies the above condition.

We extracted seed causalities in this way, kept only those that appeared in more than one language, and consequently acquired 879 seed causalities from the nine languages. We have also released the seed causalities (§6).



2.3 Seed Causality Context Extraction

As illustrated in Fig. 3, for each entity in a seed causality, we extracted its contexts from articles in multiple languages as features for the classifier.

The context window was up to 100 words to the left and right of each target entity. When a section title appeared in a context window, we shrank the window to the section title position so that the window would not cross the section boundary.

We restricted the articles from which contexts were extracted as follows. For $e_1 \rightarrow e_2$, the context of e_1 (e_2) was extracted from the article that corresponded to e_2 (e_1). For example, for *Tobacco* $\rightarrow$ *Lung cancer*, the context of *Tobacco* was extracted only from the *Lung cancer* article, and that of *Lung cancer* was extracted only from the *Tobacco* article. This reduced the processing time and helped extract only highly relevant contexts for a target causality. We extracted the contexts directly from the Wikipedia source texts with all markups kept intact, because those markups may have helped the classifier, and parsing the source texts would have slowed the process. In addition, we replaced e_1 and e_2 in the extracted contexts with the special symbols `__CAUSE__` and `__EFFECT__`.

[5] https://en.wiktionary.org/

English Wikipedia
there is sufficient evidence that involuntary smoking (exposure to secondhand or 'environmental' __CAUSE__ smoke) causes __EFFECT__ in humans.

French Wikipedia
la cause la plus fréquente de __EFFECT__ est l'exposition chronique à la fumée de [[#tabagisme|__CAUSE__]]

Spanish Wikipedia
algunos tipos de cáncer se encuentran directamente relacionados con el __CAUSE__ , como es el caso del [[__EFFECT__]] y otros cánceres del tracto respiratorio

Figure 3: Seed causality context extraction from Wikipedia articles of multiple languages.

We also removed line-break characters to extract contexts from across multiple lines.

For each seed causality, we concatenated all the contexts from multiple languages. For context extraction, we used only four languages —en, de, fr, and es— because they had the broadest coverage.

We also removed infoboxes from articles before context extraction, because we used Wikidata's triples for evaluation, and some of those have been transcribed into infoboxes.[6] This was for fairness rather than methodological considerations.

2.4 Learning Classifier

For learning of the causality classifier, we used the seed causalities as positive instances. In contrast, negative (non-causality) instances were entity pairs such that the article corresponding to one entity had a link to the article corresponding to the other entity. For example, the article on *Barack Obama* has a link to the article on *Hillary Clinton*, and hence, *Barack Obama* $\rightarrow$ *Hillary Clinton* could be used as a negative instance. In this way, we could obtain sensible negative instances, meaning that they were not totally random pairs but were semantically related to each other in some way. We obtained the same number (879) of negative instances as positive ones and similarly extracted their multilingual contexts; thus, we trained the classifier with 1,758 instances.

We used fastText (Joulin et al., 2016), a linear text classifier that averages word embeddings and makes a prediction based on the averaged embeddings, as the causality classifier because of its speed and accuracy. Among its hyperparameters, we tuned only the number of epochs and the learning rate, as detailed in §3.2. We did not use pretrained word embeddings for the classifier to minimize its dependence on external resources.

Although there would be more sophisticated approaches to modeling the multilingual contexts extracted from Wikipedia, we intentionally adopted the very simple modeling in this paper in order to show that even such a simple method could deliver good performances by using the multilingual contexts of Wikipedia. We will develop more sophisticated models in future.

[6] https://www.wikidata.org/wiki/Wikidata:WikiProject_Infoboxes

3 Experiments

Using relation triples in Wikidata (§3.1), we evaluated our method by comparing it with various baselines (§3.2). We also measured the effectiveness of using multiple languages (§3.3).

We can summarize the results as follows. Our method (1) extracted causality with precision and recall above 98% and 64%, respectively; it (2) rivaled the performance of an oracle relation extractor that worked sentence-wise; and it (3) effectively used multiple languages.

3.1 Test Data

Our experiments were based on labeled data derived from Wikidata, which has various relation triples (e_1, rel, e_2), where e_1 and e_2 are entities ("item identifiers" in Wikidata terms, such as Q1566) between which the relation rel (a "property" in Wikidata terms, such as has cause) holds.

In short, we used triples whose relations were either has cause or has effect as positive (causality) instances and those with other relations as negative (non-causality) instances. Because we aimed to extract causalities that were easy to verify by reading individual Wikipedia articles, we restricted the triples to those whose component entities co-occurred in an article. Specifically, we used only triples such that the article corresponding to one entity had a link to the article corresponding to the other entity in at least one language. Consequently, we obtained 1,524 positive instances and the same number of negative instances, giving 3,048 instances in total.

The data was in no way easy to classify, because all the negative instances were not random pairs but had semantic relations that are as natural and common as causality. For example, in Wikidata, *World War I* (Q361) and the *Paris Peace Conference* (Q199820) show causality, as the former has

the has effect relation with the latter. In contrast, *World War I* and the *German invasion of Belgium* (Q5551414) do not show causality, because they have a significant event relation between them.

The data accompany the paper (§6).

3.2 Performance of Proposed Method

Experimental Settings for Proposed Method

In this section, we denote our proposed method as PROP. In the experiments, it extracted multilingual contexts for each relation triple in the data, as described in §2.3. The data were used only for testing. Training was conducted using the automatically acquired seed causalities (§2).

Hyperparameter tuning for PROP was based on five-fold cross validation using the seed causalities so that we could maximize the F1 score on them. We only tuned the number of epochs and the learning rate of fastText; the former was chosen from 30, 50, 70, and 100, while the latter was chosen from 0.3, 0.5, 0.7, and 1.0. As a result, they were set to 100 and 1.0, respectively. The other fastText parameters were set to default values.

We used the default fastText threshold for classification. We conducted 10 runs and averaged the performance scores (accuracy, precision, recall, and F1) for evaluation.

Compared Methods

We evaluated the performance of PROP by comparing it with the following baseline methods described below: SECTION, INFOBOX, RELATED, and ORACLE RE.

SECTION This was simply the method of seed causality extraction described in §2.2, which extracted 879 causalities from Wikipedia. This was intended to evaluate two questions. The first was how well our idea of exploiting causality-describing sections in Wikipedia worked on its own. The second question was how much PROP improved the results, as it used the classifier trained on the output of the SECTION method.

INFOBOX This method extracted causality from the infoboxes in Wikipedia articles in the nine languages. Some infoboxes contain information on causality; for example, the article on *Candidiasis* has an infobox with the field *Causes*, whose value is *Candida*, which indicates *Candida* → *Candidiasis*. For the INFOBOX method to identify such causality-describing fields in infoboxes, we used the same set of keywords that PROP used to identify causality-describing sections. As discussed in §2.3, some Wikidata triples have been transcribed into infoboxes, which should give the INFOBOX method an advantage over PROP, as PROP was forbidden to use infoboxes.

RELATED This method regarded an entity pair whose entities were semantically related to each other as a causality, because such relatedness has been shown to imply causality (Do et al., 2011; Riaz and Girju, 2010). Specifically, this method used a semantic relatedness defined as $1-sr(a,b)$, where $sr(a,b)$ is a Wikipedia-link-based distance measure that was proposed by Milne and Witten (2008) and has been widely used (Lee et al., 2015). The measure is defined

$$sr(a,b) = \frac{log(max(|A|,|B|)) - log(|A \cap B|)}{log(|W|) - log(min(|A|,|B|))},$$

where a and b are the two articles (entities) of interest, A and B are the sets of all articles that link to a and b, respectively, and W is the entire set of Wikipedia articles. To classify entity pairs, we set a threshold for the relatedness score so that we could maximize F1 on the training data for PROP (§2.4). The threshold value ranged from 0.00 to 1.00 at intervals of 0.01. We used the link structure of en Wikipedia because it is the largest one.

ORACLE RE This method used an *oracle* relation extractor that, given two entities that co-occur in a sentence, never fails to determine whether they have a causal relation. For other pairs, whose component entities did not co-occur in a sentence, this method uniformly guessed that they had no causal relation. We used en Wikipedia for ORACLE RE because it has the broadest coverage. We segmented articles into sentences with spaCy,[7] which accurately recognizes sentence boundaries through dependency parsing. This method would show the upper-bound performance for our task of typical RE methods that work sentence-wise. This was an ambitious baseline given the performances of state-of-the-art RE methods: Vashishth et al. (2018) achieved a top-100 precision of 84% on the New York Time corpus (Riedel et al., 2010); Wang et al. (2016) achieved an F1 score of 88% on SemEval-2010 Task 8 (Hendrickx et al., 2010).

	Acc	Prec	Rec	F1
SECTION	50.56	100.00	1.12	2.21
INFOBOX	53.71	100.00	7.41	13.81
RELATED	68.86	66.23	76.97	71.20
ORACLE RE	75.89	100.00	51.77	68.22
PROP	81.45	98.28	64.02	**77.53**

Table 1: Performance results of the compared methods.

Results

Table 1 lists the accuracy (Acc), precision (Prec), recall (Rec), and F1 of the compared methods.

The SECTION method achieved 100% precision, which indicates that our technique of exploiting causality-describing sections in Wikipedia could accurately extract causalities. As the method's recall indicates, however, it covered only a small portion of our target causalities.

The INFOBOX method also achieved 100% precision, though its coverage was also quite limited.

The RELATED method exhibited the highest recall, but the precision was unacceptably low for the subsequent manual labor that would be required to construct the CKB.

The ORACLE RE method achieved 100% precision by design. Its recall was rather low because 67.3% of the entity pairs in the data (§3.1) consisted of entities that did NOT co-occur in a sentence. This means that most RE methods that work sentence-wise will miss a large portion of causalities, regardless of their accuracy.

Finally, PROP achieved the best F1 score, though its recall still had room for improvement. The fact that PROP outperformed the baselines, especially ORACLE RE, clearly shows the effectiveness of our method.

3.3 Language Ablation Test

We also examined the effect of using more languages for extracting contexts by comparing the performance of the following variations of PROP: PROP, PROP$_{en.de.fr}$, PROP$_{en.de.es}$, PROP$_{en.fr.es}$, PROP$_{en}$, PROP$_{en.de}$, PROP$_{en.fr}$, and PROP$_{en.es}$. Unlike PROP, which used en, de, fr, and es for extracting multilingual contexts, the others used only the languages indicated by the subscript language symbols. For example, PROP$_{en.de}$ used only en and de Wikipedia articles.

For each variation of our method, we conducted 10 runs and averaged the resulting performance scores for evaluation.

[7] https://spacy.io/

	Acc	Prec	Rec	F1
PROP$_{en.de.fr.es}$	81.45	98.28	64.02	**77.53**
PROP$_{en.de.fr}$	80.54	98.16	62.24	76.18*
PROP$_{en.de.es}$	80.82	98.65	62.49	76.51*
PROP$_{en.fr.es}$	79.20	98.14	59.52	74.10*
PROP$_{en.de}$	79.92	99.21	60.32	75.26$^{\diamond}$
PROP$_{en.fr}$	78.39	98.32	57.76	72.77$^{\diamond}$
PROP$_{en.es}$	77.91	98.91	56.45	71.88$^{\diamond}$
PROP$_{en}$	76.43	98.91	53.45	69.40

Table 2: Results of language ablation tests. PROP is denoted as PROP$_{en.de.fr.es}$ for clarity. $*$ and $\diamond$ indicate statistically significant differences from the performances of PROP$_{en.de.fr.es}$ and PROP$_{en}$, respectively (paired t-test: $p < 0.01$).

Table 2 summarizes the results of the ablation tests. The upper half of the table indicates that removing one language from PROP tended to degrade its performance, while the lower half indicates that adding one language to PROP$_{en}$ tended to improve its performance. From these results, we conclude that using multilingual contexts is effective for causality extraction from Wikipedia.

3.4 Analysis

We first examine cases in which PROP succeeded and then analyze its error cases.

Causalities whose cause and effect entities co-occur in a sentence tend to have phrases indicating the causal relation between them, which helps identify the relation. For example, for *Adipsia* $\rightarrow$ *Hypernatremia*, there is the following sentence:

(1) *Adipsia* may be seen in conditions such as diabetes insipidus and may **result in** *hypernatremia*.

For causalities whose cause and effect do not co-occur in a sentence, it is likely that their causal relation are only indicated by multi-line texts or the structure of Wikipedia article. For example, for *Hormone therapy* $\rightarrow$ *Cancer pain*, there is the following list item in the *Cause* section of the article of *Cancer pain*:

(2) *hormone therapy*, which sometimes **causes** pain flares;

Although *Cancer pain* is not written explicitly in the item, we can guess that the *pain flare* refers to *Cancer pain*, because this list item is part of the contents of the *Cause* section of the article of *Cancer pain*. PROP can identify such a causality,

because pieces of Wikipedia source text that represent this kind of structure can be included in the window of the multilingual contexts and because all contexts are extracted from the articles that correspond to either the cause or the effect.

Regarding PROP's error analysis, we focus here on its false-negative errors, as it achieved high precision while its recall had room for improvement. Such errors were mostly due to the lack of evidence of causality; in some cases, even though the cause and effect entities both appear in an article, it does not indicate their causal relation. For example, for *Psoriasis* → *Woronoff's ring*, the cause is only mentioned as a list item in the *See also* section of the effect entity's article in en Wikipedia.

Other false-negatives included entity pairs for which not only causality but other relations hold. For example, for *International University Sports Federation* → *Universiade*, both the has effect and the organizer relations hold. These tend to be cases in which the Wikipedia article describes the cause as *organizing* (instead of *causing*) the effect.

4 Discussion

4.1 Three Desiderata for CKB

In §1 we discussed the desiderata for the CKB: verifiability, translatability, and connectivity. In this section we consider how well the causalities extracted by PROP satisfied the desiderata.

Verifiability

We examined 100 samples from the causalities in the data (§3.1) that PROP correctly classified as causalities (i.e., true positives) to measure their verifiability. In other words, we examined how many of them consisted of cause and effect entities between which we could easily identify causality by reading their individual Wikipedia articles. Causalities that were not described in en Wikipedia were regarded as unverifiable, because we assumed that our target users could understand only English. Of the 100 samples, 19 were not written in en Wikipedia.

As a result, 62.0% of the samples were verifiable. If we ignore those 19 samples that were not written in en Wikipedia, 76.5% of the samples were verifiable. For example, for *Onchocerca volvulus* → *Onchocerciasis*, the article on *Onchocerca volvulus* has the following sentence:

(3) *Onchocerca volvulus* is a nematode that **causes** *onchocerciasis*.

We thus conclude that causalities extracted by PROP tend to be verifiable.

Translatability

We next examined the number of languages to which each true-positive causality was translated, by using Wikidata's links among Wikipedia articles on the same subject in different languages. We targeted each of the nine languages. We regarded each causality as translated to a language if its cause and effect were both translated.

As a result, 74.9% of the causalities were translated to more than one language, which indicates that the causalities extracted by PROP tend to exhibit a high degree of translatability. Furthermore, 16.5% were translated to all nine languages, including, e.g., *Chemotherapy* → *Vomiting* (*Q974135* → *Q127076*) and *Treaty of Versailles* → *World War II* (*Q8736* → *Q362*).

Connectivity

We also examined how many of the true positives were connected to external KBs. We first listed all external IDs,[8] which Wikidata uses to identify external KBs such as Freebase, IMDb, and ISBN-13, with a lookup function in Wikidata,[9] resulting in 3,695 external IDs. We then made a table to map each Wikidata ID to the external IDs to which it is connected. With the table we counted the number of true-positive causalities whose cause and effect entities shared at least one external ID.

Consequently, 72.3% of the true-positives were connected to external KBs. For example, *Diabetes mellitus* → *Cataract* was connected to 19 KBs such as MeSH,[10] Freebase, and BabelNet (Navigli and Ponzetto, 2012). We thus conclude that causalities extracted by PROP indicate a high degree of connectivity.

4.2 Independence of Languages

We designed PROP to be language independent so that we could exploit multilingual redundancy. Unfortunately, unintended language dependence might arise as we use more languages. We are currently aware that we will need tokenizers if we use languages for which word boundaries are not as explicit as in the nine languages here, e.g., Chinese and Japanese. It will thus be a future challenge to

[8] https://www.wikidata.org/wiki/Wikidata:Identifiers

[9] https://www.wikidata.org/wiki/Special:ListProperties

[10] https://www.ncbi.nlm.nih.gov/mesh/

use many more languages while keeping PROP as language independent as possible.

4.3 Independence of External KBs

We also designed PROP not to rely on external KBs so that we could easily keep the CKB up to date with Wikipedia. If we relaxed this design policy, we would be able to use the triples in Wikidata as additional training data for our classifier. We thus plan to explore this direction of research.

Another external resource that is useful for PROP would be pre-trained word vectors (Bojanowski et al., 2017). We evaluated PROP$_{en+}$, which is the same as PROP$_{en}$ except that it used pre-trained word vectors.[11] The pre-trained word vectors slightly improved the performance; PROP$_{en+}$ achieved a F1 of 69.51, while PROP$_{en}$'s F1 was 69.40.

5 Related Work

5.1 Causality Extraction

Causality extraction methods can be classified with regard to what constitutes cause and effect: noun phrases, verb phrases, or clauses. The noun-phrase type, e.g., *global warming* → *malaria epidemic*, has mostly been addressed by RE methods, as we discuss in §5.2. The verb-phrase type, e.g., *get fired* → *live on unemployment insurance*, has been extracted by various methods (Ning et al., 2018; Gao et al., 2018; Rehbein and Ruppenhofer, 2017; Kruengkrai et al., 2017; Hashimoto et al., 2015, 2014, 2012; Do et al., 2011; Riaz and Girju, 2010; Abe et al., 2008). The clause type, e.g., *I hid the car key* → *She's mad*, has also been studied (Dunietz et al., 2017). Other types include causal embeddings (Sharp et al., 2016), which can be used for causal question answering (Oh et al., 2017). We focused here on the noun-phrase type because noun phrases can be components of verb phrases and clauses, and hence, our work may also contribute to the extraction of other types.

Another standpoint of classifying causality extraction is the information source, e.g., newspapers (Khoo et al., 1998), the web (Kruengkrai et al., 2017), parallel corpora (Hidey and McKeown, 2016),[12] images (Gao et al., 2018), and videos (Fire and Zhu, 2016). We used Wikipedia articles in multiple languages because they tend to be more credible than other sources, and because they allowed us to exploit multilingual redundancy.

Wikipedia articles in multiple languages also provide causalities that tend to satisfy the three desiderata discussed in §1, which is the novel perspective that we proposed and that many previous studies lacked. In addition, we proposed a novel method that is better suited for extracting such causalities than previous methods were.

5.2 Relation Extraction

In SemEval-2007 Task4 (Girju et al., 2007) and SemEval-2010 Task 8 (Hendrickx et al., 2010), the target relations included "Cause-Effect"; our study is also relevant to methods for those tasks (Lee et al., 2019; Wang et al., 2016; Shen and Huang, 2016; Cai et al., 2016; Xu et al., 2016). Other methods based on RE also addressed causality (Kim and Myaeng, 2016; De Saeger et al., 2011, 2009; Schoenmackers et al., 2010).

Although our method can be regarded as a relation extractor, it is different from the above methods because it is particularly tailored to causality extraction from Wikipedia. For this task, it is important to extract relation instances whose component entities do not co-occur in a sentence.

More recent studies have addressed *inter*-sentential RE for specialized domains (Noriega-Atala et al., 2018; Quirk and Poon, 2017; Peng et al., 2017), and Mandya et al. (2018) constructed a large-scale dataset for this task. Hence, we plan to incorporate these approaches into our method.

5.3 Knowledge Extraction from Wikipedia

Knowledge extraction from Wikipedia in general is also relevant to our study. Although there have been studies on extracting class concepts (Pasca, 2018), trivia (Tsurel et al., 2017), taxonomies (Flati et al., 2014), infobox contents (Wang et al., 2013), and various semantic relations (Wu and Weld, 2010), among other things, causality extraction from Wikipedia has rarely been addressed as far as we are aware. Hidey and McKeown (2016) addressed the extraction of linguistic markers indicating causality from Wikipedia, but those markers were not causalities *per se*.

5.4 Temporal Relation Extraction

Researchers have noticed that causality extraction and temporal relation extraction (Mani et al.,

[11] We used two million word vectors trained with subword information on Common Crawl available at https://fasttext.cc/docs/en/english-vectors.html.

[12] Precisely, the task of Hidey and McKeown (2016) is identifying linguistic cues that indicate causality.

2006) share some properties and can complement each other (Ning et al., 2018; Mirza and Tonelli, 2016; Bethard and Martin, 2008). In the future, we will also explore the possibility of exploiting temporal relation extraction methods for our task.

6 Accompanying Code and Data

We hereby release the Python code to implement our method, including modules for generating relevant data, with step-by-step instructions. We also release the following data sets: (a) the keywords for identifying causality-describing sections (§2.1), (b) the seed causalities (§2.2), and (c) the test data (§3.1). The code and data will be available at `https://research-lab.yahoo.co.jp/people/chikara_hashimoto.html`.

Note that 98.1% of the seed causalities are not included in Wikidata as causality, and they can increase Wikidata causalities by about 19.8%.

7 Conclusion

We have proposed a weakly supervised method for extracting causality from Wikipedia articles in multiple languages. The causalities extracted by our method tend to be easy to *verify*, *translate* to multiple languages, and *connect* to external KBs. Our key idea is to exploit the *causality-describing sections* and *multilingual redundancy* of Wikipedia. Our method achieved precision and recall above 98% and 64%, respectively, and it could even extract causalities whose cause and effect entities did not co-occur in a sentence.

Abstract

Review summarization aims to generate a condensed summary for a review or multiple reviews. Existing review summarization systems mainly generate summary only based on review content and neglect the authors' attributes (e.g., gender, age, and occupation). In fact, when summarizing a review, users with different attributes usually pay attention to specific aspects and have their own word-using habits or writing styles. Therefore, we propose an Attribute-aware Sequence Network (ASN) to take the aforementioned users' characteristics into account, which includes three modules: an attribute encoder encodes the attribute preferences over the words; an attribute-aware review encoder adopts an attribute-based selective mechanism to select the important information of a review; and an attribute-aware summary decoder incorporates attribute embedding and attribute-specific word-using habits into word prediction. To validate our model, we collect a new dataset *TripAtt*, comprising 495,440 attribute-review-summary triplets with three kinds of attribute information: gender, age, and travel status. Extensive experiments show that ASN achieves state-of-the-art performance on review summarization in both auto-metric ROUGE and human evaluation.

1 Introduction

Review summarization aims to generate a condensed summary for a review or multiple reviews[1]. Dominating studies can be divided into two groups: extractive and abstractive approaches. Extractive approaches (Hu and Liu, 2004; Ganesan, 2010) extract sentences or phrases from a review, while abstractive methods (Gerani et al., 2014; Wang and Ling, 2016; Yang et al., 2018a; Li et al., 2019; Gao et al., 2019) summarize a review by employing graph-based or sequence-to-sequence (S2S) models which can generate new phrases and sentences that do not appear in the review.

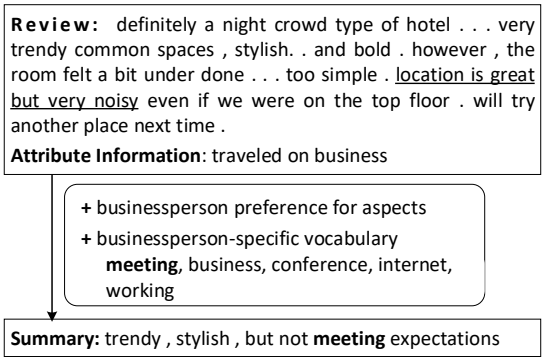

Figure 1: A review-summary pair posted by a businessperson in our dataset shows the effect of attribute information on summarizing review. Underlined words in the review indicate the important sentences that the businessperson care about when summarizing the review. Bold **word** in businessperson-specific vocabulary shows the businessperson's word-using habits may help to generate the summary.

Despite the remarkable progress of previous studies, they typically only focus on review content and neglect the attribute information of users who post these reviews (e.g., gender, age, and occupation). Actually, such information is vital for generating summaries, which contains the following characteristics. (1) People with different attributes may care about different aspects[2]. For example, when choosing hotels, business people may care about ***location*** and ***room*** more than ***price***, while solo travelers may prefer ***price*** more. Figure 1 presents a review posted by a businessper-

[1] Here, we focus on single-review summarization, and we leave adapting our model to multi-review summarization scenario to future work.

[2] Aspects refer to properties (attributes) of products or services, such as ***location*** and ***room*** for the hotel domain.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3000–3010, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

son. Although the hotel is trendy, stylish, and in a good location, it is noisy. The businessperson, therefore, summarizes that the hotel is not suitable for meeting. (2) People with different attributes have different word-using habits or writing styles to summarize a review. According to our statistics (Section 2.2), business people often summarize a review with words like "meeting", "business" and "conference", while solo travelers often utilize "budget", "inexpensive" to summarize their reviews. These attribute-specific words may help generate summaries. Figure 1 shows an example: without considering the attribute information "businessperson", it is hard to generate the word "meeting" when summarizing the review due to its missing. Intuitively, "meeting" belongs to businessperson-specific vocabulary, and such an attribute-specific vocabulary can be incorporated to further improve the summarization performance.

Inspired by the above observations, we propose a model called Attribute-aware Sequence Network (ASN) to consider attribute information into review summarization. Specifically, ASN is based on sequence to sequence models (S2S), which are popular methods in text summarization (Rush et al., 2015; See et al., 2017; Zhu et al., 2018; Li et al., 2018a) and review summarization (Wang and Ling, 2016; Ma et al., 2018). ASN updates over standard S2S are three-fold. First, except for standard encoder and decoder in S2S, we design an attribute encoder, which encodes attribute preference for using words into attribute embedding. Second, an attribute-aware review encoder is proposed to generate attribute-aware review representation. It utilizes a bidirectional-LSTM to encode a review, and then imports an attribute-based selective mechanism to select important information of it to obtain a better review representation. Third, we propose an attribute-aware summary decoder to consider different writing styles of users with different attributes. It incorporates attribute embedding and attribute-specific vocabulary memory into word prediction module to generate summaries.

To validate our approach, we collect a review summarization dataset with user attribute information named *TripAtt* from TripAdvisor website, which contains 495,440 attribute-review-summary triplets with three kinds of attribute information: gender, age and travel status. Extensive experiments show that ASN achieves state-of-the-art performance on review summarization in both autometric ROUGE and human evaluation. Our contributions are as follows:

- To the best of our knowledge, we first propose an attribute-aware S2S-based model named Attribute-aware Sequence Network (ASN) to incorporate attribute information into review summarization.
- Our model adopts an attribute-based selective mechanism to consider different user preferences for review content and applies attribute-specific vocabulary to take the different writing styles of users with different attributes into consideration when generating a summary.
- For the evaluation of review summarization with attribute information, we collect a new dataset named *TripAtt*, which is available at https://github.com/Junjieli0704/ASN.

2 Dataset

Since there is no available review summarization dataset with user attribute information, we build a new one named *TripAtt* from TripAdvisor, an online hotel review site. TripAdvisor contains lots of user-generated reviews along with their authors and titles. The title of a review often summarizes the main idea of it; therefore, we take the title as the reference summary of the review. For attribute information, we can first get users' demographic information such as age and gender from the website. Second, users also explicitly label their travel status when booking hotels, such as traveled solo or traveled on business. Therefore, We take gender, age and travel status as our attribute information, and collect near 3 million attribute-review-summary triplets.

However, users may write titles arbitrarily, and it results in many meaningless titles, such as "i will be back again", and "twice in one trip". To remove these noisy samples, we apply filters proposed by Li et al. (2019). Then, we also remove samples that the value of any attributes (gender, age, or travel status) is NULL. Finally, we construct *TripAtt* with 495,440 attribute-review-summary triplets. We randomly split the dataset into 2,000 reviews for test, 2,000 reviews for develop and the rest for training. Table 1 shows statistics of *TripAtt*.

TripAtt	Train	Dev	Test
# Review	491,440	2,000	2,000
# Sens of Review	9.66	9.59	9.54
# Words of Review	173.90	172.04	171.86
# Sens of Summary	1.0	1.0	1.0
# Words of Summary	7.18	7.05	7.20

Table 1: Data statistics of *TripAtt* dataset.

2.1 Value distribution of different attributes

Figure 2 presents the value distribution of gender, age, and travel status in *TripAtt*. Males are more likely to travel than females, middle-aged (35-64 years old) users account for near 74%, and around 40% users traveled with couples.

2.2 Attribute-specific Vocabulary

Frequent words of a user can reflect the user well. Therefore, we want to mine attribute-specific words from *TripAtt* to model attributes. We first merge all summaries posted by users with the same group (such as male or 35-49 years old users) into a document. Then we compute tf-idf scores[3] for each word appears in the document, and we finally select top-N words for different groups. The last column in Figure 2 shows top-5 words in different attribute-specific vocabularies. We find that these words can actually reflect different groups well. For example, female users often utilize "lovely", "beautiful", "cute" to summarize review while these words rarely appear in summaries of male users. Users traveled with family often care about whether the hotel is suitable for their kids since they usually summarize reviews using "kids", "disney", and "parks", while business people frequently consider whether the hotel is suitable for meeting.

3 Attribute-aware Sequence Network

3.1 Problem Formulation

Suppose we have a corpus D with $|D|$ attribute-review-summary triplets, and each triplet contains a review $x = (x_1, x_2, ..., x_{|x|})$, a summary $y = (y_1, y_2, ..., y_{|y|})$ and an attribute vector $a = (a_1, a_2, ..., a_{|a|})$ which records $|a|$ kinds of attribute information of x's author. Since we have three kinds of attribute information (gender, age, and travel status), $|a|$ equals to 3. Classical review summarization is to generate y from x, while our goal needs to consider a's characteristics on summarizing reviews when generating y.

[3]Using *tf-idf* scores means we do not include too general terms that all users commonly use, because they do not help model the specific group.

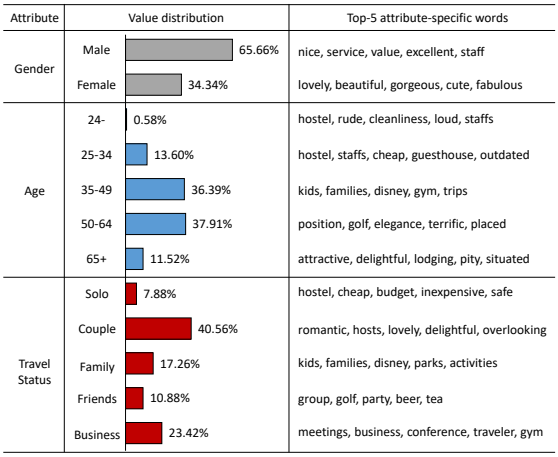

Figure 2: Value distribution and top-5 words in attribute-specific vocabulary of gender, age, and travel status in *TripAtt* dataset.

3.2 Model Framework

As shown in Figure 3, our model consists of three modules: attribute encoder, attribute-aware review encoder and attribute-aware summary decoder. Attribute encoder is based on attribute-specific words obtained from Section 2.2, which not only stores these words into attribute-specific vocabulary memory, but also utilizes multi-layer perceptron to merge them into an attribute embedding. Then we introduce four strategies to consider attribute embedding and attribute-specific vocabulary memory. Equipped with attribute embedding, our attribute-aware review encoder can select vital information from review representation. Importing attribute embedding and attribute-specific vocabulary memory into word prediction process of our attribute-aware summary decoder, our model can generate summary well.

3.3 Attribute Encoder

This module will produce attribute embedding and attribute-specific vocabulary memory. Suppose we select top-K attribute-specific words for each attribute in a, and then we concatenate these words to get attribute-specific vocabulary $A = (A_1, ..., A_K, ..., A_{2K}, ..., A_{|a|K})$, where word indexes between $(i-1) \times K + 1$ and $i \times K$ in A belong to attribute a_i. After that, we use an embedding matrix $\mathbf{E}_v$ to embed each word $\{A_i\}_{i=1}^{|a|K}$

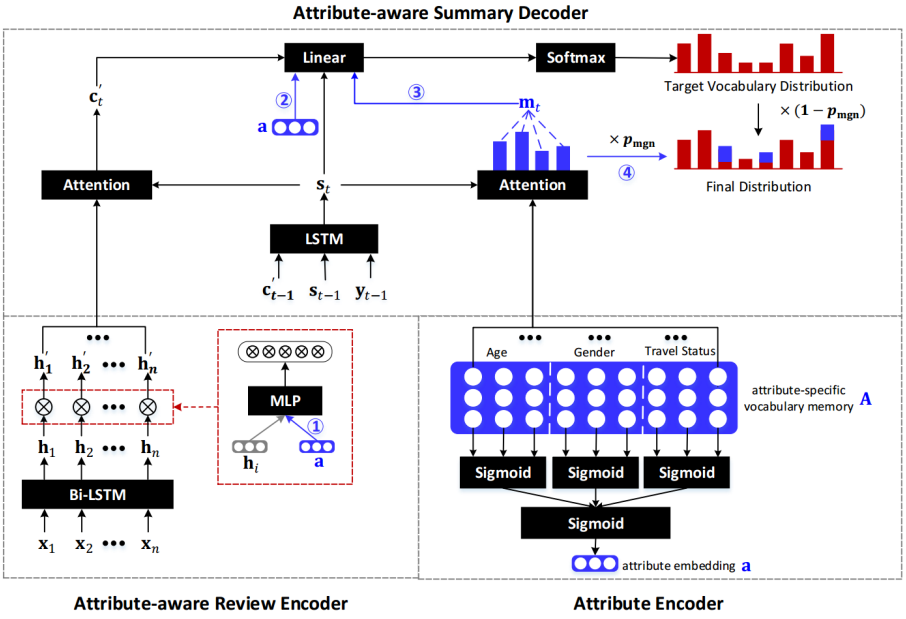

Figure 3: The architecture of Attribute-aware Sequence Network (ASN). ASN encodes two kinds of attribute information, attribute embedding (**a**) and attribute-specific vocabulary memory (**A**), into its two basic modules (*Attribute-aware Review Encoder* and *Attribute-aware Summary Decoder*). ①, and ② show strategies based on attribute embedding, and represent Attribute Selection strategy, and Attribute Prediction strategy, respectively. ③ and ④ indicate strategies based on attribute-specific vocabulary memory, and represent Attribute Memory Prediction strategy and Attribute Memory Generation strategy, respectively.

into vector $\{\mathbf{A}_i\}_{i=1}^{|a|K}$, and we get matrix $\mathbf{A}$, which is also called attribute-specific vocabulary memory. Then, we use a nonlinear layer to merge A's words belonging to attribute a_i into embedding $\mathbf{a}_i$ (See Equation (1)), which can only represent attribute a_i. After that, we merge these $|a|$ attribute embeddings $\mathbf{a}_1, \mathbf{a}_1, ..., \mathbf{a}_{|a|}$ into a nonlinear layer to get attribute embedding $\mathbf{a}$ (See Equation (2)), which is used to represent attribute vector a.

$$\mathbf{a}_i = \sigma(\mathbf{W}_a \mathbf{A}_{(i-1)\times K+1:i\times K} + \mathbf{b}_a) \quad (1)$$

$$\mathbf{a} = \sigma(\sum_{i=1}^{i=|a|} \mathbf{w}_a \mathbf{a}_i + b_a) \quad (2)$$

where $\mathbf{W}_a$, $\mathbf{w}_a$, $\mathbf{b}_a$, and b_a are learnable parameters, and σ denotes sigmoid function.

3.4 Attribute-aware Review Encoder

Given review x, it first embeds each word x_i into vector $\mathbf{x}_i$ using embedding matrix $\mathbf{E}_v$, which is the same embedding matrix in attribute encoder module. Then, these word vectors are fed into a single-layer bidirectional LSTM one by one, producing a sequence of encoder hidden states $\mathbf{h}_i$.

Classical review encoder utilizes $\mathbf{h}_i$ to represent review x and ends here. However, we find that users with different backgrounds pay attention to different content of a review. Inspired by (Zhou et al., 2017), we propose an attribute-based selective mechanism to select the important information from review for users with different attributes. The selective mechanism can construct a tailored representation of review x by considering a. In detail, our attribute-based selective network takes attribute vector $\mathbf{a}$ and the encoder hidden state $\mathbf{h}_i$ as input, and outputs a gate vector $\mathbf{gate}_i$ to select $\mathbf{h}_i$.

$$\mathbf{gate}_i = \sigma(\mathbf{W}_k[\mathbf{h}_i; \mathbf{a}] + \mathbf{b}_k) \quad (3)$$

$$\mathbf{h}'_i = \mathbf{h}_i \odot \mathbf{gate}_i \quad (4)$$

where $\mathbf{W}_k$, $\mathbf{b}_k$ are learnable parameters, $[;]$ is the concatenating operator, σ denotes sigmoid function, and $\odot$ is element-wise multiplication.

From Equation (4), we find $\mathbf{gate}_i$ is a vector whose value is between 0 and 1. A high value means most of the information in $\mathbf{h}_i$ passed from the filter, which results in the word $\mathbf{x}_i$ is important. This is the first strategy to consider attributes called ***Attribute Selection strategy***.

3.5 Attribute-aware Summary Decoder

At each decoding time step t, the decoder (a single-layer unidirectional LSTM) receives previous word embedding to obtain the new hidden state $\mathbf{s}_t$. Then it computes context vector $\mathbf{c}_t$

for time step t through the attention mechanism: where MLP stands for multi-layer perceptrons and $\alpha_{t,i}$ matches the importance score between current decoder state $\mathbf{s}_t$ and the encoder hidden state $\mathbf{h}_i^{'}$.

The classical summary decoder combines the context vector $\mathbf{c}_t$ and the decoder state $\mathbf{s}_t$, and then feeds the merged vector into a linear layer to produce the vocabulary distribution.

However, when generating a summary, users with different attributes may have their own vocabulary. Thus it is natural to take attribute-specific vocabulary memory $\mathbf{A}$ into consideration when predicting output vocabulary distribution and different words in $\mathbf{A}$ may have different effects. Thus, we utilize an attention mechanism to extract important words in $\mathbf{A}$ when obtaining vocabulary state $\mathbf{m}_t$.

$$\beta_{t,k} = \frac{\exp(\text{MLP}(\mathbf{A}_k, \mathbf{s}_t))}{\sum_k \exp(\text{MLP}(\mathbf{A}_k, \mathbf{s}_t))} \quad (5)$$

$$\mathbf{m}_t = \sum_k \beta_{t,k} \mathbf{A}_k \quad (6)$$

where $\beta_{t,k}$ measures the importance score between current decoder state $\mathbf{s}_t$ and the k-th word in attribute-aware vocabulary memory A_k.

Then we combine context vector $\mathbf{c}_t$, the decoder state $\mathbf{s}_t$, and $\mathbf{m}_t$ into the readout state $\mathbf{r}_t$. Besides, we can also enhance the readout state $\mathbf{r}_t$ by combining attribute vector $\mathbf{a}$. After that, we feed the readout state into a linear layer to produce the vocabulary distribution P_{voc}.

$$\mathbf{r}_t = \mathbf{W}_r[\mathbf{c}_t; \mathbf{s}_t; \mathbf{a}; \mathbf{m}_t] + \mathbf{b}_r \quad (7)$$

$$P_{\text{voc}} = \text{softmax}(\mathbf{W}_o \mathbf{r}_t + \mathbf{b}_o) \quad (8)$$

where $\mathbf{W}_r$ and $\mathbf{b}_r$ are learnable parameters. The strategies of adding attribute vector $\mathbf{a}$ and vocabulary state $\mathbf{m}_t$ into readout state $\mathbf{r}_t$ are called ***Attribute Prediction strategy*** and ***Attribute Memory Prediction strategy***, respectively.

Last but not least, inspired by (See et al., 2017), we also propose a soft copy mechanism to copy attribute-specific words in generating summaries, which is the 4-*th* strategy called ***Attribute Memory Generation strategy***.

The generation probability $p_{\text{mgn}} \in [0, 1]$ for timestep t is calculated from the context vector $\mathbf{c}_t$, the decoder state $\mathbf{s}_t$ and the vocabulary state $\mathbf{m}_t$:

$$p_{\text{mgn}} = \sigma(\mathbf{W}_{mg}[\mathbf{c}_t; \mathbf{s}_t; \mathbf{m}_t] + \mathbf{b}_{mg}) \quad (9)$$

where $\mathbf{W}_{mg}, \mathbf{b}_{mg}$ are learnable parameters, $[;]$ is the concatenating operator and σ is the sigmoid function. Next p_{mgn} is used as a soft switch to choose between generating a word from the target vocabulary V_t or coping a word from attribute-specific vocabulary.

$$P(w) = (1 - p_{\text{mgn}}) P_{\text{voc}}(w) + p_{\text{mgn}} \sum_{k:A_k=w} \beta_{t,k} \quad (10)$$

The first part in Equation (10) represents generating words from our vocabulary, and the second part indicates coping words from attribute-specific vocabulary memory, respectively.

3.6 Objective Function

Our goal is to maximize the output summary probability given the input sentence. Therefore, we optimize the negative log-likelihood loss function:

$$L = -\frac{1}{|D|} \sum_{(x,y) \in D} \log p(y|x) \quad (11)$$

4 Experiments

4.1 Evaluation Metric

We exploit ROUGE (Lin, 2004) as our evaluation metric. ROUGE scores reported in this paper are computed by Pyrouge package [4].

4.2 Comparison Methods

In the experiments, we compare our model with several strong baseline methods, which can be divided into two types: extractive and abstractive approaches. **LEAD1** is an extractive approach which selects the first sentence in review as summary. **LEXRANK** (Erkan and Radev, 2004) is also a famous extractive approach that computes text centrality based on PageRank algorithm. **TEXTRANK** (Mihalcea and Tarau, 2004) is an unsupervised algorithm based on weighted-graphs. **S2SATT** is a sequence to sequence model with attention implemented by us. **SEASS** (Zhou et al., 2017) employs a selective encoding model to control the information flow from encoder to decoder. **PGN** (See et al., 2017) copies words from the source text via pointing, while retaining the ability to produce novel words through the generator.

4.3 Implementation Details

Model Parameters The vocabulary is collected from the *TripAtt* training data. We lowercase the text, and there are 362,103 unique word types. We

[4] pypi.python.org/pypi/pyrouge/0.1.3

Models	RG-1	RG-2	RG-L
LEAD1	11.59	2.41	10.21
LEXRANK	8.80	1.19	7.87
TEXTRANK	10.47	1.71	9.30
S2SATT	20.61	5.96	18.95
SEASS	20.34	5.72	18.76
PGN	20.68	6.20	19.13
ASN	**21.52***	**6.61***	**19.74***

Table 2: ROUGE F1 scores (%) on the test set. RG in the Table denotes ROUGE. Models and baselines in the top half are extractive methods, while those in the bottom half are abstractive ones. The best performance is in **bold**. The superscript * indicates ASN performs significantly better than other models as given by the 95% confidence interval in the official ROUGE script.

use the top 30,000 words as the model vocabulary since they can cover 99.01% of the training data.

Model Training We set the batch size to 128. We truncate the review to 200 tokens, which is done to expedite training and testing. However we also find that truncating the review can raise the performance of the model[5]. We use the development set to choose the size of attribute-specific vocabulary and set it to 100. We also use Adam (Kingma and Ba, 2015), dropout (Srivastava et al., 2014) and gradient clipping (Pascanu et al., 2013) to make our model robust. We set the word embedding size to 128, and all LSTM hidden state sizes to 200. We use Adam as our optimizing algorithm. For the hyperparameters of Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$ respectively, and $\epsilon = 10^{-8}$. We use dropout with probability p = 0.2. We also apply gradient clipping with range $[-5, 5]$.

Model Testing At test time, We use beam search with a beam size of 4.

4.4 Results

Our results are given in Table 2. For extractive methods, we can see that LEAD1 performs best. However, it only obtains 11.59 ROUGE-1, 2.41 ROUGE-2, and 10.21 ROUGE-L F1 scores. The reason is that summaries in *TripAtt* are very succinct[6] and they often cover contents across several sentences, such as the summary in Figure 1.

For abstractive methods, we find that S2SATT is better than all extractive methods. After considering selective mechanism into S2SATT, the performance of SEASS decreases slightly. Because the selective mechanism proposed by SEASS is designed for sentence summarization, which may not be suitable for summarizing reviews. The average length of the input is less than 40 in Zhou et al. (2017), while the length in *TripAtt* is about 170. When incoporating copy mechanism into S2SATT, PGN obtains better performance.

Finally, after considering our proposed attribute encoder and four attribute-based strategies, ASN performs significantly better than all previous methods. Compared to S2SATT, our model has a 0.91 ROUGE-1, 0.65 ROUGE-2, and 0.79 ROUGE-L gains, which shows explicitly modeling attribute-related characteristics can indeed improve summarization quality. Our model also surpasses PGN by 0.84 ROUGE-1, 0.41 ROUGE-2, and 0.61 ROUGE-L and achieves the state-of-the-art performance on review summarization.

4.5 Human Evaluation on Aspect-level Coverage

Previous experiments show that ASN is better than other baselines when evaluating on ROUGE. However, ROUGE is only a word-based metric, which can not measure the semantic between two references. Table 3 illustrates an example. Since the summary generated by S2SATT contains more overlapping words with the gold summary than the one generated by ASN contains, S2SATT obtains higher ROUGE scores than ASN. However, from the view of aspects, ASN may be better. Because its summary describes ***location*** and ***service*** of a hotel, which are consistent with the gold result, while S2SATT's summary misses ***service***. Therefore, except for ROUGE, we want also to evaluate aspect-level coverage of different systems.

To perform the aspect-level evaluation, we first define seven aspects: ***location***, ***service***, ***room***, ***value***, ***facility***, ***food***, and ***hotel***, where ***hotel*** describes the overall attitude. Then, we randomly sample 1000 attribute-review-summary triplets from test set and generate summaries of these reviews using S2SATT, PGN and ASN. After that,

[5]Indeed, we found that using only the first 200 tokens of the review yields higher ROUGE scores than using all tokens.

[6]We observe in Table 1 that the average length of summary is about seven.

	A sample in test set	RG-1(%)	RG-2(%)	RG-L(%)	Aspect label
S2SATT:	good location , but small rooms	46.15	36.36	46.15	location, room
ASN:	good location , stuff needs improvements	33.33	20	33.33	location, service
Gold:	3+ good location , but some lacks in service	-	-	-	location, service

Table 3: A sample in test set shows high ROUGE may not result in better performance.

Models	Precision	Recall	F1
S2SATT	0.452	0.480	0.466
PGN	0.472	0.503	0.487
ASN	**0.491**	**0.530**	**0.510**

Table 4: Aspect-level Precision, Recall, and F1 scores (%) for different systems.

we ask two students to label aspects to these generated summaries and the reference summaries[7]. Finally, we compute aspect-level precision, recall, and F1 for different systems.

Table 4 shows the aspect-level result, and we find that ASN outperforms other models by a large margin, which shows summaries generated by our model can not only contain more correct words, but also in a higher consistency on aspects with references.

5 Discussions

In this section, we study the effect of different attributes, different attribute-specific strategies, and different attribute-specific vocabulary size on review summarization.

5.1 Effects of Different Attributes

To understand which kind of attribute information is the most important in review summarization, we perform an ablation study and give the results in Table 5.

First, all these kinds of attribute information are helpful for review summarization. Adding one kind of attribute information can obtain at least 0.41 ROUGE-1, 0.18 ROUGE-2 and 0.22 ROUGE-L gains. Second, travel status information is the most important attribute for review summarization in *TripAtt*. Because the travel status is a domain-dependent attribute, while others are domain-independent ones.

[7]Some examples about how to label aspects to summaries are shown in the last column of Table 3.

Attribute Information	RG-1	RG-2	RG-L
None	20.61	5.96	18.95
Age	21.04	6.19	19.39
Gender	20.98	6.14	19.17
Travel Status	21.09	6.22	19.41
Age + Gender	21.10	6.25	19.50
Age + Travel Status	21.21	6.46	19.63
Gender + Travel Status	21.08	6.33	19.48
ASN	21.52	6.61	19.74

Table 5: Ablation study on review summarization with attribute information.

line	ASel	APre	AMP	AMG	RG-1	RG-2	RG-L
1	–	–	–	–	20.61	5.96	18.95
2	✓	–	–	–	20.78	6.09	19.07
3	–	✓	–	–	21.03	6.15	19.21
4	–	–	✓	–	21.13	6.24	19.29
5	–	–	–	✓	21.08	6.19	19.24
6	–	✓	✓	✓	21.13	6.40	19.42
7	✓	–	✓	✓	21.52	6.49	19.70
8	✓	✓	–	✓	21.42	6.45	19.48
9	✓	✓	✓	–	21.15	6.38	19.37
10	✓	✓	✓	✓	21.52	6.61	19.74

Table 6: Effects of different attribute-based strategies on review summarization. "✓" means our model considers the specific strategy, while "–" means not. When there is no user-based strategies considered in our model, our model degrades into S2SATT (line 1).

5.2 Effects of different strategies

In this paper, we propose four attribute-based strategies to construct our attribute-aware review summarization model, which contains Attribute Selection strategy (ASel), Attribute Prediction strategy (APre), Attribute Memory Prediction strategy (AMP) and Attribute Memory Generation strategy (AMG). To evaluate the effect of each strategy on review summarization, we perform an ablation study and report results in Table 6.

First, we observe that models with only one kind of attribute-based strategy (line 2-5) can at least exceed S2SATT by (+0.17 ROUGE-1, +0.13 ROUGE-2, +0.12 ROUGE-L) points. It shows that all these strategies improve the performance of re-

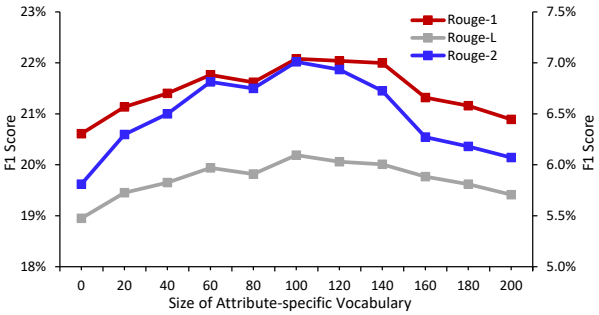

Figure 4: Effects of attribute-specific vocabulary size on review summarization on development set of *TripAtt*. When there is no any attribute-specific vocabulary (the size is 0) in ASN, our model degrades into S2SATT. The primary axis is for ROUGE-1 and ROUGE-L, and the second axis is for ROUGE-2.

view summarization. APre and AMG are the two most effective strategies, because they directly affect the word prediction module in ASN.

Second, models which deletes one kind of attribute-based strategy from ASN (line 6-9) will descend at least 0.11 in ROUGE-2 compared with ASN (line 10). It shows all our four user-based strategies are complementary. The most complementary strategies are ASel and AMG. The reason for ASel is that it is applied on the encoder module of ASN, while others are applied on the decoder module. For AMG, it differs from other decoder module strategies by affecting the decoding process through adding one more vocabulary distribution, while other strategies (APre and AMP) only add more features to classical word prediction module.

Third, ASN obtains the best result when considering all these strategies.

5.3 Effects of Attribute-specific Vocabulary Size

Since the attribute-specific vocabulary is the cornerstone for our attribute-aware model, we perform a test to detect the effect of its size on review summarization and show the result in Figure 4. First, we find that considering attribute-specific vocabulary can indeed improve the performance of review summarization, even though when the vocabulary size is very small (such as 20). Second, all curves increase firstly, and decrease with the increase of attribute-specific vocabulary size. It indicates that small vocabulary may be helpful for ASN, however large vocabulary may import much noise and be harmful to ASN. The best performance is obtained when the attribute-specific vocabulary size is 100, that's the reason why we set our attribute-vocabulary size to 100.

Review: i had the pleasure of staying at this hotel for a company ***meeting***. when you get to mco, call the hotel and they have a complimentary shuttle that will pick you up and bring you to the hotel. ... overall a great stay and if you need a place for your ***meeting*** , definately book here . . . . you wont be disappointed !
Attribute Information: 35-49, female, **traveled on business**

S2SAtt:	very nice hotel with great staff
PGN:	very nice hotel , great staff
ASN:	nice hotel for a ***meeting***
Gold:	great for a ***meeting***

(a) A sample shows the effect of travel state on review summarization

Review: estilo fashion hotel has n't been open very long but has set its standards high ! rooms are clean but not huge but everything is new and in good condition . staff are very helpful and efficient . our bedroom had a comfortable bed and was very modern . ...
Attribute Information: 50-64, **female**, traveled as a couple

S2SAtt:	modern hotel in great location
PGN:	great location , excellent service
ASN:	***lovely*** hotel and excellent service
Gold:	***lovely*** hotel with efficient staff !

(b) A sample shows the effect of gender on review summarization

Figure 5: Two samples in *TripAtt* show the effect of attributes on review summarization

5.4 Case Study

We present two cases from *TripAtt* that show the effect of attribute on review summarization in Figure 5.

Figure 5 (a) shows the effect of travel status on review summarization. Businessperson often books a hotel for working. In this case, the businesswoman stayed at the hotel for a company meeting. Whether the hotel is meet for the requirement may be the most important factor for her. She summarizes "great for a meeting". S2SATT could not get the point. Even though "meeting" appears in the review, PGN that has the effect of copying words from it also fails to generate the word. Our model containing businessperson-specific vocabulary can generate the word well and obtain a better summarization.

Figure 5 (b) shows the effect of gender on review summarization. Word-using habits in different genders are different. Female users often utilize "lovely", "beautiful", "cute" to summarize review while these words rarely appear in summaries from male users. Without considering the gender bias, S2SATT and PGN can not generate the summarization well. Incorporating such writ-

ing styles of female users in ASN, our model can generate "lovely" correctly, although it does not appear in the review.

6 Related Work

Review summarization belongs to sentiment analysis (Liu, 2016; Xia et al., 2015), which is a large area in natural language processing and contains sentiment classification (Li and Zong, 2008; Xia et al., 2011; Li et al., 2016, 2018b), emotion detection (Li et al., 2015), spam detection (Wang et al., 2017) and so on. There are two mainstream approaches for the problem: extractive and abstractive approaches.

A key task in extractive methods (Hu and Liu, 2004; Lerman et al., 2009; Xiong and Litman, 2014; Kunneman et al., 2018) is to identify important text units. For example, Hu and Liu (2004) first recognize the frequent product features and then attach extracted opinion sentences to the corresponding feature. Xiong and Litman (2014) exploit review helpfulness for review summarization. However, many studies (Carenini et al., 2013; Fabbrizio et al., 2014) have shown that abstractive approaches may be more appropriate for summarizing evaluative text than extractive ones. That is also the reason why we build our attribute-aware model based on abstractive methods.

Abstractive approaches (Ganesan, 2010; Gerani et al., 2014; Wang and Ling, 2016) are also very popular methods in review summarization. For example, Ganesan (2010) first represent review as token-based graphs based on the token order in the string and then rank summary candidates by scoring paths after removing redundant information from the graph. Gerani et al. (2014) utilize discourse structure of review to identify important aspects and then design a set of templates to generate summarizations. Wang and Ling (2016) propose an attention-based neural network model for generating abstractive summaries of opinionated text.

All of these studies focus on review summarization in the multiple review scenario, while our work focuses on the single review scenario. Recent review summarization studies (Ma et al., 2018; Yang et al., 2018a,b) also focus on the scenario. Ma et al. (2018) jointly models review summarization and sentiment classification in a unified framework. Yang et al. (2018a) study the aspect/sentiment-aware abstractive review summarization in an end-to-end manner. They mainly generate summary only based on review content and overlook the crucial influences of users. The most related work is Li et al. (2019). They study the personalized review summarization issue and also neglect the effect of user attributes on review summarization. Our proposed model fills this gap in the literature.

7 Conclusion and Future Work

In this paper, we propose an Attribute-aware Sequence Network (ASN) to consider attribute information into review summarization. ASN imports attribute-specific vocabulary to model attribute information and utilizes four attribute-based strategies to build attribute-aware review encoder and attribute-aware summary decoder. To validate our model, we construct a new dataset (*TripAtt*). Extensive experiments on *TripAtt* show that ASN achieves state-of-the-art performance on review summarization.

Abstract

In this paper, we propose a novel neural single-document extractive summarization model for long documents, incorporating both the global context of the whole document and the local context within the current topic. We evaluate the model on two datasets of scientific papers , Pubmed and arXiv, where it outperforms previous work, both extractive and abstractive models, on ROUGE-1, ROUGE-2 and METEOR scores. We also show that, consistently with our goal, the benefits of our method become stronger as we apply it to longer documents. Rather surprisingly, an ablation study indicates that the benefits of our model seem to come exclusively from modeling the local context, even for the longest documents.

1 Introduction

Single-document summarization is the task of generating a short summary for a given document. Ideally, the generated summaries should be fluent and coherent, and should faithfully maintain the most important information in the source document. This is a very challenging task, because it arguably requires an in-depth understanding of the source document, and current automatic solutions are still far from human performance (Allahyari et al., 2017).[VII]

Single-document summarization can be either extractive or abstractive. Extractive methods typically pick sentences directly from the original document based on their importance, and form the summary as an aggregate of these sentences. Usually, summaries generated in this way have a better performance on fluency and grammar, but they may contain much redundancy and lack in coherence across sentences. In contrast, abstractive methods attempt to mimic what humans do by first extracting content from the source document and then produce new sentences that aggregate and organize the extracted information. Since the sentences are generated from scratch they tend to have a relatively worse performance on fluency and grammar. Furthermore, while abstractive summaries are typically less redundant, they may end up including misleading or even utterly false statements, because the methods to extract and aggregate information form the source document are still rather noisy.

In this work, we focus on extracting informative sentences from a given document (without dealing with redundancy), especially when the document is relatively long (e.g., scientific articles).

Most recent works on neural extractive summarization have been rather successful in generating summaries of short news documents (around 650 words/document) (Nallapati et al., 2016) by applying neural Seq2Seq models (Cheng and Lapata, 2016). However when it comes to long documents, these models tend to struggle with longer sequences because at each decoding step, the decoder needs to learn to construct a context vector capturing relevant information from all the tokens in the source sequence (Shao et al., 2017).

Long documents typically cover multiple topics. In general, the longer a document is, the more topics are discussed. As a matter of fact, when humans write long documents they organize them in chapters, sections etc.. Scientific papers are an example of longer documents and they follow a standard discourse structure describing the problem, methodology, experiments/results, and finally conclusions (Suppe, 1998).

To the best of our knowledge only one previous work in extractive summarization has explicitly leveraged section information to guide the generation of summaries (Collins et al., 2017). However, the only information about sections fed into their

[VII] Sentence coloring and Roman numbering will be explained in the result sub-section 4.5.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3011–3021, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

sentence classifier is a categorical feature with values like *Highlight*, *Abstract*, *Introduction*, etc., depending on which section the sentence appears in.

In contrast, in order to exploit section information, in this paper we propose to capture a distributed representation of both the global (the whole document) and the local context (e.g., the section/topic) when deciding if a sentence should be included in the summary

Our main contributions are as follows: **(i)** In order to capture the local context, we are the first to apply LSTM-minus to text summarization. LSTM-minus is a method for learning embeddings of text spans, which has achieved good performance in dependency parsing (Wang and Chang, 2016), in constituency parsing (Cross and Huang, 2016), as well as in discourse parsing (Liu and Lapata, 2017). With respect to more traditional methods for capturing local context, which rely on hierarchical structures, LSTM-minus produces simpler models i.e. with less parameters, and therefore faster to train and less prone to overfitting. **(ii)** We test our method on the Pubmed and arXiv datasets and results appear to support our goal of effectively summarizing long documents. In particular, while overall we outperform the baseline and previous approaches only by a narrow margin on both datasets, the benefit of our method become much stronger as we apply it to longer documents. Furthermore, in an ablation study to assess the relative contributions of the global and the local model we found that, rather surprisingly, the benefits of our model seem to come exclusively from modeling the local context, even for the longest documents.[VI] **(iii)** In order to evaluate our approach, we have created oracle labels for both Pubmed and arXiv (Cohan et al., 2018), by applying a greedy oracle labeling algorithm. The two datasets annotated with extractive labels will be made public.[1]

2 Related work

2.1 Extractive summarization

Traditional extractive summarization methods are mostly based on explicit surface features (Radev et al., 2004), relying on graph-based methods (Mihalcea and Tarau, 2004), or on submodular maximization (Tixier et al., 2017). Benefiting from the success of neural sequence models in other NLP tasks, Cheng and Lapata (2016) propose a novel approach to extractive summarization based on neural networks and continuous sentence features, which outperforms traditional methods on the DailyMail dataset. In particular, they develop a general encoder-decoder architecture, where a CNN is used as sentence encoder, a uni-directional LSTM as document encoder, with another uni-directional LSTM as decoder. To decrease the number of parameters while maintaining the accuracy, Nallapati et al. (2017) present SummaRuNNer, a simple RNN-based sequence classifier without decoder, outperforming or matching the model of (Cheng and Lapata, 2016). They take content, salience, novelty, and position of each sentence into consideration when deciding if a sentence should be included in the extractive summary. Yet, they do not capture any aspect of the topical structure, as we do in this paper. So their approach would arguably suffer when applied to long documents, likely containing multiple and diverse topics.

While SummaRuNNer was tested only on news, Kedzie et al. (2018) carry out a comprehensive set of experiments with deep learning models of extractive summarization across different domains, i.e. news, personal stories, meetings, and medical articles, as well as across different neural architectures, in order to better understand the general pros and cons of different design choices. They find that non auto-regressive sentence extraction performs as well or better than auto-regressive extraction in all domains, where by auto-regressive sentence extraction they mean using previous predictions to inform future predictions. Furthermore, they find that the Average Word Embedding sentence encoder works at least as well as encoders based on CNN and RNN. In light of these findings, our model is not auto-regressive and uses the Average Word Embedding encoder.

2.2 Extractive summarization on Scientific papers

Research on summarizing scientific articles has a long history (Nenkova et al., 2011). Earlier on, it was realized that summarizing scientific papers requires different approaches than what was used for summarizing news articles, due to differences in document length, writing style and rhetorical structure. For instance, (Teufel and Moens, 2002) presented a supervised Naive Bayes

[1]The data and code are available at https://github.com/Wendy-Xiao/Extsumm_local_global_context.

Datasets	# docs	avg. doc. length	avg. summ. length

Daily Mail	219K	693	52
NY Times	655K	530	38
PubMed	133K	3016	203
arXiv	215K	4938	220

Table 1: Comparison of news datasets and scientific paper datasets(Cohan et al., 2018), the length is in terms of the number of words

classifier to select content from a scientific paper based on the rhetorical status of each sentence (e.g., whether it specified a research goal, or some generally accepted scientific background knowledge, etc.). More recently, researchers have extended this work by applying more sophisticated classifiers to identify more fine-grain rhetorical categories, as well as by exploiting citation contexts. Liakata et al. (2013) propose the CoreSC discourse-driven content, which relies on CRFs and SVMs, to classify the discourse categories (e.g. Background, Hypothesis, Motivation, etc.) at the sentence level. The recent work most similar to ours is (Collins et al., 2017) where, in order to determine whether a sentence should be included in the summary, they directly use the section each sentence appears in as a categorical feature with values like Highlight, Abstract, Introduction, etc.. In this paper, instead of using sections as categorical features, we rely on a distributed representation of the semantic information within each section, as the local context of each sentence. In a very different line of work, Cohan and Goharian (2015) form the summary by also exploiting information on how the target paper is cited in other papers. Currently, we do not use any information from citation contexts.

2.3 Datasets for long documents

Dernoncourt et al. (2018) provide a comprehensive overview of the current datasets for summarization. Noticeably, most of the larger-scale summarization datasets consists of relatively short documents, like CNN/DailyMail (Nallapati et al., 2016) and New York Times (Sandhaus, 2008). One exception is (Cohan et al., 2018) that recently introduce two large-scale datasets of long and structured scientific papers obtained from arXiv and PubMed. These two new datasets contain much longer documents than all the news datasets (See Table 1) and are therefore ideal test-beds for the method we present in this paper.

2.4 Neural Abstractive summarization on long documents

While most current neural abstractive summarization models have focused on summarizing relatively short news articles (e.g., (See et al., 2017)), few researchers have started to investigate the summarization of longer documents by exploiting their natural structure. Celikyilmaz et al. (2018) present an encoder-decoder architecture to address the challenges of representing a long document for abstractive summarization. The encoding task is divided across several collaborating agents, each is responsible for a subsection of text through a multi-layer LSTM with word attention. Their model seems however overly complicated when it comes to the extractive summarization task, where word attention is arguably much less critical. So, we do not consider this model further in this paper.

Cohan et al. (2018) also propose a model for abstractive summarization taking the structure of documents into consideration with a hierarchical approach, and test it on longer documents with section information, i.e. scientific papers. In particular, they apply a hierarchical encoder at the word and section levels. Then, in the decoding step, they combine the word attention and section attention to obtain a context vector.

This approach to capture discourse structure is however quite limited both in general and especially when you consider its application to extractive summarization. First, their hierarchical method has a large number of parameters and it is therefore slow to train and likely prone to overfitting[2]. Secondly, it does not take the global context of the whole document into account, which may arguably be critical in extractive methods, when deciding on the salience of a sentence (or even a word). The extractive summarizer we present in this paper tries to address these limitations by adopting the parameter lean LSTM-minus method, and by explicitly modeling the global context.

2.5 LSTM-Minus

The LSTM-Minus method is first proposed in (Wang and Chang, 2016) as a novel way to learn sentence segment embeddings for graph-based dependency parsing, i.e. estimating the most likely

[2]To address this, they only process the first 2000 words of each document, by setting a hard threshold in their implementation, and therefore loosing information.

dependency tree given an input sentence. For each dependency pair, they divide a sentence into three segments (prefix, infix and suffix), and LSTM-Minus is used to represent each segment. They apply a single LSTM to the whole sentence and use the difference between two hidden states $h_j - h_i$ to represent the segment from word w_i to word w_j. This enables their model to learn segment embeddings from information both outside and inside the segments and thus enhancing their model ability to access to sentence-level information. The intuition behind the method is that each hidden vector h_t can capture useful information before and including the word v_t.

Shortly after, Cross and Huang (2016) use the same method on the task of constituency parsing, as the representation of a sentence span, extending the original uni-directional LSTM-Minus to the bi-directional case. More recently, inspired by the success of LSTM-Minus in both dependency and constituency parsing, Liu and Lapata (2017) extend the technique to discourse parsing. They propose a two-stage model consisting of an intra-sentential parser and a multi-sentential parser, learning contextually informed representations of constituents with LSTM-Minus, at the sentence and document level, respectively.

Similarly, in this paper, when deciding if a sentence should be included in the summary, the local context of that sentence is captured by applying LSTM-Minus at the document level, to represent the sub-sequence of sentences of the document (i.e., the topic/section) the target sentence belongs to.

3 Our Model

In this work, we propose an extractive model for long documents, incorporating local and global context information, motivated by natural topic-oriented structure of human-written long documents. The architecture of our model is shown in Figure 1, each sentence is visited sequentially in the original document order, and a corresponding confidence score is computed expressing whether the sentence should be included in the extractive summary. Our model comprises three components: the sentence encoder, the document encoder and the sentence classifier.

3.1 Sentence Encoder

The goal of the sentence encoder is mapping sequences of word embeddings to a fixed length vector (See bottom center of Figure 1). There are several common methods to embed sentences. For extractive summarization, RNN were used in (Nallapati et al., 2017), CNN in (Cheng and Lapata, 2016), and Average Word Embedding in (Kedzie et al., 2018). Kedzie et al. (2018) experiment with all the three methods and conclude that Word Embedding Averaging is as good or better than either RNNs or CNNs for sentence embedding across different domains and summarizer architectures. Thus, we use the Average Word Embedding as our sentence encoder, by which a sentence embedding is simply the average of its word embeddings, i.e.

$$se = \frac{1}{n}\sum_{w_0}^{w_n} emb(w_i), se \in \mathbb{R}^{d_{emb}}.$$

Besides, we also tried the popular pre-trained BERT sentence embedding (Devlin et al., 2019), but initial results were rather poor. So we do not pursue this possibility any further.

3.2 Document Encoder

At the document level, a bi-directional recurrent neural network (Schuster and Paliwal, 1997) is often used to encode all the sentences sequentially forward and backward, with such model achieving remarkable success in machine translation (Bahdanau et al., 2015). As units, we selected gated recurrent units (GRU) (Cho et al., 2014), in light of favorable results shown in (Chung et al., 2014). The GRU is represented with the standard reset, update, and new gates.

The output of the bi-directional GRU for each sentence t comprises two hidden states, $h_t^f \in \mathbb{R}^{d_{hid}}, h_t^b \in \mathbb{R}^{d_{hid}}$ as forward and backward hidden state, respectively.

A. Sentence representation As shown in Figure 1(A), for each sentence t, the sentence representation is the concatenation of both backward and forward hidden state of that sentence.

$$sr_t = (h_t^f : h_t^b), sr_t \in \mathbb{R}^{d_{hid}*2}$$

In this way, the sentence representation not only represents the current sentence, but also partially covers contextual information both before and after this sentence.

B. Document representation The document representation provides global information on the

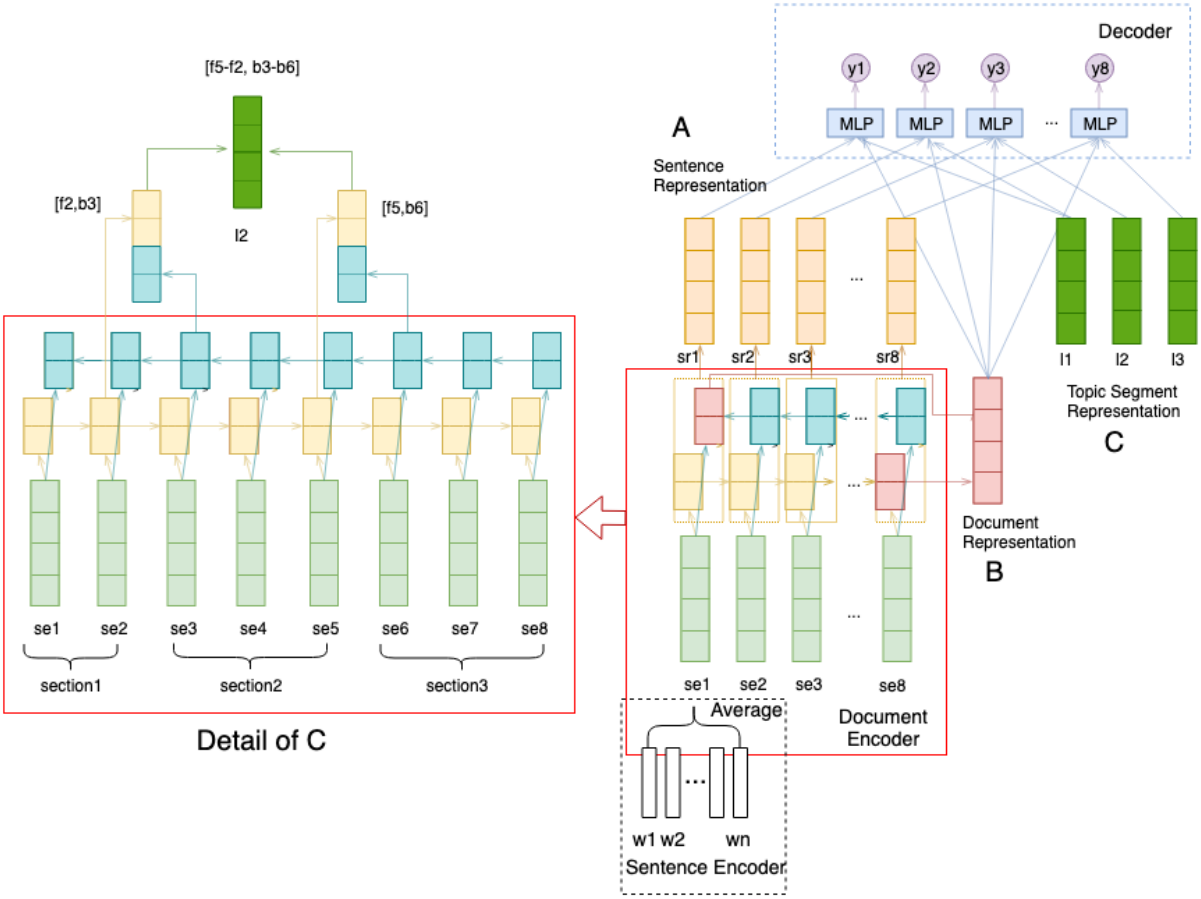

Figure 1: The structure of our model, se_i, sr_i represent the sentence embedding and sentence representation of sentence i, respectively. The binary decision of whether the sentence should be included in the summary is based on the sentence itself (A), the whole document (B) and the current topic (C). The document representation is simply the concatenation of the last hidden states of the forward and backward RNNs, while the topic segment representation is computed by applying LSTM-Minus, as shown in detail in the left panel (Detail of C).

whole document. It is computed as the concatenation of the final state of the forward and backward GRU, labeled as B in Figure 1. (Li et al., 2018)

$$d = (h_n^f : h_0^b), d \in \mathbb{R}^{d_{hid}*2}$$

C. Topic segment representation To capture the local context of each sentence, namely the information of the topic segment that sentence falls into, we apply the LSTM-Minus method[3], a method for learning embeddings of text spans. LSTM-Minus is shown in detail in Figure 1 (left panel C), each topic segment is represented as the subtraction between the hidden states of the start and the end of that topic. As illustrated in Figure 1, the representation for section 2 of the sample document (containing three sections and eight sentences overall) can be computed as $[f_5 - f_2, b_3 - b_6]$, where f_5, f_2 are the forward hidden states of sentence 5 and 2, respectively, while b_3, b_6 are the backward hidden states of sentence 3 and 6, respectively. In general, the topic segment representation l_t for segment t is computed as:

$$\begin{aligned} f_t &= h^f_{end_t} - h^f_{start_t - 1}, f_t \in \mathbb{R}^{d_{hid}} \\ b_t &= h^b_{start_t} - h^b_{end_t + 1}, b_t \in \mathbb{R}^{d_{hid}} \\ l_t &= (f_t : b_t), l_t \in \mathbb{R}^{d_{hid}*2} \end{aligned}$$

where $start_t, end_t$ is the index of the beginning and the end of topic t, f_t and b_t denote the topic segment representation of forward and backward, respectively. The final representation of topic t is the concatenation of forward and backward representation l_t. To obtain f_i and b_i, we utilize subtraction between GRU hidden vectors of $start_t$ and end_t, and we pad the hidden states with zero vectors both in the beginning and the end, to ensure the index can not be out of bound. The intuition

[3] In the original paper, LSTMs were used as recurrent unit. Although we use GRUs here, for consistency with previous work, we still call the method LSTM-Minus

behind this process is that the GRUs can keep previous useful information in their memory cell by exploiting reset, update, and new gates to decide how to utilize and update the memory of previous information. In this way, we can represent the contextual information within each topic segment for all the sentences in that segment.

3.3 Decoder

Once we have obtained a representation for the sentence, for its topic segment (i.e., local context) and for the document (i.e., global context), these three factors are combined to make a final prediction p_i on whether the sentence should be included in the summary. We consider two ways in which these three factors can be combined.

Concatenation We can simply concatenate the vectors of these three factors as,

$$input_i = (d : l_t : sr_i), input_i \in \mathbb{R}^{d_{hid}*6}$$

where sentence i is part of the topic t, and $input_i$ is the representation of sentence i with topic segment information and global context information.

Attentive context As local context and global context are all contextual information of the given sentence, we use an attention mechanism to decide the weight of each context vector, represented as

$$\begin{aligned} score_i^d &= v^T tanh(W_a(d : sr_i)) \\ score_i^l &= v^T tanh(W_a(l_t : sr_i)) \\ weight_i^d &= \frac{score_i^d}{score_i^d + score_i^l} \\ weight_i^l &= \frac{score_i^l}{score_i^d + score_i^l} \\ context_i &= weight_i^d * d + weight_i^l * l_t \\ input_i &= (sr_i : context_i), input_i \in \mathbb{R}^{d_{hid}*4} \end{aligned}$$

where the $context_i$ is the weighted context vector of each sentence i, and assume sentence i is in topic t.

Then there is a final multi-layer perceptron(MLP) followed with a sigmoid activation function indicating the confidence score for selecting each sentence:

$$\begin{aligned} h_i &= Dropout(ReLU(W_{mlp} input_i + b_{mlp})) \\ p_i &= \sigma(W_h h_i + b_h) \end{aligned}$$

4 Experiments

To validate our method, we set up experiments on the two scientific paper datasets (arXiv and PubMed). With ROUGE and METEOR scores as automatic evaluation metrics, we compare with previous works, both abstractive and extractive.

4.1 Training

The weighted negative log-likelihood is minimized, where the weight is computed as $w_{pos} = \frac{\#negative}{\#postive}$, to solve the problem of highly imbalanced data (typical in extractive summarization).

$$\begin{aligned} \mathcal{L} &= -\sum_{d=1}^{N}\sum_{i=1}^{N_d}(w_{pos} * y_i \log p(y_i|\mathbf{W}, b) \\ &+ (1 - y_i) \log p(y_i|\mathbf{W}, b)) \end{aligned}$$

where y_i represent the ground-truth label of sentence i, with $y_i = 1$ meaning sentence i is in the gold-standard extract summary.

4.2 Extractive Label Generation

In the Pubmed and arXiv datasets, the extractive summaries are missing. So we follow the work of (Kedzie et al., 2018) on extractive summary labeling, constructing gold label sequences by greedily optimizing ROUGE-1 on the gold-standard abstracts, which are available for each article. [4] The algorithm is shown in Appendix A.

4.3 Implementation Details

We train our model using the Adam optimizer (Kingma and Ba, 2015) with learning rate 0.0001 and a drop out rate of 0.3. We use a mini-batch with a batch size of 32 documents, and the size of the GRU hidden states is 300. For word embeddings, we use GloVe (Pennington et al., 2014) with dimension 300, pre-trained on the Wikipedia and Gigaword. The vocabulary size of our model is 50000. All the above parameters were set based on (Kedzie et al., 2018) without any fine-tuning. Again following (Kedzie et al., 2018), we train each model for 50 epochs, and the best model is selected with early stopping on the validation set according to Rouge-2 F-score.

4.4 Models for Comparison

We perform a systematic comparison with previous work in extractive summarization. For completeness, we also compare with recent neural abstractive approaches. In all the experiments, we use the same train/val/test splitting.

[4] For this, we use a popular python implementation of the ROUGE score to build the oracle. Code can be found here, https://pypi.org/project/py-rouge/

Table 3: Results on the Pubmed dataset. See caption of Table 2 above for details on compared models and notation.

- Traditional extractive summarization models: SumBasic (Vanderwende et al., 2007), LSA (Steinberger and Jezek, 2004), and LexRank (Erkan and Radev, 2004)
- Neural abstractive summarization models: Attn-Seq2Seq (Nallapati et al., 2016), Pntr-Gen-Seq2Seq (See et al., 2017) and Discourse-aware (Cohan et al., 2018)
- Neural extractive summarization models: Cheng&Lapata (Cheng and Lapata, 2016) and SummaRuNNer (Nallapati et al., 2017). Based on (Kedzie et al., 2018), we use the Average Word Encoder as sentence encoder for both models, instead of the CNN and RNN sentence encoders that were originally used in the two systems, respectively. [5]
- Baseline: Similar to our model, but without local context and global context, i.e. the input to MLP is the sentence representation only.
- Lead: Given a length limit of k words for the summary, Lead will return the first k words of the source document.
- Oracle: uses the Gold Standard extractive labels, generated based on ROUGE (Sec. 4.2).

4.5 Results and Analysis

For evaluation, we follow the same procedure as in (Kedzie et al., 2018). Summaries are generated by selecting the top ranked sentences by model probability $p(y_i|\mathbb{W}, b)$, until the length limit is met or exceeded. Based on the average length of abstracts in these two datasets, we set the length limit to 200 words. We use ROUGE scores[6] (Lin and Hovy, 2003) and METEOR scores[7] (Denkowski and Lavie, 2014) between the model results and ground-truth abstractive summaries as evaluation metric. The unigram and bigram overlap (ROUGE-1,2) are intended to measure the informativeness, while longest common subsequence (ROUGE-L) captures fluency to some extent (Cheng and Lapata, 2016). METEOR was originally proposed to evaluate translation systems by measuring the alignment between the system output and reference translations. As such, it can also be used as an automatic evaluation metric for summarization (Kedzie et al., 2018).

The performance of all models on arXiv and Pubmed is shown in Table 2 and Table 3, respectively. Follow the work (Kedzie et al., 2018), we use the approximate randomization as the statistical significance test method (Riezler and Maxwell, 2005) with a Bonferroni correction for multiple comparisons, at the confidence level 0.01 ($p < 0.01$). As we can see in these tables, on both datasets, the neural extractive models outperforms the traditional extractive models on informativeness (ROUGE-1,2) by a wide margin, but results are mixed on ROUGE-L. Presumably, this is due to the neural training process, which relies on a goal standard based on ROUGE-1. Exploring other training schemes and/or a combination of

[5] Aiming for a fair and reproducible comparison, we re-implemented the models by borrowing the extractor classes from (Kedzie et al., 2018), the source code can be found https://github.com/kedz/nnsum/tree/emnlp18-release

[6] We use a modified version of rouge_papier, a python wrapper of ROUGE-1.5.5, https://github.com/kedz/rouge_papier. The command line is 'Perl ROUGE-1.5.5 -e data -a -n 2 -r 1000 -f A -z SPL config_file'

[7] We use default setting of METEOR.

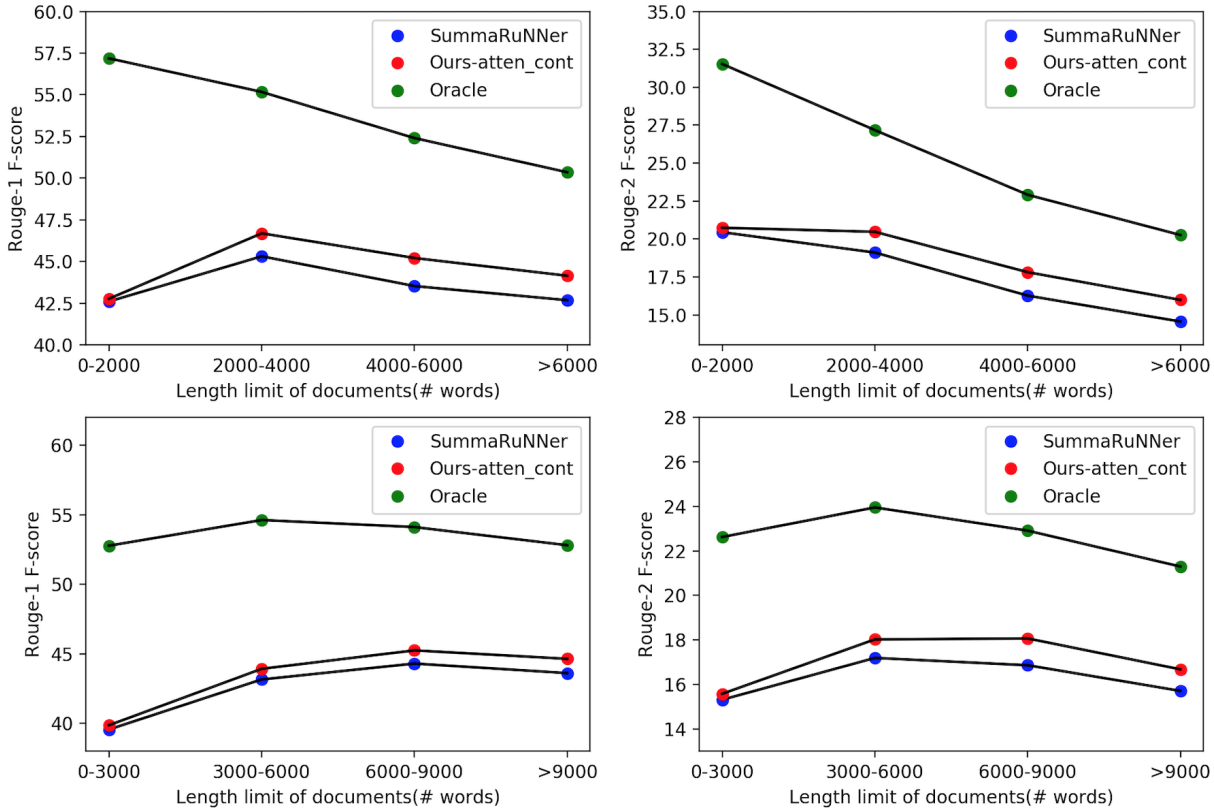

Figure 2: A Comparison between our model, SummaRuNNer and Oracle when applied to documents with increasing length, left-up: ROUGE-1 on Pubmed dataset, right-up: ROUGE-2 on Pubmed dataset, left-down: ROUGE-1 on arXiv dataset, right-down: ROUGE-2 on arXiv dataset

traditional and neural approaches is left as future work. Similarly, the neural extractive models also dominate the neural abstractive models on ROUGE-1,2, but these abstractive models tend to have the highest ROUGE-L scores, possibly because they are trained directly on gold standard abstract summaries.

Compared with other neural extractive models, our models (both with attentive context and concatenation decoder) have better performances on all three ROUGE scores, as well as METEOR. In particular, the improvements over the Baseline model show that a combination of local and global contextual information does help to identify the most important sentences (more on this in the next section). Interestingly, just the Baseline model already achieves a slightly better performance than previous works; possibly because the auto-regressive approach used in those models is even more detrimental for long documents.

Figure 2 shows the most important result of our analysis: the benefits of our method, explicitly designed to deal with longer documents, do actually become stronger as we apply it to longer documents. As it can be seen in Figure 2, the performance gain of our model with respect to current state-of-the-art extractive summarizer is more pronounced for documents with $>= 3000$ words in both datasets.

Finally, the result of Lead (Table 2, 3) shows that scientific papers have less position bias than news; i.e., the first sentences of these papers are not a good choice to form an extractive summary.

As a teaser for the potential and challenges that still face our approach, its output (i.e., the extracted sentences) *when applied to this paper* is colored in red and the order in which the sentences are extracted is marked with the Roman numbering. If we set the summary length limit to the length of our abstract, the first five sentences in the conclusions section are extracted. If we increase the length to 200 words, two more sentences are extracted, which do seem to provide useful complementary information. Not surprisingly, some redundancy is present, as dealing explicitly with redundancy is not a goal of our current proposal and left as future work.

4.6 Ablation Study

Model	*ROUGE-1(+l/+g)*	*ROUGE-2(+l/+g)*	*ROUGE-L(+l/+g)*
BSL	44.29 (na/na)	19.17 (na/na)	30.89 (na/na)

Table 5: Ablation study on arXiv dataset, with all documents (up) and a subset of long document(down, $>$ 9000 words). Results that are not significantly different from the best systems are in bold.

In order to assess the relative contributions of the global and local models to the performance of our approach, we ran an ablation study. This was done for each dataset both with the whole test set, as well as with a subset of long documents. The results for Pubmed and arXiv are shown in Table 4 and Table 5, respectively. For statistical significance, as it was done for the general results in Section 4.5, we use the approximate randomization method (Riezler and Maxwell, 2005) with the Bonferroni correction at ($p < 0.01$).

From these tables, we can see that on both datasets the performance significantly improves when local topic information (i.e. local context) is added. And the improvement is even greater when we only consider long documents. Rather surprisingly, this is not the case for the global context. Adding a representation of the whole document (i.e. global context) never significantly improves performance. In essence, it seems that all the benefits of our model come exclusively from modeling the local context, even for the longest documents. Further investigation of this finding is left as future work.

5 Conclusions and Future Work

In this paper, we propose a novel extractive summarization model especially designed for long documents, by incorporating the local context within each topic, along with the global context of the whole document.[II] Our approach integrates recent findings on neural extractive summarization in a parameter lean and modular architecture.[III] We evaluate our model and compare with previous works in both extractive and abstractive summarization on two large scientific paper datasets, which contain documents that are much longer than in previously used corpora.[IV] Our model not only achieves state-of-the-art on these two datasets, but in an additional experiment, in which we consider documents with increasing length, it becomes more competitive for longer documents.[V] We also ran an ablation study to assess the relative contribution of the global and local components of our approach. [I] Rather surprisingly, it appears that the benefits of our model come only from modeling the local context.

For future work, we initially intend to investigate neural methods to deal with redundancy. Then, it could be beneficial to integrate explicit features, like sentence position and salience, into our neural approach. More generally, we plan to combine of traditional and neural models, as suggested by our results. Furthermore, we would like to explore more sophistical structure of documents, like discourse tree, instead of rough topic segments. As for evaluation, we would like to elicit human judgments, for instance by inviting authors to rate the outputs from different systems, when applied to their own papers. More long term, we will study how extractive/abstractive techniques can be integrated; for instance, the output of an extractive system could be fed into an abstractive one, training the two jointly.

Abstract

Recent neural models for data-to-text generation rely on massive parallel pairs of data and text to learn the writing knowledge. They often assume that writing knowledge can be acquired from the training data alone. However, when people are writing, they not only rely on the data but also consider related knowledge. In this paper, we enhance neural data-to-text models with external knowledge in a simple but effective way to improve the fidelity of generated text. Besides relying on parallel data and text as in previous work, our model attends to relevant external knowledge, encoded as a temporary memory, and combines this knowledge with the context representation of data before generating words. This allows the model to infer relevant facts which are not explicitly stated in the data table from an external knowledge source. Experimental results on twenty-one Wikipedia infobox-to-text datasets show our model, KBAtt, consistently improves a state-of-the-art model on most of the datasets. In addition, to quantify when and why external knowledge is effective, we design a metric, KBGain, which shows a strong correlation with the observed performance boost. This result demonstrates the relevance of external knowledge and sparseness of original data are the main factors affecting system performance.

1 Introduction

Automatic text generation from structured data (data-to-text) is a classic task in natural language generation which aims to automatically generate fluent, truthful and informative texts based on structured data (Kukich, 1983; Holmes-Higgin, 1994; Reiter and Dale, 1997). Data-to-text is often formulated into two subproblems: *content selection* which decides what contents should be included in the text and *surface realization* which determines how to generate the text based on selected contents. Traditionally, these two subproblems have been tackled separately. In recent years, neural generation models, especially the encoder-decoder model, solve these two subproblems jointly and have achieved remarkable successes in several benchmarks (Mei et al., 2016; Lebret et al., 2016; Wiseman et al., 2017; Dušek et al., 2018; Nie et al., 2018).

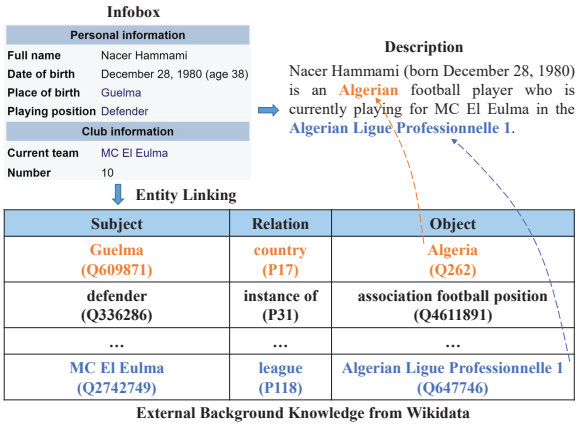

Figure 1: An example of generating description from a Wikipedia infobox. External background knowledge expanded from the infobox is helpful for generation.

Such end-to-end data-to-text models rely on massive parallel pairs of data and text to learn the writing knowledge. They often assume that all writing knowledge can be learned from the training data. However, when people are writing, they will not only rely on the data contents themselves but also consider related knowledge, which is neglected by previous methods. For example, as shown in Fig. 1, an infobox about a person called *Nacer Hammami* is paired with its corresponding biography description from the Wikipedia. However, the information in the infobox is not enough to cover all the facts mentioned in the description. To generate this description from the in-

*Contribution during internship at Microsoft Research.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3022–3032, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

fobox, we need to expand information based on external background knowledge from its related entities. For example, in the description: 1) "is an *Algerian* football player" indicates the nationality of *Nacer Hammami* which is not explicitly stated in the infobox. However, the place of birth, *Guelma*, of *Nacer Hammami* is given, therefore the nationality can be inferred from the knowledge that *Guelma* is a place in *Algeria*. 2) "playing for *MC El Eulma* in the *Algerian Ligue Professionnelle 1*" describes the fact that *MC El Eulma* is a club in the *Algerian Ligue Professionnelle 1* which is also not explicitly stated in the infobox which can be expanded from external knowledge base.

One may argue that neural models can learn such knowledge when enough parallel co-occurrence pairs such as (*Guelma*, *Algerian*) and (*MC El Eulma*, *Algerian Ligue Professionnelle 1*) are available. However even in such case, neural models still tend to make mistakes for sparse co-occurrence pairs as we will show in the experiments section.

In this paper we enhance neural-network-based data-to-text generation models with external knowledge in a simple but effective way. Besides learning the association between data and text from parallel data-text pairs as in previous work, our model attends to relevant external knowledge, encoded as a temporary memory, and combines this knowledge with the context representation of data before generating words. Specifically, both infobox and background knowledge facts are encoded and a dual-attention mechanism is proposed to guide the decoder to generate text.

To verify the effectiveness of our proposed model, **K**nowledge **B**ase enhanced **Att**ention-based sequence-to-sequence network (KBAtt), we conduct experiments on multiple Wikipedia infobox-to-text datasets including WikiBio (Lebret et al., 2016) and 20 new datasets[1]. Our experiment results show that KBAtt consistently improves a state-of-the-art neural data-to-text model to achieve higher performances on most of the datasets. To quantify when and why external knowledge is effective, we design a metric which shows a strong correlation with the observed performance boost. This result demonstrates the relevance of external knowledge and sparseness of original data are the main factors affecting system performance.

The contributions of our work can be summarized as follows:

- We demonstrate that external knowledge base could be used to enhance the performance of neural data-to-text models.
- We propose a simple yet effective model, KBAtt, to integrate external knowledge using a dual-attention mechanism.
- We design a metric, KBGain, to quantify when and why external knowledge is effective.
- We contribute twenty infobox-to-text datasets from a variety of domains.

2 The Proposed Model

Our model takes a data table D (e.g., a Wikipedia infobox) and a relevant external knowledge base (KB) containing a set of facts F as input and generates a natural language text $y = y_1, ..., y_T$ consisting of T words. To augment the infobox with external knowledge, we preserve the Wikipedia internal hyperlink information in the field values of infobox, and track these hyperlinks to get their corresponding entities from Wikidata[2] where we retrieve only one-hop facts. The backbone of our model is an attention based sequence-to-sequence model (Bahdanau et al., 2014) equipped with copy mechanism (See et al., 2017). As shown in Fig. 2, the model consists of four main components: a table encoder, a KB encoder, the dual attention mechanism and a decoder. We describe each component in the following sections.

2.1 Table Encoder

In Fig. 2, the input data table D consists of several *field name* and *field value* pairs. We follow (Sha et al., 2017; Liu et al., 2017) to tokenize the field values and transform the input table into a flattened sequence $\{(n_i, v_i)\}_{i=1}^{N}$, where each element is a token v_i from a field value paired with its corresponding field name n_i. To encode the flattened table, we map each (n_i, v_i) to vector $\boldsymbol{x}_i = [\boldsymbol{e}^{n_i}; \boldsymbol{e}^{v_i}]$, where $\boldsymbol{e}^{n_i}$ and $\boldsymbol{e}^{v_i}$ are trainable

[1]Available at https://github.com/hitercs/WikiInfo2Text

[2]We adopt Wikidata (dumps version: 20150831) as the external knowledge base. Although we extend the infobox with external knowledge by using the Wikipedia hyperlink, we can also apply entity linking to link input data to the knowledge base in practice.

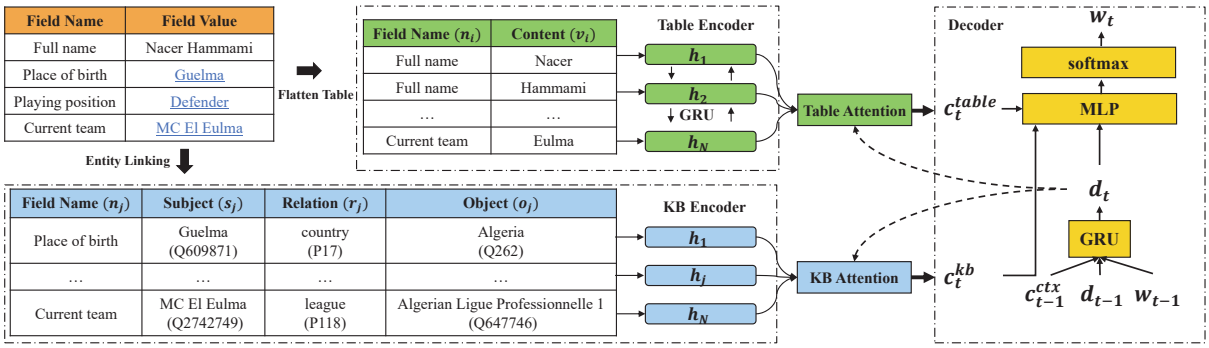

Figure 2: A diagram of the knowledge base enhanced neural data-to-text generation model. First, we transform the table into a flattened sequence, extract entities mentioned in the field value of the infobox and link them to Wikidata where we can retrieve relevant facts. Then, the table contents and external knowledge base facts are carefully encoded. Finally, a single layer GRU decoder with a dual attention mechanism decides which part of information should be used for generation.

word embeddings of n_i and v_i, and $[.;.]$ is the concatenation of vectors. Then each $\boldsymbol{x}_i$ is encoded into a hidden vector $\boldsymbol{h}_i$ using a bi-directional GRU (Cho et al., 2014).

2.2 Knowledge Base Encoder

As shown in Fig. 2, we extract entities mentioned in the field value of infobox and link them to Wikidata. Then we can retrieve relevant facts whose subject is the linked entity from Wikidata. These facts contain important background knowledge related to the infobox which is helpful for generation. The KB fact set is denoted by $F = \{(n_j, s_j, r_j, o_j)\}_{j=1}^{|F|}$, where s_j, r_j, o_j is the subject, relation and object of the fact respectively, and field name n_j indicates the current fact is linked by the field value of n_j. In order to integrate such KB facts into the neural model, we apply Multi-Layer Perceptron (MLP) to encode each fact into its representation:

$$\boldsymbol{f}_j = \tanh(\mathbf{W}_f[\boldsymbol{e}^{n_j}; \boldsymbol{e}^{s_j}; \boldsymbol{e}^{r_j}; \boldsymbol{e}^{o_j}] + \boldsymbol{b}_f) \quad (1)$$

where $\mathbf{W}_f$ and $\boldsymbol{b}_f$ are trainable weights and bias, while $\boldsymbol{e}^{n_j}$, $\boldsymbol{e}^{s_j}$, $\boldsymbol{e}^{r_j}$ and $\boldsymbol{e}^{o_j}$ is the embedding of field name n_j, subject s_j, relation r_j and object o_j respectively. To accommodate generation steps where no information from the external knowledge is needed, such as generating *name* field which is already stated in the table, we apply a simple strategy by padding a *none* fact in the knowledge base.

2.3 Dual Attention Mechanism

After encoding the table and background knowledge base facts, we apply a RNN-based decoder to generate words conditioned on both table information and background knowledge fact information. In general, given a decoder hidden state $\boldsymbol{d}_t$ at timestep t, we apply dual attention mechanism including table attention and KB attention to determine which parts that it should pay attention to. Next we will introduce table attention and KB attention briefly.

2.3.1 Table Attention

The table attention is based on similarity between decoder hidden state $\boldsymbol{d}_t$ and table contents representation $\{\boldsymbol{h}_i\}_{i=1}^{N}$. Specially we apply attention mechanism from (Bahdanau et al., 2014) to calculate the table context representation $\boldsymbol{c}_t^{table}$.

$$e_{t,i} = \mathbf{v}_a^\top \tanh(\mathbf{W}_a \boldsymbol{d}_t + \mathbf{U}_a \boldsymbol{h}_i) \quad (2)$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{i=1}^{N} \exp(e_{t,i})} \quad (3)$$

$$\boldsymbol{c}_t^{table} = \sum_{i=1}^{N} \alpha_{t,i} \boldsymbol{h}_i \quad (4)$$

where $\mathbf{W}_a$, $\mathbf{U}_a$ and $\mathbf{v}_a$ are trainable parameters. $\alpha_{t,i}$ is the table attention weight.

2.3.2 KB Attention

Besides utilizing table information, the words generated may contain facts which are not directly mentioned in the table but could be inferred from the background knowledge F. In order to integrate such knowledge into the decoder, we apply KB attention over $\{\boldsymbol{f}_j\}_{j=1}^{|F|}$. Similar to the table attention, we can get KB context representation $\boldsymbol{c}_t^{kb}$.

2.4 Decoder

The decoder is a single layer GRU equipped with copy mechanism. As for the generation mode, given a decoder hidden state $\boldsymbol{d}_t$, the decoder attends both table and knowledge base using mechanism described above, and get table context representation $\boldsymbol{c}_t^{table}$ and KB context representation $\boldsymbol{c}_t^{kb}$. So the context representation at time step t is given by:

$$\boldsymbol{c}_t = [\boldsymbol{c}_t^{table}; \boldsymbol{c}_t^{kb}] \quad (5)$$

Then given table D and knowledge base facts set F, the probability of word y_t generated from a fixed vocabulary at time step t is defined as follows:

$$P_{\text{vocab}} = \text{softmax}(f(\boldsymbol{d}_t, \boldsymbol{y}_{t-1}, \boldsymbol{c}_t)) \quad (6)$$

where $f(\cdot)$ is a non-linear function applying on the decoder hidden state $\boldsymbol{d}_t$, previous word embedding $\boldsymbol{y}_{t-1}$ and the current context vector $\boldsymbol{c}_t$.

To tackle the rare and unknown words problem, we adopt the copy mechanism (See et al., 2017). Specifically, a gate $p_{\text{gen}} \in [0, 1]$ is introduced to switch between copy mode and generation mode. The generation probability p_{gen} is defined as:

$$p_{\text{gen}} = \sigma(\mathbf{w}_c^\top \boldsymbol{c}_t^{table} + \mathbf{w}_d^\top \boldsymbol{d}_t + \mathbf{w}_y^\top \boldsymbol{y}_{t-1} + b) \quad (7)$$

where σ stands for the sigmoid function while vectors $\mathbf{w}_c$, $\mathbf{w}_d$, $\mathbf{w}_y$ and scalar b are trainable parameters. The joint probability for generating y_t at time step t is formulated as follows:

$$P(y_t|y_{<t}, D, F) = p_{\text{gen}} P_{\text{vocab}}(y_t) + (1 - p_{\text{gen}}) \sum_{i:v_i=y_t} \alpha_{t,i} \quad (8)$$

where $\alpha_{t,i}$ is the table attention weight defined in Equation 3.

2.5 Training

Given training dataset $\{(D^k, F^k, y^k)\}_{k=1}^S$ consisting of S samples, our goal is to maximize the probability of target description $y = y_1, ...y_T$ given the input table D and the background knowledge facts F. So the objective function is to minimize the negative log-likelihood:

$$J(\theta) = -\frac{1}{S} \sum_{k=1}^{S} \sum_{t=1}^{T_k} \log P(y_t^k | y_{<t}^k, D^k, F^k) \quad (9)$$

The objective function is fully differentiable, so the entire model can be trained end-to-end through backpropagation. Adam (Kingma and Ba, 2014) is used to optimize our model.

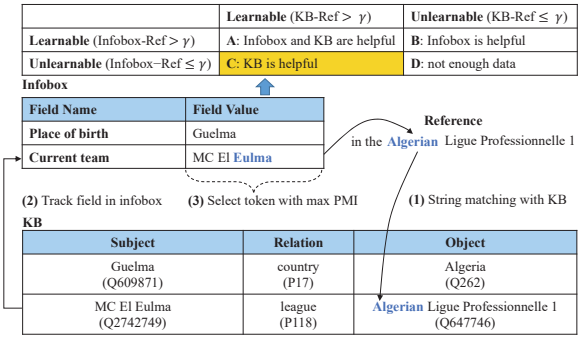

Figure 3: An illustration of KBGain metric.

3 When and Why External Knowledge is Beneficial

In this section, we introduce KBGain to quantify when and why external knowledge (KB) is effective, and then show how KBGain correlates with the performance boost of KBAtt over Seq2Seq+Copy in 21 datasets in Section 4.4. Intuitively, incorporating an external KB should improve data-to-text generation performance. However, to pinpoint the effect of the additional knowledge is not trivial since we know that (a) not all external knowledge is relevant and (b) neural models may memorize certain inference patterns when parallel data is big enough. We assume (1) matching tokens between the external KB and the references indicate relevance of the tokens in the external KB; (2) high frequency of co-occurrence of matching tokens between the infobox and the references indicate good potential for neural models to learn generation patterns which leads to less effectiveness of an external KB, i.e. no data sparsity in the original data. To characterize these factors, we introduce KBGain.

KBGain measures the portion of *learnable* tokens in the references co-occurred with their corresponding external KB entries but filter out those tokens which could also co-occurred with the infobox. We say a token is learnable from one source (infobox or KB) when the co-occurrence frequency between them is higher than a threshold γ which is the minimum size of co-occurrence above which learning will be effective[3]. The top table in Fig. 3 summarizes learnable tokens in 4 possible cases. Among them, case **C** where the frequency of infobox and reference (Infobox-Ref) token co-occurrence does not exceed this threshold but its KB and reference (KB-Ref) token co-

[3]Here, γ is set 25 by tuning on the development datasets, please see Appendix A.3 for more details.

Dataset	WikiBio	Album
Avg. # tokens per sentence	26.1	21.0
Avg. # tokens per table	53.0	57.1
Avg. # fields per table	19.7	15.9
Avg. # table tokens per sent.	11.6	9.7
Avg. # entities per table	5.9	5.5
Avg. # fact tuples per entity	19.0	7.2
Dataset size	728, 321	76, 105

Table 1: Dataset statistics for two sample datasets.

occurrence does, then this is where the KB will be effective. KBGain is defined as the average ratio between count of the tokens falling into category **C** and the length of their corresponding reference on the test set.

Specifically, for all tokens in the reference except stop words and punctuation, we select those matched[4] on string with the object tokens of KB but not with the infobox. For example, the token *Algerian* in the reference is matched with the object of the last KB tuple. The KB-Ref token pair is simply acquired by string matching while Infobox-Ref token pair can be tracked by firstly finding the corresponding field based on the matched tuple, and then selecting the token in its field value with the highest pointwise mutual information (PMI).

4 Experiments

4.1 Datasets

In the experiments, we adopt the WikiBio (Lebret et al., 2016) along with twenty new infobox-to-text datasets collected from Wikipedia[5]. The full statistics of these datasets could be found in the Appendix A.2. Table 1 shows the statistics of two sample datasets. Each dataset consists of infoboxes as input data and the first sentences of their corresponding Wikipeida articles as references. For example, on datasets WikiBio and Album, we extract 5.9 and 5.5 entities from each table, and each entity has 19.0 and 7.2 extended facts tuples, on average. WikiBio and the other 20 datasets consist of 728,321 and 668,796 instances respectively, and they together cover 84.34% infoboxes of the English Wikipedia[6].

[4]To make it simple, we adopt strict string matching. This is acceptable for rough quantification of the intended measurement since precise and semantic-aware matching is still an active research area. We also try several popular stemmers to expand tokens e.g., *Algeria* to *Algerian*, but no stemmers have such capability.

[5]These twenty datasets are similar to WikiBio but from different domains, e.g. Album, Book etc., which are characterized by infobox template category name. They are created with the similar procedure and the same Wikipedia dumps as outlined in Lebret et al. (2016). For more details about data collection, please refer to the Appendix A.1.

Table 2: BLEU-4 score with two generation models on 21 datasets.

4.2 Experiment Setup

We conduct experiments on the datasets as introduced in Section 4.1. Seq2Seq+Copy is the main baseline: a sequence-to-sequence (Seq2Seq) model equipped with copy mechanism from See et al. (2017) which is one of the state of art methods. We also compare our results with other published results using the WikiBio dataset. The model structure of our baseline model is most similar to Sha et al. (2017) by removing their specialized design on order planning which is not the focus of this paper. Since our aim is to verify the effectiveness of external knowledge for data-to-text task, we keep our baseline model as general as possible without other specialized design. Our primary model is KBAtt: a model which integrates the background knowledge into baseline model through a KB encoder and KB attention mechanism. We employ BLEU (Papineni et al., 2002) as the automatic evaluation metric. In addition to BLEU, we conduct human evaluation to assess the factual accuracy of generated sentences.

[6]Although the English Wikipedia has about 5 million entities, we totally parsed 1,656,458 infoboxes and drop some of them due to data noise which indicates nearly 2/3 entities have no infobox.

4.3 Training Details

The dimensions of all trainable word embeddings are set to 512, and the GRU hidden states sizes are set to 512. To limit the memory of our model, we set the maximum number of facts per table to 500. We initialize all the model parameters randomly using a uniform distribution between -0.08 and 0.08. For the model training, we use Adam (Kingma and Ba, 2014) with initial learning rate of 0.001 as the optimization algorithm. The training batch size is set to 64. We also apply gradient clipping (Pascanu et al., 2013) with range [-1,1] during training. We conduct experiments using single card NVIDIA Tesla V100. The largest 15 datasets with more than 9500 training instances are trained for 20 epochs, while the remaining 6 datasets are trained for 40 epochs. All the models were selected based on BLEU-4 score on the development set. All the experiments use greedy search as the decoding algorithm during testing.

4.4 Main Results

4.4.1 Overall Results

To verify the effectiveness of KBAtt, we conduct experiments on 21 Wikipedia infobox-to-text datasets. Table 2 shows the performances of KBAtt and Seq2Seq+Copy in terms of BLEU-4 score. As we can see, KBAtt consistently outperforms Seq2Seq+Copy on most of the datasets, i.e., more than 0.5 BLEU-4 improvements on 15 out of 21 datasets, and comparable on the remaining 6 categories. To get a better understanding of when and why external knowledge will be effective or not, we correlate the performance gains in terms of BLEU-4 with **KBGain** metric described in Section 3 across 21 datasets, and plot their values on the scatter plot in Fig. 4. The *Pearson correlation coefficient* (ρ) between BLUE-4 improvements and KBGain is 0.716 which indicates a strong positive correlation between them. This confirms our analysis in Section 3 that KBAtt is effective when the external knowledge is relevant and the original data is sparse.

4.4.2 Results on WikiBio

To compare with state-of-the-art models, Table 3 shows the results on the WikiBio dataset. Among them, our baseline Seq2Seq+Copy gains a performance of 44.28 which is comparable to Sha et al. (2017) and Liu et al. (2017) and significantly better than Lebret et al. (2016) and Bao et al. (2018),

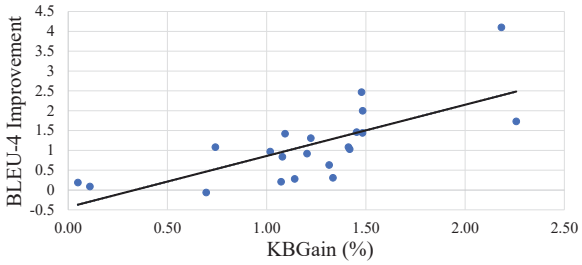

Figure 4: Strong correlation ($\rho = 0.716$) between KBGain (x) and absolute BLEU-4 improvement (y).

and this baseline model is general without specific design, e.g., order planning from Sha et al. (2017) or field-gating encoder from Liu et al. (2017). Our proposed model, namely KBAtt, obtains a BLEU-4 score of 44.59. Although the absolute improvement (+0.31 BLEU-4 points) of KBAtt over Seq2Seq+Copy is relative small, the difference between them is statistically significant under the one-tailed paired t-test at the 99% significance level. The reason why the absolute improvement is relative small is that the full WikiBio dataset consists of 728,321 parallel data-to-text pairs which are enough for neural models to memorize certain inference patterns for high frequency pairs. However, as will be shown in the Section 4.5, the baseline fails on low co-occurrence frequency pairs, but the KBAtt avoids this problem with the contributions from the external knowledge.

4.4.3 Human Evaluation

We conduct human evaluation to assess the factual accuracy of the generated sentences. Manually evaluating the generated results of all datasets is labour intensive, so we choose to evaluate two sample datasets for case study purposes. Specifically, we sample 50 instances each from the WikiBio and the Album datasets, and ask two annotators to extract facts tuples (subject, relation, object) from the references and the generated sentences[7]. In table 4, precision P_1, recall R_1 and their overall score F_1 measure the extent that the facts extracted from the generated sentences conform to those from references. As we can see, KBAtt achieves 1.21%, 7.42% improvements in terms of F_1 on WikiBio and Album respectively, which shows that KBAtt can generate more relevant facts with respect to the reference than the

[7]The generated sentences are shuffled to avoid model preferences. The Cohen's kappa between two annotators is 0.776.

Model	BLEU-4
Table NLM (Lebret et al., 2016)	34.70
Table2Seq (Bao et al., 2018)	40.26
Order Planning, full model (Sha et al., 2017)	43.91
Field-gating Seq2Seq, full model (Liu et al., 2017)	44.71
Seq2Seq+Copy	44.28
KBAtt	44.59

Table 3: BLEU-4 scores (%) on WikiBio dataset.

Dataset	Model	P_1	R_1	F_1	P_2
WikiBio	Seq2Seq+Copy	69.07%	62.45%	65.59%	88.35%
WikiBio	KBAtt	71.81%	62.45%	66.80%	91.85%
Album	Seq2Seq+Copy	73.33%	71.84%	72.58%	84.38%
Album	KBAtt	81.70%	78.37%	80.00%	90.64%

Table 4: Human based evaluation results.

Seq2Seq+Copy baseline. We further ask the annotators to judge whether the facts extracted from the generated texts are correct against information from the infobox, the external knowledge (eg. Wikidata), or even search engines. In table 4, P_2 measures the ratio of correct facts in the generated results. We observe that KBAtt improves 3.50% and 6.26% over Seq2Seq+Copy in WikiBio and Album respectively. This shows that KBAtt is more likely to generate accurate facts than Seq2Seq+Copy.

4.5 Analysis of Few-Shot Learning Ability

To examine the ability of learning writing knowledge from few examples, we design an experiment to compare the performance under different number of training samples for the baseline and our model. In the training set of WikiBio, about 78.5% tables contain *place of birth* field but only 19.0% tables include the *nationality* field. However, in the references, *nationality* of a person is frequently mentioned. This means that the ability of inferring *nationality* based on *place of birth* is important. We collect the cases from the test data with the following conditions: (a) only city level information is given in the field of place of birth; (b) nationality is not specified in the table; (c) the reference mentions country name or nationality. From these cases, we get over 400 unique places of birth to nationality inference pairs and split them into two intervals $[1, 25)$ and $[25, \infty)$ according to their co-occurrence frequency in the training set[8]. For each interval, we randomly sample 50 test cases and

[8]The interval threshold 25 is set by following that for KB-Gain.

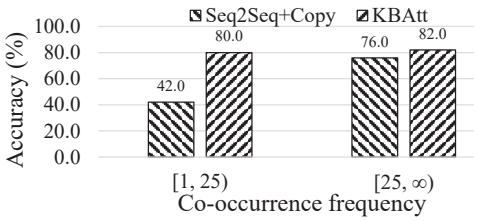

Figure 5: Accuracy (%) of nationality information in the generated sentences w.r.t different co-occurrence frequency intervals.

manually assess the accuracy of nationality information mentioned in the generated sentences[9].

Fig. 5 shows the accuracy of nationality information in the generated text with respect to different co-occurrence frequency intervals: Firstly, we found that the baseline model struggles to learn the inference from *place of birth* to *nationality* when their co-occurrence frequency in training set is less than 25, which shows the difficulty of this task; Secondly, in interval $[1, 25)$, the baseline model only gets 42.0% accuracy, but our model achieves 80.0% accuracy, a 38.0% absolute gain. This confirms our motivation that incorporating external knowledge into neural models can improve model performances especially when the original data is sparse; Finally, the accuracy of both models increases as the frequency goes from $[1, 25)$ to $[25, \infty)$, and the improvement of our model over the baseline model gradually narrows, from 38.0% to 6.0%. This shows that the baseline model could learn part of inference patterns when enough parallel data is available.

4.6 Case Study

Fig. 6 shows three examples from the development set of WikiBio dataset which can demonstrate how KBAtt succeeds or fails. Fig. 6 (a) and (b) illustrate KBAtt is helpful when original data is sparse. However when original data is dense, the baseline model still can learn it. As shown in Fig. 6 (a), the baseline model struggles to learn direct association between "german"and "gummersbach" (birth place in the table), since they only co-occur 12 times in the training data. But it is easy for KBAtt to learn since "german" co-occurs with "germany" in KB 12,437 times in the training data. As shown in Fig. 6 (b), although the national-

[9]In this experiment, a generated result is judged correct only if it generates the same nationality information as the reference.

Figure 6: Case study. Three generation examples from development set of WikiBio. Each example consists of the input infobox, parts of external knowledge base, the reference and two generated sentences by Seq2Seq+Copy and KBAtt. We mark correct fact information as blue and incorrect ones as red.

ity information is not explicitly stated in the table, both Seq2Seq+Copy and KBAtt generate correct nationality information ("australian"). The reason is that "australian" co-occurs with "melbourne" in the table 3,391 times in the training data. So, it is easy for the neural model to learn such inference patterns. Fig. 6 (c) illustrates the pattern of inferring nationality from birth place is not always correct. In this case, KBAtt makes a plausible inference on nationality from birth place, so it generates "american". However, this inference pattern doesn't hold for this case, because he is British. Hopefully, such cases are rare since the birth place conforms to the nationality in most of cases, so our methods can bring improvement as indicated by the overall better performance across almost all Wikipedia categories.

5 Related Work

Data-to-text generation is an important task in natural language generation which has been studied for decades (Kukich, 1983; Holmes-Higgin, 1994; Reiter and Dale, 1997). This task is broadly divided into two subproblems: *content selection* (Kukich, 1983; Reiter and Dale, 1997; Duboue and McKeown, 2003; Barzilay and Lapata, 2005) and *surface realization* (Goldberg et al., 1994; Reiter et al., 2005).

With the advent of neural text generation, the distinction between *content selection* and *surface realization* becomes blurred. For example, Mei et al. (2016) proposed an end-to-end encoder-aligner-decoder model to learn both content selection and surface realization jointly which shows good results on WeatherGov and RoboCub datasets. Wiseman et al. (2017) generate long descriptive game summaries from a database of basketball games where they show the current state-of-the-art neural models are quite good at generating fluent outputs, but perform poorly in content selection and capturing long-term structure. Our work falls into the task of single sentence generation from Wikipedia infoboxes. The model structure ranges from feed-forward networks work (Lebret et al., 2016) to encoder-decoder models (Sha et al., 2017; Liu et al., 2017; Bao et al., 2018; Nema et al., 2018). Recently, Perez-Beltrachini and Lapata (2018) generalize this task to multi-sentence text generation, where they focus on bootstrapping generators from loosely aligned data. However, most of the work mentioned above assume all the writing knowledge can be learned from massive parallel pairs of training data. Different from the previous work, we exploit incorporating external

knowledge into this task to improve the fidelity of generated text.

Our work is also relevant to recent works on integrating external knowledge into neural models for other NLP tasks. The motivations of incorporating external knowledge range from enriching the context information (Mihaylov and Frank, 2018) in reading comprehension, improving the inference ability of models (Chen et al., 2018) in natural language inference, to providing the model a knowledge source to copy from in language modelling (Ahn et al., 2016). Our model, KBAtt, is most relevant to Mihaylov and Frank (2018), where they focus on similarity calculation but we focus on generation in this paper. Moreover, in addition to demonstrating the positive effect of incorporating external knowledge as previous work, we also design a new metric to quantify the potential gains of external knowledge for a specific dataset which can explain when and why our model is effective.

6 Conclusion

In this paper, we propose a neural data-to-text generation model, KBAtt, that incorporates external background knowledge in a simple but effective way to improve fidelity of the generated text. Experiments on 21 Wikipedia infobox-to-text datasets show KBAtt consistently achieves better performance in BLEU than a state-of-the-art baseline on most of datasets. Meanwhile, to quantify when and why external knowledge is effective, we design a metric, KBGain, which shows a strong correlation with observed performance boost. This result indicates the relevance of external knowledge and sparseness of original data are the main factors affecting the effectiveness of KBAtt.

In the future, we plan to investigate integrating multi-hops knowledge graph behind the data which has potential to further improve the inference ability of neural models. It will be worthwhile especially when we extend the task to multiple sentence generation. The main challenge in integrating multi-hops knowledge graph is the large search space. We plan to employ reinforcement learning based techniques to allow the model to search the optimal inference paths by trial and error. Besides, we are also interested in integrating external knowledge into other types of datasets beyond Wikipedia infobox-to-text datasets.

A Supplemental Material

A.1 Dataset Collection

Our dataset is an extension of WikiBio dataset (Lebret et al., 2016) where we extend previous single Biography domain to other twenty domains (e.g. Album, Book etc.) and augment the infoboxes with external knowledge from Wikidata[10]. Our dataset consists of infoboxes as input data and the first sentence of their corresponding Wikipedia article as reference. The infoboxes are parsed from English Wikipedia dump (Sep 2015) while the reference sentences are tokenized with Stanford CoreNLP (Manning et al., 2014). Different from (Lebret et al., 2016), we keep the capitalization information which we believe is important for real-world application. To augment the infoboxes with external knowledge, we preserve the Wikipedia internal hyperlink information in the field values of infoboxes, and track these hyperlinks to get their corresponding entities from Wikidata (dumps version: 20150831). Finally we retrieve one-hop facts from Wikidata. The dataset is aviliable at `https://github.com/hitercs/WikiInfo2Text`.

A.2 Full Dataset Statistics

Table 5 summarizes the full dataset statistics about the twenty-one datasets used in this paper. As you can see, WikiBio consists of 728,321 instances which is the largest infobox-to-text dataset

[10] `https://wikidata.org`

Dataset	Avg. # tokens per sentence	Avg. # tokens per table	Avg. # fields per table	Avg. # table tokens per sent.	Avg. # entities per table	Avg. # fact tuples per entity	Dataset size

Football_club_season	24.6	82.8	30.0	9.3	8.8	6.9	4559

Table 5: Dataset statistics for all datasets used in this paper.

in Wikipedia. However, the size of remaining datasets ranges from 4,559 to 327,863 and more than 60% of them have less than 20,000 instances. So, the abundance of data such as WikiBio is not common among the Wikipedia infobox-to-text datasets. Meanwhile, these datasets vary in sentence length and length of tokens in table. In addition, the number of entities extracted from each table ranges from 0.8 to 10.1 and the average number of fact tuples per entity ranges from 5.2 to 126.1.

A.3 Threshold Tuning for KBGain metric

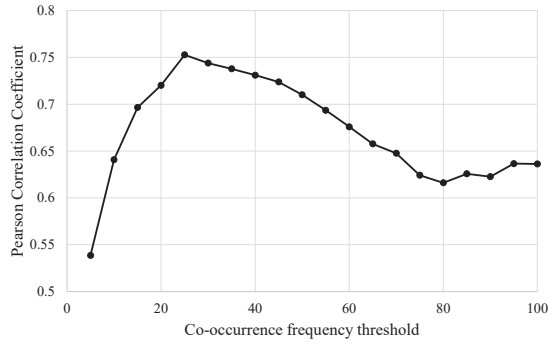

Figure 7: Pearson correlation coefficient w.r.t Co-occurrence frequency threshold.

The threshold γ in KBGain metric denotes the minimum size of co-occurrence above which learning will be effective. We tune this threshold by finding the maximum *pearson correlation coefficient* (ρ) between BLEU-4 improvements and the values of KBGain on the 21 development datasets. Fig. 7 shows the curve of *pearson correlation coefficient* w.r.t co-occurrence frequency threshold ranging from 5 to 100. As we can see, ρ reaches peak value as 0.753 when the threshold is 25. So γ is set 25 throughout this paper.

Reading Like HER: Human Reading Inspired Extractive Summarization

Abstract

In this work, we re-examine the problem of extractive text summarization for long documents. We observe that the process of extracting summarization of human can be divided into two stages: 1) a *rough reading* stage to look for sketched information, and 2) a subsequent *careful reading* stage to select key sentences to form the summary. By simulating such a two-stage process, we propose a novel approach for extractive summarization. We formulate the problem as a contextual-bandit problem and solve it with policy gradient. We adopt a convolutional neural network to encode gist of paragraphs for rough reading, and a decision making policy with an adapted termination mechanism for careful reading. Experiments on the CNN and Daily-Mail datasets show that our proposed method can provide high-quality summaries with varied length, and significantly outperform the state-of-the-art extractive methods in terms of ROUGE metrics.

1 Introduction

Automatic text summarization has wide popularity in NLP applications such as producing digests, headlines and reports. Among the supervised methods, two main types are usually explored, namely abstractive and extractive summarizations (Nenkova et al., 2011). Compared with abstractive approaches, extractive methods are more practical and applicable as they are faster, simpler and more reliable on grammar as well as semantic information (Yao et al., 2018).

Recent studies (Cheng and Lapata, 2016; Nallapati et al., 2017; Yasunaga et al., 2017; Feng et al., 2018) consider extractive summarization as a sequence labeling task, where each sentence is individually processed and determined whether it should be extracted or not. Various neural networks are used to label each sentence and trained using cross-entropy loss to maximize the likelihood of the ground-truth labeled sequences, which may derive the mismatch between the cross-entropy objective function and the evaluation criterion. On the other hand, some reinforcement learning based methods (Wu and Hu, 2018; Narayan et al., 2018; Yao et al., 2018) directly optimize the evaluation metric by combining cross-entropy loss with rewards and train model with policy gradient reinforcement learning. Note that the rewards usually reflect the quality of extracted summary and measured by standard evaluation protocol. However, they still sequentially process text and tend to extract earlier sentences over later ones due to the sequential nature of selection (Dong et al., 2018).

Although great efforts have been devoted to this field, most of the existing approaches neglect how human being reads and forms summaries. Human beings are very good at refining the main idea of a given text based on their reading cognitive process. Note that the reading habits of native speakers are varied and hard to modeled, so we adopt the three reading phases of second-language readers where there are potential behavior patterns. Such reading process of second-language readers generally includes *pre-reading*, *reading* and *post-reading* (Avery and Graves, 1997; Saricoban, 2002; Toprak and Almacıoğlu, 2009; Pressley and Afflerbach, 2012). In the *pre-reading* stage, they roughly preview the whole text to form an initial cognition and extract general but coarse-grained information at the meantime. Based on such prior knowledge, the subsequent *reading* stage is a conscious process that focuses on target-specific purposes to search fine-grained details through repeated skimming and scanning. For *post-reading*, re-reading is performed to check whether there are

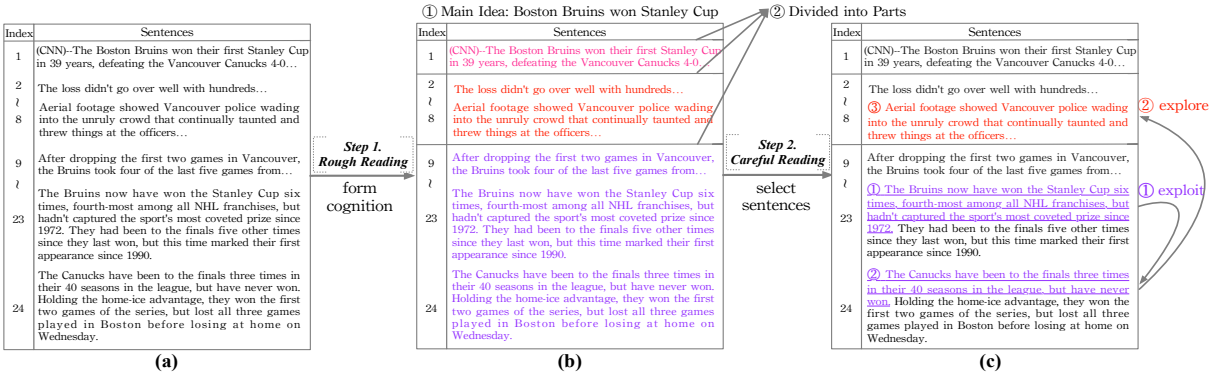

Figure 1: An example of how human beings extract summary. The article is from CNN/DailyMail dataset.

any missed details. The three-stage reading process makes it effective in capturing essential sentences of text as the extracted summarization.

Inspired by such human's reading cognitive process, in this paper, we re-examine the problem of extractive summarization and propose a new approach **HER** (**H**uman-b**E**ing-**R**eading inspired extractive summarization). We simplify the three-stage reading process to two subsequent stages called *rough reading* and *careful reading*. In *rough reading*, coarse-grained information of the original context is identified to form a general cognition. A detailed case is shown in Figure 1. In Figure 1 (a) and (b), after browsing on the whole article, the main idea is outlined and the text is roughly divided into three parts based on the gist of paragraphs at the meantime. Each part describes related but not the same contents. To implement the *rough reading* process, we use a hierarchical neural network to encode sentence vectors and derive a document representation as global feature for the main idea. Meanwhile, a convolutional neural network (CNN) is utilized to encode local features from different paragraphs.

During *careful reading*, the model searches for specific but important details through re-readings to cover the content and extract essential fine-grained information as the final summary. For instance, as shown in Figure 1 (c), after rough reading, two sentences close to the main idea "Boston Bruins won Stanley Cup" may be selected firstly. Then an earlier and more detailed sentence about "fans rioting" is appended to the summary by performing re-reading. It is a combination of people's *reading* and *post-reading* process. To accomplish this, we train a neural network to score each sentence. A multi-armed bandit policy with an adapted termination mechanism is then used to form the final summary.

In our HER model, the whole process is formulated as a contextual bandit problem. We train a reinforcement learning agent to solve it using the policy gradient method (Sutton et al., 2000). At each step, the agent takes an action which is a to-be-selected sentence set, and then receives a reward based on the correlation between extractive summary and gold-standard reference summary.

Our main contributions are as follows:

- We propose an extractive summarization method that simulates human being's reading cognitive process. We formulate it as a contextual bandit problem in which two stages including rough reading and careful reading are devised.
- We use a hierarchical neural network for rough reading which consists of a neural net to encode the whole document and another one to capture features in paragraphs. Then we use a contextual-bandit agent to flexibly select sentences during careful reading, with an adapted termination mechanism to select various but proper numbers of sentences.
- We conducted experiments on the CNN and DailyMail datasets and showed that our proposed model can outperform state-of-the-art methods and provide high-quality summaries.

2 The HER Model

In this section, we introduce the overall framework of our model, HER. We formulate extractive summarization as a contextual bandit (Langford and Zhang, 2007) trained using policy gradient reinforcement learning.

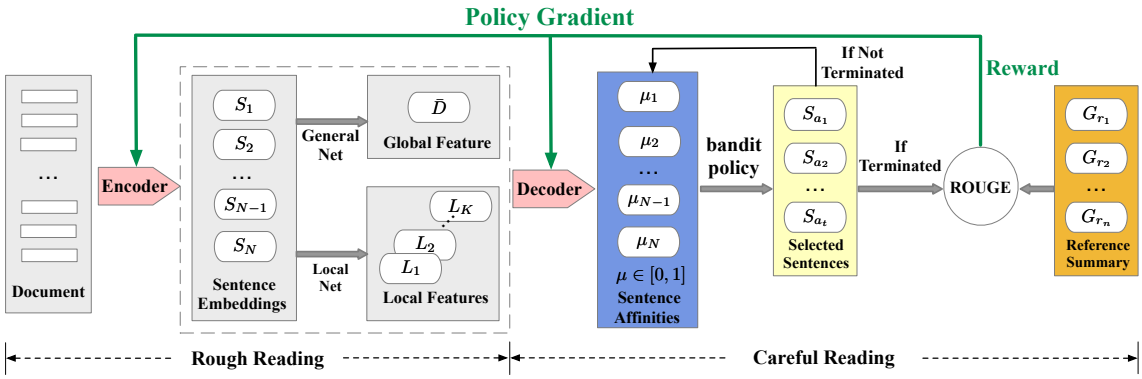

Figure 2: The overall framework of HER is formulated as a contextual bandit and can be divided into a two-stage process containing rough reading and careful reading.

As illustrated in Figure 2, the framework can be divided into two stages: rough reading and careful reading. During rough reading, a document with N sentences is encoded into sentence vectors $\{S_1, S_2, \ldots, S_N\}$ as well as a set of features denoted as F, which includes one global feature $\bar{S}$ representing the whole documentary information and K local features $\{L_1, L_2, \ldots, L_K\}$ depicting paragraphical contentsIn careful reading, sentence vectors are decoded into real-valued scores called sentence affinities $\{\mu_1, \mu_2, \ldots, \mu_N\}$, which can be considered as an estimation of sentence correlation to cover the context. Then a bandit policy is used to repeatedly choose unique sentence until the termination mechanism is triggered.

We will detail the preliminaries in Sec. 2.1, the rough reading stage in Sec. 2.2, and the careful reading stage in Sec. 2.3. The training process is illustrated in Sec. 2.4.

2.1 Summarization as Contextual-Bandit

Contextual-bandit (Langford and Zhang, 2008; Li et al., 2010; Pan et al., 2019a) is the multi-armed bandit (Auer et al., 2002) problem with featured contexts. At each step, the agent observes a context, selects an action based on the context, and then receives a reward. The agent's goal is to quickly find a decision making policy to maximize its return.

In extractive summarization, the goal of the task is to extract an undetermined number of sentences from the original document as summary. We show that it can be formulated as a contextual bandit problem if we select the sentences sequentially. Specifically, for each document, the *context* includes its documentary representation learned through rough reading. At each step $t = 1, 2, \ldots,$ we define the *action* as the index of the next sentence to select. The agent keeps selecting sentences until it reaches the termination condition (detailed in Sec. 2.3.3). Finally, the selected sentences SUM $= (S_{a_1}, \ldots, S_{a_M})$ corresponding to the selected actions $(a_1, \ldots, a_M)$ form an extractive summary. The agent will receive a reward $R(\text{SUM}; G)$. Note that G is the manually-labeled gold-standard summary of the document D, and the reward $R(\text{SUM}; G)$ measures the correlation between G and the predicted summary SUM.

2.2 Rough Reading

In rough reading, we aim to form a general cognition on a given document which encodes the document into sentence embeddings as well as produces the feature set F including global and local features.

Specifically, bidirectional LSTMs (BiLSTMs) on word- and sentence-level are first used to encode a document with N sentences into d_s-dimentional sentence embeddings $\{S_1, S_2, \ldots, S_N\}$, $S_i \in \mathbb{R}^{d_s}$. Second, a global feature $\bar{S} \in \mathbb{R}^{d_s}$ is computed as an average of all the sentence vectors. Third, we use a convolutional neural network to refine gist of different paragraphs and generate multiple local features on the sentence level, which is different from previous methods (Kim, 2014; Narayan et al., 2017; Yao et al., 2018) processing on the word level. In detail, a stacking of N sentence vectors is represented as,

$$S_{1:N} = [S_1, S_2, \cdots, S_N] \in \mathbb{R}^{N \times d_s}, \quad (1)$$

We apply 1-D convolutional neural networks on $S_{1:N}$ followed with a max-over-time pooling so that a final document-level representation can be

extracted. Specifically, we altogether used K convolutional nets with K different window sizes to summarize different gists of paragraphs. Finally, by stacking the outputs together, we get the final document-level representation for local features $L_{1:K} \in \mathbb{R}^{K \times d_s}$.

2.3 Careful Reading

Now that we have the sentence vectors and document-level features given by rough reading, we can perform careful reading to select the sentences one by one to form the summary.

2.3.1 Sentence Decoder

In order to extract high-quality summaries, we first compute the sentence affinities by a *sentence decoder*, which is observed effective in Dong et al. (2018). The sentence affinities are calculate by the following principles: (1) *Salience* (The sentences whose meanings are close to the central idea should be emphasized); (2) *Coverage* (The sentences that match different paragraphical information should be encouraged); (3) *Redundancy* (The unselected sentences which are similar to already extracted ones should be inhibited).

As we need to learn the relations between each sentence and the rest of the document, we update the sentence representations by,

$$S'_t = S_t \oplus \bar{S} \oplus L_{1:K}, t = 1, \ldots, N. \quad (2)$$

Then, we utilize a decoder Dec_1 to score the Salience and Coverage for each sentences, and a secondary score function Dec_2 to screen the sentences that might have Redundancy. Specifically,

$$\boldsymbol{\mu}_1 = (\mu_{11}, \ldots, \mu_{1N})^\top = \mathrm{Dec}_1(S'_{1:N}), \quad (3)$$
$$\boldsymbol{\mu}_2 = \mathrm{Dec}_2(S'_{1:N} \circ (1 - \boldsymbol{\mu}_1)), \quad (4)$$

We implement Dec_1 and Dec_2 as multi-layered perceptrons. Finally, we average the two scores as the final sentence affinities.

$$\boldsymbol{\mu} = (\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2)/2. \quad (5)$$

2.3.2 Bandit Policy

The overall decision making process goes as follows. The agent selects one sentence at each step based on the contextual information provided by the rough reading and sentence affinities computed by the sentence decoder. It stops taking actions once the termination mechanism is triggered. After that, all the selected sentences are formed as a summary, and a final reward can be calculated by comparing to the labeled golden summary. As there is no intermediate reward before termination, the goal of the agent is to find a policy to maximize its expected long-term return.

It is an intuitive choice to select sentences with the highest affinities as summary, which is similar to training data selection (Song et al., 2012; Liu et al., 2019). However, such an *argmax* policy is prone to only learn the easy patterns since it lacks exploration. We will show an example in Section 4.3. They should be explored to form the summary as well. Since the search space for summarization is extremely large, we must explicitly address the tradeoff between exploration and exploitation for fast learning, which is an active research area in reinforcement learning and applications (Pan et al., 2019a,b). In our work, we find the use of ϵ-greedy with stochastic policy works well enough to encourage exploration. Specifically, with a probability of $1 - \epsilon$, the agent chooses the sentence following the current policy, i.e., to sample an index $a_t \in [1, N]$ from the multinomial distribution with sentence affinities $\{\mu_1, \mu_2, \ldots, \mu_N\}$ as probabilities. Otherwise, with a small probability of ϵ, the agent randomly picks one available sentence as an exploration. Note that such exploration is only used during training.

2.3.3 Termination Mechanism

In HER, we propose a termination mechanism that is independent on future rewards to make our model flexible in extracting summary with various numbers of sentences. This mechanism is defined as follows

$$\text{Done} \sim \text{Bernoulli}(\min(\frac{\mu_{\min}}{\mu_{\max}}, 1 - \mu_{\max})), \quad (6)$$

where $\mu_{\max}$ and $\mu_{\min}$ denotes the maximal and minimal value in $\boldsymbol{\mu}$ for all the remained sentences, respectively. Thus Done $= 1$ terminates the sentence extraction when there is no key sentences left. With this mechanism, the agent will stop extraction with high probability as long as the differences among remaining affinities are small enough or the remaining sentence affinities are very low.

2.4 Training

After the agent sequentially takes an action a_t until terminated, we can derive an summary induced by a out of a document D. Then the agent would receive a reward $R(\text{SUM}; G)$ where G is the gold-standard summary of D. $R(\text{SUM}; G)$ is computed

by the average of three variants of ROUGE (Lin, 2004). To balance precision and recall, we use F-score here,

$$R(\text{SUM}; G) = \frac{1}{3}(\text{ROUGE-1}_f(\text{SUM}; G) + \text{ROUGE-2}_f(\text{SUM}; G) + \text{ROUGE-L}_f(\text{SUM}; G)). \quad (7)$$

We represent the whole extractive neural network as $p_\theta(\cdot|D)$ containing the encoder in rough reading and the decoder in careful reading. The goal of our model is to find parameters θ of p_θ to produce high-quality summary and maximize the rewards (c.f. Eq. (8)). But we cannot obtain gradient to maximize Eq. (8) with gradient ascent as it is discretely sampled. So we use the likelihood ratio gradient estimator, also known as REINFORCE (Williams, 1992; Sutton et al., 2000), to acquire the gradient by Eq. (9).

We use $Q(D)$ in Eq. (10) to construct $p_\theta(a|D)$ following Dong et al. (2018), where $z(D) = \sum_t \mu_t(D)$ and ϵ is the exploration probability of the ϵ-greedy denoted in Sec. 2.3.2. M is the number of extracted sentences this is determined jointly by the termination mechanism and the document context. $Q(D)^{\frac{1}{M}}$ is adopted to present $p_\theta(a|D)$ to avoid extracting fewer or more sentences when maximizing the objective function. Hence, $\bigtriangledown_\theta \text{log} p_\theta(a|D)$ in Eq. (9) can be easily computed.

$$J(\theta) = E[R(\text{SUM}; G)] \quad (8)$$

$$\bigtriangledown_\theta J(\theta) = E[\bigtriangledown_\theta \text{log} p_\theta(a|D) R(\text{SUM}; G)] \quad (9)$$

$$Q(D) = \prod_{j=1}^{M} \left(\frac{\epsilon}{N-j+1} + \frac{(1-\epsilon)\mu_{a_j}(D)}{z(D) - \sum_{k=1}^{j-1} \mu_{a_k}(D)}\right) \quad (10)$$

However, the exact document distribution is unknown and we cannot evaluate the expected value in Eq. (9). So we use sampling to estimate it instead. Given a document-summary pair (D, G), our HER samples B summaries induced by $a^1, \ldots, a^B$ from $p_\theta(\cdot|D)$ and obtain all the gradients, then the average value is considered as the estimation. As sample-based gradient estimate may have high variance, we use a baseline for variance reduction. The gradient of the objective function is finally represented as,

$$\bigtriangledown_\theta J(\theta) \approx \frac{1}{B} \sum_{b=1}^{B} \bigtriangledown_\theta \text{log} p_\theta(a^b|D)(R(a^b, G) - \bar{r}) \quad (11)$$

where we choose self-critical reinforcement learning to acquire the baseline $\bar{r}$ following Ranzato et al. (2015); Rennie et al. (2017); Paulus et al. (2017); Dong et al. (2018) computed by greedy encoding $\bar{r} = R(a_{greedy}; G)$. More concretely, $a_{greedy} = \text{argmax} p_\theta(a|D)$ and this baseline satisfies that the probability of a sampled sequence would be increased when the summary it induces is better than what is obtained by greedy decoding. The procedure of HER is shown in Algorithm 1.

3 Experiment Settings

In this section we present our experimental setup for evaluating the performance of the proposed HER, including the datasets, evaluation protocol, baselines and implementation details.

Datasets: We evaluate our models on three datasets: the CNN, the DailyMail and the combined CNN/DailyMail (Hermann et al., 2015; Nallapati et al., 2016). We also use the standard splits of Hermann et al. (2015) for training, validation, and test ($90,266/1,220/1,093$ documents for CNN and $196,961/12,148/10,397$ for DailyMail) with the same setting in See et al. (2017).

Evaluation: We evaluate summarization quality using F_1 ROUGE (Lin, 2004) including unigram and bigram overlap (ROUGE-1 and ROUGE-2) to assess informativeness and the longest common subsequence (ROUGE-L) to assess fluency with the reference summaries. We obtain ROUGE scores using a faster python im-

plementation[1] for training and evaluation, and the standard pyrouge package[2] for test following Dong et al. (2018).

Baselines: We compare our proposed HER against four kinds of extractive methods: (1) Lead-3 model simply selects the first three sentences. (2) NN-SE (Cheng and Lapata, 2016) and SummaRuNNer (Nallapati et al., 2017) are sequence labeling task and trained with cross-entropy loss. (3) Refresh (Narayan et al., 2018), DQN (Yao et al., 2018) and RNES (Wu and Hu, 2018) extract summary via reinforcement learning. (4) BANDITSUM (Dong et al., 2018) considers the extractive summarization as a contextual bandit but fails to simulate human reading recognition process.

Implementation Details: We initialize word embeddings with 100-dimension Glove embeddings (Pennington et al., 2014). In rough reading, the encoder is hierarchical and each layer is a two-stacked BiLSTM with a hidden size of 200. Therefore, sentence vectors and the document representation $\bar{S}$ have a dimension of 400. For the variant CNN, we adopt filter windows H in $\{1, 2, 3\}$ with 100 feature maps each and generate $K = 3$ local representations for each document. In careful reading, we set $\epsilon = 0.1$ for bandit policy. We also bound the minimum and maximum number of selected sentence to be 1 and 10 for termination mechanism. During training, we use the optimizer Adam (Kingma and Ba, 2014) with a learning rate of 10^{-5}, beta parameters as $(0, 0.999)$ and a weight decay of 10^{-6} to maximize the objective function following Dong et al. (2018). We employ gradient clipping of 1 for regularization and sample $B = 20$ times for each document. We train our model within two epochs. Note that we choose the whole document as the final summary if the document length is less than 3 sentences as the local features cannot be obtained through the CNN-based network.

4 Experimental Results

4.1 Quantitative Analysis

We first report the ROUGE metrics on the combined CNN/DailyMail test sets in Table 1 and the separate results in Table 2. We can get several observations from these two tables.

[1] https://github.com/pltrdy/rouge

[2] Pyrouge is a Python package. We compute all ROUGE scores with parameters "-a -c 95 -m -n 4 -w 1.2." Refer to https://pypi.python.org/pypi/pyrouge/0.1.3

BANDITSUM	**30.7**	**11.6**	27.4	42.1	18.9	38.3
HER	**30.7**	11.5	**27.5**	**42.7**	**19.0**	**38.5**

Table 2: Results of the test sets on the CNN and DailyMail datasets separately.

Firstly, our model generally performs the best and even surpasses 42 on ROUGE-1 score on the combined CNN/DailyMail dataset. It also shows better results on the separate datasets. We argue that global and local features from rough reading can help extract summaries by capturing deep contextual relations, and the designed structure in careful reading makes it more flexible in selecting sentence sets. Hence a two-stage framework based on the human's reading cognition is more appropriate for extractive summarization.

Secondly, directly optimizing the evaluation metric by combining cross-entropy loss with rewards may improve the extractive results. RL-based methods, Refresh (Narayan et al., 2018) and RNES (Wu and Hu, 2018), perform better than the sequence labeling methods like SummaRuNNer (Nallapati et al., 2017). BANDITSUM (Dong et al., 2018) generally performs better than the other baselines, and it reports that framing the extractive summarization based on contextual bandit is more suitable than sequential labeling setting and also has more search space than other RL-based methods (Narayan et al., 2018; Yao et al., 2018; Wu and Hu, 2018).

4.2 Ablation Test

Next, we conduct ablation test by removing the modules of the proposed HER step by step. Firstly, we replace the automatic termination mechanism with a fixed extracting strategy that always selects

Model	ROUGE		
	R1	R2	RL
HER	**42.3**	**18.9**	**37.9**
HER-3	42.0	18.5	37.6
HER-3 w/o policy	41.7	18.3	37.1
HER-3 w/o policy&L	41.2	18.4	37.0
HER-3 w/o policy&F	40.6	18.2	36.9

Table 3: The results of ablation test on the test split of the combined CNN/DailyMail dataset. L and F are short for local net and rough reading.

three sentences for every document and we present the model as HER-3. Based on HER-3, we also remove bandit policy, local net, general net gradually, and denote them as HER-3 w/o policy, HER-3 w/o policy & local net and HER-3 w/o policy & rough reading individually. The results are reported in Table 3 and it proves the effectiveness of each proposed module. Firstly, HER constructed with an automatic termination mechanism is more flexible and reliable in extracting various numbers of sentences varying different documents. Secondly, HER use ϵ-greedy to select sentences in order to raise the exploration chances on discovering important but easily ignored information. Thirdly, general cognition from rough reading process is useful in extractive summarizarion.

4.3 A Closer Look

To verify whether our proposed HER can simulate human beings' reading cognitive process, and whether such simulation are inherently helpful on extractive summarization, we conduct extensive evaluations and try to answer the following three questions.

(1) Can CNN-based network extract local features of different paragraphs?

In Figure 3, we report the distribution of selected sentences' positions on our proposed model HER, BANDITSUM and HER w/o Local Net. We test each model at 10k, 50k, 100k training steps. It shows that all the three models can focus on different parts of the context to form summary at first and BANDITSUM performs the best after training 10k steps. However, with training steps growing, BANDITSUM and HER w/o Local begin to prefer earlier sentences. HER, on the other hand, can focus on various paragraphs and extract information from different parts of the texts with constant training. The contextual bandit (CB) based frameworks seems to be able to attend on various parts of the contexts to some degree in the beginning.

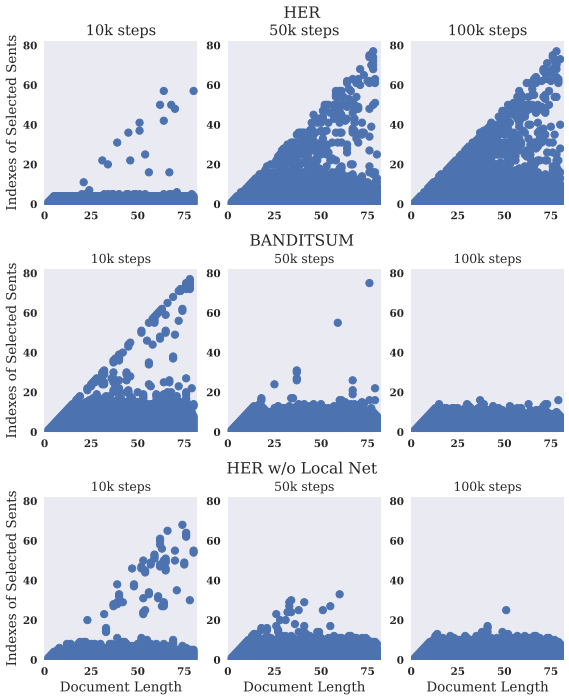

Figure 3: The statistics of model HER, BANDITSUM (Dong et al., 2018), HER w/o Local Net on the selected sentences' indexes varying different document lengths. This is reported on the documents the lengths of which are all less than 80 on the test split.

However, with constant training, both BANDITSUM and HER w/o Local start to focus on earlier sentences due to the nature that sentences similar to the main idea usually lie on the head of the text. As our proposed HER is equipped with a variant CNN to extract local features, our model can focus on gist of paragraphs rather than only the first several sentences. It also encourages the exploration on extracting information from various positions more flexibly.

(2) Can the proposed bandit policy discover low-score but easily ignored information?

To answer this question, we demonstrate a detailed case on sentence selection in Figure 4. We observe that although the fourth sentence has a high affinity, it should not be included in the summary since its meaning is close to the third sentence which has already been extracted. Instead, the 13th sentence is supposed to be selected though it has low affinity. Since our HER adopts the ϵ-greedy policy, it can explore such sentence and extract it out correctly.

(3) Can HER extract varied but proper numbers of sentences?

We answer this question by drawing the fre-

Index	Sentence	Affinity	HER	HER w/o policy
2	Two spotted leopards, two Macaque monkeys and a brown bear will be returned to Marian Thompson…	0.873	yes	yes
3	He set off a wide scare in October when he released 50 potentially dangerous animals from his farm before shooting himself.	0.872	yes	yes
4	Of the 50 animals Thompson released, 48 were killed by law enforcement, while two primates were killed by the other animals, zoo officials said.	0.767	**no**	**yes**
13	State officials have no legal power to inspect the cages before the animals are returned…	0.297	**yes**	**no**

Figure 4: A case on sentence selection of HER and HER w/o policy. The article is from CNN dataset. The highlighted indices indicate the corresponding sentences which should be extracted as summary.

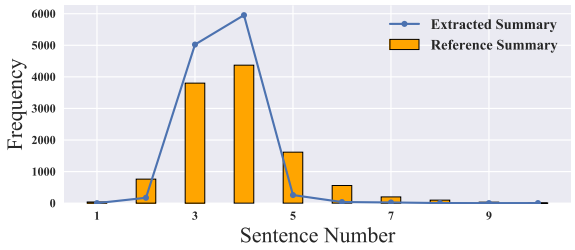

Figure 5: The statistics on extracted sentence number of our model. Frequency is the number of documents.

quency distribution of extracted sentence numbers by our model on the test set of combined CNN/DailyMail, and Figure 5 exhibits the results. We observe that the frequency distribution of extracted sentence number is basically similar to that of the gold-standard summary. Compared with BANDITSUM which extracts fixed number of sentences, our model shows more flexibility and extensibility on extractive summarization.

4.4 Human Evaluation

Lastly, we conduct a qualitative evaluation. Following Wu and Hu (2018), we randomly sample 50 documents from the test set on the combined CNN/DailyMail dataset and ask three volunteers to evaluate the summaries extracted by HER w/o Dec_2, HER w/o Local Net, BANDITSUM and HER, respectively. HER w/o Dec_2 only uses Eq. (3) to compute sentence affinities without inhibiting redundant sentences. For each document-summary pair, they are asked to rank the output of each system on three aspects, namely overall quality, coverage and non-redundancy. Notice that the best one will be marked rank 1 and so on, and two system would be ranked the same if their extracted summaries are identical. We report the average results in Table 4 and it shows that our HER is leading than BANDITSUM on overall quality and coverage. Additionally, HER w/o Dec_2 performs the worst on non-redundancy as it does not specialize these unselected sentences which are similar to already extracted ones. Furthermore, HER w/o Local Net takes on bad performance on coverage because the local features can focus on paragraphical messages and help to refine thorough information.

Model	Overall	Coverage	Non-Redundancy
HER w/o Dec_2	2.88	2.81	2.81
HER w/o L	3.02	2.96	2.75
BANDITSUM	2.06	2.07	**1.91**
HER	**1.81**	**1.75**	1.97

Table 4: Average rank of human evaluation in terms of overall performance, coverage, and non-redundancy. L is short for local Net. Lower score is better.

5 Related Work

Extractive Text Summarization Researchers have developed many statistical methods for automatic extractive summarization. Traditional methods learn to score each sentence dependently (Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Wong et al., 2008). Recently neural network based extractive methods (Cheng and Lapata, 2016; Nallapati et al., 2017; Feng et al., 2018; Shi et al., 2018) usually consider extractive summarization as sequence labeling tasks and aim to minimize the cross-entropy objective function. Narayan et al. (2017) utilizes side information to help sentence classifier while Yasunaga et al. (2017) computes the salience of each sentence for selection with graph convolutional networks. In addition, reinforcement learning based methods (Wu and Hu, 2018; Narayan et al., 2018; Yao et al., 2018) have been proposed to directly optimize the evaluation metric ROUGE by combining cross-entropy loss with rewards from policy gradient reinforcement learning. Dong et al. (2018) considered extractive summarization as a contextual bandit and it performs well especially when good summary sentences appear late in the source document. Recently, Nallapati et al. (2017); Chen and Bansal (2018); Hsu et al. (2018) propose unified models and combine the advantages of both extractive and abstractive methods.

Human Reading-inspired Strategy in NLP Recently, several pioneer researches began to study how to adapt human reading cognition process, usually including pre-reading, reading and post-reading (Avery and Graves, 1997; Saricoban,

2002; Toprak and Almacıoğlu, 2009; Pressley and Afflerbach, 2012), into various NLP-related applications. For example, Li et al. (2018) solved document-based question answering and by simulating human being's reading strategy. Luo et al. (2018, 2019) utilized the prior knowledge of human reading to solve sub-tasks in sentiment analysis. Song et al. (2017, 2018) enhanced word embeddings in a similar way. Yang et al. (2019) applied it for abstractive summarization, Zheng et al. (2019) simulated human behavior for reading comprehension, and Lei et al. (2019) utilized human-like semantic cognition for aspect-level sentiment classification. In this paper, we attempt to perform extractive summarization under the inspiration of human reading recognition.

6 Conclusion

Inspired by the reading cognition of human beings, we propose HER, a two-stage method, to mimic how people extract summaries. The whole learning process is formulated as a contextual bandit trained with policy gradient reinforcement learning. In rough reading, two neural networks are taken to encode coarse-grained information. In careful reading, repeatedly reading are conducted to select fine-grained sentences as summary. Experiments on two real-world datasets demonstrate that our proposed model can significantly outperform the state-of-the-art extractive methods on summary quality, coverage and non-redundancy.

Abstract

We propose a contrastive attention mechanism to extend the sequence-to-sequence framework for abstractive sentence summarization task, which aims to generate a brief summary of a given source sentence. The proposed contrastive attention mechanism accommodates two categories of attention: one is the conventional attention that attends to relevant parts of the source sentence, the other is the opponent attention that attends to irrelevant or less relevant parts of the source sentence. Both attentions are trained in an opposite way so that the contribution from the conventional attention is encouraged and the contribution from the opponent attention is discouraged through a novel softmax and softmin functionality. Experiments on benchmark datasets show that, the proposed contrastive attention mechanism is more focused on the relevant parts for the summary than the conventional attention mechanism, and greatly advances the state-of-the-art performance on the abstractive sentence summarization task. We release the code at https://github.com/travel-go/Abstractive-Text-Summarization.

1 Introduction

Abstractive sentence summarization aims at generating concise and informative summaries based on the core meaning of source sentences. Previous endeavors tackle the problem through either rule-based methods (Dorr et al., 2003) or statistical models trained on relatively small scale training corpora (Banko et al., 2000). Following its successful applications on machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), the sequence-to-sequence framework is also applied on the abstractive sentence summarization task using large-scale sentence summary corpora (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016), obtaining better performance compared to the traditional methods.

One central component in state-of-the-art sequence to sequence models is the use of attention for building connections between the source sequence and target words, so that a more informed decision can be made for generating a target word by considering the most relevant parts of the source sequence (Bahdanau et al., 2015; Vaswani et al., 2017). For abstractive sentence summarization, such attention mechanisms can be useful for selecting the most salient words for a short summary, while filtering the negative influence of redundant parts.

We consider improving abstractive summarization quality by enhancing target-to-source attention. In particular, a contrastive mechanism is taken, by encouraging the contribution from the conventional attention that attends to relevant parts of the source sentence, while at the same time penalizing the contribution from an opponent attention that attends to irrelevant or less relevant parts. Contrastive attention was first proposed in computer vision (Song et al., 2018a), which is used for person re-identification by attending to person and background regions contrastively. To our knowledge, we are the first to use contrastive attention for NLP and deploy it in the sequence-to-sequence framework.

In particular, we take Transformer (Vaswani et al., 2017) as the baseline summarization model, and enhance it with a proponent attention module and an opponent attention module. The former acts as the conventional attention mechanism, while the latter can be regarded as a dual module to the former, with similar weight calculation structure, but using a novel softmin function to discourage contributions from irrelevant or less relevant words.

To our knowledge, we are the first to investigate

* Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3044–3053, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Transformer as a sequence to sequence summarizer. Results on three benchmark datasets show that it gives highly competitive accuracies compared with RNN and CNN alternatives. When equipped with the proposed contrastive attention mechanism, our Transformer model achieves the best reported results on all data. The visualization of attentions shows that through using the contrastive attention mechanism, our attention is more focused on relevant parts than the baseline. We release our code at XXX.

2 Related Work

Automatic summarization has been investigated in two main paradigms: the extractive method and the abstractive method. The former extracts important pieces of source document and concatenates them sequentially (Jing and McKeown, 2000; Knight and Marcu, 2000; Neto et al., 2002), while the latter grasps the core meaning of the source text and re-state it in short text as abstractive summary (Banko et al., 2000; Rush et al., 2015). In this paper, we focus on abstractive summarization, and especially on abstractive sentence summarization.

Previous work deals with the abstractive sentence summarization task by using either rule based methods (Dorr et al., 2003), or statistical methods utilizing a source-summary parallel corpus to train a machine translation model (Banko et al., 2000), or a syntax based transduction model (Cohn and Lapata, 2008; Woodsend et al., 2010).

In recent years, sequence-to-sequence neural framework becomes predominant on this task by encoding long source texts and decoding into short summaries together with the attention mechanism. RNN is the most commonly adopted and extensively explored architecture (Chopra et al., 2016; Nallapati et al., 2016; Li et al., 2017). A CNN-based architecture is recently employed by Gehring *et al.* (2017) using ConvS2S, which applies CNN on both encoder and decoder. Later, Wang *et al.* (2018) build upon ConvS2S with topic words embedding and encoding, and train the system with reinforcement learning.

The most related work to our contrastive attention mechanism is in the field of computer vision. Song *et al.* (2018a) first propose the contrastive attention mechanism for person re-identification. In their work, based on a pre-provided person and background segmentation, the two regions are contrastively attended so that they can be easily discriminated. In comparison, we apply the contrastive attention mechanism for sentence level summarization by contrastively attending to relevant parts and irrelevant or less relevant parts. Furthermore, we propose a novel softmax softmin functionality to train the attention mechanism, which is different to Song *et al.* (2018a), who use mean squared error loss for attention training.

Other explorations with respect to the characteristics of the abstractive summarization task include copying mechanism that copies words from source sequences for composing summaries (Gu et al., 2016; Gulcehre et al., 2016; Song et al., 2018b), the selection mechanism that elaborately selects important parts of source sentences (Zhou et al., 2017; Lin et al., 2018), the distraction mechanism that avoids repeated attention on the same area (Chen et al., 2016), and the sequence level training that avoids exposure bias in teacher forcing methods (Ayana et al., 2016; Li et al., 2018; Edunov et al., 2018). Such methods are built on conventional attention, and are orthogonal to our proposed contrastive attention mechanism.

3 Approach

We use two categories of attention for summary generation. One is the conventional attention that attends to relevant parts of source sentence, the other is the opponent attention that contrarily attends to irrelevant or less relevant parts. Both categories of attention output probability distributions over summary words, which are jointly optimized by encouraging the contribution from the conventional attention and discouraging the contribution from the opponent attention.

Figure 1 illustrates the overall networks. We use Transformer architecture as our basis, upon which we build the contrastive attention mechanism. The left part is the original Transformer. We derive the opponent attention from the conventional attention which is the encoder-decoder attention of the original Transformer, and stack several layers on top of the opponent attention as shown in the right part of Figure 1. Both parts contribute to the summary generation by producing probability distributions over the target vocabulary, respectively. The left part outputs **the conventional probability** based on the conventional attention as the original Transformer does, while the right part outputs **the opponent probability** based on the opponent

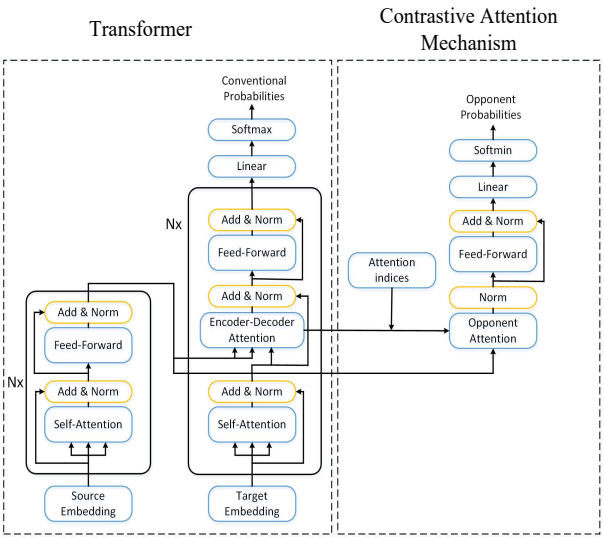

Figure 1: Overall networks. The left part is the original Transformer. The right part that takes the opponent attention as bottom layer fulfils the contrastive attention mechanism.

attention. The two probabilities in Figure 1 are jointly optimized in a novel way as explained in Section 3.3.

3.1 Transformer for Abstractive Sentence Summarization

Transformer is an attention network based sequence-to-sequence architecture (Vaswani et al., 2017), which encodes the source text into hidden vectors and decodes into the target text based on the source side information and the target generation history. In comparison to the RNN based architecture and the CNN based architecture, both the encoder and the decoder of Transformer adopt attention as main function.

Let X and Y denote the source sentence and its summary, respectively. Transformer is trained to maximize the probability of Y given X: $\prod_i P_c(y_i|y_1^{i-1}, X)$, where $P_c(y_i|y_1^{i-1}, X)$ is the conventional probability of the current summary word y_i given the source sentence and the summary generation history. P_c is computed based on the attention mechanism and the stacked deep layers as shown in the left part of Figure 1.

Attention Mechanism

Scaled dot-product attention is applied in Transformer:

$$\text{attention}(Q, K, V) = \text{softmax}(\frac{QK^{\text{T}}}{\sqrt{d_k}})V \quad (1)$$

where Q, K, V denotes query vector, key vectors, and value vectors, respectively. d_k denotes the dimension of one vector of K. Softmax function outputs the attention weights distributed over V. $\text{attention}(Q, K, V)$ is a vector of weighted sum of elements of V, and represents current context information.

We focus on the encoder-decoder attention, which builds the connection between source and target by informing the decoder which area of the source text should be attended to. Specifically, in the encoder-decoder attention, Q is the single vector coming from the current position of the decoder, K and V are the same sequence of vectors that are the outcomes of the encoder at all source positions. Softmax function distributes the **attention weights** over the source positions.

The attentions in Transformer adopts the multi-head implementation, in which each head computes attention as Equation (1) but with smaller Q, K, V whose dimension is $1/h$ times of their original dimension respectively. The attentions from h heads are concatenated together and linearly projected to compose the final attention. In this way, multi-head attention provides a multi-view of attention behavior beneficial for the final performance.

Deep Layers

The "N×" plates in Figure 1 stands for the stacked N identical layers. On the source side, each layer of the stacked N layers contains two sublayers: the self-attention mechanism, and the fully connected feed-forward network. Each sublayer employs residual connection that adds input to outcome of sublayer, then layer normalization is employed on the outcome of the residual connection.

On the target summary side, each layer contains an additional sublayer of the encoder-decoder attention between the self-attention sublayer and the feed-forward sublayer. At the top of the decoder, the softmax layer is applied to convert the decoder output to summary word generation probabilities.

3.2 Contrastive Attention Mechanism

3.2.1 Opponent Attention

As illustrated in Figure 1, the opponent attention is derived from the conventional encoder-decoder attention. Since the multi-head attention is employed in Transformer, there are N×h heads in total in the conventional encoder-decoder attention, where N denotes the number of layers, h denotes

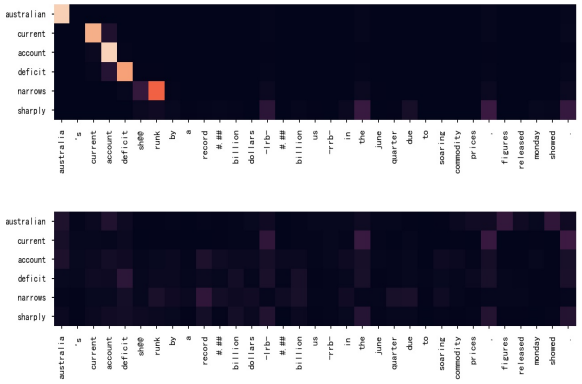

Figure 2: Heatmaps of two sampled heads from the conventional encoder-decoder attention. (a) is of the fifth head of the third layer, and (b) is of the fifth head of the first layer.

the number of heads in each layer. These heads exhibit diverse attention behaviors, posing a challenge of determining which head to derive the opponent attention, so that it attends to irrelevant or less relevant parts.

Figure 2 illustrates the attention weights of two sampled heads. The attention weights in (a) well reflect the word level relevant relation between the source sentence and the target summary, while attention weights in (b) do not. We find that such behavior characteristic of each head is fixed. For example, head (a) always exhibits the relevant relation across different sentences and different runs. Based on depicting heatmaps of all heads for a few sentences, we choose the head that corresponds well to the relevant relation between source and target to derive the opponent attention [1].

Specifically, let α_c denote the conventional encoder-decoder attention weights of the head which is used for deriving the opponent attention:

$$\alpha_c = \mathrm{softmax}(\frac{qk^{\mathrm{T}}}{\sqrt{d_k}}) \quad (2)$$

where q and k are from the head same to that of α_c. Let α_o denote the opponent attention weights. It is obtained through the opponent function applied on α_c followed by the softmax function:

$$\alpha_o = \mathrm{softmax}(\mathrm{opponent}(\alpha_c)) \quad (3)$$

The opponent function in Equation (3) performs a masking operation, which finds the maximum weight in α_c, and replaces it with the negative infinity value, so that the softmax function outputs zero given the negative infinity value input. Then the maximum weight in α_c is set zero in α_o after the opponent and softmax functions. In this way, the most relevant part of the source sequence, which receives maximum attention in the conventional attention weights α_c, is masked and neglected in α_o. Instead, the remaining less relevant or irrelevant parts are extracted into α_o for the following contrastive training and decoding.

We also tried other methods to calculate the opponent attention weights, such as $\alpha_o = \mathrm{softmax}(1 - \alpha_c)$ (Song et al., 2018a) [2] or $\alpha_o = \mathrm{softmax}(1/\alpha_c)$, which aims to make α_o contrary to α_c, but they underperform the masking opponent function on all benchmark datasets. So we present only the masking opponent in the following sections.

After α_o is obtained via Equation (3), the opponent attention is: $\mathrm{attention}_o = \alpha_o v$, where v is from the head same to that of q and k in computing α_c.

Compared to the conventional attention $\mathrm{attention}_c$, which summarizes current relevant context, $\mathrm{attention}_o$ summarizes current irrelevant or less relevant context. They constitute a contrastive pair, and contribute together for the final summary word generation.

3.2.2 Opponent Probability

The opponent probability $P_o(y_i|y_1^{i-1}, X)$ is computed by stacking several layers on top of $\mathrm{attention}_o$, and a softmin layer in the end as shown in the right part of Figure (1). In particular,

$$z_1 = \mathrm{LayerNorm}(\mathrm{attention}_o) \quad (4)$$
$$z_2 = \mathrm{FeedForward}(z_1) \quad (5)$$
$$z_3 = \mathrm{LayerNorm}(z_1 + z_2) \quad (6)$$
$$P_o(y_i|y_1^{i-1}, X) = \mathrm{softmin}(Wz_3) \quad (7)$$

where W is the matrix of the linear projection sublayer.

$\mathrm{attention}_o$ contributes to P_o via Equation (4-7) step by step. The LayerNorm and FeedForward layers with residual connection is similar to the

[1] Given manual alignments between source and target of sampled sentence-summary pairs, we select the head that has the lowest alignment error rate (AER) of its attention weights.

[2] Song *et al.* (2018a) directly let $\alpha_o = 1 - \alpha_c$ in extracting background features for person re-identification in computer vision. We have to add softmax function since the attention weights must be normalized to one in sequence-to-sequence framework.

original Transformer, while a novel softmin function is introduced in the end to invert the contribution from attention_o:

$$\text{softmin}(v_i) = \frac{e^{(-v_i)}}{\sum^j e^{(-v_j)}} \quad (8)$$

where $v = Wz_3$, i.e., the input vector to the softmin function in Equation (7). Softmin normalizes v so that scores of all words in the summary vocabulary sum to one. We can see that the bigger the v_i, the smaller the $P_{o,i}$ is.

Softmin functions contrarily to softmax. As a result, when we try to maximize $P_o(y_i = y|y_1^{i-1}, X)$, where y is the gold summary word, we effectively search for an appropriate attention_o to generate the lowest v_g, where g is the index of y in v. It means that the more irrelevant is attention_o to the summary, the lower the v_g can be obtained, resulting in higher P_o.

3.3 Training and Decoding

During training, we jointly maximize the conventional probability P_c and the opponent probability P_o:

$$\mathcal{J} = \log(P_c(y_i|y_1^{i-1}, X) + \lambda \log(P_o(y_i|y_1^{i-1}, X) \quad (9)$$

where λ is the balanced weight. The conventional probability is computed as the original Transformer does, basing on sublayers of feed-forward, linear projection, and softmax stacked over the conventional attention as illustrated in the left part of Figure 1. The opponent probability is based on similar sublayers stacked over the opponent attention, but with softmin as the last sublayer as illustrated in the right part of Figure 1.

Due to the contrary properties of softmax and softmin, jointly maximizing P_c and P_o actually maximizes the contribution from the conventional attention for summary word generation, while at the same time minimizes the contribution from the opponent attention[3]. In other words, the training objective is to let the relevant part attended by attention_c contribute more to the summarization, while let the irrelevant or less relevant parts attended by attention_o contribute less.

During decoding, we aim to find maximum $\mathcal{J}$ of Equation (9) in the beam search process.

4 Experiments

We conduct experiments on abstractive sentence summarization benchmark datasets to demonstrate the effectiveness of the proposed contrastive attention mechanism.

4.1 Datasets

In this paper, we evaluate our proposed method on three abstractive text summarization benchmark datasets. First, we use the annotated Gigaword corpus and preprocess it identically to Rush *et al.* (2015), which results in around 3.8M training samples, 190K validation samples and 1951 test samples for evaluation. The source-summary pairs are formed through pairing the first sentence of each article with its headline. We use DUC-2004 as another English data set only for testing in our experiments. It contains 500 documents, each containing four human-generated reference summaries. The length of the summary is capped at 75 bytes. The last data set we used is a large corpus of Chinese short text summarization (LCSTS) (Hu et al., 2015), which is collected from the Chinese microblogging website Sina Weibo. We follow the data split of the original paper, with 2.4M source-summary pairs from the first part of the corpus for training, 725 pairs from the last part with high annotation score for testing.

4.2 Experimental Setup

We employ Transformer as our basis architecture[4]. Six layers are stacked in both the encoder and decoder, and the dimensions of the embedding vectors and all hidden vectors are set 512. The inner layer of the feed-forward sublayer has the dimensionality of 2048. We set eight heads in the multi-head attention. The source embedding, the target embedding and the linear sublayer are shared in our experiments. Byte-pair encoding is employed in the English experiment with a shared source-target vocabulary of about 32k tokens (Sennrich et al., 2015).

Regarding the contrastive attention mechanism, the opponent attention is derived from the head

[3] We also tried replacing softmin in Equation (7) with softmax, and correspondingly setting the training objective as maximizing $\mathcal{J} = \log(P_c) - \lambda \log(P_o)$, but this method failed to train because P_o becomes too small during training, and results in negative infinity value of $\log(P_o)$ that hampers the training. In comparison, softmin and the training objective of Equation (9) do not have such problem, enabling the effective training of the proposed network.

Table 1: ROUGE scores on the English evaluation sets of both Gigaword and DUC2004. On Gigaword, the full-length F-1 based ROUGE scores are reported. On DUC2004, the recall based ROUGE scores are reported. "-" denotes no score is available in that work.

whose attention is most synchronous to word alignments of the source-summary pair. In our experiments, we select the fifth head of the third layer for deriving the opponent attention in the English experiments, and select the second head of the third layer in the Chinese experiments. All dimensions in the contrastive architecture are set 64. The λ in Equation (9) is tuned on the development set in each experiment.

During training, we use the Adam optimizer with $\beta 1 = 0.9$, $\beta 2 = 0.98$, $\varepsilon = 10^{-9}$. The initial learning rate is 0.0005. The inverse square root schedule is applied for initial warm up and annealing (Vaswani et al., 2017). During training, we use a dropout rate of 0.3 on all datasets.

During evaluation, we employ ROUGE (Lin, 2004) as our evaluation metric. Since standard Rouge package is used to evaluate the English summarization systems, we also follow the method of Hu *et al.* (2015) to map Chinese words into numerical IDs in order to evaluate the performance on the Chinese data set.

4.3 Results

4.3.1 English Results

The experimental results on the English evaluation sets are listed in Table 1. We report the full-length F-1 scores of ROUGE-1 (R-1), ROUGE2 (R-2), and ROUGE-L (R-L) on the evaluation set of the annotated Gigaword, while report the recall-based scores of the R-1, R-2, and R-L on the evaluation set of DUC2004 to follow the setting of the previous works.

The results of our works are shown at the bottom of Table 1. The performances of the related works are reported in the upper part of Table 1 for comparison. ABS and ABS+ are the pioneer works of using neural models for abstractive text summarization. RAS-Elman extends ABS/ABS+ with attentive CNN encoder. words-lvt5k-1sent uses large vocabulary and linguistic features such as POS and NER tags. RNN_{MRT}, Actor-Critic, StructuredLoss are sequence-level training methods to overcome the problem of the usual teacher-forcing methods. DRGD uses recurrent latent random model to improve summarization quality. FactAware generates summary words conditioned on both the source text and the fact descriptions extracted from OpenIE or dependencies. Besides the above RNN-based related works, CNN-based architectures of ConvS2S and $\text{ConvS2S}_{\text{ReinforceTopic}}$ are included for comparison.

Table 1 shows that we build a strong baseline using Transformer alone which obtains the state-of-the-art performance on Gigaword evaluation set, and obtains comparable performance to the state-of-the-art on DUC2004. When we introduce the contrastive attention mechanism into Transformer, it significantly improves the performance of Transformer, and greatly advances the state-of-the-art on both Gigaword evaluation set and DUC2004, as shown in the row of "Transformer+Contrastive Attention".

mances of our Transformer baseline and the integration of the contrastive attention mechanism into Transformer. We only take character sequences as source-summary pairs and evaluate the performance based on reference characters for strict comparison to the related works.

Table 2 shows that Transformer also sets a strong baseline on LCSTS that surpasses the performances of the previous works. When Transformer is equipped with our proposed contrastive attention mechanism, the performance is significantly improved and drastically advances the state-of-the-art on LCSTS.

5 Analysis and Discussion

5.1 Effect of the Contrastive Attention Mechanism on Attentions

Figure 3 shows the attention weights before and after using the contrastive attention mechanism. We depict the averaged attention weights of all heads in one layer in Figure 3a and 3b to study how it contributes to the conventional probability computation, and depict the opponent attention weights in Figure 3c to study its contribution to the opponent probability. Since we select the fifth head of the third layer to derive the opponent attention in English experiment, the studies are carried out on the third layer.

Figure 3a is from the baseline Transformer, Figure 3b is from "Transformer + ContrastiveAttention". We can see that "Transformer + ContrastiveAttention" is more focused on the source parts that are most relevant to the summary than the baseline Transformer, which scatters attention weights on summary word neighbors or even functional words such as "-lrb-" and "the". "Transformer + ContrastiveAttention" cancels such scattered attentions by using the contrastive attention mechanism.

Figure 3c depicts the opponent attention weights. They are optimized during training to generate the lowest score which is fed into softmin to get the highest opponent probability P_o. The more irrelevant to the summary word the opponent is, the lower the score can be obtained, thus resulting in higher P_o. Figure 3c shows that the attentions are formed over irrelevant parts with varied weights as the result of maximizing P_o during training.

5.2 Effect of the Opponent Probability in Decoding

We study the contribution of the opponent probability P_o by dropping it during decoding to see if it hurts the performance. Table 4 shows that dropping P_o significantly harms the performance of "Transformer + ContrastiveAtt". The performance difference between the model dropping P_o and the baseline Transformer is marginal, indicating that adding the opponent probability P_o is key for achieving the performance improvement.

5.3 Explorations on Deriving the Opponent Attention

Masking More Attention Weights for Deriving the Opponent Attention

System	Gigaword			DUC2004		
	R-1	R-2	R-L	R-1	R-2	R-L
mask maximum weight	38.72	19.09	35.82	32.22	11.04	27.59

Transformer+ContrastiveAtt	38.72	19.09	35.82
DUC2004	R-1	R-2	R-L
Transformer	31.38	10.89	27.18
Transformer+ContrastiveAtt-P_o	31.21	10.70	26.85
Transformer+ContrastiveAtt	32.22	11.04	27.59

Table 4: The effect of dropping P_o (denoted by -P_o) from Transformer+ContrastiveAtt during decoding.

In Section 3.2.1, we mask the most salient word that has the maximum weight of α_c to derive the opponent attention. In this subsection, we experimented with masking more weights of α_c by two ways: 1) masking top k weights, 2) dynamically masking. In the dynamically masking method, we order the weights from big to small at first, then go on masking two neighbors until the ratio between them is over a threshold. The threshold is 1.02 based on training and tuning on the development set.

The upper rows of Table 3 presents the performance comparison between masking maximum weight and masking more weights. It shows that masking maximum weight performs better, indicating that masking the most salient weight leaves more irrelevant or less relevant words to compute the opponent probability P_o, which is more reliable than that computed from less remaining words after masking more weights.

Selecting Non-synchronous Head or Averaged Head for Deriving the Opponent Attention

As explained in Section 3.2.1, the opponent attention is derived from the head that is most synchronous to the word alignments between source sentence and summary. We denote it "synchronous head". We also explored deriving the opponent attention from the fifth head of the first layer, which is non-synchronous to the word alignments as illustrated in Figure 2b. Its result is presented in the "non-synchronous head" row. In addition, the attention weights averaged on all heads of the third layer are used to derive the opponent attention. We denote it "averaged head".

As shown in the middle part of Table 3, both "non-synchronous head" and "averaged head" underperform "synchronous head". "non-synchronous head" performs worst, and even worse than the Transformer baseline on Gigaword. This indicates that it is better to compose the opponent attention from irrelevant parts that can be easily located in the synchronous head. "averaged head" performs slightly worse than "synchronous head", and is also slower due to the involved all heads.

5.4 Qualitative Study

Table 5 shows the qualitative results. The highlights in the baseline Transformer manifest the incorrect areas extracted by the baseline system. In contrast, the highlights in Transformer+ContrastiveAtt show that correct contents are extracted since the contrastive system distinguish relevant parts from irrelevant parts on the source side and made attending to correct areas more easily.

6 Conclusion

We proposed a contrastive attention mechanism for abstractive sentence summarization, using both the conventional attention that attends to the relevant parts of the source sentence, and a novel opponent attention that attends to irrelevant or less relevant parts for the summary word generation. Both categories of the attention constitute a contrastive pair, and we encourage contribution from the conventional attention and penalize con-

Abstract

Cross-lingual summarization (CLS) is the task to produce a summary in one particular language for a source document in a different language. Existing methods simply divide this task into two steps: summarization and translation, leading to the problem of error propagation. To handle that, we present an end-to-end CLS framework, which we refer to as Neural Cross-Lingual Summarization (NCLS), for the first time. Moreover, we propose to further improve NCLS by incorporating two related tasks, monolingual summarization and machine translation, into the training process of CLS under multi-task learning. Due to the lack of supervised CLS data, we propose a round-trip translation strategy to acquire two high-quality large-scale CLS datasets based on existing monolingual summarization datasets. Experimental results have shown that our NCLS achieves remarkable improvement over traditional pipeline methods on both English-to-Chinese and Chinese-to-English CLS human-corrected test sets. In addition, NCLS with multi-task learning can further significantly improve the quality of generated summaries. We make our dataset and code publicly available here: http://www.nlpr.ia.ac.cn/cip/dataset.htm.

1 Introduction

Given a document in one source language, cross-lingual summarization aims to produce a summary in a different target language, which can help people efficiently acquire the gist of an article in a foreign language. Traditional approaches to CLS are based on the pipeline paradigm, which either first translates the original document into target language and then summarizes the translated document (Leuski et al., 2003) or first summarizes the original document and then translates the summary into target language (Lim et al., 2004; Orasan and Chiorean, 2008; Wan et al., 2010). However, the current machine translation (MT) is not perfect, which results in the error propagation problem. Although end-to-end deep learning has made great progress in natural language processing, no one has yet applied it to CLS due to the lack of large-scale supervised dataset.

The input and output of CLS are in two different languages, which makes the data acquisition much more difficult than monolingual summarization (MS). To the best of our knowledge, no one has studied how to automatically build a high-quality large-scale CLS dataset. Therefore, in this work, we introduce a novel approach to directly address the lack of data. Specifically, we propose a simple yet effective round-trip translation strategy to obtain cross-lingual document-summary pairs from existing monolingual summarization datasets (Hermann et al., 2015; Zhu et al., 2018; Hu et al., 2015). More details can be found in Section 2 below.

Based on the dataset that we have constructed, we propose end-to-end models on cross-lingual summarization, which we refer to as Neural Cross-Lingual Summarization (NCLS). Furthermore, we consider improving CLS with two related tasks: MS and MT. We incorporate the training process of MS and MT into that of CLS under the multi-task learning framework (Caruana, 1997). Experimental results demonstrate that NCLS achieves remarkable improvement over traditional pipeline paradigm. In addition, both MS and MT can significantly help to produce better summaries.

Our main contributions are as follows:

- We propose a novel round-trip translation strategy to acquire large-scale CLS datasets from existing large-scale MS datasets. We have constructed a 370K English-to-Chinese

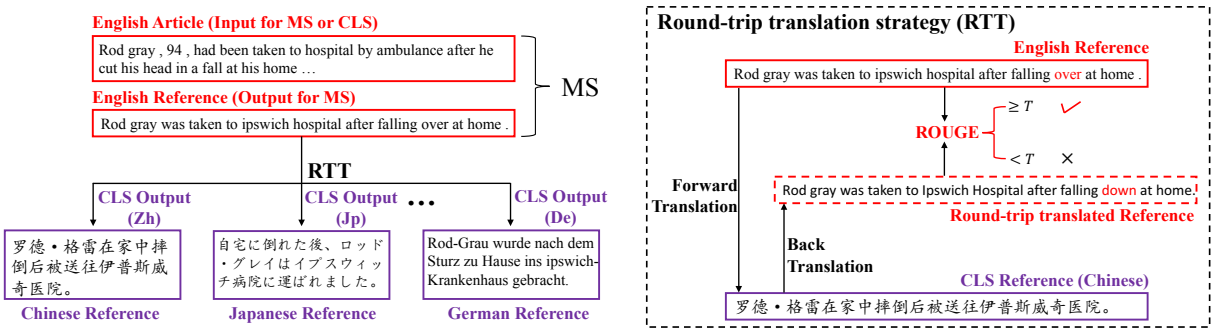

Figure 1: Overview of CLS corpora construction. Our method can be extended to many other language pairs and we focus on En2Zh and Zh2En in this paper. During RTT, we filter the sample in which ROUGE F1 score between the original reference and the round-trip translated reference is below a preset threshold T.

(En2Zh) CLS corpus and a 1.69M Chinese-to-English (Zh2En) CLS corpus.

- To train the CLS systems in an end-to-end manner, we present neural cross-lingual summarization. Furthermore, we propose to improve NCLS by incorporating MT and MS into CLS training process under multi-task learning. To the best of our knowledge, this is the first work to present an end-to-end CLS framework that trained on parallel corpora.

- Experimental results demonstrate that NCLS can achieve +4.87 ROUGE-2 on En2Zh and +5.07 ROUGE-2 on Zh2En over traditional pipeline paradigm. In addition, NCLS with multi-task learning can further achieve +3.60 ROUGE-2 on En2Zh and +0.72 ROUGE-2 on Zh2En. Our methods can be regarded as a benchmark for further NCLS studying.

2 Dataset Construction

Existing large-scale monolingual summarization datasets are automatically collected from the internet. CNN/Dailymail (Hermann et al., 2015) dataset has been collected from *CNN* and *DailyMail* websites, where the article and news highlights are treated as the input and output respectively. Similar to Hermann et al. (2015), Zhu et al. (2018) have constructed a multimodal summarization dataset MSMO where the text input and output are similar to that in CNN/Dailymail. We refer to the union set of CNN/Dailymail and MSMO as ENSUM[1]. Hu et al. (2015) introduce a large-scale corpus of Chinese short text summarization (LCSTS[2]) dataset constructed from the Chinese microblogging website *Sina Weibo*. In this section, we introduce how to construct the En2Zh and Zh2En CLS datasets based on ENSUM and LCSTS respectively.

Round-trip translation strategy. Round-trip translation[3] (RTT) is the process of translating a text into another language (forward translation), then translating the result back into the original language (back translation), using MT service[4]. Inspired by Lample et al. (2018), we propose to adopt the round-trip translation to acquire CLS dataset from MS dataset. The process of constructing our corpora is shown in Figure 1.

Taking the construction of En2Zh corpus as an example, given a document-summary pair $(D_{\text{en}}, S_{\text{en}})$, we first translate the summary S_{en} into Chinese S_{zh} and then back into English S'_{en}. The En2Zh document-summary pair $(D_{\text{en}}, S_{\text{zh}})$, which satisfies ROUGE-1$(S_{\text{en}}, S'_{\text{en}}) \geqslant T_1$ and ROUGE-2$(S_{\text{en}}, S'_{\text{en}}) \geqslant T_2$ (T_1 is set to 0.45 for English and 0.6 for Chinese respectively, and T_2 is set to 0.2 here[5]), will be regarded as a positive pair. Otherwise, the pair will be filtered. Note that there are multiple sentences in S_{en} in ENSUM, we apply the RTT to filter low-quality translated reference sentence by sentence. Once more than two-thirds of the sentences in the summary in a sample are retained, we will keep the sample. This process helps to ensure that the final compression ratio in our task does not differ too much from the actual compression ratio. Similar process is used on constructing Zh2En corpus. The ROUGE scores between Chinese sentences are calculated using Chinese characters as segmentation units.

[1]It contains 626,634 English summarization pairs.
[2]It contains 2,400,591 Chinese summarization pairs.

[5]The values are obtained by conducting a manual estimation on some samples randomly selected from two corpora.

En2ZhSum	train	valid	test	Zh2EnSum	train	valid	test
#Documents	364,687	3,000	3,000	#Documents	1,693,713	3,000	3,000
#AvgWords (S)	755.09	759.55	744.84	#AvgChars (S)	103.59	103.56	140.06
#AvgEnWords (R)	55.21	55.28	54.76	#AvgZhChars (R)	17.94	18.00	18.08
#AvgZhChars (R)	95.96	96.05	95.33	#AvgEnWords (R)	13.70	13.74	13.84
#AvgSentsWords	19.62	19.63	19.61	#AvgSentsChars	52.73	52.41	53.38
#AvgSents	40.62	41.08	40.25	#AvgSents	2.32	2.33	2.30

Table 1: Corpus statistics. **#AvgWords (S)** is the average number of English words in the source document. Each reference has a bilingual version since each reference in CLS corpus is translated from the corresponding reference in the MS corpus. **#AvgEnWords (R)** means the average number of words in English reference and **#AvgZhChars (R)** denotes the average number of characters in Chinese reference. **#AvgSentsWords** (**#AvgSentsChars**) indicates the average number of words (characters) in a sentence in the source document. **#AvgSents** refers to the average number of sentences in the source document.

Corpus Statistics. After conducting the round-trip translation strategy, we have obtained 370,759 En2Zh CLS pairs from ENSUM and 1,699,713 Zh2En CLS pairs from LCSTS. The statistics of En2Zh corpus (En2ZhSum) and Zh2En corpus (Zh2EnSum) are presented in Table 1. In order to evaluate various CLS methods more reliably, we recruit 10 volunteers to correct the reference in the test sets in two constructed corpora.

3 Approach

The traditional approaches (Section 3.1) intuitively treat CLS as a pipeline process which leads to error propagation. To handle that, we present the neural cross-lingual summarization methods (Section 3.2), which train CLS in an end-to-end manner for the first time. Due to the strong relationship between CLS, MS, and MT tasks, we propose to incorporate MS and MT into CLS training under multi-task learning (Section 3.3).

3.1 Baseline Pipeline Methods

In general, traditional CLS is composed of summarization step and translation step. The different order of these two steps leads to the following two strategies. Take En2Zh CLS as an example.

Early Translation (ETran). This strategy first translates the English document to Chinese document with machine translation. Then a Chinese summary is generated by a summarization model.

Late Translation (LTran). This strategy first summarizes the English document to a short English summary and then translates it into Chinese.

3.2 Neural Cross-Lingual Summarization

Considering the excellent text generation performance of Transformer encoder-decoder network (Vaswani et al., 2017), we implement our NCLS models entirely based on this framework in this work. As shown in Figure 2, given a set of CLS data $D = (X^{(i)}, Y^{(i)})$ where both X and Y are a sequence of tokens, the encoder maps the input document $X = (x_1, x_2, \cdots, x_n)$ into a sequence of continuous representations $z = (z_1, z_2, \cdots, z_n)$ whose size varies with respect to the source sequence length. The decoder generates a summary $Y = (y_1, y_2, \cdots, y_m)$, which is in a different language, from the continuous representations. The encoder and decoder are trained jointly to maximize the conditional probability of target sequence given a source sequence:

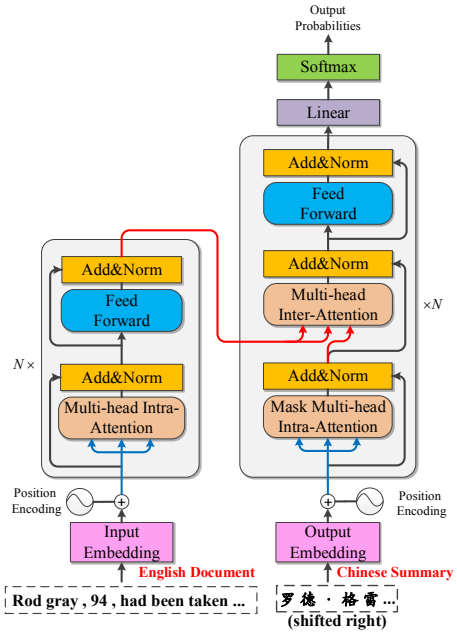

Figure 2: Transformer-based NCLS models (TNCLS).

$$L_\theta = \sum_{t=1}^{N} \log \mathrm{P}(\mathrm{y_t} | \mathrm{y_{<t}}, \mathrm{x}; \theta) \quad (1)$$

Transformer is composed of stacked encoder and decoder layers. Consisting of two blocks, the

encoder layer is a self-attention block followed by a position-wise feed-forward block. Despite the same architecture as the encoder layer, the decoder layer has an extra encoder-decoder attention block. Residual connection and layer normalization are used around each block. In addition, the self-attention block in the decoder is modified with masking to prevent present positions from attending to future positions during training.

For self-attention and encoder-decoder attention, a multi-head attention block is used to obtain information from different representation subspaces at different positions. Each head corresponds to a scaled dot-product attention, which operates on the query Q, key K, and value V:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V \quad (2)$$

where d_k is the dimension of the key.

Finally, the output values are concatenated and projected by a feed-forward layer to get final values:

$$\begin{aligned}\text{MultiHead}(Q, K, V) &= \text{Concat}(\text{head}_1, \ldots, \text{head}_h)W^O \\ \text{where head}_i &= \text{Attention}(QW_i^Q, KW_i^K, VW_i^V)\end{aligned} \quad (3)$$

where W^O, QW_i^Q, KW_i^K, and VW_i^V are learnable matrices, h is the number of heads.

3.3 Improving NCLS with MS and MT

Considering there is a strong relationship between CLS task and MS task, as well as between CLS task and MT task: (1) CLS shares the same goal with MS, i.e., to grasp the core idea of the original document, but the final results are presented in different languages. (2) From the perspective of information compression, machine translation can be regarded as a special kind of cross-lingual summarization with a compression ratio of 1:1. Therefore, we consider using MS and MT datasets to further improve the performance of CLS task under multi-task learning.

Inspired by Luong et al. (2016), we employ the one-to-many scheme to incorporate the training process of MS and MT into that of CLS. As shown in Figure 3, this scheme involves one encoder and multiple decoders for tasks in which the encoder can be shared. We study two different task combinations here: CLS+MS and CLS+MT.

CLS+MS. Note that the reference in each of CLS datasets has a bilingual version. For instance, En2ZhSum dataset contains a total of 370,687 documents with corresponding summaries in both

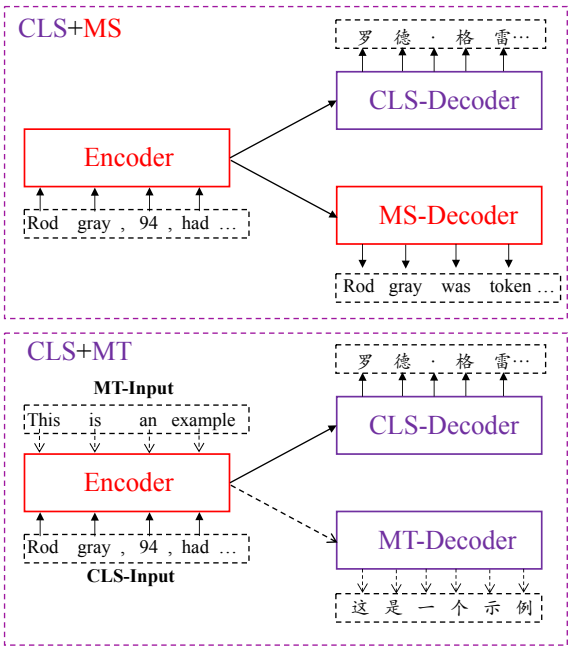

Figure 3: Overview of multi-task NCLS. The lower half is CLS+MT using alternating training strategy. Different colors represent different languages.

Chinese and English. Thus, we consider jointly training CLS and MS as follows. Given a source document, the encoder encodes it into continuous representations, and then the two decoders simultaneously generate the output of their respective tasks. The loss can be calculated as follows:

$$L_\theta = \sum_{t=1}^{N^{(1)}} \log P(y_t^{(1)} | y_{<t}^{(1)}, x; \theta) + \sum_{t=1}^{N^{(2)}} \log P(y_t^{(2)} | y_{<t}^{(2)}, x; \theta) \quad (4)$$

where $y^{(1)}$ and $y^{(2)}$ are the outputs of two tasks.

CLS+MT. Since CLS input-output pairs are different from MT input-output pairs, we consider adopting the alternating training strategy (Dong et al., 2015), which optimizes each task for a fixed number of mini-batches before switching to the next task, to jointly train CLS and MT. For MT task, we employ 2.08M[6] sentence pairs from LDC corpora with CLS dataset to train CLS+MT.

4 Experiments

4.1 Experimental Settings

For English, we apply two different granularities of segmentation, i.e., words and subwords (Sennrich et al., 2016). We lowercase all English characters. We truncate the input to 200 words and the output to 120 words (150 characters for Chinese output) . For Chinese, we employ three different

[6]LDC2000T50, LDC2002L27, LDC2002T01, LDC2002E18, LDC2003E07, LDC2003E14, LDC2003T17, LDC2004T07

Model	ROUGE-1	ROUGE-2	ROUGE-L
Gu et al. (2016)	35.00	22.30	32.00
Li et al. (2017)	36.99	24.15	34.21
Transformer	39.71	27.45	37.13

Table 2: Performance of our implemented transformer-based monolingual summarization model on LCSTS.

granularities of segmentation: characters, words, and subwords. It is worth noting that we only apply subword-based segmentation in Zh2En model since subword-based segmentation will make the English article much longer in En2Zh (especially at the Chinese target-side output), which makes the Transformer performs extremely poor. For our baseline pipeline models, the vocabulary size of Chinese characters is 10,000, and that of Chinese words, Chinese subwords, and English words are all 100,000. In our En2Zh NCLS models, the vocabulary size of source-side English words is 100,000, and that of target-side Chinese characters and words are 18,000, and 50,000 respectively. In our Zh2En models, the vocabulary size of source-side Chinese characters, words, and subwords are 10,000, 100,000, and 100,000 respectively, and that of target-side English words and subwords are all 40,000. We initialize all the parameters via Xavier initialization methods (Glorot and Bengio, 2010). We train our models using configuration *transformer_base* (Vaswani et al., 2017), which contains a 6-layer encoder and a 6-layer decoder with 512-dimensional hidden representations.

During training, in En2Zh models, each mini-batch contains a set of document-summary pairs with roughly 2,048 source and 2,048 target tokens; in Zh2En models, each mini-batch contains a set of document-summary pairs with roughly 4,096 source and 4,096 target tokens. We use Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.998$, and $\epsilon = 10^{-9}$. We use a single NVIDIA TITAN X to train our models. Convergence is reached within 1,000,000 iterations in both TNCLS models and baseline models. We train each task for about 800,000 iterations in multi-task NCLS models (reaching convergence). At test time, our summaries are produced using beam search with beam size 4.

4.2 Baselines and Model Variants

We compare our NCLS models with the following two traditional methods:

TETran: We first translate the source document via a Transformer-based machine translation model trained on LDC corpora. Then we employ LexRank (Erkan and Radev, 2004), a strong and widely used unsupervised summarization method, to summarize the translated document. The reason why we choose to apply an unsupervised method is that we lack the version of MS dataset in the target language to train a supervised model to summarize the translated document.

Model	ROUGE-1	ROUGE-2	ROUGE-L
See et al. (2017)	39.53	17.28	36.38
Transformer	39.24	16.67	36.42

Table 3: Performance of our implemented transformer-based MS model on CNN/Dailymail.

TLTran: We first build a Transformer-based MS model which is trained on the original MS dataset. Then the MS model aims to summarize the source document into a summary. Finally, we translate the summary into target language by using the Transformer-based machine translation model trained on LDC corpora. The performance of our transformer-based MS models is given in Table 2 and Table 3.

To make our experiments more comprehensive, during the process of TETran and TLTran, we replace the Transformer-based machine translation model with Google Translator[7], which is one of the state-of-the-art machine translation systems. We refer to these two methods as **GETran** and **GLTran** respectively.

There are three variants of our NCLS models:

TNCLS: Transformer-based NCLS models where the input and output are different granularities combinations of units.

CLS+MS: It refers to the multi-task NCLS model which accepts an input text and simultaneously performs text generation for both CLS and MS tasks and calculates the total losses.

CLS+MT: It trains CLS and MT tasks via alternating training strategy. Specifically, we optimize the CLS task in a mini-batch, and we optimize the MT task in the next mini-batch.

4.3 Experimental Results and Analysis

Comparison between NCLS with baselines. We evaluate different models with the standard ROUGE metric (Lin, 2004), reporting the F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L. The results are presented in Table 4.

[7] https://translate.google.com/

[8] The parameter for ROUGE script here is "-c 95 -r 1000 -n 2 -a".

	sw-sw	–	–	**35.28-16.59-31.08**	**35.45-16.86-31.28**
TNCLS	c-w	–	–	36.36-19.74-32.66	35.82-19.04-32.06
	w-c	**36.83-18.76-33.22**	**36.82-18.72-33.20**	–	–
	w-w	33.09-14.85-29.82	33.10-14.83-29.82	38.54-22.34-35.05	37.70-21.15-34.05
	sw-sw	–	–	**39.80-23.15-36.11**	**38.85-21.93-35.05**

Table 4: ROUGE F1 scores (%) on En2ZhSum and Zh2EnSum test sets. En2ZhSum* and Zh2EnSum* are the corresponding human-corrected test sets. *Unit* denotes the granularity combination of text units, where *c* means character, *w* means word, and *sw* means subword. RG refers to ROUGE for short. ↑ indicates that the larger values, the better the results are. Our NCLS models perform significantly better than baseline models by the 95% confidence interval measured by the official ROUGE script[8].

We can find that GLTran outperforms TLTran and GETran outperforms TETran, which indicates that pipeline-based methods perform better when using a stronger machine translation system. Compared with GLTran or GETran, our TNCLS models both achieve significant improvements, which can verify our motivation and demonstrate the efficacy of our constructed corpora.

In En2Zh CLS task, the results of each model on En2ZhSum are similar to those on En2ZhSum*. This is because the original ENSUM dataset comes from the news reports. Existing MT for news reports has excellent performance. Besides, we have pre-filtered samples with low translation quality during dataset construction. Therefore, the quality of the automatic test set is high. TNCLS (*w-c*) performs significantly better than TNCLS (*w-w*). This is because the character-based segmentation can greatly reduce the vocabulary size at the Chinese target-side, which leads to generating nearly no UNK token during the decoding process.

In Zh2En CLS task, the subword-based models outperform others since subword-based segmentation can greatly reduce the vocabulary size and the generation of UNK. Compared with baselines, TNCLS can achieve maximum improvement up to **+4.52 ROUGE-1**, **+6.56 ROUGE-2**, **+5.03 ROUGE-L** on Zh2EnSum and **+3.40 ROUGE-1**, **+5.07 ROUGE-2**, **+3.77 ROUGE-L** on Zh2EnSum*. The results of TNCLS drops obviously on the human-corrected test set, showing that the quality of the translated reference is not as perfect as expected. The reason is straightforward that the original LCSTS dataset comes from social media so that the proportion of abbreviations and omitting punctuation in its text is much higher than in news, resulting in lower translation quality.

In conclusion, TNCLS models significantly outperform the traditional pipeline methods on both En2Zh and Zh2En CLS tasks.

Why Back Translation? To show the influence of filtering the corpus by back translation during the RTT process, we use three kinds of datasets to train our TNCLS models and compare their performance. They are: (a) the CLS dataset obtained by simply employing forward translation on MS dataset (*Non-Filter*); (b) the CLS dataset obtained by a complete RTT process (*Filter*); (c) the dataset obtained by sampled from *Non-Filter* dataset to keep the same size as the *Filter* dataset (*Pseudo-Filter*). The results are given in Table 5. The models trained on *Filter* dataset significantly outperform the models trained on *Pseudo-Filter* dataset on both En2Zh and Zh2En tasks, which indicates that the back translation can effectively filter dirty samples and improve the overall quality of corpora, thus boosting the performance of NCLS.

CLS+MT	**40.24-22.36-36.61**	**40.23-22.32-36.59**	**41.09-23.70-37.17**	40.25-22.58-36.21

Table 6: Results of multi-task NCLS. The granularity combination of input and output in En2Zh task is "word to character" (*w-c*), and that in Zh2En task is "subword to subword" (*sw-sw*).

In En2Zh task, the model trained on *Non-Filter* dataset performs best. The reasons are two-fold: (1) the quality of machine translation for English news is reliable; (2) the scale of *Non-Filter* dataset is almost twice that of the two others so that after the amount of data reaches a certain level, it can make up for the noises caused by the translation error in the corpus. In Zh2En task, the performance of the model trained on *Non-Filter* dataset is not as good as that on *Filter*. It can be attributed to the fact that current MT is not very ideal in the translation of texts on social media so that the dataset constructed by only using forward translation contains too many noises. Therefore, when the quality of machine translation is not that ideal, backward translation is especially important during the process of constructing corpus.

Results of Multi-task NCLS. To explore whether MS and MT can further improve NCLS, we compare the multi-task NCLS with NCLS using one same granularity combination of units. The results are given in Table 6. As shown in Table 6, both CLS+MS and CLS+MT can improve the performance of NCLS, which can be attributed to that the encoder is enhanced by incorporating MS and MT data into the training process. CLS+MT significantly outperforms CLS+MS in En2Zh task while CLS+MS performs comparably with CLS+MT in Zh2En task. The reasons are two-fold: (1) In En2Zh task, MT dataset is much larger than both MS and CLS datasets, which makes it more necessary for enhancing the robustness of encoder. (2) We use the LDC MT dataset, which belongs to the news domain similar to our En2ZhSum, during the training of CLS+MT. However, Zh2EnSum belongs to social media domain, thus resulting in the greater improvement of CLS+MT in En2Zh than in Zh2En. In general, NCLS with multi-task learning achieves more significant improvement in En2Zh task than in Zh2En task, which illustrates that extra dataset in other related tasks is essentially important for boosting the performance when CLS dataset is not very large.

Human Evaluation. We conduct the human evaluation on 25 random samples from each of the En2ZhSum and Zh2EnSum test set. We compare the summaries generated by our methods (including TNCLS, CLS+MS, and CLS+MT) with the summaries generated by GLTran. Three graduate students are asked to compare the generated summaries with human-corrected references, and assess each summary from three independent perspectives: (1) How informative the summary is? (2) How concise the summary is? (3) How fluent, grammatical the summary is? Each property is assessed with a score from 1 (worst) to 5 (best). The average results are presented in Table 7.

As shown in Table 7, TNCLS can generate more informative summaries compared with GLTran, which shows the advantage of end-to-end models. The conciseness score and fluency score of TNCLS are comparable to those of GLTran. This is because both GLTtrans and TNCLS employ a single encoder-decoder model, which eas-

Input (Chinese): 在成本压力加大的情况下，流通企业不仅没有缩减IT投资反而继续增加。2011年，中国流通行业的IT投资规模由2010年的96.6亿元增加至2011年的109.2亿元。预计2012年流通行业的IT投资增速将达14.1%，规模超120亿元。 Under the circumstance of increasing cost pressure, circulation enterprises not only did not reduce IT investment but also continued to increase. In 2011, the scale of IT investment in China 's circulation industry increased from 9.66 billion yuan in 2010 to 10.92 billion yuan in 2011. It is estimated that the IT investment in the circulation industry will grow by 14.1% in 2012, with a scale exceeding 12 billion yuan.
Gold Summary: in 2012 , the scale of it investment in china 's circulation industry will exceed 12 billion yuan .
GETran: in the case of increased cost pressures, distribution companies have not only reduced it investment but continued to increase.
GLTran: it investment in china 's circulation industry will increase by 14.1 % in 2011
TNCLS: it investment in circulation industry continues to increase
CLS+MS: it investment in china 's circulation industry will exceed 12 billion yuan in 2012 .
CLS+MT: china 's circulation industry is expected to increase it investment by 14.1 % in 2012 .

Figure 4: Examples of generated summaries.

Model	En2Zh			Zh2En		
	IF	CC	FL	IF	CC	FL
GLTran	3.06	3.37	3.13	3.53	4.21	4.25
TNCLS	3.25	3.33	3.17	3.67	4.25	4.24
CLS+MS	3.53	3.58	3.53	3.72	4.31	4.28
CLS+MT	**3.58**	**3.76**	**3.63**	**3.78**	**4.43**	**4.35**

Table 7: Human evaluation results. IF, CC and FL denote informative, concise, and fluent respectively.

ily leads to under-generation and repetition. Our CLS+MS and CLS+MT can significantly improve the conciseness and fluency of generated summaries, which shows that these methods can generate shorter summaries and reduce grammatical errors. In conclusion, TNCLS can generate more informative summaries, but it is difficult to improve the conciseness and fluency. However, with the help of MT and MS tasks, conciseness and fluency scores can be significantly improved.

4.4 Case Study

We show the case study of a sample from the Zh2EnSum human-corrected test set in Figure 4. As shown in Figure 4, the summary generated by **GETran** obviously suffers from errors of machine translation ("distribution companies" should be corrected as "circulation enterprises"). Since **GETran** first translates all the source text, it is easier to bring the errors from machine translation. The **GLTran**-generated summary contracts the fact that the year in it should be 2012 instead of 2011. The translation quality of the sentence is relatively reliable, thus the errors are probably produced during the summarization step. Compared with the first two generated summaries, although the summary produced by **TNCLS** does not emphasize the time and place of occurrence, there is no mistake in the logic of its expression. The summaries generated by **CLS+MS** and **CLS+MT** are generally consistent with the facts, but their emphases are different. The **CLS+MS** summary matches the gold summary better. The flaws of both of them are that they do not reflect the "scale" in the original text. In conclusion, our methods can produce more accurate summaries than baselines.

5 Related Work

Cross-lingual summarization has been proposed to present the most salient information of a source document in a different language, which is very important in the field of multilingual information processing. Most of the existing methods handle the task of CLS via simply applying two typical translation schemes, i.e., early translation (Leuski et al., 2003; Ouyang et al., 2019) and late translation (Orasan and Chiorean, 2008; Wan et al., 2010). The early translation scheme first translates the original document into target language and then generates the summary of the translated document. The late translation scheme first summarizes the original document into a summary in the source language and then translates it into target language.

Leuski et al. (2003) translate the Hindi document to English and then generate the English headline for it. Ouyang et al. (2019) present a robust abstractive summarization system for low resource languages where no summarization corpora are currently available. They train a neural abstractive summarization model on noisy English documents and clean English reference summaries. Then the model can learn to produce fluent summaries from disfluent inputs, which allows generating summaries for translated documents. Orasan and Chiorean (2008) summarize the Romanian news with the maximal marginal relevance method (Goldstein et al., 2000) and produce the English summaries for English speakers. Wan et al. (2010) adopt the late translation scheme for the task of English-to-Chinese CLS. They extract English sentences considering both the informativeness and translation quality of sentences and automatically translate the English summary into the final Chinese summary. The above researches only make use of the information from only one language side.

Some methods have been proposed to improve CLS with bilingual information. Wan (2011) proposes two graph-based summarization methods to leverage both the English-side and Chinese-side information in the task of English-to-Chinese CLS. Inspired by the phrase-based translation models, Yao et al. (2015) introduce a compressive CLS, which simultaneously performs sentence selection and compression. They calculate the sentence scores based on the aligned bilingual phrases obtained by MT service and perform compression via deleting redundant or poorly translated phrases. Zhang et al. (2016) propose an abstractive CLS which constructs a pool of bilingual concepts represented by the bilingual elements of the source-side predicate-argument structures (PAS) and the target-side counterparts. The final summary is generated by maximizing both the salience and translation quality of the PAS elements.

However, all these researches belong to the pipeline paradigm which not only relies heavily on hand-crafted features but also causes error propagation. End-to-end deep learning has proven to be able to alleviate these two problems, while it has been absent due to the lack of large-scale training data. Recently, Ayana et al. (2018) present zero-shot cross-lingual headline generation based on existing parallel corpora of translation and monolingual headline generation. Similarly, Duan et al. (2019) propose to use monolingual abstractive sentence summarization system to teach zero-shot cross-lingual abstractive sentence summarization on both summary word generation and attention. Although great efforts have been made in cross-lingual summarization, how to automatically build a high-quality large-scale cross-lingual summarization dataset remains unexplored.

In this paper, we focus on English-to-Chinese and Chinese-to-English CLS and try to automatically construct two large-scale corpora respectively. In addition, based on the two corpora, we perform several end-to-end training methods noted as Neural Cross-Lingual Summarization.

6 Conclusion and Future Work

In this paper, we present neural cross-lingual summarization for the first time. To achieve that goal, we propose to acquire large-scale supervised data from existing monolingual summarization datasets via round-trip translation strategy. Then we apply end-to-end methods on our constructed datasets and find our NCLS models significantly outperform the traditional pipeline paradigm. Furthermore, we consider utilizing machine translation and monolingual summarization to further improve NCLS. Experimental results have shown that both machine translation and monolingual summarization can significantly help NCLS generate better summaries.

In our future work, we will adopt our RTT strategy to obtain CLS datasets of other language pairs, such as English-to-Japanese, English-to-German, Chinese-to-Japanese, and Chinese-to-German, etc.

Abstract

Sensational headlines are headlines that capture people's attention and generate reader interest. Conventional abstractive headline generation methods, unlike human writers, do not optimize for maximal reader attention. In this paper, we propose a model that generates sensational headlines without labeled data. We first train a sensationalism scorer by classifying online headlines with many comments ("clickbait") against a baseline of headlines generated from a summarization model. The score from the sensationalism scorer is used as the reward for a reinforcement learner. However, maximizing the noisy sensationalism reward will generate unnatural phrases instead of sensational headlines. To effectively leverage this noisy reward, we propose a novel loss function, Auto-tuned Reinforcement Learning (ARL), to dynamically balance reinforcement learning (RL) with maximum likelihood estimation (MLE). Human evaluation shows that 60.8% of samples generated by our model are sensational, which is significantly better than the Pointer-Gen baseline (See et al., 2017) and other RL models.

1 Introduction

Headline generation is the process of creating a headline-style sentence given an input article. The research community has been regarding the task of headline generation as a summarization task (Shen et al., 2017a), ignoring the fundamental differences between headlines and summaries. While summaries aim to contain most of the important information from the articles, headlines do not necessarily need to. Instead, a good headline needs to capture people's attention and serve as an irresistible invitation for users to read through the article. For example, the headline "$2 Billion Worth of Free Media for Trump", which gives only an intriguing hint, is considered better than the summarization style headline "Measuring Trump's Media Dominance" [1], as the former gets almost three times the readers as the latter. Generating headlines with many clicks is especially important in this digital age, because many of the revenues of journalism come from online advertisements and getting more user clicks means being more competitive in the market. However, most existing websites [2] naively generate sensational headlines using only keywords or templates. Instead, this paper aims to learn a model that generates sensational headlines based on an input article without labeled data.

To generate sensational headlines, there are two main challenges. Firstly, there is a lack of sensationalism scorer to measure how sensational a headline is. Some researchers have tried to manually label headlines as clickbait or non-clickbait (Chakraborty et al., 2016; Potthast et al., 2018). However, these human-annotated datasets are usually small and expensive to collect. To capture a large variety of sensationalization patterns, we need a cheap and easy way to collect a large number of sensational headlines. Thus, we propose a distant supervision strategy to collect a sensationalism dataset. We regard headlines receiving lots of comments as sensational samples and the headlines generated by a summarization model as non-sensational samples. Experimental results show that by distinguishing these two types of headlines, we can partially teach the model a sense of being sensational.

Secondly, after training a sensationalism scorer on our sensationalism dataset, a natural way to generate sensational headlines is to maximize the sensationalism score using reinforcement learn-

ing (RL). However, the following shows an example of a RL model maximizing the sensationalism score by generating a very unnatural sentence, while its sensationalism scorer gave a very high score of 0.99996: 十个可穿戴产品的设计原则这消息消息可惜说明 *Ten design principles for wearable devices, this message message pity introduction.* This happens because the sensationalism scorer can make mistakes and RL can generate unnatural phrases which fools our sensationalism scorer. Thus, how to effectively leverage RL with noisy rewards remains an open problem. To deal with the noisy reward, we introduce Auto-tuned Reinforcement Learning (ARL). Our model automatically tunes the ratio between MLE and RL based on how sensational the training headline is. In this way, we effectively take advantage of RL with a noisy reward to generate headlines that are both sensational and fluent.

The major contributions of this paper are as follows: 1) To the best of our knowledge, we propose the first-ever model that tackles the sensational headline generation task with reinforcement learning techniques. 2) Without human-annotated data, we propose a distant supervision strategy to train a sensationalism scorer as a reward function.3) We propose a novel loss function, Auto-tuned Reinforcement Learning, to give dynamic weights to balance between MLE and RL. Our code will be released . [3]

2 Sensationalism Scorer

To evaluate the sensationalism intensity score α_{sen} of a headline, we collect a sensationalism dataset and then train a sensationalism scorer. For the sensationalism dataset collection, we choose headlines with many comments from popular online websites as positive samples. For the negative samples, we propose to use the generated headlines from a sentence summarization model. Intuitively, the summarization model, which is trained to preserve the semantic meaning, will lose the sensationalization ability and thus the generated negative samples will be less sensational than the original one, similar to the obfuscation of style after back-translation (Prabhumoye et al., 2018). For example, an original headline like "一趟挣10万？铁总增开申通、顺丰专列" (One trip to earn 100 thousand? China Railway opens new Shentong and Shunfeng special lines) will become "中铁总将增开京广两列快递专列" (China Railway opens two special lines for express) from the baseline model, which loses the sensational phrases of "一趟挣10万？" (One trip to earn 100 thousand?) . We then train the sensationalism scorer by classifying sensational and non-sensational headlines using a one-layer CNN with a binary cross entropy loss L_{sen}. Firstly, 1-D convolution is used to extract word features from the input embeddings of a headline. This is followed by a ReLU activation layer and a max-pooling layer along the time dimension. All features from different channels are concatenated together and projected to the sensationalism score by adding another fully connected layer with sigmoid activation. Binary cross entropy is used to compute the loss L_{sen}.

2.1 Training Details and Dataset

For the CNN model, we choose filter sizes of 1, 3, and 5 respectively. Adam is used to optimize L_{sen} with a learning rate of 0.0001. We set the embedding size as 300 and initialize it from Qiu et al. (2018) trained on the Weibo corpus with word and character features. We fix the embeddings during training.

For dataset collection, we utilize the headlines collected in Qin et al. (2018); Lin et al. (2019a) from Tencent News, one of the most popular Chinese news websites, as the positive samples. We follow the same data split as the original paper. As some of the links are not available any more, we get 170,754 training samples and 4,511 validation samples. For the negative training samples collection, we randomly select generated headlines from a pointer generator (See et al., 2017) model trained on LCSTS dataset (Hu et al., 2015) and create a balanced training corpus which includes 351,508 training samples and 9,022 validation samples. To evaluate our trained classifier, we construct a test set by randomly sampling 100 headlines from the test split of LCSTS dataset and the labels are obtained by 11 human annotators. Annotations show that 52% headlines are labeled as positive and 48% headlines as negative by majority voting (The detail on the annotation can be found in Section 3.6).

2.2 Results and Discussion

Our classifier achieves 0.65 accuracy and 0.65 averaged F1 score on the test set while a random classifier would only achieve 0.50 accuracy and

[3] https://github.com/HLTCHKUST/sensational_headline

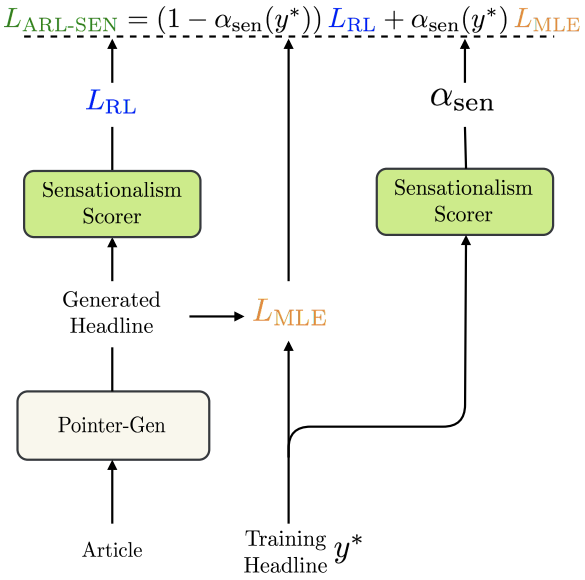

Figure 1: The loss function of Auto-tuned Reinforcement Learning is a weighted sum of L_{RL} and L_{MLE}, where the weight is decided by our sensationalism scorer.

0.50 averaged F1 score. This confirms that the predicted sensationalism score can partially capture the sensationalism of headlines. On the other hand, a more natural choice is to take headlines with few comments as negative examples. Thus, we train another baseline classifier on a crawled balanced sensationalism corpus of 84k headlines where the positive headlines have at least 28 comments and the negative headlines have less than 5 comments. However, the results on the test set show that the baseline classifier gets 60% accuracy, which is worse than the proposed classifier (which achieves 65%). The reason could be that the balanced sensationalism corpus are sampled from different distributions from the test set and it is hard for the trained model to generalize. Therefore, we choose the proposed one as our sensationalism scorer. Therefore, our next challenge is to show that how to leverage this noisy sensationalism reward to generate sensational headlines.

3 Sensational Headline Generation

Our sensational headline generation model takes an article as input and output a sensational headline. The model consists of a Pointer-Gen headline generator and is trained by ARL. The diagram of ARL can be found in Figure 1.

We denote the input article as $x = \{x_1, x_2, x_3, \cdots, x_M\}$, and the corresponding headline as $y^* = \{y_1^*, y_2^*, y_3^*, \cdots, y_T^*\}$, where M is the number of tokens in an article and T is the number of tokens in a headline.

3.1 Pointer-Gen Headline Generator

We choose Pointer Generator (Pointer-Gen) (See et al., 2017), a widely used summarization model, as our headline generator for its ability to copy words from the input article. It takes a news article as input and generates a headline. Firstly, the tokens of each article, $\{x_1, x_2, x_3, \cdots, x_M\}$, are fed into the encoder one-by-one and the encoder generates a sequence of hidden states h_i. For each decoding step t, the decoder receives the embedding for each token of a headline y_t as input and updates its hidden states s_t. An attention mechanism following Luong et al. (2015) is used:

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{attn}) \quad (1)$$

$$a^t = \text{softmax}(e^t) \quad (2)$$

$$h_t^* = \sum\nolimits_i a_i^t h_i \quad (3)$$

where v, W_h, W_s, and b_{attn} are the trainable parameters and h_t^* is the context vector. s_t and h_t^* are then combined to give a probability distribution over the vocabulary through two linear layers:

$$o_t = V([s_t, h_t^*]) + b \quad (4)$$

$$P_{\text{voc}}(w) = \text{softmax}(V^{'} o_t + b^{'}) \quad (5)$$

where V, b, $V^{'}$, and $b^{'}$ are trainable parameters. We use a pointer generator network to enable our model to copy rare/unknown words from the input article, giving the following final word probability:

$$p_{\text{gen}} = \sigma(w_{h^*}^T h_t^* + w_s^T s_t + w_x^T x^t + b_{ptr}) \quad (6)$$

$$P(w) = p_{\text{gen}} P_{\text{voc}}(w) + (1 - p_{\text{gen}}) \sum_{i:x_i=w} a_i^t \quad (7)$$

where x^t is the embedding of the input word of the decoder, $w_{h^*}^T$, w_s^T, w_x^T, and b_{ptr} are trainable parameters, and σ is the sigmoid function.

3.2 Training Methods

We first briefly introduce MLE and RL objective functions, and a naive way to mix these two by a hyper-parameter λ. Then we point out the challenge of training with noisy reward, and propose ARL to address this issue.

3.2.1 MLE and RL

A headline generation model can be trained with MLE, RL or a combination of MLE and RL. MLE

training is to minimize the negative log likelihood of the training headlines. We feed y^* into the decoder word by word and maximize the likelihood of y^*. The loss function for MLE becomes

$$L_{\text{MLE}} = -\frac{1}{T}\sum_{t=1}^{T} \log P(y_t^*) \tag{8}$$

For RL training, we choose the REINFORCE algorithm (Williams, 1992). In the training phase, after encoding an article, a headline $y^s = \{y_1^s, y_2^s, y_3^s, \cdots, y_T^s\}$ is obtained by sampling from $P(w)$ from our generator, and then a reward of sensationalism or ROUGE(RG) is calculated.

$$R_{\text{rg}} = \text{RG}(y^s, y^*) \tag{9}$$

$$R_{\text{sen}} = \alpha_{\text{sen}}(y^s) \tag{10}$$

We use the baseline reward $\hat{R}_t$ to reduce the variance of the reward, similar to Ranzato et al. (2016). To elaborate, a linear model is deployed to estimate the baseline reward $\hat{R}_t$ based on t-th state o_t for each timestep t. The parameters of the linear model are trained by minimizing the mean square loss between R and $\hat{R}_t$:

$$\hat{R}_t = W_r o_t + b_r \tag{11}$$

$$L_b = \frac{1}{T}\sum_{t=1}^{T} |R - \hat{R}_t|^2 \tag{12}$$

where W_r and b_r are trainable parameters. To maximize the expected reward, our loss function for RL becomes

$$L_{\text{RL}} = -\frac{1}{T}\sum_{t=1}^{T} (R - \hat{R}_t) \log P(w_t) \tag{13}$$

A naive way to mix these two objective functions using a hyper-parameter λ has been successfully incorporated in the summarization task (Paulus et al., 2018). It includes the MLE training as a language model to mitigate the readability and quality issues in RL. The mixed loss function is shown as follows:

$$L_{\text{RL-}*} = \lambda L_{\text{RL}} + (1-\lambda) L_{\text{MLE}} \tag{14}$$

where $*$ is the reward type. Usually λ is large, and Paulus et al. (2018) used 0.9984.

3.2.2 Auto-tuned Reinforcement Learning

Applying the naive mixed training method using sensationalism score as the reward is not obvious/trivial in our task. The main reason is that our sensationalism reward is notably more noisy and more fragile than the ROUGE-L reward or abstractive reward used in the summarization task (Paulus et al., 2018; Kryściński et al., 2018). A higher ROUGE-L F1 reward in summarization indicates higher overlapping ratio between generation and true summary statistically, but our sensationalism reward is a learned score which is fragile to be fooled with unnatural samples.

To effectively train the model with RL under noisy sensationalism reward, our idea is to balance RL with MLE. However, we argue that *the weighted ratio between MLE and RL should be sample-dependent,* instead of being fixed for all training samples as in Paulus et al. (2018); Kryściński et al. (2018). The reason is that, RL and MLE have inconsistent optimization objectives. When the training headline is non-sensational, MLE training will encourage our model to imitate the training headline (thus generating *non-sensational* headlines), which counteracts the effects of RL training to generate *sensational* headlines.

The sensationalism score is, therefore, used to give dynamic weight to MLE and RL. Our ARL loss function becomes:

$$L_{\text{ARL-SEN}} = (1 - \alpha_{\text{sen}}(y^*))\, L_{\text{RL}} + \alpha_{\text{sen}}(y^*)\, L_{\text{MLE}} \tag{15}$$

If $\alpha_{\text{sen}}(y^*)$ is high, meaning the training headline is sensational, our loss function encourages our model to imitate the sample more using the MLE training. If $\alpha_{\text{sen}}(y^*)$ is low, our loss function replies on RL training to improve the sensationalism. Note that the weight $\alpha_{\text{sen}}(y^*)$ is different from our sensationalism reward $\alpha_{\text{sen}}(y^s)$ and we call the loss function Auto-tuned Reinforcement Learning, because the ratio between MLE and RL are well "tuned" towards different samples.

3.3 Dataset

We use LCSTS (Hu et al., 2015) as our dataset to train the summarization model. The dataset is collected from the Chinese microblogging website Sina Weibo. It contains over 2 million Chinese short texts with corresponding headlines given by the author of each text. The dataset is split into 2,400,591 samples for training, 10,666 samples for validation and 725 samples for testing. We tokenize each sentence with Jieba [4] and a vocabulary size of 50000 is saved.

[4] https://github.com/fxsjy/jieba

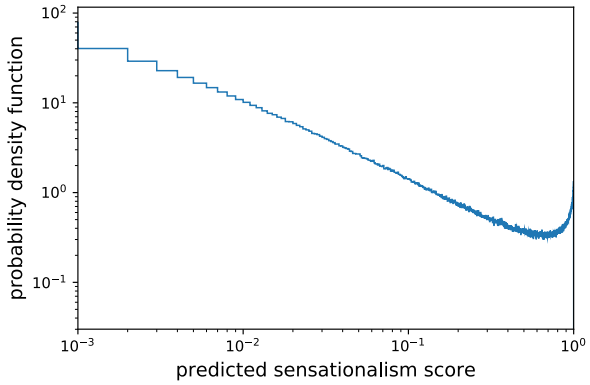

Figure 2: The probability density function (pdf) of predicted sensationalism score in log scale. Low sensationalism score has much higher probability density.

3.4 Baselines and Our Models

We experiment and compare with the following models. **Pointer-Gen** is the baseline model trained by optimizing L_{MLE} in Equation 8.

Pointer-Gen+Pos is the baseline model by training Pointer-Gen only on positive examples whose sensationalism score is larger than 0.5

Pointer-Gen+Same-FT is the model which finetunes Pointer-Gen on the training samples whose sensationalism score is larger than 0.1

Pointer-Gen+Pos-FT is the model which finetunes Pointer-Gen on the training samples whose sensationalism score is larger than 0.5

Pointer-Gen+RL-ROUGE is the baseline model trained by optimizing $L_{\text{RL-ROUGE}}$ in Equation 14, with ROUGE-L (Lin, 2004) as the reward.

Pointer-Gen+RL-SEN is the baseline model trained by optimizing $L_{\text{RL-SEN}}$ in Equation 14, with α_{sen} as the reward.

Pointer-Gen+ARL-SEN is our model trained by optimizing $L_{\text{ARL-SEN}}$ in Equation 15, with α_{sen} as the reward.

Test set is the headlines from the test set.

Note that we didn't compare to Pointer-Gen+ARL-ROUGE as it is actually Pointer-GEN. Recall that $\alpha_{\text{sen}}(y^*)$ in Equation 15 measures how good (based on reward function) is y^*. Then the loss function for Pointer-Gen+ARL-ROUGE will be

$$(1-\text{RG}(y^*,y^*))L_{\text{RL}}+\text{RG}(y^*,y^*)L_{\text{MLE}}=L_{\text{MLE}}$$

We also tried text style transfer baseline (Shen et al., 2017b), but the generated headlines were very poor (many unknown words and irrelevant).

3.5 Training Details

MLE training: An Adam optimizer is used with the learning rate of 0.0001 to optimize L_{MLE}. The batch size is set as 128 and a one-layer, bi-directional Long Short-Term Memory (bi-LSTM) model with 512 hidden sizes and a 350 embedding size is utilized. Gradients with the l2 norm larger than 2.0 are clipped. We stop training when the ROUGE-L f-score stops increasing.

Hybrid training: An Adam optimizer with a learning rate of 0.0001 is used to optimize $L_{\text{RL-*}}$ (Equation 14) and $L_{\text{ARL-SEN}}$ (Equation 15). When training Pointer-Gen+RL-ROUGE, the best λ is chosen based on the ROUGE-L score on the validation set. In our experiment, λ is set as 0.95. An Adam optimizer with a learning rate of 0.001 is used to optimize L_b. When training Pointer-Gen+ARL-SEN, we don't use the full LCSTS dataset, but only headlines with a sensationalism score larger than 0.1 as we observe that Pointer-Gen+ARL-SEN will generate a few unnatural phrases when using full dataset. We believe the reason is the high ratio of RL during training. Figure 2 shows that the probability density near 0 is very high, meaning that in each batch, many of the samples will have a very low sensationalism score. On expectation, each sample will receive 0.239 MLE training and 0.761 RL training. This leads to RL dominanting the loss. Thus, we propose to filter samples with a minimum sensationalism score with 0.1 and it works very well. For Pointer-Gen+RL-SEN, we also set the minimum sensationalism score as 0.1, and λ is set as 0.5 to remove unnatural phrases, making a fair comparison to Pointer-Gen+ARL-SEN.

We stop training Pointer-Gen+Same-FT, Pointer-Gen+Pos-FT, Pointer-Gen+RL-SEN and Pointer-Gen+ARL-SEN, when α_{sen} stops increasing on the validation set. Beam-search with a beam size of 5 is adopted for decoding in all models.

3.6 Evaluation Metrics

We briefly describe the evaluation metrics below.

ROUGE: ROUGE is a commonly used evaluation metric for summarization. It measures the N-gram overlap between generated and training headlines. We use it to evaluate the *relevance* of generated headlines. The widely used pyrouge [5] toolkit is used to calculate ROUGE-1 (RG-1), ROUGE-2

[5] https://github.com/bheinzerling/pyrouge

	RG-1	RG-2	RG-L
character-based preprocessing			
RNN context (Hu et al., 2015)	29.90	17.40	27.20
COPYNET (Gu et al., 2016)	34.40	21.60	31.30
word-based preprocessing			
RNN context (Hu et al., 2015)	26.80	16.10	24.10
COPYNET (Gu et al., 2016)	35.00	22.30	32.00
Pointer-Gen	34.51	22.21	31.68
Pointer-Gen+Pos	28.51	16.53	25.56
Pointer-Gen+Same-FT	34.60	22.00	31.48
Pointer-Gen+Pos-FT	30.92	18.76	28.02
Pointer-Gen+RL-ROUGE	**36.26**	**23.48**	**33.21**
Pointer-Gen+RL-SEN	35.06	22.37	31.91
Pointer-Gen+ARL-SEN	34.28	21.34	30.80

Table 1: Our implementation achieves similar performance to the RNN context and COPYNET. Pointer-Gen+ARL-SEN achieves good summarization performance even though it is optimized for the sensational reward. It shows its ability to summarize.

(RG-2), and ROUGE-L (RG-L).

Human evaluation: We randomly sample 50 articles from the test set and send the generated headlines from all models and corresponding headlines in the test set to human annotators. We evaluate the sensationalism and fluency of the headlines by setting up two independent human annotation tasks. We ask 10 annotators to label each headline for each task. For the sensationalism annotation, each annotator is asked one question, "Is the headline sensational?", and he/she has to choose either 'yes' or 'no'. The annotators were not told which system the headline is from. The process of distributing samples and recruiting annotators is managed by Crowdflower.[6] After annotation, we define the sensationalism score as the proportion of annotations on all generated headlines from one model labeled as 'yes'. For the fluency annotation, we repeat the same procedure as for the sensationalism annotation, except that we ask each annotator the question "Is the headline fluent?" We define the fluency score as the proportion of annotations on all headlines from one specific model labeled as 'yes'. We put human annotation instructions in the supplemental material.

4 Results

We first compare all four models, Pointer-Gen, Pointer-Gen-RL+ROUGE, Pointer-Gen-RL-SEN, and Pointer-Gen-ARL-SEN, to existing models with ROUGE in Table 1 to establish that our model produces relevant headlines and we leave the sensationalism for human evaluation. Note that we only compare our models to commonly used strong summarization baselines, to validate that our implementation achieves comparable performance to existing work. In our implementation, Pointer-Gen achieves a 34.51 RG-1 score, 22.21 RG-2 score, and 31.68 RG-L score, which is similar to the results of Gu et al. (2016). Pointer-Gen+ARL-SEN, although optimized for the sensationalism reward, achieves similar performance to our Pointer-Gen baseline, which means that Pointer-Gen+ARL-SEN still keeps its summarization ability. An example of headlines generated from different models in Table 2 shows that Pointer-Gen and Pointer-Gen+RL-ROUGE learns to summarize the main point of the article: "The Nikon D600 camera is reported to have black spots when taking photos". Pointer-Gen+RL-SEN

[6]https://www.figure-eight.com/

Article: 昨天的央视315晚会上，尼康D600相机被曝拍摄时会出现黑色斑点，反复修理也无果，而尼康竟把责任推给了雾霾，拒绝换机或退机。对此上海工商部门昨晚连夜梳理了近年对尼康的投诉案，今天上午前往位于黄浦区的尼康公司进一步调查。新民网 At the CCTV 315 party yesterday, the Nikon D600 camera is reported to have black spots when taking photos. Repeated repairs gave no results, and Nikon actually attributes the damage to the smog, refusing exchange or return. The Shanghai Industrial and Commercial Department collected the recent complaints against Nikon last night, and went to Nikon Company in Huangpu District for further investigation this morning. Xinmin Net
Pointer-Gen: 尼康D600相机被曝拍摄时会出现黑色斑点 The Nikon D600 camera is reported to have black spots when taking photos
Pointer-Gen+Same-FT: 尼康D600被曝拍出雾霾尼康已介入调查The Nikon D600 camera is reported to have smog Nikon started investigation
Pointer-Gen+Pos-FT: 尼康投诉央视315晚会尼康投诉被曝Nikon complains CCTV 315 night, Nikon is reported to be complained
Pointer-Gen+RL-ROUGE: 尼康D600相机被曝拍摄时会出现黑色斑点 The Nikon D600 camera is reported to have black spots when taking photos
Pointer-Gen+RL-SEN: 尼康D600被曝拍出奇葩事尼康把责任推给雾霾 The Nikon D600 camera is reported to have something strange and attributes the damage to the smog.
Pointer-Gen+ARL-SEN (Ours): 摊上大事了！ 尼康D600被指拍出"黑点" **In Serious Trouble!** The Nikon D600 camera is reported to have black spots when taking photos
Test set headline: 尼康称黑点怪雾霾上海工商今上门追查 Nikon attributes black spots to the smog, and Shanghai Industrial and Commercial Department start investigation today.

Table 2: Generated Chinese headlines from different models. Our model (Pointer-Gen+ARL-SEN) sensationalized the headline with the phrase "In Serious Trouble!".

Model	sensationalism	fluency
Pointer-Gen	42.6%*	80%
Pointer-Gen-Pos	40.2%*	59%*
Pointer-Gen+Same-FT	47.6%*	75.6%
Pointer-Gen+Pos-FT	47.8%*	71.4%
Pointer-Gen+RL-ROUGE	45.2%*	80%
Pointer-Gen+RL-SEN	51.8%*	79.4%
Pointer-Gen+ARL-SEN	**60.8%**	79.4%
Test set	57.8%	**80.6%**

Table 3: Comparison of sensationalism score and fluency score between different models. Pointer-Gen+ARL-SEN achieves the best performance among all models in sensationalism score. * indicates Pointer-Gen+ARL-SEN is statistically significantly better than the corresponding model.

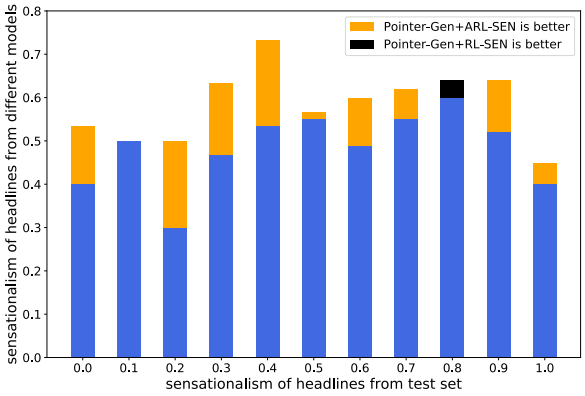

Figure 3: Comparison of sensationalism score between Pointer-Gen+ARL-SEN and Pointer-Gen+RL-SEN for different test set headlines. The blue bars denote the smaller scores between the two models. Pointer-Gen+ARL-SEN achieves better performance on most cases. Greater improvement is achieved when the test set headline is non-sensational.

makes the headline more sensational by blaming Nikon for attributing the damage to the smog. Pointer-Gen+ARL-SEN generates the most sensational headline by exaggerating the result "Getting a serious trouble!" to maximize user's attention.

We then compare different models using the sensationalism score in Table 3. The Pointer-Gen baseline model achieves a 42.6% sensationalism score, which is the minimum that a typical summarization model achieves. By filtering out low-sensational headlines, Pointer-Gen+Same-FT and Pointer-Gen+Pos-FT achieves higher sensationalism scores, which implies the effectiveness of our sensationalism scorer. Our Pointer-Gen+ARL-SEN model achieves the best performance of 60.8%. This is an absolute improvement of 18.2% over the Pointer-Gen baseline. The Chi-square test on the results confirms that Pointer-Gen+ARL-SEN is statistically significantly more sensational than all the other baseline models, with the largest p-value less than 0.01. Also, we find that the test set headlines achieves 57.8% sensationalism score, much larger than Pointer-Gen baseline, which also supports our intuition that generated headlines will be less sensational than the original one. On the other hand, we found that Pointer-Gen+Pos is much worse than other baselines. The reason is that training on sensational samples alone discards around 80% of the whole training set that is also helpful for maintaining relevance and a good language model. It shows the necessity of using RL.

In addition, both Pointer-Gen+RL-SEN and Pointer-Gen+ARL-SEN, which use the sensationalism score as the reward, obtain statistically better results than Pointer-Gen+RL-ROUGE and Pointer-Gen, with a p-value less than 0.05 by a Chi-square test. This result shows the effectiveness of RL to generate more sensational headlines. The reason is that even though our noisy classifier could also learn to classify domains, the generator during RL training is not allowed to increase the reward by shifting domains but encouraged to generate more sensational headlines, due to the consistency constraint on the domains of the headline and the article. Furthermore, Poiner-Gen+ARL-SEN gets better performance than Pointer-Gen+RL-SEN, which confirms the superiority of the ARL loss function. We also visualize in Figure 3 a comparison between Pointer-Gen+ARL-SEN and Pointer-Gen+RL-SEN according to how sensational the test set headlines are. The blue bars denote the smaller scores between the two models. For example, if the blue bar is 0.6, it means that the worse model between Pointer-Gen+RL-SEN and Pointer-Gen+ARL-SEN achieves 0.6. And the color of orange/black further indicates the better model and its score. We find that Pointer-Gen+ARL-SEN outperforms Pointer-Gen+RL-SEN for most cases. The improvement is higher when the test set headlines are not sensational (the sensationalism score is less than 0.5), which may be attributed to the higher ratio of RL training on non-sensational headlines.

Apart from the sensationalism evaluation, we measure the fluency of the headlines generated from different models. Fluency scores in Table

Table 4: Different sensationalization strategies Pointer-Gen+ARL-SEN learns.

3 show that Pointer-Gen+RL-SEN and Pointer-Gen+ARL-SEN achieve comparable fluency performance to Pointer-Gen and Pointer-Gen+RL-ROUGE. Test set headlines achieve the best performance among all models, but the difference is not statistically significant. Also, we observe that fine-tuning on sensational headlines will hurt the performance, both in sensationalism and fluency.

After manually checking the outputs, we observe that our model is able to generate sensational headlines using diverse sensationalization strategies. These strategies include, but are not limited to, creating a curiosity gap, asking questions, highlighting numbers, being emotional and emphasizing the user. Examples can be found in Table 4.

5 Related Work

Our work is related to summarization tasks. An encoder-decoder model was first applied to two sentence-level abstractive summarization tasks on the DUC-2004 and Gigaword datasets (Rush et al., 2015). This model was later extended by selective encoding (Zhou et al., 2017), a coarse to fine approach (Tan et al., 2017b), minimum risk training (Shen et al., 2017a), and topic-aware models (Wang et al., 2018). As long summaries were recognized as important, the CNN/Daily Mail dataset was used in Nallapati et al. (2016). Graph-based attention (Tan et al., 2017a), pointer-generator with coverage loss (See et al., 2017) are further developed to improve the generated summaries. Celikyilmaz et al. (2018) proposed deep communicating agents for representing a long document

for abstractive summarization. In addition, many papers (Nallapati et al., 2017; Zhou et al., 2018b; Zhang et al., 2018a) use extractive methods to directly select sentences from articles. However, none of these work considered the sensationalism of generated outputs.

RL is also gaining popularity as it can directly optimize non-differentiable metrics (Pasunuru and Bansal, 2018; Venkatraman et al., 2015; Xu and Fung, 2019). Paulus et al. (2018) proposed an intra-decoder model and combined RL and MLE to deal with summaries with bad qualities. RL has also been explored with generative adversarial networks (GANs) (Yu et al., 2017). Liu et al. (2018) applied GANs on summarization task and achieved better performance. Niu and Bansal (2018) tackles the problem of polite generation with politeness reward. Our work is different in that we propose a novel function to balance RL and MLE.

Our task is also related to text style transfer. Implicit methods (Shen et al., 2017b; Fu et al., 2018; Prabhumoye et al., 2018) transfer the styles by separating sentence representations into content and style, for example using back-translation(Prabhumoye et al., 2018). However, these methods cannot guarantee the content consistency between the original sentence and transferred output (Xu et al., 2018a). Explicit methods (Zhang et al., 2018b; Xu et al., 2018a) transfer the style by directly identifying style related keywords and modifying them. However, sensationalism is not always restricted to keywords, but the full sentence. By leveraging small human labeled English dataset, clickbait detection has been well investigated (Chakraborty et al., 2016; Shu et al., 2018; Potthast et al., 2018). However, these human labeled dataset are not available for other languages, such as Chinese.

Modeling sensationalism is also related to modeling emotion. Emotion has been well investigated in both word level(Tang et al., 2016; Xu et al., 2018b) and sentence level(Felbo et al., 2017; Winata et al., 2019, 2018; Park et al., 2018; Lee et al., 2019). It has also been considered an important factor in engaging interactive systems(Lin et al., 2019b; Winata et al., 2017; Zhou et al., 2018a). Although we observe that sensational headlines contain emotion, it is still not clear which emotion and how emotions will influence the sensationalism.

6 Conclusion and Future Work

In this paper, we propose a model that generates sensational headlines without labeled data using Reinforcement Learning. Firstly, we propose a distant supervision strategy to train the sensationalism scorer. As a result, we achieve 65% accuracy between the predicted sensationalism score and human evaluation. To effectively leverage this noisy sensationalism score as the reward for RL, we propose a novel loss function, ARL, to automatically balance RL with MLE. Human evaluation confirms the effectiveness of both our sensationalism scorer and ARL to generate more sensational headlines. Future work can be improving the sensationalism scorer and investigating the applications of dynamic balancing methods between RL and MLE in textGAN(Yu et al., 2017). Our work also raises the ethical questions about generating sensational headlines, which can be further explored.

Abstract

A quality abstractive summary should not only copy salient source texts as summaries but should also tend to generate new conceptual words to express concrete details. Inspired by the popular pointer generator sequence-to-sequence model, this paper presents a concept pointer network for improving these aspects of abstractive summarization. The network leverages knowledge-based, context-aware conceptualizations to derive an extended set of candidate concepts. The model then points to the most appropriate choice using both the concept set and original source text. This joint approach generates abstractive summaries with higher-level semantic concepts. The training model is also optimized in a way that adapts to different data, which is based on a novel method of distantly-supervised learning guided by reference summaries and testing set. Overall, the proposed approach provides statistically significant improvements over several state-of-the-art models on both the DUC-2004 and Gigaword datasets. A human evaluation of the model's abstractive abilities also supports the quality of the summaries produced within this framework.

1 Introduction

Abstractive summarization (ABS) has gained overwhelming success owing to a tremendous development of sequence-to-sequence (seq2seq) model and its variants (Rush et al., 2015; Chopra et al., 2016; Paulus et al., 2017; Guo et al., 2018; Gao et al., 2019). In tandem with seq2seq models, pointer generator was developed by See et al. (2017) as a solution to tackle the rare words and out-of-vocabulary (OOV) problem associated with generative-based models. The idea behind is to use attention as a pointer to determine the probability of generating a word from both a vocabulary distribution and the source text. Pointer generator networks have also been extensively accepted by the ABS community due to their efficacy with long document summaries (Chen and Bansal, 2018; Hsu et al., 2018), title summarization (Sun et al., 2018), etc.

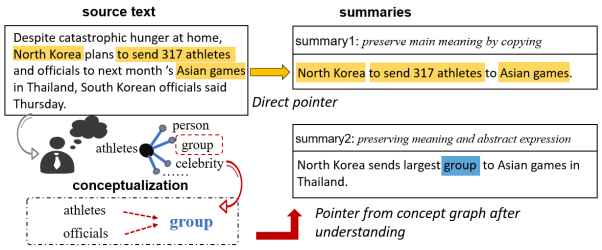

Figure 1: "summary1" only copies keyword from the source text, while "summary2" generates new concepts to convey the meaning.

However, the current power of abstractive summarization falls short of their potential. As the example in Figure 1 shows, a seq2seq model with a pointer mechanism (marked as the direct pointer) is likely to merely copy parts of the original text to form a summary using keywords and phrases, such as "317 athletes". Conversely, a more human-like summary would be based on one's own understanding of the detail in the words, expressed as higher-level concepts drawn from world knowledge—like using the word "group" to replace "athletes and officials". This indicates that a good summary should not simply copy original material, it should also generate new and even abstract concepts that reflect high-level semantics.

Therefore, a pointer generator network that solely considers the source material to generate a summary does not adequately satisfy the needs of high-quality abstractive summarization. We argue that concepts have a greater ability to express deeper meanings than verbatim words. As such, it is essential to explore the potential of us-

ing concepts from world knowledge to assist with abstractive summarization. Our developed model not only points to informative source texts but also leverages conceptual words from human knowledge in the summaries it generates.

Hence, in this paper, we propose a novel model based on a concept pointer generator that encourages the generation of conceptual and abstract words. As a hidden benefit, the model also alleviates the OOV problems. Our model uses pointer network to capture the salient information from a source text, and then employs another pointer to generalize the detailed words according to their upper level of expressions. Finally, the output is also consistent with language model by the seq2seq generator. Unique to our concept pointer is a set of concept candidates particular for a word that is drawn from a huge knowledge base. The set of candidates adheres to a concept distribution, where the probability of each concept being generated is linked to how strongly the candidate represents each word. Moreover, the concept distribution is iteratively updated to better explain the target word given the context of the source material and inherent semantics in the texts. Hence, the learned concept pointer points to the most suitable and expressive concepts or words. The optimization function is adaptive so as to cater for different datasets with distantly-supervised training. The network is then optimized end-to-end using reinforcement learning, with the distant-supervision strategy as a complement to further improve the summary.

Overall, the contributions of this paper are: 1) a novel concept pointer generator network that leverages context-aware conceptualization and a concept pointer, both of which are jointly integrated into the generator to deliver informative and abstract-oriented summaries; 2) a novel distant supervision training strategy that favors model adaptation and generalization, which results in performance that outperforms the well-accepted evaluation-based reinforcement learning optimization on a test-only dataset in terms of ROUGE metrics; 3) a statistical analysis of quantitative results and human evaluations from comparative experiments with several state-of-the-art models that shows the proposed method provides promising performance.

2 Related Work

Abstractive summarization supposedly digests and understands the source content and, consequently, the generated summaries are typically a reorganization of the wording that sometimes form new sentences. Historically, abstractive summarization has been performed through rule-based sentence selection (Dorr et al., 2003), key information extraction (Genest and Lapalme, 2011), syntactic parsing (Bing et al., 2015) and so on. However, more recently, seq2seq models with attention have played a more dominant role in generating abstractive summaries (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Zhou et al., 2017). Extensions to the seq2seq approach include an intra-decoder attention (Paulus et al., 2017) and coverage vectors (See et al., 2017) to decrease repetition in phrasing. Copy mechanism (Gu et al., 2016) has been integrated into these models to tackle OOV problem. Zhou et al. (2018) went on to propose SeqCopyNet which copies complete sequences from an input sentence to further maintain the readability of the generated summary.

Pointer mechanism (Vinyals et al., 2015) has drawn much attention in text summarization (See et al., 2017), because this technique not only provides a potential solution for rare words and OOV but also extends abstractive summarization in a flexible way (Çelikyilmaz et al., 2018). Further, pointer generator models can effectively adaptive to both extractor and abstractor networks (Chen and Bansal, 2018), and summaries can be generated by incorporating a pointer-generator and multiple relevant tasks (Guo et al., 2018), such as question or entailment generation, or multiple source texts (Sun et al., 2018).

However, work particularly targets the problem of the abstraction is rare. Abstract Meaning Representation (AMR) is used to transform a sentence into a concept graph, then merge those similar concept nodes to form a new summary graph (Liu et al., 2018). Concepts are also incorporated as auxiliary features (Guo et al., 2017). Kryscinski et al. (2018) and Weber et al. (2018) define the number of new n-grams as the primary criteria of abstractiveness. This makes sense in most cases. But, we believe that abstraction means summarizing detailed content with higher-level semantically related concepts, which has motivated the development of the model proposed in this paper.

3 The Proposed Model

Neural abstractive summarization can be described as a generation process where a sequential input is summarized into a shorter sequential output through a neural network. Suppose that the sequential input $\boldsymbol{x} = \{x_1, \ldots, x_i, \ldots, x_n\}$ is a sequence of n number of words, and i is the index of the input. The shorter (i.e., summarized) sequence of output is denoted as $\boldsymbol{y} = \{y_1, \ldots, y_t, \ldots, y_m\}$ with number of m words, and t indicates a time step. As Figure 2 shows, our model consists of two sub-modules —an encoder-decoder module and the proposed concept pointer generator module.

3.1 Encoder-Decoder Framework

This process is formulated as an encoder-decoder framework that consists of an encoder and an attention-equipped decoder. We use a two-layer bi-directional LSTM-RNN encoder and one-layer uni-directional LSTM-RNN decoder along with attention mechanism.

Formally, the encoder produces sequential hidden states as $(\overrightarrow{\boldsymbol{h}}_1, \ldots, \overrightarrow{\boldsymbol{h}}_n)$ and $(\overleftarrow{\boldsymbol{h}}_1, \ldots, \overleftarrow{\boldsymbol{h}}_n)$ in the corresponding positions, and the bi-directional $h_i = f_{LSTM}(h_{i-1}, x_i)$. Each word x_i in the sequence can be represented as a concatenation of the bi-directional hidden states, i.e., $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i]$. The decoder generates a target summary from a vocabulary distribution $P_{vocab}(w)$, which is based on a context vector $\boldsymbol{h}_t^*$ through the following process:

$$\begin{aligned} P_{vocab}(w) &= P(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x}; \theta) \\ &= \text{sfm}(\boldsymbol{W}_2(\boldsymbol{W}_1[\boldsymbol{s}_t, \boldsymbol{h}_t^*] + \boldsymbol{b}_1) + \boldsymbol{b}_2) \end{aligned} \quad (1)$$

where $\boldsymbol{s}_t$ is the hidden state of the decoder at time step t , and $\boldsymbol{h}_t^*$ is the context vector at time step t. $\boldsymbol{W}_1, \boldsymbol{W}_2, \boldsymbol{b}_1, \boldsymbol{b}_2$ are trainable parameters, and sfm$(\cdot)$ is short for softmax function.

The context vector $\boldsymbol{h}_t^*$ is computed by a weighted sum of the hidden representations of the source text, and the weight is denoted as the attention $\alpha_{t,i}$.

$$\begin{aligned} \boldsymbol{h}_t^* &= \sum\nolimits_{i=1}^{n} \alpha_{t,i} \boldsymbol{h}_i \\ \alpha_{t,i} &= \text{sfm}(\boldsymbol{v}^\top \tanh(\boldsymbol{W}_h \boldsymbol{h}_i + \boldsymbol{W}_s \boldsymbol{s}_t + \boldsymbol{b})) \end{aligned} \quad (2)$$

The softmax function normalizes the vector of a distribution over the input position, and $\boldsymbol{v}, \boldsymbol{W}_h, \boldsymbol{W}_s, \boldsymbol{b}$ are trainable parameters.

3.2 Concept Pointer Generator

Pointer networks use attention as a pointer to select segments of the input as outputs (Vinyals et al., 2015). As such, a pointer network is a suitable mechanism for extracting salient information, while remaining flexible enough to interface with a seq2seq model for generating an abstractive summarization (See et al., 2017). Our proposed model is essentially an upgrade to this configuration that integrates a new concept pointer network within a unified framework.

3.2.1 Context-aware Conceptualization

"Understanding" the instances of a word requires a taxonomic knowledge base that relates those words to a concept space. In our model, we use an isA taxonomy, called the Microsoft Concept Graph[1] (Wang et al., 2015), to serve this purpose for two reasons (Wang and Wang, 2016). First, this graph provides a huge concept space with multi-word terms that cover concepts of worldly facts as concepts, instances, relationships, and values[2]. Second, the relationships between concepts and entities are probabilistic as a measure of how strongly they are related. Moreover, the probabilities are trustworthy given they have been derived from evidence found in billions of webpages, search log data, and other existing taxonomies. Our model is data-driven and, therefore, is more easily adaptable with probabilities. All these characteristics make the Microsoft Concept Graph a suitable choice for our model. More detailed examples are available in Appendix A.

The concept graph specifies the probability that each instance x belongs to a concept c, $p(c|x)$. Given a word x, we have a distribution over a set of related concepts. Yet, this raises the question of how to identify a context-appropriate concept for a word from the distributional set of candidate concepts. For instance, *apple* in the context of "*an apple is good for you health*" tends to be associated with the concept of *fruit* instead of *company*. Formally, given a word x_i in a training sentence, a set of k concept candidates, $C_i = \{c_i^1, c_i^2, \cdots, c_i^k\}$, is linked to the word from the knowledge base, with distributional probabilities over the concepts, i.e.,

[1]The Microsoft concept graph was derived from Probase project. The public data can be downloaded via the provided API: https://concept.research.microsoft.com/Home/API

[2]The current version is mined from billions of web pages, containing 5.3 M unique concepts, 12.5 M unique entities and 85 M isA relations.

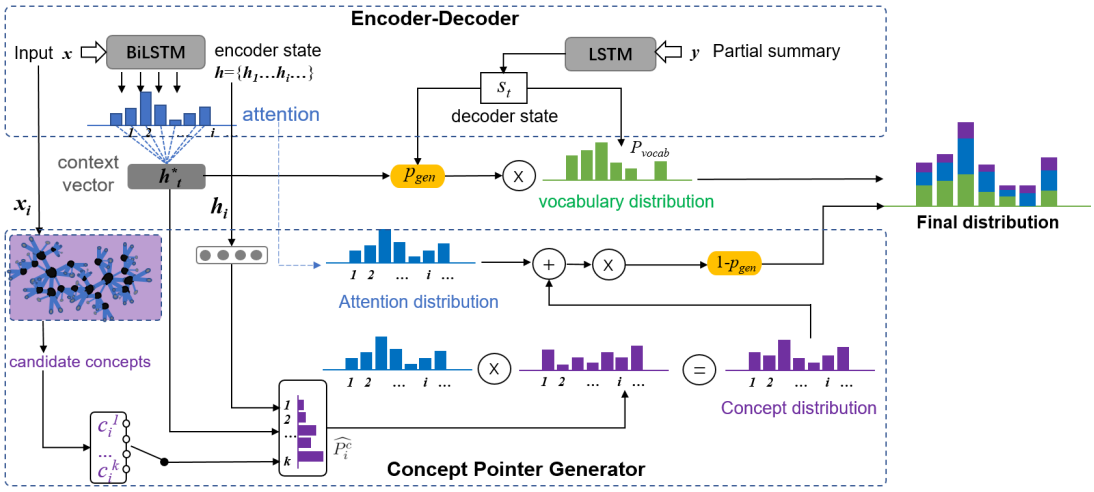

Figure 2: The architecture of our model. Blue bar represents the attention distribution over the inputs. Purple bar represents the concept distribution over the inputs. Noted that, this distribution can be sparse since not every word has its upper concept. Green bar represents the vocabulary distribution generated from seq2seq component.

$P(C|x_i) = \{p(c_i^1), p(c_i^2), \cdots, p(c_i^k)\}$. The task is to find the most suitable concept c_i^j to fit the updated context, represented by the vector $\boldsymbol{h}_t^*$ in Equation (2), at each time step t.

In the case of generating summaries given updated contexts, a weighted update of the distributional concept candidates needs to be performed. In the model, the updated weight, denoted as β_i^j, is estimated by a softmax classifier that is jointly conditioned on the hidden representation of the word $\boldsymbol{h}_i$, the context vectors $\boldsymbol{h}_t^*$, and each of concept vectors:

$$\beta_i^j = \text{softmax}(\boldsymbol{W}_{h'}[\boldsymbol{h}_i, \boldsymbol{h}_t^*, \boldsymbol{c}_i^j]) \quad (3)$$

where $j \in [1, k]$, $\boldsymbol{W}_{h'}$ is a trainable parameter, and $\boldsymbol{c}_i^j$ is the vector of the jth concept candidate, which is a representation of the input embeddings.

Together with the concept probability from the existing knowledge base $p(c_i^j)$ and the updated weights based on the contexts β_i^j, a context-aware conceptualized probability of jth concept for the word x_i, $P_{i,j}^c$, is finally estimated as

$$P_{i,j}^c = p(c_i^j) + \gamma \beta_i^j \quad (4)$$

where γ is a tunable parameter. Theoretically, we will end up with a number of k relevant concepts for each word $C_i = \{c_i^1, \cdots, c_i^k\}$ with a probability distribution over the set, which is learned as $P_i^c = \{P_{i,1}^c, \cdots, P_{i,j}^c, \cdots, P_{i,k}^c\}$.

3.2.2 Concept Pointer Generator

The basic pointer generator network contains two sub-modules, one is the pointer network and the other is the generation network. These two sub-modules jointly determine the probabilities of the words in the final generated summary. The generation probability p_{gen} for the generation network (See et al., 2017) is learned by

$$p_{gen} = \sigma(\boldsymbol{W}_{h^*}\boldsymbol{h}_t^* + \boldsymbol{W}_s\boldsymbol{s}_t + \boldsymbol{W}_y\boldsymbol{y}_{t-1} + \boldsymbol{b}_{gen}) \quad (5)$$

where σ is a sigmoid function.

For the pointer network, our model consists of a pointer to the source text and a further concept pointer to the relevant concepts that have arisen from the source content. These two separate pointers are calculated as follows. The first pointer is taken based on the attention distribution $\alpha_{t,i}$ over the source text. The second concept pointer is operated over a concept distribution of the source text that is scaled element-wise by the attention distribution.

To train the model, given the likelihood of each concept in the current context, the updates could be performed in two ways. In a hard assignment, the concept that receives the highest score would be selected for the update:

$$\widehat{P_i^c}_{\text{argmax}} = P_{i,a}^c, \text{where } a = \arg\max_j(\beta_i^j) \quad (6)$$

where a is the index of maximized generated weight based on the contexts, and $P_{i,a}^c$ is obtained by Eqs. (4).

In random selection, each of the concept candidates could be trained randomly to update the parameters:

$$\widehat{P_i^c}_{\text{random}} = P_{i,j}^c \sim P_i^C \quad (7)$$

where j represents the selected concept index. Considering the above baseline generation network and both the pointer networks, our final output distribution is

$$P_{\text{final}}(w) = p_{gen}P_{vocab}(w) + (1 - p_{gen}) \\ (\sum_{i:w_i=w} \alpha_{t,i} + \sum_{i:w_i=w} \alpha_{t,i} \times \widehat{P_i^c}) \quad (8)$$

where $\widehat{P_i^c}$ can be updated by $\widehat{P_{i\ \arg\max}^c}$, or $\widehat{P_{i\ \text{random}}^c}$. The difference between these two choices is demonstrated in the Experiments section.

3.3 Objective Learning

3.3.1 Basic MLE

The baseline objective is derived by maximizing the likelihood training for the seq2seq generation, given a reference summary $y^* = \{y_1^*, y_2^*, \cdots, y_{m'}^*\}$ for document x. The training objective is to minimize the negative log-likelihood of the target word sequence:

$$\mathcal{L}_{MLE} = -\sum_{t=1}^{m'} \log P(y_t^*|y_1^*, \cdots, y_{t-1}^*, \boldsymbol{x}) \quad (9)$$

3.3.2 Evaluation based Reinforcement Learning (RL)

Similar to Paulus et al. (2017), policy gradient methods can directly optimize discrete target evaluation metrics, such as ROUGE. The basic idea is to explore new sequences and compare them to the best greedy baseline sequence. Once the baseline sequence $\hat{y}$, or sampled sequence y^s, are generated, they are compared against the reference sequence y^* to compute the rewards $r(\hat{y})$ and $r(y^s)$, respectively. In the RL training stage, two separate output candidates at each time step are produced: y^s is sampled from the probability distribution $P(y_t^s|y_1^s, \cdots, y_{t-1}^s, x)$, and $\hat{y}$ is the baseline output. The training objective is then to minimize

$$\mathcal{L}_{RL} = (r(\hat{y}) - r(y^s)) \sum_{t=1}^{m'} \log P(y_t^s|y_1^s, \cdots, y_{t-1}^s, x) \quad (10)$$

It is noteworthy that the samples y^s are selected from a wide range of vocabularies extended by all the concept candidates. This strategy ensures that the model learns to generate sequences with higher rewards by better exploring a set of close concepts.

Thus, the combination of these two objectives yield improved task-specific scores while catering a better language model: $\mathcal{L}_{final} = \lambda\mathcal{L}_{RL} + (1 - \lambda)\mathcal{L}_{MLE}$, where λ is a soft-switch between the two objectives. The model is pre-trained with MLE loss, then switch to the final loss.

3.3.3 Distant Supervision (DS) for Model Adaption

Our intuition is that, if the summary-document pairs are dissimilar to the testing set, the model could be retrained to adapt to weaken the influence of the dissimilarity on the final loss. The result would be a training model that better fits the specific testing data. The challenge is that there are no explicit supervision labels to indicate whether the training set is close to the testing set, so a new training paradigm is needed. In answer to this need and also to provide end-to-end functionality in the model, we developed a simple approach for labeling summary-document pairs by calculating the Kullback-Leibler (KL) divergence between each training reference summary and a set of testing documents. In this way, the training pairs are distantly-labelled for training the model.

Specifically, the representations of the reference summaries and the testing set are computed by summing all the involved word embeddings. Given a testing document x_l^{d}, where $l \in [1, N^{\text{d}}]$ and N^{d} is the size of the testing corpus, the vector-based representation of one document is $\boldsymbol{x}_l^{\text{d}} = \exp(\sum_{i=1}^{n'} \boldsymbol{x}_i^{\text{d}})$, where n' is the number of document words involved. The reference summary is represented by $\boldsymbol{y^*} = \exp(\sum_{t=1}^{m'} \boldsymbol{y_t^*})$. We normalize these vectors through a softmax function to cater for KL calculation. The model adaption with the distant labels is defined as:

$$\mathcal{L}_{DS} = (\pi - \tfrac{1}{N^{\text{d}}} \sum_{l=1}^{N^{\text{d}}} D_{\text{KL}}(\boldsymbol{y^*}, \boldsymbol{x}_l^{\text{d}}))\mathcal{L}_{\text{MLE}} \quad (11)$$

where $D_{\text{KL}}(.)$ indicates the KL divergence between y^* and x_l^{d}, and π is a constant parameter that is tuned via adaption to the testing set. The divergences are averaged within the testing set, which indicates the overall distances between testing set and each of the reference summary-document pairs. In this way, the samples in the training corpus are distantly annotated as either relevant or irrelevant for model adaption, noting that the model is pre-trained with the MLE loss before switching to distantly-supervised training.

4 Experiments

ing on two popular datasets. The first was the English Gigaword Fifth Edition corpus (Parker et al., 2011). We replicated the pre-processing steps in (Rush et al., 2015) to obtain the same training/testing data. After pre-processing, the corpus contained about 3.8M sentence-summary pairs as training set and 189K pairs as the development set. Once pairs with empty titles were removed, the testing set numbered 1951 pairs. The second dataset, DUC2004, was only used for testing. This dataset consists of 500 document-headline summary pairs, where each document is paired with four reference summaries written by humans.

Evaluation Metrics: We used ROUGE (Lin, 2004) as the evaluation metric, which measures the quality of a summary by computing the overlapping lexical elements between the candidate summary and a reference summary. Following previous practice, we assessed RG-1 (unigram), RG-2 (bigram) and RG-L (longest common subsequence - LCS). Noted that the English Gigaword[3] testing set contains references of different lengths, while the DUC-2004[4] testing set fixes the summary length to 75 bytes.

Training Setups: We initialize word embeddings with 128-d vectors and fine-tune them during training. Concepts share the same embeddings with the words. The vocabulary size was set to 150k for both the source and target text. The hidden state size was set to 256. The vocabulary size is increased from around 602 to 2216 concepts w.r.t the different number ($k = 1, \cdots, 5$) of concept candidates for each word. Note that the generated concepts with UNKs were subsequently deleted. Our code is available on `https://github.com/wprojectsn/codes`, and the vocabularies and candidate concepts are also included.

We trained our models on a single GTX TITAN GPU machine. We used the Adagrad optimizer with a batch size of 64 to minimize the loss. The initial learning rate and the accumulator value were set to 0.15 and 0.1, respectively. We used gradient clipping with a maximum gradient norm of 2. At the time of decoding, the summaries were produced through a beam search of size 8. The hyper-parameter settings were $\lambda = 0.99$, $\gamma = 0.1$, $\pi = 2.92$ on DUC-2004 and $\pi = 1.68$ on Gigaword. We trained our concept pointer generator for 450k iterations yielded the best performance, then took the optimization using RL rewards for RG-L at 95K iterations on DUC-2004 and at 50K iterations on Gigaword. We took the distance-supervised training at 5K iterations on DUC-2004 and at 6.5K iterations on Gigaword.

Baselines: The following state-of-the-art baselines were used as comparators. **ABS+** (Rush

[3]The ROUGE evaluation option is, -m -n 2 -s

[4]The ROUGE evaluation option is, -n 2 -m -b 75 -s

Table 2: OOV problem analysis: percentages (%(NO. UNK/NO. all generated words)) of generating UNK w.r.t the following three models on Gigaword and DUC-2004 datasets.

Method	Gigaword	DUC-2004
seq2seq+att	4.02%(570/14183)	2.08%(85/4079)
Pointer generator	1.16%(207/17859)	0.31% (16/5140)
Concept pointer	1.12%(202/17950)	0.23%(12/5230)

Table 3: Abstractiveness: percentage of novel n-grams on Gigaword dataset.

Models	Novel n-gram (%)		
	1-gram	2-gram	3-gram
Pointer generator	14.3	41.9	63.4
Concept pointer	17.2	45.8	68.5
Reference summary	25.4	65.6	78.4

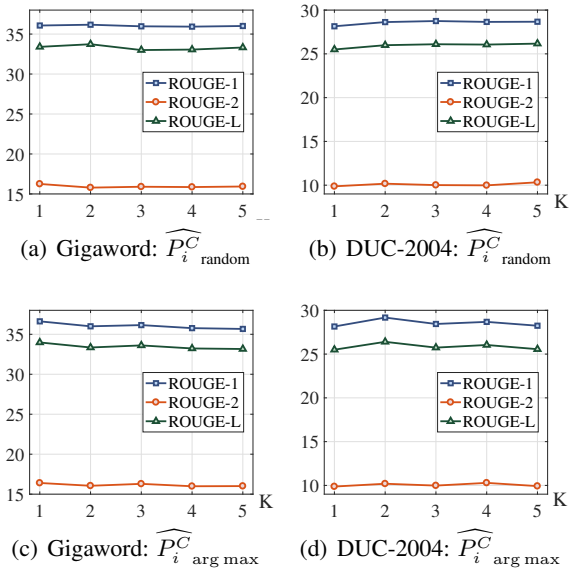
et al., 2015) is a tuned ABS model with additional features. **Luong-NMT** (Luong et al., 2015) is a two-layer LSTM encoder-decoder. **RAS-Elman** (Chopra et al., 2016) is a convolution encoder and an Elman RNN decoder with attention. **Seq2seq+att** is two-layer BiLSTM encoder and one-layer LSTM decoder equipped with attention. **lvt5k-lsent** (Nallapati et al., 2016) uses temporal attention to keep track of the past attentive weights of the decoder and restrains the repetition in later sequences. **SEASS** (Zhou et al., 2017) includes an additional selective gate to control information flow from the encoder to the decoder. **Pointer-generator** (See et al., 2017) is an integrated pointer network and seq2seq model. We implemented this baseline without its coverage mechanism since this is not our focus. Baseline models also include two pointer-generator based extensions (Guo et al., 2018; Li et al., 2018). **CGU** (Lin et al., 2018) sets a convolutional gated unit and self-attention for global encoding.

5 Results and Analysis

The following analysis focuses on investigating whether our model is, first, able to generate abstract and new concepts, and, second, how the overall quality performs against the baselines.

5.1 Quantitative Analysis

The results are presented in Table 1. We observe that our model outperformed all the strong state-of-the-art models on both datasets in all metrics except for RG-2 on Gigaword. In terms of the pointer generator performance, the improvements made by our concept pointer are statistically significant ($p < 0.01$) across all metrics.



OOV and Summary Length: OOV is another major challenge for current abstractive summarization models. Although generating longer summaries or less UNKs is not our focus, our model still showed improvements in this regard (Table 2). We counted the number of UNKs and all generated summary words and measured the proportions in both testing sets. The OOV percentages dropped from 4.02% to 1.12% on Gigaword and from 2.08% to 0.23% on DUC-2004, which demonstrates that our model is effective at alleviating OOV problems. This result also supports the superior of the concept pointer over the baseline pointer generator. From the statistics, we found that the summaries generated by our concept pointer averaged around 10.46 words, while the pointer generator summaries averaged 10.28 words per summary on DUC-2004. This shows the concept pointer is able to capture more salient content by generating relatively longer summaries.

Abstractiveness: According to Chen and Bansal (2018), abstractiveness scores are computed as the percentage of novel n-grams in the generated summaries that are not included in the source documents. As shown in Table 3, compared with human-written summaries which receive the highest novelty in terms of abstractiveness, our concept pointer generator achieves closest performance with human-written summaries against the baseline. This result demonstrates a further advantage of our model in producing new and abstract concepts. Our model is designed to improve semantic relevance and promote higher abstraction. More generated summary examples can be found in Appendix B.

5.2 Analysis on Training Strategies

To evaluate the relative impact of each training strategy with the model, we tested different combinations for comparison with each other and against the baselines.

Context-aware Conceptualization: To investigate the impact of training with both the number of concepts k and the concept update strategy mentioned in Eqs.(6) and (7), we chose a different number of concept candidates, i.e., $k = 1, 2, 3, 4, 5$, to for the context-aware conceptualization update strategy. Performance was fully

(a) Gigaword: $\widehat{P_i^C}_{\text{random}}$ (b) DUC-2004: $\widehat{P_i^C}_{\text{random}}$

(c) Gigaword: $\widehat{P_i^C}_{\arg\max}$ (d) DUC-2004: $\widehat{P_i^C}_{\arg\max}$

Figure 3: ROUGE metrics on Gigaword and DUC-2004 w.r.t a different number of concept candidates. Updates were conducted by hard assignment $\widehat{P_i^C}_{\arg\max}$ and random selection $\widehat{P_i^C}_{\text{random}}$.

evaluated with the three ROUGE metrics as shown in Figure 3. The results only vary slightly according to the number of concepts with the random selection strategy (Eq.(7)), as shown in Figure 3(a) and 3(b). This indicates that a random strategy is not very sensitive to the number of extracted topics. This is, in part, because the concept pointer may or may not be able to point to the correct concepts from multiple candidates. While in Figure 3(c) and 3(d), the optimum settings are clearly apparent, i.e., $k = 1$ on Gigaword and $k = 2$ on DUC-2004. Overall, the hard assignment strategy (Eq.(6)) provided the best performance in practical terms, while random selection (Eq.(7)) performs stably with different settings.

Training with DS vs. RL: As shown in Table 1, our model with either a distant supervision strategy (concept pointer+DS) or reinforcement learning (concept pointer+RL) were both superior to the basic concept pointer generator on both datasets. Further, the relative improvement of the concept pointer+DS over the concept pointer+RL ranged from 3.5% to 9.6% on DUC-2004 but was inferior to concept pointer+RL on Gigaword. In comparing the results, it is clear that DS training has a noticeable effect when the testing set is substantially semantically different from the training set but provides less improvement than RL when the two are close. From this analysis, we conclude that the DS strategy is better for model adaption with abstractive summarization.

Table 4: Human evaluation: scoring of three models in terms of abstraction and overall quality by human evaluators (the higher the better). The score range could be 0-20. $\star$ indicates the improvements from the baselines to the concept pointer are statistically significant.

Method	abstraction	overall quality
seq2seq+att $\star$	5.85	5.65
Pointer generator $\star$	8.95	8.10
Concept pointer	10.00	9.60

5.3 Human Evaluations

To explore the correctness of our model using human judgment, we conducted a manual evaluation with 20 post-graduate volunteers. We primarily used the following criteria to assess the generated summaries: *abstraction*, i.e., Are the abstract concepts contained in the summary appropriate?; and *overall quality*, i.e., Is the summary readable, informative, relevant, etc.? To conduct the evaluation, we randomly selected 20 examples from the DUC 2004 testing set and asked the volunteers to subjectively assess the summaries. Each example consisted of an article and three summaries, i.e., a summary by the seq2seq model, the pointer generator model, and our proposed concept pointer model. The volunteers chose the best summaries for each of the articles according to the above criteria (can be multiple choices). Obviously, the summaries were randomly shuffled, and the model used to produce each was unknown to prevent bias. The scores for each model were ranked by how many times the volunteers chose a summary w.r.t each criteria, averaged by the number of participants. The results are presented in Table 4, which show that our model outperformed both the seq2seq model and the pointer generator (See et al., 2017) in both criteria.

As a last step, we manually inspect the summaries generated by our model, and some examples are presented in Appendix B. We found that the summaries were not as abstract as human-written summary would likely be. The overarching tendency of the model is still to copy segments of the source text and rearrange the phrases into a summary. However, the overall approach does produce more high-level concepts with correct relations compared to the baselines, which demon-

strates that our solution is a promising research direction to further pursue. Additionally, the generated summaries are long, fluent, and informative.

6 Conclusion

This paper presents a novel concept pointer generator model to improve the abstractive summarization model and generate concept-oriented summaries. We also propose a novel distant supervision strategy for model adaption to different datasets. Both empirical and subjective experiments show that our model makes a statistically significant quality improvement over the state-of-the-art baselines on two popular datasets.

Surface Realisation Using Full Delexicalisation

Anastasia Shimorina

LORIA / CNRS
claire.gardent@loria.fr

Abstract

Surface realisation (SR) maps a meaning representation to a sentence and can be viewed as consisting of three subtasks: word ordering, morphological inflection and contraction generation (e.g., clitic attachment in Portuguese or elision in French). We propose a modular approach to surface realisation which models each of these components separately, and evaluate our approach on the 10 languages covered by the SR'18 Surface Realisation Shared Task shallow track. We provide a detailed evaluation of how word order, morphological realisation and contractions are handled by the model and an analysis of the differences in word ordering performance across languages.

1 Introduction

Surface realisation maps a meaning representation to a sentence. In data-to-text generation, it is part of a complex process aiming to select, compress and structure the input data into a text. In text-to-text generation, it can be used as a mean to rephrase part or all of the input content. For instance, Takase et al. (2016) used surface realisation to generate a summary based on the meaning representations of multiple input documents and Liao et al. (2018) to improve neural machine translation.

By providing parallel data of sentences and their meaning representation, the SR'18 Surface Realisation shared task (Mille et al., 2018) allows for a detailed evaluation and comparison of surface realisation models. Moreover, as it provides training and test data for multiple languages, it also allows for an analysis of how well these models handle languages with different morphological and topological properties.

The SR'18 shared task includes two tracks: a shallow track where the input is an unordered, lemmatised dependency tree and a deep track where function words are removed and syntactic relations are replaced with semantic ones. In this paper, we focus on the shallow track of the SR'18 Shared Task and we propose a neural approach which decomposes surface realisation into three subtasks: word ordering, morphological inflection and contraction generation (e.g., clitic attachment in Portuguese or elision in French). We provide a detailed analysis of how each of these phenomena (word order, morphological realisation and contraction) is handled by the model, and we discuss the differences between languages.

For reproducibility, all our experiments including data and scripts are available at https://gitlab.com/shimorina/emnlp-2019.

2 Related Work

Early approaches for surface realisation adopted statistical methods, including both pipelined (Bohnet et al., 2010) and joint (Song et al., 2014; Puduppully et al., 2017) architecture for word ordering and morphological generation.

Multilingual SR'18 was preceded by the SR'11 surface realisation task for the English language only (Belz et al., 2011). The submitted systems in 2011 had grammar-based and statistical nature, mostly relying on pipelined architecture. Recently, Marcheggiani and Perez-Beltrachini (2018) proposed a neural end-to-end approach based on graph convolutional encoders for the SR'11 deep track.

The SR'18 shallow track received submissions from eight teams with seven of them dividing the task into two subtasks: word ordering and inflection. Only Elder and Hokamp (2018) developed a joint approach, however, they participated only in the English track.

For word ordering, five teams chose an approach based on neural networks, two used a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3086–3096,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

classifier, and one team resorted to a language model. As for the inflection subtask, five teams applied neural techniques, two used lexicon-based approaches, and one used an SMT system (Basile and Mazzei, 2018; Castro Ferreira et al., 2018; Elder and Hokamp, 2018; King and White, 2018; Madsack et al., 2018; Puzikov and Gurevych, 2018; Singh et al., 2018; Sobrevilla Cabezudo and Pardo, 2018). Overall, neural components were dominant across all the participants. However, official scores of the teams that went neural greatly differ. Furthermore, two teams (Elder and Hokamp, 2018; Sobrevilla Cabezudo and Pardo, 2018) applied data augmentation, which makes their results not strictly comparable to others.

One of the interesting findings of the shared task is reported by Elder and Hokamp (2018) who showed that applying standard neural encoder-decoder models to jointly learn word ordering and inflection is highly challenging; their sequence-to-sequence baseline without data augmentation got 43.11 BLEU points on English.

Our model differs from previous work in three main ways. First, it performs word ordering on fully delexicalised data. Delexicalisation has been used previously but mostly to handle rare words, e.g. named entities. Here we argue that surface realisation and, in particular, word ordering works better when delexicalising all input tokens. This captures the intuition that word ordering is mainly determined by the syntactic structure of the input. Second, we we provide a detailed evaluation of how our model handles the three subtasks underlying surface realisation. While all SR'18 participants provided descriptions of their models, not all of them performed an in-depth analysis of model performance. Exceptions are works of King and White (2018), who provided a separate evaluation for the morphological realisation module, and Puzikov and Gurevych (2018), who evaluated both word ordering and inflection modules. However, it is not clear how each of those modules affect the global performance when merged in the full pipeline. In contrast, we propose a detailed incremental evaluation of each component of the full pipeline and show how each component impacts the final scores. Third, we introduce a linguistic analysis, based on the dependency relations, of the word ordering component, allowing for deeper error analysis of the developed systems.

Furthermore, our model explicitly integrates a module for contraction handling, as done also before by Basile and Mazzei (2018). We also address all the ten languages proposed by the shared task and outline the importance of handling contractions.

3 Data

The SR'18 data (shallow track) is derived from the ten Universal Dependencies (UD) v2.0 treebanks (Nivre et al., 2017) and consists of (T, S) pairs where S is a sentence, and T is the UD dependency tree of S after word information has been removed and tokens have been lemmatised. The languages are those shown in Table 1 and the size of the datasets (training, dev and test) varies between 7,586 (Arabic) and 85,377 (Czech) instances with most languages having around 12K instances (for more details about the data see Mille et al. (2018)).

4 Model

As illustrated by Example 1, surface realisation from SR'18 shallow meaning representations can be viewed as consisting of three main steps: word ordering, morphological inflection and contraction generation. For instance, given an unordered dependency tree whose nodes are labelled with lemmas and morphological features (1a)[1], the lemmas must be assigned the appropriate order (1b), they must be inflected (1c) and contractions may take place (1d).

(1) a. the find **be not** meaning of life it about
b. it be not about find the meaning of life
c. It **is n't** about finding the meaning of life
d. It **isn't** about finding the meaning of life

We propose a neural architecture which explicitly integrates these three subtasks as three separate modules into a pipeline: word ordering (WO) is applied first, then morphological realisation (WO+MR) and finally, contractions (WO+MR+C) are handled.

4.1 Word Ordering

For word ordering, we combine a factored sequence-to-sequence model with an "extreme delexicalisation" step which replaces matching source and target tokens with an identifier.

[1]Features and tree structures have been omitted.

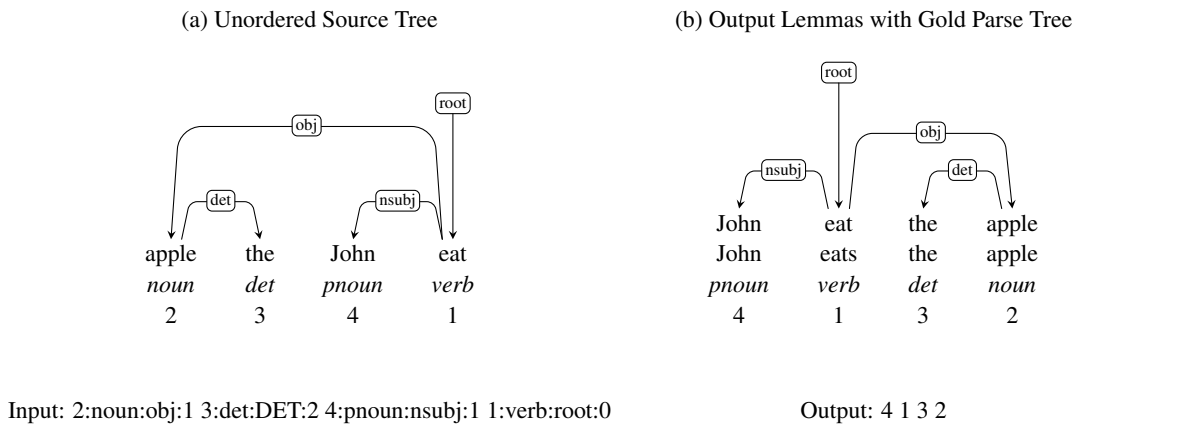

Figure 1: Delexicalising and linearising (in the parse tree of the output sentence the first row shows the lemmas, the second–the word forms, the third–the POS tags and the fourth–the identifiers). Identifiers are assigned to the source tree nodes in the order given by depth-first search.

Delexicalisation. Delexicalisation has frequently been used in neural NLG to help handle unknown or rare items (Wen et al., 2015; Dušek and Jurcicek, 2015; Chen et al., 2018). Rare items are replaced by placeholders both in the input and in the output; models are trained on the delexicalised data; and a post-processing step ensures that the generated text is relexicalised using the placeholders' original value. In these approaches, delexicalisation is restricted to rare items (named entities). In contrast, we apply delexicalisation to all input lemmas. Abstracting away from specific lemmas reduces data sparsity, allows for the generation of rare or unknown words and last but not least, it captures the linguistic intuition that word ordering mainly depends on syntactic information (e.g., in English, the subject generally precedes the verb).

To create the delexicalised data, we need to identify matching input and output elements and to replace them by the same identifier. We also store a mapping (id, L, F) specifying which identifier id refers to which (L, F) pair, where L is a lemma and F is its set of morpho-syntactic features.

We identify matching input and output elements by comparing the unordered input tree provided by the SR'18 task with the parse tree of the output sentence provided by the UD treebanks (cf. Figure 1). Source and target nodes which share the same path to the root are then mapped to the same identifier. For instance, in Figure 1, the lemma "apple" has the same path to the root (obj:eat:root) in both the input and the output tree. Hence the same identifier is assigned to the nodes. More generally, after linearisation through depth-first, left-to-right traversal of the input tree, each training instance captures the mapping between lemmas in the input tree and the same lemmas in the output sequence. For instance, given the example shown in Figure 1, delexicalisation will yield the training instance:

Input: tkn2 tkn3 tkn4 tkn1
Output: tkn4 tkn1 tkn3 tkn2

where tkn_i is the factored representation (see below) of each delexicalised input node.

Factored Sequence-to-Sequence Model. Following Elder and Hokamp (2018), we use a factored model (Alexandrescu and Kirchhoff, 2006) as a means of enriching the node representations input to the neural model. Each delexicalised tree node is modelled by a sequence of features. Separate embeddings are learned for each feature type and the feature embeddings of each input node are concatenated to create its dense representation. As exemplified in Figure 1, we model each input placeholder as a concatenation of four features: the node identifier, its POS tag, its dependency relation to the parent node and its parent identifier[2].

Sequence-to-sequence model. We use the OpenNMT-py framework (Klein et al., 2017)[3] to train factored sequence-to-sequence models with attention (Luong et al., 2015) and the copy and coverage mechanisms described in See et al. (2017). A single-layer LSTM is used for both encoder and decoder. We train using full vocabulary

[2]The parent identifier of a root node is represented as 0.

[3]commit e61589d, https://github.com/OpenNMT/OpenNMT-py

and the maximal length in the source and target for both baseline and the proposed model. Models were trained for 20 epochs, with a mini-batch size of 64, a word embedding size of 300, and a hidden unit size of 450. They were optimised with SGD with a starting learning rate of 1.0. A learning rate is halved when perplexity does not decrease on the development set. Preliminary experiments showed that the lowest perplexity was reached on average at epoch 17, so this model was kept for decoding. Decoding is done using beam search with a beam size of 5. For each language, we train three models with different random seeds, and report the average performance and standard deviation.

The model is trained on delexicalised data. At test time, the token/identifier mapping is used to relexicalise the model output.

4.2 Morphological Realisation

The morphological realisation (MR) module consists in producing inflected word forms based on lemmas coupled with morphological features. For that module, we used a model recently proposed by Aharoni and Goldberg (2017), which achieves state-of-the-art results on several morphological inflection datasets: the CELEX dataset (Baayen et al., 1993; Dreyer et al., 2008), the Wiktionary dataset (Durrett and DeNero, 2013) and the SIGMORPHON2016 dataset (Cotterell et al., 2016). Their model is based on a neural encoder-decoder architecture with hard monotonic attention and performs out-of-context morphologic realisation: given a lemma and a set of morpho-syntactic features, it produces a corresponding word form.

We trained the model of Aharoni and Goldberg (2017) on (lemma+morpho-syntactic_features[4], form) pairs extracted from the SR'18 training data. We trained the model for 20 epochs with the default parameters provided in the implementation[5].

In our pipeline architecture, morphological realisation is applied to the output of our word ordering model using the (id, L, F) mapping mentioned above. For each delexicalised token produced by the word ordering component, we retrieve the corresponding lemma and morpho-syntactic features (L, F) and apply our MR model to it so as to produce the corresponding word form.

While associating a lemma and its features to a corresponding form, the MR module operates without taking context into account, so it cannot perform some finer grained operations, such as contraction, elision, and clitic attachment. We address that issue in the following section.

4.3 Contraction Generation

Contraction handling is the last step of our surface realisation pipeline. Example 2 shows some types of contractions.

(2) French: "Le chat dort." / "L'alouette chante." (Elision for the definite article *le* before a vowel: Le → L')

Italian: *"In il mare." → "Nel mare." (Contraction of the preposition *in* and the article *il*: In il → Nel)

Portuguese: *"Eis lo." → "Ei-lo." (Clitic pronoun attachment: Eis lo → Ei-lo)

We developed two modules for the contraction generation: one based on regular expressions (C_{reg}) and another based on a sequence-to-sequence model (C_{s2s}).

The sequence-to-sequence model is trained on pairs of sentences without and with contractions. The sentence with contraction (S^{+c}) is the final sentence, i.e., the reference sentence in the SR'18 data. The sentence without contraction (S^{-c}) is the corresponding sequence of word forms extracted from the UD CoNLL data.

The regular expression module is inspired by the decomposition of multi-word expressions, such as contractions, which is applied during the tokenisation step in parsing (Martins et al., 2009). We reversed the regular expressions given in the TurboParser[6] for the surface realisation task, and also added our own to tackle, for example, elision in French. C_{s2s} and C_{reg} modules were created for three languages: French, Italian, and Portuguese[7].

5 Evaluation

We evaluate each component of our approach separately. We start by providing a detailed evaluation of how the model handles word ordering

[4] POS and morphological features

[5] https://github.com/roeeaharoni/morphological-reinflection/blob/master/src/hard_attention.py

[6] https://github.com/andre-martins/TurboParser/tree/master/python/tokenizer

[7] Although contractions are also present in Spanish, we did not develop a module for it, since the UD Spanish AnCora treebank does not split them on the token level in contrast to other UD treebanks.

Table 1: Word Ordering: BLEU scores on lemmatised data. Mean and standard deviation across three random seeds. BL: Baseline. All pairwise comparisons of BL and our model showed a statistically significant difference in BLEU via the bootstrap resampling (1000 samples, $p < .05$).

(Section 5.1). We then go on to analyse the respective contributions of morphological realisation (Section 5.2) and contraction generation (Section 5.3). Finally, we discuss the performance of the overall surface realisation model (Section 5.4). Throughout the evaluation, we used the SR'18 evaluation scripts to compute automatic metrics[8].

5.1 Word Ordering

5.1.1 BLEU scores

We evaluate our word ordering component by computing the BLEU-4 score (Papineni et al., 2002) between the sequence of lemmas it produces and the lemmatized reference sentence extracted from the UD files. The baseline is the same model without delexicalisation. As Table 1 shows, there is a marked, statistically significant, difference between the baseline and our approach which indicates that delexicalisation does improve word ordering.

5.1.2 Word Ordering Constraints

We also investigate the degree to which our results conform with the word ordering constraints of the various languages focusing on the following dependency relations: DET (determiner), NSUBJ (nominal subject), OBJ (object), AMOD (adjectival modifier) and ACL (nominal clausal modifier). For each of these dependency relations, we compare the relative ordering of the corresponding (head, dependent) pairs in the reference data and in our system predictions.

To determine whether the dependent should precede or follow its head, we use the gold standard dependency tree of the UD treebanks. Since for the system predictions we do not have a parse tree, we additionally record the distance between head and dependent (in the reference data) and we compare it with the distance between the same two items in the system output. For instance, for the DET relation, given the gold sentence (3a) and the generated sentence (3b), we extract (3c) from the UD parse tree and (3d) from the predicted sentence where each triple is of the form either (dep, head, distance) or (head, dep, distance) and distance is the distance between head and dependent.

(3) a. GOLD: The yogi tried the advanced asana
b. PRED: The yogi tried the asana advanced
c. G-triples: (the$_{dep}$, yogi$_{head}$, 1), (the$_{dep}$, asana$_{head}$, 2)
d. P-triples: (the, yogi, 1), (the, asana, 1)
Exact match: 1; Approximate match: 2

We then compute exact matches (the order and the distance to the head is exactly the same) and approximate matches (the order is preserved but the distance differs by 1 token[9]). Table 2 shows the results and compares them with a non-delexicalised approach.

Global Score. The **all deprels** column summarises the scores for all dependency relations present in the treebanks (not just DET, NSUBJ, OBJ, AMOD and ACL). For the exact match, most languages score above average (from 0.51 to 0.71). That is the relative word order and the position of the dependent with respect to the head is correctly predicted in more than half of the cases. Approximate match yields higher scores with most languages scoring between 0.65 and 0.80 suggesting that a higher proportion of correct relative orderings is achieved (modulo mispositioning and false positives).

Long Range Dependencies. It is noticeable that for all languages, accuracy drops for the ACL relation. We conjecture that two factors makes it difficult for the model to make the correct prediction: heterogeneity and long range dependencies. As the ACL relation captures different types of clausal modifiers (finite and non-finite), it is harder for the model to learn the corresponding patterns. As the modifier is a clause, the distance between head

[8] http://taln.upf.edu/pages/msr2018-ws/SRST.html#evaluation

[9] We could of course consider further approximates matches differing by, say 2, 3 or 5 tokens. But we refrain from this as this would increase the number of false positives.

(the nominal being modified) and dependent (the verb of the clause modifier) can be long which again is likely to impede learning.

Irregular Order. For cases where the head/dependent order is irregular, the scores are lower. For instance, in Dutch the object may occur either before (46.9% of the cases in the test data) or after the verb depending on whether it occurs in a subordinate or a main clause. Relatedly, the OBJ exact match score is the lowest (0.38) for this language. Similarly, in Romance languages where the adjective (AMOD relation) can either be pre- (head-final construction, HF) or post-posed (head-initial construction, HI), exact match scores are lower for this relation than for the others. For instance, the Portuguese test data contains 71% HF and 29% HI occurrences of the AMOD relation and correspondingly, the scores for that relation are much lower than for the DET, NSUBJ and OBJ relations for that language. A similar pattern can be observed for Spanish, French and Italian.

More detailed statistics, including other relations and performance with respect to head-directionality, can be found in the supplementary material.

Non-delexicalised Baseline. We also compare our delexicalised model with the non-delexicalised baseline: Δ in Table 2 shows the difference in performance between the two models.

Overall, the scores favour the delexicalised approach (negative $delta$ in the **all deprels** column for all languages) supporting the results given by the automatic metric. However, for some dependency relations, the lexicalised baseline shows usefulness of word information, for ex-

ample, while predicting AMOD relations for Romance languages (positive $delta$ for French, Italian, Spanish, and Portuguese). Indeed, preposed adjectives in those languages constitute a limited lexical group.

5.2 Morphological Realisation

Table 3 shows the results for the WO+MR model.

The top line (MR Accuracy) indicates the accuracy of the MR model on the SR'18 test data which is computed by comparing its output with gold word forms. As the table shows, the accuracy is very high overall ranging from 87.6 to 99.07, with 9 of the 10 languages having an accuracy above 90. This confirms the high accuracy of the model when performing morphological inflection out of context.

The third line (WO+MR (S^{-c})) shows the BLEU scores for our WO+MR model, i.e., when the MR model is applied to the output of the WO model. Here we use an oracle setting which ignores contractions. That is, we compare the WO+MR output not with the final sentence but with the sentence before contraction applies (the ability to handle contractions is investigated in the next section).

As the table shows, the delta in BLEU scores between the model with (WO+MR) and without (WO) morphological realisation mirrors the accuracy of the morphological realisation model: as the accuracy of the morphological inflection model decreases, the delta increases. For instance, for Arabic, the MR accuracy is among the lowest (91.05) and, correspondingly, the decrease in BLEU score when going from word ordering to word ordering with morphological realisation is the largest (-6.3).

5.3 Contraction Generation

To assess the degree to which contractions are used, we compute BLEU-4 between the gold sequence of word forms from UD treebanks and the reference sentence (Table 4, Line S^{-c}/S^{+c}). As the table shows, this BLEU score is very low for some languages (Arabic, French, Italian, Portuguese) indicating a high level of contractions.

These differences are reflected in the results of our WO+MR model: the higher the level of contractions, the stronger the delta between the BLEU score on the reference sentence without contractions (WO+MR, S^{-c}) and the reference sentence with contractions (WO+MR, S^{+c}).

This shows the limits of out-of-context morphological realisation. While the model is good at producing a word form given its lemma and a set of morpho-syntactic features, the lack of contextual information means that contractions cannot be handled.

Adding a contraction module permits improving results for those languages where contraction is frequent (Table 4, Lines WO+MR+C$_{reg}$, WO+MR+C$_{s2s}$). Gains range from +5 points for French to +12 for Portuguese when comparing to WO+MR. We achieved better results with contraction module based on regular expressions (C$_{reg}$), rather than a neural module (C$_{s2s}$). In a relatively simple task, such as contraction generation, rule-based methods are more reliable, and, overall, are preferable due to their robustness and easy repair comparing to neural models, which may, for instance, hallucinate incorrect content.

5.4 Global Evaluation

Finally, we compare our approach with the best results obtained by the SR'18 participants and with OSU's results (King and White, 2018) using BLEU-4, DIST and NIST scores. OSU results are treated separately, since some of their scores were published after the shared task had ended. Table 5 shows the results. They are mixed. Our model yields the best results for Czech (BLEU: +1.63), Finnish (BLEU: +0.87), Dutch (BLEU: +9.99) and Russian (BLEU: +2.53). However it underperforms on Arabic (BLEU: -9.8), English

Table 5: BLEU, DIST and NIST scores on the SR'18 test data (shallow track). SR'18 is the official results of the shared task but do not include OSU scores, since they are given in the line below. We also excluded the ADAPT and NILC scores as they were obtained using data augmentation. OSU is the submission of King and White (2018).

(BLEU: -13), Spanish (BLEU: -14.27), French (BLEU: -10.23), Italian (BLEU: -4.46) and Portuguese (BLEU: -1.47). Based on the evaluation of each of our modules, these results can be explained as follows.

The languages for which our model outperforms the state of the art are languages for which the WO model performs best, the accuracy of the morphological realiser is high and the level of contractions is low. For those languages, improving the accuracy of the word ordering model would further improve results.

For four of the languages where the model underperforms (namely, Arabic, French, Portuguese and Italian), the level of contraction is high. This indicates that improvements can be gained by improving the handling of contractions, e.g., by learning a joint model that would take into account both morphological inflection and contraction.

6 Conclusion

While surface realisation is a key component of NLG applications, most work in this domain has focused on the development of language specific models. By providing multi-lingual training and test set, the SR'18 shared task opens up the possibility to investigate how language specific properties such as word order and morphological variation impact performance.

In this paper, we presented a modular approach to surface realisation and applied it to the ten languages of the SR'18 shallow track.

For word ordering, we proposed a simple approach where the data is delexicalised, the input tree is linearised using depth-first search and the mapping between input tree and output lemma sequence is learned using a factored sequence-to-sequence model. Experimental results show that full delexicalisation markedly improves performance. Linguistically, this confirms the intuition that the mapping between shallow dependency structure and word order can be learned independently of the specific words involved.

We further carried out a detailed evaluation of how our word ordering model performs on the ten languages of the SR'18 shallow track. While differences in annotation consistency, number of dependency relations[10] and frequency counts for each dependency relations in each dataset make it difficult to conclude anything from the differences in overall scores between languages, the evaluation of head/dependent word ordering constraints highlighted the fact that long-distance relations, such as ACL, and irregular word ordering constraints (e.g., the position of the verb in Dutch main and subordinate clauses) negatively impact results.

For morphological realisation and contractions, we showed that applying morphological realisation out of context, as is done by most of the SR'18 participating systems[11], yields poor results for those languages (Portuguese, French, Arabic, Italian) where contractions are frequent. We explored two ways of handling contractions (a neural sequence-to-sequence model and a rule-based model) and showed that adding contraction han-

[10]The number of distinct dependency relations present in the treebank ranges between 29 (ar, es) and 44 (en).

[11]The only exception is Castro Ferreira et al. (2018) who train an SMT model on pairs of lemmatised/non-lemmatised sentences.

dling strongly improves performance (from +5.57 to 12.13 increase in BLEU score for the rule-based model depending on the language). More generally, our work on contractions points to the need for SR models to better take into account the fine-grained structure of words. For instance, in French, the article is elided (*le* $\rightarrow$ *l'*) when the following word starts with a vowel. In future work, we plan to explore the development of a joint model that simultaneously handles morphological realisation and word ordering while using finer grained word representations, such as fastText embeddings (Bojanowski et al., 2017) or byte pair encoding (BPE; Gage, 1994; Sennrich et al., 2016).

Abstract

Text attribute transfer aims to automatically rewrite sentences such that they possess certain linguistic attributes, while simultaneously preserving their semantic content. This task remains challenging due to a lack of supervised parallel data. Existing approaches try to explicitly disentangle content and attribute information, but this is difficult and often results in poor content-preservation and ungrammaticality. In contrast, we propose a simpler approach, **I**terative **M**atching **a**nd **T**ranslation (**IMaT**), which: (1) constructs a pseudo-parallel corpus by aligning a subset of semantically similar sentences from the source and the target corpora; (2) applies a standard sequence-to-sequence model to learn the attribute transfer; (3) iteratively improves the learned transfer function by refining imperfections in the alignment. In sentiment modification and formality transfer tasks, our method outperforms complex state-of-the-art systems by a large margin. As an auxiliary contribution, we produce a publicly-available test set with human-generated transfer references.[1].

1 Introduction

An intelligent natural language generation (NLG) system should be able to flexibly control linguistic attributes of the text it generates. For instance, a certain level of formality should be maintained in serious situations, while informal conversations can be improved through a more relaxed style. The ability to generate or rewrite a certain text with some attributes controlled or transferred to meet pragmatic goals is widely needed in applications such as dialogue generation (Oraby et al., 2018), author obfuscation (Kacmarcik and Gamon, 2006; Juola and Vescovi, 2011), and written communication assistance (Pavlick and Tetreault, 2016). One typical example of a text attribute is the linguistic style, which refers to features of lexicons, syntax and phonology that collectively contribute to the identifiability of an instance of language (Gatt and Krahmer, 2018). For instance, given text written in an older style like the Shakespearean genre, a system may be tasked to convert it into modern-day colloquial English (Kabbara and Cheung, 2016).

In general, a text attribute transfer system must be able to: (1) produce sentences that conform to the target attribute, (2) preserve the source sentence's content, and (3) generate fluent language. Satisfying these requirements is challenging due to the typical absence of supervised parallel corpora exemplifying the desired attribute transformations. With access to only non-parallel data, most existing approaches aim to tease apart content and attribute in a latent sentence representation. For instance, Shen et al. (2017) and Fu et al. (2018) utilize Generative Adversarial Networks (GANs) to learn this separation. Although these elaborate models can produce outputs that conform to the target attribute (requirement 1), their sentences are fraught with errors in terms of both content preservation and linguistic fluency. This is exemplified in Table 1, where the model of Shen

	Positive Sentiment ↔ Negative Sentiment
Input	I love this place, the service is always great!
CA	I know this place, the food is just a horrible!
MD	I love this place, the service is always great!
DAR	I did not like the homework of lasagna, not like it, .
Ours	I used to love this place, but the service is horrible now.

Table 1: Comparing outputs of transfer models. Our approach both transfers sentiment and preserves content. *CrossAlignment* (CA) by Shen et al. (2017) loses content, *MultiDecoder* (MD) by Fu et al. (2018) fails to modify sentiment, and *DeleteAndRetrieve* (DAR) by Li et al. (2018) produces ungrammatical output.

*Equal Contribution

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al. (2017) changes key content words from "the service" to the unrelated "the food". In an effort to avoid the issues of GAN/autoencoder approaches, Li et al. (2018) recently demonstrated that direct implementation of heuristic transformations– such as modifying high polarity words in reviews for sentiment transfer– can produce better results. Their work suggests attribute transfer can be addressed through simpler methods that avoid attempting to disentangle attribute and content information at the representation level. However, the proposed heuristic transformations are a bit too simple, relying on rule-based sentence reconstruction that often produces linguistically unnatural or ungrammatical outputs. Even worse, some unrelated words happen to be wrongly inserted by approach of Li et al. (2018), dramatically upsetting the sentence content as seen in Table 1.

In this paper, we propose the Iterative Matching and Translation (IMaT) framework which addresses the aforementioned limitations with regards to content inconsistency and ungrammaticality. Our approach first constructs a pseudo-parallel corpus by **matching** a subset of semantically similar sentences from the source and the target corpora (which possess different attributes), then applies a standard sequence-to-sequence (Seq2Seq) **translation** model (Klein et al., 2017) to learn the attribute transfer. We then use the translation results of the trained Seq2Seq model (from the previous iteration) to update the previously made pseudo-parallel corpus, so as to **refine** its quality. Such a matching-translation-refine procedure is iterated repeatedly until performance plateaus. The proposed methodology is simpler and more robust than previous GAN/autoencoder techniques, and is free of manual heuristics such as those used by Li et al. (2018).

We validate our Iterative Matching and Translation (IMaT) model in two attribute-controlled text rewriting tasks that aim to alter: the sentiment of YELP reviews, and the formality of text in the FORMALITY dataset. Both human and automatic evaluations suggest our method substantially outperforms alternative approaches (Shen et al., 2017; Fu et al., 2018; Li et al., 2018) in terms of: accuracy of attribute change, content preservation, and grammaticality. Our main contributions include:

- We propose a novel iterative matching and translation framework that is more straightforward than many existing approaches, by simply adapting a sequence-to-sequence model to perform the attribute transfer.
- We achieve state-of-the-art performance on two text rewriting tasks involving sentiment modification task and formality conversion.
- We release an additional set of 800 sentences rewritten by humans tasked with the sentiment transfer task for the YELP review test set. This enables future researchers to evaluate more diverse transfer outputs.

2 Related Work

Attribute-controlled text rewriting remains a long-standing problem in NLG, where most work has focused on studying the stylistic variation in text (Gatt and Krahmer, 2018). Early contributions in this area defined stylistic features using rules to vary generation (Brooke et al., 2010). For instance, Sheikha and Inkpen (2011) proposed an adaptation of the SimpleNLG realiser (Gatt et al., 2009) to handle formal versus informal language via constructing lexicons of formality (e.g., are not vs. aren't). More contemporary approaches have tended to eschew rules in favour of data-driven methods to identify relevant linguistic features to stylistic attributes (Ballesteros et al., 2015; Di Fabbrizio et al., 2008; Krahmer and van Deemter, 2012). For example, Mairesse and Walker's PERSONAGE system (Mairesse and Walker, 2011) uses machine-learning models to take as inputs a list of real-valued style parameters and generate sentences to project different personality traits.

In the past few years, attribute-controlled NLG has witnessed renewed interest by researchers working on neural approaches to generation (Hu et al., 2017; Jhamtani et al., 2017; Melnyk et al., 2017; Mueller et al., 2017; Zhang et al., 2018; Prabhumoye et al., 2018; Niu and Bansal, 2018). Among them, many attribute-controlled text rewriting methods similarly employ GAN-based models to disentangle the content and style of text in a shared latent space (Shen et al., 2017; Fu et al., 2018). However, existing work that applies these ideas to text suffers from both training difficulty (Salimans et al., 2016; Arjovsky and Bottou, 2017; Bousmalis et al., 2017), and ineffective manipulation of the latent space which leads to content loss (Li et al., 2018) and generation of grammatically-incorrect sentences. Other lines of research avoid adversarial training altogether. Li

et al. (2018) proposed a much simpler approach: identify style-carrying n-grams, replace them with phrases of the opposite style, and train a neural language model to combine them in a natural way. Despite outperforming the adversarial approaches, its performance is dependent on the availability of an accurate word identifier, a precise word replacement selector and a perfect language model to fix the grammatical errors introduced by the crude swap.

Recent work improves upon adversarial approaches by additionally leveraging the idea of back translation (dos Santos et al., 2018; Logeswaran et al., 2018; Lample et al., 2019; Prabhumoye et al., 2018). It was previously used for unsupervised Statistical Machine Translation (SMT) (Fung and Yee, 1998; Munteanu et al., 2004; Smith et al., 2010) and Neural Machine Translation (NMT) (Conneau et al., 2017b; Lample et al., 2017; Artetxe et al., 2017), where it iteratively takes the pseudo pairs to train a translation model and then use the refined model to generate new pseudo-parallel pairs with enhanced quality. However, the success of this method relies on good quality of the pseudo-parallel pairs. Our approach proposes using retrieved sentences from the corpus based on semantic similarity as a decent starting point and then refining them using the trained translation models iteratively.

3 Method

3.1 Task Formulation

Given two mono-style corpora $X = \{x_1, \cdots, x_n\}$ with attribute a_1 and $Y = \{y_1, \cdots, y_m\}$ with attribute a_2. Note that the alignment between X and Y corpora is not available. The unsupervised attribute-controlled rewriting task aims to learn a transformation $T^*(\cdot)$ from X to Y by optimizing the following objective:

$$T^*(\cdot) = \underset{T(\cdot)}{\operatorname{argmin}} \ \|x - T(x)\|, \quad (1)$$

$$s.t. \ \mathcal{A}(T(x)) = a_2, \quad (2)$$

where the norm $\|\cdot\|$ measures the content shift between two sentences, and $\mathcal{A}(\cdot)$ represents the attribute of a sentence. Plainly put, a good attribute rewrite should ensure the attribute is changed to the desired value, and the content shift between the original sentence and rewrite is minimized.

3.2 Iterative Matching and Translation

We propose an iterative matching and translation algorithm composed of the following three steps:

(Step 1) Matching In iteration $t = 0$, we construct a large pseudo-parallel corpus $\hat{X}$ and $\hat{Y}^{(0)}$ by pairing sentences from X with those from Y. Specifically, we calculate the semantic cosine similarity score (detailed in Section 4.4) between a sentence $x_i \in X$ and every sentence $y \in Y$, select the one with the highest score as $\hat{y}_i$, and only keep the sentence pair if the similarity exceeds a threshold γ. $\hat{X}$ denotes the subset of the original corpus X for which we find matches.

In later iterations $t \geq 1$, this matching process is different from that in the first iteration. We match the pseudo-parallel corpus $\hat{X}$ with $\hat{Y}^{(t)}$, which is refined in step 3 of the previous iteration, and obtain a *temporary* matched corpus $\texttt{Match}^{(t)}$. In this case, for any sentence $x_i \in \hat{X}$, we have two pseudo-parallel sentences $\hat{y}_i \in \hat{Y}^{(t)}$ and $\texttt{match}_i \in \texttt{Match}^{(t)}$, both of which have the opposite attribute to x_i. We then use Word Mover Distance (WMD), which will be detailed in Section 3.3, to measure the content shift between the original sentence and the rewritten one. We calculate $\text{WMD}(x_i, \hat{y}_i)$ and $\text{WMD}(x_i, \texttt{match}_i)$. If the latter one is smaller, we then replace $\hat{y}_i$ with $\texttt{match}_i$ in $\hat{Y}^{(t)}$; otherwise, we just keep the original $\hat{y}_i$. In this way, we can obtain an updated version of $\hat{Y}^{(t)}$ after this matching step.

(Step 2) Translation In each iteration $t \geq 0$, a Seq2Seq machine translation model with attention $M^{(t)}$ (Luong et al., 2015) is trained from scratch using the pseudo-parallel corpus $\hat{X}$ and $\hat{Y}^{(t)}$.

(Step 3) Refinement In this step, we refine the $\hat{Y}^{(t)}$ obtained in step 1 with the trained translation model $M^{(t)}$ in step 2. Specifically, we apply the model $M^{(t)}$ to translate each sentence $x_i \in \hat{X}$ to $\texttt{trans}_i^{(t)}$, and form a *temporary* corpus $\texttt{Trans}^{(t)}$. Again, for any sentence $x_i \in \hat{X}$, we now have two pseudo-parallel sentences $\hat{y}_i \in \hat{Y}^{(t)}$ and $\texttt{trans}_i \in \texttt{Trans}^{(t)}$, one of which is from the matching step and the other is from the translation model. We still compare $\text{WMD}(x_i, \hat{y}_i)$ with $\text{WMD}(x_i, \texttt{trans}_i)$, and choose the sentence with the smaller value and insert into $\hat{Y}^{(t+1)}$, which will be fed into step 1 of the next iteration.

Overall, the aforementioned three steps are repeated for several iterations. This process is for-

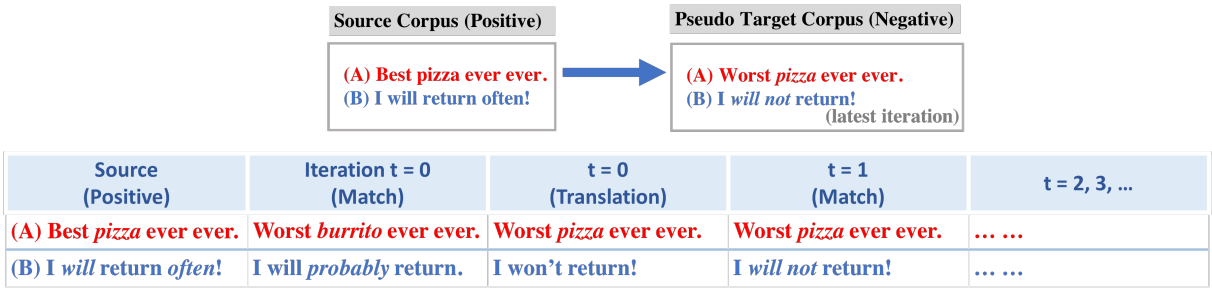

Figure 1: Iterative process of the algorithm to transfer the text style from positive to negative reviews.

malized below in Algorithm 1.

Algorithm 1 Iterative Matching and Translation

Input: Two corpora X, Y with different attributes.

        $\hat{y}_i = \underset{y \in Y}{\text{argmax}}\, \text{Sim}(x_i, y)$
        $\hat{X}$.append(x_i)
        $\hat{Y}^{(0)}$.append($\hat{y}_i$)
      end if
    else
      $\texttt{match}_i \leftarrow \underset{y \in Y}{\text{argmax}}\, \text{Sim}(\hat{y}_i, y)$
      $\hat{y}_i \leftarrow \underset{y \in \{\hat{y}_i, \texttt{match}_i\}}{\text{argmin}}\, \text{WMD}(x_i, y)$
      $\hat{Y}^{(t)}$.append($\hat{y}_i$)
    end if
  end for

  Train a Seq2Seq model $M^{(t)} : \hat{X} \rightarrow \hat{Y}^{(t)}$
  for $x_i \in \hat{X}$ **do**
    $\texttt{trans}_i \leftarrow M^{(t)}(x_i)$
    $\hat{y}_i \leftarrow \underset{y \in \{\hat{y}_i, \texttt{trans}_i\}}{\text{argmin}}\, \text{WMD}(x_i, y)$
    $\hat{Y}_i^{(t)} \leftarrow \hat{y}_i$
  end for
end for
Output: Attribute transfer model $M^{(T)} : X \rightarrow \hat{Y}^{(T)}$

3.3 Method Details

Word Mover Distance In our algorithm, WMD is used to measure the content shift from the source sentence to the rewrite. WMD is a metric of "travel cost" from sentence s_a to s_b. The detailed explanations and calculation of the distance is in the paper (Kusner et al., 2015). In brief, each sentence is represented as a weighted point cloud of embedded words. The distance between the sentence s_a to s_b is the minimum cumulative distance that words from sentence s_a need to travel to match exactly the point cloud of sentence s_b. Denote the vocabulary size as n, the travel distance from the word i in sentence s_a to the word j in sentence s_b as $T(i, j)$, and the corresponding cost of this "word travel" as $c(i, j)$. The distance calculation is formulated as

$$\text{WMD}(s_a, s_b) = \min_{\mathbf{T} \geq 0} \sum_{i,j=1}^{n} \mathbf{T_{ij}} \cdot c(i, j). \quad (3)$$

Since the initial construction of pseudo-parallel corpus is already guaranteed to have good target attribute and grammaticality, the only remaining criteria to fulfill is the minimal content change from the original sentence to the resulted output. WMD is used as a decision factor whenever an update occurs. Keeping the sentence pair with the smallest cost from each other approximates minimization of the content shift.

Advantages of the WMD over other basic measures of sentence similarity include the fact that it has no hyperparameters to tune, appropriately handles sentences with unequal number of words (via weighted word matchings that sum to 1), accounts for synonymic-similarity at the word-level (through use of pretrained word embedding vectors), and considers the entire contents of each sentence (every word must be somehow matched). Furthermore, WMD has produced high accuracy in information retrieval (Brokos et al., 2016; Kim et al., 2017), where measuring content-similarity is critical (as in our attribute transfer task).

Semantic Sentence Representation For the matching process in Step 1, the cosine similarity is computed between each pair of sentences. There is no perfect way of semantic representation of a sentence, but a state-of-the-art method is to use the sentence embeddings obtained by averaging the ELMo embeddings of all the words in the sentence (Peters et al., 2018). ELMo uses a deep, bi-directional LSTM model to create word representations within the context that they are

used. Perone et al. (2018) have shown that this approach can efficiently represent semantic and linguistic features of a sentence, outperforming more elaborate approaches such as Skip-Thought (Kiros et al., 2015), InferSent (Conneau et al., 2017a) and Universal Sentence Encoder (Cer et al., 2018).

4 Experiments

4.1 Datasets

We evaluate the proposed model on two representative tasks: sentiment modification on the YELP dataset, and text formality conversion on the FORMALITY dataset. A careful human assessment in Section 4.1.1 shows that these two datasets are significantly more suitable than the other three popular "style transfer" datasets, namely the political slant transfer dataset (Prabhumoye et al., 2018; Tian et al., 2018), gender transfer dataset (Prabhumoye et al., 2018), and humorous-to-romantic transfer dataset (Li et al., 2018).

Dataset	Style	Train	Dev	Test
YELP	Positive	270K	2K	0.5K
	Negative	180K	2K	0.5K
FORMALITY	Formal	90K	4.6K	2.7K
	Informal	96K	5.6K	2.1K

Table 2: Statistics of YELP and FORMALITY datasets.

YELP The commonly used YELP review dataset for sentiment modification (Shen et al., 2017; Li et al., 2018; Prabhumoye et al., 2018) contains a positive corpus of reviews rated above three and a negative corpus of reviews rated below three. This task requires flipping high polarity sentences such as "The food is good" and "The food is bad". We use the same train/test split as Shen et al. (2017); Li et al. (2018) (see Table 2).

FORMALITY The FORMALITY dataset stems from an aligned set of formal and informal sentences (Rao and Tetreault, 2018). It demands changes in subtle linguistic features such as "want to" to "wanna". We obtained a non-parallel dataset by shuffling the two originally aligned corpora (removing duplicates and sentences that exceed 100 words). Table 2 describes statistics of the resulting two corpora. The development/test sets are provided with four human-generated attribute transfer rewrites for each sentence (i.e. the gold standard).

4.1.1 Dataset Quality Assessment

In order to identify the best datasets for evaluation, we asked human judges to assess five popular text attribute rewriting datasets, namely YELP sentiment modification dataset, FORMALITY dataset, POLITICAL slant transfer dataset (Prabhumoye et al., 2018; Tian et al., 2018), GENDER transfer dataset (Prabhumoye et al., 2018), and HUMOROUS-to-ROMANTIC transfer dataset (Li et al., 2018). For each dataset, we randomly extracted 100 sentences (i.e. 50 per style). For each sentence, we asked two native English speakers to annotate them with one of three options, i.e. either of the two attributes or "Cannot Decide". Based on the collected annotations, we calculate three metrics: (1) *undecidable rate*, which is the percentage of "Cannot Decide" answers (we report the average percentage between the two annotators), (2) *disagreement rate*, which is the percentage of different opinions between the two annotators, and (3) *F1 score* between the human annotations and the gold labels in the original dataset ("Cannot Decide" answers were not considered).

Dataset	Unde. Rate	Dis. Rate	F1
POLITICAL	49.0	33.0	67.2
GENDER	88.0	14.0	53.6
HUMOROUS	66.0	31.0	79.3
YELP	**11.0**	16.0	**93.2**
FORMALITY	**0.5**	17.0	**87.6**

Table 3: Comparison of dataset quality. "Unde. Rate" indicates the undecidable rate, "Dis. Rate" the disagreement rate between annotators.

The scores for each dataset are summarized in Table 3. A quick comparison shows that YELP and FORMALITY obtain significantly lower *undecidable* and inter-annotator *disagreement rates*, indicating that the style of the sentences in these two datasets are less ambiguous to humans. In addition, YELP and FORMALITY have much higher F1 score than all the other datasets, which confirms the correctness of the source-target attribute split.

This comparison points out that the three datasets, including political slant, gender and romantic-to-humorous caption datasets, are ambiguous and noisy, therefore not only adding complexity to the task and its evaluation (because even human annotators struggle to identify the correct style), but also leading to models that are not useful in real practice.

	YELP				FORMALITY			
	Content	Grammar	Attribute	*Success (%)*	Content	Grammar	Attribute	*Success (%)*
CA	2.30 $\pm$1.45	2.65 $\pm$1.32	2.77 $\pm$1.69	5.5	2.45 $\pm$1.31	2.67 $\pm$1.57	1.97 $\pm$1.26	0.5
MD	2.12 $\pm$1.52	2.38 $\pm$1.49	2.25 $\pm$1.54	2.0	1.79 $\pm$1.17	2.37 $\pm$1.50	2.42 $\pm$1.56	0.0
DAR	2.93 $\pm$1.45	2.95 $\pm$1.51	3.09 $\pm$1.65	14.5	2.89 $\pm$1.39	3.02 $\pm$1.59	2.95 $\pm$1.56	7.0

Ratings are on a 1 to 5 scale.

4.2 Evaluation Strategies

Human Evaluation Following Li et al. (2018); Lample et al. (2019), we asked human judges to evaluate outputs of different models in terms of content preservation, grammaticality and attribute change correctness on a Likert scale from 1 to 5. We randomly selected 100 sentences from each corpus (100 positive and 100 negative sentences from YELP; 100 formal and 100 informal sentences from FORMALITY). Each of the twelve human judges passed a test batch prequalification before they could start evaluating, and we verified they spent a reasonable amount of time in the task.

Automatic Evaluation In addition to the human evaluation, we also programatically gauge rewriting quality via automated methods, following the practice in (Li et al., 2018; Lample et al., 2019). Here, content preservation is measured by the BLEU score between model outputs and multiple human references for each sentence. Since the previous work only introduces single human reference for YELP, we enriched the test set with four extra human references for each test sentence, in total 800 rewrites. The diverse human rewrites ensures a more variety-tolerant measurement of model outputs. Attribute accuracy is assessed via the classification results of a CNN-based text classifier (Kim, 2014). To automatically gauge fluency, we use pretrained language models (LM) to get the perplexity of output sentences. The details of the classifier, LM and the collection of human references are elaborated in Appendix A.1.

4.3 Baselines

To compare against multiple baselines, we re-implemented three recently-proposed methods (described in Sections 1 and 2): CROSSALIGNMENT (CA) from Shen et al. (2017), MULTIDECODER (MD) from Fu et al. (2018), and DELETEANDRETRIEVE (DAR) from Li et al. (2018).

4.4 Experimental settings

For the translation process, we used an off-the-shelf Seq2Seq model, a 2-layer LSTM encoder-decoder with 1024 hidden dimensions and attention. We focused on the novelty of the proposed iterative framework, so a standard and classic Seq2Seq model is used. More experimental details are described in Appendix A.2.

5 Results

5.1 Human Evaluation

In terms of human evaluation, the proposed approach shows significant gains over all baselines in terms of attribute correctness, content preservation, grammaticality, and success rate as shown in Table 4 ($p < 0.05$ using bootstrap resampling (Koehn, 2004)).

The largest improvement is in grammaticality, where we achieve an average of 4.32 on YELP and 4.42 out of 5.0 on the FORMALITY dataset. These scores are close to those of human references, prevalently outperforming the baselines. On attribute correctness, the model scores 3.43 on YELP and 3.11 on FORMALITY dataset, exceeding the previous best methods by 0.33 and 0.16 respectively. Moreover, in content preservation, we show an improvement of 0.14 and 0.72 over the previous state-of-the-art *DeleteAndRetrieve* model on the two datasets. Finally, we follow the practice of Li et al. (2018) to evaluate the *Success Rate* — an aggregate of the three previous metrics, in which a sample is successful only if it is rated 4 or 5 on all the three metrics. Our model demonstrates an improvement of 6.5% in success rate over the previous best method.

To further inspect performance of different methods, we show some typical outputs in Table 5. First, the output of our model is nearly as grammatical as the human-written sentence, compared with the loss of sentence struc-

From Positive to Negative (YELP)	
Input	Thank you ladies for being **awesome**!
CA	Thank you charge up for this food business.
MD	Thank you for it $ **poor** company.
DAR	Thank you ladies for being **didn't**.
Ours	**Thank you for wasting my time you idiots.**
Human	Thank you ladies for being the **worst**!
From Informal to Formal (FORMALITY)	
Input	**i** tried to like him, bu **i just can't**.
CA	I was to him, but I **just like I can't**.
MD	**i** tried to him like, but I **just should too**.
DAR	I do not know if you like him but I do not know he **can't**.
Ours	**I tried to like him, but I cannot.**
Human	I **attempted** to like him, **however**, I am **unable**.

Table 5: Example outputs of different systems.

	YELP			FORMALITY		
	Acc.	BLEU	PPL	Acc.	BLEU	PPL

MD	66.80	17.34	69.51	66.46	7.46	109.41
DAR	88.00	**31.07**	79.70	**78.87**	21.29	63.61
Ours	**95.90**	22.46	**14.89**	72.07	**38.16**	**32.63**

Table 6: Automatic evaluation results on both datasets. Acc. is the style/attribute classification accuracy (%).

ture in CROSSALIGNMENT (e.g. "I tried to him like") and DELETEANDRETRIEVE (e.g. "for being didn't"). Second, in terms of attribute correctness, DELETEANDRETRIEVE suffers from failure to convert the attribute-bearing words (as it wrongly converts the word "awesome" to "didn't"), and CROSSALIGNMENT is prone to missing attribute words. Third, although our method enforces content alignment, the preservation of content is an inevitable challenge for the previous approaches such as MULTIDECODER and DELETEANDRETRIEVE.

5.2 Automatic Evaluation

We also assess each method's performance via the automatic measures of attribute-accuracy, BLEU, and perplexity (Table 6). A highlight is its perplexity score, outperforming the previous methods by a large margin. This advantage owes to the fact that the Seq2Seq model is trained on pseudo-pairs similar to real samples, which can guarantee the translation quality. However, a tradeoff between the other two aspects, attribute accuracy and BLEU, can be clearly seen on both YELP and FORMALITY datasets. This is common when tuning all models, as targeting at a higher BLEU score will result in a lower attribute correctness score (Shen et al., 2017; Fu et al., 2018; Li et al., 2018). Similarly, in iterations of our model, the BLEU score gradually increases while the accuracy decreases. Therefore, the reported outputs are balanced based on all three aspects. An analysis on the limitations of automatic evaluation is in Appendix A.3.

6 Performance Analysis

Here, we analyze the performance of our model with regard to various aspects in order to understand what factors underlie its success.

6.1 Initialization of Pseudo-Parallel Corpus

The proposed model starts from the construction of an initial pseudo-parallel corpus by our matching step. Note that this initial pairing is practicable in most domains. For example, Yelp reviews naturally have positive and negative comments on the same food; different translations of the same book also shares the same content; different news agencies report with different tones on the same events. After construction, there are three properties of this pseudo-parallel corpus: First, it is a subset of the original corpus. Second, all retrieved target sentences contain the desired attribute information and are of perfect grammaticality. This property is retained throughout our iterations and is key to the high attribute transfer accuracy and fluent language generation capabilities of our model. Third, the sentence pairs are still imperfect in terms of content preservation, often similar in meaning but with certain content words altered. This is remedied by subsequent refinement steps.

Although our model needs the matched pseudo-parallel corpus as a starting point, it has high tolerance to recover from occasional low-quality matches. To demonstrate this, we randomly

picked 100 sentences and their initial pseudo-pairs from both source and target corpus, and asked human judges to rate them. For each sentence pair, three judges decided whether the sentence pair forms a good rewrite, a bad rewrite, or an ambiguous one. We mark the pseudo-pair as either good or bad if at least two annotators agree on such a judgment. The percentage of bad rewrites is 38.2% and 48.2% on YELP and FORMALITY, respectively. This indicates that subsequent iterative refinement indeed allows for $30-50\%$ low-quality pairs in the initial pseudo-parallel corpus.

6.2 Effective Denoising Translation

One of the most important gains from the iterative translation is to encourage more content preservation. We illustrate the effectiveness of translation by using automatic evaluation to gauge how the bad matches in the initial pseudo-parallel corpus change *immediately after* the first translation step. We find that after the first translation, the BLEU score of these bad matches shows a clear improvement, increasing from 9.40 to 13.18 on YELP, and 5.44 to 28.25 on FORMALITY. This shows that the translation model recognizes the noise in the first matching process and generates more proper transfer candidates, providing a good foundation for subsequent iterative refinement. An illustrative example of this refinement can be seen in the sentence (A) in Figure 1, where a bad match of "Worst burrito ever ever" was denoised and replaced with "Worst pizza ever ever" after the first translation.

6.3 Iterative Refinement

The essential increase of content preservation owes to the iterative refinement step. This process reduces erroneous alignments in the pseudo-parallel corpus by updating each existing pseudo-pair with newly generated translation-pair. Thanks to the denoising effect of the translation model, this updating could improve the quality of pseudo-pairs. Furthermore, we use WMD to measure the content shift between sentences in the pseudo-pair and the translation-pair, and accept the update only when the translation-pair possesses smaller content shift so as to avoid worsening updates. As the iteration goes on, the accuracy and perplexity stay high from the beginning, but as in Figure 2, the BLEU score keeps increasing. This shows that the new iteration outputs retains more content from the original sentences. More importantly, this refinement can prevent the model from totally relying on the fine-quality matching pairs, which contributes to the high tolerance capability on the matching quality as discussed in Section 6.1.

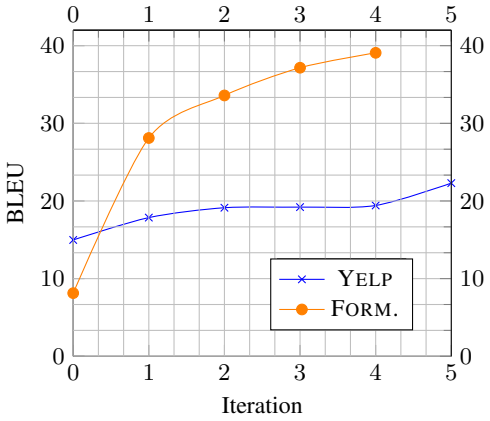

Figure 2: BLEU score evolution across training iterations on YELP and FORMALITY datasets.

The pseudo-parallel corpus in Iteration $t \geq 0$ is composed of matched pairs from the original corpora and translated pairs from the trained translation model. Both of them contribute to the good performance of our model. For further investigation, we look into the pseudo-parallel corpus $\hat{X}$ and $\hat{Y}^{(4)}$ in the final training iteration for the FORMALITY dataset. Since this dataset has ground-truth parallel pairs, we are able to calculate how many pseudo-parallel pairs are the same as the ground-truth parallel pairs, and the percentage turns out to be around 52%, which is actually not high. This reveals that the refinement step can provide the model with better pseudo-pairs even than original gold pairs and our model can still stand out without fine-quality matches.

7 Conclusion

In this work, we proposed a Seq2Seq paradigm for text attribute transfer applications, suggesting a simple but strong method for overcoming lack of parallel data. We construct a pseudo-parallel corpus by iteratively matching and updating in a way that increasingly refines the final transfer function. Our framework can employ any Seq2Seq model and outperforms previous methods under all measured criteria (content preservation, fluency, and attribute correctness) in both human and automatic evaluation. The simplicity and flexibility of our approach can be useful in applications that require intricate edits or complete sentence rewrites.

Acknowledgments

We thank Professor Peter Szolovits for supporting and funding the work, and Prof Benjamin Kao for advice on evaluation metrics. We also appreciate Tianxiao Shen, Jiang Guo, Professor Regina Barzilay, and MIT Natural Language Processing Group for insightful discussions and support. We thank Adam Fisch, Benson Chen, Jingran Zhou, Wui Wang Lui, Shuailin Yuan and many other helpers for human evaluation.

A Supplemental Material

In this Appendix, we explain the setup of automatic evaluation, experimental details, and a discussion on limitations of automatic evaluation.

A.1 Automatic Evaluation Setup

The details of the three aspects of automatic evaluation are elaborated as follows.

- **Style correctness:** Following Shen et al. (2017), we trained a CNN-based text classifier (Kim, 2014) on our original datasets, using its accuracy over the system outputs to measure their style correctness. The accuracy of this classifier is respectively 97% and 93% on the YELP and the FORMALITY datasets.

- **Content preservation:** To evaluate the content preservation, we compute the BLEU score between model outputs and multiple human references. FORMALITY dataset comes with four human references for around 2,000 formal and 2,000 informal sentences.

  For the YELP dataset, we used the same test set of 500 positive and 500 negative sentences as (Li et al., 2018), and collected four references for each sentence in the test set, in addition to the single human reference released by Li et al. (2018). We hired crowdworkers on Amazon Mechanical Turk to rewrite the source sentence with the same content but an opposite sentiment.

  These in total five human rewrites of each test sentence ensures a more tolerant measurement of model outputs. We can see a relatively large diversity in human transfers, which is measured by the average BLEU score of one randomly chosen human reference among the other four. The average difference gap between the calculated score, 52.63, and a perfect BLEU score, 100, shows that the five human rewritten sentences contain significant lexical differences. Evaluation based on all five human rewrites thus offers a better measure of transfer quality. For example, the two equally acceptable rewrites "i will definitely not return often!" and "I won't be returning any time soon." does not have a single word overlap and have a BLEU score 0 with each other. Therefore, five human references enable a more comprehensive evaluation, allowing multiple ways to transfer a sentence.

- **Fluency:** Fluency is measured by the perplexity (PPL) of the generated outputs by a pre-trained language model (LM) using GluonNLP toolkit[2]. The encoder of this LM is comprised of two long-short term memory (LSTM) layers, each of which has 200 hidden units. The embedding and output weights are tied. Dropout of 0.2 was applied to both embedding and LSTM layers. LM was optimized via stochastic gradient descent (SGD) optimizer with learning rate of 20 for 15 epochs.

A.2 Experimental Details

We adopt the 100-dimensional pretrained GloVe word embeddings (Pennington et al., 2014) as inputs of a standard machine translation sequence-to-sequence model with attention. The NLTK software package is used to generate Part-of-Speech tags and we feed them as additional input to the encoder. To ensure both a relatively high quality pseudo-parallel corpus and no significant drop in size on the two corpora, we only match sentences with vector cosine higher than an empirical similarity threshold of 0.7. We train the model until the update rate of candidate transfer is lower than 0.5%. This convergence is at iteration $T = 5$ for YELP and $T = 4$ for FORMALITY.

A.3 Limitations of Automatic Evaluation

Evaluating the quality of a transferred sentence by a pretrained classifier (style accuracy), lexicon overlap with references (BLEU), and a pretrained Language Model (perplexity) can have many limitations. First, in terms of style accuracy and perplexity, the pretrained models can be unreliable when evaluating a sentence different from the training corpus. For example, comparing human-rated and machine-evaluated score of *style correctness* (Table 4 and Table 6), we find that although the automatic score can serve as a rough assessment of the models, it does not aligns perfectly with the human ratings in Table 4. As is explained in (Li et al., 2018)'s work, the uneven distribution of some content words in two style corpora may confuse the classifier and make it overfitted on the training data.

[2] https://gluon-nlp.mxnet.io/index.html

Second, the BLEU score, which mainly relies on the lexicon overlap between evaluated sentence and references, can mistakenly favor sentences with a higher similarity to the source sentence. An illustration is that by simply copying all source sentences in the test set we can get a BLEU score of 62, despite an accuracy score close to zero. The state-of-the-art model, *DeleteAndRetrieve*, only modifies a few attribute-carrying words and copies the rest of the sentence. For example, it transfers the source sentence "My 'hot' sub *was cold* and the meat was watery." into an ungrammatical one "My 'hot' *is a great place* to the meat." but keeps the words "hot" and "meat". Consequently, it results in a high BLEU score and a poor perplexity score.

Better Rewards Yield Better Summaries: Learning to Summarise Without References

Abstract

Reinforcement Learning (RL) based document summarisation systems yield state-of-the-art performance in terms of ROUGE scores, because they directly use ROUGE as the *rewards* during training. However, summaries with high ROUGE scores often receive low human judgement. To find a better reward function that can guide RL to generate human-appealing summaries, we learn a reward function from human ratings on 2,500 summaries. Our reward function only takes the document and system summary as input. Hence, once trained, it can be used to train RL-based summarisation systems without using any reference summaries. We show that our learned rewards have significantly higher correlation with human ratings than previous approaches. Human evaluation experiments show that, compared to the state-of-the-art supervised-learning systems and ROUGE-as-rewards RL summarisation systems, the RL systems using our learned rewards during training generate summaries with higher human ratings. The learned reward function and our source code are available at https://github.com/yg211/summary-reward-no-reference.

1 Introduction

Document summarisation aims at generating a summary for a long document or multiple documents on the same topic. *Reinforcement Learning (RL)* becomes an increasingly popular technique to build document summarisation systems in recent years (Chen and Bansal, 2018; Narayan et al., 2018b; Dong et al., 2018). Compared to the supervised learning paradigm, which "pushes" the summariser to reproduce the reference summaries at training time, RL directly optimises the summariser to maximise the *rewards*, which measure the quality of the generated summaries.

The *ROUGE* metrics (Lin, 2004b) are the most widely used rewards in training RL-based summarisation systems. ROUGE measures the quality of a generated summary by counting how many n-grams in the reference summaries appear in the generated summary. ROUGE correlates well with human judgements at *system level* (Lin, 2004a; Louis and Nenkova, 2013), i.e. by aggregating system summaries' ROUGE scores across multiple input documents, we can reliably rank summarisation systems by their quality. However, ROUGE performs poorly at *summary level*: given multiple summaries for the same input document, ROUGE can hardly distinguish the "good" summaries from the "mediocre" and "bad" ones (Novikova et al., 2017). Because existing RL-based summarisation systems rely on summary-level ROUGE scores to guide the optimisation direction, the poor performance of ROUGE at summary level severely misleads the RL agents. The reliability of ROUGE as RL reward is further challenged by the fact that most large-scale summarisation datasets only have one reference summary available for each input document (e.g. CNN/DailyMail (Hermann et al., 2015; See et al., 2017) and NewsRooms (Grusky et al., 2018)).

In order to find better rewards that can guide RL-based summarisers to generate more human-appealing summaries, we learn a reward function directly from human ratings. We use the dataset compiled by Chaganty et al. (2018), which includes human ratings on 2,500 summaries for 500 news articles from CNN/DailyMail. Unlike ROUGE that requires one or multiple reference summaries to compute the scores, our reward function only takes the document and the generated summary as input. Hence, once trained, our

reward can be used to train RL-based summarisation systems without any reference summaries.

The contributions of this work are threefold: **(i)** We study the summary-level correlation between ROUGE and human judgement on 2,500 summaries (§3), explicitly showing that ROUGE can hardly identify the human-appealing summaries. **(ii)** We formulate the reward learning problem as either a regression or a preference learning problem (§4), and explore multiple text encoders and neural architectures to build the reward learning model (§5). **(iii)** We show that our learned reward correlates significantly better with human judgements than ROUGE (§6), and that using the learned reward can guide both extractive and abstractive RL-based summarisers to generate summaries with significantly higher human ratings than the state-of-the-art systems (§7).

2 Related Work

RL-based summarisation. Most existing RL-based summarisers fall into two categories: *cross-input* systems and *input-specific* systems (Gao et al., 2019). Cross-input systems learn a summarisation policy at training time by letting the RL agent interact with a ROUGE-based reward function. At test time, the learned policy is used to generate a summary for each input document. Most RL-based summarisers fall into this category (Chen and Bansal, 2018; Narayan et al., 2018b; Dong et al., 2018; Kryscinski et al., 2018; Pasunuru and Bansal, 2018; Paulus et al., 2018). As an alternative, input-specific RL (Rioux et al., 2014; Ryang and Abekawa, 2012) does not require reference summaries: for each input document at test time, a summarisation policy is trained specifically for the input, by letting the RL summariser interact with a heuristic-based reward function, e.g. ROUGE between the generated summary and the input document (without using any reference summaries). However, the performance of input-specific RL falls far behind the cross-input counterparts.

In §7 we use our learned reward to train both cross-input and input-specific RL systems. A similar idea has been explored by Gao et al. (2019), but unlike their work that learns the reward from ROUGE scores, we learn our reward directly from human ratings. Human evaluation experiments suggest that our reward can guide both kinds of RL-based systems to generate human-appealing summaries without using reference summaries.

The reward learning idea is also related to *inverse RL* (IRL) (Ng and Russell, 2000). By observing some (near-)optimal sequences of actions, IRL algorithms learn a reward function that is consistent with the observed sequences. In the case of summarisation, human-written reference summaries are the (near-)optimal sequences, which are expensive to provide. Our method only needs human ratings on some generated summaries, also known as the *bandit feedback* (Kreutzer et al., 2017), to learn the reward function. Furthermore, when employing certain loss functions (see §4 and Eq. (2)), our method can even learn the reward function from preferences over generated summaries, an even cheaper feedback to elicit (Kreutzer et al., 2018; Gao et al., 2018).

Heuristic-based rewards. Prior work proposed heuristic-based reward functions to train cross-input RL summarisers, in order to strengthen certain properties of the generated summaries. Arumae and Liu (2019) propose four reward functions to train an RL-based extractive summariser, including the *question-answering competency* rewards, which encourage the RL agent to generate summaries that can answer cloze-style questions. Such questions are automatically created by removing some words in the reference summaries. Experiments suggest that human subjects can answer the questions with high accuracy by reading their generated summaries; but the human judgement scores of their summaries are not higher than the summaries generated by the state-of-the-art supervised system. Kryscinski et al. (2018) propose a simple heuristic that encourages the RL-based abstractive summariser to generate summaries with more *novel* tokens, i.e. tokens that do not appear in the input document. However, both ROUGE and human evaluation scores of their system are lower than the state-of-the-art summarisation systems (e.g. See et al., 2017). In addition, the above rewards require reference summaries, unlike our reward that only takes a document and a generated summary as input.

Rewards learned with extra data. Pasunuru and Bansal (2018) propose two novel rewards for training RL-based abstractive summarisers: *RougeSal*, which up-weights the salient phrases and words detected via a keyphrase classifier, and *Entail* reward, which gives high scores to

logically-entailed summaries using an entailment classifier. RougeSal is trained with the SQuAD reading comprehension dataset (Rajpurkar et al., 2016), and Entail is trained with the SNLI (Bowman et al., 2015) and Multi-NLI (Williams et al., 2018) datasets. Although their system achieves new state-of-the-art results in terms of ROUGE, it remains unclear whether their system generates more human-appealing summaries as they do not perform human evaluation experiments. Additionally, both rewards require reference summaries.

Louis and Nenkova (2013), Peyrard et al. (2017) and Peyrard and Gurevych (2018) build feature-rich regression models to learn a summary evaluation metric directly from the human judgement scores (Pyramid and Responsiveness) provided in the TAC'08 and '09 datasets[1]. Some features they use require reference summaries (e.g. ROUGE metrics); the others are heuristic-based and do not use reference summaries (e.g. the Jensen-Shannon divergence between the word distributions in the summary and the documents). Their experiments suggest that with only non-reference-summary-based features, the correlation of their learned metric with human judgements is lower than ROUGE; with reference-summary-based features, the learned metric marginally outperforms ROUGE. In §6, we show that our reward model does not use reference summaries but outperforms the feature-based baseline by Peyrard and Gurevych (2018) as well as ROUGE.

Unlike the above work that attempts to learn a summary evaluation metric, the target of our work is to learn a good *reward*, which is not necessarily a good *evaluation metric*. A good evaluation metric should be able to correctly rank summaries of different quality levels, while a good reward function focuses more on distinguishing the best summaries from the mediocre and bad summaries. Also, an evaluation metric should be able to evaluate summaries of different types (e.g. extractive and abstractive) and from different genres, while a reward function can be specifically designed for a single task. We leave the learning of a generic summarisation evaluation metric for future work.

3 Summary-Level Correlation Study

In this section, we study the summary-level correlation between multiple widely used summary evaluation metrics and human judgement scores, so as to further motivate the need for a stronger reward for RL. Metrics we consider include ROUGE (full length F-score), BLEU (Papineni et al., 2002) and METEOR (Lavie and Denkowski, 2009). Furthermore, in line with Chaganty et al. (2018), we also use the cosine similarity between the embeddings of the generated summary and the reference summary as metrics: we use InferSent (Conneau et al., 2017) and BERT-Large-Cased (Devlin et al., 2019) to generate the embeddings.

The human judgement scores we use are from Chaganty et al. (2018), collected as follows. First, 500 news articles were randomly sampled from the CNN/DailyMail dataset. For each news article, four summarisation systems were used to generate summaries: the *seq2seq* and *pointer* models proposed by See et al. (2017), and the *ml* and *ml+rl* models by Paulus et al. (2018). Hence, together with the human-written reference summaries provided in the CNN/DailyMail dataset, each news article has five summaries. Crowd-sourcing workers were recruited to rate the summaries in terms of their fluency, redundancy level and overall quality, on a 3-point Likert scale from -1 to 1. Higher scores mean better quality. Each summary was rated by five independent workers. We use the averaged overall quality score for each summary as the ground-truth human judgement.

RL-based summarisation systems assume that the summaries ranked highly by the reward function (e.g. ROUGE) are indeed "good" in terms of human judgement. We define *good* summaries as follows: a summary y for a news article x is good if (**i**) the average human judgement score for y is ≥ 0.5, and (**ii**) among the five summaries for x, y is ranked within the top two. To study to what extent the above assumption is true, we not only measure the summary-level correlation (Spearman's ρ and Pearson's r) between the reward function and human judgements, but also count how many good summaries identified by the reward function are indeed good (*G-Pre*), and how many indeed good summaries are identified by the reward function (*G-Rec*). We normalise the reward scores and the human judgements to the same range.

From Table 1, we find that all metrics we consider have low correlation with the human judgement. More importantly, their G-Pre and G-Rec scores are all below .50, which means that more than half of the good summaries identified by the metrics are actually not good, and more than 50%

InferSent-Cosine	**.329**	**.339**	.417	.460
BERT-Cosine	.312	.335	**.440**	**.484**

Table 1: Quality of reward metrics. G-Pre and G-Rec are the precision and recall rate of the "good" summaries identified by the metrics, resp. All metrics here require reference summaries. We perform stemming and stop words removal as preprosessing, as they help increase the correlation. For InferSent, the embeddings of the reference/system summaries are obtained by averaging the embeddings of the sentences therein.

of the indeed good summaries cannot be identified by the considered metrics. Hence, hill-climbing on these metrics can hardly guide the RL agents to generate genuinely high-quality summaries. These observations clearly motivate the need for better rewards. Next, we formally formulate the reward learning task.

4 Problem Formulation

We focus on reward learning for single-document summarisation in this work, formulated as follows. Let $\mathcal{X}$ be the set of all input documents. For $x \in \mathcal{X}$, let Y_x be the set of all summaries for x that meet the length requirement. A *reward function* $R(x, y; \theta)$ measures the quality of summary y for document x, where θ stands for all parameters for R. Note that human judgements can be viewed as the ground-truth reward function, which we denote as R^* henceforth. At training time, suppose we have access to $\overline{\mathcal{X}} \subseteq \mathcal{X}$ documents and N summaries for each $x \in \overline{\mathcal{X}}$, denoted by $\overline{Y}_x = \{y_x^1, \cdots, y_x^N\} \subseteq Y_x$. Hence, we have $|\overline{\mathcal{X}}| \times N$ summaries at training time, and our training set includes the R^* scores for these summaries: $\bigcup_{x \in \overline{\mathcal{X}}} \{R^*(x, y_x^1), \cdots, R^*(x, y_x^N)\}$. Our target is to learn a reward function R that is as "close" to R^* as possible. Depending on the definition of "close", we explore two loss functions for reward learning, detailed below.

Regression loss. We first consider reward learning as a regression problem, by measuring the "closeness" between R and R^* by their mean squared errors:

$$\mathcal{L}^{MSE}(\theta) = \frac{1}{|\overline{\mathcal{X}}| \cdot N} \sum_{x \in \overline{\mathcal{X}}} \sum_{i=1}^{N} [R^*(x, y_x^i) - R(x, y_x^i; \theta)]^2. \quad (1)$$

Cross-entropy loss. An alternative definition of "closeness" is to measure the "agreement" between R and R^*, i.e. for a pair of summaries, whether R and R^* prefer the same summary. For two summaries $y_x^i, y_x^j \in \overline{Y}_x$, we estimate the likelihood that R prefers y_x^i over y_x^j as

$$P(y_x^i \succ y_x^j) = \frac{\exp(r^i)}{\exp(r^i) + \exp(r^j)}, \quad (2)$$

where $r^i = R(x, y_x^i; \theta)$, $r^j = R(x, y_x^j; \theta)$. Note that for each $x \in \overline{\mathcal{X}}$, we have N summaries available in $\overline{Y}_x$. Hence we can construct $N \cdot (N-1)/2$ pairs of summaries for each input x. Our target is to minimise the "disagreement" between R^* and R on the $|\overline{\mathcal{X}}| \cdot N \cdot (N-1)/2$ pairs of summaries, formally defined as the cross-entropy loss below:

$$\mathcal{L}^{CE}(\theta) = -\frac{1}{|\overline{\mathcal{X}}| N(N-1)/2} \sum_{x \in \overline{\mathcal{X}}} \sum_{i=1}^{N} \sum_{j>i}^{N} \{ \mathbb{1}[R^*(x, y_x^i) > R^*(x, y_x^j)] \log P(y_x^i \succ y_x^j) + \mathbb{1}[R^*(x, y_x^j) > R^*(x, y_x^i)] \log P(y_x^j \succ y_x^i) \}, \quad (3)$$

where $\mathbb{1}$ is the indicator function. Next, we will introduce our reward learning model that minimises the losses defined in Eq. (1) and (3).

5 Reward Learning Model

We explore two neural architectures for $R(x, y; \theta)$: *Multi-Layer Perceptron (MLP)* and *Similarity-Redundancy Matrix (SimRed)*, detailed below.

5.1 MLP

A straightforward method for learning $R(x, y_x; \theta)$ is to encode the input document x and summary y as two embeddings, and feed the concatenated embedding into a single-layer MLP to minimise the loss functions Eq. (1) and (3). We consider three text encoders to vectorise x and y_x. In supplementary material, we provide figures to further illustrate the architectures of these text encoders.

CNN-RNN. We use convolutional neural networks (CNNs) to encode the sentences in the input text, and feed the sentence embeddings into an LSTM to generate the embedding of the whole input text. In the CNN part, convolutions with different filter widths are applied independently as in (Kim, 2014). The most relevant features are selected afterwards with max-over-time pooling. In line with Narayan et al. (2018b), we reverse the order of sentence embeddings before feeding them into the LSTM. This encoder network yields strong performance on summarisation and sentence classification tasks (Narayan et al., 2018a,b).

PMeans-RNN. PMeans is a simple yet powerful sentence encoding method (Rücklé et al., 2018). PMeans encodes a sentence by computing the *power means* of the embeddings of the words in the sentence. PMeans uses a parameter p to control the weights for each word embedding: with $p = 1$, each word element is weighted equally, and with the increase of p, it assigns higher weights to the elements with higher values. With $p = +\infty$, PMeans is equivalent to element-wise max-pooling. The output of PMeans is passed to an LSTM to produce the final document embedding. Note that only the LSTM is trainable; the p value is decided by the system designer.

BERT. We use the pre-trained BERT-Large-Cased model to encode news articles and summaries. The hidden state of the final layer that corresponds to the first token (i.e. "[CLS]") is taken as embedding. Note that the pre-trained BERT models can only encode texts with at most 512 tokens. In line with Alberti et al. (2019), we therefore use a sliding window approach with the offset size of 128 tokens to encode overlength summaries and news articles. We do not fine-tune the BERT model because our dataset is relatively small (only 2,500 summaries and 500 news articles), and the sliding-window of BERT requires much resources to fine-tune.

5.2 Similarity-Redundancy Matrix (SimRed)

Good summaries should be more *informative* (i.e. contain information of higher importance from the input documents) and less *redundant* than bad summaries. Based on this intuition, we propose the SimRed architecture, which explicitly measures the informativeness and redundancy of summary y_x for document x. SimRed maintains a *Similarity* matrix and a *Redundancy* matrix. In the Similarity matrix, cell (i, j) is the cosine similarity between the embeddings of the ith sentence in summary y_x and the jth sentence in document x. In the Redundancy matrix, each cell contains the square of the cosine similarity of a pair of sentences in summary y_x. We use the average over the Similarity matrix cells to measure the informativeness of y_x, the average over the Redundancy matrix cells to measure the redundancy, and compute the weighted sum of these two averaged values to yield the reward R:

$$R_{\text{SimRed}}(y_x, x) = \frac{\alpha}{NM} \sum_{i=1}^{N} \sum_{j=1}^{M} \cos(s_i, d_j) - \frac{1-\alpha}{N(N-1)/2} \sum_{k=1}^{N} \sum_{l>k}^{N} (\cos(s_k, s_l))^2, \quad (4)$$

where $s_i, i = 1, \cdots, N$ indicates the embedding of the ith sentence in summary y_x, and $d_j, j = 1, \cdots, M$ indicates the embedding of the jth sentence in document x. The sentence embeddings are generated using CNN, PMeans and BERT as described in §5.1. Because PMeans does not have trainable parameters and BERT is kept fixed, we put a trainable layer on top of them.

6 Reward Quality Evaluation

Experimental Setup. We perform 5-fold cross-validation on the 2,500 human summaries (described in §3) to measure the performance of our reward R. In each fold, the data is split with ratio 64:16:20 for training, validation and test.

The parameters of our model are detailed as follows, decided in a pilot study on one fold of the data split. The CNN-RNN encoder (see §5.1) uses filter widths 1-10 for the CNN part, and uses a unidirectional LSTM with a single layer whose dimension is 600 for the RNN part. For PMeans, we obtain sentence embeddings for each $p \in \{-\infty, +\infty, 1, 2\}$ and concatenate them per sentence. Both these two encoders use the pre-trained GloVe word embeddings (Pennington et al., 2014). On top of these encoders, we use an MLP with one hidden ReLU layer and a linear activation at the output layer. For the MLP that uses CNN-RNN and PMeans-RNN, the dimension of its hidden layer is 100, while for the MLP with BERT as encoder, the dimension of the hidden layer is 1024. As for SimRed, we set α (see Eq. (4)) to be 0.85. The trainable layer on top of BERT and PMeans – when used with SimRed – is a single

layer perceptron whose output dimension is equal to the input dimension.

Reward Quality. Table 2 shows the quality of different reward learning models. As a baseline, we also consider the feature-rich reward learning method proposed by Peyrard and Gurevych (2018) (see §2). MLP with BERT as encoder has the best overall performance. Specifically, BERT+MLP+Pref significantly outperforms ($p < 0.05$) all the other models that do not use BERT+MLP, as well as the metrics that rely on reference summaries (see Table 1). P-values between each pair of metrics/rewards can be found in the supplementary material. In general, preference loss (Eq. (2)) yields better performance than regression loss (Eq. (1)), because it "pushes" the reward function to provide correct preferences over summaries, which leads to more precise ranking.

Fig. 1 illustrates the distribution of some rewards/metrics for summaries with different human ratings. In the left-most sub-figure in Fig. 1, we find that, for summaries with average human rating 1.0 (the highest human rating; see §3), their average ROUGE-2 scores are similar to those with lower human ratings, which indicates that ROUGE-2 can hardly distinguish the highest-quality summaries from the rest. We make similar observations for InferSent-Cosine and BERT-Cosine. BERT+MLP+Pref provides higher scores to summaries with higher human ratings (the right-most sub-figure), although it does not use reference summaries. This explains the strong G-Pre and G-Rec scores of BERT+MLP+Pref. The distributions of the other metrics/rewards can be found in the supplementary material. Next, we use the reward learned by BERT+MLP+Pref to train some RL-based summarisation systems.

7 RL-based Summarisation with Learned Rewards

We consider two RL-based summarisation systems, an extractive system *NeuralTD* (Gao et al., 2019), and an abstractive system *ExtAbsRL* (Chen and Bansal, 2018). Note that ExtAbsRL is a cross-input RL while NeuralTD is an input-specific RL (see §2). Our study is performed on the test set of the non-anonymised CNN/DailyMail dataset (See et al., 2017), which includes 11,490 news articles and one reference summary for each article.

7.1 RL-based Summarisation Systems

NeuralTD. NeuralTD is an improved version of the RL-based extractive multi-document summarisation system proposed by Ryang and Abekawa (2012). We briefly recap the original system below. Suppose the RL agent has selected some sentences and has built a draft summary d using the selected sentences. The RL agent maintains a function $V: D \rightarrow \mathbb{R}$, where D denotes the set of all possible draft summaries. $V(d; w)$ estimates the quality and potential of d, where w are the learnable parameters in V. To select which sentence to add to d next, the agent samples sentences $s \in S$ with distribution

$$\pi(s; w) = \frac{\exp[V((d, s); w)]}{\sum_{s' \in S} \exp[V((d, s'); w)]},$$

where S is the set of all sentences in the input document that has not been added to d yet, and (d, s) is the resulting summary of concatenating d and s. The original system proposed by Ryang and Abekawa (2012) models V as a linear function (i.e. $V(d; w) = w \cdot \phi(d)$, where $\phi(d)$ is the vector for draft summary d). NeuralTD instead uses a neural network with multiple hidden layers to approximate V. Gao et al. (2019) show that NeuralTD significantly outperforms the original linear algorithm in multiple benchmark datasets.

In line with (Gao et al., 2019), we use the *delayed rewards* in NeuralTD: a non-zero reward is provided to the agent only when the agent finishes the sentence selection process (i.e. when agent performs the "end-of-construction" action). The assumption underlying this reward scheme is that the reward function can only precisely measure the quality of the summary when the summary is complete. Besides our learned reward, in order to encourage the agent to select the "lead" sentences (i.e. the first three sentences in each news article), we provide the agent with a small extra reward (0.5) for each "lead" sentence the agent chooses to extract. The value for the extra reward (0.5) is decided in a pilot study, in which we manually check the quality of the generated summaries with different extra rewards (0.1, 0.3, $\cdots$, 0.9).

ExtAbsRL has an *extractor* to extract salient sentences and an *abstractor* to rephrase the extracted sentences to generate abstractive summaries. The abstractor is a simple encoder-aligner-decoder model with copying mechanism, which

Model	Encoder	*Reg. loss (Eq. (1))* ρ	r	G-Pre	G-Rec	*Pref. loss (Eq. (3))* ρ	r	G-Pre	G-Rec

Table 2: Summary-level correlation of learned reward functions. All results are averaged over 5-fold cross validations. Unlike the metrics in Table 1, all rewards in this table do not require reference summaries.

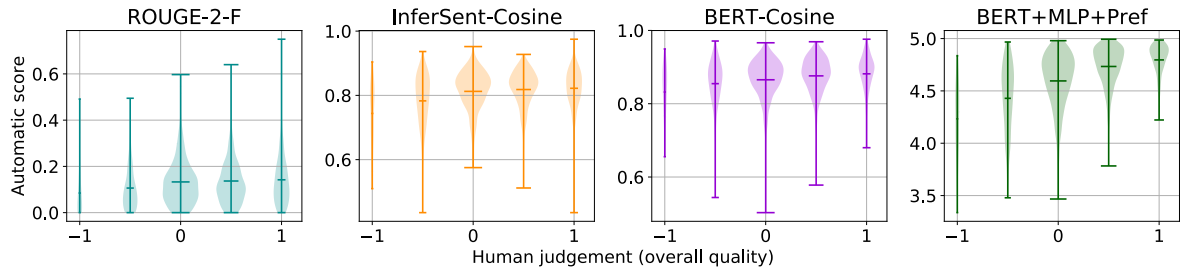

Figure 1: Distributions of some metrics/rewards for summaries with different human ratings. Among the four presented metrics/rewards, only BERT+MLP+Pref (the rightmost sub-figure) does not use reference summaries.

is pre-trained using standard supervised cross-entropy training. The extractor, on the other hand, applies an actor-critic RL algorithm on top of a pointer network. Unlike NeuralTD that uses delayed rewards, ExtAbsRL receives a non-zero reward after adding each new sentence, by computing the ROUGE-L score between the newly added sentence and the corresponding sentence in the reference summary. When the generated summary has more sentences than the reference summary, 0 is given as the reward for the extra sentences. At the final step, ROUGE-1 of the whole generated summary is granted as reward.

We follow the step-wise reward scheme in original ExtAbsRL but, instead of using ROUGE-L to compute the step-wise rewards, we apply our learned reward function to compute the score for the summary with and without the new sentence, and use their difference as reward. Similarly, for the final step reward, we also use our learned reward function. In addition, we force our summariser to stop adding new sentences when the number of tokens in the generated summary is 1.2 times as many as in the reference summary, because we find the abstractive summaries generated by the original ExtAbsRL algorithm are approximately of this length. Since the abstractor in ExtAbsRL is not RL-based, the different reward only influences the extractor.

System	Reward	R-1	R-2	R-L
(Kryscinski et al., 2018)	R-L	40.2	17.4	37.5
(Narayan et al., 2018b)	R-1,2,L	40.0	18.2	36.6
(Chen and Bansal, 2018)	R-L	41.5	18.7	37.8
(Dong et al., 2018)	R-1,2,L	41.5	18.7	37.6
(Zhang et al., 2018)	NA	41.1	18.8	37.5
(Zhou et al., 2018)	NA	41.6	19.0	38.0
(Kedzie et al., 2018)	NA	39.1	17.9	35.9
(ours) NeuralTD	Learned	39.6	18.1	36.5

Table 3: Full-length ROUGE F-scores of some recent RL-based (upper) and supervised (middle) extractive summarisation systems, as well as our system with learned rewards (bottom). R-1/2/L stands for ROUGE-1/2/L. Our system maximises the learned reward instead of ROUGE, hence receives lower ROUGE scores.

7.2 Extractive Summarisation

Table 3 presents the ROUGE scores of our system (NeuralTD+LearnedRewards) and multiple state-of-the-art systems. The summaries generated by our system receive decent ROUGE metrics, but are lower than most of the recent systems, because our learned reward is optimised towards high correlation with human judgement instead of ROUGE metrics.

To measure the human ratings on the gener-

	Ours	Refresh	ExtAbsRL

Learned (ours)	39.2	17.4	37.5	**2.20**	**75**

Table 5: Performance of ExtAbsRL with different reward functions, measured in terms of ROUGE (center) and human judgements (right). Using our learned reward yields significantly ($p = 0.0057$) higher average human rating. "Pref%": in how many percentage of documents a system receives the higher human rating.

ated summaries, we invited five users to read and rate the summaries from three systems: NeuralTD+LearnedReward, the Refresh system (Narayan et al., 2018b) and the extractive version of the ExtAbsRL system, which only extracts salient sentences and does not apply sentence rephrasing. We selected Refresh and ExtAbsRL because they both have been reported to receive higher human ratings than the strong system proposed by See et al. (2017).

We randomly sampled 30 news articles from the test set in CNN/DailyMail, and asked the five participants to rate the three summaries for each article on a 3-point Likert scale from 1 to 3, where higher scores mean better overall quality. We asked them to consider the *informativeness* (whether the summary contains most important information in the article) and *conciseness* (whether the summary is concise and does not contain redundant information) in their ratings.

Table 4 presents the human evaluation results. summaries generated by NeuralTD receives significantly higher human evaluation scores than those by Refresh ($p = 0.0088$, double-tailed t-test) and ExtAbsRL ($p \ll 0.01$). Also, the average human rating for Refresh is significantly higher ($p \ll 0.01$) than ExtAbsRL, despite receiving significantly higher ROUGE scores than both Refresh and NeuralTD (see Table 3). We find that the summaries generated by ExtAbsRL include more tokens (94.5) than those generated by Refresh (83.4) and NeuralTD (85.6). Sun et al. (2019) recently show that, for summaries whose lengths are in the range of 50 to 110 tokens, longer summaries receive higher ROUGE-F1 scores. We believe this is the reason why ExtAbsRL has higher ROUGE scores. On the other hand, ExtAbsRL extracts more redundant sentences: four out of 30 summaries by ExtAbsRL include redundant sentences, while Refresh and NeuralTD do not generate summaries with two identical sentences therein. Users are sensitive to the redundant sentences in summaries: the average human rating for redundant summaries is 1.2, lower than the average rating for the other summaries generated by ExtAbsRL (1.66). To summarise, by using our learned reward function in training an extractive RL summariser (NeuralTD), the generated summaries receive significantly higher human ratings than the state-of-the-art systems.

7.3 Abstractive Summarisation

Table 5 compares the ROUGE scores of using different rewards to train the extractor in ExtAbsRL (the abstractor is pre-trained, and is applied to rephrase the extracted sentences). Again, when ROUGE is used as rewards, the generated summaries have higher ROUGE scores.

We randomly sampled 20 documents from the test set in CNN/DailyMail and asked three users to rate the quality of the two summaries generated with different rewards. We asked the users to consider not only the informativeness and conciseness of summaries, but also their grammaticality and faithfulness (whether the information in the summary is consistent with that in the original news). It is clear from Table 5 that using the learned reward helps the RL-based system generate summaries with significantly higher human ratings. Furthermore, we note that the overall human ratings for the abstractive summaries are lower than the extractive summaries (compared to Table 4). Qualitative analysis suggests that the poor overall rating may be caused by occasional information inconsistencies between a summary and its source text: for instance, a sentence in the source article reads *"after Mayweather was almost two hours late for his workout , Pacquiao has promised to be on time"*, but the generated summary outputs *"Mayweather has promised to be on time for the fight"*. High redundancy is another reason for the low human ratings: ExtAbsRL generates six summaries with redundant sentences when applying ROUGE-L as reward, while the number drops to

two when the learned reward is applied.

8 Conclusion & Discussion

In this work, we focus on Reinforcement Learning (RL) based summarisation, and propose a reward function directly learned from human ratings on summaries' overall quality. Our reward function only takes the source text and the generated summary as input (i.e. does not require reference summaries), and correlates significantly better with human judgements than existing metrics (e.g. ROUGE and METEOR, which require reference summaries). We use our learned reward to train both extractive and abstractive summarisation systems. Experiments show that the summaries generated from our learned reward outperform those by the state-of-the-art systems, in terms of human judgements. Considering that our reward is learned from only 2,500 human ratings on 500 summaries, while the state-of-the-art systems require two orders of magnitude (287k) more document-reference pairs for training, this work clearly shows that reward learning plus RL-based summarisation is able to leverage a relatively small set of human rating scores to produce high-quality summaries.

For future work, we plan to test our method in other summarisation tasks (e.g. multi-document summarisation) and downstream tasks of summarisation (e.g. investigating whether users can correctly answer questions by reading our summaries instead of the original documents). Also, we believe the "learning reward from human judgements" idea has potential to boost the performance of RL in other natural language generation applications, e.g. translation, sentence simplification and dialogue generation.

Abstract

Generating diverse sequences is important in many NLP applications such as question generation or summarization that exhibit semantically one-to-many relationships between source and the target sequences. We present a method to explicitly separate diversification from generation using a general plug-and-play module (called SELECTOR) that wraps around and guides an existing encoder-decoder model. The diversification stage uses a mixture of experts to sample different binary masks on the source sequence for diverse content selection. The generation stage uses a standard encoder-decoder model given each selected content from the source sequence. Due to the non-differentiable nature of discrete sampling and the lack of ground truth labels for binary mask, we leverage a proxy for ground-truth mask and adopt stochastic hard-EM for training. In question generation (SQuAD) and abstractive summarization (CNN-DM), our method demonstrates significant improvements in accuracy, diversity and training efficiency, including state-of-the-art top-1 accuracy in both datasets, 6% gain in top-5 accuracy, and 3.7 times faster training over a state-of-the-art model. Our code is publicly available at https://github.com/clovaai/FocusSeq2Seq.

1 Introduction

Generating target sequences given a source sequence has applications in a wide range of problems in NLP with different types of relationships between the source and target sequences. For instance, paraphrasing or machine translation exhibit a one-to-one relationship because the source and the target should carry the same meaning. On the other hand, summarization or question generation exhibit one-to-many relationships because a single source often results in diverse target sequences with different semantics. Fig. 1 shows different questions that can be generated from a given passage.

Source Passage: in december 1878 , tesla left graz and severed all relations with his family to hide the fact that he dropped out of school .
Target: what did tesla do in december 1878?

Focus 1: in december 1878 , tesla left graz and severed all relations with his family to hide the fact that he dropped out of school.
(Ours) ⇒ what did tesla do?

Focus 2: in december 1878 , tesla left graz and severed all relations with his family to hide the fact that he dropped out of school.
(Ours) ⇒ what did tesla do in december 1878?

Focus 3: in december 1878 , tesla left graz and severed all relations with his family to hide the fact that he dropped out of school .
(Ours) ⇒ what did tesla do to hide he dropped out of school?

Figure 1: Sample questions produced by our method from given passage-answer pair (answer is underlined). Our method generates diverse questions, by selecting different tokens to focus (colored) in contrast to 3-mixture decoder (Shen et al., 2019) that generates 3 identical questions: "what did tesla do to hide the fact that he dropped out of school?".

Encoder-decoder models (Cho et al., 2014) are widely used for sequence generation, most notably in machine translation where neural models are now often almost as good as human translators in some language pairs. However, a standard encoder-decoder often shows a poor performance when it attempts to produce multiple, diverse outputs. Most recent methods for diverse sequence generation leverage diversifying decoding steps through alternative search algorithms (Fan et al., 2018; Vijayakumar et al., 2018) or mixture of decoders (He et al., 2018; Shen et al., 2019). These methods promote diversity at the decoding

step, while a more focused selection of the source sequence can lead to diversifying the semantics of the generated target sequences.

In this paper, we present a method for diverse generation that separates diversification and generation stages. The diversification stage leverages content selection to map the source to multiple sequences, where each mapping is modeled by *focusing* on different tokens in the source (one-to-many mapping). The generation stage uses a standard encoder-decoder model to generate a target sequence given each selected content from the source (one-to-one mapping). We present a generic module called SELECTOR that is specialized for diversification. This module can be used as a plug-and-play to an arbitrary encoder-decoder model for generation without architecture change.

The SELECTOR module leverages a mixture of experts (Jacobs et al., 1991; Eigen et al., 2014) to identify diverse key contents to focus on during generation. Each mixture samples a sequential latent variable modeled as a binary mask on every source sequence token. Then an encoder-decoder model generates multiple target sequences given these binary masks along with the original source tokens. Due to the non-differentiable nature of discrete sampling, we adopt stochastic hard-EM for training SELECTOR. To mitigate the lack of ground truth annotation for the mask (content selection), we use the overlap between the source and target sequences as a simple proxy for the ground-truth mask.

We experiment on question generation and abstractive summarization tasks and show that our method achieves the best trade-off between accuracy and diversity over previous models on SQuAD (Rajpurkar et al., 2016) and CNN-DM (Hermann et al., 2015; Nallapati et al., 2016; See et al., 2017) datasets. In particular, compared to the recently-introduced mixture decoder (Shen et al., 2019) that also aims to diversify outputs by creating multiple decoders, our modular method not only demonstrates better accuracy and diversity, but also trains 3.7 times faster.

2 Related Work

Diverse Search Algorithms Beam search, the most commonly used search algorithm for decoding, is known to produce samples that are short, contain repetitive phrases, and share majority of their tokens. Hence several methods are introduced to diversify search algorithms for decoding. Graves (2013); Chorowski and Jaitly (2017) tune temperature hyperparameter in softmax function. Vijayakumar et al. (2018); Li et al. (2016b) penalize similar samples during beam search in order to obtain diverse set of samples. Cho (2016) adds random noise to RNN decoder hidden states. Fan et al. (2018) sample tokens from top-k tokens at each decoding step. Our method is orthogonal to these search-based strategies, in that they diversify *decoding* while our method diversifies which content to be focused during *encoding*. Moreover, our empirical results show diversification with stochastic sampling hurts accuracy significantly.

Deep Mixture of Experts Several methods adopt a deep mixture of experts (MoE) (Jacobs et al., 1991; Eigen et al., 2014) to diversify decoding steps. Yang et al. (2018) introduce soft mixture of softmax on top of the output layer of RNN language model. He et al. (2018); Shen et al. (2019) introduce mixture of decoders with uniform mixing coefficient to improve diversity in machine translation. Among these, the closest to ours is the mixture decoder (Shen et al., 2019) that also adopts hard-EM for training, where a minimum-loss predictor is assigned to each data point, which is also known as multiple choice learning (Guzman-Rivera et al., 2012; Lee et al., 2016). While Shen et al. (2019) makes RNN decoder as a MoE, we make SELECTOR as a MoE to diversify content selection and let the encoder-decoder models one-to-one generation. As shown in our empirical results, our method achieves a better accuracy-diversity trade-off while reducing training time significantly.

Variational Autoencoders Variational Autoencoders (VAE) (Kingma and Welling, 2013) are used for diverse generation in several tasks, such as language modeling (Bowman et al., 2016), machine translation (Zhang et al., 2016; Su et al., 2018; Deng et al., 2018; Shankar and Sarawagi, 2019), and conversation modeling (Serban et al., 2017; Wen et al., 2017; Zhao et al., 2017; Park et al., 2018; Wen and Luong, 2018; Gu et al., 2019). These methods sample diverse latent variables from an approximate posterior distribution, but often suffer from a posterior collapse where the sampled latent variables are ignored (Bowman et al., 2016; Park et al., 2018; Kim et al., 2018b;

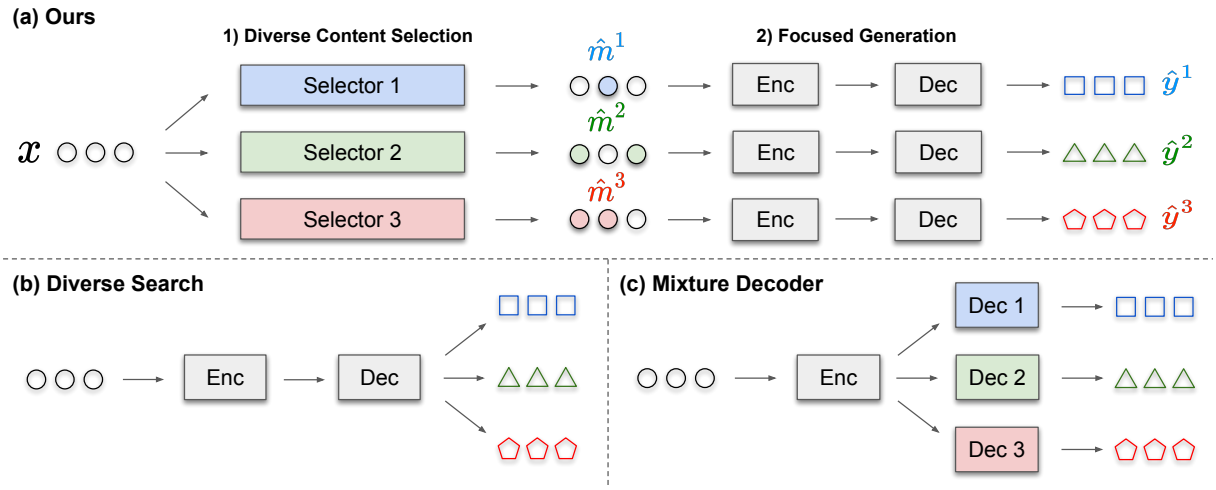

Figure 2: Overview of diverse sequence-to-sequence generation methods. (a) refers to our two-stage approach described throughout Section. 3, (b) refers to search-based methods (Vijayakumar et al., 2018; Li et al., 2016b; Fan et al., 2018), and (c) refers to mixture decoders (Shen et al., 2019; He et al., 2018).

Dieng et al., 2018; Xu and Durrett, 2018; He et al., 2019; Razavi et al., 2019). This is also observed in our initial experiments and Shen et al. (2019), where MoE-based methods significantly outperforms VAE-based methods because of the posterior collapse. Moreover, we observe that sampling mixtures makes training more stable compared to stochastic sampling of latent variables. Furthermore, our latent structure as a sequence of binary variables is different from most VAEs which use a fixed-size continuous latent variable. This gives a finer-grained control and interpretability on where to focus, especially when source sequence is long.

Diversity-Promoting Regularization Adding regularization to objective functions is used to diversify generation. Li et al. (2016a) introduce a term maximizing mutual information between source and target sentences. Chorowski and Jaitly (2017); Kalyan et al. (2018) introduce terms enforcing knowledge transfer among similar annotations. Our work is orthogonal to these methods and can potentially benefit from adding these regularization terms to our objective function.

Content Selection in NLP Selecting important parts of the context has been an important step in NLP applications (Reiter and Dale, 2000). Most recently, Ke et al. (2018); Min et al. (2018) conduct soft-/ hard-selection of key parts from source passages for question answering. Zhou et al. (2017b) use soft gating on the source document encoder for abstractive summarization. Li et al. (2018) guide abstractive summarization models with off-the-shelf keyword extractors. The most relevant work to ours are Subramanian et al. (2018) and Gehrmann et al. (2018). Subramanian et al. (2018) use a pointer network (Vinyals et al., 2015) for extracting key phrases for question generation and Gehrmann et al. (2018) use content selector to limit copying probability for abstractive summarization. The main purpose of these approaches is to enhance accuracy, while our method uses diverse content selection to enhance both accuracy and diversity (refer to our empirical results). Additionally, our method allows models to learn how to utilize information from the selected content, whereas Gehrmann et al. (2018) manually limit the copying mechanism on non-selected contents.

3 Method

In this paper, we focus on sequence generation tasks such as question generation and summarization that have one-to-many relationship. More formally, given a source sequence $\mathbf{x} = (x_1 \dots x_S) \in \mathcal{X}$, our goal is to model a conditional multimodal distribution for the target sequence $p(\mathbf{y}|\mathbf{x})$ that assigns high values on $p(\mathbf{y}^1|\mathbf{x}) \dots p(\mathbf{y}^K|\mathbf{x})$ for K valid mappings $\mathbf{x} \rightarrow \mathbf{y}^1 \dots \mathbf{x} \rightarrow \mathbf{y}^K$. For instance, Fig. 1 illustrates $K = 3$ different valid questions generated for a given passage.

For learning a multimodal distribution, it is not appropriate to use a generic encoder-decoder (Cho et al., 2014) that minimizes for the expected value of the log probability of all the valid mappings.

This can lead to a suboptimal mapping that is in the middle of the targets but not near any of them. As a solution, we propose to (1) introduce a latent variable called *focus* that factorizes the distribution into two stages, *select* and *generate* (Section 3.1), and (2) independently train the factorized distributions (Section 3.2).

3.1 Select and Generate

In order to factorize the multimodal distribution into the two stages (*select* and *generate*), we introduce a latent variable called *focus*. The intuition is that in the *select* stage we sample several meaningful *focus*, each of which indicates which part of the source sequence should be considered important. Then in the *generate* stage, each sampled focus biases the generation process towards being conditioned on the focused content.

Formally, we model *focus* with a sequence of binary variable, each of which corresponds to each token in the input sequence, i.e. $\mathbf{m} = \{m_1 \dots m_S\} \in \{0,1\}^S$. The intuition is that $m_t = 1$ indicates t-th source token x_t should be *focused* during sequence generation. For instance, in Fig. 1, colored tokens (green, red, or blue) show that different tokens are focused (i.e. values are 1) for different focus samples (out of 3). We first use the latent variable $\mathbf{m}$ to factorize $p(\mathbf{y}|\mathbf{x})$,

$$p(\mathbf{y}|\mathbf{x}) = \mathbb{E}_{\mathbf{m}\sim p_\phi(\mathbf{m}|\mathbf{x})}[p_\theta(\mathbf{y}|\mathbf{m},\mathbf{x})] \quad (1)$$

where $p_\phi(\mathbf{m}|\mathbf{x})$ is *selector* and $p_\theta(\mathbf{y}|\mathbf{x},\mathbf{m})$ is *generator*. The factorization separates focus selection from generation so that modeling multimodality (diverse outputs) can be solely handled in the *select* stage and *generate* stage can solely concentrate on the generation task itself. We now describe each component in more details.

Selector In order to directly control the diversity of the SELECTOR's outputs, we model it as a hard mixture of experts (hard-MoE) (Jacobs et al., 1991; Eigen et al., 2014), where each expert specializes in focusing on different parts of the source sequences. In Fig. 1 and 2, focus produced by each SELECTOR expert is colored differently. We introduce a multinomial latent variable $z \in \mathbb{Z}$, where $\mathbb{Z} = \{1 \dots K\}$, and let each focus $\mathbf{m}$ be assigned to one of K experts with uniform prior $p(z|\mathbf{x}) = \frac{1}{K}$. With this mixture setting, $p(\mathbf{m}|\mathbf{x})$ is recovered as follows.

$$\begin{aligned} p(\mathbf{m}|\mathbf{x}) &= \mathbb{E}_{z\sim p(z|\mathbf{x})}[p_\phi(\mathbf{m}|\mathbf{x},z)] \\ &= \frac{1}{K}\sum_{z}^{1\dots K} p_\phi(\mathbf{m}|\mathbf{x},z) \end{aligned} \quad (2)$$

We model SELECTOR with a single-layer Bi-directional Gated Recurrent Unit (Bi-GRU) (Cho et al., 2014) followed by two fully-connected layers and a Sigmoid activation. We feed (current hidden state $\mathbf{h}_t$, first and last hidden state $\mathbf{h}_1, \mathbf{h}_S$, and expert embedding $\mathbf{e}_z$) to a fully-connected layers (FC). Expert embedding $\mathbf{e}_z$ is unique for each expert and is trained from a random initialization. From our initial experiments, we found this parallel focus inference to be more effective than auto-regressive pointing mechanism (Vinyals et al., 2015; Subramanian et al., 2018). The distribution of the focus conditioned on the input $\mathbf{x}$ and the expert id z is the Bernoulli distribution of the resulting values,

$$\begin{aligned} (\mathbf{h}_1 \dots \mathbf{h}_S) &= \text{Bi-GRU}(\mathbf{x}) \\ o_t^z &= \sigma(\text{FC}([\mathbf{h}_t;\mathbf{h}_1;\mathbf{h}_S;\mathbf{e}_z])) \\ p_\phi(m_t|\mathbf{x},z) &= \text{Bernoulli}(o_t^z) \end{aligned} \quad (3)$$

To prevent low quality experts from *dying* during training, we let experts share all parameters, except for the individual expert embedding $\mathbf{e}_z$. We also reuse the word embedding of the generator in the word embedding of SELECTOR to promote cooperative knowledge sharing between SELECTOR and generator. With these parameter sharing techniques, adding a mixture of SELECTOR experts increases only a slight amount of parameters (GRU, FC, and $\mathbf{e}_z$) to sequence-to-sequence models.

Generator For maximum diversity, we sample one focus from each SELECTOR expert to approximate $p_\phi(\mathbf{m}|\mathbf{x})$. For a deterministic behavior, we threshold o_t^z with a hyperparameter th instead of sampling from the Bernoulli distribution. This gives us a list of focus $\mathbf{m}^1 \dots \mathbf{m}^K$ coming from K experts. Each focus $\mathbf{m}^z = (m_1^z \dots m_S^z)$ is encoded as embeddings and concatenated with the input embeddings of the source sequence $\mathbf{x} = (x_1 \dots x_S)$. An off-the-shelf generation function such as encoder-decoder can be used for modeling $p(\mathbf{y}|\mathbf{m},\mathbf{x})$, as long as it accepts a stream of input embeddings. We use an identical generation function with K different focus samples to produce K different diverse outputs.

Algorithm 1: Training

5 $z^{\text{best }(i)} = \underset{z}{\text{argmin}}\, L_{\text{select}}^{(i)\ z}$

/* Selector $p_\phi(\mathbf{m}|\mathbf{x}, z)$ M-step */

6 $\phi_{z^{\text{best }(i)}} = \phi_{z^{\text{best }(i)}} - \alpha \nabla_{\phi_{z^{\text{best }(i)}}} L_{\text{select}}^{(i)\ z^{\text{best }(i)}}$

/* Generator $p_\theta(\mathbf{y}|\mathbf{x}, \mathbf{m})$ Update */

7 $L^{(i)}{}_{\text{gen}} = -\log p_\theta(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}, \mathbf{m}^{\text{guide (i)}})$

8 $\theta = \theta - \alpha \nabla_\theta L_{\text{gen}}^{(i)}$

9 **end**

3.2 Training

Marginalizing the Bernoulli distribution in Eq. 3 by enumerating all possible focus is intractable since the cardinality of focus space 2^S grows exponentially with source sequence length S. Policy gradient (Williams, 1992; Yu et al., 2017) or Gumbel-softmax (Jang et al., 2017; Maddison et al., 2017) are often used to propagate gradients through a stochastic process, but we empirically found that these do not work well. We instead create *focus guide* and use it to independently and directly train the SELECTOR and the generator. Formally, a focus guide $\mathbf{m}^{\text{guide}} = (m_1^{\text{guide}} \dots m_S^{\text{guide}})$ is a simple proxy of whether a source token is *focused* during generation. We set t-th focus guide m_t^{guide} to 1 if t-th source token x_t is *focused* in target sequence $\mathbf{y}$ and 0 otherwise. During training, $\mathbf{m}^{\text{guide}}$ acts as a target for SELECTOR and is a given input for generator (teacher forcing). During inference, $\hat{\mathbf{m}}$ is sampled from SELECTOR and fed to the generator.

In question generation, we set m_t^{guide} to 1 if there is a target question token which shares the same word stem with passage token x_t. Then we set m_t^{guide} to 0 if x_t is a stop word or is inside the answer phrase. In abstractive summarization, we generate focus guide using copy target generation by Gehrmann et al. (2018), where they set source document token x_t is *copied* if it is part of the longest possible subsequence that overlaps with the target summary.

Alg. 1 describes the overall training process, which first uses stochastic hard-EM (Neal and Hinton, 1998; Lee et al., 2016) for training the SELECTOR and then the canonical MLE for training the generator.

E-step (line 2-5 in Alg. 1) we sample focus from all experts and compute their losses $-\log p_\phi(\mathbf{m}^{\text{guide}}|\mathbf{x}, z)$. Then we choose an expert z^{best} with minimum loss.

$$z^{\text{best}} = \underset{z}{\text{argmin}} -\log p_\phi(\mathbf{m}^{\text{guide}}|\mathbf{x}, z) \quad (4)$$

M-step (line 6 in Alg. 1) we only update the parameters of the chosen expert z^{best}.

Training Generator (line 7-8 in Alg. 1) The generator is independently trained using conventional teacher forcing, which minimizes $-\log p_\theta(\mathbf{y}|\mathbf{x}, \mathbf{m}^{\text{guide}})$.

4 Experimental Setup

We describe our experimental setup for question generation (Section 4.1) and abstractive summarization (Section 4.2). For both tasks, we use an off-the-shelf, task-specific encoder-decoder-based model for the generator and show how adding SELECTOR can help to diversify the output of an arbitrary generator. To evaluate the contribution of SELECTOR we additionally compare our method with previous diversity-promoting methods as the baseline (Section 4.3).

4.1 Question Generation

Question generation is the task of generating a question from a passage-answer pair. Answers are given as a span in the passage (See Fig.1).

Dataset We conduct experiments on SQuAD (Rajpurkar et al., 2016) and use the same dataset split of Zhou et al. (2017a), resulting in 86,635, 8,965, and 8,964 source-target pairs for training, validation, and test, respectively. Both source passages and target questions are single sentences. The average length of source passage and target question are 32 and 11 tokens.

Generator We use NQG++ (Zhou et al., 2017a) as the generator, which is an RNN-based encoder-decoder architecture with copying mechanism (Gulcehre et al., 2016).

4.2 Abstractive Summarization

Abstractive summarization is the task of generating a summary sentence from a source document that consists of multiple sentences.

Dataset We conduct experiments on the non-anonymized version of CNN-DM dataset (Hermann et al., 2015; Nallapati et al., 2016; See et al., 2017), whose training, validation, test splits have size of 287,113, 13,368, and 11,490 source-target pairs, respectively. The average length of the source documents and target summaries are 386 and 55 tokens. Following See et al. (2017), we truncate source and target sentences to 400 and 100 tokens during training.

Generator We use Pointer Generator (PG) (See et al., 2017) as the generator for summarization, which also leverages RNN-based encoder-decoder architecture and copying mechanism, and uses coverage loss to avoid repetitive phrases.

4.3 Baselines

For each task, we compare our method with other techniques which promote diversity at the decoding step. In particular, we compare with recent diverse search algorithms including Truncated Sampling (Fan et al., 2018), Diverse Beam Search (Vijayakumar et al., 2018), and Mixture Decoder (Shen et al., 2019). We implement these methods with NQG++ and PG. For each method, we generate K = (3 and 5) hypotheses from each source sequence. For search-based baselines (Fan et al., 2018; Vijayakumar et al., 2018), we select the top-k candidates after generation. For mixture models (Shen et al. (2019) and ours), we conduct greedy decoding from each mixture for fair comparison with search-based methods in terms of speed/memory usage.

Beam Search This baseline keeps K hypotheses with highest log-probability scores at each decoding step.

Diverse Beam Search This baseline adds a diversity promoting term to log-probability when scoring hypotheses in beam search, Following Vijayakumar et al. (2018), we use hamming diversity and diversity strength $\lambda = 0.5$.

Truncated Sampling This baseline randomly samples words from top-10 candidates of the distribution at the decoding step (Fan et al., 2018).

Mixture Decoder This baseline constructs a hard-MoE of K decoders with uniform mixing coefficient (referred as hMup in Shen et al. (2019)) and conducts parallel greedy decoding. All decoders share all parameters but use different embeddings for start-of-sequence token.

Mixture Selector (Ours) We construct a hard-MoE of K SELECTORs with uniform mixing coefficient that infers K different focus from source sequence. Guided by K focus, generator conducts parallel greedy decoding.

4.4 Metrics: Accuracy and Diversity

We use metrics introduced by previous works (Ott et al., 2018; Vijayakumar et al., 2018; Zhu et al., 2018) to evaluate the diversity promoting approaches. These metrics are extensions over BLEU-4 (Papineni et al., 2002) and ROUGE-2 F_1-score (Lin, 2004) and aim to evaluate the trade-off between accuracy and diversity.

Top-1 metric (⇑) This measures the Top-1 accuracy among the generated K-best hypotheses. The accuracy is measured using a corpus-level metric, i.e., BLEU-4 or ROUGE-2.

Oracle metric (⇑) This measures the quality of the target distribution coverage among the Top-K generated target sequences (Ott et al., 2018; Vijayakumar et al., 2018). Given an optimal ranking method (oracle), this metric measures the upper bound of Top-1 accuracy by comparing the best hypothesis with the target. Concretely, we generate hypotheses $\{\hat{\mathbf{y}}^1 \dots \hat{\mathbf{y}}^K\}$ from each source $\mathbf{x}$ and keep the hypothesis $\hat{\mathbf{y}}^{best}$ that achieves the best sentence-level metric with the target $\mathbf{y}$. Then we calculate a corpus-level metric with the greedily-selected hypotheses $\{\hat{\mathbf{y}}^{(i),best}\}_{i=1}^{N}$ and references $\{\mathbf{y}^{(i)}\}_{i=1}^{N}$.

Pairwise metric (⇓) Referred as self- (Zhu et al., 2018) or pairwise- (Ott et al., 2018) metric, this measures the within-distribution similarity. This metric computes the average of sentence-level metrics between all pairwise combinations of hypotheses $\{\hat{\mathbf{y}}^1 \dots \hat{\mathbf{y}}^K\}$ generated from each source sequence $\mathbf{x}$. Low pairwise metric indicates high diversity between generated hypotheses.

4.5 Human Evaluation Setup

We ask Amazon Mechanical Turkers (AMT) to compare our method with the baselines. For each method, we generate three questions / summaries from 100 passages sampled from SQuAD / CNN-DM test set. For every pair of methods, annotators are instructed to pick a set of questions / summaries that are more *diverse*. To evaluate *accuracy*, they see one question / summary selected

out of 3 questions / summaries with highest log-probability from each method. They are instructed to select a question / summary that is more coherent with the source passage / document. Each annotator is asked to choose either a better method (resulting in "win" or "lose") or "tie" if their quality is indistinguishable. Diversity and accuracy evaluations are conducted separately, and every pair of methods are presented to 10 annotators[1].

4.6 Implementation details

For all experiments, we tie the weights (Press and Wolf, 2017) of the encoder embedding, the decoder embedding, and the decoder output layers. This significantly reduces the number of parameters and training time until convergence. We train up to 20 epochs and select the checkpoint with the best oracle metric. We use Adam (Kingma and Ba, 2015) optimizer with learning rate 0.001 and momentum parmeters $\beta_1 = 0.9$ and $\beta_2 = 0.999$. Minibatch size is 64 and 32 for question generation and abstractive summarization. All models are implemented in PyTorch (Paszke et al., 2017) and trained on single Tesla P40 GPU, based on NAVER Smart Machine Learning (NSML) platform (Kim et al., 2018a).

Question Generation Following Zhou et al. (2017a), we use 256-dim hidden states for each direction of Bi-GRU encoder, 512-dim hidden states for GRU decoder, 300-dim word embedding initialized from GloVe (Pennington et al., 2014), vocabulary of 20,000 most frequent words, 16-dim embeddings for three linguistic features (POS, NER and word case) respectively.

Abstractive Summarization Following See et al. (2017), we use 256-dim hidden states for each direction of Bi-LSTM encoder and LSTM decoder, 128-dim word embedding trained from scratch, and vocabulary of 50,000 most frequent words. Following See et al. (2017), we train our model to generate concatenation of target summaries and split it with periods.

SELECTOR The GRU has the same size as the generator encoder, and the dimension of expert embedding $\mathbf{e}_z$ is 300 for NQG++, and 128 for PG. From simple grid search over [0.1, 0.5], we obtain focus binarization threshold th 0.15. The size of focus embedding for the generator is 16.

[1]We conducted 12 human evaluations in total: 2 tasks x 3 baselines x 2 criteria. See Table 3a and 3b.

Method	BLEU-4 (Top-1)	Oracle (Top-K)	Pairwise (Self-sim)

(2017a), and the rest are from our experiments using NQG++ as a generator. Method prefixes are the numbers of generated questions for each passage-answer pair. Best scores are bolded.

5 Results

Diversity vs. Accuracy Trade-off Tables 1 and 2 compare our method with different diversity-promoting techniques in question generation and abstractive summarization. The tables show that our mixture SELECTOR method outperforms all baselines in Top-1 and oracle metrics and achieves the best trade-off between diversity and accuracy. Moreover, both mixture models are superior to all search-based methods in the trade-off between diversity and accuracy. Standard and diverse beam search methods score low both in terms of accuracy and diversity. Truncated sampling shows the lowest self-similarity (high diversity), but it achieves the lowest score on Top-1 accuracy. Notably, our method scores state-of-the-art BLEU-4 in question generation on SQuAD and ROUGE comparable to state-of-the-art methods in abstractive summarization in CNN-DM (See also Table 4 for state-of-the-art results in CNN-DM).

Diversity vs. Number of Mixtures Here we compare the effect of number of mixtures in our SELECTOR and Mixture Decoder (Shen et al., 2019). Tables 1 and 2 show that pairwise similarity increases (diversity ⇓) when the number of mixtures increases for Mixture Decoder. While we observe a similar trend for SELECTOR in the question generation task, Table 2 shows the opposite

(b) CNN-DM abstractive summarization

Table 3: Human evaluation results

effect in the summarization task i.e., pairwise similarity decreases (diversity ⇑) for SELECTOR.

The abstractive summarization task on CNN-DM has a target distribution with more modalities than question generation task on SQuAD, which is more difficult to model. We speculate that our SELECTOR improves accuracy by focusing on more modes of the output distribution (diversity ⇑), whereas Mixture Decoder tries to improve the accuracy by concentrating on fewer modalities of the output distribution (diversity ⇓).

Upper Bound Performance The bottom rows of Tables 1 and 2 show the upper bound performance of SELECTOR by feeding focus guide to generator during test time. In particular, we assume that the mask is the ground truth overlap between input and target sequences at test time. The gap between the oracle metric (top-k accuracy) and the upper bound is very small for question generation. This indicates that the top-k masks for question generation include the ground truth mask. Future work involves improving the content selection stage for the summarization task.

Human Evaluation Table 3a and 3b show the human evaluation in two tasks of questions generation and summarization, comparing sequences generated by SELECTOR with the diversity-promoting baselines: Diverse Beam, Truncated Sampling and Mixture Decoder. The table shows that our method significantly outperforms all three baselines in terms of both diversity and accuracy with statistical significance.

Comparison with State-of-the-art Table 4 compares the performance of SELECTOR with the state-of-the-art bottom-up content selection of Gehrmann et al. (2018) in abstractive summarization. SELECTOR passes focus embeddings at the decoding step, whereas the bottom-up selection method only uses the masked words for the copy mechanism. We set K, the number of mixtures of SELECTOR, to 1 to directly compare it with the previous work (Bottom-Up (Gehrmann et al., 2018)). We observe that SELECTOR not only outperforms Bottom-Up in every metric, but also achieves a new state-of-the-art ROUGE-1 and ROUGE-L on CNN-DM. Moreover, our method scores state-of-the-art BLEU-4 in question generation on SQuAD (Table 1).

Method	R-1	R-2	R-L
PG (See et al., 2017)	39.53	17.28	36.38
Bottom-Up (Gehrmann et al., 2018)	41.22	18.68	38.34
DCA (Celikyilmaz et al., 2018)	41.69	**19.47**	37.92
SELECTOR & 10-Beam PG (Ours)	**41.72**	18.74	**38.79**

Table 4: Comparison of single-expert selector with state-of-the-art abstractive summarization methods on CNN-DM. R stands for ROUGE (Lin, 2004)

Efficient Training Table 5 shows that SELECTOR trains up to 3.7 times faster than mixture decoder (Shen et al., 2019). Training time of mixture decoder linearly increases with the number of decoders, while parallel focus inference of SELECTOR makes additional training time negligible.

Qualitative Analysis To analyze how the generator uses the selected content, we visualize attention heatmap of NQG++ in Fig.3 for question generation. The figure shows different attention

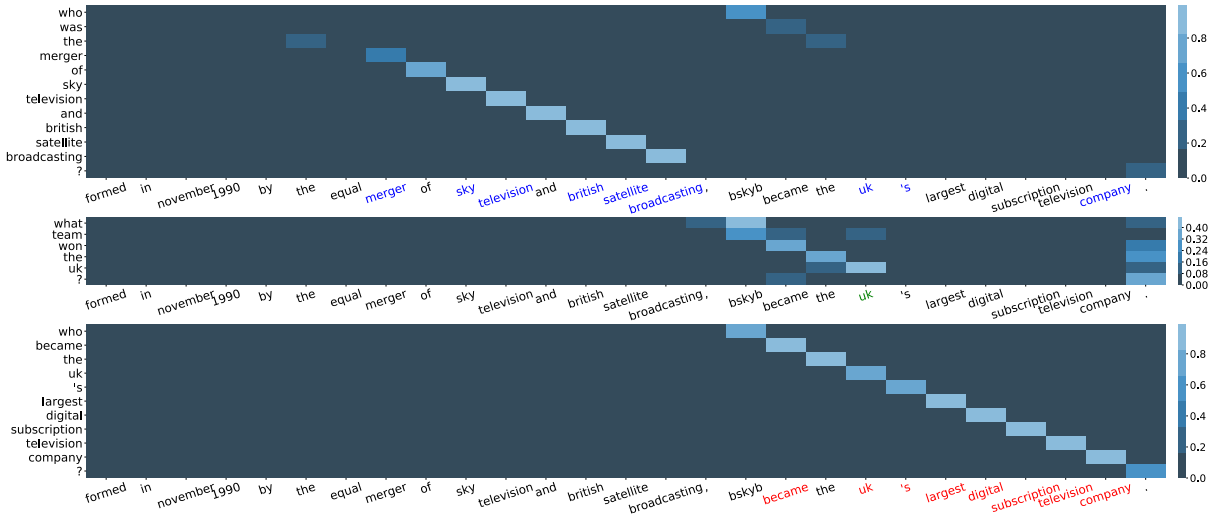

Figure 3: Attention heatmap of NQG++ decoder with three different focus by SELECTOR. This shows focus can guide generator to generate different sequences. Passage tokens are colored when corresponding focus is 1.

Method	Training time (ms. / step)
PG	641.2
3-M. Decoder	1804.1 (× 2.81)
5-M. Decoder	2367.6 (× 4.37)
SELECTOR (Ours)	692.1 (× 1.08)
3-M. SELECTOR (Ours)	740.8 (× 1.16)
5-M. SELECTOR (Ours)	747.6 (× 1.17)

Table 5: **Training time:** Comparison of training time on CNN-DM. See 4.6 for implementation details.

mechanisms depending on three different focuses inferred by different SELECTOR experts.

6 Conclusion

We introduce a novel diverse sequence generation method via proposing a content selection module, SELECTOR. Built upon mixture of experts and hard-EM training, SELECTOR identifies different key parts on source sequence to guide generator to output a diverse set of sequences.

SELECTOR is a generic plug-and-play module that can be added to an existing encoder-decoder model to enforce diversity with a negligible additional computational cost. We empirically demonstrate that our method improves both accuracy and diversity and reduces training time significantly compared to baselines in question generation and abstractive summarization. Future work involves incorporating SELECTOR for other generation tasks such as diverse image captioning.

Abstract

Generating high-quality paraphrases is a fundamental yet challenging natural language processing task. Despite the effectiveness of previous work based on generative models, there remain problems with exposure bias in recurrent neural networks, and often a failure to generate realistic sentences. To overcome these challenges, we propose the first end-to-end conditional generative architecture for generating paraphrases via adversarial training, which does not depend on extra linguistic information. Extensive experiments on four public datasets demonstrate the proposed method achieves state-of-the-art results, outperforming previous generative architectures on both automatic metrics (BLEU, METEOR, and TER) and human evaluations.

1 Introduction

Paraphrases convey the same meaning as the original sentences or text, but with different expressions in the same language. Paraphrase generation aims to synthesize paraphrases of a given sentence automatically. This is a fundamental natural language processing (NLP) task, and it is important for many downstream applications (Madnani and Dorr, 2010; Yang et al., 2016, 2017; Passonneau et al., 2018). For example, paraphrases can help diversify the response of chatbot engines (Yan et al., 2016), strengthen question answering (Harabagiu and Hickl, 2006; Duboue and Chu-Carroll, 2006; Fader et al., 2014), augment relation extraction (Romano et al., 2006), and extend the coverage of semantic parsers (Berant and Liang, 2014).

Generating accurate and diverse paraphrases automatically is still very challenging. Traditional methods (McKeown, 1983; Bolshakov and Gelbukh, 2004; Zhao et al., 2008) exploit how linguistic knowledge can improve the quality of generated paraphrases, including shallow linguistic features (Zhao et al., 2009), and syntactic and semantic information (Kozlowski et al., 2003; Ellsworth and Janin, 2007). However, they are often domain-specific and hard to scale, or yield inferior results.

With the help of growing large data and neural network models, recent studies have shown promising results. Three families of deep learning architectures have been investigated with the goal of generating high-quality paraphrases. The first is to formulate paraphrase generation as a sequence-to-sequence problem, following experience from machine translation (Bahdanau et al., 2014; Cheng et al., 2016). Prakash et al. (2016) proposes stacked residual long short-term memory networks (LSTMs), while Cao et al. (2017) makes use of the gated recurrent unit (GRU) as the recurrent unit. Shortly afterwards, several works have focused on providing extra information to enhance the encoder-decoder model. Ma et al. (2018) adds distributed word representations, Huang et al. (2018) considers a paraphrased dictionary and

Iyyer et al. (2018) utilizes a syntactic parser. Recently Wang et al. (2018) utilizes a semantic augmented Transformer (Vaswani et al., 2017); however, its accuracy largely depends on extra semantic information. The second family of models employs reinforcement learning (Li et al., 2017b). The third family is the generative architecture that we focus on. Specifically, Gupta et al. (2018) applies the conditional variational autoencoders (CVAEs) (Sohn et al., 2015) with LSTM encoder-decoders in generating paraphrases, expecting RNN's advantage of modeling local dependencies to be a good complement to the CVAE's power at learning global representations. This simple combination, however, has two major challenges.

First, CVAE may fail to generate realistic sen-

Table 1: Examples for generating paraphrases by CVAE, from which it fails to generate realistic sentences. Original: source sentence. Paraphrased: target sentence. Generated: the sentence generated by CVAE.

tences. When generating synthetic sentences by decoding random samples from the latent space, most regions of the latent space do not necessarily decode to realistic sentences; the example in Table 1 reflects this challenge. In (Bowman et al., 2016), the authors attempted to utilize RNN-based VAE to generate more diverse sentences. However, this ignores the fundamental problem of the posterior distribution over latent variables not covering the latent space appropriately. Second, when learning, the ground-truth words are used to decode, while during inference, the RNN generates words in sequence from previously *generated* words. Bengio et al. (2015) called this phenomenon "Exposure Bias" and tried to solve it by a scheduled sampling method. However, in practice, it produced unstable results, because it is fundamentally an inconsistent training strategy (Huszár, 2015).

We propose the first paraphrase generative model via adversarial training to tackle the above problems, which we believe is a natural answer to the aforementioned challenges. Specifically, we formalize CVAE as a generator of the Generative Adversarial Network (GAN) (Goodfellow et al., 2014) and tailor a discriminator to CVAE. By introducing an adversarial game between a generator and a discriminator, GAN matches the distribution of synthetic data with that of real data. The generator of GAN seeks to map samples from a given prior distribution to *realistic* synthetic data. The discriminator of GAN compares the entire real and synthetic sentences, instead of individual words, which should in principle alleviates the exposure-bias issue (Yu et al., 2017; Li et al., 2017a; Zhang et al., 2017; Guo et al., 2018). The intuition behind our model can be interpreted as using CVAE to generate similar sentences and enhancing CVAE with an extended discriminator, so that the generator and discriminator work effectively together; they provide feedback signals to each other, resulting in a mutual adversarial framework. Overall, our contributions are as follows.

- To the best of our knowledge, this work represents the first to propose an end-to-end paraphrase generation architecture via adversarial training, which does not require extra linguistic information.
- We take advantage of GAN to help choose a better latent-variable distribution. By this, we not only utilize the better latent variables but also strengthen the expressiveness of the generative model.
- Our experiments show that the proposed model is capable of generating plausible paraphrased sentences and outperforms competitive baseline models, with state-of-the-art results.

2 Preliminaries

We first provide preliminaries of variational auto-encoders and conditional variational auto-encoders.

VAE. The variational auto-encoder (VAE) (Kingma and Welling, 2013; Sohn et al., 2015) is a directed graphical model with latent variables. The generative process of VAE employs an

- (Encoder) generating a set of latent variable $\boldsymbol{z}$ from the prior distribution $p_\theta(\boldsymbol{z})$, where θ is the generative parameters;
- (Decoder) then generating the data $\boldsymbol{x}$ from the generative distribution $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ conditioned on $\boldsymbol{z}$.

Although due to intractable posterior inference, parameter estimation of directed graphical models is generally challenging, VAE parameters can be estimated efficiently by a stochastic gradient variational bayes (SGVB) estimator (Kingma and Welling, 2013), and can be optimized straightforwardly using standard stochastic gradient techniques.

SGVB treats the variational lower bound of the log-likelihood as a surrogate objective function,

which can be written as:

$$\begin{aligned}\log p_\theta(\boldsymbol{x}) &= -KL(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \parallel p_\theta(\boldsymbol{z})) \\ &\quad +KL(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \parallel p_\theta(\boldsymbol{z}|\boldsymbol{x})) \\ &\quad +\mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x})}[\log p_\theta(\boldsymbol{x}|\boldsymbol{z})] \\ &\geq -KL(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \parallel p_\theta(\boldsymbol{z})) \\ &\quad +\mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x})}[\log p_\theta(\boldsymbol{x}|\boldsymbol{z})], \quad (1)\end{aligned}$$

where the inequality follows because the second term $KL(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \parallel p_\theta(\boldsymbol{z}|\boldsymbol{x}))$ in (1) is nonnegative.

In practice, we can approximate the second term by drawing latent variable samples $\{\boldsymbol{z}^1, \boldsymbol{z}^2, ..., \boldsymbol{z}^L\}$ following $q_\phi(\boldsymbol{z}|\boldsymbol{x})$, where ϕ is the variational parameters, and the empirical objective of VAE with Gaussian latent variables can be represented as:

$$\begin{aligned}\tilde{\mathcal{L}}_{VAE}(\boldsymbol{x};\theta,\phi) &= -KL(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \parallel p_\theta(\boldsymbol{z})) \\ &\quad +\frac{1}{L}\sum_{l=1}^{L}\log p_\theta(\boldsymbol{x}|\boldsymbol{z}^l), \quad (2)\end{aligned}$$

where $\boldsymbol{z}^l = g_\phi(\boldsymbol{x}, \epsilon^l)$, and $\epsilon^l \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$. That means $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ is reparameterized with a differentiable unbiased function $g_\phi(\boldsymbol{x}, \epsilon^l)$, where $\boldsymbol{x}$ is the data and ϵ is the noise variable. VAE can be trained efficiently by stochastic gradient descent (SGD) because the reparameterization trick allows error backpropagation through the Gaussian latent variables.

CVAE. Sohn et al. (2015) develops a deep conditional generative model (CVAE) for structured output prediction using Gaussian latent variables. Different from the normal VAE, CVAE consists of three variables: input variables $\boldsymbol{x}$, output variables $\boldsymbol{y}$, and latent variables $\boldsymbol{z}$, and its prior distribution is $p_\theta(\boldsymbol{z}|\boldsymbol{x})$. CVAE is trained to maximize the conditional log-likelihood $\log p_\theta(\boldsymbol{y}|\boldsymbol{x})$, and again it is formulated in the framework of SGVB. The variational lower bound of the model is:

$$\begin{aligned}\log p_\theta(\boldsymbol{y}|\boldsymbol{x}) &\geq -KL(q_\phi(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{y}) \parallel p_\theta(\boldsymbol{z}|\boldsymbol{x})) \\ &\quad +\mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{y})}[\log p_\theta(\boldsymbol{y}|\boldsymbol{x},\boldsymbol{z})] \quad (3)\end{aligned}$$

and the empirical lower bound is represented as:

$$\begin{aligned}\tilde{\mathcal{L}}_{CVAE}(\boldsymbol{x},\boldsymbol{y};\theta,\phi) &= -KL(q_\phi(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{y}) \parallel p_\theta(\boldsymbol{z}|\boldsymbol{x})) \\ &\quad +\frac{1}{L}\sum_{l=1}^{L}\log p_\theta(\boldsymbol{y}|\boldsymbol{x},\boldsymbol{z}^l), \quad (4)\end{aligned}$$

where $z^l = g_\phi(\boldsymbol{x}, \boldsymbol{y}, \epsilon^l), \epsilon \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, and L is the number of samples.

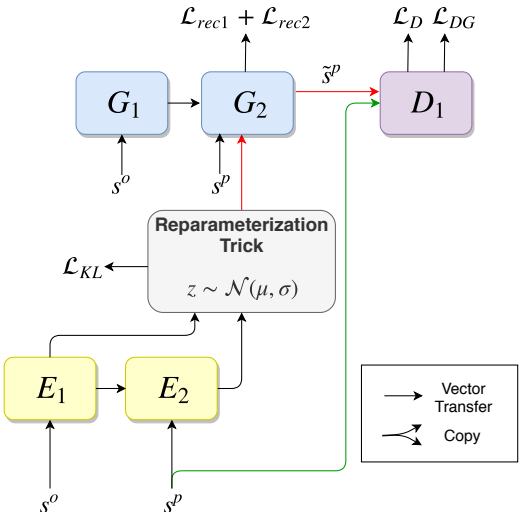

Figure 1: Our generative model. The red arrows denote the process for generating sentences and the green one denotes the transmission of target paraphrased sentences.

3 Model

Our new model, which we call GAP for Generative Adversarial Paraphrase model, targets the goal of generating plausible paraphrased sentences conditioned on the original sentences, without any extra linguistic information. We first propose our end-to-end conditional generative architecture for generating paraphrase via adversarial training. Two training techniques are then described for the proposed model.

3.1 GAP

We consider a dataset with pairs of the original sentence and the paraphrased sentence $\{(s_k^o, s_k^p)\}_{k=1}^K$. For a given sentence s, let w_t denote the t-th word. Each word w_t is embedded into a d-dimensional vector $\boldsymbol{x_t} = \mathbf{W_e}[w_t]$, where $\mathbf{W_e} \in \mathbb{R}^{d\times V}$ is a learned word embedding matrix, V is the vocabulary size, and the v-th column of $\mathbf{W_e}$ is $\mathbf{W_e}[v]$. All columns of $\mathbf{W_e}$ are normalized to have unit ℓ_2-norm, *i.e.*, $\|\mathbf{W_e}[v]\|_2 = 1, \forall v$, by dividing each column with its ℓ_2-norm. After embedding, a sentence of length T (padded when necessary) is represented as $\mathbf{X} \in \mathbb{R}^{d\times T}$, by simply concatenating its word embeddings, *i.e.*, $\boldsymbol{x_t}$ is the t-th column of $\mathbf{X}$.

The training set is $\mathcal{S} = \{(s_k^o, s_k^p)\}_{k=1}^K$ of pairwise data, where $s_k^o \in \mathcal{S}^o$ denotes the original sentence sequence, and $s_k^p \in \mathcal{S}^p$ denotes the reference paraphrased sentence sequence. The goal of our model is to learn a function f: $\mathcal{S}^o \mapsto \mathcal{S}^p$. The

overall model structure of the proposed method is shown in Figure 1. The components can be divided into three modules: encoder in yellow, decoder in blue (which is also the generator), and the discriminator in purple. The connections between them are drawn in arrows.

Encoder E. The encoder E consists of two LSTM networks E_1 and E_2, and E generates latent variable $\boldsymbol{z}$ from the input sentences. There are two different paths generating latent variable $\mathbf{z}$. In the first path, we input sampled s^o and s^p into E_1 and E_2, respectively, and generate sufficient statistics of a Gaussian distribution, mean μ and standard deviation σ. Therefore, the distribution of the latent variable $\mathbf{z}$ can be represented as $q(\mathbf{z}|s^o, s^p)$.

However, we cannot know the paraphrased sentence s^p when we evaluate or apply the trained model in real applications. The training framework is not fit for the circumstance at testing time, and only E_1 is used during the inference. Thus, we also compute the other set of sufficient statistics, mean μ' and standard deviation σ' by inputting s^o into encoder E_1. The sampled latent variable $\mathbf{z}$ is only dependent on s^o, and we can represent the distribution of $\mathbf{z}$ as $p(\mathbf{z}|s^o)$.

Decoder/Generator G. We again combine two LSTM decoders G_1 and G_2 as the generator G. At first, we feed the original sentence s^o into decoder G_1 and obtain final state $\boldsymbol{c}_T^{G_1}$, $\boldsymbol{h}_T^{G_1}$. The paraphrased sentence $\tilde{s}^p$ is predicted word by word. At each step, we concatenate the latent variable $\boldsymbol{z}$ and the previously predicted (ground truth) word, and then input it into LSTM decoder G_2 with hidden state from the last step. At timestep 0, the input word is BOS ("begin of sentence" symbol), and the hidden state is the output from G_1. Therefore, the probability of the predicted paraphrased sentence $\tilde{s}^p$, given the encoded feature vector $\boldsymbol{z}$, is defined as:

$$p(\tilde{s}^p|\boldsymbol{z}, s^o) = \prod_{t=1}^{T} p(\tilde{w}_t^p|\tilde{w}_{<t}^p, \boldsymbol{z}, s^o), \quad (5)$$

where $\tilde{w}_t^p$ is the t-th generated token, $< t \triangleq \{0, \cdots, t-1\}$. w_0^p denotes BOS. All the words in $\tilde{s}^p$ are generated sequentially using the LSTM, based on previously generated words, until the end-of-sentence symbol is generated. The t-th word $\tilde{w}_t^p$ is generated as $\tilde{w}_t^p = \text{argmax}(\mathbf{V}\boldsymbol{h}_t)$. Note that the hidden units $\boldsymbol{h}_t$ are updated through $\mathcal{E}(\tilde{\boldsymbol{x}}_{t-1}^p, \boldsymbol{h}_{t-1}, \boldsymbol{z})$, where $\mathcal{E}$ denotes the transition function in the second LSTM cell related to the updates. The transition function $\mathcal{E}(\cdot)$ is implemented with an LSTM. $\mathbf{V}$ is a weight matrix used to compute a distribution over words. $\tilde{\boldsymbol{x}}_{t-1}^p$ is the embedding vector of the previously generated word $\tilde{w}_{t-1}^p$, *i.e.*,

$$\tilde{\boldsymbol{x}}_{t-1}^p = \mathbf{W}_{\boldsymbol{e}}[\tilde{w}_{t-1}^p], \quad (6)$$

and is the input for t-th step. Consequently, the generated sentence $\tilde{s}^p = [\tilde{w}_1^p, \cdots, \tilde{w}_T^p]$ is obtained given $\boldsymbol{z}$, by simply concatenating the generated words.

Two-Path Loss. Thus far, we can compute the loss from two paths of the encoder. In the first path, we minimize the KL loss and MLE loss:

$$\begin{aligned} \min_E \quad & \text{KL}(q(\boldsymbol{z}|s^o, s^p)||p(z|s^o)) \\ & -\mathbb{E}_{q(\boldsymbol{z}|s^o,s^p)}\left[\log p(\tilde{s}^p|\boldsymbol{z}, s^o)\right]. \end{aligned} \quad (7)$$

In the second path, the loss is presented as follows:

$$\min_E \quad -\mathbb{E}_{q(\boldsymbol{z}|s^o)}\left[\log p(\tilde{s}^p|\boldsymbol{z}, s^o)\right]. \quad (8)$$

The proposed two-path reconstruction loss diminishes the gap between prediction pipelines at training and testing, and helps to generate diverse but realistic predictions.

The objective function of optimizing E and G can be written as follows:

$$\begin{aligned} \min_{E,G} \quad & \lambda_1 \text{KL}(q(\boldsymbol{z}|s^o, s^p)||p(z|s^o)) \\ & -\lambda_1 \mathbb{E}_{q(\boldsymbol{z}|s^o,s^p)}\left[\log p(\tilde{s}^p|\boldsymbol{z}, s^o)\right] \\ & -\lambda_2 \mathbb{E}_{q(\boldsymbol{z}|s^o)}\left[\log p(\tilde{s}^p|\boldsymbol{z}, s^o)\right] \\ & -\lambda_3 \mathbb{E}_{\tilde{s}^p \sim p(\tilde{s}^p|\boldsymbol{z}', s^o)} \log(D(\tilde{s}^p)), \end{aligned} \quad (9)$$

where D denotes the discriminator (described below) and $\boldsymbol{z}' \sim q(\boldsymbol{z}|s^o)$. We use λ_1, λ_2 and λ_3 to balance the weights of the different losses.

Discriminator D. We use one LSTM as the discriminator. The goal of the discriminator is to distinguish real paraphrased sentences from generated sentences. Given the embeddings of true paraphrased sentence s^p and the fake generated sentence $\tilde{s}^p$, the discriminator loss is defined as:

$$\begin{aligned} \min_D \quad & -\mathbb{E}_{\tilde{s}^p \sim p(\tilde{s}^p|\boldsymbol{z}', s^o)} \log(1 - D(\tilde{s}^p)) \\ & -\mathbb{E}_{s^p \sim p(s^p)}[\log D(s^p)], \end{aligned} \quad (10)$$

where $\boldsymbol{z}' \sim q(\boldsymbol{z}|s^o)$.

Algorithm 1 Training Pipeline

Initialize: Gradients of corresponding parameters: Encoder E parameters $g_E = [g_{E1}, g_{E2}]$, Decoder/Generator G parameters $g_G = [g_{G1}, g_{G2}]$, Discriminator D parameters g_D;

  $g_D = \nabla\mathcal{L}_D$;
  Update model parameters using Adam optimizer with gradients g_{E1}, g_{E2}, g_G and g_D.
end while

3.2 Training Techniques

We summarize the training pipeline in Algorithm 1. At each iteration, a pair of original and paraphrased sentences are fed into two paths for sentence reconstruction. A discriminator is also used to distinguish between real and generated sentences, which is helpful to the exposure bias problem.

Policy Gradient. Backpropagation of gradients from the discriminative model to the generative model is difficult for sequence generative models. Following Yu et al. (2017), we use the REINFORCE algorithm (Williams, 1992) to approximate gradients with respect to the generator and encoder. In the experiments, we regard the generator G as the stochastic policy and the output of discriminator D as its reward. In this way, we can propagate the gradients from the discriminator to both the generator models and encoder models.

Warm-up Training. It is difficult to train GAN using gradient-based methods (Goodfellow et al., 2014). Previous generative models (Zhang et al., 2017) often pre-train the generator using a supervised model, like an auto-encoder. In this paper, we propose a warm-up technique to train our generative model. Following the notation in Algorithm 1, we suppose a warm-up step t_{wp}. In the training process, we gradually increase the weight of $\mathcal{L}_{DG}$ to a fixed value λ_3. From step $t = 0$ to t_{wp}, the update of λ_3^t can be represented as

$$\lambda_3^t = \frac{t}{t_{wp}} \cdot \lambda_3. \tag{11}$$

When $t \geq t_{wp}$, we fix $\lambda_3^t = \lambda_3$ as a constant.

We also need to balance the losses between (7) and (8). The second loss (8) represents that during inference, z is generated only depending on x^o. We let $\lambda_1 = 1 - \lambda_2^t$ and increase the value of λ_2^t gradually until t_{wp}. Similarly, λ_2^t is updated from $t = 0$ to t_{wp} through:

$$\lambda_2^t = \frac{t}{t_{wp}} \cdot \lambda_2. \tag{12}$$

If $t \geq t_{wp}$, we fix $\lambda_2^t = \lambda_2$.

4 Experiments

We assess the performance of our GAP model and compare it with previous methods. We first describe the datasets we use, then present the details of experimental setup, and finally analyze both quantitative and qualitative results.

4.1 Datasets

Following previous work (Prakash et al., 2016), we conduct experiments on the same four standard datasets that are used widely for paraphrase generation. Their content is specified below.

MSCOCO. MSCOCO was originally an image-captions dataset, containing over 120K images, with five different captions from five different annotators per image. All the annotations toward one image describe the most prominent object or action in this image, which is suitable for the paraphrase generation task. Specifically, the dataset has two divisions: training dataset ("Train2014", over 82K images) and validation dataset ("Val2014", over 40K images). We follow the operations of previous papers, randomly choosing four captions out of five as two source-reference pairs and limit the length of sentence to be 15 words (removing the words beyond the first 15), so that we can compare our results with published work.

Quora. Quora consists of over 400K lines of potential question pairs which are duplicate to each

other if a particular position of this line is annotated with 1. Again, we follow the operations of previous work and filter out those pairs annotated with 1. There are 155K such question pairs in total, among which three sub-datasets are created, *i.e.*, training dataset 50K, 100K, 150K and test dataset 4K. The goal of using three sub-datasets is to show how the size of dataset can affect the results of paraphrase generation.

4.2 Experimental Setup

Encoders E_1, E_2 and generators G_1, G_2 are constructed using 2-layer LSTMs (Hochreiter and Schmidhuber, 1997). For discriminator D, it is also 2-layer LSTM. At the beginning, we map each word to a 300-dimensional feature vector and it is initialized with 300-dimensional GloVe vectors (Pennington et al., 2014). Therefore, a sentence of length N can be represented by a matrix of size $N \times 300$. Before inputting the embedding vector into LSTM models, we pre-process these vectors using a two-layer highway network (Srivastava et al., 2015). We set the dimension of latent variables $\boldsymbol{z}$ to be 300. To balance these losses, we set $\lambda_2 = 0.5$ and $\lambda_3 = 0.01$. The warm-up step is 1×10^4 in all experiments.

We use Adam optimizer (Kingma and Ba, 2014) with learning rate 1×10^{-4} and other parameters as default, for all models. Following (Sutskever et al., 2014), we clip gradients of the encoder and generator parameters if the norm of the parameter vector exceeds 10, and we clip the gradients of the discriminator if the norm of the parameter vector exceeds 5. Greedy search is employed to generate paraphrases in the experiment.

4.3 Automatic Evaluation

We follow previous papers to choose the same three well-known automatic evaluation metrics: BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007), and TER (Snover et al., 2006). As studied by (Wubben et al., 2010), human judgments on generated paraphrases correlate well with these metrics. We then compare our results on these metrics with previous baselines below.

Baselines. Our GAP model contains LSTM and VAE components, so we compare it with (i) the basic attentive sequence-to-sequence model from Machine Translation (seq2seq) (Bahdanau et al., 2014), (ii) the stacked residual LSTM model doing paraphrase generation (Residual LSTM) (Prakash et al., 2016), and (iii) a VAE model based on LSTM together with its variants (VAE-S, VAE-SVG, VAE-SVG-eq) (Gupta et al., 2018). Beyond these, we also evaluate other baselines including Transformer (Vaswani et al., 2017), semantic augmented Transformer which requires extra linguistic information (Transformer-PB) (Wang et al., 2018), and a deep reinforcement learning approach (RbM-SL) (Li et al., 2017b).

Model	Measure	MSCOCO		
		BLEU↑	METEOR↑	TER↓
Seq2Seq + Att	-	18.60	16.80	63.00
Residual LSTM	-	37.00	27.00	51.60
Transformer	-	41.00	32.80	40.50
Transformer-PB	-	44.00	34.70	37.10
VAE-SVG	best-B	41.70	30.80	41.70
VAE-SVG	best-M	41.30	31.00	41.60
VAE-SVG	best-T	41.30	30.90	40.80
VAE∗	avg	42.53	32.77	41.38
Ours	best-B	**45.60**	35.72	39.47
Ours	best-M	41.32	**36.17**	40.52
Ours	best-T	42.46	34.79	**36.83**

Table 2: Test accuracy on MSCOCO dataset, in percentage. VAE∗ is our implementation of VAE. "best-B", "best-M" and "best-T" represent the scores with the best BLEU, METEOR and TER respectively. "avg" denotes an average over "best-B", "best-M", and "best-T". All other results are directly cited from the respective papers. For different model variants exist in one paper, we only show the one with highest scores here. For the arrows ↑ of BLEU and TER, a higher score is better. ↓ of TER represents a lower score is better. The best results are in boldface.

Results and Analysis. The results on MSCOCO are shown in Table 2. We find that our GAP model outperforms the baseline models on all metrics. For example, comparing our scores on MSCOCO dataset when we achieve the best BLEU with the ones from VAE-SVG, we improve the results about 4 BLEU, 5 METEOR, and 4 TER, respectively.

Table 3 shows the performance on Quora dataset. We notice that our accuracy increases with the increasing size of data. Meanwhile, our model is more robust for a relatively smaller dataset such as Quora-50K, leveraging its advantage in learning with fewer data. For example, we achieve much better results than VAE and its variants on the smaller Quora-50k.

Ablation Study. VAE∗ in Table 3 extends the pre-

Model	Measure	Quora-50K			Quora-100K			Quora-150K		
		BLEU↑	METEOR↑	TER↓	BLEU↑	METEOR↑	TER↓	BLEU↑	METEOR↑	TER↓
Seq2Seq + Att	-	26.06	20.35	-	36.55	26.28	-	-	-	-
Residual LSTM	-	27.32	22.37	-	37.38	28.17	-	-	-	-
RbM-SL	-	35.81	**28.12**	-	43.54	**32.84**	-	-	-	-
VAE-S	best-B	15.80	20.10	69.40	17.50	21.60	67.10	19.80	22.60	63.90
VAE-S	best-M	15.60	21.10	71.50	17.50	22.70	69.50	19.70	23.80	66.90
VAE-SVG	best-B	17.10	21.30	63.10	22.50	24.60	55.70	30.30	28.50	47.30
VAE-SVG	best-M	17.10	22.20	63.80	22.40	25.50	55.60	30.30	29.20	47.10
VAE-SVG-eq	best-B	17.40	21.40	61.90	22.90	24.70	55.00	31.40	29.00	46.80
VAE-SVG-eq	best-M	17.30	22.20	62.60	22.90	25.50	54.90	32.00	30.00	46.10
VAE∗	avg	33.54	22.36	60.45	41.33	28.46	58.24	43.31	28.25	42.36
Ours	best-B	**38.23**	22.51	56.66	**45.05**	31.49	55.54	**47.06**	30.94	41.32
Ours	best-M	37.14	**24.09**	61.43	45.05	**31.49**	55.54	45.51	**34.31**	40.49
Ours	best-T	36.19	22.22	**50.50**	44.41	27.73	**46.41**	42.30	29.60	**39.47**

Table 3: Test accuracy on Quora dataset, in percentage. VAE∗ is our implementation of VAE. "best-B", "best-M" and "best-T" represent the scores with the best BLEU, METEOR and TER respectively. "avg" denotes an average over "best-B", "best-M", and "best-T". All other results are directly cited from the respective papers, and "-" means no such results reported. For the arrows ↑ of BLEU and TER, a higher score is better. ↓ of TER represents a lower score is better. The best results are in boldface.

vious VAE-SVG in (Gupta et al., 2018) by using our proposed two-path loss. We observe that our VAE∗ usually outperforms previous VAE-based models. It demonstrates the proposed two-path reconstruction loss can improve the quality of generated paraphrases. Moreover, our proposed method via adversary training, denoted as "Ours", also has superior performance than VAE∗. Therefore, our proposed adversarial training and two-path loss take an apparently positive effect on alleviating the exposure bias problem and generating diverse but realistic predictions.

4.4 Human Evaluation

Data Preparation. The accurate evaluation of paraphrases is an open problem. We believe that automatic evaluation is not enough for evaluating paraphrases from a fine-grained perspective, in terms of three attributes: grammar correctness (plausibility), equivalence to the original sentence (equivalence), diversity expression (diversity). For both MSCOCO and Quora datasets, we randomly sample 100 sentence pairs (original sentence, paraphrased sentence) from the test corpus, and apply the generative architectures, including both the VAE∗ model and our GAP model, to generating paraphrases. Thus, we obtain three different sentence pairs: (original sentence, "generated" sentence) by the reference, (original sentence, generated paraphrase) by VAE∗, and by our GAP model. To make the analysis fair, we randomly shuffled all of them. We then partitioned them into ten buckets.

Process. We set up an Amazon Mechanical Turk experiment; ten human judges are asked to evaluate the quality of paraphrases. We hope our judges play similar roles to the discriminator in our model, to make a true/fake judgment. It is easier for them to make a binary choice than score how good the paraphrased sentences are from a wide score range. These ten human judges are finally involved in evaluating the total 600 sentence pairs. Each pair is judged by two different judges, and the average score is the final judgment. The agreement between judges is moderate (kappa=0.42). These ten human judges confirmed that they were proficient in English and they had understood the goals of the annotation process very well. They were trained by means of instructions and examples. If the meaning of a generated sentence contains a grammatical error or does not express the same meaning as the original sentence, or lacks diversity, we asked the annotators to score 0 for the corresponding attributes, and 1 otherwise.

Results and Analysis. We report the results in Table 4. Our model generates paraphrases with higher scores in terms of plausibility, equivalence, diversity than the previous VAE model, and their differences are statistically significant (paired t-test, p-value < 0.01). The failure cases we observed include implausible sentences, inequiva-

Model	MSCOCO			Quora		
	Plausibility	Equivalence	Diversity	Plausibility	Equivalence	Diversity
Reference	0.79	0.68	0.59	0.87	0.75	0.66
VAE∗	0.30	0.26	0.22	0.35	0.31	0.26
Ours	0.43	0.38	0.35	0.46	0.45	0.37

Table 4: Human judgments for paraphrase generation on different models.

original (MSCOCO)	a group of kids are eating pizza and drinking soda
paraphrased generated-VAE	a person sits at a table eating pizza
generated-VAE	a man sitting at a table with a pizza
generated-Ours	a man sitting at a table eating **a plate of** pizza and soda
original (Quora-50K)	What is the **fastest** possible way to lose weight?
paraphrased generated-VAE	What are some ways to lose weight **fast**?
generated-VAE	How can I lose weight weight?
generate-Ours	How can I lose weight **in a month**?
original (Quora-100K)	What were the **immediate** and most important causes that led to World War 1?
paraphrased generated-VAE	What were the causes of World War I?
generated-VAE	What were the main causes of World War I?
generated-Ours	What were the **direct** and main causes of World War 1?
original (Quora-150K)	What could be the reason behind Arnab Goswami **quitting** Times Now?
paraphrased generated-VAE	Is Arnab Goswami **quitting** from Times now?
generated-VAE	Why did Arnab Goswami quit?
generated-Ours	Why did Arnab Goswami **resign** from Times Now?

Table 5: Samples of generated paraphrases from MSCOCO and Quora. Note that for the last two examples, our generated result is even better than the ground truth where our model paraphrasing "immediate" using "direct", and paraphrasing "quit" using "resign".

lent, and inaccurate expressions. It is believed that the reason for this is related to the input training data. It contains noise caused by the length limitation of $\leq$ 15 words. But note that even for the reference paraphrase, the accuracy cannot be as high as 100%. Here is an example from the real data: for the original sentence "children are playing soccer on a field with several adults observing nearby", the reference paraphrase is "soccer player hits another player in the face". Considering this, the results show that our GAP generates relatively more plausible and diverse paraphrase sentence, compared to the baseline model.

Case Study. In Table 5, we show examples sampled from both MSCOCO and Quora. We observe that our model generates paraphrases with higher diversity than VAE, with no loss of information. What's more, we discover some results where our model is even better than the ground truth, which are shown in the last two examples in the Table 5.

5 Related Work

Generative models or conditional generative models have experienced remarkable progress in the visual domain, such as VAEs in (Kingma et al., 2014; Sohn et al., 2015) and InfoGAN (Chen et al., 2016). Recent work (Larsen et al., 2015; Chen et al., 2017) also considers combining autoencoders or variational autoencoders with GAN to demonstrate superior performance on image generation. In the area of NLP, generation can be summarized from two perspectives: *text generation* with the goal of yielding diverse and plausible sentences given an original sentence, and *conditional text generation* aiming to generate new sentences conditioned on an original sentence. Considering the latter, examples include generating a new sentence similar to an original sentence (paraphrase generation), in a different style from the original sentence (style transfer), or dependent on dialogue history (dialogue generation). Attempts at using VAEs (Bowman et al., 2016; Wang et al., 2019), GANs (Yu et al., 2017; Zhang et al., 2016), and both (Hu et al., 2017) have been made to address generic text generation. However, all of them are not suitable for conditional text generation. Recent work in (Gupta et al., 2018) tries to handle paraphrase generation using VAEs. However, it suffers from challenges common to VAEs. Our method addresses these challenges with the help of GAN. To the best of our knowledge, this is the first work on using GAN with VAEs for paraphrase generation task.

6 Conclusions

We propose the first deep conditional generative architecture for generating paraphrases via adversarial training, in the hope of combining advantages of CVAE to generate similar distributions with the advantage of GAN to generate plausible

sentences. Experimental results evaluated on automatic metrics demonstrate the advantages of our model, with human evaluations also verifying effectiveness. In future work, we intend to accelerate the training of our encoders and decoders with the techniques in (Huo et al., 2018) and apply our architecture and training techniques to other NLP tasks. Overall, we believe that our research makes an important step for using generative models in NLP, especially in conditional text generation.

Table-to-Text Generation with Effective Hierarchical Encoder on Three Dimensions (Row, Column and Time)

Heng Gong, Xiaocheng Feng, Bing Qin*, Ting Liu
Harbin Institute of Technology, China
{hgong, xcfeng, qinb, tliu}@ir.hit.edu.cn

Abstract

Although Seq2Seq models for table-to-text generation have achieved remarkable progress, modeling table representation in one dimension is inadequate. This is because (1) the table consists of multiple rows and columns, which means that encoding a table should not depend only on one dimensional sequence or set of records and (2) most of the tables are time series data (e.g. NBA game data, stock market data), which means that the description of the current table may be affected by its historical data. To address aforementioned problems, not only do we model each table cell considering other records in the same row, we also enrich table's representation by modeling each table cell in context of other cells in the same column or with historical (time dimension) data respectively. In addition, we develop a table cell fusion gate to combine representations from row, column and time dimension into one dense vector according to the saliency of each dimension's representation. We evaluated our methods on ROTOWIRE, a benchmark dataset of NBA basketball games. Both automatic and human evaluation results demonstrate the effectiveness of our model with improvement of 2.66 in BLEU over the strong baseline and outperformance of state-of-the-art model.

1 Introduction

Table-to-text generation is an important and challenging task in natural language processing, which aims to produce the summarization of numerical table (Reiter and Dale, 2000; Gkatzia, 2016). The related methods can be empirically divided into two categories, pipeline model and end-to-end model. The former consists of content selection, document planning and realisation, mainly for early industrial applications, such as weather forecasting and medical monitoring, etc. The latter generates text directly from the table through a standard neural encoder-decoder framework to avoid error propagation and has achieved remarkable progress. In this paper, we particularly focus on exploring how to improve the performance of neural methods on table-to-text generation.

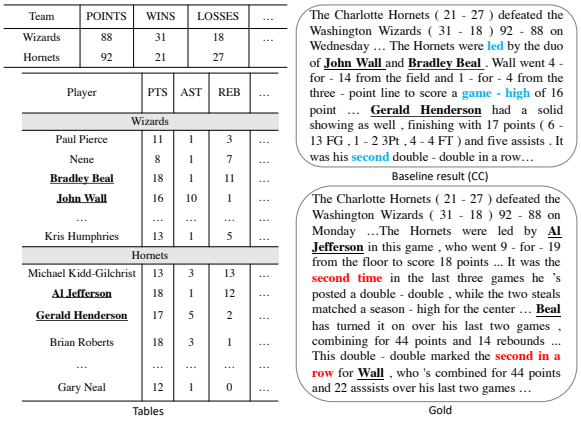

Figure 1: Generated example on ROTOWIRE by using Conditional Copy (CC) as baseline (Wiseman et al., 2017). Text that accurately reflects records in the table is in red, and text that contradicts the records is in blue.

Recently, ROTOWIRE, which provides tables of NBA players' and teams' statistics with a descriptive summary, has drawn increasing attention from academic community. Figure 1 shows an example of parts of a game's statistics and its corresponding computer generated summary. We can see that the tables has a formal structure including table row header, table column header and table cells. "Al Jefferson" is a table row header that represents a player, "PTS" is a table column header indicating the column contains player's score and "18" is the value of the table cell, that is, Al Jefferson scored 18 points. Several related models have been proposed . They typically encode the table's records separately or as a long sequence and generate a long descriptive summary

by a standard Seq2Seq decoder with some modifications. Wiseman et al. (2017) explored two types of copy mechanism and found conditional copy model (Gulcehre et al., 2016) perform better . Puduppully et al. (2019) enhanced content selection ability by explicitly selecting and planning relevant records. Li and Wan (2018) improved the precision of describing data records in the generated texts by generating a template at first and filling in slots via copy mechanism. Nie et al. (2018) utilized results from pre-executed operations to improve the fidelity of generated texts. However, we claim that their encoding of tables as sets of records or a long sequence is not suitable. Because (1) the table consists of multiple players and different types of information as shown in Figure 1. The earlier encoding approaches only considered the table as sets of records or one dimensional sequence, which would lose the information of other (column) dimension. (2) the table cell consists of time-series data which change over time. That is to say, sometimes historical data can help the model select content. Moreover, when a human writes a basketball report, he will not only focus on the players' outstanding performance in the current match, but also summarize players' performance in recent matches. Lets take Figure 1 again. Not only do the gold texts mention Al Jefferson's great performance in this match, it also states that "It was the second time in the last three games he's posted a double-double". Also gold texts summarize John Wall's "double-double" performance in the similar way. Summarizing a player's performance in recent matches requires the modeling of table cell with respect to its historical data (time dimension) which is absent in baseline model. Although baseline model Conditional Copy (CC) tries to summarize it for Gerald Henderson, it clearly produce wrong statements since he didn't get "double-double" in this match.

To address the aforementioned problems, we present a hierarchical encoder to simultaneously model row, column and time dimension information. In detail, our model is divided into three layers. The first layer is used to learn the representation of the table cell. Specifically, we employ three self-attention models to obtain three representations of the table cell in its row, column and time dimension. Then, in the second layer, we design a record fusion gate to identify the more important representation from those three dimension and combine them into a dense vector. In the third layer, we use mean pooling method to merge the previously obtained table cell representations in the same row into the representation of the table's row. Then, we use self-attention with content selection gate (Puduppully et al., 2019) to filter unimportant rows' information. To the best of our knowledge, this is the first work on neural table-to-text generation via modeling column and time dimension information so far. We conducted experiments on ROTOWIRE. Results show that our model outperforms existing systems, improving baseline BLEU from 14.19 to 16.85 (+18.75%), P% of relation generation (RG) from 74.80 to 91.46 (+22.27%), F1% of content selection (CS) from 32.49 to 41.21 (+26.84%) and content ordering (CO) from 15.42 to 20.86 (+35.28%) on test set. It also exceeds the state-of-the-art model in terms of those metrics.

2 Preliminaries

2.1 Notations

The input to the model are tables $S = \{s^1, s^2, s^3\}$. s^1, s^2, and s^3 contain records about players' performance in home team, players' performance in visiting team and team's overall performance respectively. We regard each cell in the table as record. Each record r consists of four types of information including value $r.v$ (e.g. 18), entity $r.e$ (e.g. Al Jefferson), type $r.c$ (e.g. POINTS) and a feature $r.f$ (e.g. visiting) which indicate whether a player or a team compete in home court or not. Each player or team takes one row in the table and each column contains a type of record such as points, assists, etc. Also, tables contain the date when the match happened and we let k denote the date of the record. We also create timelines for records. The details of timeline construction is described in Section 2.2. For simplicity, we omit table id l and record date k in the following sections and let $r_{i,j}$ denotes a record of i^{th} row and j^{th} column in the table. We assume the records come from the same table and k is the date of the mentioned record. Given those information, the model is expected to generate text $y = (y_1, ..., y_t, ..., y_T)$ describing these tables. T denotes the length of the text.

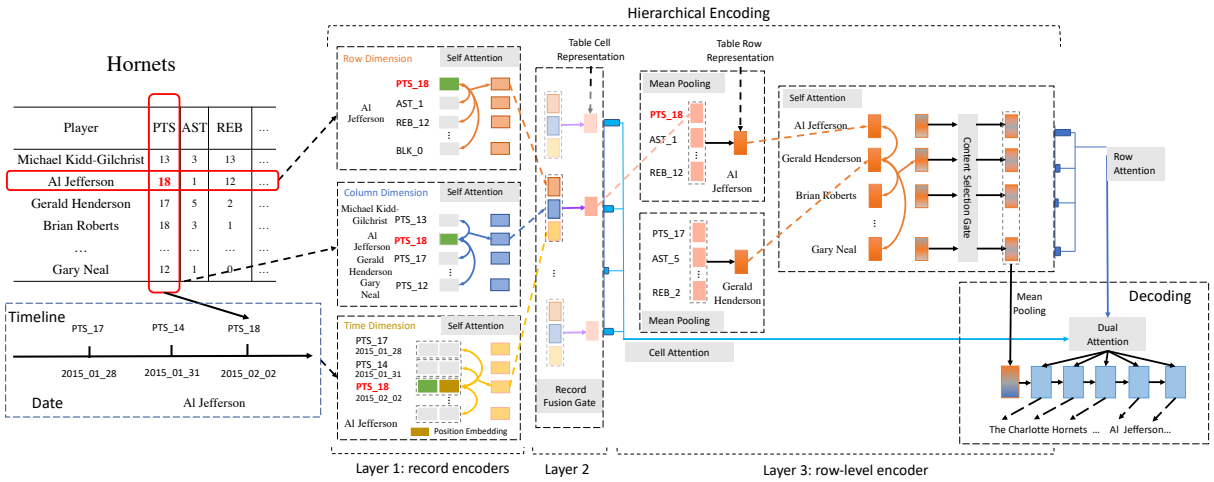

Figure 2: The architecture of our proposed model.

2.2 Record Timeline Constrcution

In this paper, we construct timelines $tl = \{tl_{e,c}\}_{e=1,c=1}^{E,C}$ for records. E denotes the number of distinct record entities and C denotes the number of record types. For each timeline $tl_{e,c}$, we first extract records with the same entity e and type c from dataset. Then we sort them into a sequence according to the record's date from old to new. This sequence is considered as timeline $tl_{e,c}$. For example, in Figure 2, the "Timeline" part in the lower-left corner represents a timeline for entity Al Jefferson and type PTS (points).

2.3 Baseline Model

We use Seq2Seq model with attention (Luong et al., 2015) and conditional copy (Gulcehre et al., 2016) as the base model. During training, given tables S and their corresponding reference texts y, the model maximized the conditional probability $P(y|S) = \prod_{t=1}^{T} P(y_t|y_{<t}, S)$. t is the timestep of decoder. First, for each record of the i^{th} row and j^{th} column in the table, we utilize 1-layer MLP to encode the embeddings of each record's four types of information into a dense vector $\boldsymbol{r_{i,j}}$, $\boldsymbol{r_{i,j}} = ReLU(\boldsymbol{W_a}[\boldsymbol{r_{i,j}.e}; \boldsymbol{r_{i,j}.c}; \boldsymbol{r_{i,j}.v}; \boldsymbol{r_{i,j}.f}] + \boldsymbol{b_a})$. $\boldsymbol{W_a}$ and $\boldsymbol{b_a}$ are trainable parameters. The word embeddings for each type of information are trainable and randomly initialized before training following Wiseman et al. (2017). $[;]$ denotes the vector concatenation. Then, we use a LSTM decoder with attention and conditional copy to model the conditional probability $P(y_t|y_{<t}, S)$. The base model first use attention mechanism (Luong et al., 2015) to find relevant records from the input tables and represent them as context vector. Please note that the base model doesn't utilize the structure of three tables and normalize the attention weight $\alpha_{t,i',j'}$ across every records in every tables. Then it combines the context vector with decoder's hidden state $\boldsymbol{d_t}$ and form a new attentional hidden state $\tilde{\boldsymbol{d_t}}$ which is used to generate words from vocabulary $P_{gen}(y_t|y_{<t}, S) = softmax(\boldsymbol{W_d}\tilde{\boldsymbol{d_t}} + \boldsymbol{b_d})$ Also the conditional copy mechanism is adopted in base model. It introduces a variable z_t to decide whether to copy from tables or generate from vocabulary. The probability to copy from table is $P(z_t = 1|y_{<t}, S) = sigmoid(\boldsymbol{w_e} \cdot \boldsymbol{d_t} + b_e)$. Then it decomposes the conditional probability of generating t^{th} word $P(y_t|y_{<t}, S)$, given the tables S and previously generated words $y_{<t}$, as follows.

$$P(y_t, z_t|y_{<t}, S) = \begin{cases} P(z_t = 1|y_{<t}, S) \sum_{y_t \leftarrow \boldsymbol{r_{i',j'}}} \alpha_{t,i',j'} & z_t = 1 \\ P(z_t = 0|y_{<t}, S) P_{gen}(y_t|y_{<t}, S) & z_t = 0 \end{cases} \quad (1)$$

3 Approach

In this section, we propose an effective hierarchical encoder to utilize three dimensional structure of input data in order to improve table representation. Those three dimensions include row, column and time. As shown in Figure 2, during encoding, our model consists of three layers including record encoders, record fusion gate and row-level encoder. Given tables S as described in Section 2.1, we first encode each record in each dimension respectively. Then we use the record fusion gate to combine them into a dense representation. Afterwards, we obtain row-level representation via mean pooling and self-attention with content selection gate. In decoding phase, the decoder

can first find important row then attend to important record when generating texts. We describe model's details in following parts.

3.1 Layer 1: Record Encoders

3.1.1 Row Dimension Encoder

Based on our observation, when someone's points is mentioned in texts, some related records such as "field goals made" (FGM) and "field goals attempted" (FGA) will also be included in texts. Taken gold texts in Figure 1 as example, when Al Jefferson's point 18 is mentioned, his FGM 9 and FGA 19 are also mentioned. Thus, when modeling a record, other records in the same row can be useful. Since the record in the row is not sequential, we use a self-attention network which is similar to Liu and Lapata (2018) to model records in the context of other records in the same row. Let $\boldsymbol{r^{row}_{i,j}}$ be the row dimension representation of the record of i^{th} row and j^{th} column. Then, we obtain the context vector in row dimension $\boldsymbol{c^{row}_{i,j}}$ by attending to other records in the same row as follows. Please note that $\alpha^{row}_{i,j,j'} \propto exp(\boldsymbol{r^T_{i,j} W_o r_{i,j'}})$ is normalized across records in the same row i. $\boldsymbol{W_o}$ is a trainable parameter.

$$\boldsymbol{c^{row}_{i,j}} = \sum_{j',j' \neq j} \alpha^{row}_{i,j,j'} \boldsymbol{r_{i,j'}} \tag{2}$$

Then, we combine record's representation with $\boldsymbol{c_{i,j}}$ and obtain the row dimension record representation $\boldsymbol{r^{row}_{i,j}} = tanh(\boldsymbol{W_f}[\boldsymbol{r_{i,j}}; \boldsymbol{c^{row}_{i,j}}])$. $\boldsymbol{W_f}$ is a trainable parameter.

3.1.2 Column Dimension Encoder

Each input table consists of multiple rows and columns. Each column in the table covers one type of information such as points. Only few of the row may have high points or other type of information and thus become the important one. For example, in "Column Dimension" part of Figure 2, "Al Jefferson" is more important than "Gary Neal" because the former one have more impressive points. Therefore, when encoding a record, it is helpful to compare it with other records in the same column in order to understand the performance level reflected by the record among his teammates (rows). We employ self-attention similar to the one used in Section 3.1.1 in column dimension to compare between records. We let $\boldsymbol{r^{col}_{i,j}}$ be the column representation of the record of i^{th} row and j^{th} column. We obtain context vector in column dimension $\boldsymbol{c^{col}_{i,j}}$ as follows. Please note that $\alpha_{j,i,i'}$ is normalized across records from different rows i' but of the same column j. The column dimension representation $\boldsymbol{r^{col}_{i,j}}$ is obtained similar to row dimension.

$$\boldsymbol{c^{col}_{i,j}} = \sum_{i',i' \neq i} \alpha^{col}_{j,i,i'} \boldsymbol{r_{i',j}} \tag{3}$$

3.1.3 Time Dimension Encoder

As mentioned in Section 1, we find some expressions in texts require information about players' historical (time dimension) performance. So the history information of record $\boldsymbol{r_{i,j}}$ is important. Note that we have already constructed timeline for each record entity and type as described in Section 2.2. Given those timelines, We collect records with same entity and type in the timeline which has date before date k of the record $\boldsymbol{r_{i,j}}$ as history information. Since for some record, the history information can be too long, we set a history window. Thus, we keep most recent history information sequence within history window and denote them as $hist(\boldsymbol{r_{i,j}})$. We model this kind of information in time dimension via self-attention. However, unlike the unordered nature of rows and columns, the history information is sequential. Therefore, we introduce a trainable position embedding $\boldsymbol{emb_{pos}(k')}$ and add it to the record's representation and obtain a new record representation $\boldsymbol{rp_{k'}}$. It denotes the representation of a record with the same entity and type of $\boldsymbol{r_{i,j}}$ but of the date k' before k in the corresponding history window. We use $\boldsymbol{r^{time}_{i,j}}$ to denote the history representation of the record of i^{th} row and j^{th} column. Then the history dimension context vector is obtained by attending to history records in the window. Please note that we use 1-layer MLP as score function here and $\alpha^{time}_{k,k'}$ is normalized within the history window. We obtain the time dimension representation $\boldsymbol{r^{time}_{i,j}}$ similar to row dimension.

$$\alpha^{time}_{k,k'} \propto exp(score(\boldsymbol{rp_k}, \boldsymbol{rp_{k'}})) \tag{4}$$

$$\boldsymbol{c^{time}_{i,j}} = \sum_{k' < k} \alpha^{time}_{k,k'} \boldsymbol{rp_{k'}} \tag{5}$$

3.2 Layer 2: Record Fusion Gate

After obtaining record representations in three dimension, it is important to figure out which representation plays a more important role in reflecting the record's information. If a record stands

out from other row's records of same column, the column dimension representation may have a higher weight in forming the overall record representation. If a record differs from previous match significantly, the history dimension representation may have a higher weight. Also, some types of information may appear in texts more frequently together which can be reflected by row dimension representation. Therefore, we propose a record fusion gate to adaptively combine all three dimension representations. First, we concatenate $\boldsymbol{r}_{i,j}^{\boldsymbol{row}}$, $\boldsymbol{r}_{i,j}^{\boldsymbol{col}}$ and $\boldsymbol{r}_{i,j}^{\boldsymbol{time}}$, then adopt a 1-layer MLP to obtain a general representation $\boldsymbol{r}_{i,j}^{\boldsymbol{gen}}$ which we consider as a baseline representation of records' information. Then, we compare each dimension representation with the baseline and obtain its weight in the final record representation. We use 1-layer MLP as the score function. Equation 6 shows an example of calculating column dimension representation's weight in the final record representation. The weight of row and time dimension representation is obtained similar to the weight of column dimension representation.

$$\alpha_{fus}^{col} \propto exp(score(\boldsymbol{r}_{i,j}^{\boldsymbol{col}}, \boldsymbol{r}_{i,j}^{\boldsymbol{gen}})) \quad (6)$$

In the end, the fused record representation $\tilde{\boldsymbol{r}}_{\boldsymbol{i,j}}$ is the weighted sum of the three dimension representations.

$$\tilde{\boldsymbol{r}}_{\boldsymbol{i,j}} = \alpha_{fus}^{row}\boldsymbol{r}_{i,j}^{\boldsymbol{row}} + \alpha_{fus}^{col}\boldsymbol{r}_{i,j}^{\boldsymbol{col}} + \alpha_{fus}^{time}\boldsymbol{r}_{i,j}^{\boldsymbol{time}} \quad (7)$$

3.3 Layer 3: Row-level Encoder

For each row, we combine its records via mean pooling (Equation 8) in order to obtain a general representation of the row which may reflect the row (player or team)'s overall performance. C denotes the number of columns.

$$\boldsymbol{row}_{\boldsymbol{i}} = MeanPooling(\tilde{\boldsymbol{r}}_{\boldsymbol{i,1}}, \tilde{\boldsymbol{r}}_{\boldsymbol{i,2}}, ..., \tilde{\boldsymbol{r}}_{\boldsymbol{i,C}}) \quad (8)$$

Then, we adopt content selection gate $\boldsymbol{g}_{\boldsymbol{i}}$, which is proposed by Puduppully et al. (2019) on rows' representations $\boldsymbol{row}_{\boldsymbol{i}}$, and obtain a new representation $\tilde{\boldsymbol{row}}_{\boldsymbol{i}} = \boldsymbol{g}_{\boldsymbol{i}} \odot \boldsymbol{row}_{\boldsymbol{i}}$ to choose more important information based on each row's context.

3.4 Decoder with Dual Attention

Since record encoders with record fusion gate provide record-level representation and row-level encoder provides row-level representation. Inspired by Cohan et al. (2018), we can modify the decoder in base model to first choose important row then attend to records when generating each word. Following notations in Section 2.3, $\beta_{t,i} \propto exp(score(\boldsymbol{d}_{\boldsymbol{t}}, \boldsymbol{row}_{\boldsymbol{i}}))$ obtains the attention weight with respect to each row. Please note that $\beta_{t,i}$ is normalized across all row-level representations from all three tables. Then, $\gamma_{t,i,j} \propto exp(score(\boldsymbol{d}_{\boldsymbol{t}}, \tilde{\boldsymbol{r}}_{\boldsymbol{i,j}}))$ obtains attention weight for records. Please note that we normalize $\gamma_{t,i,j}$ among records in the same row.

We use the row-level attention $\beta_{t,i}$ as guidance for choosing row based on row's general representation. Then we use it to re-weight the record-level attention $\gamma_{t,i,j}$ and change the attention weight in base model to $\tilde{\alpha}_{t,i,j}$. Please note that $\tilde{\alpha}_{t,i,j}$ sum to 1 across all records in all tables.

$$\tilde{\alpha}_{t,i,j} = \beta_{t,i}\gamma_{t,i,j} \quad (9)$$

3.5 Training

Given a batch of input tables $\{S\}_G$ and reference output $\{Y\}_G$, we use negative log-likelihood as the loss function for our model. We train the model by minimizing L. G is the number of examples in the batch and T_g represents the length of g^{th} reference's length.

$$L = -\frac{1}{G}\sum_{g=1}^{G}\sum_{t=1}^{T_g} logP(y_{t,g}|y_{<t,g}, S_g) \quad (10)$$

4 Experiments

4.1 Dataset and Evaluation Metrics

We conducted experiments on ROTOWIRE (Wiseman et al., 2017). For each example, it provides three tables as described in Section 2.1 which consists of 628 records in total with a long game summary. The average length of game summary is 337.1. In this paper, we followed the data split introduced in Wiseman et al. (2017): 3398 examples in training set, 727 examples in development set and 728 examples in test set. We followed Wiseman et al. (2017)'s work and use BLEU (Papineni et al., 2002) and three extractive evaluation metrics RG, CS and CO (Wiseman et al., 2017) for evaluation. The main idea of the extractive evaluation metrics is to use an Information Extraction (IE) model to identify records mentioned in texts. Then compare them with tables or records extracted from reference to evaluate the model. RG (Relation Generation) measures content fidelity of

texts. CS (Content Selection) measures model's ability on content selection. CO (Content Ordering) measures model's ability on ordering the chosen records in texts. We refer the readers to Wiseman et al. (2017)'s paper for more details.

4.2 Implementation Details

Following configurations in Puduppully et al. (2019), we set word embedding and LSTM decoder hidden size as 600. The decoder's layer was set to be 2. Input feeding (Luong et al., 2015) was also used for decoder. We applied dropout at a rate 0.3. For training, we used Adagrad (Duchi et al., 2010) optimizer with learning rate of 0.15, truncated BPTT (block length 100), batch size of 5 and learning rate decay of 0.97. For inferring, we set beam size as 5. We also set the history windows size as 3 from {3,5,7} based on the results. Code of our model can be found at https://github.com/ernestgong/data2text-three-dimensions/.

4.3 Results

4.3.1 Automatic Evaluation

Table 1 displays the automatic evaluation results on both development and test set. We chose Conditional Copy (CC) model as our baseline, which is the best model in Wiseman et al. (2017). We included reported scores with updated IE model by Puduppully et al. (2019) and our implementation's result on CC in this paper. Also, we compared our models with other existing works on this dataset including OpATT (Nie et al., 2018) and Neural Content Planning with conditional copy (NCP+CC) (Puduppully et al., 2019). In addition, we implemented three other hierarchical encoders that encoded tables' row dimension information in both record-level and row-level to compare with the hierarchical structure of encoder in our model. The decoder was equipped with dual attention (Cohan et al., 2018). The one with LSTM cell is similar to the one in Cohan et al. (2018) with 1 layer from {1,2,3}. The one with CNN cell

(Gehring et al., 2017) has kernel width 3 from {3, 5} and 10 layer from {5,10,15,20}. The one with transformer-style encoder (MHSA) (Vaswani et al., 2017) has 8 head from {8, 10} and 5 layer from {2,3,4,5,6}. The heads and layers mentioned above were for both record-level encoder and row-level encoder respectively. The self-attention (SA) cell we used, as described in Section 3, achieved better overall performance in terms of F1% of CS, CO and BLEU among the hierarchical encoders. Also we implemented a template system same as the one used in Wiseman et al. (2017) which outputted eight sentences: an introductory sentence (two teams' points and who win), six top players' statistics (ranked by their points) and a conclusion sentence. We refer the readers to Wiseman et al. (2017)'s paper for more detailed information on templates. The gold reference's result is also included in Table 1. Overall, our model performs better than other neural models on both development and test set in terms of RG's P%, F1% score of CS, CO and BLEU, indicating our model's clear improvement on generating high-fidelity, informative and fluent texts. Also, our model with three dimension representations outperforms hierarchical encoders with only row dimension representation on development set. This indicates that cell and time dimension representation are important in representing the tables. Compared to reported baseline result in Wiseman et al. (2017), we achieved improvement of 22.27% in terms of RG, 26.84% in terms of CS F1%, 35.28% in terms of CO and 18.75% in terms of BLEU on test set. Unsurprisingly, template system achieves best on RG P% and CS R% due to the included domain knowledge. Also, the high RG # and low CS P% indicates that template will include vast information while many of them are deemed redundant. In addition, the low CO and low BLEU indicates that the rigid structure of the template will produce texts that aren't as adaptive to the given tables and natural as those produced by neural models. Also, we conducted ablation study on our model to evaluate each component's contribution on development set. Based on the results, the absence of row-level encoder hurts our model's performance across all metrics especially the content selection ability.

Row, column and time dimension information are important to the modeling of tables because subtracting any of them will result in performance drop. Also, position embedding is critical when modeling time dimension information according to the results. In addition, record fusion gate plays an important role because BLEU, CO, RG P% and CS P% drop significantly after subtracting it from full model. Results show that each component in the model contributes to the overall performance. In addition, we compare our model with delayed copy model (DEL) (Li and Wan, 2018) along with gold text, template system (TEM), conditional copy (CC) (Wiseman et al., 2017) and NCP+CC (NCP) (Puduppully et al., 2019). Li and Wan (2018)'s model generate a template at first and then fill in the slots with delayed copy mechanism. Since its result in Li and Wan (2018)'s paper was evaluated by IE model trained by Wiseman et al. (2017) and "relexicalization" by Li and Wan (2018), we adopted the corresponding IE model and re-implement "relexicalization" as suggested by Li and Wan (2018) for fair comparison. Please note that CC's evaluation results via our re-implemented "relexicalization" is comparable to the reported result in Li and Wan (2018). We applied them on models other than DEL as shown in Table 2 and report DEL's result from (Li and Wan, 2018)'s paper. It shows that our model outperform Li and Wan (2018)'s model significantly across all automatic evaluation metrics in Table 2.

Model	RG		CS		CO	BLEU
	P%	#	P%	R%	DLD%	
Gold	96.01	17.17	100.00	100.00	100.00	100.00
TEM	**99.97**	**54.14**	23.88	**72.63**	11.90	8.33
CC	75.26	16.37	32.63	39.62	15.34	14.03
DEL*	84.86	19.31	30.81	38.79	16.34	16.19
NCP	87.99	24.50	35.97	55.85	16.98	16.22
Ours	92.51	22.73	**38.52**	52.98	**19.95**	**16.69**

Table 2: Automatic evaluation results on test set. Results were obtained using Wiseman et al. (2017)'s trained extractive evaluation models with relexicalization (Li and Wan, 2018). * We include delayed copy (DEL)'s result in the paper (Li and Wan, 2018) for comparison.

4.3.2 Human Evaluation

In this section, we hired three graduates who passed intermediate English test (College English Test Band 6) and were familiar with NBA games to perform human evaluation.

First, in order to check if history information is important, we sampled 100 summaries from train-

Model	#Sup	#Cont	#Gram	#Coher	#Conc
Gold	3.48	0.19	16.67	24.22	25.78
Temp	7.83	0.00	11.56	-16.67	21.11
CC	3.91	1.23	-11.33	-7.78	-28.00
NCP	5.15	0.82	-17.33	-5.33	-17.11
Ours	3.63	0.44	0.44	5.56	-1.78

Table 3: Human evaluation results.

ing set and asked raters to manually check whether the summary contained expressions that need to be inferred from history information. It turns out that 56.7% summaries of the sampled summaries need history information.

Following human evaluation settings in Puduppully et al. (2019), we conducted the following human evaluation experiments at the same scale. The second experiment is to assess whether the improvement on relation generation metric reported in automatic evaluation is supported by human evaluation. We compared our full model with gold texts, template-based system, CC (Wiseman et al., 2017) and NCP+CC (NCP) (Puduppully et al., 2019). We randomly sampled 30 examples from test set. Then, we randomly sampled 4 sentences from each model's output for each example. We provided the raters of those sampled sentences with the corresponding NBA game statistics. They were asked to count the number of supporting and contradicting facts in each sentence. Each sentence is rated independently. We report the average number of supporting facts (#Sup) and contradicting facts (#Cont) in Table 3. Unsurprisingly, template-based system includes most supporting facts and least contradicting facts in its texts because the template consists of a large number of facts and all of those facts are extracted from the table. Also, our model produces less contradicting facts than other two neural models. Although our model produces less supporting facts than NCP and CC, it still includes enough supporting facts (slightly more than gold texts). Also, comparing to NCP+CC (NCP)s tendency to include vast information that contain redundant information, our models ability to select and accurately convey information is better. All other results (Gold, CC, NCP and ours) are significantly different from template-based system's results in terms of number of supporting facts according to one-way ANOVA with posthoc Tukey HSD tests. All significance difference reported in this paper are less than 0.05. Our model is also significantly different from the NCP model. As for average number of contradicting facts, our model is significantly different from other two neural models. Surprisingly, gold texts were found containing contradicting facts. We checked the raters's result and found that gold texts occasionally include wrong field-goal or three-point percent or wrong points difference between the winner and the defeated team. We can treat the average contradicting facts number of gold texts as a lower bound.

In the third experiment, following Puduppully et al. (2019), we asked raters to evaluate those models in terms of grammaticality (is it more fluent and grammatical?), coherence (is it easier to read or follows more natural ordering of facts?) and conciseness (does it avoid redundant information and repetitions?). We adopted the same 30 examples from above and arranged every 5-tuple of summaries into 10 pairs. Then, we asked the raters to choose which system performs the best given each pair. Scores are computed as the difference between percentage of times when the model is chosen as the best and percentage of times when the model is chosen as the worst. Gold texts is significantly more grammatical than others across all three metrics. Also, our model performs significantly better than other two neural models (CC, NCP) in all three metrics. Template-based system generates significantly more grammatical and concise but significantly less coherent results, compared to all three neural models. Because the rigid structure of texts ensures the correct grammaticality and no repetition in template-based system's output. However, since the templates are stilted and lack variability compared to others, it was deemed less coherent than the others by the raters.

4.3.3 Qualitative Example

Our model: The Charlotte Hornets (21 - 27) defeated the Washington Wizards (31 - 18) 92 - 88 on Monday … The Hornets were led by **Al Jefferson** , who recorded a **double - double** of his own with 18 points (9 - 19 FG , 0 - 2 FT) and 12 rebounds . It was his **second double - double** over his last three games … The only other Wizard to reach **double - digit points** was **Kris Humphries** , who came off the bench for 13 points (4 - 8 FG , 5 - 6 FT) and five rebounds in 26 minutes …

Figure 3: An generation example of our model based on the same tables in Figure 1. Text that accurately reflects players (Al Jefferson and Kris Humphries) performance is in red.

Figure 3 shows an example generated by our model. It evidently has several nice properties: it can accurately select important player "Al Jef-

ferson" from the tables who is neglected by baseline model, which need the model to understand performance difference of a type of data (column) between each rows (players). Also it correctly summarize performance of "Al Jefferson" in this match as "double-double" which requires ability to capture dependency from different columns (different type of record) in the same row (player). In addition, it models "Al Jefferson" history performance and correctly states that "It was his second double-double over his last three games", which is also mentioned in gold texts included in Figure 1 in a similar way.

5 Related Work

In recent years, neural data-to-text systems make remarkable progress on generating texts directly from data. Mei et al. (2016) proposes an encoder-aligner-decoder model to generate weather forecast, while Jain et al. (2018) propose a mixed hierarchical attention. Sha et al. (2018) proposes a hybrid content- and linkage-based attention mechanism to model the order of content. Liu et al. (2018) propose to integrate field information into table representation and enhance decoder with dual attention. Bao et al. (2018) develops a table-aware encoder-decoder model. Wiseman et al. (2017) introduced a document-scale data-to-text dataset, consisting of long text with more redundant records, which requires the model to select important information to generate. We describe recent works in Section 1. Also, some studies in abstractive text summarization encode long texts in a hierarchical manner. Cohan et al. (2018) uses a hierarchical encoder to encode input, paired with a discourse-aware decoder. Ling and Rush (2017) encode document hierarchically and propose coarse-to-fine attention for decoder. Recently, Liu et al. (2019) propose a hierarchical encoder for data-to-text generation which uses LSTM as its cell. Murakami et al. (2017) propose to model stock market time-series data and generate comments. As for incorporating historical background in generation, Robin (1994) proposed to build a draft with essential new facts at first, then incorporate background facts when revising the draft based on functional unification grammars. Different from that, we encode the historical (time dimension) information in the neural data-to-text model in an end-to-end fashion. Existing works on data-to-text generation neglect the joint representation of tables' row, column and time dimension information. In this paper, we propose an effective hierarchical encoder which models information from row, column and time dimension simultaneously.

6 Conclusion

In this work, we present an effective hierarchical encoder for table-to-text generation that learns table representations from row, column and time dimension. In detail, our model consists of three layers, which learn records' representation in three dimension, combine those representations via their sailency and obtain row-level representation based on records' representation. Then, during decoding, it will select important table row before attending to records. Experiments are conducted on ROTOWIRE, a benchmark dataset of NBA games. Both automatic and human evaluation results show that our model achieves the new state-of-the-art performance.

Abstract

In multi-document summarization, a set of documents to be summarized is assumed to be on the same topic, known as the *underlying topic* in this paper. That is, the underlying topic can be collectively represented by all the documents in the set. Meanwhile, different documents may cover various different subtopics and the same subtopic can be across several documents. Inspired by topic model, the underlying topic of a document set can also be viewed as a collection of different subtopics of different importance. In this paper, we propose a summarization model called *STDS*. The model generates the underlying topic representation from both document view and subtopic view in parallel. The learning objective is to minimize the distance between the representations learned from the two views. The contextual information is encoded through a hierarchical RNN architecture. Sentence salience is estimated in a hierarchical way with subtopic salience and relative sentence salience, by considering the contextual information. Top ranked sentences are then extracted as a summary. Note that the notion of subtopic enables us to bring in additional information (*e.g.,* comments to news articles) that is helpful for document summarization. Experimental results show that the proposed solution outperforms state-of-the-art methods on benchmark datasets.

1 Introduction

Multi-document summarization (MDS) is useful in many applications, *e.g.,* summarizing answers in forums (Song et al., 2017) and reports of burst events (Kedzie et al., 2016). In MDS, the documents in a set are assumed to share the same underlying topic. Given a set of documents to be summarized, the important information is collectively determined by all the documents in the set, rather than simple integration of key points in each document. Hence, the correlations among documents become crucial for identifying the important information to be included in a summary. Moreover, each sentence should not be interpreted independently. Its context (or the surrounding sentences) does affect the information expressed in a sentence (Nenkova et al., 2006; Ren et al., 2017). Therefore, both correlations among documents and contextual information within a single document should be considered in MDS.

Various methods have been developed for MDS. Graph-based models (Mihalcea and Tarau, 2004; Erkan and Radev, 2004) blend sentences from different documents together and attempt to leverage the correlations among documents to extract the most representative sentences. Nonetheless these methods are less effective when the sentence graph is not well connected. Thus, many studies attempt to construct well connected graphs, *e.g.,* group sentences into clusters (Wan and Yang, 2008; Banerjee et al., 2015) and construct dense features with distributed embeddings (Yasunaga et al., 2017). However, these methods do not address the context information for sentences in each individual document. There are also models exploring fine-grained word or phrase level information (Li et al., 2015, 2017a,b). The resultant summary consists of salient words or phrases that are selected by integer linear programming (ILP). Recently, many studies have taken advantage of the strengths of neural models (Ren et al., 2017; Zhou et al., 2018; Lebanoff et al., 2018). However, these models are not designed to well deal with both correlations among documents in the set and the contextual information in each individual document.

To address the two aforementioned issues, we propose a subtopic-driven summarization solution, named *STDS*. To encode sequential context information, we adopt a hierarchical bidirectional RNN to produce representations for sentences,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3153–3162, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

documents, and the underlying topic. As stated earlier, within a document set, the documents may cover various subtopics and the same subtopic can be across several articles. These subtopics implicitly reflect the correlations among documents. Inspired by topic model (Blei et al., 2003), we simply assume that k latent subtopics are depicted by the documents. We design our model to learn the representations of "subtopics" by itself, by assigning sentences to different subtopics in a soft manner instead of hard clustering. Thus, the underlying topic of a given document set can be presented from document view and subtopic view, in parallel. The subtopic view also gives us the flexibility of incorporating additional information (*e.g.,* comments to news articles). Readers' comments have been found useful for highlighting crucial information (Li et al., 2017a). The salience of subtopics are estimated by using attention mechanism (Bahdanau et al., 2015) with respect to the underlying topic generated from the document view. Similarly, relative sentence salience can be estimated for each subtopic by considering context information. By multiplying the saliences of subtopics and sentences, an overall ranking of sentences can be obtained. Top-ranked sentences are extracted as a summary within a given length limit. The contributions of this work are as follows:

- We propose to explore correlations among documents with "subtopics". The subtopics and documents provide us parallel views of the underlying topic and enable sentence and subtopic salience estimation in an unsupervised fashion.
- We build up a unified model that tackles the correlations among documents and contextual information within each document together in an inherent way.
- Our model can be applied to documents with or without comments. Extensive experiments are conducted on benchmark datasets, *i.e.,* RA-MDS and DUC 2004. The experimental results show that our STDS outperforms state-of-the-art baselines.

2 Related Work

2.1 Extractive Methods

Extractive methods select sentences from documents to form a summary. A typical framework is based on a graph, where sentences are vertices and similarities between sentences are edge weights, *e.g.,* TextRank (Mihalcea and Tarau, 2004) and LexRank (Erkan and Radev, 2004). They apply a random walk to explore the relationships among sentences and then produce a sentence ranking. MEAD (Radev et al., 2000) is a centroid-based method, which ranks sentences based on a set of features, including centroid value, positional value, first sentence overlap and redundancy.

However, the graph-based models do not perform well when the sentence graph is not well connected. Wan and Yang (2008) claim that the document set is usually composed of a few themes, which are represented by sets of sentences. They apply conditional Markov Random Walk and HITS on clusters, separately. Alternatively, Haghighi and Vanderwende (2009) adopt a hierarchical Latent Dirichlet Allocation based model to discover the multiple themes within a document set. Similarly, Gong *et al.* (2010) use the theme structure to define the representation for each sentence. However, their solutions only consider statistical knowledge. Semantic and contextual information among sentences are neglected.

Following the idea of themes, Banerjee *et al.* (2015) suggest that the sentences in the most important document of the set are relevant to the sentences in the other documents. Hence, they cluster sentences based on those in the most important document. However, there may not always exist a most important document in the set. Further, the relationships among documents are not necessarily to be conclusive. In fact, there are many kinds of relationships among documents (*e.g.,* similar, complementary, or evolutionary).

Liu *et al.* (2015) adopt the idea of reconstruction. They apply a two-level sparse representation model and reconstruct the document by extracted sentences with constraints. Similarly, Ma *et al.* (2016) try to minimize the reconstruction error between selected sentences and the document set with a neural model. Cao *et al.* (2017) make use of multi-task learning by incorporating classification task with summarization to train better sentence representations for reconstruction.

2.2 Abstractive Methods

Summarizing multiple documents in an abstractive way is even harder. The generation should take many inputs into account. Some abstrac-

tive methods on single document summarization have been proposed recently (See et al., 2017; Zhou et al., 2018), and they benefit from an attentive sequence-to-sequence model (Sutskever et al., 2014). In fact, abstractive approaches for MDS are more like words or phrases recombination.

Bing *et al.* (2015) propose an abstractive MDS solution. They extract salient noun and verb phrases from a constituency tree, then produce sentences with representative phrases via integer linear programming. Later, Li *et al.* (2017b; 2017c) adopt a similar two-stage model, but they first estimate sentence and phrase salience via an auto-encoder framework.

Recently, some studies have turned to readers' comments to help identify crucial points to include in a summary. Li *et al.* (2015) propose a sparse coding method to generate summaries that not only cover key content in news but also focuses highlighted by readers' comments. However, they do not consider semantic information. Later, they propose a deep learning method (Li et al., 2017a) that jointly models the focuses of news set and readers' comments. But they do not tackle sequential context information among sentences and treat them as separate instances. In contrast, we deal with sequential context information within each document and the relationships among documents.

3 Preliminary

We define our problem as follows. Given a set of news documents on the same topic, $D = \{d_1, d_2, ..., d_n\}$, we also have a set of comments $C_i = \{c_{i,1}, c_{i,2}, ..., c_{i,h}\}$ for each document d_i. Both news d_i and comment $c_{i,j}$ consist of a sequence of sentences, *i.e.,* $d_i = \{s_1, s_2, ..., s_{|d_i|}\}$ and $c_{i,j} = \{y_1, y_2, ..., y_{|c_{i,j}|}\}$. We aim to extract representative *news sentences* to summarize the set of news articles by considering both news and comments.

To better leverage comments, we explore the correlation between news and comments based on the dataset provided by Li *et al.* (2017a). The dataset contains 45 topics (*i.e.,* sets of news articles), and each topic includes 10 news articles. The number of comments associated with each news article is not evenly distributed and ranges from 0 to 248. Overall, on average, each topic is associated with 215 comments and 940 comment sentences.

The correlations between news and comments determines how we use them. Thus, we make the following analysis. Since the news documents share the same topic, comments about one news may also be related to the others. Meanwhile, it is common for users to make comments after reading through several topic-related news articles. Thus, comments for one news could also contain information from related articles. To verify our assumption, we calculate the ratio of overlapped vocabulary for each news and its comments, over news vocabulary, and the average is 0.345. Against news-comments pairs, we compute the ratio of overlapped vocabulary for all the news and comments of the same topic, over news vocabulary, and the average is 0.447. Thus, considering comments as related to the whole news set is more reasonable than news-comment pairs, which coincides with (Li et al., 2015, 2017a).

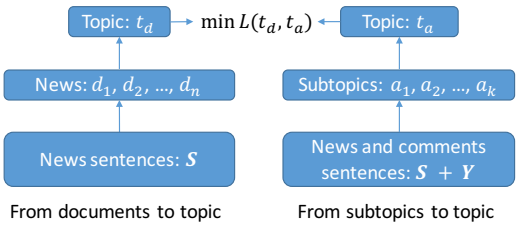

Figure 1: Framework of STDS. The underlying topic of the news set is represented from a document view and a subtopic view respectively. The target is to minimize the distance between the two representations $L(t_d, t_a)$.

In short, our model inputs are a news set $D = \{d_1, d_2, ..., d_n\}$ with news sentences S, and a set of comments $C = \{c_1, c_2, ..., c_m\}$ with comment sentences Y. Later, we will use boldface of each notation to represent its embedding.

4 Model Description

Our model tackles correlations among documents and sequential context in each individual document, through "subtopics" and hierarchical semantic embedding. We first introduce the embedding generation with context for sentences, documents, and subtopics in Sections 4.1 and 4.2. Then, we describe salience estimation for subtopics and sentences in Sections 4.3 and 4.4.

4.1 Sentence and Document Representation

We start representation generation from words, and pre-train word embedding $\boldsymbol{W} \in \mathbb{R}^{|\mathcal{V}| \times u}$ by Word2Vec (Mikolov et al., 2013) on both news and comments, where $\mathcal{V}$ is the overall vocabulary.

Note that we use u to represent the vector dimension throughout the model description (specific value settings are given in Section 5). The representations for news sentences $\boldsymbol{S}$ and news documents $\boldsymbol{D}$ are learned in a hierarchical structure, as shown in Figure 2. Specifically, the embeddings of words $\boldsymbol{w}$ in each sentence are fed into a bidirectional RNN encoder-decoder framework (Cho et al., 2014), which inherently encodes word sequence information in sentence representations. GRU (Chung et al., 2014) is adopted as the basic RNN unit. Each sentence acts as both encoder input and decoder target. Thus, the encoder-decoder could be considered as an RNN auto-encoder. The concatenation of hidden vectors in both directions at the last step of the encoder is adopted as the sentence embedding, $\boldsymbol{s} = [\overrightarrow{\boldsymbol{h}_{|s|}}^\top; \overleftarrow{\boldsymbol{h}_{|s|}}^\top]^\top$. The comment sentence embedding $\boldsymbol{Y}$ is generated in the same way. The loss function for the RNN encoder-decoder is:

$$\mathcal{L}_e = -\sum_{X \in S \cup Y} \log p(X'|X;\theta) \qquad (1)$$

where X' is the predicted result and θ denotes the parameters.

Then, news sentence embeddings $\boldsymbol{s}$ are fed into the next level bidirectional RNN in order, as shown in Figure 2, to generate a document representation $\boldsymbol{D} \in \mathbb{R}^{|D| \times u}$. Note that no decoding process exists from sentence to document. At each encoding step for document embedding, we obtain the hidden vectors on both directions for each sentence, which contain contextual information along with sentences. We concatenate them as a context-enriched sentence embedding $\tilde{\boldsymbol{S}} \in \mathbb{R}^{|S| \times u}$, where $\tilde{\boldsymbol{s}}_i = [\overrightarrow{\boldsymbol{h}_i}^\top; \overleftarrow{\boldsymbol{h}_i}^\top]^\top$. Again, we take the concatenation of hidden vectors in both directions at the last step as the document embedding $\boldsymbol{d} = [\overrightarrow{\boldsymbol{h}_{|d|}}^\top; \overleftarrow{\boldsymbol{h}_{|d|}}^\top]^\top$.

For now, the sequential contextual information in an individual document is encoded in the context-enriched sentence embedding $\tilde{\boldsymbol{S}}$ with the hierarchical bidirectional RNN inherently.

4.2 Subtopic Representation

As stated in Section 1, we assume a news set contains k latent subtopics, which are expected to be learned automatically from sentences of news and comments. This is because readers' comments are found useful to highlight important information in news (Li et al., 2015, 2017a).

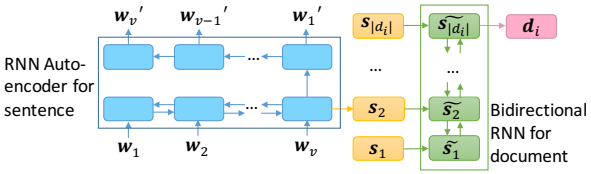

Figure 2: Hierarchical RNN structure for sentence representation $\boldsymbol{s}_j$ and document representation $\boldsymbol{d}_i$ construction. $\boldsymbol{w}_i$ is the embedding of words in each sentence and $\boldsymbol{s}_j$ is the concatenation of hidden vectors in both directions at the last step of the sentence encoder. $\tilde{\boldsymbol{s}}_j$ is a context-enriched sentence embedding, which is the concatenation of hidden states at each step of the document encoder.

Recall that we construct a document embedding from news sentence representations $\boldsymbol{S}$, which are generated from a word sequence. For subtopic representation, we also utilize $\boldsymbol{S}$, and incorporate the comment sentence embedding $\boldsymbol{Y}$. That is, we only take a single sentence without context information to build subtopic representations, as in a typical topic model. Then, a soft clustering is employed, so that sentences of news and comments $\boldsymbol{E} = [\boldsymbol{S}^\top; \boldsymbol{Y}^\top]^\top \in \mathbb{R}^{(|S|+|Y|) \times u}$ can be partial membership of multiple subtopics. Next, a nonlinear transformation $tanh$ is utilized to fuse clustered sentence information into subtopic representations $\boldsymbol{A} \in \mathbb{R}^{k \times u}$ as follows:

$$\boldsymbol{A} = tanh((\boldsymbol{H}\boldsymbol{E} + \boldsymbol{b}_h)\boldsymbol{U} + \boldsymbol{b}_u) \qquad (2)$$

where $\boldsymbol{H}, \boldsymbol{U}, \boldsymbol{b}_h, \boldsymbol{b}_u$ are trainable parameters.

We hope that each subtopic embedding can represent a unique facet of the underlying topic. That means the overlap across different subtopics should be as small as possible. Inspired by Luxburg (2007), we constrain the subtopic embedding to be orthogonal with each other:

$$\mathcal{L}_r = \|\boldsymbol{A}\boldsymbol{A}^\top - \boldsymbol{I}_{k \times k}\|. \qquad (3)$$

4.3 Salience Estimation for Subtopic

The purpose of introducing subtopics is not to make the summary diverse. Instead, we aim to identify the important information (and relieve distractions from less crucial content) in the news set, through the notion of subtopics. This is achieved by subtopic salience estimation. We consider the underlying topic of a news set from two parallel perspectives, as shown in Figure 1: (i) the explicit composition of documents, and (ii) the implicit constitution of subtopics. Therefore, from either document view or subtopic view, we should

be able to obtain similar representations for the underlying topic of the news set.

From documents to the underlying topic. We obtain a document representation $\boldsymbol{d}$ with a hierarchical RNN. Again, we adopt a bidirectional RNN to encode document embeddings to a topic representation $\boldsymbol{t}_d$, which is the concatenation of hidden vectors in both directions at the last step. Here, the document sequences do not significantly affect model performance in our experiments. In fact, one can also try to use a CNN to get $\boldsymbol{t}_d$. However, our experiments suggest RNN performs better than CNN.

From subtopics to the underlying topic. As we stated before, not all subtopics are equally important to the underlying topic. We estimate subtopic salience in order to focus on key information *i.e.,* to generate a distilled topic representation $\boldsymbol{t}_a$. This is different from the topic vector $\boldsymbol{t}_d$ constructed from documents, which encodes all information from all documents.

To estimate subtopic salience, we apply an attention mechanism (Bahdanau et al., 2015) on each subtopic representation $\boldsymbol{a}_i$ with respect to the topic representation $\boldsymbol{t}_d$, which encodes comprehensive information from documents:

$$\alpha_i = \frac{\exp(e_i)}{\sum_{k=1}^{m}\exp(e_k)}, e_i = \boldsymbol{v}^\top tanh(\boldsymbol{H}\boldsymbol{a}_i + \boldsymbol{U}\boldsymbol{t}_d) \tag{4}$$

where $\boldsymbol{H}$, $\boldsymbol{U}$ and $\boldsymbol{v}$ are trainable parameters. We feed the weighted subtopic embedding $\alpha_i \boldsymbol{a}_i$ into a bidirectional RNN. The reason for using an RNN is the same as that for t_d generation, mentioned above. The concatenation of hidden vectors in both directions at the last step is taken as the topic representation $\boldsymbol{t}_a$, generated from subtopics. Both topic representations $\boldsymbol{t}_a$ and $\boldsymbol{t}_d$ should be similar to each other, because they denote the same underlying topic. Since the two vectors are from identical structure as Siamese network (Koch et al., 2015), we adopt contrastive loss (Hadsell et al., 2006) to measure the distance between them:

$$\mathcal{L}_t = \beta * (max\{0, 1 - \boldsymbol{t}_d^\top \boldsymbol{t}_a\})^2 + (1-\beta) * (\boldsymbol{t}_d - \boldsymbol{t}_a)^2 \tag{5}$$

where β is a hyper-parameter, empirically set to 0.5.

4.4 Salience Estimation for Sentence

Note that, each sentence is also of different importance with respect to different subtopics, which is called *relative sentence salience*. Recall that we claim the sequential context information affects sentence salience. Thus, we adopt the context-enriched sentence embedding $\tilde{\boldsymbol{s}}_j$, (which is presented in Section 4.1), to estimate relative sentence salience $\gamma_{i,j}$ for each subtopic $\boldsymbol{a}_i$, similar as Equation 4.

The subtopic representations are generated from both news $\boldsymbol{S}$ and comments $\boldsymbol{Y}$. On the other hand, the subtopics represent information conveyed by the news set. Thus, we should also be able to construct subtopic vectors solely based on news sentences. To avoid diminishing of comments $\boldsymbol{Y}$, we use the context-enriched news sentence embedding $\tilde{\boldsymbol{S}}$ to approximate subtopic representations $\boldsymbol{A}$, similar as Equation 2:

$$\boldsymbol{A}_{\tilde{s}} = tanh(\boldsymbol{\gamma}\tilde{\boldsymbol{S}}\boldsymbol{H} + \boldsymbol{b_h}) \tag{6}$$

where $\boldsymbol{H}$ and $\boldsymbol{b_h}$ are trainable parameters. $\boldsymbol{A}$ and $\boldsymbol{A}_{\tilde{s}}$ should be similar and we measure the distance between them with contrastive loss:

$$\mathcal{L}_a = \beta * (max\{0, \|\boldsymbol{I} - \boldsymbol{A}\boldsymbol{A}_{\tilde{s}}^\top\|\})^2 + (1-\beta) * (\boldsymbol{A} - \boldsymbol{A}_{\tilde{s}})^2 \tag{7}$$

where β is a hyper-parameter, empirically set to 0.5. With backpropagation, relative sentence salience scores $\boldsymbol{\gamma}$ can be learned.

The overall training objective becomes:

$$\mathcal{L} = \mathcal{L}_e + \mathcal{L}_r + \mathcal{L}_t + \mathcal{L}_a. \tag{8}$$

To obtain the global salience score for each sentence, we multiply the max relative salience of each sentence over subtopics $\max \boldsymbol{\gamma}_{:,j}$, with the corresponding subtopic salience α_i, (*i.e.,* $i = \arg\max \boldsymbol{\gamma}_{:,j}$). Top ranked sentences are extracted as a summary with length limited (*i.e.,* 100 words).

5 Experiments

5.1 Datasets and Experimental Settings

Our model is proposed to incorporate comments for summarization, but it can also be applied when no comments are available. Hence, we evaluate our model on two benchmark datasets: one includes comments and the other does not.

RA-MDS (Li et al., 2017a): This dataset includes comments and is the one we conduct analysis on in Section 3. For each topic, 4 reference summaries within 100 words are generated by human. The average news length is 27 sentences, and each sentence contains 25 words on average. To alleviate comment bias when generating subtopics, we randomly sample 50 comments

for each topic, and repeat the sampling 10 times. Thus, we obtain 450 news document sets. At test stage, for each topic, we randomly select 50 comments, together with the news set for evaluation.

DUC2004[1]: The data is from Task 2 of DUC 2004. It has 50 topics, each of which consists of 10 news articles. For each topic, multiple reference summaries generated by human judges are provided.

Experimental settings. The notation u in Section 4 generally represents the hidden vector dimension. We set the word embedding dimension as 300. The hidden units for all GRU cells in one direction are 128, so the hidden vector dimension after concatenating both directions is 256. The dimensions of the linear operations in Equations 2 and 6 are also set to 256. We perform sensitivity experiments on the subtopic number and empirically set the number k to 5. The word embeddings are pre-trained on two datasets separately and are immutable during the training process.

The batch size is 1, which is the data from one news set. One iteration is training one batch of data. We adopt Adam (Kingma and Ba, 2015) as the optimizer. The learning rate is 0.001 and the value is decayed by 0.96 after 1,000 iterations. To reduce the vanishing and exploding gradient problems for RNN training, we apply gradient norm clipping strategy (Pascanu et al., 2013) and set the bounded norm as 1. We stop training when the loss stops decreasing after more than 3 iterations. Our model is implemented with TensorFlow version 1.3[2] and runs on a single GPU.[3]

5.2 Baseline Models

We compare our model with both traditional methods and state-of-the-art models on both datasets.

Lead: For news, the first several sentences usually act as good summarization. The news sentences are ordered chronologically and top ones are extracted until meeting the length limit.

MEAD (Radev et al., 2000): It detects the topics of given document set and uses information from the centroid of each topic to select sentences.

LexRank (Erkan and Radev, 2004), **TextRank** (Mihalcea and Tarau, 2004): Both are unsupervised graph-based models. They perform PageRank on a sentence graph, where sentence similarities are edge weights.

APSM (Bing et al., 2015): It extracts noun and verb phrases from a contiguity tree and estimates the phrase salience based on handcrafted features. Then, an integer linear programming process is employed to optimize the phrase selection.

RA-Sparse (Li et al., 2015): This model tackles reader-aware MDS problem. A sparse-coding-based method is used to calculate sentence salience by jointly considering news documents and readers' comments.

RAVAESum, RAVAESum/NC (Li et al., 2017a): They explore the relationships between news and comments via representation matrix multiplication, from which a weight matrix is obtained. The magnitudes of the weight matrix are taken as sentence salience. Then, integer linear programming is used to optimize the summary construction. RAVAESum/NC removes readers' comments from the input and trains the model solely based on news.

The methods below are baselines used on DUC 2004 dataset without comments.

CLASSY04 (Conroy et al., 2004): It performs the best on the official DUC 2004 evaluation. It applies a Hidden Markov Model and uses topic signature as feature.

GreedyKL (Haghighi and Vanderwende, 2009): It focuses on words distribution, and aims to minimize the KL divergence between word probability distribution estimated from summary and that from the input using a greedy approach.

RegSum (Hong et al., 2014): This is a supervised method. It adopts weights estimated from three unsupervised methods with a set of handcrafted features for salience estimation.

ILPSumm (Banerjee et al., 2015): It groups similar sentences and generates K-shortest paths from sentences in each cluster using a word-graph structure. Then, it selects sentences from the set of shortest paths via ILP.

AAPRW (Wang et al., 2017): This is an adjustable affinity-preserving random walk model to keep the summary diverse.

GRU-GCN (Yasunaga et al., 2017): It employs an RNN to obtain sentence embedding and feeds them to a Graph Convolutional Network (GCN) as node features. High-level features are generated from the GCN for sentence salience estimation.

CRSum,CRSum-SF (Ren et al., 2017): CRSum

	CRSum-SF	0.395	0.106
Unsupervised Method	LexRank	0.359	0.075
	GreedyKL	0.379	0.085
	AAPRW	0.389	0.101
	ILPSum	0.392	**0.119**
	STDS/NC	**0.397**	0.107

Table 2: ROUGE ***Recall*** for the proposed method and baselines on DUC 2004 dataset. Best ***Recall*** scores are in bold and second best are underlined.

exploits context features within sentences and among sentences with a two-level attention mechanism. CRSum-SF refers to the model combining surface features.

PG-MMR (Lebanoff et al., 2018): It leverages the Maximal Marginal Relevance method to select representative sentences from input documents avoiding duplicates, and uses an existing abstractive encoder-decoder model (See et al., 2017) to generate an abstractive summary.

Our Model STDS: We feed the first 25 words of each sentence and the first 27 sentences of each document into our model (*i.e.,* which are the average numbers of words and sentences of RA-MDS dataset). Experimental results suggest no significant difference when feeding all the data. Since STDS requires readers' comments, we only evaluate it on RA-MDS dataset.

Our Model STDS/NC: This is a variant of STDS without readers' comments as input. The subtopic embeddings are generated solely based on news sentence embedding $\boldsymbol{s}$. For DUC 2004, the first 20 words of each sentence and the first 20 sentences of each document are fed into the model. The other settings remain the same. When no readers' comments exists, our model can be applied in this manner and we test STDS/NC on both datasets.

5.3 Performance Comparison

We evaluate the models by pyrouge[4], which is a python wrapper of the official ROUGE toolkit (Lin, 2004). We limit the summary length to 100 words on both datasets to compare with baselines. Following Li *et al.* (2017a), we report ROUGE F_1 on RA-MDS in Table 1. For DUC 2004, we report ROUGE $Recall$ following previous studies (Wang et al., 2017) in Table 2.

RA-MDS: From Table 1, we observe that our STDS outperforms all baselines on all of ROURGE-1, ROUGE-2 and ROUGE-SU4, which demonstrates the superiority of our model. By incorporating readers' comments, STDS and RAVAESum achieve better results than STDS/NC and RAVAESum/NC. Thus, readers' comments do help construct better summaries. The variant of our model, STDS/NC, achieves comparable performance with the best baseline, RAVAESum, on ROUGE-1. This shows the subtopics and contextually enriched semantic embedding are important for summarization.

MEAD, LexRank and TextRank all tackle correlations among documents, but they do not consider surrounding context influence. STDS and STDS/NC take both elements into consideration and perform much better than these baselines. Thus, context information contributes to better summaries. If this comparison is not direct enough because our models STDS and STDS/NC can benefit from neural model, we compare STDS and RAVAESum next. Both RAVAESum and STDS are neural models. The difference is that our STDS does not take all news and comment sentences as a whole set. STDS distributes sentences into different subtopics of varying importance and incorporates surrounding sentences as context to produce sentence representations. Our model performs better than RAVAESum. Therefore, both

[Extracted] d2s1t1: Facebook launches Internet.org app to let users access basic Internet services for free. **d6s2t1:** Facebook's Internet.org project is taking another step toward its goal of bringing the Internet to people who are not yet online, launching an app Thursday in Zambia. **d3s4t2:** Facebook will not pay Airtel for the bandwidth, Rosen said, but Airtel will benefit as users who are exposed to Internet services eventually decide to pay for broader, unrestricted access. **d8s3t1:** The Internet.org app will give subscribers of Zambia's Airtel phone company access to a set of basic internet services for free.
[Reference] r1: Facebook launched an Internet.org app in Zambia to provide free access to Facebook and other online services including Wikipedia, Google Search, AccuWeather and websites offering health and other services. **r2:** Facebook aims to bring the Internet to people who are not yet online. **r3:** The new app has the potential to boost the size of Facebooks audience, which currently totals 1.32 billion monthly users. **r4:** Facebook will not pay Airtel for the bandwidth, but Airtel will benefit as users may decide to pay for unrestricted access. **r5:** Google has run its own zero-data initiative called Free Zone including a partnership with Airtel in India.

Table 3: Summary example.

Subtopic	Salience	Top-ranked sentence of the subtopic
t1	0.312	Facebook launches Internet.org app to let users access basic Internet services for free.
t2	0.284	Facebook will not pay Airtel for the bandwidth, Rosen said, but Airtel will benefit as users who are exposed to Internet services eventually decide to pay for broader, unrestricted access.
t3	0.197	Online services accessible through the app range from AccuWeather to Google search, Wikipedia, a job search site as well as a breadth of health information.
t4	0.122	Mark Zuckerberg has said that making connectivity affordable and convincing people that the Internet is something they need are bigger hurdles to connecting people than "satellites or balloons."
t5	0.085	The app works on Android phones as well as the simple "feature phones" that are used by the majority of people in Zambia, said Guy Rosen, product management director at Internet.org.

Table 4: Subtopic example.

subtopics and context information contribute to STDS's good performance. Since our model is unified, (*i.e.,* sentence and subtopic salience estimation relies on both subtopics and contextual information), we cannot carry out ablation experiments to verify the effectiveness of the two factors individually.

DUC 2004: Note that our model STDS is designed to incorporate readers' comments. When no comments are available, STDS/NC performs fairly well, as shown in Table 2. We observe that STDS/NC achieves comparable results as state-of-the-art unsupervised method ILPSum and supervised method CRSum-SF, and outperforms the other strong baselines. Both GRU-GCN and STDS/NC exploit the correlations among documents, but STDS/NC encodes contextual information into the sentence embedding. The better performance of STDS/NC than GRU-GCN indicates the effectiveness of surrounding context. Moreover, both CRSum and STDS/NC encode contextual information into sentence embedding, and STDS/NC outperforms the supervised CRSum. Thus, this suggests that our model benefits from the subtopics with different saliences. They provide a better understanding of the correlations among documents and lead to the important subtopics. With the comparisons, we demonstrate the effectiveness of both factors: subtopics and context information.

In a word, without training using reference summaries, STDS and STDS/NC outperform most baseline methods and achieve comparable results with state-of-the-art methods. This shows that our model can be applied to common situations without readers' comments.

5.4 Case Study with Example Summary

We present one summary example in Table 3. The notations before extracted sentences represent **d**ocument, **s**entence, and sub**t**opic respectively. The number following **d** is the document number, labeled in the raw dataset. The number after **s** is the sentence position in the document. And the number following **t** indicates the subtopic ranking position based on subtopic salience, which is the same as in Table 4.

As observed, the extracted summary aligns to content of **r1**, **r2** and **r4** in reference summary. After checking the raw documents, we find few content is related to reference sentences **r3** and **r5**.

Table 4 shows the identified subtopic information of the same document set as for Table 3. We list the salience scores and top-ranked sentences to better understand the subtopics. We consider that the top-ranked sentence regarding each subtopic represents the main content of the subtopic. In

this case, the subtopics do capture different aspects of the document set. And they provide a structured way to understand the set of documents. The salience scores demonstrate that the subtopics are not equally important. The salience estimation of subtopics aims to facilitate the summarization process focusing on important information and reduce the distraction from trivial content. As in Table 3, the extracted summary sentences only cover two most important subtopics and they come from different documents. Thus, many overlaps exist among different documents, which complement each other and form the final subtopics identified by our model.

However, redundancy occurs in the extracted summary, *e.g.,* both **d2s1t1** and **d8s3t1** mention "Internet.org app provide Internet services for free". Besides, incoherence also exists, *e.g.,* **d8s3t1** should be in front of **d3s4t2**. This is the inherent drawback of extractive summarization. Thus, there is still great room for improvement. We will deal with these issues in our future work.

6 Conclusion

In this paper, we propose an unsupervised MDS solution, which deals with both sequential context information in a single document and the correlations among documents. Hierarchical RNN is adopted to encode context information in sentence and document embeddings. We transform correlations among documents into subtopics expressed by sentences in different documents. Readers' comments are incorporated into subtopics formation to highlight important information in news. The subtopics provide us another angle to understand the underlying topic besides the document view. The sentence salience is estimated with subtopic salience and relative sentence salience in the hierarchical way as well. Extensive experiments show that the proposed model outperforms state-of-the-art baselines.

Referring Expression Generation Using Entity Profiles

Meng Cao **Jackie Chi Kit Cheung**

School of Computer Science, McGill University, Montreal, QC, Canada
MILA, Montreal, QC, Canada

{meng.cao@mail, jcheung@cs}.mcgill.ca

Abstract

Referring Expression Generation (REG) is the task of generating contextually appropriate references to entities. A limitation of existing REG systems is that they rely on entity-specific supervised training, which means that they cannot handle entities not seen during training. In this study, we address this in two ways. First, we propose task setups in which we specifically test a REG system's ability to generalize to entities not seen during training. Second, we propose a profile-based deep neural network model, PROFILEREG, which encodes both the local context and an external profile of the entity to generate reference realizations. Our model generates tokens by learning to choose between generating pronouns, generating from a fixed vocabulary, or copying a word from the profile. We evaluate our model on three different splits of the WebNLG dataset, and show that it outperforms competitive baselines in all settings according to automatic and human evaluations.

1 Introduction

Entities can be expressed by various types of linguistic expressions, including by their names (e.g., *Barrack Obama*), a definite description (e.g., *the former president of the United States*), a pronoun (e.g., *he*, *him*, *his*), or a demonstrative (e.g., *that person*). Many factors play a role in determining what type of expression is appropriate in a particular context (Henschel et al., 2000), including information status, familiarity with the entity, and referential clarity. In this study, we aim to design a model that can generate appropriate referring expressions of entities in an extended passage. Such a system is useful in a variety of natural language generation settings, from dialogue systems to automatic summarization applications (Reiter and Dale, 2000; Krahmer and Van Deemter, 2012).

Referring expression generation (REG) can be broken into two steps. The first is to decide the *form* of referring expression; that is, what type of reference should be used (e.g., a proper name). The second is to determine the *content* of the referring expression (e.g., *Ernest Hemingway*).

Many computational approaches, both rule-based and machine-learning-based, have been proposed for REG. Rule-based models use predefined heuristics and algorithms to determine referential form (Reiter and Dale, 2000; Henschel et al., 2000; Callaway and Lester, 2002). Machine learning-based approaches require training on samples to predict referring expressions (Nenkova and McKeown, 2003; Greenbacker and McCoy, 2009; Ferreira et al., 2016, 2017), often as a classification task.

The common limitation of previous REG systems is that they are incapable of generating referring expressions for new, unseen entities. Previous REG setups have tended to focus on form selection rather than content generation, or else they provide a static list of attributes or realization options for models to select from (Belz et al., 2010; Gatt and Belz, 2008). The recent NeuralREG model generates referring expressions in an integrated, end-to-end setup, but it requires seeing instances of the entity being referred to in the training set (Ferreira et al., 2018).

In this work, we address this problem by proposing new REG task setups which test for REG systems' ability to handle new entities at test time. We also develop a REG system which can handle entities not seen during training using external knowledge about them, generated using extracts of their Wikipedia page.

From a practical perspective, it is reasonable to assume that such an entity profile exists for common entities such as popular locations and celebrities, as well as for targeted entities of interest that

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3163–3172, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

should be handled by an in-domain NLG system. We make the minimal assumption that the profile contains just a few sentences about the entity, so that these profiles can easily be written by non-experts or be automatically extracted.

Our model, PROFILEREG, uses a learned switch variable to decide whether to generate a token from a fixed vocabulary, generate a pronoun, or use information from the profile in order to generate appropriate referring expressions in context. We evaluate our model on the WebNLG corpus (Gardent et al., 2017a). Experimental results show that our model is capable of handling unseen entities that prior work simply cannot handle in our new evaluation setups, while also outperforming them in the original setting.[1]

Our contributions are as follows. First, we address an important limitation in prior REG studies by creating new test setups that evaluate neural REG models specifically on entities that are not seen in the training set. Second, we propose a new REG model, PROFILEREG, which outperforms existing REG models in all tested settings according to automatic and human evaluation measures.

2 Related Work

Previous work in REG can be divided into two groups: rule-based and machine learning-based.

Rule-based approaches use pre-defined rules or algorithms to determine the form or content of generated referring expressions. For example, Reiter and Dale (2000) proposed a straightforward heuristic for REG: a proper name should be used in the first mention of an entity and a pronominal form should be used for the subsequent references if there is no mention of any other entity of the same gender between the reference and its antecedent. Henschel et al. (2000) presented an algorithm for the pronominalization of third person discourse entities.

Machine learning-based approaches predict the form or content of referring expressions using features extracted from the context. Commonly used context features include syntactic position, referential status (initial or a subsequent mention) and distance. For instance, Nenkova and McKeown (2003) built a Markov chain model to capture how the subsequent referring expressions are conditioned by earlier mentions. Frank and Goodman (2012) proposed a rational speaker-listener model based on the assumptions that speakers attempt to be informative and that listeners use Bayesian inference to recover the speakers' intended referents. Orita et al. (2015) extended the previous model by introducing the referent's discourse salience and a cost term. Ferreira et al. (2016) proposed a naive Bayes model to predict the probability of a particular referential form given a set of feature values, including syntactic position, referential status and recency of references. Similarly, Ferreira et al. (2017) used a naive Bayes model based on syntactic position and referential status to predict the form of a proper name reference.

In recent years, deep neural networks have achieved great success in a variety of NLP applications (e.g., machine translation (Bahdanau et al., 2014) and automatic summarization (Rush et al., 2015; See et al., 2017)). To the best of our knowledge, there have only been two models that use deep neural networks for REG. The first is by Ferreira et al. (2016), who use recurrent neural networks (RNNs) to predict the form of referring expressions. They use RNNs to encode a sequence of discourse features and apply a softmax layer to generate referential form distribution.

The other is the NeuralREG model proposed by Ferreira et al. (2018), an end-to-end system that predicts both the form and content of the referring expression. NeuralREG has an encoder-decoder structure, using LSTM units to encode contextual information and to decode referring expressions. Since each entity is represented as an embedding vector in the model, it cannot handle new entities that are outside the training set.

Generating entity descriptions based on source data has also been explored in the context of concept-to-text generation Lebret et al. (2016). We focus here on generating referring expressions from unstructured source data, which may be more readily available in some settings.

3 Data

The WebNLG corpus (Gardent et al., 2017a) was initially introduced in the WebNLG challenge 2017 (Gardent et al., 2017b). The WebNLG dataset is made up of (data, text) pairs where the data is a set of triples that consists of entities and their relationships and the text is a verbalisation of these triples. In this challenge, the participants are asked to map the triple data to text.

In this study, we use a delexicalized version

Table 1: A sample in the original WebNLG dataset (above) and the delexicalized dataset (below). In this case, referring expression "He", which refers to *Elliot_See*, is first delexicalized as elliot_see and then extracted from the text.

of WebNLG corpus introduced by Ferreira et al. (2018). The authors manually extracted each referring expression in the text and kept only the ones referring to Wikipedia entities. As a result, each sample of the delexicalized dataset consists of a Wikipedia ID, a true-cased tokenized referring expression (extracted from the text) and a lowercased, tokenized discourse context preceding and following the target reference (referred as the pre- and post-context). Table 1 shows one sample from the corpus. The dataset consists of 78,901 referring expressions for 1,501 Wikipedia entities. Among the expressions, 71.4% (56,321) are proper names, 5.6% (4,467) are pronouns, 22.6% (17,795) are descriptions and 0.4% (318) are demonstratives.

In the delexicalized version of WebNLG corpus, references to other discourse entities in the pre- and pos-contexts are represented by their one-word ID removing quotes and replacing white spaces with underscores. Since our model does not rely on any entity ID, we replaced each ID with its corresponding referring expression.

3.1 Profile Generation

We create a profile for each entity that appears in the corpus as a form of external knowledge for REG. The profile consists of the first three sentences of the entity's Wikipedia page, which is retrieved automatically using the entity's Wikipedia ID and the Python wikipedia 1.4.0 library. We choose the first three sentences of the Wikipedia page since they usually contain the most important information about an entity such as its name, country, or occupation.

We tokenized the crawled Wikipedia sentences and removed all phonetic symbols as well as other special characters. For the Wikipedia IDs that are ambiguous (e.g., New York may refer to New York City or New York (State)), we manually checked the discourse context to determine which entry was appropriate. For the entities that are constant numbers or dates which have no meaningful profiles, we make the profile content the same as the entity ID but replaced each underscore in the ID with white spaces. We generated a total of 1,501 profiles, one per entity in the dataset.

3.2 Setups

In the current way that WebNLG is set up for REG, entities in the training set and test set are overlapped, which makes it impossible to examine the effect that previously unseen entities have on REG performance. To address this limitation, we split the dataset in three different ways as follows:

Original. The original split of data from Ferreira et al. (2018). There are 63,061, 7,097 and 8,743 referring expressions in the training, development and test set respectively. In this dataset, all entities in the development and test set also appear in the training set.

Entity-separated. We separated the entities in the training, development and test set by splitting the delexicalized WebNLG dataset by entity IDs. The ratio of the number of entities in the training set, validation set, and test set is 8:1:1. As a result, there are 63,840, 7,978 and 7,083 referring expressions of different entities in each dataset.

Random. We randomly split all referring expressions in WebNLG with ratio 8:1:1. The final training, development and test set contains 63,121, 7,890 and 7,890 referring expressions respectively. In this dataset, some entities in the test set appear in training, but not all. We also test our models on this dataset since we believe it better reflects a realistic setting in which a REG model might be applied.

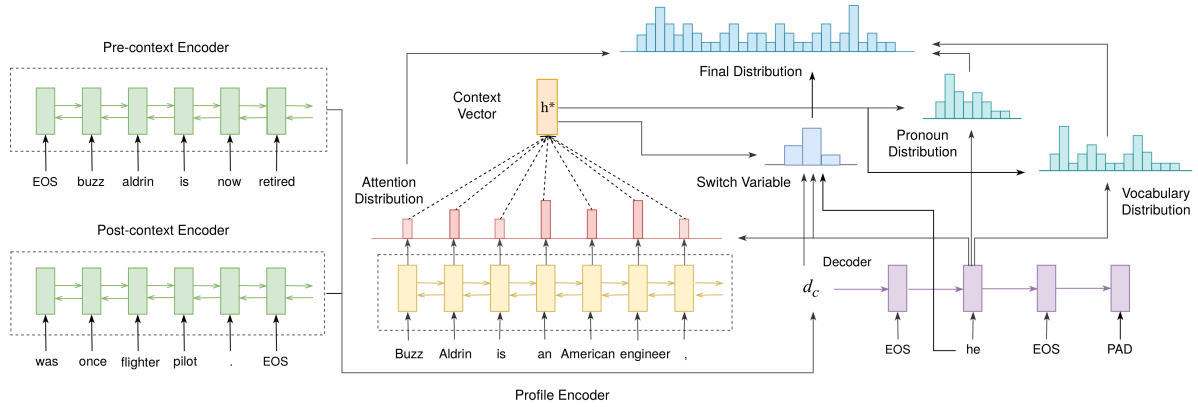

Figure 1: Our PROFILEREG model. The model uses two bi-directional LSTMs (green) to encode the pre- and post-context and one bi-directional LSTM (yellow) to encode the profile. At the decoding step, we calculate three distributions: attention distribution, pronoun distribution and vocabulary distribution. These three distributions together with the switch variable are used to determine the final distribution.

4 Model

In this section, we present our model, PROFILEREG (Figure 1). In our task setup, the input of the model consists of pre- and post-context texts of lengths H and N, and an entity profile of length L. The output is a sequence of tokens that make up the referring expression. We use three bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoders to encode the pre- and post-context and the profile, and a unidirectional LSTM decoder to generate the output at inference time. We also apply an attention mechanism and a switch variable to calculate the final output distribution. We now introduce each component in more detail.

4.1 Context Encoders

We use two bi-directional LSTMs to encode the pre- and post-contexts, which are the entire sequences of tokens before and after the referring expression in the discourse context. The pre-context, a sequence of tokens $\{w_1^{(pre)}, ..., w_H^{(pre)}\}$, is first mapped to a distributed vector space through an embedding layer, resulting in a sequence of vectors $\{x_1^{(pre)}, ..., x_H^{(pre)}\}$. Then, the word embeddings are given to a bidirectional LSTM. We call the forward and backward hidden-state vectors at time t $\overrightarrow{h}_t^{(pre)}$ and $\overleftarrow{h}_t^{(pre)}$ respectively. We extract the two hidden-state vectors at the last step time H, and concatenate them to form the final vector representation $h_H^{(pre)} = [\overrightarrow{h}_H^{(pre)}; \overleftarrow{h}_H^{(pre)}]$, which summarizes the information in the entire pre-context. The same process is repeated for the post-context using another bi-directional LSTM. This results in $h_N^{(post)} = [\overrightarrow{h}_N^{(post)}; \overleftarrow{h}_N^{(post)}]$. Finally, we concatenate the pre- and post-context vector representations and pass them through a hidden layer:

$$d_c = \tanh(W_d[h_H^{(pre)}; h_N^{(post)}]) \quad (1)$$

where W_d is a weight matrix mapping the concatenated hidden state vectors into a joint vector representation d_c, which is used as the initial state of the decoder.

4.2 Profile Encoder

The profile encoder is another bi-directional LSTM that receives a series of profile words $\{w_1, ..., w_L\}$ as input. All words in the profile are first converted to lowercase and mapped to a sequence of word embeddings $\{x_1, ..., x_L\}$ through the same embedding layer as for the pre- and post-contexts. Then the embedded sequence are passed through the bi-directional LSTM, resulting in forward and backward hidden states $\{\overrightarrow{h}_1, ..., \overrightarrow{h}_L\}$ and $\{\overleftarrow{h}_1, ..., \overleftarrow{h}_L\}$. At each word position t, the forward and backward representations are concatenated as the final representation $h_t = [\overrightarrow{h}_t; \overleftarrow{h}_t]$.

We also calculate a character-level embedding for each word using another bidirectional LSTM encoder. The last hidden-state vector of the forward and backward LSTMs are concatenated and given to a separate non-linear layer to form an output vector. This output vector is concatenated with the word-level embedding as our final word representation.

4.3 Attention-based Decoder

Our referring expression decoder is a unidirectional LSTM. At each decoding step t, the decoder receives the word embedding of the previous word and generates a decoder hidden state s_t. Then, we calculate the attention distribution a_t over the entity profile using the attention mechanism introduced by Bahdanau et al. (2014):

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{attn}) \quad (2)$$

$$a^t = \text{softmax}(e^t), \quad (3)$$

where h_i is the sequence of profile encoder hidden states, W_h, W_s, v^T and b_{attn} are all trainable parameters. The attention distribution, a^t, determines the degree of contribution of each token in the profile at expression generation step t. A final summary h_t^* is calculated by summing the profile encoder states h_i weighted by the attention probabilities a^t:

$$h_t^* = \sum_i a_i^t h_i \quad (4)$$

Then, h_t^* is concatenated with the decoder hidden state s_t and passed through a linear layer, producing the vocabulary distribution P_{voc}:

$$P_{voc} = \text{softmax}(V[s_t; h_t^*] + b) \quad (5)$$

where V and b are both trainable parameters in the model. P_{voc} contains the generation probability of each word in the vocabulary. We will actually modify this distribution to account for out-of-vocabulary items and pronouns by introducing a copying mechanism, which we will discuss in the next section. This results in the final generation probability, $P(w_t^*)$ of the target (gold-standard) word at time t.

During training, we take the negative log likelihood of the target word in the gold standard, $\hat{w}_t^*$, as the loss of the model at step t. The overall loss is the sum of the loss at each time step:

$$\text{loss} = \frac{1}{T} \sum_{t=0}^{T} -\log P(\hat{w}_t^*) \quad (6)$$

At test time, the word with the highest generation probability will be the output at the current time step and the input to the next step.

4.4 Switch Mechanism

In PROFILEREG, we apply a switch mechanism that allows the model to generate different referential forms, inspired by the pointer-generator network of See et al. (2017). In particular, our model can choose to: i) **copy** a word from the profile, which is especially useful for named entities with rare names which are not part of a fixed vocabulary, ii) generate a **pronoun**, or iii) **generate** from a fixed vocabulary. Although pronouns are part of our fixed vocabulary, we choose to distinguish them as a separate category to model, due to their importance and frequency in the REG task.

We define a switch variable Σ which can take on one of three values, COPY, PRO, and GEN, corresponding to the three decoder actions. Let the associated probabilities be σ_{COPY}, σ_{PRO}, and σ_{GEN}. After computing h_t^* and vocabulary distribution P_{voc} at time step t, we compute these probabilities using the summary vector h_t^*, the encoder final state d_c, the decoder hidden state s_t and the input x_t:

$$[\sigma_{\text{COPY}}, \sigma_{\text{PRO}}, \sigma_{\text{GEN}}] = \text{softmax}(H_{h^*} h_t^* + H_d d_c + H_s s_t + H_x x_t + b_s), \quad (7)$$

where H_{h^*}, H_d, H_s, H_x and b_s are learnable parameters with output dimension of three. The final generation probability of the target word w_t^* is then computed as follows:

if w_t^* is a pronoun **then**

$$P(w_t^*) = \sigma_{\text{PRO}} P_{voc}(w_t^*) + \sigma_{\text{COPY}} \sum_{i:w_i=w_t^*} a_i^t$$

else if w_t^* is a vocabulary word **then**

$$P(w_t^*) = \sigma_{\text{GEN}} P_{voc}(w_t^*) + \sigma_{\text{COPY}} \sum_{i:w_i=w_t^*} a_i^t$$

else

$$P(w_t^*) = \sigma_{\text{COPY}} \sum_{i:w_i=w_t^*} a_i^t$$

end if

In the formula, a^t is the attention distribution computed in the previous section. When w_t^* is a pronoun or vocabulary word, the probability $P(w_t^*)$ consists of two terms since the word in the vocabulary could also be in the profile. $P(w_t^*)$ will be used in the Equation 6.

One important difference between our model and the pointer-generator network is that the pointer-generator model only computes one *generation probability* $p_{gen} \in [0, 1]$, which is used to decide whether generate a word or copy a token from the source document. In our model, however, we compute a probability distribution S_{switch} over three values. Our intention is that the model can better distinguish between different forms of referring expressions, especially between pronouns and demonstrative or definite description forms.

5 Experiments

We evaluate our model and the baselines on three different data splits mentioned in Section 3.2: **Original**, **Entity-separated** and **Random**, where the entities are overlapped, all separated and randomly mixed in training, validation and test set.

5.1 Baselines

We compared our model against three baselines: *OnlyName*, *Ferreira* and *NeuralREG*. In our first *OnlyName* baseline, we use the name of the entity as the final realization regardless of the context. This baseline is inspired by the fact that 71.4% of the referring expressions in WebNLG are proper names. Given the Wikipedia profile of an entity, we obtain the name of the entity by extracting the first few capitalized words in that profile. If the name cannot be found in this way, we will use the first word of the profile (except articles).

Our second baseline makes use of the Naive Bayes model proposed by Ferreira et al. (2016), dubbed *Ferreira*. This model takes features including syntactic position, referential status (initial or a subsequent mention at the level of text and sentence) and recency (distance between references) as input. The original model is only used to determine the form of the referring expression. We adapt the model by adding a content generation component. Once the form of the referent is decided, the content of the referential expression is decided as follows: we use the *OnlyName* model to get the name of the entity and find the most frequent pronoun expressions in the profile as the content for pronoun form (using "it" if no pronoun expressions can be found). We use the gold-standard content for the demonstrative and description categories from the WebNLG dataset, which provides an upper bound on the potential performance of this system.

Our third baseline is the NeuralREG model proposed by Ferreira et al. (2018). NeuralREG is a sequence-to-sequence neural network model with an attention mechanism. All words and entities in NeuralREG are represented as embeddings which are randomly initialized and learned during training. We tested the best-performing CAtt version of NeuralREG.

5.2 Metrics

Following prior work, we calculate the overall accuracy and the String Edit Distance (SED) between the generated and the reference expressions. The overall accuracy is calculated by comparing the generated string with the real referring expression. We post-processed the output to ignore differences in capitalization, accent and certain non-alphabetic characters (e.g., "Desteaptate" vs. "Deşteaptă-te", and "Tranmere Rovers FC" vs. "Tranmere Rovers F.C.").

We also evaluate the performance of our model with regard to a particular referential form. We computed name accuracy, pronoun accuracy, precision, recall and F1-score. The name and pronoun accuracy are computed by comparing names and pronouns in the test set with the generated referring expressions. Pronoun classification evaluation takes all generated referring expressions as two forms: pronoun or non-pronoun and do not consider the actual content.

5.3 Experiment Setting

For all experiments, our model has 100-dimensional hidden states for the encoder and decoder LSTMs and 50 dimensional for the character LSTM. The word and character embeddings are both set to 100-dimensional. We initialize the word embeddings using pre-trained GloVe vectors (Pennington et al., 2014) and all character embeddings are randomly initialized. The model is trained for up to 35 epochs, or until the performance on the development set does not improve for 5 epochs. We set the learning rate to 0.0037 and the batch size to 64. We apply gradient clipping with a maximum gradient norm of 5. We adopt dropout training with a dropout rate of 0.5. At test time, all referring expressions are generated using greedy decoding. These settings were selected by tuning on the development set.

6 Results

6.1 Automatic Evaluation

As shown in Table 2 PROFILEREG outperforms the three baselines in all experiments. Our model in particular excels at the measures of pronoun accuracy and pronoun classification.

On the **Original** dataset, our model is slightly better than NeuralREG in total accuracy and SED. This result indicates that our model is as good as or better than NeuralREG model when dealing with previously seen entities. On pronoun classification, *OnlyName* model has a performance of zero since it cannot generate any pronouns.

Dataset	Models	SED	Total Acc.	Name Acc.	Pronoun Acc.	Pronoun Classif.		
						Prec.	Rec.	F1
Original	OnlyName	5.57	53.47%	66.22%	0.00%	0.00	0.00	0.00
	Ferreira	4.56	56.50%	65.11%	63.58%	0.60	0.96	0.74
	NeuralREG	2.33	74.13%	**81.64%**	74.92%	0.77	0.78	0.78
	PROFILEREG	**2.22**	**74.67%**	80.51%	**87.17%**	0.72	0.89	**0.80**
Entity-separated	OnlyName	6.28	54.71%	61.44%	0.00%	0.00	0.00	0.00
	Ferreira	5.91	55.67%	60.11%	64.25%	0.45	0.97	0.61
	NeuralREG	–	–	–	–	–	–	–
	PROFILEREG	**5.17**	**60.60%**	**67.20%**	**75.57%**	0.53	0.80	**0.64**
Random	OnlyName	5.59	53.21%	67.02%	0.00%	0.00	0.00	0.00

	PROFILEREG	**2.11**	**75.33%**	**81.85%**	**83.89%**	0.76	0.85	**0.80**

Table 2: REG performance on the original, entity separated and random dataset. PROFILEREG is the model proposed in this work. Note that NeuralREG cannot be applied to the entity-separated dataset.

Entity-separated demonstrates our model's ability to handle new entities, compared to the baselines. There is a clear drop on most metrics compared to the original dataset, but this is expected since the test set consists of unseen entities. As previously explained, the NeuralREG model cannot be applied to this dataset without extensive modifications. On **Random**, PROFILEREG outperforms NeuralREG. For the unseen entities, NeuralREG generates a random string, since the embeddings of unseen entities are not updated by training. Our model, however, is capable of producing accurate referring expressions for both previously mentioned and new entities.

Table 3 shows an example of the generated text of each model. The entity in this example is *Acharya Institute of Technology*. Note that only the bold text is generated by the models. The output of the *OnlyName* model is clearly the least readable one.

6.2 Seen Entities vs. Unseen Entities

In the evaluation, we also distinguished the results for seen and unseen entities. We trained the model on a training set contains 64,353 referring expressions and evaluate the model on a test set with 3,591 referring expressions related to seen entities and 2,955 expressions related to unseen entities. Table 4 shows the evaluation results. From Table 4, it is easy to see that the model performs better when generating referring for seen entities. Among four referring expression types, the accuracy of description type drops dramatically for unseen entities, from 48.72% to 20.54%. This is probably due to the fact that compared with name and pronoun, description type is often hard to identify and more flexible. For instance, one of the gold-standard descriptions in the test set is *the comic character , amazing-man*. The model's generation for this referring expression is *amazing-man*.

Also notice that the accuracy of demonstrative type is zero for both seen and unseen entities. We think this is because the dataset is unbalanced and there are too few demonstrative samples in the training set. The model did not have enough samples to learn to identify demonstratives.

6.3 Human Evaluation

Method. In addition to automatic evaluation, we also performed a human evaluation, comparing our model to the original text and to the three baseline models. We concatenated the pre- and post-contexts with the generated referring expression to form an overall passage. We showed participants the output of our model and a comparison model, and asked them to make a pairwise preference judgment between the two passages.

Specifically, we randomly selected 100 samples from the **Random** test set. We presented the two

passages in random order, asking participants to consider the readability, grammaticality and fluency of texts. We then asked them to select the passage that they prefer, or to say they are equally good. We recruited 20 participants, each evaluating 20 samples.

Results. Figure 2 shows the human evaluation results. The most common choice made by participants is "equal". This is because many generated referring expressions by the models are actually identical. When our model was compared to the original text, 86 of the 100 generated texts are identical or very similar to the original text. This demonstrates our model's ability to generate high quality referring expressions. Also, we can see from the chart that our model tends to be preferred over the three baseline models.

6.4 Analyzing Switch Variable Behaviour

We now examine the behaviour of the switch variable, Σ. As mentioned in Section 4.4, each word is generated with a probability distribution (σ_{COPY}, σ_{PRO} and σ_{GEN}). We expect this distribution to vary based on the form of the referring expression. For instance, when a proper name expected, σ_{COPY} should be relatively high if the model copies words from the entity profile.

Table 5 shows three examples of generated referring expressions with the values of the switch

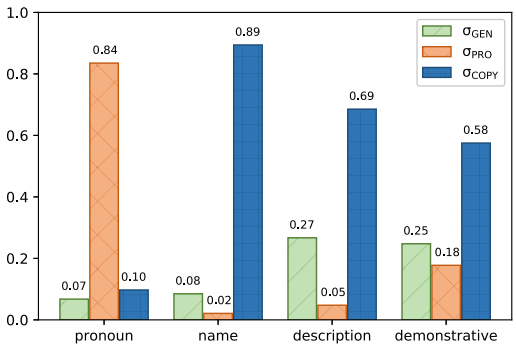

Figure 3: The average probabilities of the switch variable values for each referential form on the **Random** test set.

variable. We put the gold-standard referring expression, pre- and post-context together in Context. The words in yellow, green and orange highlight are copied words, vocabulary words and generated pronouns respectively and each word is followed by the corresponding switch value. These examples show that our model is able to switch between the three actions to generate a coherent, fluent referring expression. We further show the average value of the switch variable on the **Random** test set separated by the gold-standard referential form (Figure 3).

7 Conclusions

In this work, we have proposed new test setups on WebNLG dataset that evaluate the performance of REG models when dealing with previously unseen entities. We also introduced PROFILEREG, an end-to-end deep neural network model for REG. Unlike previous REG models that only model the local context, PROFILEREG incorporates both the context information and an entity profile that allows it to generate references for unseen entities. Our results show that PROFILEREG can accurately generate referring expressions for both new and previously mentioned entities, outperforming three strong baselines. One future direction is to model larger contexts with this approach. It would also be interesting to integrate our model into an existing language generation system (e.g., as part of an abstractive summarization system).

Acknowledgments

We would like to thank the reviewers for their valuable comments. This research was supported by the Mitacs Globalink Program and the Canada CIFAR AI Chair program.

Abstract

Paraphrasing plays an important role in various natural language processing (NLP) tasks, such as question answering, information retrieval and sentence simplification. Recently, neural generative models have shown promising results in paraphrase generation. However, prior work mainly focused on single paraphrase generation, while ignoring the fact that diversity is essential for enhancing generalization capability and robustness of downstream applications. Few works have been done to solve diverse paraphrase generation. In this paper, we propose a novel approach with two discriminators and multiple generators to generate a variety of different paraphrases. A reinforcement learning algorithm is applied to train our model. Our experiments on two real-world datasets demonstrate that our model not only gains a significant increase in diversity but also improves generation quality over several state-of-the-art baselines.

1 Introduction

Paraphrases refer to texts with identical meaning but expressed in different ways. Paraphrase generation has a wide range of applications. For example, paraphrases can be used to extend the reference texts for the automatic evaluation of text generation tasks, which make the evaluation more robust and accurate (Madnani and Dorr, 2010). In addition to increasing reference texts, paraphrases can also augment training data for text classification problems, especially for tasks lack of training data. Besides, paraphrases can be used as variations of queries for information retrieval and question answering systems. Query paraphrasing can narrow the gap between system comprehension and user questions (Fader et al., 2014; Yin et al., 2015). And systems can obtain better results from multiple feedbacks for different query variants.

Traditional paraphrase generation approaches leverage manual-crafted rules (McKeown, 1983; Hassan et al., 2007). In recent years, sequence to sequence learning techniques have achieved improvements in a variety of NLP tasks, such as machine translation (Bahdanau et al., 2014; Cho et al., 2014), text summarization (Nallapati et al., 2016) and dialogue systems (Serban et al., 2017). Specifically, the paraphrase generation can also be formulated as a sequence to sequence problem. Existing neural paraphrase generation works (Prakash et al., 2016; Gupta et al., 2018; Li et al., 2018) also demonstrate the effectiveness of deep learning method.

Although prior paraphrase generation methods mainly consider only one single output for each input, the nature of paraphrasing indicates that we can paraphrase one sentence into several different sentences. Therefore, we hope to generate a variety of paraphrases while ensuring quality. However, most of the previous work dedicated to improving the quality of top generated sentence, but did not conduct in-depth research on the diversity of paraphrase generation. In fact, diversity is very important in many applications. More diverse paraphrases will be beneficial to robustness and accuracy of automatic text evaluation, text classification, and can avoid the blandness caused by repetitive patterns.

A straightforward way to generate multiple different sentences is using beam search to select the top k sentences. However, beam search generates suboptimal sentences, and the resulting sentences are very similar to each other. Gupta et al. (2018) employ a variational auto-encoder framework to produce multiple sentences according to different noise input. Xu et al. (2018b) learn a shared decoder with different decoder embeddings for various decoding pattern. Although we can get multiple outputs with different noise inputs or de-

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

coder embeddings, different outputs may have slight changes or even no difference.

In order to address the problem, in this paper, we utilize multiple generators to generate diverse paraphrases without sacrificing quality. Reinforcement learning makes it possible for every generator to explore different generation pattern, breaking the restriction of learning the same target sentences given by data in supervised learning. Thus, we design a reinforcement learning algorithm to guide the models learning procedure. The proposed framework contains two discriminators. One discriminator is to examine whether two sentences convey the same meaning, the other one is to distinguish the sentence is generated by which generator. The higher the confidence of one text be judged as generated by a certain generator is, indicating the more obvious the differences between that text and texts generated by other generators are. We combine the scores of the two discriminators as guiding signals to the generators using reinforcement learning. Therefore, generators can learn to synthesize texts with apparent differences and good quality.

Our approach can automatically discover the solution to diverse paraphrase generation through the jointly learning of the discriminators and generators. And the model uses the same data pairs as in learning mono-paraphrase generation without extra annotations. Experiments on two real-world datasets show that our model improves both in quality and diversity. There are mainly two contributions in our work: the first one is proposing a novel framework as well as a corresponding learning procedure to generate various paraphrases, the second one is performing experiments demonstrating that our method achieves improvement regarding both generation diversity and quality.

2 Related Work

Paraphrase generation In the early years, various traditional techniques have been developed to solve the paraphrase generation problem. McKeown (1983) makes use of manually defined rules. Hassan et al. (2007) use thesaurus-based method for lexical substitution. And statistical machine translation (SMT) has also been used. Quirk et al. (2004) train SMT tools on a large number of sentence pairs collected from newspapers. Wubben et al. (2010) propose a phrase-based SMT model trained on aligned news headlines. Zhao et al. (2008) utilize multiple resources to strengthen a log-linear SMT model. Recently, deep neural models have also been applied to paraphrase generation due to their great success on natural language processing tasks. Prakash et al. (2016) design a deep stacked network with residual connections, Gupta et al. (2018) propose a conditional variational auto-encoder which can produce multiple paraphrases, Iyyer et al. (2018) learn a model to generate syntactically controlled paraphrase, Li et al. (2018) propose a generator-evaluator architecture coupled with deep reinforcement learning. Although being similar to the architecture proposed in (Li et al., 2018), our framework targets a different goal. Our work focuses on generating multiple diverse paraphrases, while theirs dedicates to improving the quality of the top generated paraphrase. The main difference is that our approach utilizes a generator discriminator to encourage more diverse paraphrases, which is essential for diversity.

Diverse text generation A few works have explored to produce diverse generation by changing decoding schemes or introducing random noise. Methods that change decoding schemes are orthogonal and complementary to our work. Li et al. (2016) modify the score function in decoding to encourage usage of novel words and penalize words after the same partially generated sentence. Dai et al. (2017) utilize conditional generative adversarial network (GAN) to generate diverse image caption according to the input noise. Gupta et al. (2018) employ a variational auto-encoder framework with both encoder and decoder conditioned on source input. Shi et al. (2018) employ inverse reinforcement learning for unconditional diverse text generation. Xu et al. (2018a) propose a modified GAN to generate diverse and informative outputs for different inputs. Xu et al. (2018b) train a generator with different embeddings to generate multiple paraphrases, only the decoder embedding with lowest cross entropy can get updated.

3 Methods

3.1 Problem Definition

Given a source sentence X, we aim to generate multiple target sentences $S = \{Y_1, Y_2, ..., Y_k\}$. Specifically, our goal is to learn a model which can generate S such that every Y_i (i=1..k) has the

same meaning as X and obvious differences between each other.

3.2 Models

Our diverse paraphrase generation framework consists of three parts: one paraphrase discriminator, one generator discriminator and multiple generators. Paraphrase discriminator determines whether two sentences have the same meaning, and the generator discriminator determines the sentence is generated by which generator. The goal of multiple paraphrase generators is to generate sentences that are judged as paraphrases of the input sentence, and the differences between sentences should be as large as possible. The intuition is that sentences with quite different expressions can be easily distinguished by the generator discriminator and will be judged as generated by the corresponding generator with high confidence.

3.2.1 Paraphrase generator

We frame paraphrase generation as a sequence-to-sequence (Seq2Seq) problem and adopt the encoder-decoder framework. Multiple generators share the same encoder yet with their own decoder. The generation posterior of the i-th generator is:

$$G_i(Y|X) = \prod_{t=1}^{T} P(y_t|y_{1:t-1}, X; \theta_i),$$

where $y_{1:t-1}$ indicates the subsequence from timestep 1 to timestep $t-1$, T denotes the length of output sentence Y, θ_i represents the parameter of the i-th generator, we omit θ_i in the following illustration for conciseness. We use pointer-generator (See et al., 2017) for our generators to alleviate the out-of-vocabulary problem and enhance the performance. In pointer-generator, the decoder can generate not only words from the chosen vocabulary as standard decoders but also words from the input sentences by copying them from the input. The probability of copying words can be represented as

$$p_{copy}(y_t|y_{1:t-1}, X) = a_{ti},$$

$$a_{ti} = \frac{exp(f(s_{t-1}, h_i))}{\sum_i exp(f(s_{t-1}, h_i))},$$

where s_{t-1} is the decoder state at timestep $t-1$, h_i is the encoder hidden state at timestep i. p_{copy} is actually a_{ti}, which is the attention distribution at timestep t. We use attention in (Bahdanau et al., 2014), thus f is a linear function. The probability of extracting the next word from vocabulary is:

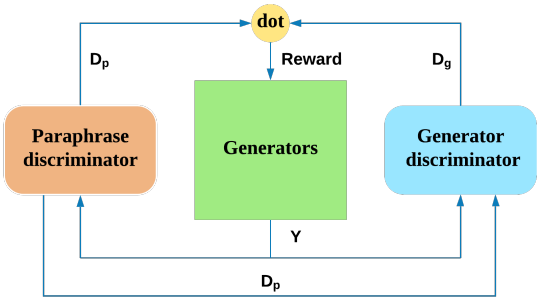

Figure 1: The overall framework

$$p_{vocab}(y_t|y_{1:t-1}, X) = g(s_{t-1}, y_{t-1}, c_t),$$

$$c_t = \sum_i a_{ti} * h_i,$$

where y_{t-1} is the word generated last step, c_t means the context vector at timestep t, g is a linear function with softmax output. The overall probability of the next word is

$$p(y_t|y_{1:t-1}, X) = p_{gen} * p_{vocab} + (1 - p_{gen}) * p_{copy},$$

$$p_{gen} = m(s_t, y_{t-1}, c_t)$$

where m is a linear transformation with sigmoid activation output. p_{gen} acts as a gate to control whether the next word is generated from vocabulary or is copied from the input.

3.2.2 Paraphrase discriminator

We follow (Li et al., 2018) to cast paraphrase recognition as a sentence matching problem. In our work, we use a model with two recurrent neural networks (RNN). Assume giving a pair of sentences (X, Y), paraphrase discriminator will score a value to evaluate the semantic similarity between X and Y.

$$\alpha = RNN_\alpha(X),\ \beta = RNN_\beta(Y),$$

$$\gamma = \tanh(W_\alpha * \alpha + b_\alpha) * \tanh(W_\beta * \beta + b_\beta),$$

$$D_p = softmax(W_p * f_c(\gamma) + b_p),$$

sentence X and sentence Y are encoded using RNN-based encoder. The encoded representations α and β are integrated into γ. Then we input γ into a fully connected network f_c and finally output a softmax classification probability, which represents the degree of meaning similarity between

X and Y. We optimize the cross entropy loss for paraphrase discriminator.

$$L = -\log(D_p(X, Y+)) - \log(1 - D_p(X, Y-)),$$

where$(X, Y-)$ means sentence $Y-$ is not a paraphrase of X and $(X, Y+)$ means sentence $Y+$ is a paraphrase of X. Paraphrase discriminator separate the negative sentence pairs from the positive ones.

3.2.3 Generator discriminator

In order to distinguish sentences generated by different generators, we learn a sentence discriminator. Suppose there is a set of sentences $\{S_1, S_2, ..., S_k\}$, where S_i denotes sentences generated by the i-th generator. We hope our generator discriminator can separate sentences in S_i $(i = 1..k)$ from sentences generated by other generators. If there are obvious differences between sentences in S_i and those generated by other generators, generator discriminator can determine the sentence is generated by the i-th generator with high confidence. Otherwise, if sentences in S_i are very similar to those generated by other generators, generator discriminator will get confused and misclassify the sentences into another generator, thus confidence will be low as well. For simplicity, we use a RNN to extract feature from sentences and use a softmax output as activation function.

$$e = RNN(Y),\ D_g(y|Y) = softmax(e)$$

where e indicates the sentence feature and y means which generator generates Y. The generator discriminator is pretrained using data generated by the pretrained generators. During the reinforcement learning phase, generator discriminator updates iteratively using new samples produced by all generators.

3.3 Learning

3.3.1 Maximum likelihood estimation

The most typical technique to train a Seq2Seq model is teacher forcing (Williams and Zipser, 1989), which is also referred to as maximum likelihood estimation (MLE).

$$L = \sum_{t=1}^{T} \log p(y_t^* | y_{1:t-1}^*, X) \qquad (1)$$

where y_t^* denotes the t-th word in the target sentence given by training sample. We pretrain all generators using teacher forcing. However, teacher forcing suffers from exposure bias (Ranzato et al., 2015). During training, the next word to generate is conditioned on the correctly annotated word subsequence. But in the inference stage, the model predicts the next word conditioned on words generated by itself, which causes inconsistency between training and inference. As model may generate wrong words, future generation conditioned on the generated subsequence will also be affected, leading to accumulated errors. One solution to this problem is finetuning generators via reinforcement learning after pretraining.

Algorithm 1: Training Procedure of our framework

Input : A data with paraphrase pairs $\{(X, Y)\}$ and non-paraphrase pairs $\{(X, Y-)\}$
Output : Generators $\{G_i\}_{i=1}^{i=k}$

Random initialize all generators $\{G_i\}_{i=1}^{i=k}$;
Pre-train all generators G_i with $\{(X, Y)\}$;
Generate sentences $\{S_i\}_{i=1}^{i=k}$, $S_i = \{\hat{Y}\}_i$ using G_i;
Train paraphrase discriminator with $\{(X, Y)\}$ and $\{(X, Y-)\}$;
Pre-train generator discriminator with $\{S_i\}_{i=1}^{i=k}$;
while *not converge* **do**
    Sample sentences $\{X\}$ from the paraphrase corpus;
    for $i = 1$ *To* k **do**
        Using G_i to generate sentences $\{\hat{Y}\}_i$ by sampling and $\{\bar{Y}\}_i$ by greedy search;
        Compute the rewards using Eq(3);
        Update generators by minimizing Eq(4);
    end
    Generate sentences $\{S_i\}_{i=1}^{i=k}$ using $\{G_i\}_{i=1}^{i=k}$;
    Update generator discriminator with $\{S_i\}_{i=1}^{i=k}$ by minimizing Eq(7);
end
Return $\{G_i\}_{i=1}^{i=k}$

3.3.2 Reinforcement learning

Regarding a generator as an agent interacting with the environment (i.e. the word input and context vector). The objective function of the generator can be written as

$$L = \sum_{\hat{Y}} R(\hat{Y}), \hat{Y} \sim \pi_\theta \qquad (2)$$

$\hat{Y}$ indicates the word sequence sampled from the generator. R is the reward function, and a batch of sentences is sampled to approximate the objective function since it is intractable to use all sentences. The optimization objective is to minimize the negative expected rewards of generated texts, in other words, maximize the expected rewards.

The reward of each sentence is determined by the paraphrase discriminator and the generator discriminator together. The reward of the i-th generator is

$$R_i = D_p(X, Y_i) \odot D_g(y = i|Y_i), \quad (3)$$

where Y_i indicates the sentence generated by the i-th generator. The i-th generator can get a high reward only when sentence Y_i is recognized as a paraphrase of X by the paraphrase discriminator and the differences between Y_i and sentences generated by other generators is so large that generator discriminator takes Y_i as a sentence generated by the i-th generator.

Specifically, we use the self-critical algorithm (Rennie et al., 2017) as our reinforcement learning method. In order to reduce the variance of policy gradient method, a typical technique is subtracting baseline values from the original rewards. In the self-critical algorithm, the baseline is the reward of sentences generated in inference. At each training iteration, the generator generates two sentences. One sentence is sampled from the output probability distribution, $\hat{y}_t \sim p(y_t|\hat{y}_{1:1-t}, X)$. The other sentence is generated by greedy search, $\bar{y}_t = \arg\max_{y_t} P(y_t|\bar{y}_{1:t-1}, X)$, the word with the highest probability is selected at each step. The reward of the sentence generated by greedy search is used as a baseline. We use rewards subtracted by baseline values to update the model

$$L = \sum_{t=1}^{T} (R(\hat{y}) - R(\bar{y})) \log p(y_t|y_{1:t-1}, X), \quad (4)$$

which means that we compare the rewards of the sampled sentences $\hat{y}$ and those of the sentences $\bar{y}$ which are produced by greedy search. Only the generated sentences that outperform the sentence $\bar{y}$ are given positive signals. As a result, Rewards will be increased as the generators increase the generation probability of better sequences while decreasing the chances of worse sequence generation.

3.3.3 The overall objective

Our goal is to generate multiple diverse paraphrases of high quality. We illustrate the reason why our model can achieve this goal from the aspect of the whole optimization objective. Given input X, we hope to generate multiple high-quality sentences Y. We make the assumption that y is only dependent on Y, that is, $D_g(y|Y, X) = D_g(y|Y)$. The weaker condition forces the generator discriminator to only focus on the generated sentences and encourages stronger diversity. The overall objective can be written as:

$$\begin{aligned} &\sum_{Y} R(X, Y) P(Y|X) \\ =&\sum_{Y} \sum_{y} R(X, Y) P(Y, y|X) \\ =&\sum_{Y} \sum_{i=1}^{k} R(X, Y) D_g(y = i|Y) G_i(Y|X) \end{aligned} \quad (5)$$

where $R(X, Y)$ is the reward evaluating output Y for input sentence X. Multiple generators G_i generate their own sequences for each input and D_g learns to separate sentences generated by different generators. We can define different rewards for corresponding applications and we use $D_p(X, Y)$ for our paraphrase task. We define θ_d as the parameter of generator discriminator and θ_i as the parameter of the i-th generator. The derivative of $J(\theta)$ is computed as follow:

$$\begin{aligned} &\nabla_\theta J(\theta) \\ =&\sum_{i=1}^{k} \sum_{Y} [R(X, Y) G_i(Y|X) \nabla_{\theta_d} D_g(y = i|Y) \\ &\quad + R(X, Y) D_g(y = i|Y) \nabla_{\theta_i} G_i(Y|X)] \\ =&\sum_{i=1}^{k} \mathbb{E}_{G_i(Y|X)} [R(X, Y) \nabla_{\theta_d} D_g(y = i|Y) \\ &\quad + R(X, Y) D_g(y = i|Y) \nabla_{\theta_i} \log(G_i(Y|X))] \end{aligned} \quad (6)$$

Since the gradient can not be propagated backward to G_i and D_g by gradient descent, we use reinforcement learning to update both D_g and G_i. And directly optimizing the above objective will reduce the reward of a good output Y^* to zero for all generators except the one with the highest generation probability for this output Y^*. We should lower the reward of that good output for other generators, but reducing the reward of Y^* to zero will affect the stability of other generators. To address this issue, we can regularize D_g by adding entropy or we propose to scale the gradient of D_g by $1/D_g$. The derived cost function of generator discriminator is:

$$L = -\sum_{i=1}^{k} \mathbb{E}_{G_i(Y|X)} R(X, Y) \log(D_g(y = i|Y)) \quad (7)$$

The outputs generated by G_i are not equally contributed to $D_g(y = i|Y)$, outputs that have better quality are more encouraged by D_g. High-quality sentences Y generated by G_i maximize $D_g(y = i|Y)$ while minimizing $D_g(y = j|Y)$ $(j \neq i)$ to force other generators to generate different sentences. The i-th generator maximizes $R(X, Y)D_g(y = i|Y)$ so that sentences generated by the i-th generator satisfy both the quality and diversity requirement. The complete learning procedure is shown in algorithm 1.

4 Experiment

4.1 Dataset

	Generator			Paraphrase discriminator	
Dataset	#Train	#Validation	#Test	#Positive	#Negative
Quora	100K	3K	30K	100K	160K
Twitter	110K	1K	5K	10K	40K

Table 1: Statistics of datasets.

To validate our model's capability to generate diverse paraphrases, we conduct experiments on two real-world datasets: Quora question paraphrase dataset [1] and Twitter URL paraphrasing dataset (Lan et al., 2017).

Quora dataset contains a large corpus of question pairs collected from Quora. The Quora dataset totally contains about 400k data pairs. All the data are manually labeled whether two sentences convey the identical meaning. We randomly select 100k pairs for training, 3k for validation and 30k for test. The twitter dataset contains sentence pairs collected from Twitter. It also marks whether the sentence pairs are paraphrases. But the difference is that some of them are manually labeled and some are automatically labeled by the algorithm. For generators, we split test set and validation set from the manually labeled subset. The training set contains the rest data from the manually labeled subset and data from the automatically labeled paraphrase pairs. In order to avoid bias induced by the labelling algorithm, we only use the manually labeled data for the paraphrase discriminator. A summary of dataset statistics is given in Table 1.

4.2 Evaluation metric and baseline

We evaluate our model's performance for both quality and diversity. For sentence quality, we use two commonly used metrics: BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007). BLEU measures word overlapping between generated sentences and reference texts. METEOR introduces stemming and synonym matching to alleviate problems caused by only exact matching in BLEU. BLEU and METEOR scores are averaged for multiple generated sentences. To evaluate sentence quality more reliably, we also conduct human evaluations to compare the quality of sentences generated by different models. For diversity, we use self-BLEU (Zhu et al., 2018). To compute self-BLEU of a set of outputs, every output is picked once as candidate and others are used as references to compute BLEU score. And the average of all the BLEU scores computed for this set is self-BLEU. A lower self-BLEU score indicates better diversity.

Several basic models and existing neural-based methods are used as baseline models for comparison. For both datasets, we report results of attentive Seq2Seq (Bahdanau et al., 2014), variational auto-encoder (VAE-SVG-eq) (Gupta et al., 2018), conditional GAN (Dai et al., 2017) with the generator replaced by Seq2Seq, diversity-promoting GAN (DP-GAN) (Xu et al., 2018a), the generator with inverse reinforcement learning (IRL) (Shi et al., 2018), the generator with multiple decoder embeddings (D-PAGE) (Xu et al., 2018b) and pointer-generator (See et al., 2017). We use beam search for attentive Seq2Seq (Seq2Seq-BS), and pointer-generator (PG-BS) to generate multiple outputs. Top three outputs of each method are obtained for evaluation.

4.3 Implementation

We use the following experimental setting for our model. For generators, we randomly initialize all generators and train them by teacher forcing in the same way. We use three generators and utilize single-layer LSTM (Hochreiter and Schmidhuber, 1997) for both encoder and decoders. The hidden dimension of encoder and decoders is set to 256, the word embedding dimension is 128. We use Adam optimizer (Duchi et al., 2011) with a learning rate of 1e-3 in MLE pretrain. In reinforcement learning, the learning rate decreases to 2e-5 and the batch size is fixed at 32. We also use ground-truth with reward of D_g to stabilize the training. We strengthen the performance of D-PAGE by replacing the basic Seq2Seq with pointer-generator.

Table 4: Human evaluation results.

For paraphrase discriminator and generator discriminator, the sentence encoders are all built with one-layer LSTM with 256-dimensional hidden units and the dimension of word embeddings is set to 256. For each of the two discriminators, Adam optimizer with a learning rate of 1e-4 is used to optimize the loss function. The batch size is kept at 64 for paraphrase discriminator. We employ a 3-layer fully connected network with ReLU activation in paraphrase discriminator and set the dropout to 0.2.

5 Results

Results of automatic evaluation on Quora is shown in Table 2. Our model achieves the best METEOR score among all the models. As BLEU only calculate the exact overlapping between generated sentences and reference sentences, lower BLEU score does not necessarily indicate bad quality. In addition, every test case only has one reference text, which makes automatic evaluation more difficult to measure the real quality of multiple generated sentences. Since METEOR compares the generated sentences with the reference text using not only exact word matching but also stemming and synonym matching, we believe it measures the generation quality more accurately.

For human evaluation, we randomly select 100 input sentences from the test set of each dataset and get the generated results of different models for these inputs. We follow the human evaluation guideline in (Li et al., 2018). The sentence pairs are scored for two aspects of the generated results: *fluency* (whether the generated sentence is fluent and grammatical) and *consistency* (the meaning similarity between the input sentence and the generated sentence). Each output is given two ratings, scaling from 1 to 5, on fluency and consistency separately. An input and outputs generated for the input from different systems form a test group. The outputs from different systems in the test group are shuffled. The test groups are randomly assigned to annotators. Every test group is evaluated by two annotators and scores for each output are averaged. The agreement between annotators is moderate (kappa=0.54). The final score for each system is the average score for all outputs. Table 4 shows our model achieves better scores in both meaning similarity and fluency than baseline models.

Table 5: Example paraphrases on Quora

In terms of diversity, our approach outperforms other methods by a large margin. VAE-SVG-eq, GAN and D-PAGE do not show better results than beam search. As discussed in (Xu et al., 2018b), beam search guarantees that multiple generated sentences are different from each other by at least one word, which yields better diversity. GAN methods often suffer from mode collapse problems and generate similar outputs. For VAE-SVG-eq, different random noise sampled from a Gaussian prior is used identically in training, so different noise inputs may produce the same sentences. The generator with IRL and DP-GAN have no obvious improvement in diversity in our task. Although the generator with IRL and DP-GAN also claim to improve diversity, their goal is essentially different from ours. The generator with IRL was proposed to tackle the unconditional text generation problem, where texts are generated without any input or condition. DP-GAN generates a more informative output for each input to avoid repetitive response for different inputs. In the experiment, we notice that VAE-SVG-eq and GAN generate similar or even identical sentences according to different random noise, which is consistent with the results posted in (Xu et al., 2018b). D-PAGE may able to find different patterns for very short sentences or phrases, but results in our experiments show that D-PAGE does not separate different patterns in longer sentences and the generated sentences lack diversity.

Table 3 shows scores on Twitter dataset. Our model achieves the best BLEU score and outperforms all baselines for METEOR. The human evaluation results presented in table 4 also show that our model produces better quality paraphrases. For diversity, our model again performs considerably better than other models. Since part of sentence pairs in Twitter dataset may be mislabelled by the labeling algorithm, it is harder to generate high-quality paraphrases on Twitter. Paraphrases generated by our model have not only more diverse expression but also better quality compared to those generated by other models.

Table 5 demonstrates some examples generated by pointer-generator using beam search and our model. Although pointer-generator indeed generates different sentences, it only yields little diversity. Sentences produced by pointer-generator can be very similar, many of them only differ from others by one word. Compared to sentences generated by pointer-generator, those produced by our model has obvious differences between each other. In the first example, our model uses different types of interrogative. In contrast, pointer-generator generates sentences that are almost the same. In the second example, pointer-generator generates similar sentences and yields obvious meaning changes from the input sentence. The sentences generated by our model are in different expressions and more relevant to the input sentence. In the third example, the sentences generated by pointer-generator show minor variations, while those generated by our model present richer expressions.

6 Conclusion

In this paper, we present a novel approach to generate diverse paraphrases. Multiple generators are pretrained in the same way, then learn different generation pattern and enhance generation quality via reinforcement learning. Paraphrase discriminator evaluates the meaning similarity between two sentences, generator discriminator distinguishes sentences generated from different generators. Experiments show that our model has better results concerning both diversity and quality. In the future, we would like to apply our framework to increase reference texts for automatic evaluation or augment training data for text classification.

Abstract

Generating text from graph-based data, such as Abstract Meaning Representation (AMR), is a challenging task due to the inherent difficulty in how to properly encode the structure of a graph with labeled edges. To address this difficulty, we propose a novel graph-to-sequence model that encodes different but complementary perspectives of the structural information contained in the AMR graph. The model learns parallel top-down and bottom-up representations of nodes capturing contrasting views of the graph. We also investigate the use of different node message passing strategies, employing different state-of-the-art graph encoders to compute node representations based on incoming and outgoing perspectives. In our experiments, we demonstrate that the dual graph representation leads to improvements in AMR-to-text generation, achieving state-of-the-art results on two AMR datasets[1].

1 Introduction

Abstract Meaning Representation (AMR; Banarescu et al. (2013)) is a linguistically-grounded semantic formalism that represents the meaning of a sentence as a rooted directed graph, where nodes are concepts and edges are semantic relations. As AMR abstracts away from surface word strings and syntactic structure producing a language neutral representation of meaning, its usage is beneficial in many semantic related NLP tasks, including text summarization (Liao et al., 2018) and machine translation (Song et al., 2019).

The purpose of AMR-to-text generation is to produce a text which verbalises the meaning encoded by an input AMR graph. This is a challenging task as capturing the complex structural information stored in graph-based data is not trivial, as these are non-Euclidean structures, which implies that properties such as global parametrization, vector space structure, or shift-invariance do not hold (Bronstein et al., 2017). Recently, Graph Neural Networks (GNNs) have emerged as a powerful class of methods for learning effective graph latent representations (Xu et al., 2019) and graph-to-sequence models have been applied to the task of AMR-to-text generation (Song et al., 2018; Beck et al., 2018; Damonte and Cohen, 2019; Guo et al., 2019).

In this paper, we propose a novel graph-to-sequence approach to AMR-to-text generation, which is inspired by pre-neural generation algorithms. These approaches explored alternative (top-down, bottom-up and mixed) traversals of the input graph and showed that a hybrid traversal combining both top-down (TD) and bottom-up (BU) information was best as this permits integrating both global constraints top-down from the input and local constraints bottom-up from the semantic heads (Shieber et al., 1990; Narayan and Gardent, 2012).

Similarly, we present an approach where the input graph is represented by two separate structures, each representing a different view of the graph. The nodes of these two structures are encoded using separate graph encoders so that each concept and relation in the input graph is assigned both a TD and a BU representation.

Our approach markedly differs from existing graph-to-sequence models for MR-to-Text generation (Marcheggiani and Perez Beltrachini, 2018; Beck et al., 2018; Damonte and Cohen, 2019) in that these approaches aggregate all the immediate neighborhood information of a node in a single representation. By exploiting parallel and complementary vector representations of the AMR graph, our approach eases the burden on the neural model in encoding nodes (concepts) and edges (relations) in a single vector representation. It also elimi-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3183–3194, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

nates the need for additional positional information (Beck et al., 2018) which is required when the same graph is used to encode both TD and BU information, thereby making the edges undirected.

Our main contributions are the following:

- We present a novel architecture for AMR-to-text generation which explicitly encodes two separate TD and BU views of the input graph.
- We show that our approach outperforms recent AMR-to-text generation models on two datasets, including a model that leverages additional syntactic information (Cao and Clark, 2019).
- We compare the performance of three graph encoders, which have not been studied so far for AMR-to-text generation.

2 Related Work

Early works on AMR-to-text generation employ statistical methods (Flanigan et al., 2016b; Pourdamghani et al., 2016; Castro Ferreira et al., 2017) and apply linearization of the graph by means of a depth-first traversal.

Recent neural approaches have exhibited success by linearising the input graph and using a sequence-to-sequence architecture. Konstas et al. (2017) achieve promising results on this task. However, they strongly rely on named entities anonymisation. Anonymisation requires an ad hoc procedure for each new corpus. The matching procedure needs to match a rare input item correctly (e.g., "United States of America") with the corresponding part in the output text (e.g., "USA") which may be challenging and may result in incorrect or incomplete delexicalisations. In contrast, our approach omits anonymisation. Instead, we use a copy mechanism (See et al., 2017), a generic technique which is easy to integrate in the encoder-decoder framework and can be used independently of the particular domain and application. Our approach further differs from Konstas et al. (2017) in that we build a dual TD/BU graph representation and use graph encoders to represent nodes.

Cao and Clark (2019) factor the generation process leveraging syntactic information to improve the performance. However, they linearize both AMR and constituency graphs, which implies that important parts of the graphs cannot well be represented (e.g., coreference).

Several graph-to-sequence models have been proposed. Marcheggiani and Perez Beltrachini (2018) show that explicitly encoding the structure of the graph is beneficial with respect to sequential encoding. They evaluate their model on two tasks, WebNLG (Gardent et al., 2017) and SR11Deep (Belz et al., 2011), but do not apply it to AMR benchmarks. Song et al. (2018) and Beck et al. (2018) apply recurrent neural networks to directly encode AMR graphs. Song et al. (2018) use a graph LSTM as the graph encoder, whereas Beck et al. (2018) develop a model based on GRUs. We go a step further in that direction by developing parallel encodings of graphs which are able to highlight different graph properties.

In a related task, Koncel-Kedziorski et al. (2019) propose an attention-based graph model that generates sentences from knowledge graphs. Schlichtkrull et al. (2018) use Graph Convolutional Networks (GCNs) to tackle the tasks of link prediction and entity classification on knowledge graphs.

Damonte and Cohen (2019) show that off-the-shelf GCNs cannot achieve good performance for AMR-to-text generation. To tackle this issue, Guo et al. (2019) introduce dense connectivity to GNNs in order to integrate both local and global features, achieving good results on the task. Our work is related to Damonte and Cohen (2019), that use stacking of GCN and LSTM layers to improve the model capacity and employ anonymization. However, our model is substantially different: (i) we learn dual representations capturing top-down and bottom-up adjuvant views of the graph, (ii) we employ more effective graph encoders (with different neighborhood aggregations) than GCNs and (iii) we employ copy and coverage mechanisms and do not resort to entity anonymization.

3 Graph-to-Sequence Model

In this section, we describe (i) the representations of the graph adopted as inputs, (ii) the model architecture, including the Dual Graph Encoder and (iii) the GNNs employed as graph encoders.

3.1 Graph Preparation

Let $G = (V, E, R)$ denote a rooted and directed AMR graph with nodes $v_i \in V$ and labeled edges $(v_i, r, v_j) \in E$, where $r \in R$ is a relation type.

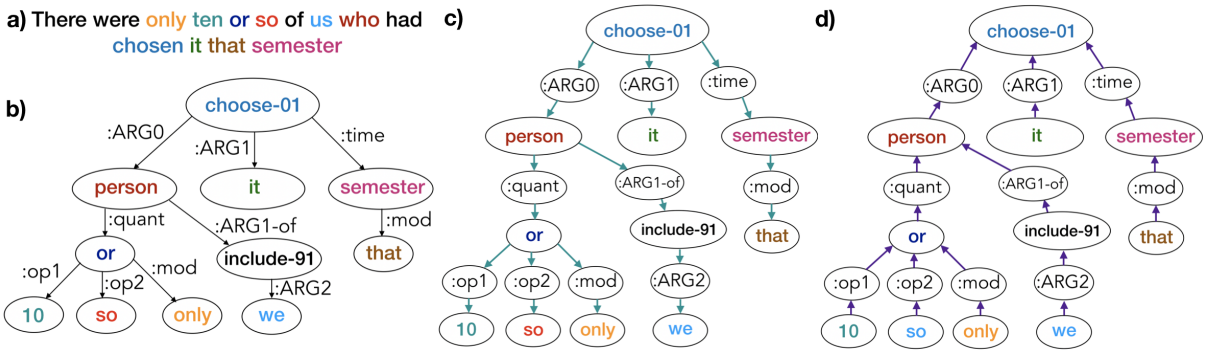

Figure 1: (a) an example sentence, (b) its original AMR graph (G) and different graph perspectives: (c) top-down (G_t) and (d) bottom-up (G_b).

Let $n = |V|$ and $m = |E|$ denote the numbers of nodes and edges, respectively.

We convert each AMR graph into an unlabeled and connected bipartite graph $G_t = (V_t, E_t)$, transforming each labeled edge $(v_i, r, v_j) \in E$ into two unlabeled edges $(v_i, r), (r, v_j) \in E_t$, with $|V_t| = n + m$ and $|E_t| = 2m$. This process, called Levi Transformation (Beck et al., 2018), turns original edges into nodes creating an unlabeled graph. For instance, the edge between `semester` and `that` with label `:mod` in Figure 1(b) is replaced by two edges and one node in 1(c): an edge between `semester`, and the new node `:mod` and another one between `:mod` and `that`. The new graph allows us to directly represent the relationships between nodes using embeddings. This enables us to encode label edge information using distinct message passing schemes employing different GNNs.

G_t captures a TD view of the graph. We also create a BU view of the graph $G_b = (V_t, E_b)$, where each directed edge $e_k = (v_i, v_j) \in E_t$ becomes $e_k = (v_j, v_i) \in E_b$, that is, we reverse the direction of original edges. An example of a sentence, its AMR graph and the two new graphs G_t and G_b is shown in Figure 1.

3.2 Dual Graph Encoder

We represent each node $v_i \in V_t$ with a node embedding $\mathbf{e}_i \in \mathbb{R}^d$, generated from the node label. In order to explicitly encode structural information, our encoder starts with two graph encoders, denoted by GE_t and GE_b, that compute representations for nodes in G_t and G_b, respectively.

Each GE learns node representations based on the specific view of its particular graph, G_t or G_b. Since G_t and G_b capture distinct perspectives of the graph structure, the information flow is propagated throughout TD and BU directions, respectively. In particular, for each node v_i, the GE receives the node embeddings of v_i and its neighbors, and computes its node representation:

$$\mathbf{h}_i^t = GE_t(\{\mathbf{e}_i, \mathbf{e}_j : j \in \mathcal{N}_t(i)\}),$$
$$\mathbf{h}_i^b = GE_b(\{\mathbf{e}_i, \mathbf{e}_j : j \in \mathcal{N}_b(i)\}),$$

where $\mathcal{N}_t(i)$ and $\mathcal{N}_b(i)$ are the immediate incoming neighborhoods of v_i in G_t and G_b, respectively.

Each node v_i is represented by two different hidden states, $\mathbf{h}_i^t$ and $\mathbf{h}_i^b$. Note that we learn two representations per relation and node of the original AMR graph. The hidden states $\mathbf{h}_i^t$ and $\mathbf{h}_i^b$, and embedding $\mathbf{e}_i$ contain different information regarding v_i. We concatenate them building a final node representation:

$$\mathbf{r}_i = \left[\, \mathbf{h}_i^t \,\|\, \mathbf{h}_i^b \,\|\, \mathbf{e}_i \,\right].$$

This approach is similar to bidirectional RNNs (Schuster and Paliwal, 1997). Bidirectional RNNs benefit from left-to-right and right-to-left propagation. They learn the hidden representations separately and concatenate them at the end. We perform a similar encoding: first we learn TD and BU representations independently, and lastly, we concatenate them.

The final representation $\mathbf{r}_i$ is employed in a sequence input of a bidirectional LSTM. For each AMR graph, we generate a node sequence by depth-first traversal order. In particular, given a representation sequence from $\mathbf{r}_1$ to $\mathbf{r}_n$, the hidden forward and backward states of $\mathbf{r}_i$ are defined as:

$$\overrightarrow{\mathbf{h}}_i = LSTM_f(\mathbf{r}_i, \overrightarrow{\mathbf{h}}_{i-1}),$$
$$\overleftarrow{\mathbf{h}}_i = LSTM_b(\mathbf{r}_i, \overleftarrow{\mathbf{h}}_{i-1}),$$

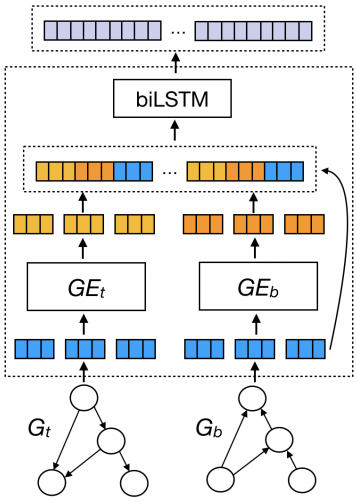

Figure 2: Dual Graph Encoder. The encoder receives the two graph views and generates structural node representations that are used by the decoder. Representations in blue, yellow and orange are $\mathbf{e}_i$, $\mathbf{h}_i^t$ and $\mathbf{h}_i^b$, respectively.

where $LSTM_f$ is a forward LSTM and $LSTM_b$ is a backward LSTM. Note that, for the backward LSTM, we feed the reversed input as the order from $\mathbf{r}_n$ to $\mathbf{r}_1$. Lastly, we obtain the final hidden state by concatenating them as:

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i \,\|\, \overleftarrow{\mathbf{h}}_i].$$

The resulting hidden state $\mathbf{h}_i$ encodes the information of both preceding and following nodes.

Stacking layers was demonstrated to be effective in graph-to-sequence approaches (Marcheggiani and Perez Beltrachini, 2018; Koncel-Kedziorski et al., 2019; Damonte and Cohen, 2019) and allows us to test for their contributions to the system performance more easily. We employ different GNNs for both graph encoders (Section 3.3). Figure 2 shows the proposed encoder architecture.

3.3 Graph Neural Networks

The GEs incorporate, in each node representation, structural information based on both views of the graph. We explore distinct strategies for neighborhood aggregation, adopting three GNNs: Gated Graph Neural Networks (GGNN, Li et al. (2016)), Graph Attention Networks (GAT, Veličković et al. (2018)) and Graph Isomorphic Networks (GIN, Xu et al. (2019)). Each GNN employs a specific message passing scheme which allows capturing different nuances of structural information.

Gated Graph Neural Networks GGNNs employ gated recurrent units to encode node representations, reducing the recurrence to a fixed number of steps. In particular, the l-th layer of a GGNN is calculated as:

$$\mathbf{h}_i^{(l)} = GRU\Big(\mathbf{h}_i^{(l-1)}, \sum_{j \in \mathcal{N}(i)} \mathbf{W_1} \mathbf{h}_j^{(l-1)}\Big),$$

where $\mathcal{N}(i)$ is the immediate neighborhood of v_i, $\mathbf{W_1}$ is a parameter and GRU is a gated recurrent unit (Cho et al., 2014). Different from other GNNs, GGNNs use back-propagation through time (BPTT) to learn the parameters. GGNNs also do not require to constrain parameters to ensure convergence.

Graph Attention Networks GATs apply attentive mechanisms to improve the exploitation of non-trivial graph structure. They encode node representations by attending over their neighbors, following a self-attention strategy:

$$\mathbf{h}_i^{(l)} = \alpha_{i,i} \mathbf{W_2} \mathbf{h}_i^{(l-1)} + \sum_{j \in \mathcal{N}(i)} \alpha_{i,j} \mathbf{W_2} \mathbf{h}_j^{(l-1)},$$

where attention coefficients $\alpha_{i,j}$ are computed as:

$$\alpha_{i,j} = \text{softmax}\left(\sigma\left(\mathbf{a}^\top [\mathbf{W_2}\mathbf{h}_i^{(l-1)} \,\|\, \mathbf{W_2}\mathbf{h}_j^{(l-1)}]\right)\right),$$

where σ is the activation function and $\|$ denotes concatenation. $\mathbf{W_2}$ and $\mathbf{a}$ are model parameters. The virtue of the attention mechanism is its ability to focus on the most important parts of the node neighborhood. In order to learn attention weights in different perspectives, GATs can employ multi-head attentions.

Graph Isomorphic Networks GIN is a GNN as powerful as the Weisfeiler-Lehman (WL) graph isomorphism test (Weisfeiler and Lehman, 1968) in representing isomorphic and non-isomorphic graphs with discrete attributes. Its l-th layer is defined as:

$$\mathbf{h}_i^{(l)} = h_{\mathbf{W}}\Big(\mathbf{h}_i^{(l-1)} + \sum_{j \in \mathcal{N}(i)} \mathbf{h}_j^{(l-1)}\Big),$$

where $h_{\mathbf{W}}$ is a multi-layer perceptron (MLP). In contrast to other GNNs, which combine node feature with its aggregated neighborhood feature, GINs do not apply the combination step and simply aggregate the node along with its neighbors.

Each of these GNNs applies different approaches to learn structural features from graph data and has achieved impressive results on many graph-based tasks (Li et al., 2016; Veličković et al., 2018; Xu et al., 2019).

3.4 Decoder

An attention-based unidirectional LSTM decoder is used to generate sentences, attending to the hidden representations of edges and nodes. In each step t, the decoder receives the word embedding of the previous word (during training, this is the previous word of the reference sentence; at test time it is the previously generated word), and has the decoder state $\mathbf{s}_t$. The attention distribution $\mathbf{a}^t$ is calculated as in See et al. (2017):

$$\mathbf{e}_i^t = \mathbf{v} \cdot \tanh(\mathbf{W}_h \mathbf{h}_i + \mathbf{W}_s \mathbf{s}_t + \mathbf{w}_c \mathbf{s}_c + \mathbf{b}),$$
$$\mathbf{a}^t = \text{softmax}(\mathbf{e}^t),$$

where $\mathbf{s}_c$ is the coverage vector and $\mathbf{v}$, $\mathbf{W}_h$, $\mathbf{W}_s$, $\mathbf{w}_c$ and $\mathbf{b}$ are learnable parameters. The coverage vector is the accumulation of all attention distributions so far.

Copy and Coverage Mechanisms Previous works (Damonte and Cohen, 2019; Cao and Clark, 2019) use anonymization to handle names and rare words, alleviating the data sparsity. In contrast, we employ copy and coverage mechanisms to address out-of-vocabulary issues for rare target words and to avoid repetition (See et al., 2017).

The model is trained to optimize the negative log-likelihood:

$$\mathcal{L} = -\sum_{t=1}^{|Y|} \log\, p(y_t | y_{1:t-1}, X; \theta),$$

where $Y = y_1, \ldots, y_{|Y|}$ is the sentence, X is the AMR graph and θ represents the model parameters.

4 Data

We use two AMR corpora, LDC2015E86 and LDC2017T10[2]. In these datasets, each instance contains an AMR graph and a sentence. Table 1 shows the statistics for both datasets. Figure 3 shows the distribution of the AMR graph diameters and node degrees for both datasets. The AMR graph structures are similar for most examples. Note that 90% of AMR graphs in both datasets have the diameter less than or equal to 11 and 90% of nodes have the degree of 4 or less. Very structurally similar graphs pose difficulty for the graph encoder by making it harder to learn the differences between their similar structures. Therefore, the word embeddings used as additional input play an important role in helping the model to deal with language information. That is one of the reasons why we concatenate this information in the node representation $\mathbf{r}_i$.

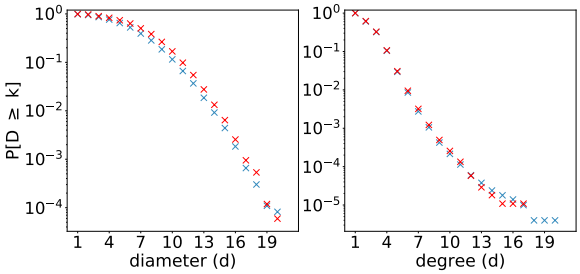

Figure 3: Distribution of the AMR graph diameter (left) and node degree (right) in the training set for LDC2015E86 (red) and LDC2017T10 (blue) datasets.

5 Experiments and Discussion

Implementation Details We extract vocabularies (size of 20,000) from the training sets and initialize the node embeddings from GloVe word embeddings (Pennington et al., 2014) on Common Crawl. Hyperparameters are tuned on the development set of the LDC2015E86 dataset. For GIN, GAT, and GGNN graph encoders, we set the number of layers to 2, 5 and 5, respectively. To regu-

larize the model, during training we apply dropout (Srivastava et al., 2014) to the graph layers with a rate of 0.3. The graph encoder hidden vector sizes are set to 300 and hidden vector sizes for LSTMs are set to 900.

The models are trained for 30 epochs with early stopping based on the development BLEU score. For our models and the baseline, we used a two-layer LSTM decoder. We use Adam optimization (Kingma and Ba, 2015) as the optimizer with an initial learning rate of 0.001 and 20 as the batch size. Beam search with the beam size of 5 is used for decoding.

Results We call the models G2S-GIN (isomorphic encoder), G2S-GAT (graph-attention encoder), and G2S-GGNN (gated-graph encoder), according to the graph encoder utilized. As a baseline (S2S), we train an attention-based encoder-decoder model with copy and coverage mechanisms, and use a linearized version of the graph generated by depth-first traversal order as input. We compare our models against several state-of-the-art results reported on the two datasets (Konstas et al., 2017; Song et al., 2018; Beck et al., 2018; Damonte and Cohen, 2019; Cao and Clark, 2019; Guo et al., 2019).

Model	External	BLEU

G2S-GGNN	200K	**32.23**

Table 3: Results on LDC2015E86 test set when models are trained with additional Gigaword data.

We use both BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014) as evaluation metrics[3]. In order to mitigate the effects of random seeds, we report the averages for 4 training runs of each model along with their standard deviation. Table 2 shows the comparison between the proposed models, the baseline and other neural models on the test set of the two datasets.

For both datasets, our approach substantially outperforms the baselines. In LDC2015E86, G2S-GGNN achieves a BLEU score of 24.32, 4.46% higher than Song et al. (2018), who also use the copy mechanism. This indicates that our architecture can learn to generate better signals for text generation. On the same dataset, we have competitive results to Damonte and Cohen (2019). However, we do not rely on preprocessing anonymisation not to lose semantic signals. In LDC2017T10, G2S-GGNN achieves a BLEU score of 27.87, which is 3.33 points higher than Damonte and Cohen (2019), a state-of-the-art model that does not employ external information. We also have competitive results to Guo et al. (2019), a very recent state-of-the-art model.

We also outperform Cao and Clark (2019) improving BLEU scores by 3.48% and 4.00%, in LDC2015E86 and LDC2017T10, respectively. In contrast to their work, we do not rely on (i) leveraging supplementary syntactic information and (ii) we do not require an anonymization preprocessing step. G2S-GIN and G2S-GAT have comparable performance on both datasets. Interestingly, G2S-GGNN has better performance among our models. This suggests that graph encoders based on gating mechanisms are very effective in text generation models. We hypothesize that the gating mechanism can better capture long-distance dependencies between nodes far apart in the graph.

[3]For BLEU, we use the multi-BLEU script from the MOSES decoder suite (Koehn et al., 2007). For METEOR, we use the original meteor-1.5.jar script (https://github.com/cmu-mtlab/meteor).

Model	BLEU	METEOR	Size
biLSTM	22.50	30.42	57.6M
GE_t + biLSTM	26.33	32.62	59.6M
GE_b + biLSTM	26.12	32.49	59.6M
GE_t + GE_b + biLSTM	27.37	33.30	61.7M

Table 4: Results of the ablation study on the LDC2017T10 development set.

Additional Training Data Following previous works (Konstas et al., 2017; Song et al., 2018; Guo et al., 2019), we also evaluate our models employing additional data from English Gigaword corpus (Napoles et al., 2012). We sample 200K Gigaword sentences and use JAMR[4] (Flanigan et al., 2016a) to parse them. We follow the method of Konstas et al. (2017), which is fine-tuning the model on the LDC2015E86 training set after every epoch of pretraining on the Gigaword data. G2S-GGNN outperforms others with the same amount of Gigaword sentences (200K), achieving a 32.23 BLEU score, as shown in Table 3. The results demonstrate that pretraining on automatically generated AMR graphs enhances the performance of our model.

Ablation Study In Table 4, we report the results of an ablation study on the impact of each component of our model on the development set of LDC2017T10 dataset by removing the graph encoders. We also report the number of parameters (including embeddings) used in each model. The first thing we notice is the huge increase in metric scores (17% in BLEU) when applying the graph encoder layer, as the neural model receives signals regarding the graph structure of the input. The dual representation helps the model with a different view of the graph, increasing BLEU and METEOR scores by 1.04 and 0.68 points, respectively. The complete model has slightly more parameters than the model without graph encoders (57.6M vs 61.7M).

Impact of Graph Size, Arity and Sentence Length The good overall performance on the datasets shows the superiority of using graph encoders and dual representations over the sequential encoder. However, we are also interested in estimating the performance of the models concerning different data properties. In order to evaluate how the models handle graph and sentence features, we perform an inspection based on different sizes of graph diameter, sentence length, and max node out-degree. Table 5 shows METEOR[5] scores for the LDC2017T10 dataset.

Model	Graph Diameter					
	0-7	Δ	7-13	Δ	14-20	Δ
S2S	33.2		29.7		28.8	
G2S-GIN	35.2	+6.0%	31.8	+7.4%	31.5	+9.2%
G2S-GAT	35.1	+5.9%	32.0	+7.8%	31.5	+9.51%
G2S-GGNN	36.2	+9.0%	33.0	+11.4%	30.7	+6.7%
	Sentence Length					
	0-20	Δ	20-50	Δ	50-240	Δ
S2S	34.9		29.9		25.1	
G2S-GIN	36.7	+5.2%	32.2	+7.8%	26.5	+5.8%
G2S-GAT	36.9	+5.7%	32.3	+7.9%	26.6	+6.1%
G2S-GGNN	37.9	+8.5%	33.3	+11.2%	26.9	+6.8%
	Max Node Out-degree					
	0-3	Δ	4-8	Δ	9-18	Δ
S2S	31.7		30.0		23.9	
G2S-GIN	33.9	+6.9%	32.1	+6.9%	25.4	+6.2%
G2S-GAT	34.3	+8.0%	32.0	+6.7%	22.5	-6.0%
G2S-GGNN	35.0	+10.3%	33.1	+10.4%	22.2	-7.3%

Table 5: METEOR scores and differences to the S2S, in the LDC2017T10 test set, with respect to the graph diameter, sentence length and max node out-degree.

The performances of all models decrease as the diameters of the graphs increase. G2S-GGNN has a 17.9% higher METEOR score in graphs with a diameter of at most 7 compared to graphs with diameters higher than 13. This is expected as encoding a bigger graph (containing more information) is harder than encoding smaller graphs. Moreover, 71% of the graphs in the training set have a diameter less than or equal to 7 and only 2% have a diameter bigger than 13 (see Figure 3). Since the models have fewer examples of bigger graphs to learn from, this also leads to worse performance when handling graphs with higher diameters. We also investigate the performance with respect to the sentence length. The models have better results when handling sentences with 20 or fewer tokens. Longer sentences pose additional challenges to the models.

G2S-GIN has a better performance in handling graphs with node out-degrees higher than 9. This indicates that GINs can be employed in tasks where the distribution of node degrees has a long

G2S-GGNN	51.32	8.82	39.86
	GEN ⇒ REF		
Model	**ENT**	**CON**	**NEU**
S2S	73.79	12.75	13.46
G2S-GIN	76.27	10.65	13.08
G2S-GAT	77.54	8.54	13.92
G2S-GGNN	77.64	9.64	12.72

Table 6: Entailment (ENT), contradiction (CON) and neutral (NEU) average percentages for the LDC2017T10 test set. **(Top)** The premise and the hypothesis are the generated (GEN) and reference (REF) sentences, respectively. **(Bottom)** The hypothesis and the premise are the generated (GEN) and reference (REF) sentences, respectively.

tail. Surprisingly, S2S has a better performance than G2S-GGNN and G2S-GAT when handling graphs that contain high degree nodes.

Semantic Equivalence We perform an entailment experiment using BERT (Devlin et al., 2019) fine-tuned on the MultiNLI dataset (Williams et al., 2018) as a NLI model. We are interested in exploring whether a generated sentence (hypothesis) is semantically *entailed* by the reference sentence (premise). In a related text generation task, Falke et al. (2019) employ NLI models to rerank alternative predicted abstractive summaries.

Nevertheless, uniquely verifying whether the reference (REF) entails the generated sentence (GEN) or vice-versa (GEN entails REF) is not sufficient. For example, suppose that *"Today Jon walks"* is the REF and *"Jon walks"* is the GEN. Even though REF entails GEN, GEN does not entail REF, that is, GEN is too general (missing information). Furthermore, suppose that *"Jon walks"* is the REF and *"Today Jon walks"* is the GEN, GEN entails REF but REF does not entail GEN, that is, GEN is too specific (added information). Therefore, in addition to verify whether the reference entails the generated sentence, we also verify whether the generated sentence entails the reference.

Table 6 shows the average probabilities for entailment, contradiction and neutral classes on the LDC2017T10 test set. All G2S models have higher entailment compared to S2S. G2S-GGNN has 33.5% and 5.2% better entailment performances than S2S, when REF entails GEN and GEN entails REF, respectively. G2S models also generate sentences that contradict the reference sentences less. This suggests that our models are capable of capturing better semantic information from the graph generating outputs semantically related to the reference sentences.

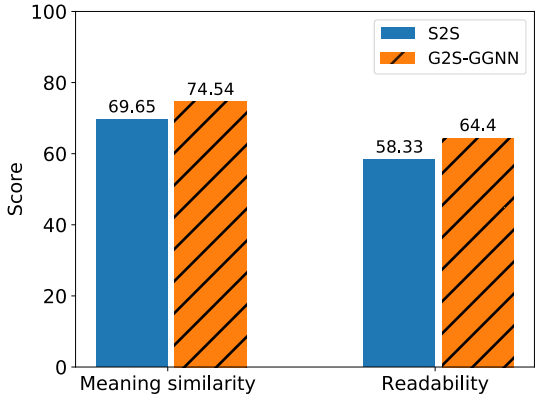

Figure 4: Human evaluation of the sentences generated by S2S and G2S-GGNN models. Results are statistically significant with $p < 0.05$, using Wilcoxon rank-sum test.

Human Evaluation To further assess the quality of the generated sentences, we conduct a human evaluation. We employ the *Direct Assessment* (DA) method (Graham et al., 2017) via Amazon Mechanical Turk. Using the DA method inspired by Mille et al. (2018), we assess two quality criteria: (i) *meaning similarity*: how close in meaning the generated text is to the gold sentence; and (ii) *readability*: how well the generated sentence reads (Is it good fluent English?).

We randomly select 100 sentences generated by S2S and G2S-GGNN and randomly assign them to HITs (following Mechanical Turk terminology). Human workers rate the sentences according to meaning similarity and readability on a 0-100 rating scale. The tasks are executed separately and workers were first given brief instructions. For each sentence, we collect scores from 5 workers and average them. Models are ranked according to the mean of sentence-level scores. We apply a quality control step filtering workers who do not score some faked and known sentences properly.

Figure 4 shows the results. In both metrics, G2S-GGNN has better human scores for meaning similarity and readability, suggesting a higher

GOLD	China and Kyrgyzstan agreed in a joint communique that terrorism, separatism and extremism still pose major threats to regional security and stability.
S2S	In the joint communique, China and Kyrgyzstan still agreed to threaten terrorism, separatism, extremism and regional stability.
Song et. al (2018)	In a joint communique, China and Kyrgyzstan have agreed to still be a major threat to regional security, and regional stability.
G2S-GGNN	At a joint communique, China and Kyrgyzstan agreed that terrorism, separatism and extremism are still a major threat to region security and stability.

Table 7: An example of an AMR graph and generated sentences. GOLD refers to the reference sentence.

Model	ADDED	MISS
S2S	47.34	37.14
G2S-GIN	48.67	33.64
G2S-GAT	48.24	33.73
G2S-GGNN	48.66	34.06
GOLD	50.77	28.35

Table 8: Fraction of elements in the output that are not present in the input (ADDED) and the fraction of elements in the input graph that are missing in the generated sentence (MISS), for the test set of LDC2017T10. The token lemmas are used in the comparison. GOLD refers to the reference sentences.

quality of the generated sentences regarding S2S. The Pearson correlations between meaning similarity and readability scores, and METEOR[6] scores are 0.50 and 0.22, respectively.

Semantic Adequacy We also evaluate the semantic adequacy of our model (how well does the generated output match the input?) by comparing the number of added and missing tokens that occur in the generated versus reference sentences (GOLD). An added token is one that appears in the generated sentence but not in the input graph. Conversely, a missing token is one that occurs in the input but not in the output. In GOLD, added tokens are mostly function words while missing tokens are typically input concepts that differ from the output lemma. For instance, in Figure 1, *there* and *of* are added tokens while *person* is a missing token. As shown in Table 8, G2S approaches outperform the S2S baseline. G2S-GIN is closest to GOLD with respect to both metrics suggesting that this model is better able to generate novel words to construct the sentence and captures a larger range of concepts from the input AMR graph, covering more information.

Manual Inspection Table 7 shows sentences generated by S2S, Song et al. (2018), G2S-GAT, and the reference sentence. The example shows that our approach correctly verbalises the subject of the embedded clause *"China and ... agreed that terrorism, separatism and extremism$_{SUBJ}$ ... pose major threats to ..."*, while S2S and Song et al. (2018) are fooled by the fact that *agree* frequently takes an infinitival argument which shares its subject (*"China ...$_{SUBJ}$ agreed to threaten / have agreed to be a major threat"*). While this is a single example, it suggests that dual encoding enhances the model ability to take into account the dependencies and the graph structure information, rather than the frequency of n-grams.

6 Conclusion

We have studied the problem of generating text from AMR graphs. We introduced a novel architecture that explicitly encodes two parallel and adjuvant representations of the graph (top-down and bottom-up). We showed that our approach outperforms state-of-the-art results in AMR-to-text generation. We provided an extensive evaluation of our models and demonstrated that they are able to achieve the best performance. In the future, we will consider integrating deep generative graph models to express probabilistic dependencies among AMR nodes and edges.

Abstract

The automated generation of information indicating the characteristics of articles such as headlines, key phrases, summaries and categories helps writers to alleviate their workload. Previous research has tackled these tasks using neural abstractive summarization and classification methods. However, the outputs may be inconsistent if they are generated individually. The purpose of our study is to generate multiple outputs consistently. We introduce a multi-task learning model with a shared encoder and multiple decoders for each task. We propose a novel loss function called *hierarchical consistency loss* to maintain consistency among the attention weights of the decoders. To evaluate the consistency, we employ a human evaluation. The results show that our model generates more consistent headlines, key phrases and categories. In addition, our model outperforms the baseline model on the ROUGE scores, and generates more adequate and fluent headlines.

1 Introduction

Headlines and other information such as key phrases, summaries and categories about articles are crucial for readers to search articles on demand. To attract more readers, writers manually create headlines and summaries by summarizing the articles, extract key phrases and classify articles into categories. Figure 1 shows an example of job advertisement articles. In addition to the job description text, the headline, key phrase and category are labeled for each article. Thus job seekers can easily retrieve the job advertisements they desire by reading them. However, it is a burden for writers to create these headlines, key phrases and categories manually for extremely large numbers of articles. Hence, an automatic generation system is highly demanded.

Headline: We Want Android[1] Engineer to Develop our New Service "Wantedly People[2] "!
Key Phrase: Android Engineer
Category: Engineer
Description Text (Truncated): We released a new service "Wantedly People" in November 2016, and released new features in July 2017! Our "People team", developing rapidly growing "Wantedly People" service, is recruiting an Android Engineer! If you love to work on new services, or if you want to try to develop new apps as your representative work, we are looking forward to your application!

Figure 1: An example job advertisement article with consistency. Each article contains a headline, key phrase and category. The underlined topic "Engineer" is consistently noted in the headline, key phrase and category. A Japanese-English translation is applied.

For automated generation of multiple outputs, consistency among outputs is crucial. A lack of consistency among outputs causes incorrect information in the outputs. In Figure 1, for example, the "Engineer" position is consistently noted in the headline, key phrase and category. An occupation is consistent and salient information for headlines, key phrases and categories. If the article was to be misclassified as a "Designer" category or the key phrase wrongly noted as "Robotics Engineer," an inconsistency among the headline, key phrase and category would occur. Thus, readers would be confused by these inconsistencies. We must force generators to predict multiple outputs consistently. This leads to the correctness of the occupation in the outputs, and thus the quality of the generated outputs also improves.

In previous research, neural networks have achieved significant improvements in individual tasks, such as abstractive summarization (Rush et al., 2015; See et al., 2017; Shi et al., 2018),

headline generation (Takase et al., 2016), key phrase generation (Meng et al., 2017) and text classification (Zhang et al., 2015) tasks. However, consistency among multiple outputs is not considered in the strategy to predict multiple outputs with separate models.

The purpose of our study is to maintain consistency among automatic generated sentences and classified categories. We adopt multi-task learning (Caruana, 1997) to predict the headlines, key phrases and categories of articles in one unified model. We handle the key phrase generation and classification tasks not as auxiliary tasks, but as the desired outputs of our system. Multi-task learning enables the encoder to focus on the common and salient features in the input text.

We propose a novel *hierarchical consistency loss* to maintain consistency among the multiple outputs. A hierarchical consistency loss forces the attention weights of the decoders to focus on the same words in the input text, considering the hierarchical relation among tasks. There is a hierarchical relation among the tasks; the headline generator generally focuses on the wider range of words including the key phrase generator focus upon. In addition, this loss has a flexibility that alleviate the influences of errors propagated from other tasks, similar to soft-parameter sharing methods (Guo et al., 2018).

We design human evaluations using crowdsourcing to score the following three metrics: fluency, adequacy and consistency among the outputs. We implement human evaluations of the job advertisement dataset, and the results indicate that our model improves not only the consistency score but also the fluency and adequacy scores.

In addition, we conduct automatic evaluations of the job advertisement dataset and the modified CNN-DailyMail (CNN-DM) dataset (Nallapati et al., 2016). The automatic evaluations show that our method improves the ROUGE metric scores on both datasets, which has multiple outputs.

Overall, our contributions are as follows:

- We propose a multi-task sentence generation and document classification model.
- A novel *hierarchical consistency loss* is introduced to train the weights of attention to focus more on the same part of the input text among the task-specific decoders.

Our designed human evaluations show that our model generates more consistent outputs. Our proposed model generates more adequate and fluent outputs on a human evaluation, and achieves the best ROUGE score on an automatic evaluation.

2 Related Work

Abstractive summarization. Abstractive summarization is a task to generate a short summary that captures the core meaning of the original text. Rush et al. (2015) used a neural attention model, and See et al. (2017) introduced a pointer-generator network to copy out-of-vocabulary (OOV) words from the input text. Hsu et al. (2018) combined abstractive and extractive summarization with an inconsistency loss to encourage consistency between word-level attention weights of the abstracter and sentence-level attention weights of the extractor. Abstractive summarization techniques are generally applied to a headline generation because this is a similar task (Shen et al., 2017; Tan et al., 2017).

Multi-task learning. Multi-task learning, which trains different tasks in one unified model, has achieved success in many natural language processing tasks (Luong et al., 2016; Hashimoto et al., 2017; Liu et al., 2019). Typical multi-task learning models have a structure with a shared encoder to encode the input text and multiple decoders to generate outputs of each task. Multi-task learning has a benefit in that the shared encoder captures common features among tasks; in addition, the encoder focuses more on relevant and beneficial features, and disregards irrelevant and noisy features (Ruder, 2017).

Although a multi-task learning model is beneficial in training a shared encoder, it is still difficult to share information among task-specific decoders. Some studies have constructed a multi-task learning model using techniques that encourages information sharing among decoders. Isonuma et al. (2017) proposed an extractive summarization model that the outputs of the sentence extractor are directly used for a document classifier. Anastasopoulos and Chiang (2018) introduced a triangle model to transfer the decoder information of the second task to the decoder of the first task. Tan et al. (2017) introduced a coarse-to-fine model to generate headlines using important sentences chosen in the extracter. These methods are cascade models that additionally input the information of the first tasks directly into

the second tasks. They consider the hierarchy among tasks, but these models suffer from the errors of the previous tasks.

Guo et al. (2018) proposed a decoder sharing method with soft-parameter sharing to train the summarization and entailment tasks. Soft-parameter sharing has a benefit in that it provides more flexibility between the layer of summarization and entailment tasks; however, this method does not consider the hierarchy among tasks.

Our study extends the method in Hsu et al. (2018) to a multi-task learning model in which the models need to generate multiple outputs with consistency. Hierarchical consistency loss combines two advantages. This loss considers the hierarchy among tasks, and has flexibility among tasks, similar to soft-parameter sharing methods. We assess the advantages of this loss in Section 4.2.

3 Method

3.1 Problem Definition

We define the tasks of our study and describe the overview of the datasets.

Let $x = \{x_1, x_2, ...x_S\}$ be a sequence of input text. The target of our multi-task model is to generate two types of sentences and to predict the category of the input article. Our model predicts the exactly one category tag y^1 for each input sentence. Our model also predicts $y^2 = \{y^2_1, y^2_2, ...y^2_{T^2}\}$ and $y^3 = \{y^3_1, y^3_2, ...y^3_{T^3}\}$, which are the sequence of sentences.

For the job advertisement dataset, the targets of our model are to classify articles into occupation categories y^1 (task 1), generate key phrases regarding the occupation y^2 (task 2) and generate headlines y^3 (task 3). For the CNN-DM dataset, the targets are to predict the article categories y^1 (task 1), headlines y^2 (task 2) and multi-sentence summaries y^3 (task 3).

Here, S is the length of the input texts, and T^2 and T^3 are the lengths of the output sequences, respectively. T^2 is generally smaller than T^3 in both datasets. Hence, task 3 is generally more difficult than task 2, and more information is needed to generate y^3 than y^2.

3.2 Encoder-Decoder model

Encoder-decoder model with attention mechanism. Our model is based on an encoder-decoder model (Cho et al., 2014). The encoder RNN transforms the input text into hidden vectors $h^e = \{h^e_1, h^e_2, ..., h^e_S\}$, and the decoder RNN then predicts the generation probability of each word $P_{vocab,t}$:

$$h^e_t = \mathrm{RNN}_{enc}(x_t, h^e_{t-1}) \quad (1)$$

$$h^d_t = \mathrm{RNN}_{dec}(y_{t-1}, h^d_{t-1}, h^e_S) \quad (2)$$

$$P_{vocab,t} = \mathrm{softmax}(W_{d2v} h^d_t + b_{d2v}) \quad (3)$$

where the weight matrices W_{d2v} and bias vector b_{d2v} are trainable parameters.

Rush et al. (2015) used an attention mechanism to handle long input sentences. The attention mechanism obtains the hidden vector of attention $\bar{h}^d_t$ from the hidden vector and context vector c^e_t, which is defined as the weighted sum of the hidden vectors of the encoder:

$$e^e_{tj} = v^T \tanh(W_e h^e_j + W_d h^d_t + b_{attn}) \quad (4)$$

$$\alpha^e_{tj} = \mathrm{softmax}(e^e_{tj}) \quad (5)$$

$$c^e_t = \sum_j \alpha^e_{tj} h^e_j \quad (6)$$

$$\bar{h}^d_t = W_c[h^d_t, c^e_t] + b_c \quad (7)$$

Note that $[h^d_t, c^e_t]$ indicates the concatenation of vectors h^d_t and c^e_t. Weight matrices W_e, W_d and W_c and the bias vectors b_{attn} and b_c are trainable parameters.

Pointer-generator network. We adopt a pointer-generator network (See et al., 2017) for the decoders to handle OOV words. The decoder generates words under the probability of p_{gen,y_t} and copies words from the input sentence under the probability of $1 - p_{gen,y_t}$.

Coverage mechanism. See et al. (2017) also introduced a coverage mechanism to alleviate the repetition problem. The coverage loss L_{cov} is added to the loss function to penalize the attention mechanism to avoid focusing on the same input words.

3.3 Multi-Task Learning for Generation and Classification

We introduce multi-task learning to predict multiple outputs simultaneously in one unified model. Figure 2 describes an overview of our multi-task learning model. A multi-task learning model comprises one shared layer, two task-specific decoders for generation tasks, and one classifier.

Shared encoder. First, shared encoder RNN_{enc} transforms the input text into the shared hidden

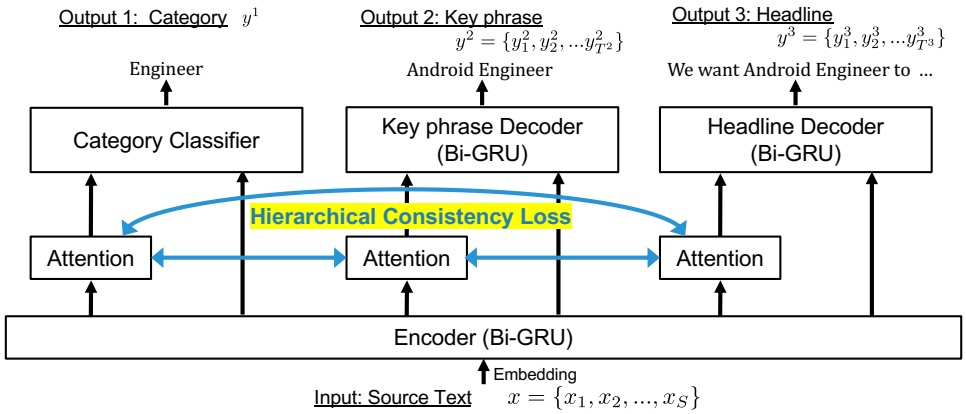

Figure 2: An overview of our multi-task learning model. The shared embedding layer and encoder first transform the input text into a shared hidden vector, and the task-specific layers then predict the outputs of each task. Hierarchical consistency loss penalizes the inconsistency between the attention weights of the pairs of decoders.

vector h_t^e. We use a 2-layer bi-directional GRU (Cho et al., 2014) for the encoder.

Classifier. The classifier transforms a shared hidden vector into the category probability P_{cat}. We implement the classifier as 2-layer perceptron with an attention mechanism:

$$o^c = \mathrm{ReLU}(W_1^c([h_S^e, c_t^e] + b_1^c)) \quad (8)$$

$$P_{cat} = \mathrm{softmax}(W_2^c o^c + b_2^c) \quad (9)$$

where the weight matrices W_1^c and W_2^c, and bias vectors b_1^c and b_2^c are trainable parameters.

Decoders. The hidden vector of encoder h_S^e is first transformed into $\hat{h_0^d}$ in the bridge layer, and the decoders RNN_{dec} of each task then generate output sequences y^2 and y^3 from $\hat{h_0^d}$. A bridge is an additional fully connected layer used to fit the hidden vector into each task. We expect that multi-task learning will enable the shared encoder to capture more common and salient parts of an article, that is, the parts of the text that mention the occupation.

3.4 Hierarchical Consistency Loss

The main objective of our method is to maintain consistency among multiple outputs. If each decoder focuses on the same word in the input text, the model can generate a more consistent output. Hence, consistency between attention weights leads to consistency between multiple outputs. For example, in Figure 3, inconsistency regarding the occupation occurs because the word "engineer" is inconsistently focused on the attention weights of the key phrase generator. From this, the key phrase generator predicts an incorrect key phrase. By penalizing such inconsistencies, the model enables the generation of more consistent outputs.

However, perfect consistency between attention weights occasionally disturbs the model to generate proper outputs. Because headlines contain more information than key phrases, the headline generator must focus on a wider range of words in the input text than the key phrase generator. For example, in Figure 3, the headline generator focuses on the words "user interface." In contrast, the key phrase generator does not focus on these words. Therefore, the attention weights among tasks generally maintain a hierarchical relation. That is, the higher tasks (headline generation and summarization) need to focus on a wider range of words, and the lower tasks (classification) focus on the range on which the higher tasks focused.

We introduce a novel "hierarchical consistency loss" to penalize inconsistency among multiple outputs. We define hierarchical consistency loss between task s and task t as follows:

$$L_{hcl}^{st} = \frac{\lambda_{hcl}}{S} \sum_{i=1}^{S} |\max_j e_{ij}^{ds} - \max_j e_{ij}^{dt}|_+ \quad (10)$$

where e_{ij}^{ds} is the non-normalized attention weight of the output word j toward the input word i. Note that a ramp function $|x|_+$ is used to compare two attention weights. Task t is a task that needed to focus on a wider range of words than the input task s. For example, in Figure 3, task s is a key phrase generation, and task t is a headline generation.

The aim of hierarchical consistency loss is to penalize inconsistency between two attention weights. For example, in Figure 3, the loss forces the attention weight corresponding to the word

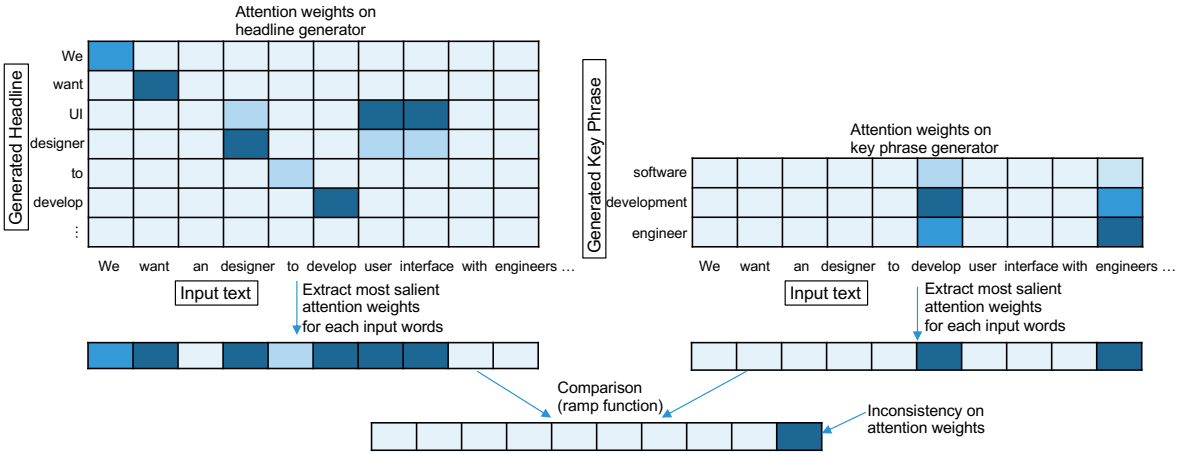

Figure 3: An overview illustration of our hierarchical consistency loss. This loss penalizes a case in which inconsistency occurs between two outputs. The decoder of the key phrase generator focuses on the word "engineers." However, the headline generation decoder does not focus on this word. Hierarchical consistency loss treats this difference as an inconsistency.

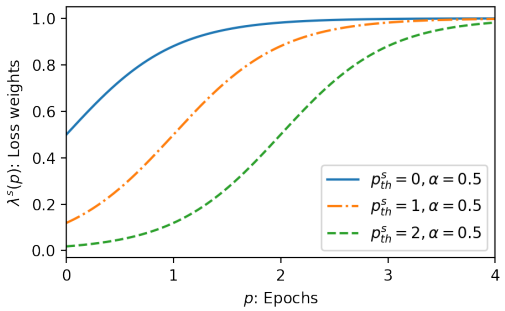

Figure 4: An illustration of our training scheduling strategy. The loss weights $\lambda^s(p)$ gradually increase as the training proceeds.

"engineers" to a higher weight because the word "engineers" is crucial to generate consistent and adequate outputs. Figure 3 shows the process of the loss. The most salient attention weights for each input word are extracted, and the extracted attention weights between two tasks are then compared. A ramp function enables this loss to consider the hierarchical relation between two tasks.

3.5 Learning Scheduling for Multi-Task Learning

We also introduce a new multi-task learning scheduling strategy to effectively train several tasks with different levels of difficulty. Kiperwasser and Ballesteros (2018) introduced a strategy that gradually changes the probability that the training examples will be picked from each dataset as the training proceeds. We modify this idea to a situation in which the input text is in common among multiple tasks, adjusting the hyperparameters of the weighted sum of loss functions. This strategy enables us to train our model in such a way that our model focuses on learning easy tasks at the beginning, and then gradually focuses more on learning difficult tasks.

We determine the weights of the loss function $\lambda^s(p)$ for task s with a sigmoid function:

$$\lambda^s(p) = \lambda^s_{const} \frac{1}{1 + \exp((p^s_{th} - p)/\alpha)} \quad (11)$$

where λ^s_{const} and p^s_{th} are hyperparameters for each task. Parameter p describes the number of epochs trained thus far. We set hyperparameter α to 0.5 for all tasks. As illustrated in Figure 4, $\lambda^s(p)$ becomes larger as the training proceeds.

3.6 Overall Loss Function

The overall loss function of the proposed model is calculated as the weight sum of losses from three tasks, coverage losses and hierarchical consistency loss:

$$\begin{aligned} L_{all} &= \lambda^1(p)L_1 + \lambda^2(p)L_2 + \lambda^3(p)L_3 \\ &+ \lambda^2_{cov}L^2_{cov} + \lambda^3_{cov}L^3_{cov} \\ &+ \lambda^{all}_{hcl}L^{all}_{hcl} \end{aligned} \quad (12)$$

where $\lambda^1(p)$, $\lambda^2(p)$, $\lambda^3(p)$, λ^2_{cov}, λ^3_{cov} and λ^{all}_{hcl} are hyperparameters. In addition, $\lambda^1(p)$, $\lambda^2(p)$, and $\lambda^3(p)$ are calculated using Eqn.11. Moreover, L_1, L_2 and L_3 signify the loss of the classification, key phrase generation and headline generation tasks, respectively. L^2_{cov} and L^3_{cov} are the coverage losses

of two generators, and L_{hcl}^{all} is the sum of the hierarchical consistency losses:

$$L_{hcl}^{all} = L_{hcl}^{12} + L_{hcl}^{13} + L_{hcl}^{23} \quad (13)$$

where L_{hcl}^{st} indicates the hierarchical consistency loss between task s and t.

4 Experiments and Results

4.1 Experimental Settings

We use two datasets, namely, a job advertisement dataset and the CNN-DailyMail (CNN-DM) dataset. We evaluate the headline generation, key phrase generation and classification tasks in these datasets. As an example, Figure 1 shows the headlines, key phrases and categories, which generally include common features, that is, the words mentioning occupations.

We also use the CNN-DM dataset (See et al., 2017) in an automatic evaluation under different task settings. We evaluate the multi-sentence summarization, headline generation and classification tasks in this dataset. Note that we train and evaluate the CNN and DailyMail datasets separately because they have different taxonomies.

The original CNN-DM dataset does not contains headlines or categories, and thus we extract the headlines and categories from the raw HTMLs. The Supplementary section describes the details and modification of the CNN-DM dataset.

We employ pointer-generator models without multi-task learning as baselines of the sentence generators, and a 2-layer GRU with attention as the baseline of the classifier. We chose all hyperparameters based on the learning curve and the scores of the validation set. Details of our model, such as the hyperparameters of the RNNs, the weights of the loss function and the optimizers, are described in the Supplementary section for reproducibility.

4.2 Results

Human evaluation of job advertisement dataset. We conduct a human evaluation of the job advertisement dataset to measure the quality of the generated outputs. Ten crowd-sourcing workers measure 250 randomly selected samples. We defined the following four metrics:

- Consistency: Measure whether the outputs include the same occupation. We choose a pair of outputs, and if both outputs mention the same type of occupation, we regard this pair as consistent.
- Adequacy: Measure how well the headline describes the correct information.
- Fluency: Measure how natural the generated headline is.
- Occupation Adequacy: Measure how well the headline mentions the correct occupation. For example, in Figure 1, if the generated headline implies that the occupation "engineer" is recruited, we regard this headline as adequate regarding the occupation. We assume that consistency of the occupation improves the score of the occupation adequacy.

	HG-KG	HG-CC	KG-CC	3 Outputs
Baseline	56.8%	37.6%	37.6%	30.0%
Proposed	**58.8%**	**39.6%**	**39.2%**	**32.4%**
Gold	65.2%	44.4%	48.8%	35.2%

Table 1: Comparison of human evaluation results with their consistency. HG-KG, HG-CC and KG-CC indicate the consistency scores between the headline generation and key phrase generation, headline generation and category classification and key phrase generation and category classification, respectively.

	Adequacy	Fluency	Occupation Adequacy
Baseline	3.34	3.69	3.45
Proposed	**3.76**	**3.86**	**3.89**
Gold	4.09	4.12	4.13

Table 2: Comparison of human evaluation results for headlines. Scores are an average of ten crowd-sourcing workers with five scale rating.

First, we conduct a human evaluation to measure the consistency among three outputs. Table 1 shows the evaluation results with their consistency. The scores are the percentage of articles evaluated as consistent by a majority of workers. We consider all three outputs as consistent if all pairs of outputs are consistent. The results indicate that the proposed method improves the consistency of the three generated outputs [1].

Second, to evaluate the quality of the generated headline, we implement a human evaluation to measure the adequacy and fluency. Table 2 shows the evaluation result along with the adequacy and fluency. The proposed method improves the

[1]Note that the consistency of HG-CC and KG-CC is relatively low because some categories are too abstractive (for example, "other types of engineers").

	Headline generation			Key phrase generation			Classification
	R-1	R-2	R-L	R-1	R-2	R-L	Accuracy
Baseline (Pointer-Generator Network)	25.1	5.3	21.1	30.9	10.6	28.7	62.8
Multi-Task Learning (MTL)	26.2	5.8	21.6	32.3	10.9	30.0	64.1
MTL + Scheduling (SD)	26.3	6.0	21.8	32.3	10.4	29.9	63.9

Table 3: Automatic evaluation results based on the ROUGE metrics and accuracy (%) of classification of job advertisement dataset. R-1, R-2 and R-L indicate the F_1 scores of ROUGE-1, ROUGE-2 and ROUGE-L, respectively. The proposed method (MTL + SD + HCL) achieved the best scores (bold) for all tasks, and the ROUGE scores are statistically significant from the baseline model ($p < 0.05$) in both the headline and key phrase (indicated as $*$). Lead-1 is the baseline score, which uses the first sentence of the input article as a predicted headline.

		Summarization			Headline Generation			Classification
		R-1	R-2	R-L	R-1	R-2	R-L	Accuracy
CNN	Baseline	30.7	10.6	27.3	19.5	5.0	17.0	43.8
	Proposed (MTL + SD + HCL)	$*$**31.0**	$*$**10.9**	$*$ **27.8**	**19.6**	**5.0**	**17.1**	**43.9**
	Lead	33.4	12.2	26.1	17.2	5.0	11.1	-
DailyMail	Baseline	38.4	15.8	35.0	43.1	25.3	39.6	89.0
	Proposed (MTL + SD + HCL)	$*$**38.9**	$*$**16.3**	$*$**35.4**	$*$**43.7**	**25.5**	$*$**40.1**	**89.8**
	Lead	43.8	19.2	37.3	27.7	10.9	21.7	-

Table 4: Automatic evaluation results based on the ROUGE metrics and accuracy (%) of classification of the CNN and DailyMail datasets. The metrics are the same as in Table 3. The proposed method (MTL + SD + HCL) improved the scores for all tasks. The scores with $*$ indicate that the scores are statistically significant from the baseline model ($p < 0.05$). The lead is the score that uses the first three sentences of the input article as a predicted summary, and the first sentence of the input article as a predicted headline.

adequacy by $0.42pt$ and the occupation adequacy by $0.44pt$. Proposed method can generate more adequate outputs, particularly for the occupation.

Automatic evaluation of job advertisement corpus. We implement an automatic evaluation using the ROUGE metrics (Lin, 2004) and accuracy. We conduct the experiment ten times, and calculate the average score. Table 3 shows the effect of the proposed methods: multi-task learning (MTL), scheduling strategy (SD) and hierarchical consistency loss (HCL). From this result, the proposed method (MTL + SD + HCL) achieves the best score on all three tasks. MTL and HCL improve for all three tasks, and SD improves the score of the headline generation.

Automatic evaluation of the CNN-DM dataset. Table 4 shows the results of the CNN and DailyMail datasets, respectively. For both datasets, the proposed method improves the ROUGE scores of the summarization and headline generation.

From Table 5, headlines and key phrases of the job advertisement dataset have more overlap than the summaries and headlines of the CNN-DM dataset. Therefore, tasks of the job advertisement dataset benefit more from maintaining the consistency. For this reason, the scores of the job advertisement dataset achieve greater improvement than the CNN-DM dataset.

	ROUGE-1	ROUGE-2	ROUGE-L
Job Ads	48.4	15.9	47.9
CNN	42.8	13.7	38.8
DailyMail	37.9	12.6	34.0

Table 5: ROUGE recall scores of task 2 (key phrases for the Job Ads, headlines for CNN-DM) gold sentences against task 3 (headlines for Job Ads, summaries for CNN-DM) gold sentences in the validation set. Higher scores indicate that words appearing in the sentence of task 2 are overlapped by the sentence of task 3.

Comparison of the decoder information sharing methods. To validate the advantages of our hierarchical consistency loss, we compare five decoder information sharing methods: a cascade model, soft-parameter sharing, non-hierarchical consistency loss, hierarchical consistency loss with normalized attention weights and our hierarchical consistency loss. Table 6 presents the comparison of the five methods for the job advertisement dataset.

The cascade model, similar to Isonuma et al.

	Headline Generation			Key Phrase Generation			Classification
	R-1	R-2	R-L	R-1	R-2	R-L	Accuracy
Baseline (Pointer-Generator Network)	25.1	5.3	21.1	30.9	10.6	28.7	62.8
Proposed (MTL + SD + HCL)	**26.9**	**6.1**	**22.4**	**32.8**	**11.2**	**30.5**	64.4
Comparison of Decoder Information Sharing Method							
MTL + SD	26.3	6.0	21.8	32.3	10.4	29.9	63.9
MTL + SD + Cascade Model	26.3	5.6	21.6	31.8	10.6	29.5	64.4
MTL + SD + Cascade Model (Gold)	26.5	5.8	21.9	32.8	10.4	30.3	**64.5**
MTL + SD + Soft-Parameter Sharing	25.8	5.9	21.4	32.1	10.0	29.6	64.0
MTL + SD + Non-Hierarchical Consistency Loss	25.9	6.0	21.4	32.6	10.9	30.2	64.0
MTL + SD + HCL with Normalized Attention Weights	26.2	6.0	21.7	31.9	10.5	29.5	63.9
Comparison of Encoder Information Sharing Method							
HCL (SD and MTL are not applied)	25.8	5.6	21.2	31.0	10.1	28.7	63.1
SD + HCL (MTL is not applied)	25.6	5.6	21.5	31.2	10.2	28.9	62.6

Table 6: Comparison of the decoder information sharing methods and encoder sharing methods for the job advertisement dataset. The metrics are the same as in Table 3. The proposed method (adopting HCL) achieved the best scores (bold) compared to the other sharing methods.

(2017); Anastasopoulos and Chiang (2018), uses the output of the classifier as an additional input of the headline and key phrase generators. Meanwhile, the cascade model (gold) uses the gold classification category as the additional input of the generators during training and inference.

It can be observed from Table 6 that the cascade model achieves a lower score than MTL + SD. However, the cascade model (gold) improves the ROUGE-L score. This result indicates that the classification error propagates to the generators when the cascade model is applied. Our proposed HCL has an advantage in that it does not suffer from an error of the classifier, and thus this method achieves the best score.

Furthermore, we compare our proposed HCL model with other settings. A soft-parameter sharing method (Guo et al., 2018) penalizes the difference between parameters in pairs of decoders. The non-hierarchical consistency loss is almost the same as the hierarchical consistency loss (Eqn. 10). We replace a ramp function in Eqn. 10 with an absolute value function. Neither the soft-parameter sharing method nor the non-hierarchical consistency loss has the ability to consider the hierarchy among tasks.

It can be observed from Table 6 that both methods achieved a lower score than the hierarchical consistency loss. This is because our hierarchical consistency loss enables the model to penalize a multi-task model with hierarchy among the tasks.

Although the HCL with normalized-attention weights adopts the hierarchical consistency loss model indicated in Eqn. 10, however, we substitute the normalized attention weights $\alpha_{ij}^{d^s}$ for non-normalized attention weights $e_{ij}^{d^s}$.

HCL with normalized attention weights is not as effective as HCL with non-normalized attention weights. Our HCL is based on the assumption that if one specific input word is important for both the shorter and longer text generation tasks, the attention weights of the words for the shorter text generation task would be smaller than the attention weights for the longer text generation task. However, the distributions of the normalized attention weights converge to a few words for the shorter text generation task; thus the normalized attention weights does not satisfy the assumption. As a result, our proposed HCL with non-normalized attention weights can accurately compute this inconsistency, contrary to the HCL with normalized attention weights.

Comparison of encoder information sharing methods. To determine the dependence of HCL on MTL, we conduct two experiments. HCL applies the hierarchical consistency loss without MTL and SD, while SD + HCL applies the scheduling sampling and hierarchical consistency loss; however, multi-task learning is not applied. Table 6 presents the results of two methods for the job advertisement dataset.

In comparison with the MTL applied models, both models do not improve the performance of the classification task. Encoder information sharing is beneficial for both the classification and generation tasks, whereas the attention infor-

Figure 5: An example of an input article, generated headlines and key phrases. Underlined words indicate that the attention weights of the headline generator between these words and the output words are high. **Blue colored words** indicate that the attention weights of these words are consistently high between the two decoders. In contrast, ***red colored italic words*** indicate that the attention weights of these words are high in the key phrase generator, but low in the headline generator, that is, inconsistency occurs between the two decoders. A Japanese-English translation is applied.

	ROUGE-1	ROUGE-2	ROUGE-L
Baseline	29.1	5.5	29.0
Proposed	53.7	19.2	53.4

Table 7: Comparison of ROUGE recall scores of generated key phrases against generated headlines for the job advertisement dataset. The proposed method significantly increases the word overlap between generated sentences.

mation sharing method is beneficial only for the generation task. This can be attributed to the asymmetry in the task settings. Generally, the generation task need to focus on a wider range of input words than the classification tasks. For the generation task, it is important that which words are focused on in the classification task. However, this is not always the case that the words focused on in the generation task are important for the classification task.

Analysis of word overlap between output sentences. To estimate the consistency between output sentences, we evaluate the word overlap between generated headlines and key phrases. Table 7 presents the ROUGE recall scores of the generated key phrases computed against generated headlines for the job advertisement dataset. Therefore, our proposed method generates significantly similar word outputs, resulting in improvement in the consistency between two sentences.

4.3 Example of Predicted Outputs

We visualize the attention weights of the decoders to assess the performance of the proposed method. The upper part of Figure 5 indicates an example of the attention weights of the headline and key phrase generators. The proposed method increases the consistency and decreases the inconsistency between the attention weights of the two decoders. With the proposed method, both decoders commonly focus on the word "Ruby on Rails," and thus both outputs consistently contain the word "Ruby." From this result, the proposed method, which avoids inconsistency, improves the quality of the outputs.

5 Conclusion

We introduced a novel multi-task learning method to maintain consistency among outputs. Hierarchical consistency loss was introduced to penalize inconsistency between two attention weights of decoders. We implemented a manual evaluation using crowd-sourcing, and the results indicates that our method generates more consistent outputs. An automatic evaluation showed that proposed method achieves the best ROUGE scores on both datasets. As a future work, we would like to explore whether our method is applicable to other tasks such as multi-task learning for object detection and image caption generation.

Abstract

In this paper, we introduce a novel task called feedback comment generation — a task of automatically generating feedback comments such as a hint or an explanatory note for writing learning for non-native learners of English. There has been almost no work on this task nor corpus annotated with feedback comments. We have taken the first step by creating learner corpora consisting of approximately 1,900 essays where all preposition errors are manually annotated with feedback comments. We have tested three baseline methods on the dataset, showing that a simple neural retrieval-based method sets a baseline performance with an F-measure of 0.34 to 0.41. Finally, we have looked into the results to explore what modifications we need to make to achieve better performance. We also have explored problems unaddressed in this work.

1 Introduction

In this paper, we introduce a novel task called *Feedback Comment Generation*. Feedback comment generation is[1] the task of generating hints or explanatory notes (hereafter, feedback comments) for language learners[2]. Figure 1 shows an example of feedback comments on preposition use. As in this example, feedback comments are typically given to erroneous words in a given text so that the writer can understand why their writing is not good together with underlying grammatical rules and more importantly so that they can improve their writing skill.

Feedback comment generation complements grammatical error detection/correction in language learning. With the advent of Deep Neural Networks (DNN), their performance has dramatically improved in recent years. However, they are not capable of explaining why detected words are erroneous nor why they should be corrected as indicated. This limitation is particularly problematic for beginner to intermediate learners. They might not be able to understand and acquire the underlying rules; if so, they will likely make similar errors in the future. This is exactly where feedback comment generation comes in. Namely, it complements grammatical error detection/correction by generating feedback comments to help learners understand and acquire the underlying rules. This form of feedback should be useful for language learners as Bitchener et al. (2005)[3] and Sheen (2007) show.

Despite its usefulness, there has been almost no work on feedback comment generation as Sect. 2 will describe. One of the major reasons is that there exists no publicly available dataset for research on feedback comment generation. It is costly and time-consuming to annotate writings of non-native learners with feedback comments. It is not straightforward to decide what information one should give to learners of English as feedback comments and how; as far as we are aware of, the current work on feedback for writing learning (e.g., Bitchener et al. (2005); Ferris and Roberts (2001); Robb et al. (1986); Sheen (2007)) focuses on the comparison of the salience of feedback (only detection results, detection and correction results, or those with error types and so on). Besides, even if a dataset existed, it would still be a difficult task to generate human-like feedback comments.

To attack the above difficulties, we take the first step towards feedback comment generation targeting preposition use. The reason for the choice of preposition use is that (a) preposition er-

[1] The strict definition will be introduced in Subsect. 3.

[2] In this paper, *language learners* refer to learners of English as Foreign Language (EFL).

[3] Note that in their work, human teachers did error correction in written form and provided the learners with feedback comments orally.

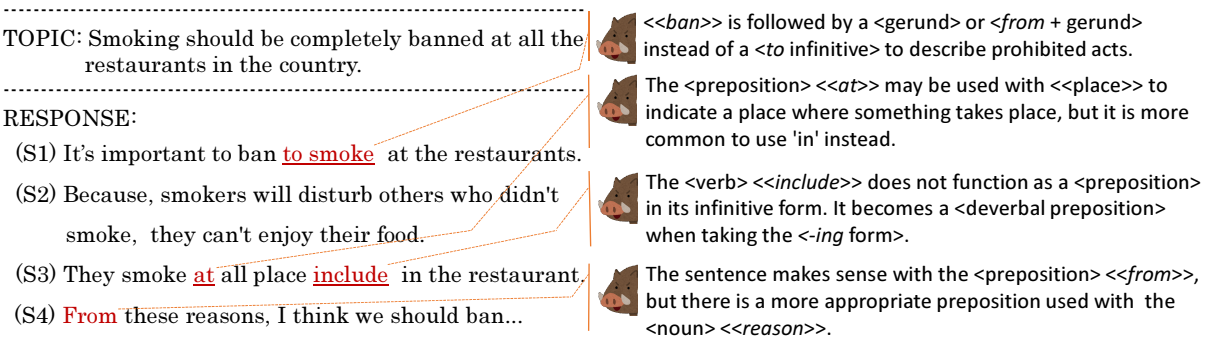

Figure 1: Example of Feedback Comments on Preposition Use.

rors are one of the most frequent error types in learner English (Tetreault and Chodorow, 2008); (b) they are relatively explainable (c.f., article errors); and (c) it would be a good starting point for feedback comment generation research considering the potential difficulty of the task. Specifically, we have annotated learner corpora with feedback comments, written in English and Japanese, on preposition use; we have released a part of the dataset to the public. Using the created dataset, we have trained and tested three baseline methods to estimate the feasibility of the task. In addition, we have looked into the results to reveal what problems we have left to achieve more complete feedback comment generation.

2 Related Work

The work most related to feedback comment generation is probably grammatical error detection/correction. The former is a task of detecting where errors exist in a given sentence whereas the latter is of retrieving its corrected form. In the beginning, researchers focused on specific error types – the most frequent ones such as errors in article (Han et al., 2006), preposition (Felice and Pulman, 2008), and number (Nagata et al., 2006). The state-of-the-art methods typically solve the problems as sequence labeling (e.g., Rei and Yannakoudakis (2016); Rei (2017); Kaneko et al. (2017)) or Machine Translation (MT) with DNNs (e.g., Junczys-Dowmunt et al. (2018); Napoles and Callison-Burch (2017)). As a result, performance has dramatically improved.

Unlike grammatical error correction, there has been almost no work on feedback comment generation. To the best of our knowledge, no work has even formally defined the task of feedback comment generation as we do in this paper. Some researchers (Kakegawa et al., 2000; McCoy et al., 1996; Nagata et al., 2014) made an attempt to develop rule-based methods for diagnosing errors in line with grammatical error detection/correction. Rule-based methods typically parse the input sentence and then apply rules to the resulting parse to diagnose errors. However, they encounter the tremendous difficulty of covering a wide variety of errors and of maintaining a large set of rules.

Comment generation for program source code is another task of comment generation. Its input and output are a piece of program source code such as a Java method and its comment or summary, respectively. Iyer et al. (2016) and Hu et al. (2018) solved the task as an MT problem (source code to comment) by using sequence-to-sequence models. This implies that feedback comment generation may be solved in the same manner (i.e., learner sentence to feedback comment).

3 Task Definition

Feedback comment generation in general is the task of generating feedback comments given a text (referred to as *essay*, hereafter). Thus, the input is an essay. The output is a set consisting of pairs of an offset and a feedback comment. An offset is a range of integers indicating where the paired feedback comment applies in the input essay. A feedback comment is a string that helps the writer (learner) improve their writing skill. It is typically a comment about a grammatical error, but can be about other things including discourse, organization, and content. It may be a side note to make the present writing better or praise to motivate the writer.

Note that because of the above, the range in feedback comment generation does not necessary match that in grammatical error detec-

tion/correction. Also note that there are cases where the input has no or more than one feedback comments; on the one hand, there exist sentences that receive no feedback comment at all as in (S2) in Fig. 1; on the other hands there exit sentences that receive more than one feedback comments as in (S3).

Our present target, feedback comment generation for preposition use, follows this task definition. Here, it is worthwhile to mention that we include *to*-infinitives in preposition use as in (S1) in Fig. 1. We also include errors that can be classified into multiple error types (preposition and other types). For example, in the sentence **Have a part-time job is easy.*, the underlined word *Have* can be interpreted as a missing *to*-infinitive (i.e., *To have*) or as a verb form error (i.e., *Having*). We include such cases in our targets to provide richer information.

4 Data Development

We created a dataset for feedback comment generation for preposition use. We used it in the evaluation as described in Sect. 6. We have released a part of it to the public on the web[4].

We selected the written essays in the International Corpus Network of Asian Learners of English (hereafter, ICNALE) as our base corpus. Their essay topics are controlled; all essays are written on two common topics: (a) *It is important for college students to have a part-time job.* and (b) *Smoking should be completely banned at all the restaurants in the country.*, which hereafter will be referred to as *PART-TIME JOB* and *SMOKING*, respectively. This simulates the condition common to the language learning settings that essays are often written on one topic in language learning as in writing exercises in class and writing tasks in language proficiency tests. The writers are college students (including graduate students) from 10 countries and regions in Asian (although we only used the Chinese, Indonesian, Japanese, and Korean portions for time and cost reasons). Their proficiency levels are estimated to be from A2 to B2+ in the CEFR metric. As preprocessing, we split the essays into sentences and in turn tokenized them by using the Stanford Statistical Natural Language Parser (ver.2.0.3) (de Marneffe et al., 2006).

[4]The corpus data are available at `https://www.gsk.or.jp/en/catalog//`.

Before annotation, we had to choose in which language we would create feedback comments. Basically, the choice would be either English or the writer's native language. We chose Japanese, one of the writers' native languages, for the following reasons: (1) Beginner to intermediate learners may have difficulty in understanding feedback comments in English when working on writing exercises; (2) it will likely be more technically challenging and interesting to generate feedback comments on English in a different language; (3) it would be too costly to create feedback comments in all the native languages and accordingly we chose the one we can understand. For accessibility, we manually translated them into English for future research. In this work, we only used the Japanese feedback comments.

In addition, we created two special symbols to augment feedback comments: grammatical term ($<$, $>$) and citation ($<<$, $>>$). Grammatical terms are tagged with $<$ and $>$ as in $<$*intransitive verb*$>$. With this, one can make links to corresponding grammatical items in a grammar book, for example, as an additional source of information for the user[5]. Citation is used to denote that the word(s) inside the symbols is cited from the commented sentence as in $<<$*agree*$>>$. This makes feedback comments more flexible. That is, the word(s) inside $<<$ and $>>$ in a generated feedback comment may be replaced with another word(s) in the commented sentence.

This is the big picture of how we created the data. More details are described in the guideline accompanied with the dataset[6].

We hired two professional annotators who had a good command of English. Both of them have had experience in English syntactic annotation for more than ten years; one of them had two years of professional English writing teaching experience where she provided high school and college students with feedback comments as in this work.

We sampled out 1,040 essays from ICNALE and assigned them to either annotator. The annotators read an entire essay first one at a time and then added feedback comments to all preposition errors they found, plus other parts on which they wanted to annotate (e.g., praise). They used the commenting function in MS-Word for this annotation.

[5]We have also created a grammar database with a list of grammar items and their explanations. However, it is not included in the dataset due to copyright issues.

[6]The guideline is included in the dataset.

comments/sent.	0.18	0.18	0.17	0.16	0.18	0.17	0.17	0.17

Table 1: Statistics on the created dataset.

Finally, we split 1,040 essays into training, development, and test sets as shown in Table 1[7]. We transformed the MS-Word format into a TSV format (learner sentence, offset, feedback comment[8]) and used the resulting essays for evaluation.

5 Baseline Methods

To examine the feasibility of feedback comment generation for preposition use, we implemented the following three simple baseline methods: a neural retrieval-based method, a sequence-to-sequence model, and a rule-based method. The following subsections describe each method in detail.

5.1 Neural Retrieval-based Method

This method solves the task as a feedback comment retrieval problem. The procedure consists of:
(0) Preprocessing
(I) Feedback comment vector encoding
(II) Detection and context vector extraction
(III) Mapping between the two vectors
(IV) Feedback comment retrieval
(V) Output
The main steps (I)–(IV) are depicted in Fig. 2.

(0) Preprocessing is applied to the input essay in both training and prediction. First, it is split into sentences. Then, each sentence is tokenized and put into lowercase. Finally, tokens whose occurrence is lower than a certain threshold are replaced with the special symbol <unk>. The same procedures except sentence splitting are applied to feedback comments in the training data.

In **(I) Feedback comment encoding**, the preprocessed feedback comments are encoded as vectors (Fig. 2 (I)) by using LSTM-based Language Models (LSTMLMs). Tokens in a feedback comment are turned into their corresponding word embeddings in an embedding layer and then passed on to an LSTM, which is trained to predict the next token. After training, all feedback comments are once again passed through the trained network. Its final hidden state of the final layer, which is merely a vector, can be regarded as an abstract representation of a feedback comment. In addition, another LSTMLM of the same architecture, which takes as input each token in reverse order, is used to augment the representation power. The two final states are simply concatenated to produce a vector for the input feedback comment. In the end, all feedback comments are abstractly represented as vectors, which will be used later in (III).

(II) Detection and context vector extraction consist of two subtasks. The first is to detect where to comment in the input essay. Hereafter, each sentence in the input essay is processed (namely, given to the network) one at a time. Under this condition, the subtask can be regarded as a binary sequence labeling problem in which input and output are a sequence of tokens and a sequence of 0/1 (to comment or not), respectively as in the sequence labelling-based error detection (e.g., Rei and Yannakoudakis (2016); Rei (2017); Kaneko et al. (2017)).

Following the work (Kaneko et al., 2017), this paper uses a BiLSTM-based sequence labeling model as shown in Fig. 2 (II). To be precise, each token is transformed into its corresponding word embedding, then is given to a BiLSTM, and finally to a softmax layer that estimates the probabilities of 0 and 1. During training, the information about where to comment is given as offsets. For simplicity, we used word-based offsets. In addition, if a feedback comment refers to more than one words, we used the position of the central word as its offset. The loss function to minimize is simply the cross-entropy loss. During prediction, each token

[7]We are still conducting the annotation over ICNALE and another learner corpus (Konan-JIEM learner corpus (Nagata and Sakaguchi, 2016)). At the time of submission, the number of annotated essays has reached 1,900.

[8]The offset and feedback comment columns may be none or repeated an arbitrary number of times.

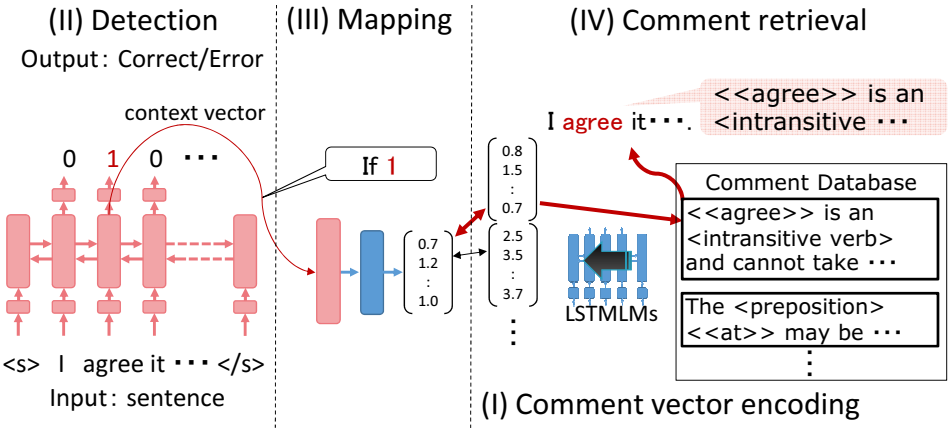

Figure 2: Neural Retrieval-based Method.

in the target sentence is given to the network to estimate the probabilities of 0 and 1.

The second subtask is to represent the surrounding context of the detected word abstractly. This is actually already done in the course of the first subtask. Namely, the corresponding BiLSTM hidden states can be used as context vectors because at each time step, the information about its surrounding words are recurrently accumulated in them.

In **(III) Mapping between the two vectors**, the detected context vectors are mapped onto the feedback comment vector space[9]. This is done by a Feed Forward Neural Network (FFNN) (Fig. 2 (III)). The purpose is to map context vectors near the corresponding comment vectors in the space. Accordingly, the mean square error can be naturally used as a loss function. Note that the whole networks (BiLSTM for sequence labeling in (II) and FFNN for vector mapping in (III)) are trained simultaneously (i.e., multi-task learning). The total loss l is defined by $l = (1-\beta)l_{\mathrm{s}} + \beta l_{\mathrm{m}}$ where l_{s}, l_{m}, and β are the losses for sequence labeling and vector mapping, and a hyperparameter that controls the weighting between the two, respectively.

(IV) Feedback comment retrieval and the following procedures are applied only during prediction. After (II) and (III), words to be commented on are detected and their context vectors are transformed into feedback comment vectors. This means that one can retrieve the most appropriate feedback comments by searching the space for feedback comment vectors similar to the mapped context vector. The similarity is measured by the cosine similarity between two vectors.

To improve performance, it is important to filter out inappropriate results. In some cases, a discrepancy occurs between the word detected in (II) (say, *at*) and the word to which the retrieved comment applies in the training data (say, *in*). In that case, the retrieved feedback comment will likely be inappropriate no matter how high its similarity is (in the above example, a feedback comment concerning *in* is applied to *at*). Consequently, these feedback comments are excluded from the results. In addition, the cosine similarity should be a good indicator to determine whether the retrieved feedback comments are appropriate or not, and thus retrieved feedback comments are discarded if their similarity is lower than a certain threshold. In other words, we do not generate feedback comments if we cannot find similar feedback comments in the training data.

In **(V) Output**, the most appropriate feedback comment (according to their similarities) for each commented word is displayed to the user.

5.2 Sequence-to-sequence Model-based Method

This method is an implementation of the sequence-to-sequence (encoder-decoder) model with an attention mechanism (Bahdanau et al., 2014)). It takes a learner sentence as input. It then puts the input sentence into a feedback comment.

Each word in the input learner sentence, which is preprocessed just as in the neural retrieval-based method, is encoded by a word embedding layer and a BiLSTM-based encoder. Then, a feedback

[9]Recall all comments in the training data have already been transformed into vectors in (I).

comment is generated by another word embedding layer and an LSTM-based decoder with an attention mechanism.

During the development phase, we observed that the network trained on the entire training data almost always resulted in generating no feedback comments. We observed a similar tendency when it was trained with a fixed feedback comment for the correct sentences (such as *There is no preposition error in this sentence.*). Considering this, we trained (and tested) the sequence-to-sequence model-based method on only sentences that had feedback comments to show the upper bound of this method.

5.3 Case frame-based Method

This method is an implementation of the case frame-based method (Nagata et al., 2014). The method automatically induces case frames by comparing learner and native corpora, to detect preposition errors with feedback comments.

We apply the exact same preprocessing as in the neural retrieval-based method to both learner and native corpora to induce case frames. We then manually created feedback comments for each induced case frame.

6 Evaluation

6.1 Conditions and Procedures

We implemented and trained the baseline methods with the created dataset. We first obtain word embeddings for learner sentences from the corpora as shown in Appendix A. We also used the word embeddings for English words in the LSTMLMs to encode feedback comments. For the rest (i.e., Japanese words), we initialized them using random-valued vectors. We used MeCab[10] to tokenize the feedback comments. With these word embeddings, we trained the networks on the training set of the respective subsets (PART-TIME JOB and SMOKING). We implemented the case frame-based method with the following corpora: British National Corpus (BNC) (Burnard, 1995), the EDR corpus (Japan electronic dictionary research institute Ltd, 1993) as a native corpus and the training and development set of the corresponding dataset[11] as a learner corpus. As a result, we obtained two versions of each method. We determined the hyperparameters by using the corresponding development set[12]. We tested the resulting models on the corresponding test set.

For evaluation, one of the professional annotators, who had been involved in the data creation, manually evaluated the results. She labeled each generated feedback comment as *appropriate*, *partially appropriate*, or *inappropriate*; *partially appropriate* refers to the case that the feedback comment is not completely appropriate but would become appropriate if part of it were edited.

We measured performance by recall, precision. We also used F-measure targeting *appropriate* feedbacks. We calculated their values considering only *appropriate* as correct generation. We also used their relaxed versions regarding *partially appropriate* as appropriate generation.

6.2 Results

Table 2 shows the results. It turns out that the simple application of the sequence-to-sequence model does not work well at all on this task; note that it is provided with the information about which sentence should have a feedback comment (i.e., tested on only the sentences having feedback comments). Nevertheless, its performance is very poor. This suggests that it requires modifications to achieve better performance with the sequence-to-sequence framework. *Case frame-based* successfully generates feedback comments in some cases. However, its recall is quite low. In contrast, the neural retrieval-based method achieves a far better performance in recall, achieving a precision comparable to that of *case frame-based*.

At the same time, Table 2 shows that there is still room for improvement. Subsect. 7.1 will investigate the generation results to reveal what has been solved by the methods.

[10] http://taku910.github.io/mecab/

[11] Because it does not require a development set for hyperparameter tuning, the development set was added to the training set.

[12] The hyperparameters are as follows: LSTMLMs: number of LSTM layers: 2, number of hidden states: 600; BiLSTM: number of LSTM layers: 1, number of hidden states: 600×2; FFNN: number of layers:1 (with dimension 1,200); BiLSTM encoder: number of LSTM layers:1, number of hidden states 600×2; LSTM decoder: number of LSTM layers:1, number of hidden states 600. Common hyperparameters: batch size: 64, number of epochs: 200 (with early stopping (patience: 10)), dropout rate: 0.5, optimization algorithm: Adam (step size: 0.01, the first and second moment: 0.9 and 0.999, respectively), threshold for <unk>: 5 in essays and 2 in feedback comments, threshold for the cosine similarity: 0.971 (PART-TIME JOB) and 0.976 (SMOKING), weight β for losses: 0.9.

Method	PART-TIME JOB			SMOKING		
	Recall	Precision	F-measure	Recall	Precision	F-measure
Retrieval-based	0.23 (0.25)	0.61 (0.67)	0.34 (0.37)	0.28 (0.30)	0.72 (0.78)	0.41 (0.44)
Seq2seq	0.06 (0.07)	0.07 (0.08)	0.07 (0.08)	0.10 (0.13)	0.11 (0.13)	0.10 (0.13)
Case frame-based	0.10 (0.10)	0.62 (0.62)	0.16 (0.16)	0.05 (0.05)	0.75 (0.75)	0.09 (0.09)

Table 2: Generation Performance (numbers in brackets correspond to the relaxed measures).

7 Discussion

7.1 Analysis of Generated Comments

Looking into the generation results reveals that the neural retrieval-based method successfully generates feedback comments on errors typical to the topics (e.g., (S3) and (S4) in Fig. 3) and typical to argumentative essays (e.g., (S1) and (S7)), or more general ones (e.g., (S6)). While the superficial variations of these typical errors are large in general, they correspond to one or a few feedback comments. Actual examples are: *I/People (don't) agree the/this statement/opinion/that/thinking* and *(more) harmful (not only) for anyone/people/smokers/non-smokers*. These findings suggest that abstractly representing feedback comments and contexts and tying them in the feedback comment space, is effective in generating feedback comment on typical preposition errors.

It would probably be possible to create rule-based methods covering such typical errors. It would, however, take the expertise of at least a teacher of English and also a computer engineer to achieve it; the former would have to think of what is typical in the given topic and then to make a set of rules; the latter then would have to turn them into computer-readable forms. In contrast, the neural retrieval-based method only requires a teacher of English to annotate a given corpus with feedback comments, without examining what is typical, which is much more effective and efficient.

More importantly, there exist typical errors to which rules-based methods do not apply well. Examples include the word *Have* in (S2) and the word *include* in (S6) in Fig. 3. On the one hand, it would require a successful parsing to recognize the sources of the errors. On the other hand, it would require successful error detection to parse them correctly. Accordingly, rule-based methods, which normally require parsing, fail in generation in these cases. In contrast, the neural retrieval-based method gives a simple solution to this *parsing-first* or *error detection-first* dilemma because it does not depend on parsing at all.

To see the upper bound of the performance of the neural retrieval-based method, we evaluated its performance using the oracle offsets (where to comment). As a result, the strict recall and precision respectively improved to 0.27 and 0.73 in PART-TIME JOB and 0.30 and 0.79 in SMOKING. We also evaluated its detection performance as another upper bound of performance; if we cannot detect errors, we will never be able to generate feedback comments for them. We obtained a recall of 0.27 and a precision of 0.71 in PART-TIME JOB and a recall of 0.31 and a precision of 0.79 in SMOKING. The comparison between the two upper bounds suggests that one can successfully generate feedback comments for detected errors. This is partly because we used the same training data for error detection and feedback comment generation.

All these findings show neural retrieval-based methods are promising to generate feedback comments for typical errors. It is important from the viewpoint of language learning assistance to be able to generate feedback comments for typical errors considering that feedback is normally given to typical errors first in language learning (rather than to rare, irregular errors). More sophisticated retrieval-based methods such as the work by Hashimoto et al. (2018) and Qiu et al. (2017) will likely improve generation performance.

7.2 Model Analysis

One would probably think of using an attention mechanism to improve the neural retrieval-based method. We actually investigated its effectiveness during the development phase. It turned out that the neural retrieval-based method with and without an attention mechanism performed similarly; to be precise, the F-measure (of comment word detection) of the one with an attention mechanism was often slightly worse.

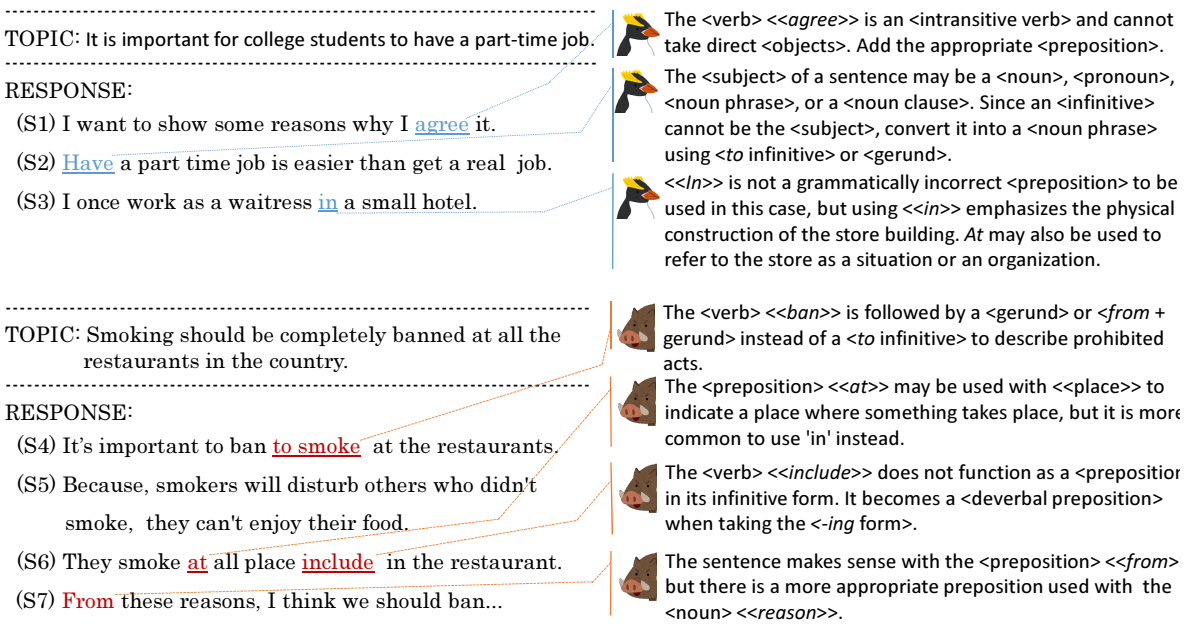

Figure 3: Example of Feedback Comments on Preposition Use Generated by Neural Retrieval-based Method.

This is partly because one can often tell from a narrow context why the usage of a given preposition is erroneous as in *agree it*. BiLSTM can handle well the information in such a narrow window without an attention mechanism. Having said that, we need further investigations to confirm that this argument is true; in particular, it might be necessary to generate feedback comments in general. Another reason would be that the amount of training data was not enough to train the attention layer, which also might be a reason why the sequence-to-sequence model (with an attention mechanism) does not perform well.

7.3 Unaddressed Problems

Sect. 6 has shown that feedback comments for preposition use can be automatically generated to some extent. The question now is whether the same argument can be made about feedback comment generation in general. Intuitively, it is a more difficult task because there are more variations in other grammatical errors. There are much more variations in feedback comments concerning other writing skills such as discourse and organization.

To answer the question, we have annotated and (are still annotating) learner corpora with feedback comments in general (together with those for preposition use). At the time of submission, the number of annotated essays has reached 2,300 (and will be 4,000 in the end) over two learner corpora (ICNALE and Konan-JIEM learner corpus (Nagata and Sakaguchi, 2016)). They range over a wide variety of writing skills including discourse, word choice, and organization. We will test the neural retrieval-based method on the dataset.

Another factor that makes the task hard is how to evaluate generated feedback comments. While, in this paper, we have applied manual evaluation, it is highly costly and time-consuming. For this reason, it would be difficult to make a thorough comparison between various methods or various model settings. One should have an efficient way of evaluating generated feedback comments to facilitate feedback comment generation research.

BLEU (Papineni et al., 2002) would be a choice for solving this problem as can be seen in machine translation research. As a pilot study, we estimated the validity of BLEU in this task. We randomly sampled out 702 feedback comments from the dataset and manually extracted pairs that had the same content. As a result, it turned out that the BLEU value ranged from as low as 0.15 to as high as 0.99; the average and the standard deviation were 0.61 and 0.25, respectively[13]. For comparison, we also calculated the BLEU value for pairs randomly chosen from the rest (that had not been paired previously); the average and the stan-

[13] We excluded the exact matches.

dard deviation were 0.13 and 0.09, respectively[14]. These numbers show that while BLEU can distinguish between appropriate and inappropriate feedback comments to some extent, it can be unreliable in some cases. All these observations suggest that we should have other evaluation methods together with BLEU.

8 Conclusions

In this paper, we introduced a novel task called feedback comment generation. We first described the task definition and created a dataset for the task of feedback comment generation for preposition use. We then tested a rule-based and two neural-based baselines on the dataset, showing that retrieval-based methods were promising. We further analyzed what the neural retrieval-based method can generate. We also discussed unaddressed problems. Especially, we pointed out that the evaluation was costly and time-consuming and that we needed a more efficient way of evaluation.

In future work, we will investigate how we can generate more flexible feedback comments. One way of achieving it is to apply a more sophisticated retrieval-based method such as (Hashimoto et al., 2018) to this task. We will also investigate how we can efficiently evaluate generation results.

Abstract

Question generation (QG) is the task of generating a question from a reference sentence and a specified answer within the sentence. A major challenge in QG is to identify answer-relevant context words to finish the declarative-to-interrogative sentence transformation. Existing sequence-to-sequence neural models achieve this goal by proximity-based answer position encoding under the intuition that neighboring words of answers are of high possibility to be answer-relevant. However, such intuition may not apply to all cases especially for sentences with complex answer-relevant relations. Consequently, the performance of these models drops sharply when the relative distance between the answer fragment and other non-stop sentence words that also appear in the ground truth question increases. To address this issue, we propose a method to jointly model the unstructured sentence and the structured answer-relevant relation (extracted from the sentence in advance) for question generation. Specifically, the structured answer-relevant relation acts as the to the point context and it thus naturally helps keep the generated question to the point, while the unstructured sentence provides the full information. Extensive experiments show that to the point context helps our question generation model achieve significant improvements on several automatic evaluation metrics. Furthermore, our model is capable of generating diverse questions for a sentence which conveys multiple relations of its answer fragment.

1 Introduction

Question Generation (QG) is the task of automatically creating questions from a range of inputs, such as natural language text (Heilman and Smith, 2010), knowledge base (Serban et al., 2016) and image (Mostafazadeh et al., 2016). QG is an increasingly important area in NLP with various application scenarios such as intelligence tutor systems, open-domain chatbots and question answering dataset construction. In this paper, we focus on question generation from reading comprehension materials like SQuAD (Rajpurkar et al., 2016). As shown in Figure 1, given a sentence in the reading comprehension paragraph and the text fragment (i.e., the answer) that we want to ask about, we aim to generate a question that is asked about the specified answer.

Sentence: The daily mean temperature in January, the area's coldest month, is 32.6 °F (0.3 °C); however, temperatures usually drop to 10 °F (-12 °C) several times per winter and reach 50 °F (10 °C) several days each winter month.
Reference Question: What is New York City 's daily January mean temperature in degrees celsius ?
Baseline Prediction: What is the coldest temperature in Celsius ?
Structured Answer-relevant Relation: (The daily mean temperature in January; is; 32.6 °F (0.3 °C))

Figure 1: An example SQuAD question with the baseline's prediction. The answer ("0.3 °C") is highlighted.

Question generation for reading comprehension is firstly formalized as a declarative-to-interrogative sentence transformation problem with predefined rules or templates (Mitkov and Ha, 2003; Heilman and Smith, 2010). With the rise of neural models, Du et al. (2017) propose to model this task under the sequence-to-sequence (Seq2Seq) learning framework (Sutskever et al., 2014) with attention mechanism (Luong et al., 2015). However, question generation is a one-to-many sequence generation problem, i.e., several aspects can be asked given a sentence. Zhou et al. (2017) propose the answer-aware question generation setting which assumes the answer, a contiguous span inside the input sentence, is al-

>10 (27.2% of #)	35.67	21.72	14.82	10.46	16.72	37.63

Table 1: Performance for the average relative distance between the answer fragment and other non-stop sentence words that also appear in the ground truth question. (Bn: BLEU-n, MET: METEOR, R-L: ROUGE-L)

ready known before question generation. To capture answer-relevant words in the sentence, they adopt a BIO tagging scheme to incorporate the answer position embedding in Seq2Seq learning. Furthermore, Sun et al. (2018) propose that tokens close to the answer fragments are more likely to be answer-relevant. Therefore, they explicitly encode the relative distance between sentence words and the answer via position embedding and position-aware attention.

Although existing proximity-based answer-aware approaches achieve reasonable performance, we argue that such intuition may not apply to all cases especially for sentences with complex structure. For example, Figure 1 shows such an example where those approaches fail. This sentence contains a few facts and due to the parenthesis (i.e. "the area's coldest month"), some facts intertwine: "The daily mean temperature in January is 0.3°C" and "January is the area's coldest month". From the question generated by a proximity-based answer-aware baseline, we find that it wrongly uses the word "coldest" but misses the correct word "mean" because "coldest" has a shorter distance to the answer "0.3°C".

In summary, their intuition that "the neighboring words of the answer are more likely to be answer-relevant and have a higher chance to be used in the question" is not reliable. To quantitatively show this drawback of these models, we implement the approach proposed by Sun et al. (2018) and analyze its performance under different relative distances between the answer and other non-stop sentence words that also appear in the ground truth question. The results are shown in Table 1. We find that the performance drops at most 36% when the relative distance increases from "$0 \sim 10$" to "> 10". In other words, when the useful context is located far away from the answer, current proximity-based answer-aware approaches will become less effective, since they overly emphasize neighboring words of the answer.

To address this issue, we extract the structured answer-relevant relations from sentences and propose a method to jointly model such structured relation and the unstructured sentence for question generation. The structured answer-relevant relation is likely to be to the point context and thus can help keep the generated question to the point. For example, Figure 1 shows our framework can extract the right answer-relevant relation ("The daily mean temperature in January", "is", "32.6°F (0.3°C)") among multiple facts. With the help of such structured information, our model is less likely to be confused by sentences with a complex structure. Specifically, we firstly extract multiple relations with an off-the-shelf Open Information Extraction (OpenIE) toolbox (Saha and Mausam, 2018), then we select the relation that is most relevant to the answer with carefully designed heuristic rules.

Nevertheless, it is challenging to train a model to effectively utilize both the unstructured sentence and the structured answer-relevant relation because both of them could be noisy: the unstructured sentence may contain multiple facts which are irrelevant to the target question, while the limitation of the OpenIE tool may produce less accurate extracted relations. To explore their advantages simultaneously and avoid the drawbacks, we design a gated attention mechanism and a dual copy mechanism based on the encoder-decoder framework, where the former learns to control the information flow between the unstructured and structured inputs, while the latter learns to copy words from two sources to maintain the informativeness and faithfulness of generated questions.

In the evaluations on the SQuAD dataset, our system achieves significant and consistent improvement as compared to all baseline methods. In particular, we demonstrate that the improvement is more significant with a larger relative distance between the answer and other non-stop sentence words that also appear in the ground truth question. Furthermore, our model is capable of generating diverse questions for a single sentence-answer pair where the sentence conveys multiple relations of its answer fragment.

Sentence: Beyoncé received critical acclaim and commercial success, selling one million digital copies worldwide in six days; The New York Times noted the album's unconventional, unexpected release as significant.
N-ary Relations:
0.85 (Beyoncé; received commercial success selling; one million digital copies worldwide; in six days)
0.92 (The New York Times; noted; the album's unconventional, unexpected release as significant)

Sentence: The daily mean temperature in January, the area's coldest month, is 32.6 °F (0.3 °C); however, temperatures usually drop to 10 °F (-12 °C) several times per winter and reach 50 °F (10 °C) several days each winter month.
N-ary Relations:
0.95 (The daily mean temperature in January; is; 32.6 °F (0.3 °C))
0.94 (temperatures; drop; to 10 °F (12 °C); several times per winter; usually)
0.90 (temperatures; reach; 50 °F)

Figure 2: Examples for n-ary extractions from sentences using OpenIE. Confidence scores are shown at the beginning of each relation. Answers are highlighted in sentences. Waved relations are selected according to our criteria in Section 2.2.

2 Framework Description

In this section, we first introduce the task definition and our protocol to extract structured answer-relevant relations. Then we formalize the task under the encoder-decoder framework with gated attention and dual copy mechanism.

2.1 Problem Definition

We formalize our task as an answer-aware Question Generation (QG) problem (Zhao et al., 2018), which assumes answer phrases are given before generating questions. Moreover, answer phrases are shown as text fragments in passages. Formally, given the sentence S, the answer A, and the answer-relevant relation M, the task of QG aims to find the best question $\overline{Q}$ such that,

$$\overline{Q} = \arg\max_{Q} \text{Prob}(Q|S, A, M), \qquad (1)$$

where A is a contiguous span inside S.

2.2 Answer-relevant Relation Extraction

We utilize an off-the-shelf toolbox of OpenIE [1] to the derive structured answer-relevant relations from sentences as to the point contexts. Relations extracted by OpenIE can be represented either in a triple format or in an n-ary format with several secondary arguments, and we employ the latter to keep the extractions as informative as possible and avoid extracting too many similar relations in different granularities from one sentence. We join all arguments in the extracted n-ary relation into a sequence as our to the point context. Figure 2 shows n-ary relations extracted from OpenIE. As we can see, OpenIE extracts multiple relations for complex sentences. Here we select the most informative relation according to three criteria in the order of descending importance: (1) having the maximal number of overlapped tokens between the answer and the relation; (2) being assigned the highest confidence score by OpenIE; (3) containing maximum non-stop words. As shown in Figure 2, our criteria can select answer-relevant relations (waved in Figure 2), which is especially useful for sentences with extraneous information. In rare cases, OpenIE cannot extract any relation, we treat the sentence itself as the to the point context.

[1] http://openie.allenai.org/

	Sentence	Answer-relevant Relation
Avg. length	32.46	13.04
# overlapped words	2.87	1.86
Copy ratio	8.85%	14.26%

Table 2: Comparisons between sentences and answer-relevant relations. Overlapped words are those non-stop tokens co-occurring in the source (sentence/relation) and the target question. Copy ratio means the proportion of source tokens that are used in the question.

Table 2 shows some statistics to verify the intuition that the extracted relations can serve as more to the point context. We find that the tokens in relations are 61% more likely to be used in the target question than the tokens in sentences, and thus they are more to the point. On the other hand, on average the sentences contain one more question token than the relations (1.86 v.s. 2.87). Therefore, it is still necessary to take the original sentence into account to generate a more accurate question.

2.3 Our Proposed Model

Overview. As shown in Figure 3, our framework consists offour components (1) Sentence Encoder and Relation Encoder, (2) Decoder, (3) Gated Attention Mechanism and (4) Dual Copy Mechanism. The sentence encoder and relation encoder encode the unstructured sentence and the structured answer-relevant relation, respectively. To select and combine the source information from the two encoders, a gated attention mechanism is

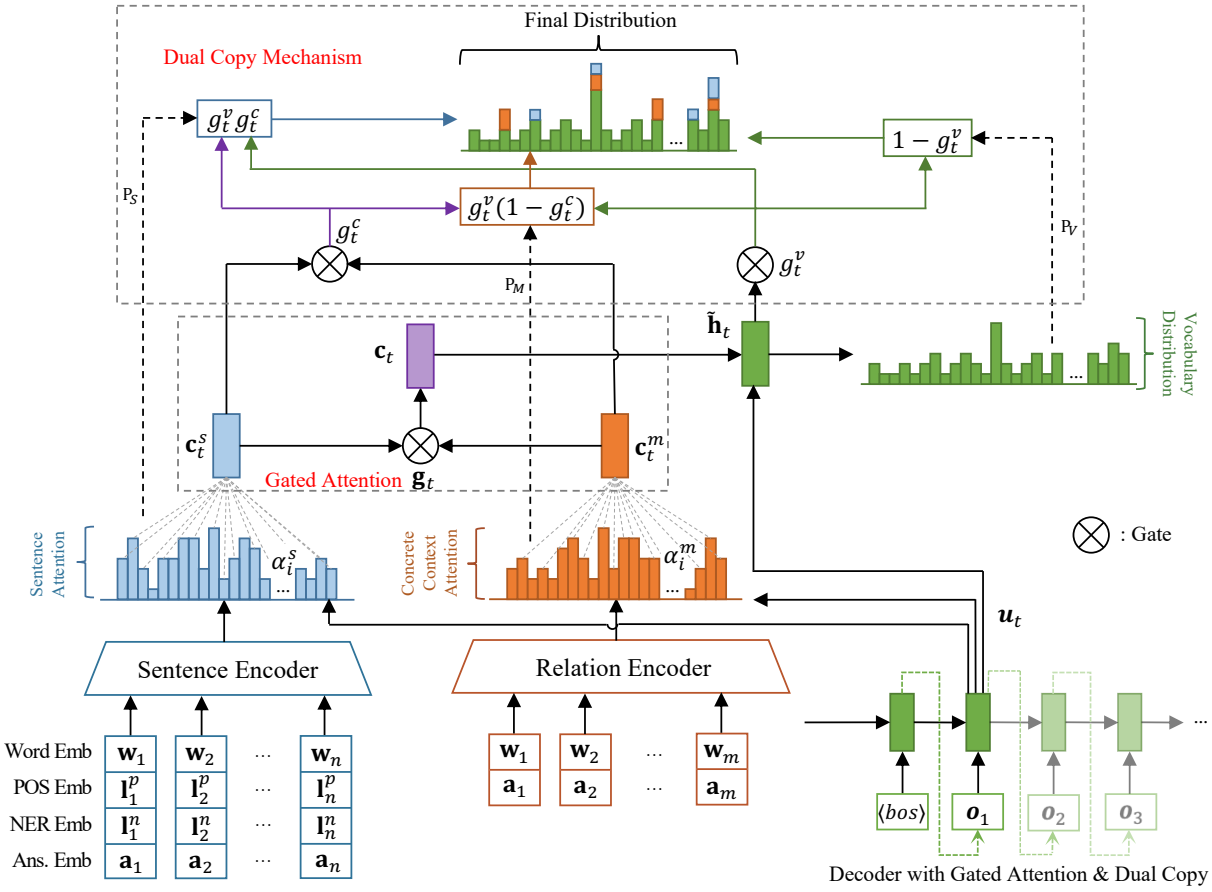

Figure 3: The framework of our proposed model. *(Best viewed in color)*

employed to jointly attend both contextualized information sources, and a dual copy mechanism copies words from either the sentence or the relation.

Answer-aware Encoder. We employ two encoders to integrate information from the unstructured sentence S and the answer-relevant relation M separately. Sentence encoder takes in feature-enriched embeddings including word embeddings $\mathbf{w}$, linguistic embeddings $\mathbf{l}$ and answer position embeddings $\mathbf{a}$. We follow (Zhou et al., 2017) to transform POS and NER tags into continuous representation ($\mathbf{l}^p$ and $\mathbf{l}^n$) and adopt a BIO labelling scheme to derive the answer position embedding (B: the first token of the answer, I: tokens within the answer fragment except the first one, O: tokens outside of the answer fragment). For each word w_i in the sentence S, we simply concatenate all features as input: $\mathbf{x}_i^s = [\mathbf{w}_i; \mathbf{l}_i^p; \mathbf{l}_i^n; \mathbf{a}_i]$. Here $[\mathbf{a}; \mathbf{b}]$ denotes the concatenation of vectors $\mathbf{a}$ and $\mathbf{b}$.

We use bidirectional LSTMs to encode the sentence $(\mathbf{x}_1^s, \mathbf{x}_2^s, ..., \mathbf{x}_n^s)$ to get a contextualized representation for each token:

$$\overrightarrow{\mathbf{h}}_i^s = \overrightarrow{\text{LSTM}}(\overrightarrow{\mathbf{h}}_{i-1}^s, \mathbf{x}_i^s), \quad \overleftarrow{\mathbf{h}}_i^s = \overleftarrow{\text{LSTM}}(\overleftarrow{\mathbf{h}}_{i+1}^s, \mathbf{x}_i^s),$$

where $\overrightarrow{\mathbf{h}}_i^s$ and $\overleftarrow{\mathbf{h}}_i^s$ are the hidden states at the i-th time step of the forward and the backward LSTMs. The output state of the sentence encoder is the concatenation of forward and backward hidden states: $\mathbf{h}_i^s = [\overrightarrow{\mathbf{h}}_i^s; \overleftarrow{\mathbf{h}}_i^s]$. The contextualized representation of the sentence is $(\mathbf{h}_1^s, \mathbf{h}_2^s, ..., \mathbf{h}_n^s)$.

For the relation encoder, we firstly join all items in the n-ary relation M into a sequence. Then we only take answer position embedding as an extra feature for the sequence: $\mathbf{x}_i^m = [\mathbf{w}_i; \mathbf{a}_i]$. Similarly, we take another bidirectional LSTMs to encode the relation sequence and derive the corresponding contextualized representation $(\mathbf{h}_1^m, \mathbf{h}_2^m, ..., \mathbf{h}_n^m)$.

Decoder. We use an LSTM as the decoder to generate the question. The decoder predicts the word probability distribution at each decoding timestep to generate the question. At the t-th timestep, it reads the word embedding $\mathbf{w}_t$ and the hidden state $\mathbf{u}_{t-1}$ of the previous timestep to gen-

erate the current hidden state:

$$\mathbf{u}_t = \text{LSTM}(\mathbf{u}_{t-1}, \mathbf{w}_t). \quad (2)$$

Gated Attention Mechanism. We design a gated attention mechanism to jointly attend the sentence representation and the relation representation. For sentence representation $(\mathbf{h}^s_1, \mathbf{h}^s_2, ..., \mathbf{h}^s_n)$, we employ the Luong et al. (2015)'s attention mechanism to obtain the sentence context vector $\mathbf{c}^s_t$,

$$a^s_{t,i} = \frac{\exp(\mathbf{u}_t^\top \mathbf{W}_a \mathbf{h}^s_i)}{\sum_j \exp(\mathbf{u}_t^\top \mathbf{W}_a \mathbf{h}^s_j)}, \ \mathbf{c}^s_t = \sum_i a^s_{t,i} \mathbf{h}^s_i,$$

where $\mathbf{W}_a$ is a trainable weight. Similarly, we obtain the vector $\mathbf{c}^m_t$ from the relation representation $(\mathbf{h}^m_1, \mathbf{h}^m_2, ..., \mathbf{h}^m_n)$. To jointly model the sentence and the relation, a gating mechanism is designed to control the information flow from two sources:

$$\mathbf{g}_t = \text{sigmoid}(\mathbf{W}_g[\mathbf{c}^s_t; \mathbf{c}^m_t]), \quad (3)$$

$$\mathbf{c}_t = \mathbf{g}_t \odot \mathbf{c}^s_t + (\mathbf{1} - \mathbf{g}_t) \odot \mathbf{c}^m_t, \quad (4)$$

$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{W}_h[\mathbf{u}_t; \mathbf{c}_t]), \quad (5)$$

where $\odot$ represents element-wise dot production and $\mathbf{W}_g, \mathbf{W}_h$ are trainable weights. Finally, the predicted probability distribution over the vocabulary V is computed as:

$$\text{P}_V = \text{softmax}(\mathbf{W}_V \tilde{\mathbf{h}}_t + \mathbf{b}_V), \quad (6)$$

where $\mathbf{W}_V$ and $\mathbf{b}_V$ are parameters.

Dual Copy Mechanism. To deal with the rare and unknown words, the decoder applies the pointing method (See et al., 2017; Gu et al., 2016; Gulcehre et al., 2016) to allow copying a token from the input sentence at the t-th decoding step. We reuse the attention score α^s_t and α^m_t to derive the copy probability over two source inputs:

$$\text{P}_S(w) = \sum_{i:w_i=w} \alpha^s_{t,i}, \ \text{P}_M(w) = \sum_{i:w_i=w} \alpha^m_{t,i}.$$

Different from the standard pointing method, we design a dual copy mechanism to copy from two sources with two gates. The first gate is designed for determining copy tokens from two sources of inputs or generate next word from P_V, which is computed as $g^v_t = \text{sigmoid}(\mathbf{w}^v_g \tilde{\mathbf{h}}_t + b^v_g)$. The second gate takes charge of selecting the source (sentence or relation) to copy from, which is computed as $g^c_t = \text{sigmoid}(\mathbf{w}^c_g[\mathbf{c}^s_t; \mathbf{c}^m_t] + b^c_g)$. Finally, we combine all probabilities P_V, P_S and P_M through two soft gates g^v_t and g^c_t. The probability of predicting w as the t-th token of the question is:

$$\begin{aligned} \text{P}(w) = &(1 - g^v_t)\text{P}_V(w) \\ &+ g^v_t g^c_t \text{P}_S(w) + g^v_t(1 - g^c_t)\text{P}_M(w). \end{aligned} \quad (7)$$

Training and Inference. Given the answer A, sentence S and relation M, the training objective is to minimize the negative log-likelihood with regard to all parameters:

$$\mathcal{L} = -\sum_{Q \in \{Q\}} log\ \text{P}(Q|A, S, M; \theta), \quad (8)$$

where $\{Q\}$ is the set of all training instances, θ denotes model parameters and $\log P(Q|A, S, M; \theta)$ is the conditional log-likelihood of Q.

In testing, our model targets to generate a question Q by maximizing:

$$\overline{Q} = \arg\max_Q log\ \text{P}(Q|A, S, M; \theta). \quad (9)$$

	Du Split	Zhou Split

Question avg. tokens	11.42	11.31

Table 3: Dataset statistics on Du Split (Du et al., 2017) and Zhou Split (Zhou et al., 2017).

3 Experimental Setting

3.1 Dataset & Metrics

We conduct experiments on the SQuAD dataset (Rajpurkar et al., 2016). It contains 536 Wikipedia articles and 100k crowd-sourced question-answer pairs. The questions are written by crowd-workers and the answers are spans of tokens in the articles. We employ two different data splits by following (Zhou et al., 2017) [2] and (Du et al., 2017) [3]. In (Zhou et al., 2017), the original SQuAD development set is evenly divided into dev and test sets, while (Du et al., 2017) treats SQuAD development set as its test set and splits SQuAD training set into a training set (90%) and a development set (10%). We also filter out questions which do not have any overlapped non-stop words with the corresponding sentences and perform some preprocessing steps, such as tokenization and sentence splitting. The data statistics are given in Table 3.

Table 4: The main experimental results for our model and several baselines. '-' means no results reported in their papers. (Bn: BLEU-n, MET: METEOR, R-L: ROUGE-L)

We evaluate with all commonly-used metrics in question generation (Du et al., 2017): BLEU-1 (B1), BLEU-2 (B2), BLEU-3 (B3), BLEU-4 (B4) (Papineni et al., 2002), METEOR (MET) (Denkowski and Lavie, 2014) and ROUGE-L (R-L) (Lin, 2004). We use the evaluation script released by Chen et al. (2015).

3.2 Baseline Models

We compare with the following models.

- s2s (Du et al., 2017) proposes an attention-based sequence-to-sequence neural network for question generation.
- NQG++ (Zhou et al., 2017) takes the answer position feature and linguistic features into consideration and equips the Seq2Seq model with copy mechanism.
- M2S+cp (Song et al., 2018) conducts multi-perspective matching between the answer and the sentence to derive an answer-aware sentence representation for question generation.
- s2s+MP+GSA (Zhao et al., 2018) introduces a gated self-attention into the encoder and a max-out pointer mechanism into the decoder. We report their sentence-level results for a fair comparison.
- Hybrid (Sun et al., 2018) is a hybrid model which considers the answer embedding for the question word generation and the position of context words for modeling the relative distance between the context words and the answer.
- ASs2s (Kim et al., 2019) replaces the answer in the sentence with a special token to avoid its appearance in the generated questions.

3.3 Implementation Details

We take the most frequent 20k words as our vocabulary and use the GloVe word embeddings (Pennington et al., 2014) for initialization. The embedding dimensions for POS, NER, answer position are set to 20. We use two-layer LSTMs in both encoder and decoder, and the LSTMs hidden unit size is set to 600.

We use dropout (Srivastava et al., 2014) with the probability $p = 0.3$. All trainable parameters, except word embeddings, are randomly initialized with the Xavier uniform in $(-0.1, 0.1)$ (Glorot and Bengio, 2010). For optimization in the training, we use SGD as the optimizer with a minibatch size of 64 and an initial learning rate of 1.0. We train the model for 15 epochs and start halving the learning rate after the 8th epoch. We set the gradient norm upper bound to 3 during the training.

We adopt the teacher-forcing for the training. In the testing, we select the model with the lowest perplexity and beam search with size 3 is employed for generating questions. All hyper-parameters and models are selected on the validation dataset.

4 Results and Analysis

4.1 Main Results

Table 4 shows automatic evaluation results for our model and baselines (copied from their papers). Our proposed model which combines structured answer-relevant relations and unstructured sentences achieves significant improvements over proximity-based answer-aware models (Zhou et al., 2017; Sun et al., 2018) on both dataset splits. Presumably, our structured answer-relevant relation is a generalization of the context explored by the proximity-based methods because they can only capture short dependencies around answer fragments while our extractions can capture both short and long dependencies given the answer fragments. Moreover, our proposed framework is a general one to jointly leverage structured

(a) Evaluation results on all sentences.

	Hybrid			Our Model		
	BLEU	MET	R-L	BLEU	MET	R-L
0∼10 (72.8% of #)	28.54	21.54	46.26	29.73 (4.17%)	22.03 (2.27%)	46.85 (1.28%)
>10 (27.2% of #)	20.67	16.72	37.63	22.12 (7.01%)	17.46 (4.43%)	38.47 (2.23%)

0∼10 (58.3% of #)	28.00	21.03	45.37	29.11 (3.96%)	21.50 (2.21%)	45.97 (1.31%)
>10 (26.6% of #)	20.58	16.66	37.53	22.04 (7.09%)	17.38 (4.30%)	38.37 (2.24%)

Table 5: Performance for the average relative distance between the answer fragment and other non-stop sentence words that also appear in the ground truth question (BLEU is the average over BLEU-1 to BLEU-4). Values in parenthesis are the improvement percentage of Our Model over Hybrid. (a) is based on all sentences while (b) only considers long sentences with more than 20 words.

relations and unstructured sentences. All compared baseline models which only consider unstructured sentences can be further enhanced under our framework.

Recall that existing proximity-based answer-aware models perform poorly when the distance between the answer fragment and other non-stop sentence words that also appear in the ground truth question is large (Table 1). Here we investigate whether our proposed model using the structured answer-relevant relations can alleviate this issue or not, by conducting experiments for our model under the same setting as in Table 1. The broken-down performances by different relative distances are shown in Table 5a. We find that our proposed model outperforms Hybrid (our re-implemented version for this experiment) on all ranges of relative distances, which shows that the structured answer-relevant relations can capture both short and long term answer-relevant dependencies of the answer in sentences. Furthermore, comparing the performance difference between Hybrid and our model, we find the improvements become more significant when the distance increases from "$0 \sim 10$" to "> 10". One reason is that our model can extract relations with distant dependencies to the answer, which greatly helps our model ignore the extraneous information. Proximity-based answer-aware models may overly emphasize the neighboring words of answers and become less effective as the useful context becomes further away from the answer in the complex sentences. In fact, the breakdown intervals in Table 5a naturally bound its sentence length, say for "> 10", the sentences in this group must be longer than 10. Thus, the length variances in these two intervals could be

Sentence: Beyoncé received critical acclaim and commercial success, selling one million digital copies worldwide in six days; The New York Times noted the album 's unconventional, unexpected release as significant.
Reference Question: How many digital copies of her fifth album did Beyonc sell in six days?
Baseline Prediction: How many digital copies did the New York Times sell in six days ?
Structured Answer-relevant Relation: (Beyoncé; received commercial success selling; one million digital copies worldwide; in six days)
Our Model Prediction: How many digital copies did Beyoncé sell in six days ?

Sentence: The daily mean temperature in January, the area's coldest month, is 32.6 °F (0.3 °C); however, temperatures usually drop to 10 °F (-12 °C) several times per winter and reach 50 °F (10 °C) several days each winter month.
Reference Question: What is New York City 's daily January mean temperature in degrees celsius ?
Baseline Prediction: What is the coldest temperature in Celsius ?
Structured Answer-relevant Relation: (The daily mean temperature in January; is; 32.6 °F (0.3 °C))
Our Model Prediction: In degrees Celsius , what is the average temperature in January ?

Figure 4: Example questions (with answers highlighted) generated by crowd-workers (ground truth questions), the baseline model and our model.

significant. To further validate whether our model can extract long term dependency words. We rerun the analysis of Table 5b only for long sentences (length > 20) of each interval. The improvement percentages over Hybrid are shown in Table 5b, which become more significant when the distance increases from "$0 \sim 10$" to "> 10".

4.2 Case Study

Figure 4 provides example questions generated by crowd-workers (ground truth questions), the base-

line Hybrid (Sun et al., 2018), and our model. In the first case, there are two subsequences in the input and the answer has no relation with the second subsequence[4]. However, we see that the baseline model prediction copies irrelevant words "The New York Times" while our model can avoid using the extraneous subsequence "The New York Times noted ..." with the help of the structured answer-relevant relation. Compared with the ground truth question, our model cannot capture the cross-sentence information like "her fifth album", where the techniques in paragraph-level QG models (Zhao et al., 2018) may help. In the second case, as discussed in Section 1, this sentence contains a few facts and some facts intertwine. We find that our model can capture distant answer-relevant dependencies such as "mean temperature" while the proximity-based baseline model wrongly takes neighboring words of the answer like "coldest" in the generated question.

4.3 Diverse Question Generation

Another interesting observation is that for the same answer-sentence pair, our model can generate diverse questions by taking different answer-relevant relations as input. Such capability improves the interpretability of our model because the model is given not only what to be asked (i.e., the answer) but also the related fact (i.e., the answer-relevant relation) to be covered in the question. In contrast, proximity-based answer-aware models can only generate one question given the sentence-answer pair regardless of how many answer-relevant relations in the sentence. We think such capability can also validate our motivation: questions should be generated according to the answer-aware relations instead of neighboring words of answer fragments. Figure 5 show two examples of diverse question generation. In the first case, the answer fragment 'Hugh L. Dryden' is the appositive to 'NASA Deputy Administrator' but the subject to the following tokens 'announced the Apollo program ...'. Our framework can extract these two answer-relevant relations, and by feeding them to our model separately, we can receive two questions asking different relations with regard to the answer.

[4]One might think that the two subsequences should be regarded as individual sentences, however, several off-the-shelf tools do recognize them as one sentence.

Sentence: In July 1960, NASA Deputy Administrator Hugh L. Dryden announced the Apollo program to industry representatives at a series of Space Task Group conferences.
Relation 1: (Hugh L. Dryden; [is] Deputy Administrator [of]; NASA)
Question 1: Who was the NASA Deputy Administrator in 1960 ?
Relation 2: (NASA Deputy Administrator Hugh L. Dryden; announced; the Apollo program to industry representatives at a series of Space Task Group conferences; In July 1960)
Question 2: Who announced the Apollo program to industry representatives ?

Sentence: One of the network's strike-replacement programs during that time was the game show Duel, which premiered in December 2007.
Relation 1: (the game show Duel; premiered; in December 2007)
Question 1: What game premiered in December 2007 ?
Relation 2: (One of the network's strike-replacement programs during that time; was; the game show Duel)
Question 2: What was the name of an network 's strike - replacement programs ?

Figure 5: Example diverse questions (with answers highlighted) generated by our model with different answer-relevant relations.

5 Related Work

The topic of question generation, initially motivated for educational purposes, is tackled by designing many complex rules for specific question types (Mitkov and Ha, 2003; Rus et al., 2010). Heilman and Smith (2010) improve rule-based question generation by introducing a statistical ranking model. First, they remove extraneous information in the sentence to transform it into a simpler one, which can be transformed easily into a succinct question with predefined sets of general rules. Then they adopt an overgenerate-and-rank approach to select the best candidate considering several features.

With the rise of dominant neural sequence-to-sequence learning models (Sutskever et al., 2014), Du et al. (2017) frame question generation as a sequence-to-sequence learning problem. Compared with rule-based approaches, neural models (Yuan et al., 2017) can generate more fluent and grammatical questions. However, question generation is a one-to-many sequence generation problem, i.e., several aspects can be asked given a sentence, which confuses the model during train and prevents concrete automatic evaluation. To tackle this issue, Zhou et al. (2017) propose the answer-aware question generation setting which assumes the answer is already known

and acts as a contiguous span inside the input sentence. They adopt a BIO tagging scheme to incorporate the answer position information as learned embedding features in Seq2Seq learning. Song et al. (2018) explicitly model the information between answer and sentence with a multi-perspective matching model. Kim et al. (2019) also focus on the answer information and proposed an answer-separated Seq2Seq model by masking the answer with special tokens. All answer-aware neural models treat question generation as a one-to-one mapping problem, but existing models perform poorly for sentences with a complex structure (as shown in Table 1).

Our work is inspired by the process of extraneous information removing in (Heilman and Smith, 2010; Cao et al., 2018). Different from Heilman and Smith (2010) which directly use the simplified sentence for generation and Cao et al. (2018) which only consider aggregate two sources of information via gated attention in summarization, we propose to combine the structured answer-relevant relation and the original sentence. Factoid question generation from structured text is initially investigated by Serban et al. (2016), but our focus here is leveraging structured inputs to help question generation over unstructured sentences. Our proposed model can take advantage of unstructured sentences and structured answer-relevant relations to maintain informativeness and faithfulness of generated questions. The proposed model can also be generalized in other conditional sequence generation tasks which require multiple sources of inputs, e.g., distractor generation for multiple choice questions (Gao et al., 2019b).

6 Conclusions and Future Work

In this paper, we propose a question generation system which combines unstructured sentences and structured answer-relevant relations for generation. The unstructured sentences maintain the informativeness of generated questions while structured answer-relevant relations keep the faithfulness of questions. Extensive experiments demonstrate that our proposed model achieves state-of-the-art performance across several metrics. Furthermore, our model can generate diverse questions with different structured answer-relevant relations. For future work, there are some interesting dimensions to explore, such as difficulty levels (Gao et al., 2019a), paragraph-level information (Zhao et al., 2018) and conversational question generation (Gao et al., 2019c).

Abstract

Most text-to-text generation tasks, for example text summarisation and text simplification, require copying words from the input to the output. We introduce copycat, a transformer-based pointer network for such tasks which obtains competitive results in abstractive text summarisation and generates more abstractive summaries. We propose a further extension of this architecture for automatic post-editing, where generation is conditioned over two inputs (source language and machine translation), and the model is capable of deciding where to copy information from. This approach achieves competitive performance when compared to state-of-the-art automated post-editing systems. More importantly, we show that it addresses a well-known limitation of automatic post-editing – overcorrecting translations – and that our novel mechanism for copying source language words improves the results.

1 Introduction

Text-to-text generation is generally addressed using sequence to sequence neural models (Sutskever et al., 2014). While initially proposed for machine translation (Bahdanau et al., 2015), these models have been shown to perform very well in monolingual variants of these tasks, such as text summarisation and text simplification (Nallapati et al., 2016a; Scarton and Specia, 2018). One limitation of such models is that they tend to be "over creative" when generating outputs, i.e. create a completely new output, which is not what they should do. Different strategies have been used to mitigate this issue, primarily in the context of abstractive text summarisation. The most prominent strategy is the use of pointer networks, which substantially outperform vanilla sequence to sequence models (Nallapati et al., 2016b; Gu et al., 2016; See et al., 2017). Pointer networks (Vinyals et al., 2015) are an extension of attentive recurrent neural network (RNN) architectures to use attention as a pointer to select which tokens of the input sequence should be copied to the output, as a switching mechanism between copying and generating new words.

In this paper we propose copycat, a flexible pointer network framework for text-to-text generation tasks. It differs from previous work in the following main ways: it is based on transformer networks (Vaswani et al., 2017), which have been shown to achieve superior performance in text generation tasks. While Gehrmann et al. (2018b) also provide contrastive experiments using transformers, they however randomly choose one of the attention heads as the copy-distribution, while we let the networks learn through all layers and use the attention heads from the final layer of the decoder to learn the distribution; thereby the decision between copying input words and generating new words is made at the highest level of abstraction. Further, in our model, we do not use coverage penalty and achieve similar performance as Gehrmann et al. (2018b).

For text summarisation, we show that our copycat model performs competitively with comparable models, but achieves a much higher novel n-gram generation rate (wrt original article) and a low repetition rate (within a summary) without any coverage penalty.

We further extend this architecture to the dual-source setting, where it is conditioned on two inputs and can copy from either of them. We apply this approach to automatic post-editing, where the network can generate new words, or copy words from either the source language or the original machine translation. We show that this is a promising approach especially to avoid overcorrecting high quality machine translations and for text domains where terminology (or jargon) should be preserved

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3227–3236, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

across languages, rather than translated.

To sum up, our **main contributions** are: (i) `copycat` networks – a transformer-based pointer network for text-to-text generation tasks (Section 3.2); ; and (ii) an extension of this model which can copy from multiple inputs (Section 3.3). Our models produce SOTA results in summarisation. Our datasets and settings are described in Section 4, and the experiments with text summarisation and automatic post-editing, in Section 5.

2 Related work

In this section we highlight the most closely related work on abstractive summarisation and automatic post-editing.

Abstractive Summarisation SOTA approaches using sequence to sequence models have evolved from vanilla attentional models (Rush et al., 2015; Nallapati et al., 2016a) to more advanced architectures that include the use of pointer networks (Nallapati et al., 2016b; See et al., 2017; Gu et al., 2016; Paulus et al., 2017), reinforcement learning (Paulus et al., 2017; Li et al., 2018; Pasunuru and Bansal, 2018; Chen and Bansal, 2018; Hsu et al., 2018) and content selection (Gehrmann et al., 2018a; Pasunuru and Bansal, 2018; Chen and Bansal, 2018).

Nallapati et al. (2016b) and Gu et al. (2016) propose the use of pointer-generator RNN-based networks to reduce out-of-vocabulary (OOV) rate. This idea was followed by See et al. (2017), which incorporates a coverage mechanism to avoid repetition of input words by keeping track of what has already been covered.

Reinforcement learning (RL) approaches optimise objectives for summarisation in addition to maximum likelihood. Paulus et al. (2017) combine `ROUGE` and maximum likelihood as training objectives, use a pointer network and – to avoid repetition – introduce intra-attention to the encoder and decoder that attends over the input and continuously generated output separately. Li et al. (2018) use a global summary quality estimator which is a binary classifier aiming to make the generated summaries indistinguishable from the human-written ones. Pasunuru and Bansal (2018) have a loss function based on whether keywords detected as salient are included in a summary, while Hsu et al. (2018) modulate the attention based on how likely a sentence is to be included in a summary, and Chen and Bansal (2018) follow an extractive-abstractive hybrid architecture to first extract full sentences from a document using a sentence-level policy gradient and then compress them.

Gehrmann et al. (2018a) also perform content selection, but on the level of phrases by treating this process as a sequence labelling task, and without RL. They first build a selection mask for the source document and then constrain a decoder on this mask.

The latter two represent the best overall approaches on common datasets, using either an RNN- or a Transformer- based architecture. We show that our `copycat` approach is competitive and is more abstractive (we describe this in the following sections).

Automatic Post-Editing (APE) (Simard and Foster, 2013; Chatterjee et al., 2017) aims to automatically correct errors in machine translation (MT) outputs in order to reduce the burden of human post-editors, especially with simple and repetitive corrections (e.g. typographic errors).

APE is usually addressed by monolingual translation models that "translate" from the raw MT to fixed MT (post-edits, PE). Given the high quality of current neural MT (NMT) outputs, the task has become particularly challenging. Human corrections to those outputs are rare and very context-dependent, which makes them difficult to capture and generalise. This increases the chance of APE systems to overfit or overcorrect new inputs at test time.

SOTA APE approaches tackle the task with the multi-source transformer architectures (Junczys-Dowmunt and Grundkiewicz, 2018; Tebbifakhr et al., 2018). Two encoders encode the source and the raw MT, respectively, and an additional target-source multi-head attention component is stacked on top of the original target-source multi-head attention component. These models are trained with millions of <source, MT, PE> triplets, which does not fit realistic scenarios where only a handful of post-editions exist. Special parallel training corpora with additional MT data are released to help the development (Negri et al., 2018). According to (Chatterjee et al., 2018), these SOTA systems modify up to 30% of the NMT input, out of which only 50% are positive changes, the rest are unnecessary paraphrases or deteriorate the output.

Our `copycat` networks address this problem: they are conservative and make very few careful

corrections to good quality raw MT – as a result of learning predominantly to copy, while still making substantial corrections when the raw MT is not as good.

3 copycat Networks

3.1 Transformer Architecture

We make use of the SOTA sequence to sequence modelling framework – the Transformer architecture (Vaswani et al., 2017). Our implementation is a multi-layer encoder-decoder architecture that uses the `tensor2tensor`[1] (Vaswani et al., 2018) library. We briefly describe the encoder and decoder blocks in what follows.

Encoder block ($\mathcal{E}$): The encoder block is made of 6 layers, each containing two sub-layers of multi-head self-attention mechanism followed by a fully connected feed forward neural network. We follow the standard implementation and employ residual connections between each layer, as well as layer normalisation. The output of the encoder forms the encoder memory which consists of contextualised representations for each of the source tokens ($M_{\mathcal{E}}$).

Decoder block ($\mathcal{D}$): The decoder block is similar to the standard transformer architecture and comprises of 6 layers. It contains an additional sub-layer that performs multi-head attention over the outputs of the encoder block. Specifically, a decoding layer d_{l_i} is the result of multi-head attention over the outputs of the encoder which in turn is a function of the encoder memory and the outputs from the previous layer: $A_{\mathcal{D}\to\mathcal{E}} = f(M_{\mathcal{E}}, d_{l_{i-1}})$ where, the keys and values are the encoder outputs and the queries correspond to the decoder input.

In all cases we tie the source and target vocabulary. We also use Byte Pair Encoding (BPE) (Sennrich et al., 2016) word segmentation approach to pre-process the data before we fix the vocabulary. This also helps us in reducing the OOV rate and makes the models less dependent on the vocabulary of the training data. We train all our models with the cross entropy loss.

3.2 Pointer-generator Network

We base our pointer-generator on the approach of See et al. (2017), however we significantly depart from their formulation. We first obtain an attention distribution over the source and decoder at each time step. We use a simple dot product $\mathbf{a_t}$ over output of the last decoder layer ($A^{\text{fin}}_{\mathcal{D}\to\mathcal{E}}$) and the contextualised encoder representations for each of the source language tokens ($M_{\mathcal{E}}$):

$$\mathbf{a_t} = \texttt{softmax}(A^{\text{fin}}_{\mathcal{D}\to\mathcal{E}} \cdot M_{\mathcal{E}}) \quad (1)$$

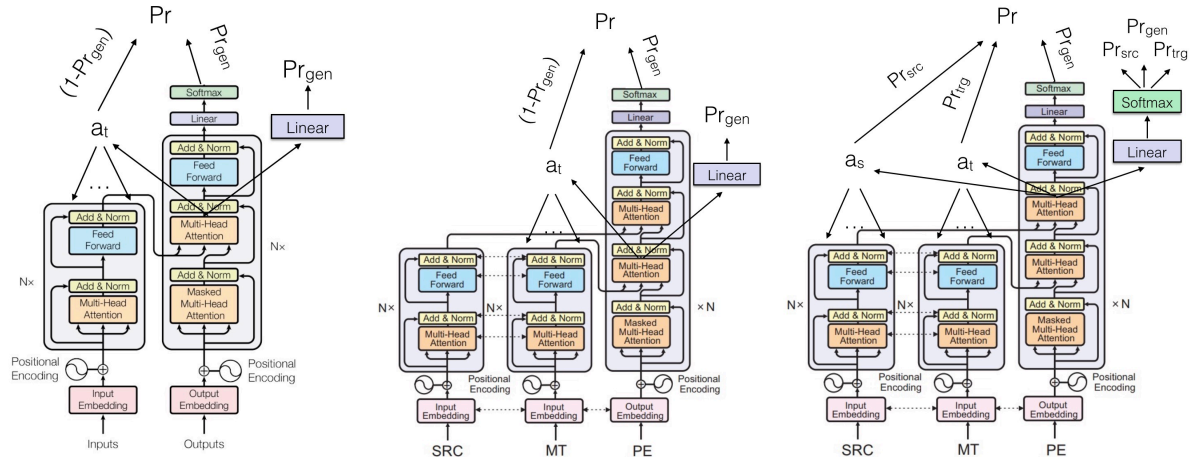
where $A^{\text{fin}}_{\mathcal{D}\to\mathcal{E}}$ comes from final ($n = 6$) layer, just before applying layer normalisation and passing it through feed forward layers as shown in Figure 1. $A_{\mathcal{D}\to\mathcal{E}}$ already contains information from the source encoder. This differs both the RNN-based implementation in (See et al., 2017) and the copy-transformer (Gehrmann et al., 2018b) formulation, where a randomly chosen attention-head forms the basis for the copy-distribution. The generation probability $\Pr_{\text{gen}}$ for each time step is computed from the output of the decoder layer as:

$$\Pr_{\text{gen}} = \sigma(W^{\top}_{\text{gen}} A^{\text{fin}}_{\mathcal{D}\to\mathcal{E}}) \quad (2)$$

where W is learned parameters and σ is the `sigmoid` function which restricts $\Pr_{\text{gen}} \in [0, 1]$.

We then follow (Vinyals et al., 2015) and use $\Pr_{\text{gen}}$ as the switching function to decide between generating a word from the decoder vocabulary or copying the word directly from the source sequence by using $\mathbf{a_t}$ as:

$$\Pr = \Pr_{\text{gen}} \Pr_{\text{d}}(w_d) + (1 - \Pr_{\text{gen}})\mathbf{a_t} \quad (3)$$



where, $\Pr_{\text{d}}(w_d)$ is decoder's probability of generating output word from the decoder vocabulary.

We empirically observed that getting the new attention representation over the final layer is extremely important for obtaining a good estimate of the attention distribution.

3.3 Dual-source extension

We extend `copycat` networks for the case of APE where a dual-source encoder-decoder architecture has been shown to obtain superior results (Junczys-Dowmunt and Grundkiewicz, 2018). As previously mentioned, most of the translations in current APE datasets (Chatterjee et al., 2018) already have optimal quality, thereby models that alter these already accurate translations are sub-optimal. Based on this observation we propose a dual-source extension to our `copycat` model. We add an extra encoder ($\mathcal{E}_s$) that encodes the sentence in source language and

[1] https://github.com/tensorflow/tensor2tensor

(a) `copycat` network (b) Dual-source `copycat` (c) Dual-source double-attention `copycat`

Figure 1: `copycat` architectures: (a) shows our `copycat` model for summarisation, where a_t is computed on the final decoder layer and the last encoder layer; (b) is the dual-source extension for APE with an additional encoder; and (c) further extends (b) with an additional attention mechanism over the source language encoder. Down arrows indicate attention over encoder states. Last decoder state participates in this dot product computation. Then $\mathbf{a_s}$ and $\mathbf{a_t}$ participate in the final probability computation Pr.

the standard encoder ($\mathcal{E}$) which encodes the machine translated output. We also add an additional decoder layer $A'_{\mathcal{D}\to\mathcal{S}} = f(M_{\mathcal{E}_s}, A_{\mathcal{D}\to\mathcal{E}})$, where $A_{\mathcal{D}\to\mathcal{E}}$ is the standard decoding layer.

We maintain the pointer generator over the final decoder layer ($n = 6$) – $A^{\text{fin}}_{\mathcal{D}\to\mathcal{E}}$, similarly to Equation 3.

Dual-source with double attention We further extend the dual-source `copycat` network such that it now attends over both the source-language encoder and the translated output encoder, and therefore words from the source language can also be copied. We believe that copying words from source language would especially be useful for APE. Some corrections may involve retaining the original words in the source language due to a variety of reasons, including the use of proper nouns and jargon. Our extension involves modification in two components:

- **Attention over source:** We build on Equation 1 and add a similar attention over the source encoder as:

$$\mathbf{a_s} = \texttt{softmax}(A'^{\text{fin}}_{\mathcal{D}\to\mathcal{S}} \cdot M_{\mathcal{E}_s}) \qquad (4)$$

  where $M_{\mathcal{E}_s}$ is the source language encoder outputs.

- **Pointer-generation with multiple sources:** As there are three signals of information that influence the output decision – copy from source language, copy from the translated language and generate from decoder – we treat them as three different tasks. We thus modify Equation 2 with a normalised exponential function (`softmax`) instead of the `sigmoid` in the former. This results in:

$$\text{Pr}_{\text{gen}} = \frac{\exp\left(W_{\text{i=gen}} \cdot A'^{\text{fin}}_{\mathcal{D}\to\mathcal{S}}\right)}{\sum_{j\in\text{tasks}} \exp\left(W_j \cdot A'^{\text{fin}}_{\mathcal{D}\to\mathcal{S}}\right)} \qquad (5)$$

  where tasks $= \{\text{gen}, \text{trg}, \text{src}\}$; trg is for attention over the target language encoder, and src is for attention over the source language encoder. Notice that we use $A'^{\text{fin}}_{\mathcal{D}\to\mathcal{S}}$ as this includes both information from the target language encoder *and* the source language encoder.

- **Switching function:** Based on the probabilities from Equation 5, the new Pr is:

$$\text{Pr} = \text{Pr}_{\text{gen}}\text{Pr}_{\text{d}}(w_d) + \text{Pr}_{\text{trg}}\mathbf{a_t} + \text{Pr}_{\text{src}}\mathbf{a_s}$$

Figure 1 shows the variants of the `copycat` architectures.

4 Data and Settings

Summarisation We use the CNN/Daily Mail dataset, the most widely use dataset for abstractive summarisation (Hermann et al., 2015; Nallapati et al., 2016b). It contains online news articles

(800 tokens on average) and their abstracts (60 tokens on average). We used scripts provided by See et al. (2017) to obtain the same version of the the data, which has around 300K training pairs, 13K validation pairs and 11,490 test pairs. We apply BPE for word segmentation approach with 32K merge operations (Sennrich et al., 2016). During training and test we truncate articles to 400 BPE units as is standard practice (See et al., 2017).

APE Our APE datasets consist of <source, target, human post-edit> triplets. We use two variants: (i) the English-German (EN-DE) dataset from the IT domain provided by the WMT18/WMT19 APE shared task, and translated by a high-performing NMT system (45.8 BLEU).[2] It contains 13,442, 1,000 and 1,023 training, development and test triplets, respectively. (ii) the English-Latvian (EN-LV) dataset from the life sciences domain made available by Specia et al. (2018) containing 12,936 training / 1,000 development / 1,448 test triplets. Here, the outputs from NMT are of a lower quality (38.4 BLEU).

We use HTER (Snover et al., 2009) as the main metric and BLEU (Papineni et al., 2002) as the secondary metric, as in the WMT APE shared tasks (Chatterjee et al., 2018). HTER is defined as the minimum number of edits (substitution, insertion, deletion and shift) required to change an MT hypothesis so that it exactly matches a human post-edition of this hypothesis. BLEU measures n-gram precision between MT hypotheses and post-edits.

The EN-DE task is very challenging as the training data contains very few edits (0.15 HTER) and contain few context-dependent human corrections that are difficult to capture with machine learning methods. The EN-LV dataset has twice more edits (0.29 HTER). Actually, 36% of the German NMT data requires no corrections, and only 14% of the Latvian NMT data requires no correction.

Hyperparameters: For both tasks, we use Adam as optimiser (Kingma and Ba, 2014) and train the model until convergence with a fixed batch size of 50. Across experiments, we use shared source and target embeddings. We build on the tensor2tensor implementation using the transformer_base_v2 parameters for summarisation as best practise.[3] The transformer_base_v1 parameters with a learning rate of 0.05 with 8K warmup steps are used for APE. For other hyperparameters we use the default values in tensor2tensor.

For both tasks we apply early stopping with the patience of 10 epochs based on the validation ROUGE-L or BLEU score, for summarisation and APE respectively. For summarisation, we use a randomly chosen validation subset of 2k abstracts. During decoding, we use a beam search of size 5 and tune the α parameter (length penalty) on the validation subset. During decoding for APE, we use a beam search of size 10.

5 Results

In this section we present results of our experiments, first for summarisation (Section 5.1) and then for APE experiments (Section 5.2).

5.1 Summarisation

Table 1 shows results of our summarisation experiments. We report F1-scores for a standard set of ROUGE (Lin, 2004) scores: ROUGE-1, ROUGE-2 and ROUGE-L. They measure unigram, bigram recall and the longest in-sequence common to the generated and the reference abstracts, respectively. The scores are measured with the pyrouge toolkit.[4]

We also report results for a range of conceptually different systems, including the LEAD-3 baseline (the top 3 sentences of the source). copycat performs on par with the CopyTransformer. Our generated sentences for both systems are of 62 tokens on average, with references of 58 tokens on average.

To understand the model, we look at two aspects (i) the level of repetition within the generated abstracts, and (ii) the level of transfer from original to summarised text (i.e. the novelty rate).

Figure 2 reports the results of our analysis of repetitions in the outputs of our system and the reference abstracts. For unigrams, our model is comparable to the coverage mechanism of See et al. (2017). However, we note that our model is less effective than the one in See et al. (2017) for higher order n-grams, where repetitions are almost completely eliminated. This is done at the cost

[2] http://www.statmt.org/wmt19/ape-task.html. We also experimented with the additional – English-Russian – WMT19 dataset, but its quality is very questionable, as confirmed in personal communication with the task organisers.

Table 2: Examples of articles, their copycat and human reference summaries. Bold highlights segments repeated by copycat.

of generating fewer novel n-grams, as compared to the original abstract. Specifically, See et al. (2017) are only able to generate around 10% novel quadrigrams, whereas we generate 22%. Figure 3, which depicts the percentage of novel n-grams and sentences introduced by our copycat models as compared to full articles (without truncation).

The percentage of new words (unigrams) introduced by copycat is already in line with or higher than the percentage reported for other models (2.2% in (See et al., 2017), 0.5% Gehrmann et al. (2018a) and 1% in our case). The manual inspection of newly-introduced words confirmed their validity. From this inspection, we observed that the risk of creating new words as a consequence of combining BPE segments is very *low* (e.g., *constadedmind* produced by combining *con*, *sta*, *de*, *d* and *mind*).

We further manually inspect outputs of copycat systems to gain insights into their performance. Table 2 lists an example of produced outputs. We notice that the model is capable of

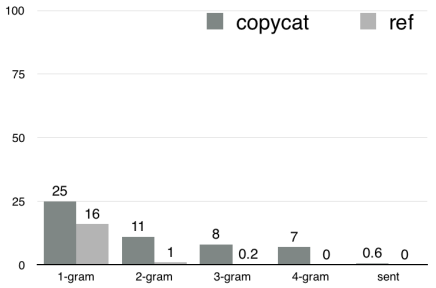

Figure 2: Percentage of repetitive n-grams (freq > 1) per sentence and sentences introduced by reference and `copycat`.

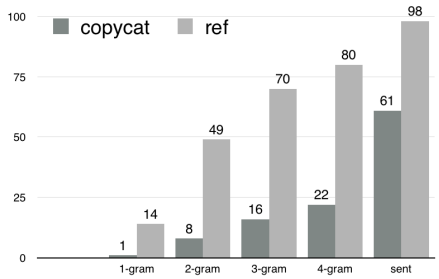

Figure 3: Percentage of novel n-grams per sentence and sentences introduced by reference and `copycat`.

both to selectively copying relevant parts of an article, as well as making deductions about the content, which often results in an abstract *different* from the reference abstract. Overall, the model actively attends to different parts of input and is capable of efficiently reorganising the information in the original article.

5.2 APE

We perform experiments with three models: (a) `NO-PNT` which is a reimplementation of the dual-source Transformer model of (Junczys-Dowmunt and Grundkiewicz, 2018); (b) `PNT-TRG`, `copycat` with attention over the MT; (c) `PNT-TRG+SRC`, `copycat` with double attention. Our baseline (`BASE`) is the standard "do nothing", i.e. the raw MT as provided in the datasets.

As the sizes of the APE datasets are very small, training only using this data is not successful. We thus pre-train all our models, as is a common practise for the APE task (Tebbifakhr et al., 2018). However, we do not generate new MT data. Instead we mimic MT data: we randomly delete, insert, shift or substitute words in the target side of parallel data to match `HTER` statistics of a respective APE dataset. For German, we randomly select 500K parallel data (only source and target) from the eSCAPE data provided with the task (Negri et al., 2018). For Latvian, we select those 500K from a corpus created by merging the Europarl (version 8)[5] and EMEA corpora.[6]

The data is truecased using the Moses toolkit scripts (Koehn et al., 2007). We again apply the BPE with 32K merge operations (Sennrich et al., 2016). Parameters of encoders for our dual `copycat` are shared. We use the label smoothing of 0.1. For the fine-tuning experiments, we reduce the learning rate to 0.001.

Table 4 shows results of our APE experiments. We compare our three setups to the baseline MT quality (`BASE`) without any APE.[7] We see that the performance of our `copycat` systems depends on the difficulty of the task: we observe an improvement for Latvian (+1 absolute `HTER` point improvement) with the lowest baseline quality (`HTER`= 0.29), and minor improvements for German with a higher baseline quality (on average 0.14 `HTER`). As a comparison, the best performing SOTA systems achieve only up to 0.4 `HTER` improvement for the German dataset and this is by using millions of training data, combined losses and ensembling techniques, whereas we use minimum external resources (Tebbifakhr et al., 2018; Junczys-Dowmunt and Grundkiewicz, 2018).[8]

For EN-DE, our `PNT-TRG` model performs a small number of corrections (mostly *accurate*) to the outputs: only 50 sentences, compared to the 200-300 sentences modified by the SOTA EN-DE APE systems (Chatterjee et al., 2018). For EN-LV, given the the raw translations are of lower quality, our models make more corrections: 330 sentences, which lead to overall improvements.

As a general observation, for both training sets, post-edit operations repeated more than once make around only 10% of all corrections. And this is not taking into account the fact that corrections also occur in different contexts. The majority of repetitive post-edits are corrections to punctuation (e.g., deletion of a comma) or auxiliary words (e.g., insertion/deletion of prepositions or articles). Therefore, we believe that especially in

[5] http://www.statmt.org/wmt17/translation-task.html

[6] http://opus.nlpl.eu/EMEA.php

[7] Our baseline scores differ from those provided by the task organisers because of differences in truecasing strategies.

[8] For instance, Junczys-Dowmunt and Grundkiewicz (2018) report 16.5/75.44 HTER↓/BLEU↑ for EN-DE over the 16.84/74.73 "do nothing" baseline.

DE	17.8 / 72.3	18.5 / 71.2	17.9 / 72.3	17.8 / 72.4

Table 4: HTER↓ / BLEU↑ scores for the APE task. Boldface values mark statistically significant improvements over BASE, i.e. the raw MT output. We have performed significance testing via bootstrap resampling using the Multeval tool (Clark et al., 2011), the standard practice in APE.

the case of Latvian, this is probably the limit of what can be potentially learned from these small training datasets.

Furthermore, our intuition of the potential benefit of copying from the source is confirmed and for Latvian we observe an additional increase of 0.4 HTER for this model as compared to PNT-TRG.

The non-pointer system (NO-PNT) is not competitive and decreases the raw MT quality for both languages. The highest decrease is observed for Latvian (over 30 HTER points). We believe that the performance for Latvian drops so much because of the noisy original MT with a lot of repetitions that are carried to the output. These are mostly repetitions of the last word (typical error of low-quality NMT), that could be observed by eyeballing the output.

To assess the quality of corrections our systems perform to MT outputs, we manually analyse the corrections for German, for which we have in-house expertise for the type of analysis we present. For both PNT-TRG and PNT-TRG+SRC, 60% of the modified sentences are positive changes. The model is thus able to capture and make use of modification patterns found in the training data. These are mostly corrections of punctuation, deletions of prepositions, articles and auxiliary verbs. Negative changes are the same types of correction but in wrong contexts. For PNT-TRG+SRC, relevant source segments (those that the BASE MT failed to restore) are copied to the APE output: e.g., a correct web link, while it is distorted in the raw MT. Table 3 provides examples of positive and negative changes for both setups.

6 Conclusions

In this paper we propose copycat networks, a novel transformer-based pointer-generator network. For summarisation, we observe that copycat network is not only able to keep the repetition rate low, but also substantially increases the rate of novel n-grams. We further extend the copycat for automatic post-editing by conditioning over dual sources (source language and target language) and introducing the double-attention to copy from both sources. copycat is able to learn (a) more conservative models that copy more and generate less when the raw translations are already good, and (b) more aggressive models that make more corrections when the original translation quality is not as good. This shows that the architectures are flexible and adapt well to different datasets. Our source code is available at: https://github.com/ImperialNLP/CopyCat.

Abstract

In this paper, we propose a novel model *RevGAN* that automatically generates *controllable* and *personalized* user reviews based on the arbitrarily given sentimental and stylistic information. RevGAN utilizes the combination of three novel components, including self-attentive recursive autoencoders, conditional discriminators, and personalized decoders. We test its performance on the several real-world datasets, where our model significantly outperforms state-of-the-art generation models in terms of sentence quality, coherence, personalization and human evaluations. We also empirically show that the generated reviews could not be easily distinguished from the organically produced reviews and that they follow the same statistical linguistics laws.

1 Introduction

With the ever increasing interests in user-generated reviews on online marketplace websites, such as Amazon, Yelp and TripAdvisor, it is necessary to provide a range of tools that would encourage users to provide feedback in a more efficient and effective manner, as only a small fraction of users really take time to write their own reviews (Chen and Xie, 2008). Automatic review generation, for example, takes the product information and user behavior as input and generates user reviews following the arbitrarily given users' sentiment designation and writing style personalized towards the specific product and user.

Researchers have proposed various types of product review generation methods (Yao et al., 2017; Dong et al., 2017; Lipton et al., 2015; Radford et al., 2017) and achieved great performance. However, they did not consider the inner hierarchical word-sentence-paragraph structure within user reviews, thus making their generation results significantly limited in length and coherence. (Li et al., 2015; Zang and Wan, 2017) did include the hierarchical connection in their review generation model, but they did not address the problem of *controllable* and *personalized* review generation targeted at the specific product and user, which is essential for the usefulness of generated reviews. Most importantly, all the aforementioned generative models did not include *production descriptions* in the generation process, thus their generation results lack credibility and diversity.

To address these problems, we propose a novel model *RevGAN* that automatically generates high-quality user reviews given the information of product descriptions, sentiment labels and users' historical reviews. The proposed RevGAN model follows a three-staged process: In Stage 1, we propose to use *Self-Attentive Recursive Autoencoder* for mapping the discrete user reviews and product descriptions into continuous embeddings for the advantage of capturing the ''essence" of textual information and the convenience for subsequent optimization processes. In Stage 2, we utilize a novel *Conditional Discriminator* structure to control the sentiment of generated reviews by conditioning sentiment on the discriminator and forced the generator to adapt its generation policy correspondingly. Finally in Stage 3, to improve the personalization of generated reviews, we use a new *Personalized Decoder* method to decode the generated review embeddings according to users' writing styles extracted from their history corpus.

We conduct extensive experiments using multiple real-world datasets and show that the proposed RevGAN model significantly and consistently outperforms state-of-the-art baseline models and lead to the automated generation of reviews that are indeed very similar in style and content to the set of original reviews.

In general, this paper makes the following contributions:

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3237–3245,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

a. We propose a novel *RevGAN* model that automatically generates *controllable* and *personalized* reviews from product information, a set of user reviews and their writing styles. Especially. we propose three novel components of the generative framework: *Self-Attentive Recursive Autoenocder* that captures the hierarchical structure and latent semantic meanings of user reviews, *Conditional Discriminator* that generates controllable user reviews by conditioning the sentimental information on the discriminator to improve the generation performance in terms of sentence quality and context accuracy, and *Personalized Decoder* that takes the personalized writing style into account by concatenating the users' vocabulary preference onto the decoder to improve the personalization and credibility of the generated results, which is validated by the empirical human evaluation.

b. We empirically demonstrate that our proposed RevGAN model achieves state-of-the-art review generation performance, statistically and empirically outperforming several important benchmarks on multiple datasets. We also empirically show that the reviews generated by our method are very similar to the organically generated reviews and that the linguistic features of generated reviews follow the same statistical linguistics laws as reviews organically produced by the users.

2 Related Work

In this section, we briefly summarize the related work following two aspects covering previous work on automated review generation and GAN for NLG. We point out the connection and difference between our proposed model and prior literature, which leads to significant improvements of review generation performance.

2.1 Automated Review Generation

Researchers have been utilizing multiple versions of Seq2Seq(Sutskever et al., 2014) framework to generate online product reviews of good quality, including Aspect-Aware Representations (Ni and McAuley, 2018), Gated Contexts to Sequences(Tang et al., 2016), RNN(Yao et al., 2017), Aspect-Sentiment Score(Zang and Wan, 2017), Generative Concatenative Nets(Lipton et al., 2015) and Sentiment Units(Radford et al., 2017). In particular, (Li et al., 2015) proposed a two-stage LSTM neural network to construct a hierarchical autoencoder for long-text representation and generation.

However, these review generative models include neither product information nor users' writing styles into the generation process, thus making the generated reviews less persuasive. Also, they are limited in length and lack of coherence for neglecting the hierarchical connections within sentences, which are very important elements towards the helpfulness of a specific review(Mudambi and Schuff, 2010). Our RevGAN model, on the other hand, utilizes the combination of self-attentive hierarchical autoencoder and conditional discriminator for improved and controllable review generation, while we concatenate the contextual labels and users' history corpus into the personalized decoder at the same time. Experimental results support that our proposed model indeed achieves significantly better generation results compared to the prior literature.

2.2 GAN for NLG

GAN(Goodfellow et al., 2014) has become a powerful method for reconstruction and generation in real data space, which leaves great potential to be used for natural language generation purposes. Various methods have been proposed to get over the major problem of the discontinuity of textual information, including SeqGAN(Yu et al., 2017), TextGAN(Zhang et al., 2017), RankGAN(Lin et al., 2017) and LeakGAN(Guo et al., 2017). However, regarding long-text generation tasks, for all the models above, the computation complexity might be too high, thus failing to provide satisfying results. Nor do these models take contextual and personalized information into consideration for controllable generation. Conditional GAN(Mirza and Osindero, 2014; Hu et al., 2017; Dong et al., 2017) concatenates the supervised labels into the input of generator and is able to control the generation of simple sentences. However, considering the high dimension of latent embedding vectors, concatenating significantly lower dimensional supervised information into the input might not be strong enough to force the generator to update towards the designated direction.

Therefore, to address these problems, we propose a novel conditional discriminator model which conditions the sentiment label on the discriminator to artificially change how the discriminator works, and force it backpropagate the loss

function that could make the generator to learn what the user really want. Experimental results reported in Section 5 show that we outperform all other GAN-based-NLG models in the generation performance, and outperform Conditional GAN in terms of sentiment accuracy as well.

3 Models

In this section, we introduce the proposed *RevGAN* model for review generation that includes three novel components: Self-Attentive Recursive AutoEncoder, Conditional Discriminator and Personalized Decoder. We first use Self-Attentive Recursive AutoEncoder to map the discontinuous user reviews and product descriptions into a latent continuous space, and utilize a novel version of cGAN to generate review embeddings for subsequent personalized decoding and review generation. Experimental results show that the combination of all three novel components achieves state-of-the-art review generation performance.

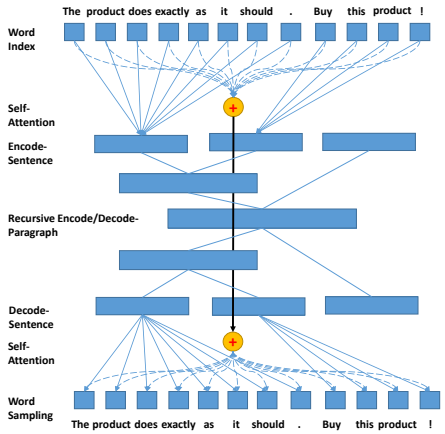

Figure 1: A Brief Overview of Self-Attentive Recursive AutoEncoder

3.1 Self-Attentive Recursive AutoEncoder

The proposed Self-Attentive Recursive AutoEncoder is illustrated in Figure 1. We implement a bidirectional Gated Recurrent Unit (GRU) (Cho et al., 2014) neural network as the encoder and the decoder in the model respectively. Compared with classical models like RNN or LSTM, GRU is computationally more efficient and better captures latent semantic meanings. We split each user review or product description into single sentences, and then map each sentence to their corresponding word indexes in the pre-defined dictionary. The index sequences constitute the input of our proposed model.

We use R to represent a certain review consisting of N^R sentences as $R = \{s^1, s^2, \cdots, s^{N_R}\}$. Each sentence s consists of N^s words as $s = \{w^1, w^2, \cdots, w^{N_s}\}$, where w_i represents the index of certain word in the vocabulary with size V. We denote $[W^z, W^r, U^z, U^r]$ as the weight matrices for update gates and reset gates, z_t, r_t as the status for the update gate and reset gate, and x_t, h_t as the input and output vector at time t respectively. GRU learns the hidden representations using the following equations, while the hidden state h_t at the end of the sequence constitutes latent sentence embeddings.

$$z_t = \sigma_g(W_z x_t + U_z h_{t-1} + b_z)$$

$$r_t = \sigma_g(W_r x_t + U_r h_{t-1} + b_r)$$

$$h_t = (1-z_t)h_{t-1} + z_t \sigma_h(W_h x_t + U_h(r_t h_{t-1}) + b_h)$$

Besides, to capture the relative position representations. we incorporate self-attentive mechanism (Shaw et al., 2018) during encoding process. Typically, each output element h_i is computed as weighted sum of a linearly transformed input elements

$$h_i = \sum_{j=1}^{n} \alpha_{ij}(x_j W^V)$$

Each weight coefficient α_{ij} is computed using a softmax function

$$\alpha_{ij} = \frac{expe_{ij}}{\sum_{k=1}^{n} expe_{ik}}$$

And e_{ij} is computed using a compatibility function that compares two input elements correspondingly. We visualize the self-attention mechanism with an example in Figure 2.

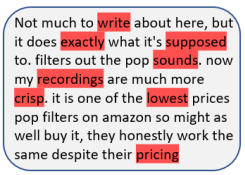

Figure 2: Visualization of Self-Attentive Mechanism

After getting the sentence-level embeddings within each review, we merge those sentence embeddings in a recursive way to obtain paragraph embeddings via a binary tree structure. We denote the embedding for sentence s as e_s, and during the

encoding process the first parent node y_2 is computed from the first two children node (e_1, e_2) by the standard neural network layer:

$$y_2 = f(W_e(e_1 : e_2) + b)$$

where $(e_1 : e_2)$ is the natural concatenation of these two embedding vectors, W_e is the weight matrix with twice the size of the embedding vectors. The second parent node y_3 will be computed from the concatenation of the first parent node y_2 and the following embedding vector e_3:

$$y_3 = f(W_e(y_2 : e_3) + b)$$

We obtain the representation of the rest nodes similarly. The embedding for root node constitutes the entire review embeddings. The training process of W_e follows a standard MLP network, where we optimize the reconstruction loss over every layer of the binary tree.

To unfold the recursive autoencoder, we'll start from the root node y_{N^R} of the binary tree. By utilizing another MLP network, we expand the paragraph embedding vector to two vectors: the leaf node and the lower level parent node, where the parent node would go through the same procedure until all of the leaf nodes in the binary tree are deciphered.

$$(y_{N^R-1} : e_{N^R}) = f'(W'_e y_{N^R} + b)$$

Finally, we assemble the paragraph from the bottom leaf node to the top one such that $R = \{e_1, e_2, \cdots, e_{N^R}\}$ to complete the review reconstruction process.

3.2 Conditional Discriminator

To generate meaningful reviews from the product information, we construct a cGAN model to transfer product descriptions into user reviews given specific sentiment labels. However, unlike the traditional conditional GAN methods (Mirza and Osindero, 2014; Hu et al., 2017), we do not concatenate the sentiment label directly into latent codes; considering the relatively high dimensions of latent embeddings, concatenating the sentiment scalar into the input might not be powerful enough to force the generator to update itself to match with the designated sentiment. Thus, we condition the sentiment labels on the discriminator to artificially change the rules that the discriminator works, and force it backpropagate loss functions that update generator policy correspondingly. The generated reviews and original reviews with the opposite sentiment are judged as negative examples, while only the original reviews that matches with the given sentiment are judged as positive examples by the conditional discriminator, as we propose the novel conditional discriminator D (for positive sentiment):

$$D(x|c) = \begin{cases} 1, \text{organic positive reviews} \\ 0, \text{others} \end{cases}$$

For generator, the model is optimized to minimize the reconstruction error between generated reviews and original reviews, $L(\theta^G) = KL(p_{real}(x)||p_G(x;\theta))$ where KL stands for Kullback-Leibler divergence. The loss function of discriminator D is: $L(\theta^D, \theta^G) = -\frac{1}{2}E_{x\sim data}logD(x) - \frac{1}{2}E_x log(1 - D(G(z)))$ Under ideal circumstances when generator and discriminator both reach their equilibrium, we could get that $D(x) = D(G(x)) = \frac{1}{2}$ and that the generated reviews are indeed indistinguishable from the original reviews from the discriminator point of view.

The core idea lies in that, by artificially forcing the discriminator to take certain type of reviews as real samples, generator should learn the conditioned information and then transform the generated data distribution. This unique structure of GANs makes possible the controllable review generation process, and experimental results support the strength of our model over classical cGAN models.

3.3 Personalized Decoder

To personalize the generation process, apart from the conditioning of sentiment labels, we also take the users' specific writing styles into account. We provide the definition of writing style according to (Zheng et al., 2006) :

Writing Style refers to the user's distinctive vocabulary choices and style of expression in his review creations.

Assuming that the historical reviews written by user i contain $[R_{i1}, R_{i2}, \cdots, R_{iN_i}]$, we calculate the usage frequency of each word from the corpus, which is denoted as a V-dimensional writing style vector W_{style}. The intuition is that, during the decoding process, instead of generating each word right from the calculated word distribution via GRU network, we concatenate the writing

style vector onto the distribution and sample the generated word afterwards, which would be determined by both the writing style vector W_{style} and the distribution vector W:

$$W' = W * W_{style}$$

Note that, to deal with the cold start problem when the user has no historical reviews, we could simply set the writing style vector as identity matrix $W_{style} = I$ and generate the reviews under normal settings. Experimental results show that the involvement of personalized information (sentiment information and writing style) indeed improve the generation results and the helpfulness score from the empirical study as well.

4 Experimental Results

4.1 Dataset

To empirically validate our proposed model, we implemented RevGAN on three subsets of the Amazon Review Dataset(He and McAuley, 2016; McAuley et al., 2015)[1], namely Musical Instrument, Automotive and Patio which include 44,006 reviews written by 3,697 users on 6.039 items.

4.2 Experiment Settings

The self-attentive recursive autoencoder is implemented by bidirectional GRUs with embedding dimension 300. GRU parameters and word embeddings are initialized from a uniform distribution between [-0.1,0.1]. The initial learning rate is 1e-3, which will be halved every 50 epochs until convergence. Batch size is set to 128 (128 sentences across review documents) for batch normalization(Ioffe and Szegedy, 2015). Sentences would be padded to the maximum length within each batch. Gradient clipping(Gulrajani et al., 2017) is adopted by scaling the gradients when the norm exceeds the threshold 1. For the recursive structure, the parameter settings are the same with sentence-level autoencoder only except that the size of the weight matrix is 600×300. The beam size for beam searching(Wiseman and Rush, 2016) would be fixed as 3. To validate the emotion label for each review, we implemented the state-of-the-art sentiment classifier VADER(Gilbert, 2014)[2] to label the sentiment score for each review. The baseline SeqGAN, RankGAN and LeakGAN models are implemented through the Texygen(Zhu et al., 2018)[3] toolkit. The generator and the conditional discriminator of GANs are both set as Multilayer Perceptron(Rumelhart et al., 1985) (MLP) with 300 hidden layers. Their parameters are initialized from the normal distribution N(0,0.02). The learning rates for generator and conditional discriminator are fixed at 5e-5 and 1e-5 respectively. During each epoch, generator G would iterate 5 times while discriminator D would only iterate 1 time. The model updates 30,000 times in total. We implemented our model on a Tesla K80 GPU within PyTorch[4] environment, where the whole training takes about 12 hours.

4.3 Evaluation Metrics

To demonstrate that our purposed model indeed achieves the state-of-the-art review generation performance, we implement various evaluation metrics, including distribution-based Log-Likelihood and Perplexity, coherence-based Word Mover Distance (WMD) (Kusner et al., 2015), ngram-based BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004), contextual label accuracy and human evaluation to measure the performance of review generation. Specifically, following the same metric as (Dong et al., 2017), we use sentiment accuracy, the ratio of the reviews whose sentiment matches with the given label, as an important indication of the personalization ability of the generator. The higher sentiment accuracy is, the better it could provide supervised generated results. Besides, we conduct the human evaluation to assess the quality and helpfulness of generated results by randomly selecting the same number of reviews from the original dataset, the generation of RevGAN and the generation of other baseline models and asking the participants to analyze which ones are generated by the machine and which ones are really created by humans, where significance test shows that our generated reviews are indeed indistinguishable from the original data.

4.4 Baseline Models

To demonstrate that our purposed model indeed achieves the state-of-the-art review generation performance, we compare our model across various evaluation metrics with several important benchmarks, including charRNN (Yao et al., 2017),

[1] http://jmcauley.ucsd.edu/data/amazon/
[2] https://github.com/cjhutto/vaderSentiment
[3] https://github.com/geek-ai/Texygen
[4] https://pytorch.org/

MLE (Bahl et al., 1990), SeqGAN (Yu et al., 2017), LeakGAN (Guo et al., 2017), RankGAN (Lin et al., 2017) and Attr2Seq (Dong et al., 2017). Besides, to verify the effectiveness of combining three novel components into the RevGAN model, we also compare the performance between RevGAN+CD (Conditional Discriminator), RevGAN+CD+SA (Self-Attentive Autoencoder) and RevGAN+CD+SA+PD (Personalized Decoder). The results show that our model indeed outperforms all the selected benchmark models significantly and consistently.

4.5 Significance Testing

We conduct significance tests to identify whether the difference between two review generation algorithms could indicate a difference in true system quality. Typically, following(Koehn, 2004), we use bootstrap re-sampling methods to get the asymptotic standard error of the estimated value of the evaluation metrics. Then the paired two-sample t-test could be used to test the significance whether their population means differ statistically.

In terms of the indistinguishableness of the generated results, we conduct a chi-square test for independence to test whether there is a significant association between the human assessment and the actual value. As the results of statistical test are insignificant, we could then claim that our generated reviews are indistinguishable from original ones in the sense that human can't separate them apart.

4.6 Evaluation of review generation

To illustrate the superiority and generalizability of our RevGAN model, we implement our model on three different domains of the Amazon Review Dataset including musical instruments, automotive and patio products. The summary of our experiment results is reported in Table 1, from which we could clearly observe that, compared with the baseline text-generation models, our proposed RevGAN model performs significantly better in sentence quality and coherence performance. On average, we could witness a 5% increase in Word Mover Distance (WMD), 80% improvement in BLEU and 10% rising in ROUGE. Besides, the comparison between different variations of RevGAN model verifies that indeed the combination of all three novel components gives the best generation performance. By deploying bootstrap re-sampling techniques introduced in the previous section, we conduct hypothesis tests where all the tests confirm the significant improvement of our RevGAN model. In that sense, we claim that our model achieved the state-of-the-art results on review generation. We also showcase some generated reviews at the end of this section.

4.7 Evaluation of controllable generation

In this part, we evaluate the controllable generation performance of our purposed model by pre-setting the contextual labels. We fixed the sentiment label as 'positive' and 'negative' respectively conditioned on the discriminator, and then evaluate the sentiment accuracy of the generated reviews. The results are reported in Table 2, where our model beats the state-of-the-art algorithm Attr2Seq(Dong et al., 2017) and the classical model Conditional GAN where we condition the same sentiment on these two models as well.

4.8 Evaluation of Personalized Generation

Besides the statistical and semantical metrics, we also design an empirical study to test the personalized performance of our generated reviews. We randomly select 15 reviews to include in each questionnaire, 5 from the original dataset, 5 from RevGAN generated results with personalization and 5 from RevGAN generated results without personalization, and ask participants to analyze which ones are generated by the machine and which ones are really created by humans. Besides, they are also asked to assess the helpfulness of each review by choosing the helpfulness score scale 1-5 for each review. We sent out 100 questionnaires in total, and get 36 responses, the confusion matrix of which is reported in Table 3. To test that whether the RevGAN generated reviews are indeed statistically indistinguishable from original ones, we run chi-test for significance testing:

$$\chi^2 = 0.012 < \chi^1_{0.95}$$

which shows that, under 95% confident interval, we could claim that there's no statistical difference between our machine-generated reviews and those actually written by humans.

Besides, the results indicate that our generated reviews have no statistical difference in terms of the helpfulness scores from those written by consumers towards certain products, with average helpfulness scores 3.10 and 3.03 for machine-generated and real-world reviews respectively. Thus, based on the t-test, we accept the hypothesis that there's no statistical difference between

4.9 Showcase

We present several showcases of our generated results with different contextual labels and domains as shown in Table 4. Additionally, we showcase the modification process in Table 5, where the personalized generated reviews tend to use more words from the user's history corpus.

Besides, we check if reviews generated by RevGAN would have the same linguistic features by testing two major statistical laws of linguistics(Altmann and Gerlach, 2016): Zipf Law(Zipf, 1935) and Heap Law(Herdan, 1964). The former states that if words are ranked according to their frequency of appearance $r = 1, 2, \cdots, V$, the frequency f(r) of the r-th word scales with the rank as $f(r) = \frac{\beta_Z}{r^{\alpha_Z}}$, while the latter states that the number of different words V scales with database size N measured in the total number of words as $V \sim N^{\alpha_H}$. As shown in Figure 3 and 4, both the original reviews and the generated ones satisfy those two linguistic laws.

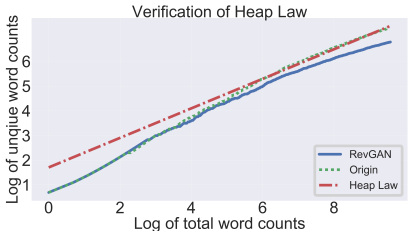

Figure 3: Verification of Heap's Law

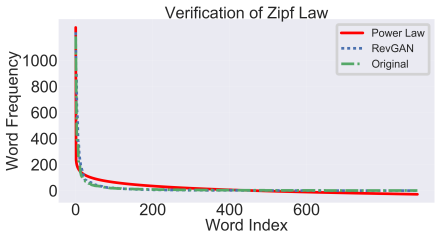

Figure 4: Verification of Zipf's Law

5 Conclusion

In this paper, we proposed *RevGAN* that automatically generates personalized product reviews from product embeddings as opposed to labels, which could output results targeting on specific products and users. To do this, we incorporate three novel components: self-attentive recursive autoen-

Domain	Sentiment	Generated Reviews
Musical	Positive	These chords got me to play my guitar better in less than one day. An excellent overdrive and an incredible value. I'll use them all the time.
Musical	Negative	These pedals are not budget friendly. If you are looking for classic rock sounds, you won't love these expensive hardware.
Automotive	Positive	I bought two sets of seat covers and this roll kit. Both fit well and look good. They were much easier to slide over the leather seats.
Automotive	Positive	These seat covers look good and seem to be made of a good quality material. For the price, these are a great buy.
Patio	Negative	It is not recommended. The cover is a little tight and hard to open and close.
Patio	Positive	These traps have caught more mice than ever give. You only need a little peanut butter for the bait and tomcat would caught so many mice in one night. Will order again if needed .

Table 4: Selected Personalized Generation Examples

User History Reviews	RevGAN	RevGAN+PD
1.They play well and hold up well(never had one break) They are my second favorite pick. But this pick is **better** in some songs than my favorite. 2.I ordered 5 different kind of picks and these were my favorite picks. They have a very **comfortable feel** and great sound!	The guitar has always made a quality and you would really love that life from it!	The guitar has always made **better** quality and you would really love that **comfortable feel** from it!

Table 5: Personalized Review Generation Examples

coder, conditional discriminator and personalized decoder. Experimental results show that RevGAN performs significantly better than other baseline models and that our generated reviews are very similar to organically generated user reviews, as shown in Section 5.2 and Table 3.

As a part of the future work, we would like to improve the review generation process in a way that could receive several key words from users as input and generate reviews based on these prior information. Another direction of the future research, however, lies in developing novel methods that distinguish the type of reviews described in the paper and organic reviews.

Abstract

Abstractive summarization approaches based on Reinforcement Learning (RL) have recently been proposed to overcome classical likelihood maximization. RL enables to consider complex, possibly non-differentiable, metrics that globally assess the quality and relevance of the generated outputs. ROUGE, the most used summarization metric, is known to suffer from bias towards lexical similarity as well as from suboptimal accounting for fluency and readability of the generated abstracts. We thus explore and propose alternative evaluation measures: the reported human-evaluation analysis shows that the proposed metrics, based on Question Answering, favorably compares to ROUGE – with the additional property of not requiring reference summaries. Training a RL-based model on these metrics leads to improvements (both in terms of human or automated metrics) over current approaches that use ROUGE as a reward.

1 Introduction

Summarization systems aim at generating relevant and informative summaries given a variable-length text as input. They can be roughly divided under two main categories, those adopting an *extractive* approach, *i.e.* identifying the most informative pieces from the input text and concatenating them to form the output summary; and those producing *abstractive* summaries, *i.e.* generating an output text whose tokens are not necessarily present in the input text.

While closer to human summarization, abstractive summarization is a much harder task and the need for faithful evaluation metrics is crucial to measure and drive the progress of such systems. The standard for evaluation of summarization systems is ROUGE (Lin, 2004): this metric can be considered as an adaptation of BLEU (Papineni et al., 2002), a scoring method for evaluation of machine translation systems; both based on *n*-gram co-occurrences, the latter favors precision while the former emphasizes recall.

Recent research works (Paulus et al., 2017; Pasunuru and Bansal, 2018; Arumae and Liu, 2019) have proposed to use evaluation metrics – and ROUGE in particular – to learn the model parameters through Reinforcement Learning (RL) techniques. This makes the choice of a good evaluation metric even more important. Unfortunately, ROUGE is known to incur several problems: in particular, its poor accounting for fluency and readability of the generated abstracts, as well as its bias towards lexical similarity (Ng and Abrecht, 2015). To emphasize the latter point, since ROUGE evaluates a summary against given human references, summarization models incur the risk of being unfairly penalized: a high quality summary might still have very few tokens/*n*-grams in common with the reference it is evaluated against.

In this work, we propose to overcome *n*-gram matching based metrics, such as ROUGE, by developing metrics which are better predictors of the quality of summaries. The contributions of this paper can be summarized as follows:

- Extending recent works (Eyal et al., 2019; Chen et al., 2018), we introduce new metrics, based on Question Answering, that do not require human annotations.
- We report a quantitative comparison of various summarization metrics, based on correlations with human assessments.
- We leverage the accuracy of the proposed metrics in several reinforcement learning schemes for summarization, including two unsupervised settings: *in-domain* (raw texts from the target documents) and *out-of-domain* (raw texts from another document collection).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3246–3256, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- Besides a quantitative evaluation of the generated summarizes, we qualitatively evaluate the performances of the different approaches through human assessment.

Our main results can be summarized as follows:

1. We show that fitting human judgments from carefully chosen measures allows one to successfully train a reinforcement learning-based model, improving over the state-of-the-art (in terms of ROUGE and human assessments).

2. we show that dropping the requirement for human-generated reference summaries, as enabled by the proposed metrics, allows to leverage texts in a self-supervised manner and brings clear benefits in terms of performance.

Section 2 introduces the metrics. Section 3 reviews related summarization systems and presents our proposed approaches. Section 4 presents our experimental results and discussions.

2 Evaluation Metrics

This section first describes our selection of existing summarization metrics and introduces our proposals. Then, we quantitatively compare them for abstractive summarization. For a comprehensive list of evaluation metrics, we refer the reader to Liu et al. (2016).

2.1 *n*-grams-based metrics

TextRank Automated summarization started with the development of extractive text summarization models. Many unsupervised models, that aim at computing a score between a sentence and document(s) were developed – the score attempting to reflect whether the sentence should be selected for building a summary (Nenkova, 2011). Such scores can thus be used as a proxy of the summary quality. We chose TextRank (Mihalcea and Tarau, 2004) – an extractive non-parametric summarization system inspired by PageRank (Page et al., 1999) – since it is well performing for extractive tasks and could be easily adapted for our needs. The algorithm builds a graph of sentences within a text based on their co-occurrences. Then, it assigns an importance score for each sentence based on a random walk on the resulting graph. The most important elements of the graph are considered as the ones that best describe the text. As a derivative usage, we propose to consider these importance scores to assess the quality of abstractive summaries in our study. This metric is referred to as TextRank in the following.

ROUGE Arguably the most popular metric for summarization at the moment, it provides a set of measures to compare automatically generated texts against one or more references (Lin, 2004). In particular, ROUGE-N is based on the count of overlapping *n*-grams, while ROUGE-L accounts for the longest common sub-sequence between the candidate and its corresponding reference(s).

Novelty As noted by See et al. (2017), abstractive summarization models do not produce novel *n*-grams as often as the reference summaries. Thus, to favor the generation of unseen words and produce more abstractive summaries, Kryściński et al. (2018) integrated *novelty* as a reward for reinforcement learning. It is defined as the fraction of unique *n*-grams in the summary that are novel, normalized by the length ratio of the generated and reference summaries.

2.2 Beyond n-grams

2.2.1 Language Modeling

We investigate the use of language models as an evaluation metric. (ShafieiBavani et al., 2018) proposed to exploit word embeddings to train a model able to rate the generated summaries. Following neural language models (LM), we propose to consider the perplexity of the generated summary according to the BERT LM (Devlin et al., 2019), which demonstrated state of the art results in many NLP tasks. For our experiments, we used the publicly available pre-trained English "base" model.

2.2.2 Question-Answering based Metrics

Question-Answering is related to summarization: the first work in this direction (Wu et al., 2002) introduced the notion of Answer-Focused Summarization, where answers to relevant questions on the source text are used to build the corresponding summary. Based on the intuition that a good-quality summary should provide the answers to the most relevant questions on a given input text, several works have proposed to adapt Question Answering (QA) for summary quality evaluation.

In that vein, (Pasunuru and Bansal, 2018) proposed to measure if answers contain the most *salient* tokens. Closer to our work, (Eyal et al.,

2019) proposed *APES*, a novel metric for evaluating summarization, based on the hypothesis that the quality of a generated summary is linked to the number of questions (from a set of relevant ones) that can be answered by reading it. In their proposed setup, two components are thus needed: (a) a set of relevant questions for each source document; and (b) a QA system. For each summary to assess, questions are successively generated from a reference summary, by masking each of the named entities present in this reference, following the methodology described in (Hermann et al., 2015). This results in as many triplets $(input, question, answer)$ as named entities present in the reference summary, where *input* denotes the summary to assess, *question* refers to the sentence containing the masked entity and *answer* refers to this masked entity to retrieve. Thus, for each summary to assess, metrics can be derived from the ability of the QA system to retrieve the correct answers from each of the associated triplets.

F1 score For each triplet, an F1 score is computed according to the responses retrieved by the considered QA system. This score, commonly used for QA evaluation (Rajpurkar et al., 2016), measures the average overlap between predictions and ground truth answers. For each summary to assess, the is the average of the F1 score computed over each triplet. In the following, we denote this metric as QA_{fscore}*(sup)*.

QA confidence Complementary to the F1 score, we propose to also consider the confidence of the QA system for its retrieved answer. This corresponds, for each triplet, to the probability of the true answer according to the QA model. Confidence scores are averaged for each summary to assess over its associated triplets. In the following, we denote this metric as QA_{conf}*(sup)*.

Besides considering the simple presence of the expected answers in the generated summary, QA-based metrics also account to some extent for readability. They indeed require that the considered QA system, trained on natural language, be able to find the answer in the input to assess, despite the variability of the generated texts.

Extension to the unsupervised setting While being a useful complement to ROUGE, the two QA-based metrics described above still need human-generated summaries. In this paper, we investigate and propose extending the previously described QA-based approach in an unsupervised setting.

	Readability	**Relevance**
Readability	1.0	0.77 **
Relevance	0.77 **	1.0
ROUGE-1 (sup)	0.14 *	0.18 **
ROUGE-2 (sup)	0.12 *	0.18 **
ROUGE-L (sup)	0.13 *	0.18 **
TextRank (unsup)	0.14 *	0.13 **
Novelty (unsup)	-0.13 *	-0.1 *
Bert LM (unsup)	0.21 **	0.08 *
QA_{fscore} (sup)	0.14 *	0.19 **
QA_{conf} (sup)	0.19 **	0.23 **
QA_{fscore} (unsup)	0.08	0.2 **
QA_{conf} (unsup)	0.33 **	0.31 **

Table 1: Spearman's ρ for the different metrics w.r.t. Readability and Relevance (*: $p < .05$, **: $p < .005$).

With this aim, we extended the above metrics at *the document level* (*i.e.*, questions and answers are generated from the source article text rather than from the reference summary), dispensing of the need for human-generated reference summaries. Thus, in line with the *APES* approach described above, we propose two unsupervised QA-based metrics, to which we refer to as QA_{fscore}*(unsup)* and QA_{conf}*(unsup)*. Accounting for both quality and informativeness of a generated summary, those metrics have the appealing property of not requiring reference summaries.

2.3 Quantitative Analysis

We exploit human judgments obtained for 3 types of automatically generated summaries by Paulus et al. (2017) on 100 samples of the CNN/Daily Mail summarization dataset (see detail in section 4.1), in terms of readability (how well written the summary is) and relevance (how well does the summary capture the important parts of the article). The summaries are generated by the three different systems proposed in the original work. Those samples have been scored, via Amazon Mechanical Turk, for Readability and Relevance (scores from 1 to 10 for both metrics).

In Table 1, we report Spearman's rank correlations on this data, where we compare summaries rankings obtained according to the assessed metrics. Scores render the ability of the various metrics to reproduce human preferences (in terms

of readability and relevance). First, we observe that readability and relevance are naturally intertwined: intuitively, an unreadable summary will bear very little information, one of the facts that explains the high correlation between *readability* and *relevance*.

From this correlation analysis against human judgments, we observe that, as expected, the Language Model metric captures *readability* better than ROUGE, while falling short on *relevance*.

On the other hand, the results obtained using the proposed QA-based metrics indicate their potential benefits especially under the *unsupervised* setting, with QA_{conf} and QA_{fscore} capturing *readability* and *relevance* better than all the others reported metrics, including ROUGE. We thus conclude that the proposed metrics, which favorably correlate with *readability* and *relevance* under human evaluation, are worth of a deeper experimental investigation: in the following sections we provide a thorough evaluation of their contributions as Reinforcement Learning rewards signals.

2.4 Learned Metric

Finally, we also leverage the qualitative data obtained by Paulus et al. (2017) – which compounds to 50 samples evaluated by annotators in terms of *readability* and *relevance* – to *learn* an aggregate metric for evaluation. We use a Ridge regression (with a regularization $\lambda = 1$) to learn to predict the geometric mean of readability and relevance from the metrics defined above. The geometric means was chosen since we want the generated summary to be both readable and relevant.

We randomly sampled 50% of the data to fit the linear model with various subsets of our base metrics. Then, we measured the correlation w.r.t. the expected geometric mean on the remaining 50% data. We performed this procedure 1000 times. Our experiments show that the best performing set of metrics consists of ROUGE-L in conjunction with QA_{conf} and QA_{fscore}, both computed at an article-level, and hence unsupervised.

This learned metric is thus defined as (with *unsup* versions of QA-based scores):

$$\alpha ROUGE_L + \beta QA_{conf} + \delta QA_{fscore} \quad (1)$$

with $\alpha = 0.8576$, $\beta = 2.274$ and $\delta = 0.6413$. We leverage this learned metric in our RL-based summarization model, as described below.

2.5 Implementation details

As QA system we use the BERT "base" pre-trained model (Devlin et al., 2019), finetuned on the SQuAD dataset (Rajpurkar et al., 2016) using the recommended parameters for the task[1]. This differs from the approach adopted by (Eyal et al., 2019) who trained their QA model on CNN-DM (the same data used for the summarization task).

3 Summarization Models

Abstractive summarization systems were originally designed as a post-processing of an extractive system – by compressing sentences (Nenkova, 2011). A lot of activity takes place nowadays in designing neural networks sequence to sequence architectures (Sutskever et al., 2014), which allow to consider the problem as a whole rather than a two-step process. Such models reached state-of-the-art performance. To tackle the summarization, which deals with a long text and possibly out-of-vocabulary tokens, See et al. (2017) proposed to leverage an attention over the input (Bahdanau et al., 2014), as well as a copy mechanism (Vinyals et al., 2015).

One problem of sequence-to-sequence models is that they tend to repeat text in the output. To deal with this problem, (See et al., 2017) use a *coverage mechanism*, and Paulus et al. (2017) introduced *Intra-Decoder Attention* with the same goal of avoiding duplicate information within the output sequences.

More recently, the model proposed by See et al. (2017) was further extended (Gehrmann et al., 2018), with the addition of an attention mask during inference: a pre-trained sequence tagger trained to select which input tokens should be copied and used to filter the copy mechanism. Such a filter, called *Bottom-Up Copy Attention*, was shown to help prevent copying from the source text sequences that are too long, hence resulting in more abstractive summaries. On the CNN/Daily Mail dataset, (Gehrmann et al., 2018) found this two-step process to yield significant improvements in terms of ROUGE – resulting in the current state-of-the-art system. We base our experiments on this model.

The differentiable loss function commonly used for training summarization models, negative log-likelihood, has several known limitations. Among

[1] https://github.com/huggingface/pytorch-transformers.

those, exposure bias and failure to cope with the large number of potentially valid summaries.

To overcome this, approaches based on reinforcement learning have recently been proposed, allowing the models to learn via reward signals. Ranzato et al. (2015) used the REINFORCE algorithm (Williams, 1992) to train RNNs for several generation tasks, showing improvements over previous supervised approaches. Narayan et al. (2018) used such an approach in an extractive summarization setting, learning to select the most relevant sentences within the input text in order to construct its summary. (Paulus et al., 2017) combined supervised and reinforcement learning, demonstrating improvements over competing approaches both in terms of ROUGE and on human evaluation. However, the main limit of these works is that they rely on standard summarization metrics which are known to be biased.

Finally, closer to our work, Arumae and Liu (2019) proposed to use question-answering rewards to learn an *extractive* summarization model in a reinforcement learning setup. Compared to what we propose, their system is extractive, and relies on hand-written summaries.

3.1 Mixed Training Objectives

In our experiments, we follow the reinforcement learning scheme described below. The main difference with previous works is our reward function, which was based on our study of metrics (section 2). We consider a mixed loss L_{ml+rl} combining supervised and reinforcement learning schemes:

$$L_{ml+rl} = \gamma L_{rl} + (1-\gamma) L_{ml} \tag{2}$$

where we define the reinforcement loss L_{rl} and the maximum likelihood L_{ml} in the following paragraphs.

Maximum Likelihood Under a supervised training setup, the teacher forcing algorithm (Williams and Zipser, 1989) can be applied, and corresponds to maximizing the likelihood (ML) or equivalently to minimizing the negative log likelihood (NLL) loss defined as:

$$L_{ml} = -\sum_{t=0}^{m} \log p(y_t^* | y_0^*, ..., y_{t-1}^*, X) \tag{3}$$

where $X = [x_1, ..., x_n]$ is the input text of n tokens and $Y^* = [y_1^*, ..., y_m^*]$ is the corresponding reference summary of m tokens.

Policy Learning Several RL-based summarization (Kryściński et al., 2018; Li et al., 2018; Pasunuru and Bansal, 2018; Paulus et al., 2017) apply the self-critical policy gradient training algorithm (Rennie et al., 2017). Following (Paulus et al., 2017) we use REINFORCE algorithm, using as the baseline a greedy decoding algorithm according to the conditional distribution $p(y|X)$, giving rise to a sequence $\widehat{Y}$. The model is sampled using its Markov property, that is, one token at a time, giving rise to the sequence Y^s.

Following the standard RL actor-critic scheme, with $r(Y)$ the reward function for an output sequence Y, the loss to be *minimized* is then defined as:

$$L_{rl} = (r(\widehat{Y}) - r(Y^s)) \sum_{t=0}^{m} \log p(y_t^s | y_0^s, ..., y_{t-1}^s, X) \tag{4}$$

As ROUGE is the most widely used evaluation metric, Paulus et al. (2017) used ROUGE-L as the reward r for the L_{rl} function and tested the following three different setups:

- *ML*: the model trained with L_{ml} ($\gamma = 0$);
- *RL*: the model trained with L_{rl} ($\gamma = 1$);
- *ML+RL*: the model trained with L_{ml+rl} ($\gamma = 0.9984$).

The human evaluation conducted on the three models shows that *RL* performs worse than *ML*, and *ML+RL* performs best for both *readability* and *relevance*. The authors also conclude that "despite their common use for evaluation, ROUGE scores have their shortcomings and should not be the only metric to optimize on summarization model for long sequences", which is translated in the very high optimal γ. We show that using a more sensible metric to optimize leads to a better model, and to a lower γ.

4 Experiments

In our experiments, we evaluate the effect of substituting the ROUGE reward in the reinforcement-learning model of (Paulus et al., 2017) by our proposed metric (section 2). We, moreover, study the effect of using metrics that do not necessitate human-generated summaries.

4.1 Data Used

Task-specific corpora for building and evaluating summarization models associate a human-generated reference summary with each text provided. We resort to the CNN/Daily Mail (CNN-DM) dataset (Hermann et al., 2015; Nallapati et al., 2016) for our experiments. It includes 287,113 article/summary pairs for training, 13,368 for validation, and 11,490 for testing. The summary corresponding to each article consists of several bullet points displayed on the respective news outlet webpage. In average, summaries contain 66 tokens ($\sigma = 26$) and 4.9 bullet points. Consistently with See et al. (2017) and Gehrmann et al. (2018), we use the non-anonymized version of the dataset, the same training/validation splits, and perform truncation of source documents and summaries to 400 and 100 tokens, respectively.

To assess the possible benefits of reinforcing over the proposed QG-based metric, which does not require human-generated reference summaries, we employ TL;DR[2], a large-scale dataset for automatic summarization built on social media data, compounding to 4 Million training pairs (Völske et al., 2017). Both CNN-DM and TL;DR datasets are in English.

4.2 Models

For all our experiments, we build on top of the publicly available OpenNMT implementation[3], consistently with Gehrmann et al. (2018) to which we refer to as a baseline. The encoder is composed of a one-layer bi-LSTM with 512 hidden states, and 512 hidden states for the one-layer decoder. The embedding size is set at 128. The model is trained with Adagrad, with an initial learning rate of 0.15, and an initial accumulator value of 0.1. We continue training until convergence; when the validation perplexity does not decrease after an epoch, the learning rate is halved. We use gradient-clipping with a maximum norm of 2.

Gehrmann et al. (2018) showed that increasing the number of hidden states leads to slight improvements in performance, at the cost of increased training time; thus, as reinforcement learning is computationally expensive, we build on top of the smallest model – nonetheless, we include the largest model by Gehrmann et al. (2018) in our discussion of results.

All the experimented reinforcement approaches use the mixed training objectives defined in equation 2, with the ML part corresponding to the previously described baseline model pretrained on the CNN-DM dataset. Compared models differ on the considered reward signals. They also differ on their use of additional unsupervised data, either *In-Domain* or *Out-of-Domain*, as discussed below.

4.2.1 Reward Signals

The three reward signals used throughout our experiments, are detailed below:

1. **ROUGE**: We use only ROUGE-L as reward signal within the baseline architecture, consistently with Paulus et al. (2017);

2. **QA**$_{learned}$: Conversely, we compute the reward by applying the learned coefficients to the three components of the learned metric, as obtained in Section 2.4.

3. **QA**$_{equally}$: We apply the mixed training objective function, using as a reward the three metric components of the learned metric (ROUGE-L, QA$_{conf}$, and QA$_{fscore}$) equally weighted: this corresponds to setting a value of 1 for α, β and δ in Eq. 1. This allows to see to which extent learning is sensitive to fitting human assessments.

For (2) and (3), we set γ (Eq. 2) to 0.5[4]. This shows that, compared to (Paulus et al., 2017), we do not need to use NLL to avoid the model from generating unreadable summaries.

4.2.2 In-Domain vs Out-of-Domain

Finally, we experiment with the proposed QA$_{conf}$ and QA$_{fscore}$ metrics in an unsupervised fashion, as they can be computed at article level – *i.e.* without accessing the reference human-generated summaries. We investigate the potential benefits of using this approach both *in-domain* and *out-of-domain*: for the former, we resort to the test set of the CNN-Daily Mail (CNN-DM) dataset; for the latter, we leverage the TL;DR corpus.

As the CNN-Daily Mail is built from mainstream news articles, and the TL;DR data comes from social media sources, we consider the latter

[2] https://tldr.webis.de

[3] http://opennmt.net/OpenNMT-py/Summarization.html

[4] We have run experiments with $\gamma = 0.5$, and $\gamma = 0.9984$ as Paulus et al. (2017); we report here the best performance which was obtained with the former.

as out-of-domain in comparison. From the latter, which includes circa 4 million samples, we randomly draw sample subsets of size comparable with CNN-DM for training, validation and testing splits.

Due to computational costs, we restrict these experiments to the model trained under reinforcement using the $\text{QA}_{learned}$ metric. Under this setup, the model has access at training time both to:

- *supervised* samples for which a reference summary is given (and thus all metrics, including ROUGE and NLL, can be computed as a training objective), coming from the training set of CNN-Daily Mail corpus ;
- *unsupervised* samples, for which no reference is available, thus allowing to only compute QA_{conf}(unsup) and QA_{fscore}(unsup). Three unsupervised settings are considered in the following:

  TL;DR, corresponding to the *out-of-domain* setting where we use articles from the *TL;DR* dataset;

  CNN-DM (VAL), corresponding to an *in-domain* setting where we use texts from the validation set from the CNN/Daily Mail dataset;

  and, *CNN-DM (TEST)* for an *in-domain* setting where we use the articles from the test set (thus containing texts used for evaluation purposes).

While all the data is from the CNN-DM train dataset in the *supervised* setups, for the *unsupervised* setups, we set the proportion of unsupervised data to 50% (either CNN-DM VAL, CNN-DM TEST for *in-domain* or TL;DR for *out-of-domain* data). Thus, for 50% of the data, the model has access only to the QA_{conf} and QA_{fscore} reward signals, since the ROUGE-L reward can only be computed on *supervised* batches.

Therefore, for all the unsupervised setups, in order to keep consistency in the reward signal throughout the training, we multiply by a factor of 2 the weight associated with ROUGE-L when this reward is computable, and set it to 0 otherwise.

4.3 Results

In Table 2, we report the results obtained from our experiments in comparison with previously proposed approaches. We observe that, unsurprisingly, reinforcing on ROUGE-L allows to obtain significant improvements over the state-of-the-art, in terms of ROUGE but at the cost of lower QA-based metrics. Conversely, reinforcing on the proposed metric improves consistently all its components (ROUGE-L, QA_{conf} and QA_{fscore}).

However, increasing the reward does not necessarily correlate with better summaries. The human inspection as reported by (Paulus et al., 2017) shows that the generated summaries reinforced on ROUGE-L are consistently on the low end in terms of readability and relevance.

A closer inspection of the generated summaries revealed that the sequences generated by this model seem to qualitatively degrade as the number of produced tokens grows: they often start with a reasonable sub-sequence, but quickly diverge towards meaningless outputs. This can be explained by the aforementioned drawbacks of ROUGE, which are likely amplified when used both as evaluation and reward: the system might be optimizing for ROUGE, at the price of losing the information captured with the NLL loss by its language model.

We hence conducted a human evaluation for the different setups, reported in Table 3, assessing their outputs for *readability* and *relevance* in line with Paulus et al. (2017). We randomly sampled 50 articles from the CNN-DM test set; since the learned metric used in our experiments is derived from the subset manually evaluated in Paulus et al. (2017) we ensured that there was no overlap with it. For each of those 50 articles, three English speakers evaluated the summaries generated by the 7 different systems reported in Table 2.

We observe that reinforcing using the proposed metric – which includes QA based metrics, leads to comparable performance in terms of ROUGE w.r.t. state-of-the-art approaches, while clear benefits emerge from the results of the human evaluation: a significant improvement in terms of relevance, particularly when leveraging *in-domain* data in an *unsupervised* setup. Not surprisingly, we observe an improvement for our model when reinforced through the learned metric compared to the one equally weighted. The slightly lower relevance scores observed for the $\text{QA}_{learned}$ w.r.t. $\text{QA}_{equally}$ are consistent with the lower ROUGE-L and QA_{fscore} reported in Table 2. This is explained by the lower coefficients for ROUGE-L

	R-1	R-2	R-L	QA$_{fscore}$	QA$_{conf}$
See et al. (2017)	39.53	17.28	36.38	-	-

+ QA$_{learned}$ + CNN-DM (TEST)	42.74	17.25	37.96	**16.17**	**42.14**

Table 2: Comparison with previous works. On top, we report the results obtained by Gehrmann et al. (2018) using their largest architecture, as well as those by See et al. (2017). Next, we report results recently obtained by reinforcement learning approaches. Finally, we indicate the scores obtained by our baseline – the "small" model by Gehrmann et al. (2018) – and the six reinforced models we build on top of it.

and QA$_{fscore}$ (see 2.4), and the relatively stronger correlation of those two metrics with *relevance* (see Table 1).

Consistently with the figures reported in Table 2, the human evaluation results – reported in Tables 3 and 4 – confirm the progressive improvements of our different proposed models when using unsupervised data closer to the test set documents:

- adding *unsupervised* data from the out-of-domain TL;DR brings a slight improvement using QA$_{learned}$;
- when it comes to the same domain (*i.e.* CNN-DM validation) the improvements increase;
- finally, when unsupervised samples come from the same set as those used for testing, we observe even better results.

These results show that using the proposed QA-based metrics, that do not depend on reference summaries, allows to leverage raw text data; and, that fine-tuning (without supervision) on the documents to be summarized is beneficial.

To elaborate further, we notice that applying the learned coefficients for 1 to the results obtained by models reinforced on QA$_{\text{learned}}$ and QA$_{\text{equally}}$, see Table 2, we obtain very similar scores (namely, 136.43 for QA$_{\text{equally}}$ and 136.4 for QA$_{\text{learned}}$). However, the qualitative analysis reported in Tables 3 and 4 shows that while they perform similarly in terms of *relevance*, a significantly lower score for *readability* is obtained using QA$_{\text{equally}}$. This can be explained by the stronger weight of ROUGE_L for this setup, a fact which might lead to a degradation of the quality of the output consistently with the observations reported in (Paulus et al., 2017) as well as in our ROUGE experiment.

Another observation from Tables 3 and 4 is that while QA$_{\text{learned}}$ performs significantly better in term of *readability* than QA$_{\text{learned}}$ + CNN-DM (VAL), the opposite holds for *relevance*. This could be explained by the setup difference during training: as detailed in section 4.2.2, for unsupervised setups (*i.e.* QA$_{\text{learned}}$ + CNN-DM (VAL)) only the QA-based metrics are computed for the portion of data for which no reference is available. While testing (TEST) and validation (VAL) splits come the same dataset (CNN-DM), we observe that using the samples from TEST in an unsupervised fashion allows for maintaining comparably high *relevance* compared to QA$_{\text{learned}}$ + CNN-DM (VAL), while also obtaining similar *readability* to QA$_{\text{learned}}$. This shows the possible benefits that can be obtained by exposing the model to the evaluation data in unsupervised setups. To further study our unsupervised metrics, we performed additional experiments on the TL;DR corpus. We observed more than one absolute point of improvement w.r.t CNN-DM TEST in terms of ROUGE-L, QA$_{fscore}$ (unsup) and QA$_{conf}$ (unsup).

This indicates that the proposed unsupervised

	Readability	Relevance
human reference	7.27*	7.4**

metrics allow the model to better transfer to new domains such as TL;DR. These results pave the way for leveraging large numbers of texts, in a self-supervised manner, to train automatic summarization models.

5 Conclusions

We have presented the analysis of novel QA-based metrics[5], and have shown promising results when using them as a reward in a RL setup. Crucially, those metrics do not require a human reference, as they can be computed from the text to be summarized.

From our experiments this proves particularly beneficial, allowing to leverage both *in-domain* and *out-of-domain* unlabeled data.

The promising results obtained indicate a path towards partially self-supervised training of summarization models, and suggest that progress in automated question generation can bring benefits for automatic summarization.

Finally, to our knowledge, this paper is the first to compare two architectures with the same reinforcement setup on the same data: the one proposed by See et al. (2017) and extended by Gehrmann et al. (2018), versus the one by Paulus et al. (2017). In terms of ROUGE, we observe better results than those reported by Paulus et al. (2017) – see Table 2 – indicating a possible edge for the architecture proposed by See et al. (2017).

Abstract

Existing neural methods for data-to-text generation are still struggling to produce long and diverse texts: they are insufficient to model input data dynamically during generation, to capture inter-sentence coherence, or to generate diversified expressions. To address these issues, we propose a Planning-based Hierarchical Variational Model (PHVM). Our model first plans a sequence of groups (each group is a subset of input items to be covered by a sentence) and then realizes each sentence conditioned on the planning result and the previously generated context, thereby decomposing long text generation into dependent sentence generation sub-tasks. To capture expression diversity, we devise a hierarchical latent structure where a global planning latent variable models the diversity of reasonable planning and a sequence of local latent variables controls sentence realization. Experiments show that our model outperforms state-of-the-art baselines in long and diverse text generation.

1 Introduction

Data-to-text generation is to generate natural language texts from structured data (Gatt and Krahmer, 2018), which has a wide range of applications (for weather forecast, game report, product description, advertising document, etc.). Most neural methods focus on devising encoding scheme and attention mechanism, namely, (1) exploiting input structure to learn better representation of input data (Lebret et al., 2016; Liu et al., 2018), and (2) devising attention mechanisms to better employ input data (Mei et al., 2016; Liu et al., 2018; Nema et al., 2018) or to dynamically trace which part of input has been covered in generation (Kiddon et al., 2016). These models are able to produce fluent and coherent short texts in some applications.

However, to generate long and diverse texts such as product descriptions, existing methods are still unable to capture the complex semantic structures and diversified surface forms of long texts. **First**, existing methods are not good at modeling input data dynamically during generation. Some neural methods (Kiddon et al., 2016; Feng et al., 2018) propose to record the accumulated attention devoted to each input item. However, these records may accumulate errors in representing the state of already generated prefix, thus leading to wrong new attention weights. **Second**, inter-sentence coherence in long text generation is not well captured (Wiseman et al., 2017) due to the lack of high-level planning. Recent studies propose to model planning but still have much space for improvement. For instance, in (Puduppully et al., 2019) and (Sha et al., 2018), planning is merely designed for ordering input items, which is limited to aligning input data with the text to be generated. **Third**, most methods fail to generate diversified expressions. Existing data-to-text methods inject variations at the conditional output distribution, which is proved to capture only low-level variations of expressions (Serban et al., 2017).

To address the above issues, we propose a novel Planning-based Hierarchical Variational Model (PHVM). To better model input data and alleviate the inter-sentence incoherence problem, we design a novel planning mechanism and adopt a compatible hierarchical generation process, which mimics the process of human writing. Generally speaking, to write a long text, a human writer first arranges contents and discourse structure (i.e., *high-level planning*) and then realizes the surface form of each individual part (*low-level realization*). Motivated by this, our proposed model first performs

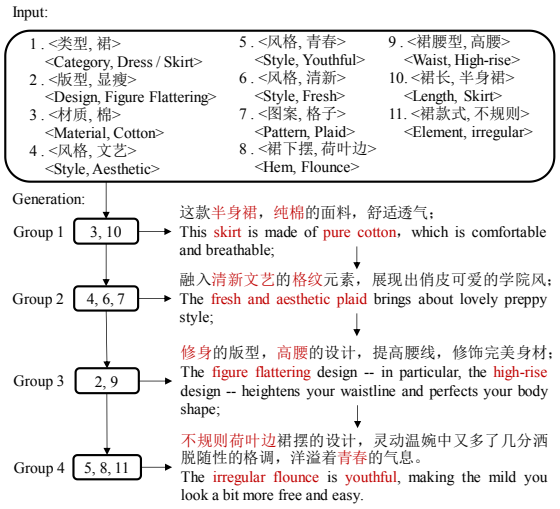

Figure 1: Generation process of PHVM. After encoding a list of input attribute-value pairs, PHVM first conducts planning by generating a sequence of groups, each of which is a subset of input items. Each sentence is then realized conditioned on the corresponding group and its previous generated sentences.

planning by segmenting input data into a sequence of groups, and then generates a sentence conditioned on the corresponding group and preceding generated sentences. In this way, we decompose long text generation into a sequence of dependent sentence generation sub-tasks where each sub-task depends specifically on an individual group and the previous context. By this means, the input data can be well modeled and inter-sentence coherence can be captured. Figure 1 depicts the process.

To deal with expression diversity, this model also enables us to inject variations at both high-level planning and low-level realization with a hierarchical latent structure. At high level, we introduce a global planning latent variable to model the diversity of reasonable planning. At low level, we introduce local latent variables for sentence realization. Since our model is based on Conditional Variational Auto-Encoder (CVAE) (Sohn et al., 2015), expression diversity can be captured by the global and local latent variables.

We evaluate the model on a new advertising text[1] generation task which requires the system to generate a long and diverse advertising text that covers a given set of attribute-value pairs describing a product (see Figure 1). We also evaluate our model on the recipe text generation task from (Kiddon et al., 2016) which requires the system to correctly use the given ingredients and maintain coherence among cooking steps. Experiments on advertising text generation show that our model outperforms state-of-the-art baselines in automatic and manual evaluation. Our model also generalizes well to long recipe text generation and outperforms the baselines. Our contributions are twofold:

- We design a novel Planning-based Hierarchical Variational Model (PHVM) which integrates planning into a hierarchical latent structure. Experiments show its effectiveness in coverage, coherence, and diversity.
- We propose a novel planning mechanism which segments the input data into a sequence of groups, thereby decomposing long text generation into dependent sentence generation sub-tasks. Thus, input data can be better modeled and inter-sentence coherence can be better captured. To capture expression diversity, we devise a hierarchical latent structure which injects variations at both high-level planning and low-level realization.

2 Related Work

Traditional methods (Reiter and Dale, 1997; Stent et al., 2004) for data-to-text generation consist of three components: content planning, sentence planning, and surface realization. Content planning and sentence planning are responsible for what to say and how to say respectively; they are typically based on hand-crafted (Kukich, 1983; Dalianis and Hovy, 1993; Hovy, 1993) or automatically-learnt rules (Duboue and McKeown, 2003). Surface realization generates natural language by carrying out the plan, which is template-based (McRoy et al., 2003; van Deemter et al., 2005) or grammar-based (Bateman, 1997; Espinosa et al., 2008). As these models are shallow and the two stages (planning and realization) often function separately, traditional methods are unable to capture rich variations of texts.

Recently, neural methods have become the mainstream models for data-to-text generation due to their strong ability of representation learning and scalability. These methods perform well in generating weather forecasts (Mei et al., 2016) or very short biographies (Lebret et al., 2016; Liu

[1] An advertising text describes a product with attractive wording. The goal of writing such texts is to advertise a product and attract users to buy it.

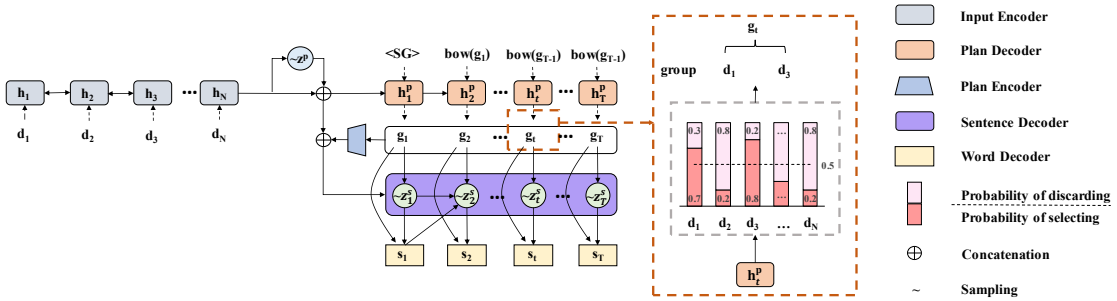

Figure 2: Architecture of PHVM. The model controls planning with a global latent variable z^p. The plan decoder conducts planning by generating a sequence of groups $g = g_1 g_2 ... g_T$ where g_t is a subset of input items and specifies the content of sentence s_t to be generated. The sentence decoder controls the realization of s_t with a local latent variable z_t^s; dependencies among z_t^s are explicitly modeled to better capture inter-sentence coherence.

et al., 2018; Sha et al., 2018; Nema et al., 2018) using well-designed data encoder and attention mechanisms. However, as demonstrated in Wiseman et al. (2017) (a game report generation task), existing neural methods are still problematic for long text generation: they often generate incoherent texts. In fact, these methods also lack the ability to model diversity of expressions.

As for long text generation, recent studies tackle the incoherence problem from different perspectives. To keep the decoder aware of the crucial information in the already generated prefix, Shao et al. (2017) appended the generated prefix to the encoder, and Guo et al. (2018) leaked the extracted features of the generated prefix from the discriminator to the generator in a Generative Adversarial Nets (Goodfellow et al., 2014). To model dependencies among sentences, Li et al. (2015) utilized a hierarchical recurrent neural network (RNN) decoder. Konstas and Lapata (2013) proposed to plan content organization with grammar rules while Puduppully et al. (2019) planned by reordering input data. Most recently, Moryossef et al. (2019) proposed to select plans from all possible ones, which is infeasible for large inputs.

As for diverse text generation, existing methods can be divided into three categories: enriching conditions (Xing et al., 2017), post-processing with beam search and rerank (Li et al., 2016), and designing effective models (Xu et al., 2018). Some text-to-text generation models (Serban et al., 2017; Zhao et al., 2017) inject high-level variations with latent variables. Variational Hierarchical Conversation RNN (VHCR) (Park et al., 2018) is a most similar model to ours, which also adopts a hierarchical latent structure. Our method differs from VHCR in two aspects: (1) VHCR has no planning mechanism, and the global latent variable is mainly designed to address the KL collapse problem, while our global latent variable captures the diversity of reasonable planning; (2) VHCR injects distinct local latent variables without direct dependencies, while our method explicitly models the dependencies among local latent variables to better capture inter-sentence connections. Shen et al. (2019) proposed ml-VAE-D with multi-level latent variables. However, the latent structure of ml-VAE-D consists of two global latent variables: the top-level latent variable is introduced to learn a more flexible prior of the bottom-level latent variable which is then used to decode a whole paragraph. By contrast, our hierarchical latent structure is tailored to our planning mechanism: the top level latent variable controls planning results and a sequence of local latent variables is introduced to obtain fine-grained control of sentence generation sub-tasks.

We evaluated our model on a new advertising text generation task which is to generate a long and diverse text that covers all given specifications about a product. Different from our task, the advertising text generation task in (Chen et al., 2019) is to generate personalized product description based on product title, product aspect (e.g., "appearance"), and user category.

3 Task Definition

Given input data $x = \{d_1, d_2, ..., d_N\}$ where each d_i can be an attribute-value pair or a keyword, our task is to generate a long and diverse text $y = s_1 s_2 ... s_T$ (s_t is the t^{th} sentence) that covers x as much as possible. For the advertising

text generation task, x consists of specifications about a product where each d_i is an attribute-value pair $< a_i, v_i >$. For the recipe text generation task, x is an ingredient list where each d_i is an ingredient. Since the recipe title r is also used for generation, we abuse the symbol x to represent $< \{d_1, d_2, ..., d_N\}, r >$ for simplification.

4 Approach

4.1 Overview

Figure 2 shows the architecture of PHVM. PHVM first samples a global planning latent variable z^p based on the encoded input data; z^p serves as a condition variable in both planning and hierarchical generation process. The plan decoder takes z^p as initial input. At time step t, it decodes a group g_t which is a subset of input items (d_i) and specifies the content of the t^{th} sentence s_t. When the plan decoder finishes planning, the hierarchical generation process starts, which involves the high-level sentence decoder and the low-level word decoder. The sentence decoder models inter-sentence coherence in semantic space by computing a sentence representation h_t^s and sampling a local latent variable z_t^s for each group. h_t^s and z_t^s, along with g_t, guide the word decoder to realize the corresponding sentence s_t.

The planning process decomposes the long text generation task into a sequence of dependent sentence generation sub-tasks, thus facilitating the hierarchical generation process. With the hierarchical latent structure, PHVM is able to capture multi-level variations of texts.

4.2 Input Encoding

We first embed each input item d_i into vector $\boldsymbol{e}(d_i)$. The recipe title r is also embedded as $\boldsymbol{e}(r)$. We then encode x[2] with a bidirectional Gated Recurrent Unit (GRU) (Cho et al., 2014). For advertising text generation, x is represented as the concatenation of the last hidden states of the forward and backward GRU $\boldsymbol{enc}(x) = [\overrightarrow{h_N}; \overleftarrow{h_1}]$; for recipe text generation, $\boldsymbol{enc}(x) = [\overrightarrow{h_N}; \overleftarrow{h_1}; \boldsymbol{e}(r)]$. $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$ is the context-aware representation of d_i. Note that input encoder is not necessarily an RNN; other neural encoders or even other encoding schemes are also feasible, such as multi-layer perceptron (MLP) and bag of words.

[2]For advertising text generation, x is first ordered by attributes so that general attributes are ahead of specific ones; for recipe text generation, we retain the order in the dataset

4.3 Planning Process

The planning process generates a subset of input items to be covered for each sentence, thus decomposing long text generation into easier dependent sentence generation sub-tasks. Due to the flexibility of language, there may exist more than one reasonable text that covers the same input but in different order. To capture such variety, we model the diversity of reasonable planning with a global planning latent variable z^p. Different samples of z^p may lead to different planning results which control the order of content. This process can be formulated as follows:

$$g = argmax_g P(g|x, z^p) \quad (1)$$

where $g = g_1 g_2 ... g_T$ is a sequence of groups, and each group g_t is a subset of input items which is a main condition when realizing the sentence s_t.

The global latent variable z^p is assumed to follow the isotropic Gaussian distribution, and is sampled from its prior distribution $p_\theta(z^p|x) = \mathcal{N}(\mu^p, \sigma^{p2}\mathbf{I})$ during inference and from its approximate posterior distribution $q_{\theta'}(z^p|x, y) = \mathcal{N}(\mu^{p'}, \sigma^{p'2}\mathbf{I})$ during training:

$$[\mu^p; \log \sigma^{p2}] = \boldsymbol{MLP}_\theta(x) \quad (2)$$

$$[\mu^{p'}; \log \sigma^{p'2}] = \boldsymbol{MLP}_{\theta'}(x, y) \quad (3)$$

We solve Eq. 1 greedily by computing $g_t = argmax_{g_t} P(g_t|g_{<t}, x, z^p)$ with the plan decoder (a GRU). Specifically, at time step t, the plan decoder makes a binary prediction for each input item by estimating $P(d_i \in g_t|g_{<t}, x, z^p)$:

$$P(d_i \in g_t) = \boldsymbol{\sigma}(v_p^T \boldsymbol{tanh}(W_p[h_i; h_t^p] + b_p)) \quad (4)$$

where $\boldsymbol{\sigma}$ denotes the sigmoid function, h_i is the vector of input item d_i, and h_t^p is the hidden state of the plan decoder. Each group is therefore formed as $g_t = \{d_i|P(d_i \in g_t) > 0.5\}$ (If this is empty, we set g_t as $\{argmax_{d_i} P(d_i \in g_t)\}$.).

We feed $bow(g_t)$ (the average pooling of $\{h_i|d_i \in g_t\}$) to the plan decoder at the next time step, so that h_{t+1}^p is aware of what data has been selected and what has not. The planning process proceeds until the probability of stopping at the next time step is over 0.5:

$$P_t^{stop} = \boldsymbol{\sigma}(W_c h_t^p + b_c) \quad (5)$$

The hidden state is initialized with $\boldsymbol{enc}(x)$ and z^p. The plan decoder is trained with full supervision, which is applicable to those tasks where

reference plans are available or can be approximated. For both tasks we evaluate in this paper, we approximate the reference plans by recognizing the subset of input items covered by each sentence with string match heuristics. The loss function at time step t is given by:

$$\begin{aligned} -\log P(g_t = \widetilde{g}_t | \widetilde{g_{<t}}, x, z^p) \\ = -\sum_{d_i \in \widetilde{g}_t} \log P(d_i \in g_t) \\ -\sum_{d_i \notin \widetilde{g}_t} \log(1 - P(d_i \in g_t)) \end{aligned} \quad (6)$$

where $\widetilde{g}_t$ is the reference group. As a result, z^p is forced to capture features of reasonable planning.

4.4 Hierarchical Generation Process

The generation process produces a long text $y = s_1 s_2 ... s_T$ in alignment with the planning result $g = g_1 g_2 ... g_T$, which is formulated as follows:

$$c = \{x, z^p\} \quad (7)$$

$$y = argmax_y P(y|g, c) \quad (8)$$

We perform sentence-by-sentence generation and solve Eq. 8 greedily by computing $s_t = argmax_{s_t} P(s_t|s_{<t}, g, c)$. s_t focuses more on g_t than on the entire plan g. The generation process is conducted hierarchically, which consists of sentence-level generation and word-level generation. Sentence-level generation models inter-sentence dependencies at high level, and interactively controls word-level generation which conducts low-level sentence realization.

Sentence-level Generation The sentence decoder (a GRU) performs sentence-level generation; for each sentence s_t to be generated, it produces a sentence representation h^s_t and introduces a local latent variable z^s_t to control sentence realization.

The latent variable z^s_t is assumed to follow the isotropic Gaussian distribution. At time step t, the sentence decoder samples z^s_t from the prior distribution $p_\phi(z^s_t|s_{<t}, g, c) = \mathcal{N}(\mu^s_t, \sigma^{s2}_t \mathbf{I})$ during inference and from the approximate posterior distribution $q_{\phi'}(z^s_t|s_{\leq t}, g, c) = \mathcal{N}(\mu^{s'}_t, \sigma^{s'2}_t \mathbf{I})$ during training. h^s_t and the distribution of z^s_t are given by:

$$h^s_t = \boldsymbol{GRU}_s([z^s_{t-1}; h^w_{t-1}], h^s_{t-1}) \quad (9)$$

$$[\mu^s_t; \log \sigma^{s2}_t] = \boldsymbol{MLP}_\phi(h^s_t, bow(g_t)) \quad (10)$$

$$[\mu^{s'}_t; \log \sigma^{s'2}_t] = \boldsymbol{MLP}_{\phi'}(h^s_t, bow(g_t), s_t) \quad (11)$$

where h^w_{t-1} is the last hidden state of the word decoder after decoding sentence s_{t-1}, and $\boldsymbol{GRU}_s$ denotes the GRU unit of the sentence decoder. By this means, we constrain the distribution of z^s_t in two aspects. First, to strengthen the connection from the planning result g, we additionally condition z^s_t on g_t to keep z^s_t focused on g_t. Second, to capture the dependencies on $s_{<t}$, we explicitly model the dependencies among local latent variables by inputting z^s_{t-1} to the sentence decoder, so that z^s_t is conditioned on $z^s_{<t}$ and is expected to model smooth transitions in a long text.

We initialize the hidden state h^s_0 by encoding the input x, the global planning latent variable z^p and the planning result g:

$$h^g_t = \boldsymbol{GRU}_g(bow(g_t), h^g_{t-1}) \quad (12)$$

$$h^s_0 = W_s[\boldsymbol{enc}(x); z^p; h^g_T] + b_s \quad (13)$$

where h^g_T is the last hidden state of $\boldsymbol{GRU}_g$ that encodes the planning result g.

Word-level Generation The word decoder (a GRU) conducts word-level generation; it decodes a sentence $s_t = argmax_{s_t} P(s_t|s_{<t}, z^s_t, g, c)$ conditioned on $\{h^s_t, z^s_t, g_t\}$. Specifically, we sample word w^t_k of s_t as follows:

$$w^t_k \sim P(w^t_k | w^t_{<k}, s_{<t}, z^s_t, g, c) \quad (14)$$

4.5 Loss Function

We train our model end-to-end. The loss function has three terms: the negative evidence lower bound (ELBO) of $\log P(y|x)$ ($\mathcal{L}_1$), the loss of predicting the stop signal ($\mathcal{L}_2$) and the bag-of-word loss (Zhao et al., 2017) ($\mathcal{L}_3$).

We first derive the ELBO:

$$\begin{aligned} \log P(y|x) \geq E_{q_{\theta'}(z^p|x,y)}[\log P(y|x, z^p)] \\ - D_{KL}(q_{\theta'}(z^p|x, y)||p_\theta(z^p|x)) \end{aligned} \quad (15)$$

$$\begin{aligned} \log P(y|x, z^p) = \log P(g, y|x, z^p) \\ = \sum_{t=1}^{T} \log P(g_t|g_{<t}, x, z^p) \\ + \log P(s_t|s_{<t}, g, x, z^p) \end{aligned} \quad (16)$$

$$\begin{aligned} \log P(s_t|s_{<t}, g, x, z^p) \\ \geq E_{q_{\phi'}(z^s_t|s_{\leq t}, g, x, z^p)}[\log P(s_t|s_{<t}, z^s_t, g, x, z^p)] \\ - D_{KL}(q_{\phi'}(z^s_t|s_{\leq t}, g, x, z^p)||p_\phi(z^s_t|s_{<t}, g, x, z^p)) \end{aligned} \quad (17)$$

We can obtain the ELBO by unfolding the right hand side of Eq. 15 with Eq. 16 and 17. During

training, we use linear KL annealing technique to alleviate the KL collapse problem(Bowman et al., 2016).

$\mathcal{L}_2$ is given by:

$$\mathcal{L}_2 = \sum_{t=1}^{T-1} \log P_t^{stop} + \log(1 - P_T^{stop}) \quad (18)$$

$\mathcal{L}_3$ is the sum of bag-of-word loss (Zhao et al., 2017) applied to each sentence, which is another technique to tackle the KL collapse problem.

5 Experiments

5.1 Dataset

We evaluated PHVM on two generation tasks. The first task is the new advertising text generation task which is to generate a long advertising text that covers all given attribute-value pairs for a piece of clothing. The second task is the recipe generation task from (Kiddon et al., 2016) which is to generate a correct recipe for the given recipe title and ingredient list.

Advertising Text Generation We constructed our dataset from a Chinese e-commerce platform. The dataset consists of 119K pairs of advertising text and clothing specification table. Each table is a set of attribute-value pairs describing a piece of clothing. We made some modifications to the original specification tables. Specifically, if some attribute-value pairs from a table do not occur in the corresponding text, the pairs are removed from the table. We also recognized attribute values by string matching with a dictionary of attribute values. If a pair occurs in the text but not in the table, the pair is added to the table.

The statistics are shown in Table 1 and Table 2.

Category	Tops	Dress / Skirt	Pants
# Type	22	23	9
# Attr.	13	16	11
# Val.	264	284	203
Avg. # Input Pairs	7.7	7.7	6.6
Avg. Len.	110	111	108
# Instances	48K	47K	24K

Table 1: Detailed statistics of our dataset. *# Attr.* / *# Val.*: the total number of attributes / attribute values.

Our dataset consists of three categories of clothing: tops, dress / skirt, and pants, which are further divided into 22, 23, and 9 types respectively (E.g., shirt, sweater are two types of tops). Other categories (e.g., hats and socks) are discarded because these categories have insufficient data for training. The average length of advertising text is about 110 words. To evaluate the expression diversity of our dataset, we computed distinct-4 (see Section 5.3) on 3,000 randomly sampled texts from our dataset. The distinct-4 score is 85.35%, much higher than those of WIKIBIO (Lebret et al., 2016) and ROTOWIRE (Wiseman et al., 2017) (two popular data-to-text datasets). Therefore, our dataset is suitable for evaluating long and diverse text generation[3].

# Attr.	# Val.	Vocab	Avg. # Input Pairs	Avg. # Len.
28	633	54.9K	7.5	110.2

Table 2: General statistics of our dataset. We counted the size of vocabulary after removing brand names.

We left 1,070 / 3,127 instances for validation / test, and used the remainder for training.

Recipe Text Generation We used the same train-validation-test split (82,590 / 1,000 / 1,000) and pre-processing from (Kiddon et al., 2016). In the training set, the average recipe length is 102 tokens, and the vocabulary size of recipe title / text is 3,793 / 14,103 respectively. The recipe dataset covers a wide variety of recipe types indicated by the vocabulary size of recipe title.

5.2 Baselines

We compared our model with four strong baselines where the former two do not perform planning and the latter two do:

Checklist: This model utilizes an attention-based checklist mechanism to record what input data has been mentioned, and focuses more on what has not during generation (Kiddon et al., 2016).

CVAE: The CVAE model proposed by Zhao et al. (2017) uses a latent variable to capture the diversity of responses in dialogue generation. We adapted it to our task by replacing the hierarchical encoder with a one-layer bidirectional GRU.

Pointer-S2S: A two-stage method (Puduppully et al., 2019) that decides the order of input data with Pointer Network (Vinyals et al., 2015) before generation with Sequence-to-Sequence (Seq2Seq) (Bahdanau et al., 2015).

Link-S2S Link-S2S (Sha et al., 2018) is a Seq2Seq with link-based attention mechanism

[3]We presented a detailed comparison with other benchmark corpora in Appendix A.2.

Models	BLEU (%)	Coverage (%)	Length	Distinct-4 (%)	Repetition-4 (%)
Checklist	**4.17**	84.52**	83.61**	21.95**	46.40**
CVAE	4.02	77.65**	80.96**	41.69**	36.58**
Pointer-S2S	3.88**	85.97**	74.88**	18.16**	36.78**
Link-S2S	3.90**	70.49**	**95.65**	16.64**	59.83**
PHVM (ours)	2.85**	**87.05**	89.20**	**72.87**	**3.90**
w/o z^p	3.07**	84.74**	91.97**	70.51**	4.19
w/o z_t^s	3.38**	84.89**	75.28**	42.32**	20.88**

Table 3: Automatic evaluation for advertising text generation. We applied bootstrap resampling (Koehn, 2004) for significance test. Scores that are significantly worse than the best results (in bold) are marked with ** for p-value < 0.01.

where a link matrix parameterizes the probability of describing one type of input item after another.

5.3 Implementation Details

For both advertising text generation and recipe text generation, the settings of our model have many in common. The dimension of word embedding is 300. All embeddings were randomly initialized. We utilized GRU for all RNNs. All RNNs, except the input encoder, the plan decoder, and the plan encoder, have a hidden size of 300. The global planning latent variable and local latent variables have 200 dimensions. We set batch size to 32 and trained our model using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001 and gradient clipping threshold at 5. We selected the best model in terms of $\mathcal{L}_1 + \mathcal{L}_2$ on the validation set.

As we need to train the plan decoder with full supervision, we extracted plans from the texts by recognizing attribute values (or ingredients) in each sentence with string match heuristics. Some sentences do not mention any input items; we associated these sentences with a special tag, which is treated as a special input item for Pointer-S2S, Link-S2S, and our model. Although our extraction method can introduce errors, the extracted plans are sufficient to train a good plan decoder[4].

Advertising Text Generation We embedded an attribute-value pair by concatenating the embedding of attribute and the embedding of attribute value. Embedding dimensions for attribute and attribute value are 30 and 100 respectively. The input encoder, the plan decoder, and the plan encoder all have a hidden size of 100.

Recipe Text Generation We embedded a multi-word title (ingredient) by taking average pooling of the embeddings of its constituent words. Embedding dimensions for title word and ingredient word are 100 and 200 respectively. The input encoder, the plan decoder, and the plan encoder all have a hidden size of 200.

[4]Our corpus and code are available at /https://github.com/ZhihongShao/Planning-based-Hierarchical-Variational-Model.

5.4 Automatic Evaluation Metrics

We adopted the following automatic metrics. (1) **Corpus BLEU**: BLEU-4 (Papineni et al., 2002). (2) **Coverage**: This metric measures the average proportion of input items that are covered by a generated text. We recognized attribute values (ingredients) with string match heuristics. For the advertising text generation task, synonyms were also considered. (3) **Length**: The average length of the generated texts. (4) **Distinct-4**: Distinct-n (Li et al., 2016) is a common metric for diversity which measures the ratio of distinct n-grams in generated tokens. We adopted distinct-4. (5) **Repetition-4**: This metric measures redundancy with the percentage of generated texts that repeat at least one 4-gram.

5.5 Advertising Text Generation

5.5.1 Automatic Evaluation

Table 3 shows the experimental results. As our dataset possesses high expression diversity, there are many potential expressions for the same content, which leads to the low BLEU scores of all models. Our model outperforms the baselines in terms of coverage, indicating that it learns to arrange more input items in a long text. With content ordering, Pointer-S2S outperforms both Checklist and CVAE in coverage. By contrast, our planning mechanism is even more effective in controlling generation: each sentence generation subtask is specific and focused, and manages to cover 95.16% of the corresponding group on average. Noticeably, Link-S2S also models planning but

Models	Grammaticality			κ	Coherence			κ
	Win (%)	Lose (%)	Tie (%)		Win (%)	Lose (%)	Tie (%)	
PHVM vs. Checklist	59.0**	23.5	17.5	0.484	54.5*	42.5	3.0	0.425
PHVM vs. CVAE	69.5**	13.5	17.0	0.534	60.0**	37.0	3.0	0.426
PHVM vs. Pointer-S2S	76.5**	17.0	6.5	0.544	56.5**	39.0	4.5	0.414
PHVM vs. Link-S2S	66.0**	28.5	5.5	0.462	62.5**	31.5	6.0	0.415

Table 4: Manual pair-wise evaluation for advertising text generation. We conducted Sign Test for significance test. Scores marked with * mean p-value < 0.05 and ** for p-value < 0.01. κ denotes Fleiss' kappa, all indicating *moderate agreement*.

has the lowest coverage, possibly because a static link matrix is unable to model flexible content arrangement in long text generation. As for diversity, our model has substantially lower repetition-4 and higher distinct-4, indicating that our generated texts are much less redundant and more diversified. Notably, Link-S2S has the longest texts but with the highest repetition-4, which produces many redundant expressions.

To investigate the influence of each component in the hierarchical latent structure, we conducted ablation tests which removed either global latent variable z^p or local latent variables z_t^s. As observed, removing z^p leads to significantly lower distinct-4, indicating that z^p contributes to expression diversity. The lower coverage is because the percentage of input items covered by a planning result decreases from 98.4% to 94.4% on average, which indicates that z^p encodes useful information for planning completeness. When removing z_t^s, distinct-4 drops substantially, as the model tends to generate shorter and more common sentences. This indicates that z_t^s contributes more to capturing variations of texts. The significantly higher repetition-4 is because removing z_t^s weakens the dependencies among sentences so that the word decoder is less aware of the preceding generated context. The lower coverage is because each generated sentence covers less planned items (from 95.16% to 93.07% on average), indicating that z_t^s keeps sentence s_t more focused on its group.

5.5.2 Manual Evaluation

To better evaluate the quality of the generated texts, we conducted pair-wise comparisons manually. Each model generates texts for 200 randomly sampled inputs from the test set. We hired five annotators to give preference (win, lose or tie) to each pair of texts (ours vs. a baseline, 800 pairs in total).

Metrics Two metrics were independently evaluated during annotation: **grammaticality** which measures whether a text is fluent and grammatical, and **coherence** which measures whether a text is closely relevant to input, logically coherent, and well-organized.

Results The annotation results in Table 4 show that our model significantly outperforms baselines in both metrics. Our model produces more logically coherent and well-organized texts, which indicates the effectiveness of the planning mechanism. It is also worth noting that our model performs better in terms of grammaticality. The reason is that long text generation is decomposed into sentence generation sub-tasks which are easier to control, and our model captures inter-sentence dependencies through modeling the dependencies among local latent variables.

5.5.3 Diversity of Planning

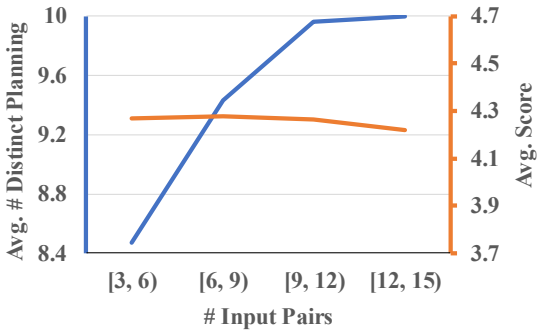

Figure 3: Average number of distinct planning results (left) / average score of generation quality (right) when the number of input pairs varies.

To evaluate how well our model can capture the diversity of planning, we conducted another manual evaluation. We randomly sampled 100 test inputs and generated 10 texts for each input by repeatedly sampling latent variables. Five annotators were hired to score (a Likert scale $\in [1, 5]$)

Models	BLEU (%)	Coverage (%)	Length	Distinct-4 (%)	Repetition-4 (%)
Checklist §	3.0	67.9	N/A	N/A	N/A
Checklist	2.6**	66.9*	67.59	30.67**	39.1**
CVAE	4.6	63.0**	57.49**	52.53**	38.7**
Pointer-S2S	4.3	70.4**	59.18**	30.72**	36.4**
Link-S2S	1.9**	53.8**	40.34**	24.93**	31.6**
PHVM (ours)	**4.6**	**73.2**	**70.92**	**67.86**	**17.3**

Table 5: Automatic evaluation for recipe text generation. Checklist was trained with its own source code. We also re-printed results from (Kiddon et al., 2016) (i.e., Checklist §). We applied bootstrap resampling (Koehn, 2004) for significance test. Scores that are significantly worse than the best results (in bold) are marked with * for p-value $<$ 0.05 or ** for p-value $<$ 0.01.

a text about whether it is a qualified advertising text, which requires comprehensive assessment in terms of fluency, redundancy, content organization, and coherence. We computed the average of five ratings as the final score of a generated text.

Results The average score of a generated text is 4.27. Among the 1,000 generated texts, 79.0% of texts have scores above 4. These results demonstrate that our model is able to generate multiple high-quality advertising texts for the same input.

We further analyzed how our model performs with different numbers of input attribute-value pairs (see Figure 3). A larger number of input items indicates more potential reasonable ways of content arrangement. As the number of input items increases, our model produces more distinct planning results while still obtaining high scores (above 4.2). It indicates that our model captures the diversity of reasonable planning. The average score drops slightly when the number of input pairs is more than 12. This is due to insufficient training data for this range of input length (accounting for 6.5% of the entire training set).

To further verify the planning diversity, we also computed self-BLEU (Zhu et al., 2018) to evaluate how different planning results (or texts) for the same input overlap (by taking one planning result (or text) as hypothesis and the rest 9 for the same input as reference and then computing BLEU-4). The average self-BLEU of the planning results is 43.37% and that of the texts is 16.87%, which demonstrates the much difference among the 10 results for the same input.

Annotation Statistics The Fleiss' kappa is 0.483, indicating *moderate agreement*.

5.6 Recipe Text Generation

Table 5 shows the experimental results. Our model outperforms baselines in terms of coverage and diversity; it manages to use more given ingredients and generates more diversified cooking steps. We also found that Checklist / Link-S2S produces the general phrase "all ingredients" in 14.9% / 24.5% of the generated recipes, while CVAE / Pointer-S2S / PHVM produce the phrase in 7.8% / 6.3% / 5.0% of recipes respectively. These results demonstrate that our model may generalize well to other data-to-text generation tasks.

6 Case Study

We present examples for both tasks in Appendix B.

7 Conclusion and Future Work

We present the Planning-based Hierarchical Variational Model (PHVM) for long and diverse text generation. A novel planning mechanism is proposed to better model input data and address the inter-sentence incoherence problem. PHVM also leverages a hierarchical latent structure to capture the diversity of reasonable planning and sentence realization. Experiments on two data-to-text corpora show that our model is more competitive to generate long and diverse texts than state-of-the-art baselines.

Our planning-based model may be inspiring to other long text generation tasks such as long text machine translation and story generation.

{akhilesh, bhargav, arjun}@agaralabs.com

Abstract

Text style transfer is the task of transferring the style of text having certain stylistic attributes, while preserving non-stylistic or content information. In this work we introduce the Generative Style Transformer (GST) - a new approach to rewriting sentences to a target style in the absence of parallel style corpora. GST leverages the power of both, large unsupervised pre-trained language models as well as the Transformer. GST is a part of a larger 'Delete Retrieve Generate' framework, in which we also propose a novel method of deleting style attributes from the source sentence by exploiting the inner workings of the Transformer. Our models outperform state-of-art systems across 5 datasets on sentiment, gender and political slant transfer. We also propose the use of the GLEU metric as an automatic metric of evaluation of style transfer, which we found to compare better with human ratings than the predominantly used BLEU score.

1 Introduction

Text style transfer is an important Natural Language Generation (NLG) task, and has wide-ranging applications from adapting conversational style in dialogue agents (Zhou et al., 2017), obfuscating personal attributes (such as gender) to prevent privacy intrusion (Reddy and Knight, 2016), altering texts to be more formal or informal (Rao and Tetreault, 2018), to generating poetry (Yang et al., 2018). The main challenge faced in building style transfer systems is the lack of parallel corpora between sentences of a particular style and sentences of another, such that sentences in a pair differ only in style and not content (non-stylistic part of the sentence). This has given rise to methods that circumvent the need for such parallel corpora.

Previous approaches using non-parallel corpora, that employ learned latent representations to disentangle style and content from sentences, are typically adversarially trained (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018). However these models a) are hard to train and take long to converge, b) need to be re-trained from scratch to change the trade-off between content retention and style transfer c) suffer from sparsity of latent disentangled representations, d) produce sentences of bad quality (according to human ratings) and e) do not offer fine-grained control over target style attributes.

Li et al. (2018) find that style attributes are more often than not, localized to a small subset of words of a sentence. Building on this inductive bias, they model style transfer in a "Delete Retrieve Generate" framework (hereby referred to as DRG) which aims to 1) delete only the set of attribute words from a sentence to give the content, 2) retrieve attribute words from the target style corpus, and 3) use a neural editor (an encoder-decoder LSTM) to generate the final sentence from the content and retrieved attributes.

While DRG as a framework leads to output sentences that are better in quality than previous approaches, their individual Delete and Generate methods are susceptible to: a) removing core content words which would preserve crucial context, b) failing to remove source style attributes that should be replaced with target style attributes, c) the LSTM-based encoder-decoder model not being robust to errors made by the Delete and Retrieve models, d) generating sentences that are not fluent, by abruptly forcing retrieved attributes into the source sentence and e) failing on longer input sentences.

In this work, we propose a novel approach to rewrite sentences into a target style, that leverages the power of both a) transfer learning by using an unsupervised language model trained on a large corpus of unlabeled text, as well as b) the Trans-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3269–3279,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

former (Vaswani et al., 2017). We refer to our Transformer as the Generative Style Transformer **(GST)**. We use the DRG framework proposed by Li et al. (2018) but we overcome the shortcomings of their a) Delete mechanism, by using the attention weights of another Transformer that we refer to as the Delete Transformer **(DT)**, and b) Generate mechanism by using **GST**, which does away with the need for (and consequent shortfalls of) a sequence-to-sequence encoder-decoder architecture using LSTMs.

We outperform the current state-of-art systems on transfer of a) sentiment[1], b) gender and c) political slant. Our approach is advantageous in that it is simple, controllable and exploits the important inductive bias described, while at the same time it leverages the power of Transformers in novel ways.

All code, data and results for this work can be found in our Github repository [2].

2 Our Approach

Given a dataset $D = \{(x_1, s_1), ..., (x_m, s_m)\}$ where x_i is a sentence and $s_i \in S$ is a specific style, our goal is to learn a conditional distribution $P(y|x, s^{tgt})$ such that $Style(y) = s^{tgt}$, where style is determined by an oracle that can accurately determine the style of a given sentence. For instance, for the sentiment transfer task, $S = \{$'Positive', 'Negative'$\}$. Using the DRG framework, we model our task in 3 steps:
(1) A **Delete** model which learns $P(c, a|x)$ such that c and a are non-stylistic and stylistic components of x respectively, $Style(c) \notin S$ (i.e., c does not have any particular style) and x can be completely reconstructed from c and a, **(2)** A **Retrieve** model which retrieves a set of (optional) target attributes a^{tgt} from $D_{s^{tgt}}$, the corpus of sentences of target style, and **(3)** A **Generate** model in two flavors: a) one which learns to generate a sentence in the target distribution $P(y|c, s^{tgt})$ and b) another which learns to generate a sentence in the target distribution $P(y|c, a^{tgt})$, both such that $Style(y) = s^{tgt}$. We now elaborate on each of these components individually.

[1]We use style in a broad socio-linguistic sense that encompasses sentiment too, for the purpose of this work

[2]https://github.com/agaralabs/transformer-drg-style-transfer

2.1 Delete

For an input sentence "The restaurant was *big* and *spacious*", in the case of a style transfer task from positive to negative sentiment, the Delete model should be capable of deleting the style attributes *big* and *spacious*.

Our approach to attribute deletion is based on 'input reduction' (Feng et al., 2018), based on the observation that certain words and phrases significantly contribute to the style of a sentence. For a sentence x of style s_j having a set of attributes a, a style classifier will be confused about its style if the attributes in a are removed from x. We describe a mechanism to assign an *importance* score to each token in x, which is reflective of its contribution to style. These scores allows us to distinguish style attributes from content.

2.1.1 Delete Transformer

To build intuition, any attention-based style classifier defines a probability distribution over style labels:

$$p(s|x) = g(v, \alpha) \tag{1}$$

where v is a tensor such that $v[i]$ is an encoding of $x[i]$, and α is a tensor of attention weights such that $\alpha[i]$ is the weight attributed to $v[i]$ by the classifier in deciding probabilities for each s_j. The α scores can be treated as *importance* scores and be used to identify attribute words, (which typically tend to have higher scores). Motivated by the recent successes of the Transformer (Vaswani et al., 2017) and more specifically, BERT (Devlin et al., 2018), on a number of text classification tasks (including achieving state-of-art results on sentiment classification), we use a BERT-based transformer as our style classifier and refer to it as Delete Transformer **(DT)**. However, since **DT** has multiple attention heads and multiple blocks (layers), extracting a single set of attention weights α is a non-trivial task. This is further complicated by the fact that every layer and head encodes different aspects of semantic and linguistic structure (Vig, 2019). We then use a novel method to extract a specific attention head and layer combination that encodes style information and that can be directly used as *importance* scores.

Attribute extraction: We use the same input representation as Figure 3(b) in Devlin et al. (2018) wherein a '[CLS]' token is added before the sentence tokens. Since the softmax classifica-

tion layer is used over the attention stack of the '[CLS]' token in BERT classifiers, the attention weights of other input tokens that correspond to '[CLS]' are of special interest in identifying significant sentence tokens. First, we iterate over each pair $< h, l >$ (head-layer pair) and extract the attention scores for every token w of x as follows:

$$\alpha_{h,l}(w) = softmax_{w \in x}(Q_{h,l,[CLS]} K^T_{h,l,w}) \quad (2)$$

where 'Q' and 'K' carry the same original connotations of query and key vectors as used by Vaswani et al. (2017), in the Transformer as:

$$Att(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (3)$$

We then remove the top $\gamma|x|$ tokens from x, based on *importance* scores calculated as in Eq. 2. Keeping in line with Feng et al. (2018), we call this removal a 'reduction', and denote the resulting reduced sentence as $x'_{h,l}$. γ is a parameter we tune to each dataset which allows us to control the proportion of words in a sentence to be deleted, and $|x|$ denotes the number of tokens in x. We calculate a score $z(x'_{h,l})$:

$$z(x'_{h,l}) = \frac{p(s|x'_{h,l}) + \lambda}{\sum_{s'} p(s'|x'_{h,l}) + \lambda} \quad (4)$$

where λ is a smoothing parameter, s is the style label assigned maximum probability by the softmax distribution over all styles in the label set S, and $s' = S - \{s\}$. The final pair $< h_s, l_s >$ out of combinations of all heads H and layers L, is obtained by averaging the score in Eq. 4 over a validation set of 'reduced' sentences D'_{val} as follows:

$$(h_s, l_s) = \underset{h \in H, l \in L}{\text{argmin}} \frac{\sum_{x'_{h,l} \in D'_{val}} z(x'_{h,l})}{|D'_{val}|} \quad (5)$$

A 'reduction' of any input sentence x based on $< h_s, l_s >$ gives us x'_{h_s,l_s} which we refer to as the content c. The removed tokens are the attributes a.

Evaluation of Extracted Attributes: We evaluate our Delete method using human evaluation on Amazon Mechanical Turk[3], on which annotators were asked to choose if all the style-related attributes are extracted correctly by our Delete mechanism, and if any non-style attributes are wrongly deleted. We used 200 random sentences from our test set for sentiment transfer, for this evaluation. Our method deleted all style attributes on 89% of examples, and wrongly deleted non-style attributes only 12% of the time. In comparison, the Delete mechanism proposed by Li et al. (2018) deleted all style attributes only 67% of the time, and wrongly deleted non-style attributes over 29% of the time.

[3]https://www.mturk.com/

2.2 Retrieve

We retrieve a sentence from the target style corpus of sentences according to:

$$x^{tgt} = argmin_{x' \in D_{stgt}} d(c_x, c_{x'}) \quad (6)$$

where d is a distance metric, such that contents which are closer according to d will have compatible attributes as they occur in similar contexts. We experiment with multiple retrieval mechanisms, using cosine similarity over different sentence representations: a) TF-IDF weighted, b) Averaged-GloVe over all tokens of a sentence and c) Universal Sentence Encoder (Cer et al., 2018). We obtain best retrieval results using TF-IDF vector similarity.

2.3 Generate

Our approach to generate sentences of the target style leverages both the power of transfer learning by using an unsupervised language model trained on a large corpus of unlabeled text, as well as the Transformer model. The model we use is a multi-layer 'decoder-only' Transformer which is based on the Generative Pre-trained Transformer (GPT) of Radford et al.. This is our Generative Style Transformer **(GST)**. **GST** has masked attention heads that enable it to look only at the tokens to its left, and not to those to its right. **GST** derives inspiration from the fact that recently, many large generatively pre-trained Transformer models have shown state-of-art performance upon being finetuned on a number of downstream tasks. It is trained to learn a representation of content words and (retrieved) attribute words presented to it, and generate fluent sentences in the domain of the target style while attending to both content and attribute words appropriately.

2.3.1 Variants of GST (B-GST and G-GST)

Taking cues from Li et al. (2018), we train GST in two flavors: the Blind Generative Style

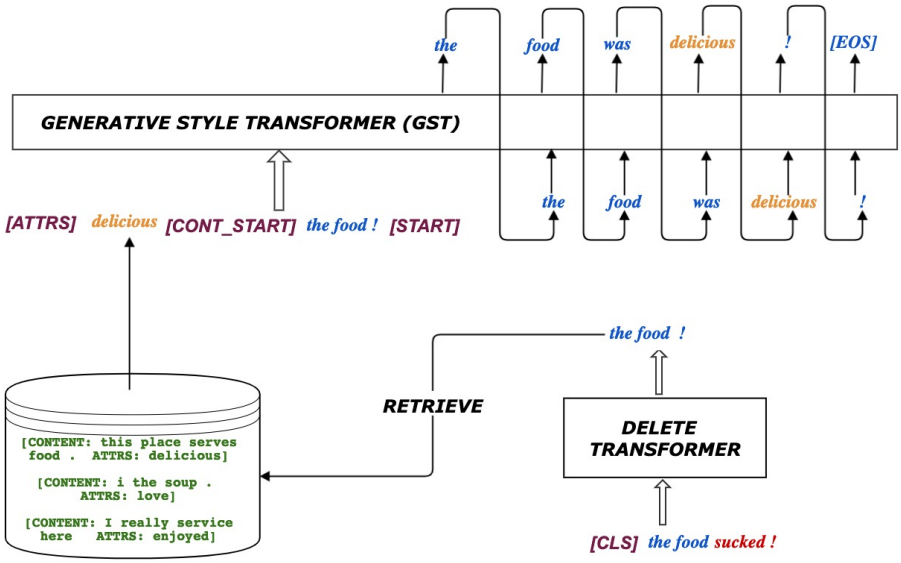

Figure 1: Our architecture, with an example from the Yelp dataset for the task of sentiment transfer

Transformer **(B-GST)** and the Guided Generative Style Transformer **(G-GST)**. For a sentence x of a source style s^{src} with content c and retrieved (target style) attributes a^{tgt}, the two variations are learnt as follows.

B-GST: The inputs to this model are only c, and s^{tgt}. The output y of the model is the generated sentence in the target style. In this setting, the model is free to generate the output sentence, given the content and the target style, and is **blind** to specific desired target attributes. **B-GST** can be useful in cases when the target corpus does not have sentences that are similar to the source corpus, which causes the Retrieve model to retrieve incompatible target attributes.

G-GST: The inputs to this model are c, and a^{tgt}, and the output y of the model is the generated sentence in the target style. In this setting, the model is **guided** towards generating a target sentence with desired attributes. **G-GST** is useful for two reasons. Firstly, in cases when the target corpus has similar sentences to the source corpus, it reduces sparsity by giving the model information of target attributes. Secondly, and more importantly, it allows fine-grained control of output generation by manually specifying target attributes that we desire during inference time, without even using the Retrieve component. This controllability is an important feature of G-GST that most other latent-representation based style transfer approaches do not offer.

2.3.2 Input Representation and Output Decoding

Taking inspiration from Devlin et al. (2018), we add special tokens to indicate target style, and to indicate the demarcation between content and attributes. For **B-GST** the input at timestep t of target sentence prediction consists of special tokens to denote: a) target style s^{tgt}, b) the start of content c, d) the start of output, followed by all target tokens up till and including timestep $t-1$. **G-GST** has a similar input representation, except that a special token to indicate start of retrieved attributes is added, and the retrieved attributes are provided before the content. The target style s^{tgt} is not provided. Our end-to-end architecture for **G-GST** is depicted in Figure 1, including input representation. **B-GST** is similar in nature, except that it does not use a retrieve component. At timestep t, both **GST**s predict the t^{th} output token, by generating a probability distribution over words in the vocabulary according to: a) $p(y_t|c, y_1, y_2, ..y_{t-1})$ for **B-GST**, and b) $p(y_t|c, a^{tgt}, y_1, y_2, ..y_{t-1})$ for **G-GST**. This is done by using a softmax layer over the topmost Transformer block corresponding to y_{t-1}. During training time, we use the 'teacher forcing' or 'guided approach' (Bengio et al., 2015; Williams and Zipser, 1989) over decoded tokens. During test time, we beam search using softmax probabilities with a look-left window of 1 and a beam width of 5. The output beam (out of the top 5 final beams) that obtains the highest target-style match

score using the Delete Transformer described earlier, is chosen as the output sentence.

2.3.3 Training

Since we do not have a parallel corpus, both GSTs are trained to minimize the reconstruction loss. Specifically, for a sentence x, the model learns to reconstruct $y = x$ given c_x, its own attributes a_x (only for **G-GST**) and its own style s^{src} (only for **B-GST**). More formally **B-GST** learns to maximize the following objective:

$$L(\theta) = \sum_{(x,s^{src})\in D} \log p(x|c_x, s^{src}; \theta) \quad (7)$$

However, training **G-GST** using the reconstruction loss in this manner results in the model learning to trivially combine c_x and a_x to generate x back. In reality we want it to be capable of *adapting* target attributes into the context of the source content, in a non-trivial manner to produce a fluent sentence in the target style. To this end, we noise the inputs of the **G-GST** model during training time, by choosing random attributes for 10% of the examples (5% from the source style and 5% from the target style), to replace a_x. Denoting the chosen attribute for an example (either noisy or its own) to be a'_x, **G-GST** learns to maximize the following objective:

$$L(\theta) = \sum_{(x,s^{src})\in D} \log p(x|c_x, a'_x; \theta) \quad (8)$$

2.3.4 Model Details and Pre-training

We use the PyTorch implementation of the pre-trained Transformer by HuggingFace[4], which uses the pre-trained OpenAI GPT model[5]. This model is pre-trained by Radford et al. on the BookCorpus dataset[6] of over 7000 books (around 800M words). **GST** has a sequence length of 512, 12 blocks (or layers), and 12 attention-heads in each block. All internal states (keys, queries, values, word embeddings, positional embeddings) are 768-dimensional. Input text is tokenized using Byte-Pair Encoding (BPE).

3 Experiments

3.1 Datasets

We use 5 different datasets for our experiments. These datasets have been used in previous works on style transfer.

Dataset	Style	Train	Dev	Test
YELP	Positive	270K	2000	500
	Negative	180K	2000	500
CAPTIONS	Romantic	6000	300	0
	Humorous	6000	300	0
	Factual	0	0	300
AMAZON	Positive	277K	985	500
	Negative	279K	1015	500
POLITICAL	Democrat	270K	2000	28K
	Republican	270K	2000	28K
GENDER	Male	1.34M	2250	267K
	Female	1.34M	2250	267K

Table 1: Dataset statistics

We use the YELP, AMAZON and CAPTIONS datasets as used by Li et al. (2018), and we retain the same train-dev-test split that they use. Further, they also provide human gold standard references for the test sets of all 3 of the above. We use the POLITICAL (Voigt et al., 2018) and GENDER (Reddy and Knight, 2016) datasets as used by Prabhumoye et al. (2018). We have retained the same train-dev-test split that they use. Table 1 shows statistics of these datasets. Following are brief descriptions of the datasets:

YELP: Reviews of businesses on Yelp, with each review labelled as having either positive or negative sentiment.

AMAZON: Product reviews on Amazon, with each review labelled as having either positive or negative sentiment.

CAPTIONS: Image captions, with each caption labeled as either factual, romantic, or humorous. The task is to convert factual sentences into romantic and humorous ones.

POLITICAL: Top-level comments on Facebook posts from members of the United States Senate and House who have public Facebook pages, with each comment labelled as having been posted by either a Republican or a Democrat politician.

GENDER: Reviews of food businesses on Yelp, with each review labelled as either of the two genders (male or female) corresponding to markers of sex.

3.2 Comparison to Previous Works

On the Yelp, Amazon, and Captions dataset, we compare with 3 previous adversarially trained models: StyleEmbedding **(SE)** (Fu et al., 2018), MultiDecoder **(MD)** (Fu et al., 2018),

CrossAligned **(CA)** (Shen et al., 2017)) and the 2 best models - DeleteOnly **(D)** and DeleteAndRetrieve **(D&R)** of Li et al. (2018) trained using the DRG framework. A brief description of the first 3, and a detailed description of the last 2 models can be found in Li et al. (2018), so we omit elaborating on them here. At the time of writing this paper, these models are the top performing models on Yelp, Amazon and Captions, with the **D&R** model of Li et al. (2018) showing state-of-art performance. Output sentences of each of these 5 models on fixed test sets, also annotated with human reference gold standards **(H)** on all 3 datasets are provided by Li et al. (2018). We use the same for our comparison and evaluation. On the Political and Gender datasets, we compare our models against that of Prabhumoye et al. (2018), which is the state-of-art on these 2 datasets at the time of writing this paper. Their trained models for both these datasets are made publicly available. They use back-translation **(BT)** using an LSTM as a mechanism to learn latent representations of source sentences, and then employ adversarial generation techniques to make the output match a desired style (Prabhumoye et al., 2018).

4 Evaluation of Results

The widely agreed upon goals for a style transfer system are 1) Content preservation of the non-stylistic parts of the source sentence, 2) Style transfer strength of the stylistic attributes to the target style and 3) Fluency and correct grammar of the generated target sentence (Mir et al., 2019). To this end, we use both human and automatic evaluation to measure model performance.

4.1 Human Evaluation

YELP, AMAZON and CAPTIONS: Li et al. (2018) report state-of-art results which we corroborate through manual and automatic metrics. We then proceed to obtain human evaluations on these models along with ours through Amazon Mechanical Turk[7]. Specifically, we ask annotators to rate each pair of generated sentences given the source sentence, on content preservation, style transfer strength, fluency, and overall success. For each parameter, they are asked to choose which of the generated sentences is better, or neither of the two if they are unable to decide. Table 2 presents results on our best scoring model **B-GST** with the previous best scoring model **D&R** as a percentage of times one was preferred over the other.

POLITICAL and GENDER: On these 2 datasets, (Prabhumoye et al., 2018) report state-of-art results using their model **BT**, which we similarly corroborate. A comparison of our best model **B-GST**, with their results using **BT** is presented in Table 3 as a percentage of times one was preferred over the other. Since judging target style strength on these two tasks are hard for MTurkers, they only rate these datasets for content and fluency.

4.2 Automatic Evaluation

As has been done by previous works, we attempt to use automatic methods of evaluation to assess the performance of different models. To estimate target style strength, we use style classifiers that we train on the same training-dev-test split of Table 1, using FastText[8] (Joulin et al., 2017). These classifiers achieve 98%, 86%, 80%, 92% and 82% accuracies on the test sets of Yelp, Amazon, Captions, Political and Gender respectively. To measure content preservation, we calculate the BLEU score (Papineni et al., 2001) between the gener-

Table 5: Automatic evaluation results (BL_s = BLEU; PL = Perplexity; AC = Target Style Accuracy; SRC = Input Sentence; B-GST and G-GST are our models)

ated and source sentences. To measure fluency, we finetune a large pre-trained language model, OpenAI GPT-2 (note that this is different from GPT-1 on which our Generate model is based) on the target sentences using the same training-dev-test split of Table 1. We use this language model to measure perplexity of generated sentences. The language models achieve perplexities of 24, 33, 34, 63 and 81 on the test sets of Yelp, Amazon, Captions, Political and Gender respectively. As we analyze in the next section, automatic metrics are inadequate at measuring the success of a good style transfer system.

GLEU: As a step towards finding an automatic metric that compares with human judgements, we propose the use of the Generalized Language Evaluation Understanding Metric (GLEU) (Napoles et al., 2015) - originally proposed as a grammatical error correction (GEC) metric. In the interest of space, we omit writing the elaborate equations and explanation for GLEU in this paper, but instead point the reader to Section 4 of Napoles et al. (2015) for the same. The formulation of GEC is quite similar to our formulation of style transfer in that style transfer involves making localized edits to the input sentence. Unlike BLEU, which takes only the target reference and the generated output into consideration, GLEU considers both of these as well as the source sentence too. It is a suitable metric for style transfer because it a) penalizes words of the source that were wrongly changed in the generated sentence, b) rewards words that were successfully changed and c) rewards those that were successfully retained from the source sentence to match those in the reference sentence. We use the implementation of GLEU[9] provided by Napoles et al. (2015).

Tables 4 and 5 show a comparison of automatic metrics between our models and previous models described earlier.

4.3 Result Analysis

From human evaluations in Tables 2 and 3, we see that our models (specifically, **B-GST**) outperform state-of-art systems by a good margin on almost all parameters as judged by humans, across all datasets. More importantly, as Table 6 shows, our models generate realistic and natural-sounding sentences while retaining core content - an aspect on which previous models seem to be seriously lacking. While our **G-GST** model does worse than **B-GST** due to a weak Retrieve mechanism, **G-GST** provides us a way to guide the generation and control attributes, making it more suitable for real-world applications after improving Retrieve in future. We find that metrics based on learned models - perplexity and accuracy, do not correlate entirely well with human evaluations, an observation also shared by Li et al. (2018). They are also heavily dependant on the distribution of data that they are trained on. A system that simply chooses a random sentence from the target training corpus as its output will score highly on both these metrics. For instance, the **BT** model in Table 5 has a high style but a considerably lower BLEU

Example #1	**YELP (Positive to Negative)**	**YELP (Negative to Positive)**
SRC	i love this place , the service is always great !	the store is dumpy looking and management needs to change .
SE	i love this place , the service is always great !	the store is bought the building does n't deal .
D	i paid _num_ minutes before the gifted , not , a huge plus , n't .	the store is dumpy looking and management is fantastic and needs to change .
D&R	i did not like the homework of lasagna , not like it , .	the store is clean and well dumpy looking and management needs to change .
G-GST	**i used this place , the service is always awful !**	**the store is looking and management is excellent to .**
B-GST	**i hate this place , the service is always terrible !**	**the store is looking great and management to perfection .**
Example #2	**AMAZON (Positive to Negative)**	**AMAZON (Negative to Positive)**
SRC	i finally made he purchase and am glad i did .	i m just looking forward to the day i get to replace it .
SE	i finally made he purchase and am glad i did .	i m just looking forward to the right away i get it for it .
D	i finally made it and was excited to purchase and am glad i did .	i m just looking forward to the day i get to replace my old one .
D&R	i finally made i will try another purchase and am glad i did .	looking forward to using it on turkey day ! .
G-GST	**i finally made he purchase and am embarrassed i smell pungent .**	**i m looking to the same day i get to use it .**
B-GST	**i finally made him purchase and am sorry i did .**	**i m looking forward to using the day i get to use it .**
Example #3	**CAPTIONS (Factual to Romantic)**	**CAPTIONS (Factual to Humorous)**
SRC	people gather around a life size chess game .	three brown and black dogs are splashing in the water .
SE	people gather at a red wooden advertisement of players enjoy .	three small and brown dog are splashing in the water .
D	two young boys have working around a dream line and dream of childhood.	three black and brown dogs are sitting in the water to search of fish .
D&R	people gather around a carnival event , all determined to win the game .	two black and brown dogs are running in the water like a fish.
G-GST	**people gather around a life size chess game to celebrate life ' s happiness .**	**three brown and black dogs are splashing in the water talking to each other .**
B-GST	**two people gather around a life size chess game to celebrate life .**	**three brown and black dogs are splashing in the water looking for mermaids .**
Example #4	**POLITICAL (Democrat to Republican)**	**POLITICAL (Republican to Democrat)**
SRC	thank you for your commitment to a strong public education system , senator !	i absolutely agree with senator paul's actions .
BT	thanks for your vote for a balanced budget amendment , sir !	i ' m merchandising with the rhetoric of senator warren .
G-GST	**thank you for your commitment to a strong conservative system , governor !**	**i absolutely agree with brian ' s dire actions . .**
B-GST	**thank you for your commitment to a strong constitutional system , senator scott !**	**i absolutely agree with elizabeth warren ' s actions .**
Example #5	**GENDER (Male to Female)**	**GENDER (Female to Male)**
SRC	this is a spot that ' s making very solid food , with good quality product .	this a great place for a special date or to take someone from out of town .
B-GST	**this is a cute spot that ' s making me very happy , with good quality product .**	**this a great place for a bachelor or to meet someone from out of town .**

Table 6: Examples of generated sentences to be compared down a column (B-GST and G-GST are our models, SRC is the input sentence). Attributes are colored.

score than **B-GST**. It is important therefore, to not consider them in isolation. Further, human reference sentences themselves score poorly using both these metrics as shown in these tables. Manual inspection of classifier accuracies shows that these classifiers give unreliable outputs that do not match human ratings. This is the case with the **CA** model in Table 2. Similar problems exist with regarding BLEU in isolation. A system that simply copies the source sentence will obtain high BLEU scores.

GLEU, however seems to strike a balance between target style match and content retention, as it takes the source, reference as well as predicted sentence into account. We see that GLEU scores also correlate with our own human evaluations as well as those of Li et al. (2018). While a detailed statistical correlation study is left for future work, the fact remains that GLEU is not susceptible to the weaknesses of other automatic metrics described above. Our uniformly state-of-art GLEU scores possibly indicate that we make only necessary edits to the source sentence.

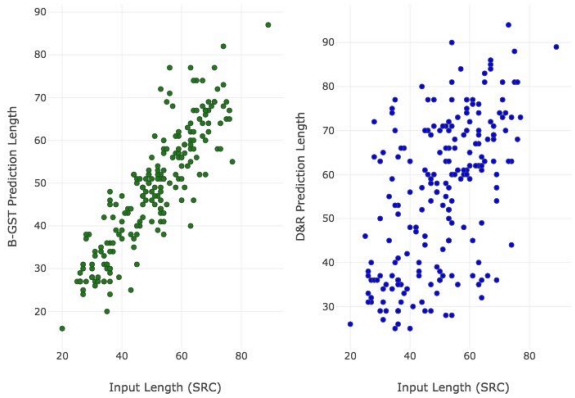

Figure 2: Correlation of B-GST (ours, left) with input sentence lengths vs D&R's (right) sentence lengths with input sentence lengths.

Keeping all the above considerations in mind, automatic metrics are still indicative and useful as they can be scaled to evaluate larger sets of models and datasets. From Tables 4 and 5, we see that we consistently outperform current state-of-art systems on BLEU. As shown by our high BLEU scores, one can conclude to some extent that our models retain non-stylistic parts well. Figure 2 shows that unlike the current state-of-art **D&R** model, the lengths of our generated sentences closely correlate with source sentence lengths. **B-GST** scores well on perplexity across datasets, a consistency that is not exhibited by any other model.

5 Related Work

One category of previous approaches is based on training adversarial networks to learn a latent representation of content and style. Shen et al. (2017) train a cross-aligned auto-encoder, with a shared content and separate style distribution. Hu et al. (2017) use VAEs with attribute discriminators to learn similar latent representations. This approach has been later encapsulated in encoder-decoder frameworks (Fu et al., 2018; John et al., 2018; Zhang et al., 2018a,b). Problems with these approaches have been discussed in the introduction.

Approaches that do not rely on a latent representation to separate content and attribute exist too. These include reinforcement learning based approaches (Xu et al., 2018; Gong et al., 2019), an unsupervised machine translation based approach (Subramanian et al., 2018) and the DRG approach (Li et al., 2018). The former two approaches suffer from sparsity and convergence issues and hence generate sentences of low-quality.

Previous approaches to use attention weights to extract attribute significance exist (Feng et al., 2018; Li et al., 2016; Globerson and Roweis, 2006), including the salience deletion method of Li et al. (2018) but they do not perform well on understanding sentence context while choosing attributes, and do not leverage the contextual capacity of a Transformer. Lastly, Dai et al. (2019) describe the use of Transformers for style transfer in an adversarial generator-discriminator setting, by adding an additional style embedding to the transformer. We are unable to do a comparitive study as they do not yet publish their code or outputs. The same is the case for Subramanian et al. (2018).

6 Conclusion

We propose the Generative Style Transformer that outperforms state-of-art systems on sentiment, gender and political slant. Our model leverages the DRG framework, massively pre-trained language models and the Transformer network itself.

Abstract

Abstractive summarization systems aim to produce more coherent and concise summaries than their extractive counterparts. Popular neural models have achieved impressive results for single-document summarization, yet their outputs are often incoherent and unfaithful to the input. In this paper, we introduce **SENECA**, a novel System for ENtity-drivEn Coherent Abstractive summarization framework that leverages entity information to generate informative and coherent abstracts. Our framework takes a two-step approach: (1) an *entity-aware content selection* module first identifies salient sentences from the input, then (2) an *abstract generation* module conducts cross-sentence information compression and abstraction to generate the final summary, which is trained with rewards to promote coherence, conciseness, and clarity. The two components are further connected using reinforcement learning. Automatic evaluation shows that our model significantly outperforms previous state-of-the-art on ROUGE and our proposed coherence measures on New York Times and CNN/Daily Mail datasets. Human judges further rate our system summaries as more informative and coherent than those by popular summarization models.

Input Article:
. . . **Prime Minister Bertie Ahern** of Ireland called Sunday for a general election on May 24.
[**Mr. Ahern**] and his centrist party have governed in a coalition government since 1197 . . .
Under Irish law, which requires legislative elections every five years, **Mr. Ahern** had to call elections by midsummer.
On Sunday, {**he**} said **he** would base **his** campaign for reelection on **his** work to strengthen the economy and efforts to revive **Northern Ireland's** stalled peace process this year.
Political analysts said they expected **Mr. Ahern 's** work in **Northern Ireland** to be an asset . . .

Human Summary:
① **Prime Min Bertie Ahern** of Ireland calls for general election on May 24.
② [**He**] is required by law to call elections by midsummer.
③ Opinion polls suggest **his** centrist government is in danger of losing its majority in Parliament because of public disgruntlement about overburdened public services.
④ {**Ahern**} says **he** would base **his** campaign for reelection on **his** work to strengthen economy and **his** efforts to revive **Northern Ireland's** stalled peace process.
⑤ Analysts expect **his** work in **Northern Ireland** to be asset.

Figure 1: Sample summary of an article from the New York Times corpus (Sandhaus, 2008). Mentions of the same entity are colored. Underlined sentence in the article occurs relatively at an earlier position in the summary (②) to improve topical coherence. Mentions in brackets ("[]","{}") show different ways in which the same entity is referred to in the article and the summary. Detailed explanation is given in §1.

1 Introduction

Automatic abstractive summarization carries strong promise for producing concise and coherent summaries to facilitate quick information consumption (Luhn, 1958). Recent progress in neural abstractive summarization has shown end-to-end trained models (Nallapati et al., 2016; Tan et al., 2017a; Celikyilmaz et al., 2018; Kryściński et al., 2018) excelling at producing fluent summaries. Though encouraging, their outputs are frequently found to be unfaithful to the input and lack inter-sentence coherence (Cao et al., 2018; See et al., 2017; Wiseman et al., 2017). These observations suggest that existing methods have difficulty in identifying salient entities and related events in the article (Fan et al., 2018), and that existing model training objectives fail to guide the generation of coherent summaries.

In this paper, we present **SENECA**, a System for ENtity-drivEn Coherent Abstractive summarization.[1] We argue that entity-based modeling

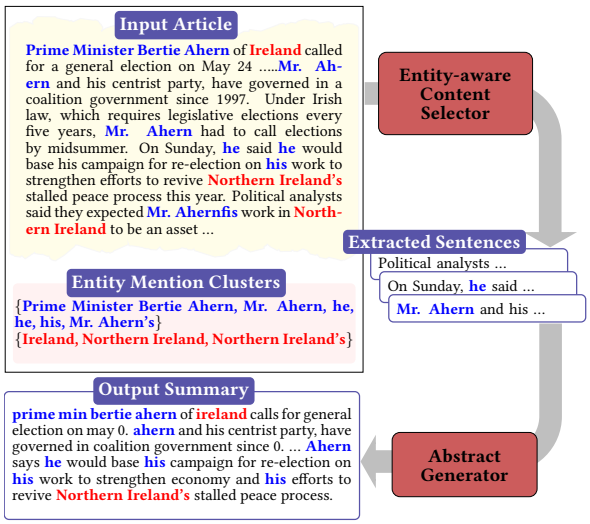

Figure 2: Our proposed entity-driven abstractive summarization framework. Entity-aware content selector extracts salient sentences and abstract generator produces informative and coherent summaries. Both components are connected using reinforcement learning.

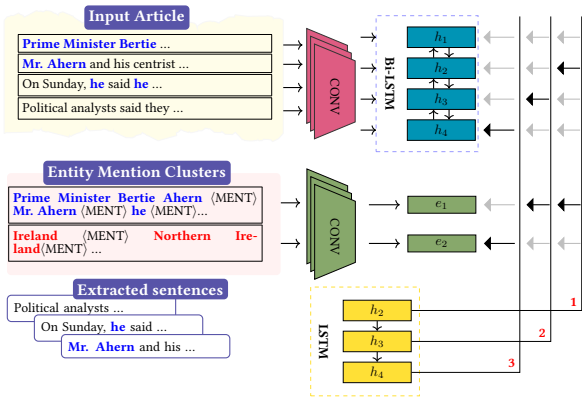

Figure 3: Our proposed entity-aware content selector. Arrows denote attention, with darker color representing higher weights.

enables enhanced *input text interpretation*, *salient content selection*, and *coherent summary generation*, three major challenges that need to be addressed by single-document summarization systems (Jones et al., 1999). We use a sample summary in Fig. 1 to show entity usage in summarization. Firstly, frequently mentioned entities from the input, along with their contextual information, underscores the salient content of the article (Nenkova, 2008). Secondly, as also discussed in prior work (Barzilay and Lapata, 2008; Siddharthan et al., 2011), patterns of entity distributions and how they are referred to contribute to the coherence and conciseness of the text. For instance, a human writer places the underlined sentence in the input article next to the first sentence in the summary to improve topical coherence as they are about the same topic ("elections"). Moreover, the human often optimizes on conciseness by referring to entities with pronouns (e.g., "he") or last names (e.g., "Ahern") without losing clarity.

We therefore propose a two-step neural abstractive summarization framework to emulate the way humans construct summaries with the goal of improving both informativeness and coherence of the generated abstracts. As shown in Fig. 2, an **entity-aware content selection** component first selects important sentences from the input that includes references to salient entities. An **abstract generation** component then produces coherent summaries by conducting cross-sentence information ordering, compression, and revision. Our abstract generator is trained using reinforcement learning with rewards that promote informativeness and optionally boost coherence, conciseness, and clarity of the summary. To the best of our knowledge, we are the first to study coherent abstractive summarization with the inclusion of linguistically-informed rewards.

We conduct both automatic and human evaluation on popular news summarization datasets. Experimental results show that our model yields significantly better ROUGE scores than previous state-of-the-art (Gehrmann et al., 2018; Celikyilmaz et al., 2018) as well as higher coherence scores on the New York Times and CNN/Daily Mail datasets. Human subjects also rate our system generated summaries as more informative and coherent than those of other popular summarization models.

2 Summarization Framework

In this section, we describe our entity-driven abstractive summarization framework which follows a two-step approach as shown in Fig. 2. It comprises of (1) an *entity-aware content selection component*, that leverages entity guidance to select salient sentences (§2.1), and (2) an *abstract generation component* (§2.2), that is trained with reinforcement learning to generate coherent and concise summaries (§2.3). Finally, we describe how the two components are connected to further improve the generated summaries (§2.4).

2.1 Entity-Aware Content Selection

We design our content selection component to capture the interaction between entity mentions and the input article. Our model learns to identify salient content by aligning entity mentions

and their contexts with human summaries. Concretely, we employ two encoders: one learns entity representations by encoding their mention clusters and the other learns sentence representations. A pointer-network-based decoder (Vinyals et al., 2015b) selects a sequence of important sentences by jointly attending to the entities and the input, as depicted in Fig. 3.

Entity Encoder. We run off-the-shelf coreference resolution system from Stanford CoreNLP (Manning et al., 2014) on the input articles to extract entities, each represented as a cluster of mentions. Specifically, from each input article, we extract the coreferenced entities, and construct the mention clusters for all the mentions of each entity in that article. We also consider non coreferenced entity mentions as singleton entity mention clusters. Among all these mention clusters, for our experiments, we only consider salient entity mention clusters. We label clusters as "salient" based on two rules: (1) mention clusters with entities appearing in the first three sentences of the article, and (2) top k clusters containing most numbers of mentions. We experimented with different values of k and found that $k = 6$ gives us the best set of salient mention clusters having an optimal overlap with entity mentions in the ground truth summary.

For each mention cluster, we concatenate mentions of the same entity as they occur in the input into one sequence, segmented with special tokens (<MENT>). Finally, we get entity representations $\mathbf{e}_i$ for the i-th entity by encoding each cluster via a temporal convolutional model (Kim, 2014).

Input Article Encoder. For article encoding, we first learn sentence representations $\mathbf{r}_j$ by encoding words in the j-th sentence with another temporal convolutional model. Then, we utilize a bidirectional LSTM (biLSTM) to aggregate sentences into a sequence of hidden states $\boldsymbol{h}_j$. Both the encoders use a shared word embedding matrix to allow better alignment.

Sentence Selection Decoder. We employ a single-layer unidirectional LSTM with hidden states $\mathbf{s}_t$ to recurrently extract salient sentences. At each time step t, we first compute an entity context vector $\mathbf{c}_t^e$ based on attention mechanism (Bahdanau et al., 2014):

$$\mathbf{c}_t^e = \sum_i a_{it}^e \mathbf{e}_i \quad (1)$$

$$\mathbf{a}_t^e = \text{softmax}(\mathbf{v}^e \tanh(\mathbf{W}^{e1}\mathbf{s}_t + \mathbf{W}^{e2}\mathbf{e}_i)) \quad (2)$$

where $\mathbf{a}_t^e$ are attention weights, $\mathbf{v}^*$ and $\mathbf{W}^{**}$ denote trainable parameters throughout the paper. Bias terms are omitted for simplicity. We further use a *glimpse operation* (Vinyals et al., 2015a) to compute a sentence context vector $\mathbf{c_t}$ as follows:

$$\mathbf{c}_t = \sum_j a_{jt}^h \mathbf{W}^{h2}\mathbf{h}_j \quad (3)$$

$$\mathbf{a}_t^h = \text{softmax}(\mathbf{v}^h \tanh(\mathbf{W}^{h1}\mathbf{s}_t + \mathbf{W}^{h2}\mathbf{h}_j)) \quad (4)$$

where $\mathbf{a}_t^h$ are attention weights. Finally, sentence extraction probabilities that consider both entity and input context are calculated as:

$$p(y_t^l | y_{1:t-1}^l) = \text{softmax}(\mathbf{v}^q \tanh(\mathbf{W}^{p1}\mathbf{s}_t + \mathbf{W}^{p2}\mathbf{c_t} + \mathbf{W}^{p3}\mathbf{c_t^e})) \quad (5)$$

where the sentence y_t^l with the highest probability is selected. The process stops when the model picks the end-of-selection token.

Selection Label Construction. We train our content selection component with a cross-entropy loss: $-\sum_{(\mathbf{y}^l,\mathbf{x})\in D} \log p(\mathbf{y}^l \mid \mathbf{x}; \theta)$, here $\mathbf{y}^l$ are the ground truth sentence selection labels and $\mathbf{x}$ is the input article. θ denotes all model parameters.

To acquire training labels for sentence selection, we collect positive sentences in the following way. First, we employ greedy search to select the best combination of sentences that maximizes ROUGE-2 F1 (Lin and Hovy, 2003) with reference to human summary, as described by Zhou et al. (2018). We further include sentences whose ROUGE-L recall is above 0.5 when each is compared with its best aligned summary sentence. In cases where no sentence is selected, we label the first two sentences from the article as positive. Our combined construction strategy selects an average of 2.96 and 3.18 sentences from New York Times and CNN/Daily Mail articles respectively.

2.2 Abstract Generation with Reinforcement Learning

Our abstract generation component takes the selected sentences as input and produces the final summary. This abstract generator is a sequence-to-sequence network with attention over input (Bahdanau et al., 2014). The copying mechanism from See et al. (2017) is adopted to allow out-of-vocabulary words to appear in the output.

The abstract generator is first trained with maximum likelihood (ML) loss followed by additional training with policy-based reinforcement learning

(RL). For ML training, we use teacher forcing algorithm (Williams and Zipser, 1995), to minimize the following loss:

$$\mathcal{L}_{\text{ml}} = -\sum_{(\mathbf{y},\mathbf{x}^{ext})\in D} \log p(\mathbf{y}\,|\,\mathbf{x}^{ext};\theta) \quad (6)$$

where D is the training set, $\mathbf{x}^{ext}$ are extracted sentences from our label construction.

Self-Critical Learning. Following Paulus et al. (2017), we use the self-critical training algorithm based on policy gradients to use discrete metrics as RL rewards. At each training step, we generate two summaries: a *sampled* summary $\mathbf{y}^s$, obtained by sampling words from the probability distribution $p(\mathbf{y}^s|\,\mathbf{x}^{ext};\theta)$ at each decoding step, and a *self-critical baseline* summary $\hat{\mathbf{y}}$, yielded by greedily selecting words that maximize the output probability at each time step (Rennie et al., 2017). We then calculate rewards based on the average of ROUGE-L F1 and ROUGE-2 F1 of the two summaries against that of the ground-truth summary, and define the following loss function:

$$\mathcal{L}_{\text{rl}} = -\frac{1}{N'}\sum_{(\mathbf{y}^s,\mathbf{x}^{ext})\in D'} (\mathbf{R}(\mathbf{y}^s) - \mathbf{R}(\hat{\mathbf{y}}))\log p(\mathbf{y}^s|\,\mathbf{x}^{ext};\theta) \quad (7)$$

where D' represents set of sampled summaries paired with extracted input sentences and N' represents the total number of sampled summaries. $\mathbf{R}(\mathbf{y}) = \mathbf{R}_{\text{Rouge}}(\mathbf{y}) = \frac{1}{2}\big(\mathbf{R}_{\text{Rouge-L}}(\mathbf{y}) + \mathbf{R}_{\text{Rouge-2}}(\mathbf{y})\big)$, is the overall ROUGE reward for a summary $\mathbf{y}$.

2.3 Rewards with Coherence and Linguistic Quality

So far, we have described the *two basic components* of our SENECA framework. As noted in prior work (Liu et al., 2016), optimizing for an ngram-based metric like ROUGE does not guarantee improvement over readability of the generations. We thus augment our framework with additional rewards based on *coherence* and *linguistic quality* as described below.

Entity-Based Coherence Reward ($\mathbf{R}_{\text{Coh}}$). We use a separately trained **coherence model** to score summaries and guide our abstract generator to produce more coherent outputs by adding a reward $\mathbf{R}_{\text{Coh}}$ in the aforementioned RL training process. The new reward takes the following form:

$$\mathbf{R}(\mathbf{y}) = \mathbf{R}_{\text{Rouge}}(\mathbf{y}) + \gamma_{\text{Coh}}\mathbf{R}_{\text{Coh}}(\mathbf{y}) \quad (8)$$

Here we show how to calculate $\mathbf{R}_{\text{Coh}}$, to capture both entity distribution patterns and topical continuity. Since summaries are short, (e.g. 2.0 sentences on average per summary in the New York Times data), we decide to build our coherence model on top of local coherence estimation for pairwise sentences. We adopt the architecture of neural coherence model developed by Wu and Hu (2018), but train it with samples that enable coherence modeling based on entity presence and their context. Here we briefly describe the model, and refer the readers to the original paper for details.

Given a pair of sentences S_A and S_B, convolution layers first transform them into hidden representations, from which a multi-layer perceptron is utilized to yield a coherence score $\mathbf{Coh}(S_A, S_B) \in [-1, 1]$. We train the model with hinge-loss by leveraging both coherent positive samples and incoherent negative samples:

$$\mathcal{L}(S_A, S_B^+, S_B^-) = \max\{0, 1 + \mathbf{Coh}(S_A, S_B^+) - \mathbf{Coh}(S_A, S_B^-)\} \quad (9)$$

where S_A is a target sentence, S_A and S_B^+ is a positive pair, and S_A and S_B^- is a negative pair.

Note that Wu and Hu (2018) only consider *position* information for training data construction, i.e., S_A and S_B^+ must be adjacent, and S_A and S_B^- are at most 9 sentences away with S_B^- randomly picked. We instead introduce two notable features to construct our training data. In addition to being adjacent, we further constrain S_A and S_B^+ to have at least one coreferred entity and that S_B^- does not. Since our initial experiments show that coherence model trained in this manner cannot discern pure repetition of sentences, e.g., simply duplicating words leads to higher coherence, we reuse the target sentences themselves as the negative pairs.

Finally, since this model outputs pairwise coherence scores, for a summary containing more than two sentences, we use the average of all adjacent sentence pairs' scores as the final summary coherence score. Summaries containing only one sentence get 0 coherence score. We also conduct correlation study to show average aggregation works reasonably well (details in Supplementary).

Linguistic Quality Rewards ($\mathbf{R}_{\text{Ref}}$ & $\mathbf{R}_{\text{App}}$). We further consider two linguistically-informed rewards to further improve summary clarity and conciseness by penalizing (1) improper usage of referential pronouns, and (2) redundancy introduced by non-restrictive appositives and relative clauses.

Pronominal Referential Clarity. Referential pronouns occurring without the antecedents in a summary decreases its readability. For instance, a text with a pronoun "*they*" occurring before the required referred entity is introduced, would be less comprehensible. Therefore, at the RL step, we either penalize a summary with a reward of -1 for such improper usage, or give 0 otherwise. In our implementation, we define improper usage as the presence of a third personal pronoun or a possessive pronoun before any noun phrase occurs. The new reward is written as $\mathbf{R}(\mathbf{y}) = \mathbf{R}_{\text{Rouge}}(\mathbf{y}) + \gamma_{\text{Ref}}\mathbf{R}_{\text{Ref}}(\mathbf{y})$.

Apposition. Next, we consider a reward to teach the model to use apposition and relative clause minimally, which improves summary conciseness. For this, we focus on the non-restrictive appositives and relative clauses, which often carry non-critical information (Conroy et al., 2006; Wang et al., 2013) and can be automatically detected based on comma usage patterns. Specifically, a sentence contains a non-restrictive appositive if i) it contains two commas, and ii) the word after first comma is a possessive pronoun or a determinant (Geva et al., 2019). We penalize a summary with -1 for using non-restrictive appositives and relative clauses, henceforth referred to as apposition, or give 0 otherwise. Similarly, we have the total reward as $\mathbf{R}(\mathbf{y}) = \mathbf{R}_{\text{Rouge}}(\mathbf{y}) + \gamma_{\text{App}}\mathbf{R}_{\text{App}}(\mathbf{y})$.

2.4 Connecting Selection and Abstraction

Our entity-aware content selection component extracts salient sentences whereas our abstract generation component compresses and paraphrases them. Until this point, they are trained separately without any form of parameter sharing. We add an *additional step to connect these two networks* by training them together via the self-critical learning algorithm based on policy gradient (the same methodology as in §2.2).

Following the Markov Decision Process formulation, at each time step t, our content selector generates a set of extracted sentences ($\hat{\mathbf{x}}^{ext}$) from an input article. Our abstract generator uses $\hat{\mathbf{x}}^{ext}$ to generate a summary. This summary, evaluated against the respective human summary, receives ROUGE-1 as reward (See Eq. (7)). Note that the abstract generator, that has been previously trained with average of ROUGE-L and ROUGE-2 as reward to promote fluency, is not updated during this step. In this extra stage, if our content selector accurately selects salient sentences, the abstract generator is more likely to produce a high-quality summary, and such action will be encouraged. Whereas, action resulting in inferior selections will be discouraged.

3 Experimental Setups

Datasets and Preprocessing. We evaluated our models on two popular summarization datasets: New York Times (NYT) (Sandhaus, 2008) and CNN/Daily Mail (CNN/DM) (Hermann et al., 2015). For NYT, we followed the preprocessing steps by Paulus et al. (2017) to obtain similar training $(588,909)$, validation $(32,716)$ and test $(32,703)$ samples. Here, we additionally replaced author names with a special token. For CNN/DM, we followed the preprocessing steps in See et al. (2017), obtaining $287,188$ training, $13,367$ validation and $11,490$ testing samples.

For training our coherence model for CNN/DM, we used $890,419$ triples constructed from summaries and input articles sampled from the CNN/DM training set. Similarly for NYT, we sampled $884,494$ triples from NYT training set. For the validation and test set for the two models, we sampled roughly 10% from the validation and test set of the respective datasets. Our coherence model for CNN/DM achieves 86% accuracy and for NYT, 84%. Additional evaluation for this model is reported in §4.1.

Training Details and Parameters. We used a vocabulary of $50K$ most common words in the training set (See et al., 2017), with 128-dimensional word embeddings randomly initialized and updated during training. In the content selection component, for both entity and sentence encoders, we implemented one-layer convolutional network with 100 dimensions and used a shared embedding matrix between the two. We employed LSTM models with 256-dimensional hidden states for the input article encoder (per direction) and the content selection decoder (Chen and Bansal, 2018). We used a similar setup for the abstract generator encoder and decoder. During ML training of both components, Adam (Kingma and Ba, 2015) is applied with a learning rate 0.001 and a gradient clipping 2.0, and the batch size 32. During RL stage, we reduced learning rate to 0.0001 (Paulus et al., 2017) and set batch size to 50. For our abstract generator, to reduce variance during RL training,

we sampled 5 sequences for each data point and took an average over these samples using batch size 10. We set $\gamma_{\text{Coh}} = 0.01$, $\gamma_{\text{Ref}} = 0.005$, $\gamma_{\text{App}} = 0.005$ for NYT and CNN/DM with grid search on validation set.

During inference, we adopted the trigram repetition avoidance strategy (Paulus et al., 2017; Chen and Bansal, 2018), with additional length normalization to encourage the generation of longer sequences as in (Gehrmann et al., 2018).

Baselines and Comparisons. Besides baseline LEAD-3, we compare with popular and existing state-of-the-art abstractive summarization models on NYT and CNN/DM datasets: (1) pointer-generator model with coverage (See et al., 2017) (POINTGEN+COV); (2) sentence rewriting model (Chen and Bansal, 2018) (SENTREWRITE); (3) RL-based abstractive summarization (Paulus et al., 2017) (DEEPREINFORCE); (4) bottom-up abstraction (Gehrmann et al., 2018) (BOTTOMUP); and (5) deep communicating agents-based summarization (Celikyilmaz et al., 2018) (DCA).

We show comparison models' results reported as in the original publications. For significant tests, we run code released by the authors of POINTGEN+COV and SENTREWRITE, and by our implementation of DEEPREINFORCE on both datasets for training and testing. Since we do not have access to model outputs from Paulus et al. (2017), we re-implement their model, and achieve comparable ROUGE scores (e.g. on NYT, our ROUGE-1,2,L are 46.61, 29.76, and 43.46). For BOTTOMUP, we obtain model outputs from the authors for both CNN/DM and NYT datasets, whereas for DCA, we acquire summaries only for CNN/DM dataset.

In addition to SENECA base model, which combines entity-aware content selection and RL-based abstract generation (with average of ROUGE-L F1 and ROUGE-2 F1 as reward), we also report results on its variants with additional rewards during abstract generator training. We further consider SENECA (i) without entities, and (ii) end-to-end trained but with sentence selection only, i.e., the abstract generator simply repeats the input.

4 Results

In §4.1, we first evaluate our entity-based coherence model, which produces the coherence reward (R_{Coh}). We then present automatic evaluation for summarization models on content, coherence, and linguistic quality (§4.2). We further discuss human evaluation results in §4.3.

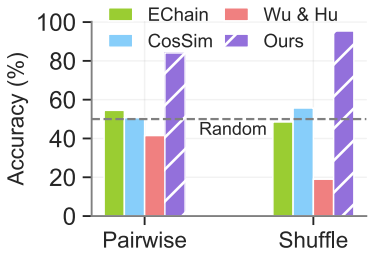

Figure 4: Accuracy of our coherence model compared to different baselines and Wu and Hu (2018) on PAIRWISE and SHUFFLE test sets.

4.1 Coherence Model Evaluation

We evaluate our entity-based coherence model on two tasks constructed from NYT test set: PAIRWISE and SHUFFLE. PAIRWISE is constructed as described in §2.2 with equal number of positive pairs and negative pairs. SHUFFLE comprises of full summaries, where half are original summaries, and the other half contain their shuffled version.

In Fig. 4, we show a comparison of our model against a version trained based on the same amount of samples constructed as done by Wu and Hu (2018). Also shown are two baselines: ECHAIN, that labels a pair of sentences as more coherent if they have one or more entity mentions coreferred, and COSSIM, that labels a pair of sentences with higher cosine similarity as more coherent. Our model yields significantly higher accuracy (greater than 80%) on both tasks than the comparisons, which is due to the difference in training data construction. Wu and Hu (2018) only consider position information, whereas we capture entity-based coherence. The improvement in performance of the coherence model indicates the effectiveness of our training data construction in capturing multiple aspects of coherence.

4.2 Automatic Summary Evaluation

Results on NYT. We first report the new state-of-the-art results for ROUGE-2 and ROUGE-L (Lin and Hovy, 2003), where our models outperform the previous best performing model DCA. Our SENECA models also outperform all comparisons on coherence score. This indicates that our models' summaries not only contain more salient information but are also more coherent.

Table 2: Results on CNN/Daily Mail. Our best results are achieved by the variant with sentence selection only, yielding significantly better R-1 and R-2 than all comparisons except BOTTOM-UP and DCA (Welch's t-test, $p < 0.05$). For COH., our best model is also significantly better (Welch's t-test, $p < 0.05$). We re-evaluate DCA output against full length human summaries. *: scores taken from original paper. †: significant test done on outputs by running code released by their authors or our implementation.

Amongst our models, the base SENECA model reports higher ROUGE and coherence score (0.73) compared to the version without entity as input. This demonstrates the importance of entity guidance during content selection as well as abstract generation. SENECA model trained with Apposition reward (R_{App}) reports the highest ROUGE-L (44.60), but shows a drop in the coherence score to 0.69. Whereas, SENECA with all rewards R_{Coh}+R_{Ref}+R_{App} reports the highest coherence score of 0.76 and a drop in ROUGE-L (44.01).

Results on CNN/DM. Since CNN/DM summaries are more extractive than that of NYT (Grusky et al., 2018), all SENECA models produce higher ROUGE-1 scores with SENECA base model achieving the highest, outperforming the previous best performing models on ROUGE-1. We also report the highest coherence score (0.63), which is even higher than that reported on human summaries (0.55). Since CNN/DM gold summaries are comprised of concatenated human written highlights for input articles, they are about the same topic and are cohesive, but lack entity-based coherent structure, for instance fewer entities get coreferred in subsequent sentences. Therefore, our coherence evaluation, which tests for entity-based coherence, gives lower coherence score to CNN/DM gold summaries.

Additionally for CNN/DM, the generated summaries sometimes contain less relevant words, e.g. stopwords, at the end of the summaries. This effect however improves the ROUGE scores while adversely affecting the coherence scores of the summaries. Training with additional coherence reward alleviates the issue by appending additional sentences, thereby improving overall coherence.

Amongst our models, we observe the overall trend to be similar to that in NYT results. Our base SENECA model reports higher ROUGE and coherence score compared to SENECA without entity input, again, indicating the usefulness of entity information. SENECA model with all rewards also yields the highest coherence score of 0.63, whereas SENECA model with coherence reward performs considerably better on ROUGE-L with a drop in coherence score.

Linguistic Quality Evaluation. We further do a preliminary evaluation of system summaries on two important linguistic qualities: clarity and conciseness. To measure *clarity*, we focus on the percentage of summaries that improperly use referential pronouns (Ref.), defined as third person pro-

[2]Significant test was not performed with BOTTOMUP as they use different test split than Paulus et al. (2017), and with DCA, since their outputs are unavailable on NYT.

System	NYT			CNN/DM

Table 3: % of system summaries improperly using referential pronouns (Ref.), or containing relative clauses (RelCl.) or appositives (App.) (lowest values in bold). Lower values indicate better performance.

nouns or possessive pronouns being used before any noun phrase. Similarly, to measure *conciseness*, we report how often summaries contain at least one non-restrictive relative clause (RelCl.) or non-restrictive appositives (App.). For model summaries, we report these measures in reference to the respective gold summaries. Lower values are better.

As can be seen from Table 3, our models report the least percentage of improper usage of referential pronouns. Particularly on NYT, the model trained with R_{Ref} reward makes much fewer mistakes in this category. Similarly, adding R_{App} reports the least amount of usage of relative clause or apposition, making summaries easier to read.

4.3 Human Evaluation

Human evaluation is conducted to analyze the informativeness and readability of the summaries generated by our models. We randomly select 30 articles from the NYT test set and ask three proficient English speakers to rate summaries generated by POINTGEN+COV, DEEPREINFORCE (Paulus et al., 2017), our SENECA, and SENECA + R_{Coh},[3] along with HUMAN written summaries. Each rater reads the article and scores the summaries against each other on a Likert scale of 1 (worst) to 5 (best) on the following three aspects: **informativeness**—whether summary covers salient points from the input, **grammaticality**, and **coherence**—whether summary presents content and entity mentions in coherent order. Detailed guidelines with sample ratings and explanation are shown in the Supplementary.

[3]To clearly discern the improvement in coherence in the summaries after adding coherence reward without introducing effects of additional rewards, we did not consider SENECA model with all rewards for human evaluation.

	Inf.	Gram.	Coh.
HUMAN	4.58	4.42	4.16
POINTGEN+COV	3.63	**4.47**	3.89
DEEPREINFORCE	3.63	3.21	3.16
SENECA	4.26	4.11	4.05
SENECA + R_{Coh}	**4.32***	4.10	**4.11***

Table 4: Human evaluation on informativeness (Inf.), grammaticality (Gram.) and coherence (Coh.). Best results among systems are in bold, with significance reported over other comparisons with $*$ (approximate randomization test (Edgington, 1969), $p < 0.0005$). The Krippendorf's α for the three aspects are 0.46, 0.64, and 0.48.

Table 4 shows that our model SENECA + R_{Coh} ranks significantly higher on informativeness as well as coherence, reaffirming our observations from automatic evaluation. Surprisingly, SENECA + R_{Coh} ranks higher on informativeness even when compared to SENECA, which reports higher on ROUGE (see Table 1). Through manual inspection, we find that SENECA model often generates summaries whose second or third sentence misses the subject, whereas SENECA + R_{Coh} tends to avoid this problem. Though not significant, POINTGEN+COV ranks higher on grammaticality than SENECA + R_{Coh}. We believe this is due to the fact that SENECA + R_{Coh} learns to merge sentences from the input article while making some grammatical errors. We further show sample summaries in Figure 5.

5 Related Work

Neural Abstractive Summarization. Two-step abstractive summarization approaches have become popular in recent years, where the two steps, content selection and abstraction, are conveniently separated from each other. In these approaches, salient content is first identified, usually at sentence-level (Hsu et al., 2018; Li et al., 2018; Tan et al., 2017b; Chen and Bansal, 2018) or phrase-level (Gehrmann et al., 2018), followed by abstract generation. However, prior work mainly focuses on improving the informativeness of abstractive summaries, e.g. copying and coverage mechanisms (See et al., 2017), and reinforcement learning methods optimizing on ROUGE scores (Paulus et al., 2017). Coherence and other aspects of linguistic quality that capture the overall readability of summaries are largely ignored.

Figure 5: Sample summaries for an NYT article. Our model with coherence reward overlaps the most with human summary (**green** is ours, **blue** denotes human).

In this work, besides informativeness, we also aim to improve upon these aspects of summaries.

Role of Entities and Coherence in Summarization. Entities in a text carry useful contextual information (Nenkova, 2008) and therefore play an important role in multi-document summarization (Li et al., 2006) and event summarization for selecting salient sentences (Li et al., 2015). Moreover, entity mentions connecting sentences have also been used to extract non-adjacent yet coherent sentences (Siddharthan et al., 2011; Parveen et al., 2016). For abstractive summarization, Amplayo et al. (2018) find it beneficial to leverage entities that are linked to existing knowledge bases. Unfortunately, it fails to capture the entities that do not exist in these knowledge bases.

Grammar role-based entity transitions have been widely employed to model coherence in text generation tasks (Barzilay and Lee, 2004; Lapata and Barzilay, 2005; Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013; Tien Nguyen and Joty, 2017), which often requires intensive feature engineering. Neural coherence models (Mesgar and Strube, 2018; Li and Hovy, 2014) have, therefore, gained popularity due to their end-to-end nature. However, coherence has mainly been investigated in extractive summarization systems (Alonso i Alemany and Fuentes Fort, 2003; Christensen et al., 2013; Parveen et al., 2015; Wu and Hu, 2018). To the best of our knowledge, we are the first to leverage entity information to improve coherence for neural abstractive summarization along with other important linguistic qualities.

6 Conclusion

We present an entity-driven summarization framework to generate informative and coherent abstractive summaries. An entity-aware content selector chooses salient sentences from the input article and an abstract generator produces a coherent abstract. Linguistically-informed guidance further enhances conciseness and clarity, thus improving the summary quality. Our model obtains the new state-of-the-art ROUGE scores on the NYT and CNN/DM datasets. Human evaluation further indicates that our system produces more coherent summaries than other popular methods.

Neural Extractive Text Summarization with Syntactic Compression

Jiacheng Xu and **Greg Durrett**

Abstract

Recent neural network approaches to summarization are largely either selection-based extraction or generation-based abstraction. In this work, we present a neural model for single-document summarization based on joint extraction and syntactic compression. Our model chooses sentences from the document, identifies possible compressions based on constituency parses, and scores those compressions with a neural model to produce the final summary. For learning, we construct oracle extractive-compressive summaries, then learn both of our components jointly with this supervision. Experimental results on the CNN/Daily Mail and New York Times datasets show that our model achieves strong performance (comparable to state-of-the-art systems) as evaluated by ROUGE. Moreover, our approach outperforms an off-the-shelf compression module, and human and manual evaluation shows that our model's output generally remains grammatical.

1 Introduction

Neural network approaches to document summarization have ranged from purely extractive (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018) to abstractive (Rush et al., 2015; Nallapati et al., 2016; Chopra et al., 2016; Tan et al., 2017; Gehrmann et al., 2018). Extractive systems are robust and straightforward to use. Abstractive systems are more flexible for varied summarization situations (Grusky et al., 2018), but can make factual errors (Cao et al., 2018; Li et al., 2018) or fall back on extraction in practice (See et al., 2017). Extractive and compressive systems (Berg-Kirkpatrick et al., 2011; Qian and Liu, 2013; Durrett et al., 2016) combine the strengths of both approaches; however, there has been little work studying neural network models in this vein, and the approaches that have been employed typically use seq2seq-based sentence compression (Chen and Bansal, 2018).

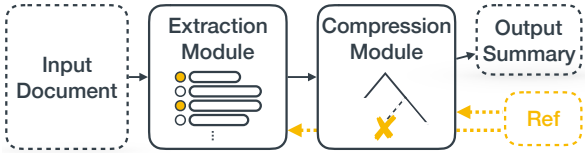

Figure 1: Diagram of the proposed model. Extraction and compression are modularized but jointly trained with supervision derived from the reference summary.

In this work, we propose a model that can combine the high performance of neural extractive systems, additional flexibility from compression, and interpretability given by having discrete compression options. Our model first encodes the source document and its sentences and then sequentially selects a set of sentences to further compress. Each sentence has a set of compression options available that are selected to preserve meaning and grammaticality; these are derived from syntactic constituency parses and represent an expanded set of discrete options from prior work (Berg-Kirkpatrick et al., 2011; Wang et al., 2013). The neural model additionally scores and chooses which compressions to apply given the context of the document, the sentence, and the decoder model's recurrent state.

A principal challenge of training an extractive and compressive model is constructing the oracle summary for supervision. We identify a set of high-quality sentences from the document with beam search and derive oracle compression labels in each sentence through an additional refinement process. Our model's training objective combines these extractive and compressive components and learns them jointly.

We conduct experiments on standard single document news summarization datasets: CNN, Daily Mail (Hermann et al., 2015), and the New

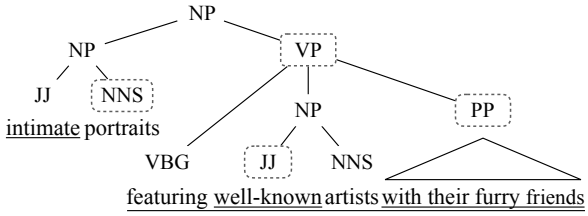

Figure 2: Text compression example. In this case, "intimate", "well-known", "with their furry friends" and "featuring ... friends" are deletable given compression rules.

York Times Annotated Corpus (Sandhaus, 2008). Our model matches or exceeds the state-of-the-art on all of these datasets and achieves the largest improvement on CNN (+2.4 ROUGE-F_1 over our extractive baseline) due to the more compressed nature of CNN summaries. We show that our model's compression threshold is robust across a range of settings yet tunable to give different-length summaries. Finally, we investigate the fluency and grammaticality of our compressed sentences. The human evaluation shows that our system yields generally grammatical output, with many remaining errors being attributed to the parser.[1]

2 Compression in Summarization

Sentence compression is a long-studied problem dealing with how to delete the least critical information in a sentence to make it shorter (Knight and Marcu, 2000, 2002; Martins and Smith, 2009; Cohn and Lapata, 2009; Wang et al., 2013; Li et al., 2014). Many of these approaches are syntax-driven, though end-to-end neural models have been proposed as well (Filippova et al., 2015; Wang et al., 2017). Past non-neural work on summarization has used both syntax-based (Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2011) and discourse-based (Carlson et al., 2001; Hirao et al., 2013; Li et al., 2016) compressions. Our approach follows in the syntax-driven vein.

Our high-level approach to summarization is shown in Figure 1. In Section 3, we describe the models for extraction and compression. Our compression depends on having a discrete set of valid compression options that maintain the grammaticality of the underlying sentence, which we now proceed to describe.

[1]The code, full model output, and the pre-trained model are available at https://github.com/jiacheng-xu/neu-compression-sum

Compression Rules We refer to the rules derived in Li et al. (2014), Wang et al. (2013), and Durrett et al. (2016) and design a concise set of syntactic rules including the removal of: 1. Appositive noun phrases; 2. Relative clauses and adverbial clauses; 3. Adjective phrases in noun phrases, and adverbial phrases (see Figure 2); 4. Gerundive verb phrases as part of noun phrases (see Figure 2); 5. Prepositional phrases in certain configurations like *on Monday*; 6. Content within parentheses and other parentheticals.

Figure 2 shows examples of several compression rules applied to a short snippet. All combinations of compressions maintain grammaticality, though some content is fairly important in this context (the VP and PP) and should not be deleted. Our model must learn not to delete these elements.

Compressability Summaries from different sources may feature various levels of compression. At one extreme, a summary could be fully sentence-extractive; at another extreme, the editor may have compressed a lot of content in a sentence. In Section 4, we examine this question on our summarization datasets and use it to motivate our choice of evaluation datasets.

Universal Compression with ROUGE While we use syntax as a source of compression options, we note that other ways of generating compression options are possible, including using labeled compression data. However, supervising compression with ROUGE is critical to learn what information is important for this particular source, and in any case, labeled compression data is unavailable in many domains. In Section 5, we compare our model to off-the-shelf sentence compression module and find that it substantially underperforms our approach.

3 Model

Our model is a neural network model that encodes a source document, chooses sentences from that document, and selects discrete compression options to apply. The model architecture of sentence extraction module and text compression module are shown in Figure 3 and 4.

3.1 Extractive Sentence Selection

A single document consists of n sentences $D = \{s_1, s_2, \cdots, s_n\}$. The i-th sentence is denoted as $s_i = \{w_{i1}, w_{i2}, \cdots, w_{im}\}$ where w_{ij} is the

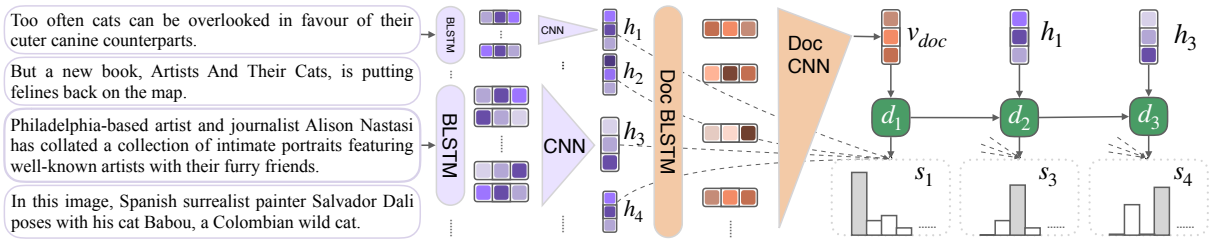

Figure 3: Sentence extraction module of JECS. Words in input document sentences are encoded with BiLSTMs. Two layers of CNNs aggregate these into sentence representations h_i and then the document representation v_{doc}. This is fed into an attentive LSTM decoder which selects sentences based on the decoder state d and the representations h_i, similar to a pointer network.

j-th word in s_i. The content selection module learns to pick up a subset of D denoted as $\hat{D} = \{\hat{s}_1, \hat{s}_2, \cdots, \hat{s}_k, |\hat{s}_i \in D\}$ where k sentences are selected.

Sentence & Document Encoder We first use a bidirectional LSTM to encode words in each sentence in the document separately and then we apply multiple convolution layers and max pooling layers to extract the representation of every sentence. Specifically, $[h_{i1}, \cdots, h_{im}] = \text{BiLSTM}([w_{i1}, \cdots, w_{im}])$ and $h_i = \text{CNN}([h_{i1}, \cdots, h_{im}])$ where h_i is a representation of the i-th sentence in the document. This process is shown in the left side of Figure 3 illustrated in purple blocks. We then aggregate these sentence representations into a document representation v_{doc} with a similar BiLSTM and CNN combination, shown in Figure 3 with orange blocks.

Decoding The decoding stage selects a number of sentences given the document representation v_{doc} and sentences' representations h_i. This process is depicted in the right half of Figure 3. We use a sequential LSTM decoder where, at each time step, we take the representation h of the last selected sentence, the overall document vector v_{doc}, and the recurrent state d_{t-1}, and produce a distribution over all of the remaining sentences excluding those already selected. This approach resembles pointer network-style approaches used in past work (Zhou et al., 2018). Formally, we write this as:

$$d_t = \text{LSTM}(d_{t-1}, h_k, v_{doc})$$
$$\text{score}_{t,i} = W_m \tanh(W_d d_t + W_h h_i)$$
$$p(\hat{s}_t = s_i | d_t, h_k, v_{doc}, h_i) = \text{softmax}(\text{score}_{t,i})$$

where h_k is the representation of the sentence selected at time step $t-1$. d_{t-1} is the decoding hidden state from last time step. W_d, W_h, W_m, and parameters in LSTM are learned. Once a sentence is selected, it cannot be selected again. At test time, we use greedy decoding to identify the most likely sequence of sentences under our model.[2]

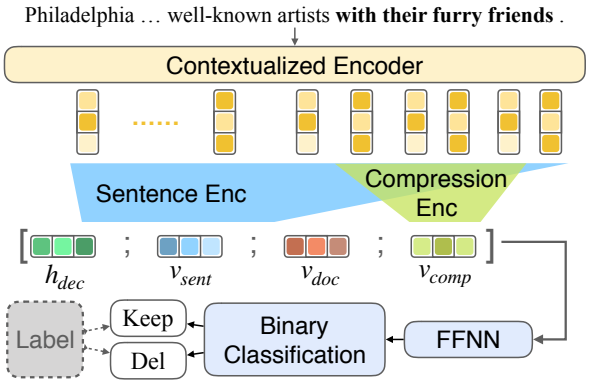

Figure 4: Text compression module. A neural classifier scores the compression option (*with their furry friends*) in the sentence and broader document context and decides whether or not to delete it.

3.2 Text Compression

After selecting the sentences, the text compression module evaluates our discrete compression options and decides whether to remove certain phrases or words in the selected sentences. Figure 4 shows an example of this process for deciding whether or not to delete a PP in this sentence. This PP was marked as deletable based on rules described in Section 2. Our network then encodes this sentence and the compression, combines this information with the document context v_{doc} and decoding context h_{dec}, and uses a feedforward network to decide whether or not to delete the span.

[2]For our experiments, we decode for a fixed number of sentences, tuned for each dataset, as in prior extractive work (Narayan et al., 2018). We experimented with dynamically choosing a number of sentences and found this to make little difference.

Let $C_i = \{c_{i1}, \cdots, c_{il}\}$ denote the possible compression spans derived from the rules described in Section 2. Let $y_{i,c}$ be a binary variable equal to 1 if we are deleting the cth option of the ith sentence. Our text compression module models $p(y_{i,c}|D, \hat{s}_t = s_i)$ as described in the following section.

Compression Encoder We use a contextualized encoder, ELMo (Peters et al., 2018) to compute contextualized word representations. We then use CNNs with max pooling to encode the sentence (shown in blue in Figure 4) and the candidate compression (shown in light green in Figure 4). The sentence representation v_{sent} and the compression span representation v_{comp} are concatenated with the hidden state in sentence decoder h_{dec} and the document representation v_{doc}.

Compression Classifier We feed the concatenated representation to a feedforward neural network to predict whether the compression span should be deleted or kept, which is formulated as a binary classification problem. This classifier computes the final probability $p(y_{i,c}|D, \hat{s}_t = s_i) = p(y_{i,c}|h_{dec}, v_{doc}, v_{comp}, s_i)$. The overall probability of a summary $(\hat{s}, \hat{y})$, where $\hat{s}$ is the sentence oracle and $\hat{y}$ is the compression label, is the product of extraction and compression models: $p(\hat{s}, \hat{y}|D) = \prod_{t=1}^{T} \left[p(\hat{s}_t|D, \hat{s}_{<t}) \prod_{c \in C_i} p(\hat{y}_{t,c}|D, \hat{s})\right]$.

Heuristic Deduplication Inspired by the trigram avoidance trick proposed in Paulus et al. (2018) to reduce redundancy, we take full advantage of our linguistically motivated compression rules and the constituent parse tree and allow our model to compress deletable chunks with redundant information. We therefore take our model's output and apply a postprocessing stage where we remove any compression option whose unigrams are completely covered elsewhere in the summary. We perform this compression after the model prediction and compression.

4 Training

Our model makes a series of sentence extraction decisions $\hat{s}$ and then compression decisions $\hat{y}$. To supervise it, we need to derive gold-standard labels for these decisions. Our oracle identification approach relies on first identifying an oracle set of sentences and then the oracle compression options.[3]

Document: ... **Philadelphia-based** artist and journalist Alison Nastasi has collated a collection of **intimate** portraits **featuring well-known artists with their furry friends**. ...

Compression $R_{bf} = 19.4$	R_{af}	Ratio	Label
Philadelphia-based	19.8	1.02	DEL
intimate	19.8	1.02	DEL
well known	20.4	1.05	DEL
featuring ... their furry friends	18.1	0.93	KEEP

Table 1: Oracle label computation for the text compression module. R_{bf} and R_{af} are the ROUGE scores before and after compression. The ratio is defined as $\frac{R_{af}}{R_{bf}}$. ROUGE increases when words not appearing in the reference are deleted. ROUGE can decrease when terms appearing in the reference summary, like *featuring*, are deleted.

4.1 Oracle Construction

Sentence Extractive Oracle We first identify an oracle set of sentences to extract using a beam search procedure similar to Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998). For each additional sentence we propose to add, we compute a heuristic cost equal to the ROUGE score of a given sentence with respect to the reference summary. When pruning states, we calculate the ROUGE score of the combination of sentences currently selected and sort in descending order. Let the beam width be β. The time complexity of the approximate approach is $O(nk\beta)$ where in practice $k \ll n$ and $\beta \ll n$. We set $\beta = 8$ and $n = 30$ which means we only consider the first 30 sentences in the document.

The beam search procedure returns a beam of β different sentence combinations in the final beam. We use the sentence extractive oracle for both the extraction-only model and the joint extraction-compression model.

Oracle Compression Labels To form our joint extractive and compressive oracle, we need to give the compression decisions binary labels $y_{i,c}$ in each set of extracted sentences. For simplicity and computational efficiency, we assign each sentence

[3]Depending on which sentences are extracted, different compression decisions may be optimal; however, re-deriving these with a dynamic oracle (Goldberg and Nivre, 2012) is prohibitively expensive during training.

Category	CNN	DM	NYT
Bad	27%	48%	49%
Weak Positive	58%	43%	47%
Strong Positive	15%	10%	4%

Table 2: Compressibility: The oracle label distribution over three datasets. Compressions in the "Bad" category decrease ROUGE and are labeled as negative (do not delete), while weak positive (less than 5% ROUGE improvement) and strong positive (greater than 5%) both represent ROUGE improvements. CNN features much more compression than the other datasets.

a single $y_{i,c}$ independent of the context it occurs in. For each compression option, we assess the value of it by comparing the ROUGE score of the sentence with and without this phrase. Any option that increases ROUGE is treated as a compression that should be applied. When calculating this ROUGE value, we remove stop words include stemming.

We run this procedure on each of our oracle extractive sentences. The fraction of positive and negative labels assigned to compression options is shown for each of the three datasets in Table 2. CNN is the most compressable dataset among CNN, DM and NYT.

ILP-based oracle construction Past work has derived oracles for extractive and compressive systems using integer linear programming (ILP) (Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011). Following their approach, we can directly optimize for ROUGE recall of an extractive or compressive summary in our framework if we specify a length limit. However, we evaluate on ROUGE F_1 as is standard when comparing to neural models that don't produce fixed-length summaries. Optimizing for ROUGE F_1 cannot be formulated as an ILP, since computing precision requires dividing by the number of selected words, making the objective no longer linear. We experimented with optimizing for ROUGE F_1 indirectly by finding optimal ROUGE recall summaries at various settings of maximum summary length. However, these summaries frequently contained short sentences to fill up the budget, and the collection of summaries returned tended to be less diverse than those found by beam search.

4.2 Learning Objective

Often, many oracle summaries achieve very similar ROUGE values. We therefore want to avoid committing to a single oracle summary for the learning process. Our procedure from Section 4.1 can generate m extractive oracles s_i^*; let $s_{i,t}^*$ denote the gold sentence for the i-th oracle at timestep t. Past work (Narayan et al., 2018; Chen and Bansal, 2018) has employed policy gradient in this setting to optimize directly for ROUGE. However, because oracle summaries usually have very similar ROUGE scores, we choose to simplify this objective as $\mathcal{L}_{\text{sent}} = -\frac{1}{m}\sum_{i=1}^{m}\sum_{t=1}^{T}\log p(s_{i,t}^*|D, s_{i,<t}^*)$. Put another way, we optimize the log likelihood averaged across m different oracles to ensure that each has high likelihood. We use $m = 5$ oracles during training. The oracle sentence indices are sorted according to the individual salience (ROUGE score) rather than document order.

The objective of the compression module is defined as $\mathcal{L}_{\text{comp}} = -\sum_{i=1}^{m}\sum_{c=1}^{C}\log p(y_{i,c}^*|D, \hat{s})$ where $p(y_{i,c}^*)$ is the probability of the target decision for the c-th compression options of the i-th sentence. The joint loss function is $\mathcal{L} = \mathcal{L}_{\text{sent}} + \alpha\mathcal{L}_{\text{comp}}$. We set $\alpha = 1$ in practice.

5 Experiments

We evaluate our model on two axes. First, for content selection, we use ROUGE as is standard. Second, we evaluate the grammaticality of our model to ensure that it is not substantially damaged by compression.

5.1 Experimental Setup

Datasets We evaluate the proposed method on three popular news summarization datasets: the New York Times corpus (Sandhaus, 2008), CNN and Dailymail (DM) (Hermann et al., 2015).[4]

As discussed in Section 2, compression will give different results on different datasets depending on how much compression is optimal from the standpoint of reproducing the reference summaries, which changes how measurable the impact of compression is. In Table 2, we show the "compressability" of these three datasets: how valuable various compression options seem to be from the standpoint of improving ROUGE. We found that CNN has significantly more positive compression options than the other two. Critically, CNN also has the shortest references (37 words on average,

[4]More details about the experimental setup, implementation details, and human evaluation are provided in the Appendix.

CBDec (Jiang and Bansal, 2018)	40.7	17.9	37.1
FARS (Chen and Bansal, 2018)	40.9	17.8	**38.5**
LEADDEDUP	40.5	17.4	36.5
LEADCOMP	40.8	17.4	36.8
EXTRACTION	40.7	18.0	36.8
JECS	**41.7**	**18.5**	**37.9**

Table 4: Experimental results on the test sets of CNNDM. The portion of CNN is roughly one of tenth of DM. Gains are more pronounced on CNN because this dataset features shorter, more compressed reference summaries.

compared to 61 for Daily Mail; see Appendix). In our experiments, we first focus on CNN and then evaluate on the other datasets.

Models We present several variants of our model to show how extraction and compression work jointly. In extractive summarization, the LEAD baseline (first k sentences) is a strong baseline due to how newswire articles are written. LEADDEDUP is a non-learned baseline that uses our heuristic deduplication technique on the lead sentences. LEADCOMP is a compression-only model where compression is performed on the lead sentences. This shows the effectiveness of the compression module in isolation rather than in the context of abstraction. EXTRACTION is the extraction only model. JECS is the full Joint Extractive and Compressive Summarizer.

We compare our model with various abstractive and extractive summarization models. NeuSum (Zhou et al., 2018) uses a seq2seq model to predict a sequence of sentences indices to be picked up from the document. Our extractive approach is most similar to this model. Refresh (Narayan et al., 2018), BanditSum (Dong et al., 2018) and LatSum (Zhang et al., 2018) are extractive summarization models for comparison. We also compare with some abstractive models including PointGen-Cov (See et al., 2017), FARS (Chen and Bansal, 2018) and CBDec (Jiang and Bansal, 2018).

We also compare our joint model with a pipeline model with an off-the-shelf compression module. We implement a deletion-based BiLSTM model for sentence compression (Wang et al., 2017) and run the model on top of our extraction output.[5] The pipeline model is denoted as EXTLSTMDEL.

5.2 Results on CNN

Table 3 shows experiments results on CNN. We list performance of the LEAD baseline and the performance of competitor models on these datasets. Starred models are evaluated according to our ROUGE metrics; numbers very closely match the originally reported results.

Our model achieves substantially higher performance than all baselines and past systems (+2 ROUGE F1 compared to any of these). On this dataset, compression is substantially useful. Compression is somewhat effective in isolation, as shown by the performance of LEADDEDUP and LEADCOMP. But compression in isolation still gives less benefit (on top of LEAD) than when combined with the extractive model (JECS) in the joint framework. Furthermore, our model beats the pipeline model EXTLSTMDEL which shows the necessity of training a joint model with ROUGE supervision.

5.3 Results on Combined CNNDM and NYT

We also report the results on the full CNNDM and NYT although they are less compressable. Table 4 and Table 5 shows the experimental results on these datasets.

Our models still yield strong performance compared to baselines and past work on the CNNDM

[5]We reimplemented the authors' model following their specification and matched their accuracy. For fair comparison, we tuned the deletion threshold to match the compression rate of our model; other choices did not lead to better ROUGE scores.

Model	R-1	R-2	R-L
Lead	41.8	22.6	35.0
LEADDEDUP	42.0	22.8	35.0
LEADCOMP	42.4	22.7	35.4
EXTRACTION	44.3	25.5	37.1
JECS	45.5	25.3	38.2

Table 5: Experimental results on the NYT50 dataset. ROUGE-1, -2 and -L F_1 is reported. JECS substantially outperforms our Lead-based systems and our extractive model.

Model	Preference (%) ↑	Error ↓	R-1 ↑
EXT LEAD3	–	22	29.1
EXTDROP	12%	161	30.2
EXTLSTMDEL	43%	**24**	30.6
JECS	**45**%	31	**32.7**

Table 6: Human preference, ROUGE and Grammarly grammar checking results. We asked Turkers to rank the models' output based on grammaticality. Error shows the number of grammar errors in 500 sentences reported by Grammarly. Our JECS model achieves the highest ROUGE and is preferred by humans while still making relatively few errors.

dataset. The EXTRACTION model achieves comparable results to past successful extractive approaches on CNNDM and JECS improves on this across the datasets. In some cases, our model slightly underperforms on ROUGE-2. One possible reason is that we remove stop words when constructing our oracles, which could underestimate the importance of bigrams containing stopwords for evaluation. Finally, we note that our compressive approach substantially outperforms the compression-augmented LatSum model. That model used a separate seq2seq model for rewriting, which is potentially harder to learn than our compression model.

On NYT, we see again that the inclusion of compression leads to improvements in both the LEAD setting as well as for our full JECS model.[6]

5.4 Grammaticality

We evaluate grammaticality of our compressed summaries in three ways. First, we use Amazon Mechanical Turk to compare different compression techniques. Second, to measure absolute grammaticality, we use an automated out-of-the-box tool Grammarly. Finally, we conduct manual analysis.

Human Evaluation We first conduct a human evaluation on the Amazon Mechanical Turk platform. We ask Turkers to rank different compression versions of a sentence in terms of grammaticality. We compare our full JECS model and the off-the-shelf pipeline model EXTLSTMDEL, which have matched compression ratios. We also propose another baseline, EXTRACTDROPOUT, which randomly drops words in a sentence to match the compression ratio of the other two models. The results are shown in Table 6. Turkers give roughly equal preference to our model and the EXTLSTMDEL model, which was learned from supervised compression data. However, our JECS model achieves substantially higher ROUGE score, indicating that it represents a more effective compression approach.

We found that absolute grammaticality judgments were hard to achieve on Mechanical Turk; Turkers' ratings of grammaticality were very noisy and they did not consistently rate true article sentences above obviously noised variants. Therefore, we turn to other methods as described in the next two paragraphs.

Automatic Grammar Checking We use Grammarly to check 500 sentences sampled from the outputs of the three models mentioned above from CNN. Both EXTLSTMDEL and JECS make a small number of grammar errors, not much higher than the purely extractive LEAD3 baseline. One major source of errors for JECS is having the wrong article after the deletion of an adjective like *an [awesome] style*.

Manual Error Analysis To get a better sense of our model's output, we conduct a manual analysis of our applied compressions to get a sense of how many are valid. We manually examined 40 model summaries, comparing the output with the raw sentences before compression, and identified the following errors: 1. Eight bad deletions due to parsing errors like *a UK [JJ national] from London*. 2. Eight inappropriate adjective deletions causing correctness issues with respect to the reference document like *[former] president* and *[nuclear] weapon*. 3. Three other errors: partial deletion of slang, inappropriate PP attachment deletion, and an unhandled grammatical construction:

[6] Paulus et al. (2018) do not use the NYT50 dataset, so our results are not directly comparable to theirs. Durrett et al. (2016) use a different evaluation setup with a hard limit on the summary length and evaluation on recall only.

Reference Summary	Prediction with Compressions
Mullah Omar, the reclusive founder of the Afghan Taliban, is still in charge, a new biography claims. An ex-Taliban insider says there have been rumors that the one-eyed militant is dead.	(CNN) Mullah Mohammed Omar is "still the leader" of the Taliban's self-declared Islamic Emirate of Afghanistan. The Taliban's "Cultural Commission" released the 11-page document in several different translations on the movement's website, ostensibly to commemorate the 19th anniversary of an April 4, 1996, meeting in Afghanistan's Kandahar province when an assembly of Afghans swore allegiance to Omar.
Rebecca Francis' photo with a giraffe was shared by Ricky Gervais. Francis was threatened on Twitter for the picture. Francis, a hunter, said the giraffe was "close to death" and became food for locals.	(CNN) Five years ago, Rebecca Francis posed for a photo while lying next to a dead giraffe. The trouble started Monday, when comedian Ricky Gervais tweeted the photo with a question. Francis, who has appeared on the NBC Sports Network outdoor lifestyle show "Eye of the Hunter" and was the subject of an interview with Hunting Life in late March, responded in a statement to HuntingLife.com on Tuesday, which was posted on its Facebook page.
Frida Ghitis: President Barack Obama is right to want a deal, but this one gives Iran too much. She says the framework agreement starts lifting Iran sanctions much too soon.	(CNN) President Barack Obama tied himself to the mast of a nuclear deal with Iran even before he became the Democratic candidate for president. Reaching a good, solid agreement with Iran is a worthy, desirable goal. But the process has unfolded under the destructive influence of political considerations, weakening America's hand and strengthening Iran.

Table 7: Examples of applied compressions. The top two are sampled from among the most compressed examples in the dataset. Our JECS model is able to delete both large chunks (especially temporal PPs giving dates of events) as well as individual modifiers that aren't determined to be relevant to the summary (e.g., the specification of the *19th* anniversary). The last example features more modest compression.

students [first], athletes [second].

Examples of output are shown in Table 7. The first two examples are sampled from the top 25% of the most compressed examples in the corpus. We see a variety of compression options that are used in the first two examples, including removal of temporal PPs, large subordinate clauses, adjectives, and parentheticals. The last example features less compression, only removing a handful of adjectives in a manner which slightly changes the meaning of the summary.

Improving the parser and deriving a more semantically-aware set of compression rules can help achieving better grammaticality and readability. However, we note that such errors are largely orthogonal to the core of our approach; a more refined set of compression options could be dropped into our system and used without changing our fundamental model.

6 Compression Analysis

Compression Threshold Compression in our model is an imbalanced binary classification problem. The trained model's natural classification threshold (probability of DEL > 0.5) may not be optimal for downstream ROUGE. We experiment with varying the classification threshold from 0 (no deletion, only heuristic deduplication) to 1 (all compressible pieces removed). The results on CNN are shown in Figure 5, where we show the average ROUGE value at different compression thresholds. The model achieves the best performance at 0.45 but performs well in a wide range from 0.3 to 0.55. Our compression is therefore robust yet also provides a controllable parameter to change the amount of compression in produced summaries.

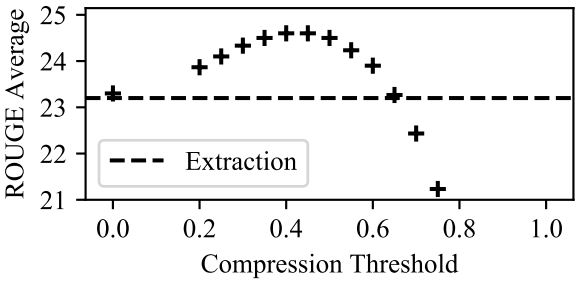

Figure 5: Effect of changing the compression threshold on CNN. The y-axis shows the average of the F1 of ROUGE-1,-2 and -L. The dotted line is the extractive baseline. The model outperforms the extractive model and achieves nearly optimal performance across a range of threshold values.

Compression Type Analysis We further break down the types of compressions used in the model. Table 8 shows the compressions that our model ends up choosing at test time. PPs are often compressed by the deduplication mechanism because the compressible PPs tend to be temporal and location adjuncts, which may be redundant across sen-

Node Type	Len	% of comps	Comp Acc	Dedup
JJ	1.0	34%	72%	30%
PP	3.4	26%	47%	72%
ADVP	1.4	17%	79%	17%
PRN	2.2	6%	80%	5%

Table 8: The compressions used by our model on CNN; average lengths and the fraction of that constituency type among compressions taken by our model. Comp Acc indicates how frequently that compression was taken by the oracle; note that error, especially keeping constituents that we shouldn't, may have minimal impact on summary quality. Dedup indicates the percentage of chosen compressions which arise from deduplication as opposed to model prediction.

tences. Without the manual deduplication mechanism, our model matches the ground truth around 80% of the time. However, a low accuracy here may not actually cause a low final ROUGE score, as many compression choices only affect the final ROUGE score by a small amount. More details about compression options are in the Supplementary Material.

7 Related Work

Neural Extractive Summarization Neural networks have shown to be effective in extractive summarization. Past approaches have structured the decision either as binary classification over sentences (Cheng and Lapata, 2016; Nallapati et al., 2017) or classification followed by ranking (Narayan et al., 2018). Zhou et al. (2018) used a seq-to-seq decoder instead. For our model, text compression forms a module largely orthogonal to the extraction module, so additional improvements to extractive modeling might be expected to stack with our approach.

Syntactic Compression Prior to the explosion of neural models for summarization, syntactic compression (Martins and Smith, 2009; Woodsend and Lapata, 2011) was relatively more common. Several systems explored the usage of constituency parses (Berg-Kirkpatrick et al., 2011; Wang et al., 2013; Li et al., 2014) as well as RST-based approaches (Hirao et al., 2013; Durrett et al., 2016). Our approach follows in this vein but could be combined with more sophisticated neural text compression methods as well.

Neural Text Compression Filippova et al. (2015) presented an LSTM approach to deletion-based sentence compression. Miao and Blunsom (2016) proposed a deep generative model for text compression. Zhang et al. (2018) explored the compression module after the extraction model but the separation of these two modules hurt the performance. For this work, we find that relying on syntax gives us more easily understandable and controllable compression options.

Contemporaneously with our work, Mendes et al. (2019) explored an extractive and compressive approach using compression integrated into a sequential decoding process; however, their approach does not leverage explicit syntax and makes several different model design choices.

8 Conclusion

In this work, we presented a neural network framework for extractive and compressive summarization. Our model consists of a sentence extraction model joined with a compression classifier that decides whether or not to delete syntax-derived compression options for each sentence. Training the model involves finding an oracle set of extraction and compression decision with high score, which we do through a combination of a beam search procedure and heuristics. Our model outperforms past work on the CNN/Daily Mail corpus in terms of ROUGE, achieves substantial gains over the extractive model, and appears to have acceptable grammaticality according to human evaluations.

Abstract

Text style transfer without parallel data has achieved some practical success. However, in the scenario where less data is available, these methods may yield poor performance. In this paper, we examine domain adaptation for text style transfer to leverage massively available data from other domains. These data may demonstrate domain shift, which impedes the benefits of utilizing such data for training. To address this challenge, we propose simple yet effective domain adaptive text style transfer models, enabling domain-adaptive information exchange. The proposed models presumably learn from the source domain to: (i) distinguish stylized information and generic content information; (ii) maximally preserve content information; and (iii) adaptively transfer the styles in a domain-aware manner. We evaluate the proposed models on two style transfer tasks (sentiment and formality) over multiple target domains where only limited non-parallel data is available. Extensive experiments demonstrate the effectiveness of the proposed model compared to the baselines.

1 Introduction

Text style transfer, which aims to edit an input sentence with the desired style while preserving style-irrelevant content, has received increasing attention in recent years. It has been applied successfully to stylized image captioning (Gan et al., 2017), personalized conversational response generation (Zhang et al., 2018a), formalized writing (Rao and Tetreault, 2018), offensive to non-offensive language transfer (dos Santos et al., 2018), and other stylized text generation tasks (Akama et al., 2017; Zhang et al., 2019).

Text style transfer has been explored as a sequence-to-sequence learning task using parallel datasets (Jhamtani et al., 2017). However, parallel datasets are often not available, and hand-annotating sentences in different styles is expensive. The recent surge of deep generative models (Kingma and Welling, 2013; Goodfellow et al., 2014) has spurred progress in text style transfer without parallel data by learning disentanglement (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018; Li et al., 2018; Prabhumoye et al., 2018). These methods typically require massive amounts of data (Subramanian et al., 2018), and may perform poorly in limited data scenarios.

A natural solution to the data-scarcity issue is to resort to massive data from other domains. However, directly leveraging abundant data from other domains is problematic due to the discrepancies in data distribution on different domains. Different domains generally manifest themselves in domain-specific lexica. For example, sentiment adjectives such as "*delicious*", "*tasty*", and "*disgusting*" in restaurant reviews might be out of place in movie reviews, where the sentiment words such as "*imaginative*", "*hilarious*", and "*dramatic*" are more typical. Domain shift (Gretton et al., 2009) is thus apt to result in feature misalignment.

In this work, we take up the problem of domain adaptation in scenarios where the target domain data is scarce and misaligned with the distribution in the source domain. Our goal is to achieve successful style transfer into the target domain, with the help of the source domain, while the transferred sentences carry relevant characteristics in the target domain.

We present two first-of-their-kind domain adaptive text style transfer models that facilitate domain-adaptive information exchange between the source and target domains. These models effectively learn generic content information and distinguish domain-specific information. Generic content information, primarily captured by modeling a large corpus from the source domain, fa-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 3304–3313,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

cilitates better content preservation on the target domain. Meanwhile, domain-specific information, implicitly imposed by domain vectors and domain-specific style classifiers, underpins the transferred sentences by generating target-specific lexical terms.

Our contributions in this paper are threefold: (i) We explore a challenging domain adaptation problem for text style transfer by leveraging massively-available data from other domains. (ii) We introduce simple text style transfer models that preserve content and meanwhile translate text adaptively into target-domain-specific terms. (iii) We demonstrate through extensive experiments the robustness of these methods for style transfer tasks (sentiment and formality) on multiple target domains where only limited non-parallel data is available. Our implementation is available at https://github.com/cookielee77/DAST.

2 Related Work

Text Style Transfer. Text style transfer using neural networks has been widely studied in the past few years. A common paradigm is to first disentangle latent space as content and style features, and then generate stylistic sentences by tweaking the style-relevant features and passing through a decoder. Hu et al. (2017); Fu et al. (2018); Shen et al. (2017); Yang et al. (2018); Gong et al. (2019); Lin et al. (2017) explored this direction by assuming the disentanglement can be achieved in an auto-encoding procedure with a suitable style regularization, implemented by either adversarial discriminators or style classifiers. Li et al. (2018); Xu et al. (2018); Zhang et al. (2018c) achieved disentanglement by filtering the stylistic words of input sentences. Recently, Prabhumoye et al. (2018) has proposed to use back-translation for text style transfer with a de-noising auto-encoding objective (Logeswaran et al., 2018; Subramanian et al., 2018). Our work differs in that we leverage domain adaptation to deal with limited target domain data, whereas previous methods require massive target domain style-labelled samples.

Domain Adaptation. Domain adaptation has been studied in various natural language processing tasks, such as sentiment classification (Qu et al., 2019), dialogue system (Wen et al., 2016), abstractive summarization (Hua and Wang, 2017; Zhang et al., 2018b), machine translation (Koehn and Schroeder, 2007; Axelrod et al., 2011; Sennrich et al., 2016b; Michel and Neubig, 2018), etc. However, little or no work explores domain adaptation on text style transfer. To the best of our knowledge, we are the first to explore the adaptation of text style transfer models to a new domain with limited non-parallel data available. The task requires both style transfer and domain-specific generation on the target domain. To differentiate different domains, Sennrich et al. (2016a); Chu et al. (2017) appended domain tokens to the input sentences. Our model uses learnable domain vectors combining domain-specific style classifiers, which force the model to learn distinct stylized information in each domain.

3 Preliminary

We first describe a standard text style transfer approach, which only considers data in the target domain. We limit our discussion to the scenario where only non-parallel data is available, since large amounts of parallel data is typically not feasible.

Given a set of style-labelled sentences $\mathcal{T} = \{(x_i, l_i)\}_{i=1}^{N}$ in the target domain, the goal is to transfer sentence x_i with style l_i to a sentence $\widetilde{x}_i$ with another style $\widetilde{l}_i$, where $\widetilde{l}_i \neq l_i$. $l_i, \widetilde{l}_i$ belong to a set of style labels $l^{\mathcal{T}}$ in the target domain: $l_i, \widetilde{l}_i \in l^{\mathcal{T}}$. Typically, an encoder encodes the input x_i to a semantic representation c_i, while a decoder controls or modifies the stylistic property and decodes the sentence $\widetilde{x}_i$ based on c_i and the pre-specific style $\widetilde{l}_i$.

Specifically, we denote an encoder-decoder model as (E, D). The semantic representation c_i of sentence x_i is extracted by the encoder E, i.e., $c_i = E(x_i)$. The decoder D aims to learn a conditional distribution of $\widetilde{x}_i$ given the semantic representation c_i and style $\widetilde{l}_i$:

$$p_D(\widetilde{x}_i|c_i, \widetilde{l}_i) = \prod_{t=1}^{T} p_D(\widetilde{x}_i^t|\widetilde{x}_i^{<t}, c_i, \widetilde{l}_i), \quad (1)$$

where $\widetilde{x}_i^t$ is the t^{th} token of $\widetilde{x}_i$, and $\widetilde{x}_i^{<t}$ is the prefix of $\widetilde{x}_i$ up to the t^{th} token.

Directly estimating Eqn. (1) is impractical during training due to a lack of parallel data $(x_i, \widetilde{x}_i)$. Alternatively, the original sentence x_i should have high probability under the conditional distribution $p_D(x_i|c_i, l_i)$. Thus, an auto-encoding reconstruc-

tion loss could be formulated as:

$$L_{ae}^{\mathcal{T}} = - \mathop{\mathbb{E}}_{x_i \sim \mathcal{T}} \log p_D(x_i|c_i, l_i)\,. \quad (2)$$

Note that we assume that the decoder D recovers x_i's original stylistic property as accurate as possible when given the style label l_i. To achieve text style transfer, the decoder manipulates the style of generated sentences by replacing l_i with a desired style $\widetilde{l}_i$. Specifically, the generated sentence $\widetilde{x}_i$ is sampled from $\widetilde{x}_i \sim p_D(\widetilde{x}_i|c_i, \widetilde{l}_i)$. However, by directly optimizing Eqn. (2), the encoder-decoder model tends to ignoring the style labels and collapses to a reconstruction model, which might simply copy the input sentence, hence fails to transfer the style. To force the model to learn meaningful style properties, Hu et al. (2017, 2018) apply a style classifier for the style regularization. The style classifier ensures the encoder-decoder model to transfer $\widetilde{x}_i$ with its correct style label $\widetilde{l}_i$:

$$L_{style}^{\mathcal{T}} = - \mathop{\mathbb{E}}_{\widetilde{x}_i \sim p_D(\widetilde{x}_i|c_i, \widetilde{l}_i)} \log P_{C^{\mathcal{T}}}(\widetilde{l}_i|\widetilde{x}_i)\,, \quad (3)$$

where $C^{\mathcal{T}}$ is the style classifier pretrained on the target domain. The overall training objective for text style transfer within the target domain $\mathcal{T}$ is written as:

$$L^{\mathcal{T}} = L_{ae}^{\mathcal{T}} + L_{style}^{\mathcal{T}}\,. \quad (4)$$

4 Domain Adaptive Text Style Transfer

In this section, we present Domain Adaptive Style Transfer (DAST) models to perform style transfer on a target domain by borrowing the strength from a source domain, while maintaining the transfer to be domain-specific.

4.1 Problem Definition

Suppose we have two sets of style-labelled sentences $\mathcal{S} = \{(x'_i, l'_i)\}_{i=1}^{N'}$, $\mathcal{T} = \{(x_i, l_i)\}_{i=1}^{N}$ in the source domain $\mathcal{S}$ and the target domain $\mathcal{T}$, respectively. x'_i denotes the i^{th} source sentence. l'_i denotes the corresponding style label, which belongs to a source style label set: $l'_i \in l^{\mathcal{S}}$ (e.g., positive/negative). l'_i can be available or unknown. Likewise, pair (x_i, l_i) represents the sentence and style label in the target domain, where $l_i \in l^{\mathcal{T}}$.

We consider domain adaptation in two settings: (i) the source style $l^{\mathcal{S}}$ is unknown, e.g., we may have a large corpus, such as Yahoo! Answers, but the underlying style for each sample is not available; (ii) the source styles are available, and are the same as the target styles, i.e., $l^{\mathcal{T}} = l^{\mathcal{S}}$, e.g., both IMDB movie reviews and Yelp restaurant reviews have the same style classes (negative and positive sentiments).

In both scenarios, we assume that the target domain $\mathcal{T}$ only has limited non-parallel data. With the help of source domain data $\mathcal{S}$, the goal is to transfer (x_i, l_i) to $(\widetilde{x}_i, \widetilde{l}_i)$ in the target domain. The transferred sentence $\widetilde{x}_i$ should simultaneously hold: (i) the main content with x_i, (ii) a different style $\widetilde{l}_i$ from l_i, and (iii) domain-specific characteristics of the target data distribution $\mathcal{T}$.

4.2 DAST with unknown-stylized source data

In this section, we investigate the case that the source style $l^{\mathcal{S}}$ is unknown. We first examine a drawback of limited target data to motivate our method. With limited target data, Eqn. (4) may yield an undesirable transferred text, where the generated text tends to use the most discriminative words that the target style prefers while ignoring the content. This is because the classifier $C^{\mathcal{T}}$ typically requires less data to train than a sequence autoencoder (E, D). The classifier objective $L_{style}^{\mathcal{T}}$ thus dominates Eqn. (4), rendering the generator to bias the sentences with most representative stylized (e.g., positive or negative) words rather than preserving the contents (see Table 5 for examples).

We consider alleviating this issue by leveraging massive source domain data to enhance the content-preserving ability, though the underlying styles in the source domain are unknown. By jointly training an auto-encoder on both the source and target domain data, the learned generic content information enables the model to yield better content preservation on the target domain.

To utilize the source data, we consider that $l^{\mathcal{S}}$ only contains a special unknown-style label l^u, separated from the target style $l^{\mathcal{T}}$. We assume the semantic representation of the source data c'_i is encoded by the encoder, i.e., $c'_i = E(x'_i)$. The decoder takes c'_i with style l^u to generate the sentences on the source domain. The auto-encoding reconstruction objective of the source domain is:

$$L_{ae}^{\mathcal{S}} = - \mathop{\mathbb{E}}_{x'_i \sim \mathcal{S}} \log p_D(x'_i|c'_i, l^u), \quad (5)$$

where the encoder-decoder model (E, D) is shared in both domains. Therefore, the corresponding objective can be written as:

$$L_{\text{DAST-C}} = L_{ae}^{\mathcal{T}} + L_{style}^{\mathcal{T}} + L_{ae}^{\mathcal{S}}\,. \quad (6)$$

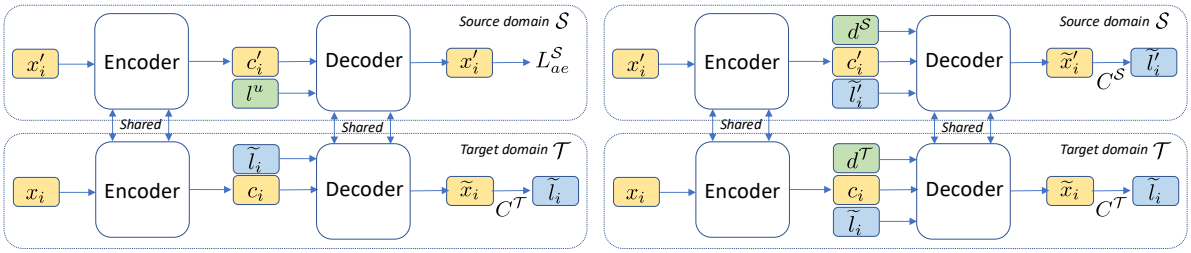

Figure 1: Illustration of the proposed **DAST-C** (left) and **DAST** (right) model. DAST-C learns the generic content information through $L_{ae}^{\mathcal{S}}$ on massive source domain data with unknown style l^u. For DAST, $d^{\mathcal{T}}, d^{\mathcal{S}}$ and $C^{\mathcal{T}}, C^{\mathcal{S}}$ denote domain vectors and domain-specific style classifiers, respectively. Better looked in color.

This can be perceived as combining the source domain data with the target domain data to train a better encoder-decoder framework, while target-specific style information on the target domain is learned through $L_{style}^{\mathcal{T}}$.

Note that $L_{ae}^{\mathcal{T}}$ and $L_{ae}^{\mathcal{S}}$ are conditional on domain-specific styles labels: $l^{\mathcal{T}}$ and l^u, which implicitly encourages the model to learn domain-specific features. The decoder could thus generate target sentences adaptively with $l^{\mathcal{T}}$, while achieving favorable content preservation with the generic content information modeled by $L_{ae}^{\mathcal{S}}$. We refer this model, which is illustrated in Figure 1(left), as *Domain Adaptive Style Transfer with generic Content preservation (DAST-C)*.

4.3 DAST with stylized source data

We further explore the scenario where $l^{\mathcal{S}} = l^{\mathcal{T}}$. In this case, besides the generic content information, there is much style information from the source domain that could be leveraged, e.g., generic stylized expressions like "*fantastic*" and "*terrible*" for sentiment transfer can be applied to both restaurant and movie reviews. We thus consider to borrow the full strength of the source data, by sharing learned knowledge on both the generic content and style information.

A straightforward way to achieve this is to train Eqn. (4) on both domains. However, simply mixing the two domains together will lead to undesirable style transfers, where the transfer is not domain-specific. For example, when adapting the IMDB movie reviews to the Yelp restaurant reviews, directly sharing the style transfer model without specifying the domain will inevitably result in generations like *"The pizza is dramatic!"*.

To alleviate this problem, we introduce additional domain vectors, encouraging the model to perform style transfer in a domain-aware manner. The proposed DAST model is illustrated in Figure 1(right). Consider two domain vectors: $d^{\mathcal{S}}$ for the source domain and $d^{\mathcal{T}}$ for the target domain, respectively. We rewrite the auto-encoding loss as:

$$\begin{aligned} L_{ae}^{\mathcal{S},\mathcal{T}} = &- \mathop{\mathbb{E}}_{x'_i \sim \mathcal{S}} \log p_D(x'_i | c'_i, d^{\mathcal{S}}, l'_i) \\ &- \mathop{\mathbb{E}}_{x_i \sim \mathcal{T}} \log p_D(x_i | c_i, d^{\mathcal{T}}, l_i)\,, \end{aligned} \tag{7}$$
