Abstract

Gang-involved youth in cities such as Chicago sometimes post on social media to express their aggression towards rival gangs and previous research has demonstrated that a deep learning approach can predict aggression and loss in posts. To address the possibility of bias in this sensitive application, we developed an approach to systematically interpret the state of the art model. We found, surprisingly, that it frequently bases its predictions on stop words such as "a" or "on", an approach that could harm social media users who have no aggressive intentions. To tackle this bias, domain experts annotated the rationales, highlighting words that explain why a tweet is labeled as "aggression". These new annotations enable us to quantitatively measure how justified the model predictions are, and build models that drastically reduce bias. Our study shows that in high stake scenarios, accuracy alone cannot guarantee a good system and we need new evaluation methods.

1 Introduction

There has been increased interest in using natural language processing to help understand the root causes of violence in cities such as Chicago. Researchers in social work found that posts on social media by gang-involved youth mirror their life on the physical street (Patton et al., 2016, 2017) and suggested that if community outreach workers could use tools to help identify posts of aggression and grief, they could intervene before grief turns to retribution and help avert violence. Early research in this area (Blevins et al., 2016) used support vector machines for the three-way classification task of *aggression*, *loss* and *other* and recent work (Chang et al., 2018) demonstrated a significant increase in accuracy through the use of a neural net approach along with the representation of contextual information from previous conversations. In both of these approaches, computer scientists and social work researchers worked side by side to enable qualitative analysis of the data to use in machine learning and to provide meaningful error analyses.

Given the interest in using this work in a live setting to identify situations where community outreach workers could intervene, we are concerned with *how* the model makes the decision. This is especially important since this is a high stakes domain and machine learning systems are known to incorporate bias. For example, the COMPAS Recidivism Algorithm, which assesses the likelihood of a criminal defendant to re-offend and influences judges' sentencing decisions, is known to be biased against African Americans (Feller et al., 2016). To avoid similar errors in the gang-violence application, we examined whether the model is biased through systematic investigation of how the model makes the predictions. Since misclassifying a tweet as *aggression* might potentially criminalize a vulnerable population (young black and latino youth) that is already over criminalized, we focus on classification of the *aggression* class in our paper.

Our finding is surprising: in at least 10% of the cases the Chang et al. (2018) model relies on stop words such as "a" and "on" to classify a tweet as aggression; these words carry no semantic or pragmatic indication of aggression or loss. We recognized that there might be more hidden biases, so we developed novel metrics to quantitatively compare the difference between how humans and models make their classification. To achieve this, we ask domain experts to annotate the rationale for the aggression tweets by highlighting words and phrases that indicate why experts classify them as

The first author is now a PhD student at University of California, Berkeley.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4765–4775, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

aggression. We compare the rationale against the models' interpretation.

We also develop a model to incorporate human rationales, and show that the system can make predictions based on similar reasons to those of domain experts. Our F-score is slightly improved over Chang et al. (2018) and we are able to reduce the bias drastically. We show how important this is by using an adversarial approach which demonstrates that we can change the prediction of posts predicted as *other* to *aggression* by the simple insertion of the non-offending function words. This implies that high F-score alone does not guarantee a good system, and that researchers in other high stakes domain should evaluate their algorithms from various angles.

Our contributions include:

- A validated finding that the previous state-of-the-art model is biased.
- A rich dataset created by domain experts containing annotated human rationales.
- New metrics to evaluate models' robustness under adversary, and the difference between model interpretations and human rationales.
- A model that incorporates human rationales in training and behaves more as humans do.

We also include an in-depth discussion on how misinterpretation might emerge when labels are being annotated by the experts. The battle against bias is far from solved, and we hope our insights and methodologies can guide future research in high stakes domains.

2 Revealing Model Biases

We used the code and data from Chang et al. (2018) and fully reproduced the state-of-the-art model that uses a Convolutional Neural Network, domain specific word embeddings and context features.

2.1 Locating Biases

We examine the model using the simple leave-one-out method similar to Ribeiro et al. (2016). Suppose each tweet T is a sequence of l tokens $[e_1, e_2...e_l]$ and the model gives the prediction confidence score y. For each token e_i, we calculate the model's prediction confidence y_{-i} on the same tweet with e_i masked as an unknown word; hence the influence of the i^{th} token I_i is approximated by $I_i = y - y_{-i}$. Then we manually examine the top two influential uni-grams for each tweet that the model classified as aggression.

As we expect, tokens strongly associated with aggression, such as "[redacted]", "dead" and many other curse words appear frequently as the most influential tokens. However, surprisingly, words such as "a" and "on" are frequently considered the most influential by the model as well. Out of 419 tweets that the model classifies as aggression, 15/32 times the model considers the token "a" to be the top first or second most influential token and "on" 24/51 times the top first or second, respectively. We also found that the model is biased against other stop words, such as "into" and "of". This indicates that more than **10%** of the time the model heavily relies on these unintentional differences of language use to classify tweets as aggression!

2.2 Confirming Biases Exist

Initially, we found this unexpected result surprising, so we checked the second order sensitivity (Feng et al., 2018) and constructed adversarial data sets.

Second Order Consistency Feng et al. (2018) defined this term when they found that the leave-one(token)-out (LOO) method might find a completely different set of most influential words if the most un-influential word is dropped from the sentence. However, we do not observe this problem in our case: out of 419 predictions, 379 times the most influential word remains the most influential and 33 times it becomes the second most influential one after we drop the most un-influential words.

Adversarial Dataset If we can identify a weakness of the model, we must be able to break it in a corresponding way. To manifest that there is indeed bias against "a" and "on," for each of these two words, we inserted it in each labeled tweet and counted the number of times the model changes its prediction from non-aggression to aggression.

To ensure that our insertions are natural, we trained a large language model (Peters et al., 2018) on the unlabeled corpus ($\sim$ 1 million tweets) used by Chang et al. (2018), and score the naturalness of the insertion by the change of perplexity given by the language model. For each tweet we calculate the most "natural" position to insert our biased word and only took the top 800 natural

tweets out of $\sim$ 7000 candidates as our adversarial dataset. We also subsample this dataset and check the subsample manually to make sure that these insertions make sense. In fact, since most tweets in the dataset are grammatically flexible in the first place, our insertion methods usually do not make them more unnatural - we have fewer constraints than adversarial attacks (Alzantot et al., 2018) conducted in domains such as IMDB reviews (Maas et al., 2011) or Textual Entailment (Bowman et al., 2015).

We find that even with these naive and seemingly harmless insertions, the model changes the prediction from non-aggression to aggression for about 3%/5% of the generated tweets when inserting "a"/"on". With this overwhelming evidence, we conclude that the model is biased.

The simplest way to fix this specific bias is a post-mortem one - just remove "a" and "on" in training and prediction. However, this only works if these are the only two points of bias and we suspect that there are many more biases lurking in the model. Hence, we need to comprehensively study the difference between how humans and models make their decision. We need a new dataset with annotated human rationales to achieve this goal.

3 Data

We use the same dataset and cross validation folds as in Chang et al. (2018), which contains 329 Aggression tweets, 734 Loss tweets, with the Other class comprising the remaining 3,873 tweets. The language in the dataset is hyper-local to the community we are studying and differs significantly from standard American English. Therefore, most of the toolkits (e.g. pre-trained language models, parsers, etc) developed for standard English do not apply. We extend their dataset by asking domain experts to annotate the rationales and additional information on context for each of the tweets labeled as aggression. Below is the set of annotation instructions.

- **Rationales in Tweets** We ask the domain experts to annotate the most important word/words (rationales) in the tweet that makes them think the tweet is aggression/loss; or say, the removal of which would make them not consider it as an aggressive tweet. We ask them to annotate the "minimum set of words" that is important for their final decision, thus excluding words that are not very meaningful, such as "on", "basically", "lol", etc. Examples are shown in Table 1.

- **Aggressive by Context** Sometimes the tweet itself does not contain aggressive content if we interpret them at face level, but placing it into context reveals that the user in fact conveyed aggressive intent. We ask the experts to label this attribute as True whenever they use an outside source to provide additional information needed to label a tweet. These sources can include news sources, past posts, interactions, online dictionaries, or reddit threads.

- **Aggressive by Mention/Retweet** Similarly, interactions between users that are suspected to be affiliated with the same or rival gangs might contain aggressive intent. For example, users may communicate with others in the same gang about the possibility of retaliation or they may directly taunt members of rival gangs. We ask the annotators to label this attribute as True if the context of interaction between users contributes to the aggression label. This corresponds to the pairwise interaction feature in Chang et al. (2018).

- **Aggressive by Picture/URL** This attribute indicates whether the picture or URL in the tweet contains aggressive content. Since our study is natural language processing based, we do not make use of this piece of information in this paper.

- **Controversial Labels** Occasionally our experts would interpret a tweet previously considered aggressive as non-aggressive. We do not use these labels in our experiments for fair comparison with Chang et al. (2018), but we include them in our new dataset.

Out of the 329 aggression tweets, 274 contain rationales in the tweet, while the other aggression labels are inferred by context rather than the content within the tweet itself. To keep notations uncluttered, we refer to all the "aggressive by *" labels as *context labels* in the rest of this paper. The meta-statistics on this can be seen in table 2. Additionally, 39 (12% of aggression) tweets are considered controversial by our experts. We also ask the annotator to write down thoughts and observa-

Tweets
"@user_ do you think it's cool yo ass slow ? You sound dumb asf"
"Rob you fucking goofys that got some to say about rage just to show y'all bitches"
"GlizzyGang Bitch We Got Out Glocks Up😈"

Table 1: Typical aggression tweets in our dataset, which includes annotations with human rationales (underlined).

tions while annotating, and we share these insights in our discussion section. [1]

Context Label Types	Yes	No	N/A
Context	107	74	148
Mention/Retweet	36	35	258
URL	9	3	317
Picture	14	15	300

Table 2: Whether aggressive intent is observed in Context, Mention/Retweet, URL and/or Picture. Many of the context label cannot be annotated due to Twitter access policy.

4 Methods

We compare the Convolutional Neural Network (CNN) model from Chang et al. (2018), an LSTM (Long Short Term Memory) Network model with attention mechanism (architecture defined below) and our new model that incorporates rationales by trained attention (Zhong et al., 2019).[2]

4.1 Overview of Chang et al. (2018)

Here we give a quick overview of their CNN model with context features. Let l denote the length of the pre-processed tweet, $T = [e_1, e_2 ... e_l]$ be the input sequence, and c the context feature. First each token e_i is mapped to an embedded representation w_i through their domain specific word embeddings. Then they used a convolution layer with kernel size 1 and 2, followed by a maxpooling layer and a linear fully connected layer to produce the tweet representation z. Finally, they concatenated z with the context feature c and fed it to the final classification layer. We refer the readers to their original paper for further details.

4.2 LSTM with Attention

We use a standard LSTM model with attention mechanism. The model encodes the embedded sequence $[w_1, w_2, ..., w_l]$ with an LSTM to obtain hidden state representation h_i with hidden dimension 64 for each position i and then calculate an attention weight for each position based on h_i. The final representation z is a weighted average of the hidden states concatentated with the context feature, which we pass to the final classification layer. Formally,

$$\alpha_i = tanh(\mathbf{v}h_i), A(i) = \frac{e^{\alpha_i}}{\sum_j e^{\alpha_j}} \quad (1)$$

$$z = [\sum_{i=1}^{l} A(i)h_i, c] \quad (2)$$

where $\mathbf{v}$ are trainable weights we used to calculate the attention. We used binary cross entropy loss between the final prediction and the ground truth label, which we denote as $\mathcal{L}_{clf}$

4.3 Trained Attention with Rationale

We guide the model attention to attend to human rationales. We introduce a "ground truth attention" A^*, which is uniformly distributed over all the positions where the token is an annotated rationale. For example, if $R = \{r_1, r_2 \dots r_d\}$ are indexes of the tokens that are rationale words, then the ground truth attention distribution A^* is defined as:

$$A^*(i) = \frac{1}{d} \text{ if } i \in R, 0 \text{ otherwise} \quad (3)$$

Then we impose a KL divergence loss component between the ground truth attention and the model's attention. We optimize the weighted sum between the label classification and the attention loss, i.e.

$$\mathcal{L}_{attn} = KL(A^*||A), \mathcal{L} = \mathcal{L}_{clf} + \lambda_{attn}\mathcal{L}_{attn} \quad (4)$$

where we fix $\lambda_{attn} = 4$ after tuning.

To make a fair comparison with Chang et al. (2018), we use the same set of hyper-parameters and training procedures. We find that taking the majority vote of an ensemble of 5 neural networks trained on the same data can improve the F-score by 1∼2 points, so we report both the averaged and the majority vote result across 5 independent

[1] Due to privacy concerns we cannot release the additional annotation publicly, but we will make it available to researchers who sign an MOU specifying their intended use of the data and their agreement with our ethical guidelines. Send email to the dp2787@columbia.edu. Please contact the authors of Chang et al. (2018) for the original dataset.

[2] Our code is publicly available at https://github.com/David3384/GI_2019

runs. We also experiment with representations from a large scale language model trained on our unlabeled corpus (Peters et al., 2018), but it only brought marginal improvements. For simplicity we do not include these experiments in our paper.

5 Evaluation Metrics

Besides the macro F-score in (Chang et al., 2018), we use rationale rank to characterize the difference between how humans and models make the decisions. We also quantitatively evaluate how the model uses the context feature. For fair comparison, we used the same labels as in (Chang et al., 2018) even though some labels are re-labeled as "controversial".

5.1 Rationale Rank

We first use the leave-one-out-method to approximate the influence I_i of each token e_i as documented in section 2.1. If the model makes predictions based on similar rationale words as human, I_i should be large when e_i is a rationale word, and should be small when e_i is not a rationale. Therefore, a rationale word should have lower ranks if all the tokens are sorted by its influence on model's prediction in descending order. We define the influence rank of the i^{th} token $rank(i)$ as the number of tokens in the tweet that have higher influence score than the i^{th} token.

We further relax our requirement for the model: we do not have the unrealistic hope that the model is relying on every rationale word; instead, we only consider the lowest ranking rationale. Formally, suppose there are multiple rationale words with indexes $R = \{r_1, r_2..r_d\}$, then we define the "rationale rank" as:

$$rationalerank = min_{i \in R} rank(i) \quad (5)$$

We calculate the average rationale rank for all tweets that are classified as aggression and have rationale annotations on the cross validation test set for each fold.

Since the majority of tweets usually has rationale rank 0, the averaged rationale rank is small and the difference between each model is "diluted" by the prevailing zeros. Therefore, for each model, we also report the percentage of tweets that has rationale 0 or 1, respectively. This more intuitively reflects on what fraction of the tweets the models' reasoning agrees with human rationales.

5.2 Context Feature Evaluation

Chang et al. (2018) claimed that their pair-wise interaction feature captures information about users' past interactions, and they supported it by showing significant improvement when incorporating it into the CNN model. Nevertheless, it does not automatically entail that the model is using this feature in a way that humans do. Here we examine this claim quantitatively with our annotated interpretation of context.

Chang et al. (2018) concatenated the context features before the final classification softmax layer, so we can directly calculate the impact of a context feature by taking its dot product with the corresponding weight learned by the model. Formally, let c_1 be the "emotional state" feature, c_2 the "user history", c_3 the "pair-wise user interaction" and the pooled tweet representation is z, then the final prediction score is given by:

$$y = \sigma(w_z z + \sum_{i=1}^{3} w_i c_i + b) \quad (6)$$

where, $w_{(\cdot)}$ are trainable weights and b the bias term.

We group the tweets by the annotated context label "by mention/retweet", a single label, annotated as described in section 3. If the pair-wise interaction feature c_3 truly models domain experts' interpretation of user interaction as Chang et al. (2018) has hypothesized, $w_3 c_3$ should be higher for those tweets that are annotated as "aggressive by mention/retweet" than those that are not. We do not examine use of other context labels and features, since other context features do not model URL, pictures or a general type of context.

6 Prediction Flips under Adversary

6.1 Generating Adversarial Tweets

We consider the simplest operation: inserting certain candidate neutral unigrams $u \in U = \{$ "a", "on", "da", "into", "of", "that"$\}$ that the model strongly associates with aggression. [3] Assuming that we have already trained a language model that gives a perplexity score $p(T)$ for a tweet $T = [e_1, e_2, \ldots e_l]$, then for each $u \in U$ we create a

[3] We describe how we choose these unigrams in the appendix A.2. We also experimented with "in", "be", "do", "any", "u", "out", "basically", "yea", "ever", "UP", "👉", "we" etc, but the results are not significant so we present them in the appendix.

dataset by inserting it into all of the tweets T in our labeled dataset $\mathcal{T}$. We describe how we train the language model in the appendix section A.1.

For each $T \in \mathcal{T}$, there are $|T| + 1$ positions to insert the unigram u. We pick the resulting tweet T' with u inserted that has the highest likelihood score $p(T')$ among all the $|T| + 1$ possible insertions, and calculate the corresponding "insertion naturalness score" $p(T') - p(T)$. After inserting the unigram u into all the tweets in the labeled dataset $\mathcal{T}$, we obtain a corresponding dataset $\mathcal{T}'$ and pick the top 800 tweets that have the highest "insertion naturalness score".

Then we calculate how many times a model would flip its prediction from non-aggression to aggression among these 800 pairs of tweets, before and after inserting the unigram u. Notice that even one percent of "flip rate" is significant: the unigrams u we consider here are not rare words and thus have high coverage. If the model is deployed at a large scale, millions of tweet will be classified, and tens of thousands of tweets will be influenced, not mentioning that we are considering only one unigram and there are many potential other tokens biased by the model.

6.2 Evaluating Generation Naturalness

Since words are discrete, generating adversarial text inputs has been a hard problem in other domains for at least two reasons: 1) one perturbation might be large enough to change the label. 2) we cannot guarantee that the resulting text is still a natural input. However, these challenges do not play much of a role in our domain. First, the candidate words we are inserting are "function words", which we know should not cause the model to flip their predictions. Second, the large proportion of tweets we are working with are grammatically flexible in the first place. Therefore, in contrast to genres that follow the conventions of Standard American English grammar, we suspect that adding function words will not make the tweets look unnatural to the domain experts and we test this hypothesis.

To evaluate the plausibility of our generated tweets, we sample 18 tweets from all the generated tweets and 18 existing tweets from our labeled dataset. Then we ask our experts to try their best to classify whether each tweet comes from model generation or the existing dataset. We also ask them to annotate whether each tweet is "natural", "reasonable but awkward" or "nonsensical".

The experts classified 25 of them correctly ($\sim 70\%$), only slightly better than the 50% random guess baseline even though they are aware that we are generating tweets by inserting function words. Out of 18 generated tweets, they considered 7 as "natural", 8 "reasonable but awkward" and 3 as "non-sensical". In comparison, out of the 18 existing tweets, they considered 14 as "natural", 1 as "reasonable but awkward" and 3 as "non-sensical." These results imply that although our generated tweets might not all be fluent, they are still reasonable enough as adversarial tweets. Interestingly, they also considered 3 existing tweets as "non-sensical", partly because the tweets are highly grammatically flexible and we told them that there are generated tweets.

7 Results

The model F-score performances are shown in table 3 and rationale rank in table 4. We present our results for macro F-score, Rationale Rank, Prediction Flips on Adversarial Dataset and Context Feature Evaluation. We also evaluate the models from (Blevins et al., 2016) for completeness. [4]

F-score We first notice that taking the ensemble of 5 independent runs trained on the same data consistently improves the performance over averaged individual run performance, so we report all of our results on ensemble models. Compared to Chang et al. (2018), our LSTM+Rationale model differs by at most one point on all of the macro-F score metrics, and sometimes achieves the best performance.

Rationale Rank A closer look at the rationale rank result reveals a huge difference (p-value $< 10^{-5}$): our model significantly beats all other models on this metrics.

Prediction Flips under Adversary The results are shown in table 5. For each candidate unigram we count the number of times the model flips its prediction from non-aggression to aggression among the top 800 insertions. By incorporating rationales into the model, we achieve the fewest flips for half of the unigrams and under none of the six cases does it flip the most predictions.

These two results demonstrate that although the CNN model (Chang et al., 2018) only slightly un-

[4] For consistency, we used their model but first classify aggression vs. rest, rather than other vs. rest as in (Blevins et al., 2016). The training procedure is deterministic, so the ensemble gives the same performance as individual ones.

Model	Average Macro F1	Ensemble Agg. F1	Ensemble Loss F1	Ensemble Other F1	Ensemble Macro F1
Blevins et al. (2016)	63.5	34.5	67.3	88.7	63.5
Chang et al. (2018)	**68.2**	41.3	**75.4**	91.3	69.4
CNN + Twitter	65.8	36.2	73.9	91.3	67.1
LSTM	67.0	38.4	74.2	91.3	68.0
LSTM + Rationale	**68.2**	**43.0**	75.0	**91.6**	**69.8**

Table 3: Results comparing different model architectures. Chang et al. (2018) refers to the full CNN model with domain specific embedding and context feature; "CNN Twitter" replaces the domain specific embedding with GloVe twitter embeddings (Pennington et al., 2014); LSTM refers to LSTM Attention described in section 4.2; LSTM Rationale refers to the same LSTM Attention with trained attention described in section 4.3. For each column, the best performing entry is boldered.

Model	Avg RR	RR = 0	RR = 1
Blevins et al. (2016)	1.70	0.60	0.13
Chang et al. (2018)	1.42	0.54	0.17
CNN + Twitter	1.82	0.43	0.25
LSTM	1.73	0.50	0.15
LSTM + Rationale	**0.86**	**0.69**	0.14

Table 4: Results on (averaged) rationale rank (RR), fraction of tweets when RR = 0 and RR = 1, respectively. For (averaged) rationale rank and RR = 0, the best performing entry is boldered. We do not bolder the column RR = 1 since it is sub-optimal.

derperforms our model in terms of F-score performance, it behaves very differently behind the scene. Our model is more robust and makes predictions that match human predictions. This implies that traditional F-score measure alone neither provides us deeper understanding of the model, nor reveals the underlying biases.

Context Feature Evaluation We calculate the correlation between "how the human uses context" and "how the model uses context" as described in section 5.2. The mean difference of $w_3 c_3$ between the two groups split by the label value is 1.61 with statistical significance 10^{-3}, indicating that the pairwise interaction feature correlates well with how domain experts interpret users' retweet/mentions.

8 Related Work

Patton et al. (2013) initiated a new field of study, coining the term *internet banging* to describe the phenomenon whereby online altercations lead to offline violence. This work is further motivated by challenging gun violence statistics in the city of Chicago which saw a 58% spike between 2015 and 2016. In addition, the number of homicides stemming from physical altercations decreased during that period with little empirical evidence to explain this shift (Kapustin et al., 2016). Investigating internet banging represents an important first step in understanding why gun deaths increase despite fewer physical altercations.

Blevins et al. (2016) is a collaboaration between social work and computer science experts that brings together social work's substantive knowledge of communities, youth development, and gun violence with data science's innovative machine learning tools. They developed a new analytical system that leverages community participatory methods and machine learning to automatically detect the expression of loss and aggression on Twitter. Blevins et al. (2016) collected and annotated tweets posted by Gakirah Barnes, a deceased gang members prolific on twitter, as well as her top communicators. Chang et al. (2018) extended this dataset to be six times larger and achieved the state-of-the-art result by using a CNN.

Our interpretability method is most similar to the leave-one-out (LOO) approach by Ribeiro et al. (2016). Nevertheless, it risks making the sentence ungrammatical, hence producing "rubbish examples" (Goodfellow et al., 2014) and pathological interpretations (Feng et al., 2018). We explicitly address this concern by checking the second-order consistency proposed in Feng et al. (2018). To further ensure that the removal of a word results in a "blank state", erasure-based method proposed in Li et al. (2016) can be used. It would also be interesting to explore different interpretability methods, such as using the influence function (Koh and Liang, 2017) or nearest neighbor in the feature space (Strobelt et al., 2019). Our method of automatically generating adversarial data accord-

Models \ Unigrams	a	on	da	into	of	that
Blevins et al. (2016)	44.16[!]	121.00[!]	37.44[!]	117.72[!]	36.84[!]	74.48 [!]
Chang et al. (2018)	26.56	36.00	8.52*	21.68	19.20	7.52*
CNN + Twitter	38.40	35.80	17.60	15.88	5.24*	7.64
LSTM	16.16	40.28	21.52	26.92	13.20	13.12
LSTM + Rationale	13.52*	23.16*	12.40	10.28*	11.40	8.96

Table 5: The number of model's prediction flip from non-aggressive to aggressive, out of the 800 attacking tweets generated by inserting a specified "neutral" unigram. To obtain a stable estimate, the count of number of flips of each model is averaged across 5 model runs and models trained on 5 folds - thus leading to non-integer results. For each column, the worst performing entry is marked with "!" and best with "*".

ing to a pre-identified weakness of a model without accessing the model output and parameters is most similar to Jia and Liang (2017). From Alzantot et al. (2018), we borrowed the idea of using a language model to ensure naturalness of generated sentences, and it is a promising next step to collect natural human-generated adversarial examples (Wallace et al., 2018). In the future, studying white-box (Ebrahimi et al., 2017; Bělohlávek, 2017) and character level attacks (Gröndahl et al., 2018) are important directions to provide additional robustness in this critical domain.

Trained attention was explored in event detection (Liu et al., 2017), machine translation (Mi et al., 2016) and sentiment analysis (Zhong et al., 2019). More sophisticated approaches include deriving attention from human rationales (Yujia Bao, 2018). Finding better ways to make use of this kind of information is a promising avenue, especially in this low-resource domain.

Ensuring machine learning fairness has increasingly caught researchers' attention (Corbett-Davies and Goel, 2018) since algorithms can create concerning negative societal impacts (Feller et al., 2016). Biases might be based on gender (Bolukbasi et al., 2016; Zhao et al., 2017), race (Kiritchenko and Mohammad, 2018; Rudinger et al., 2017), writing styles (Madnani et al., 2017), or other factors. More broadly, bias can also occur when annotators label the data. For example, Golbeck et al. (2017) found it hard to distinguish between mere offensive speech and hate speech.

9 Discussion

9.1 Limitations of the Annotation Instruction

The instructions for annotating rationales in tweets do not fully recognize the complex nature of language. Current annotation reduces the experts' underlying reason to annotate a tweet as aggression to a set of key words, which is not flexible enough to convey more complicated inferences. The experts' analyses are far more complex: they use context to disambiguate the meaning of the rationale words rather than identifying key words. Since the language is hyper-local and many of the non-aggressive tweets might appear aggressive in outsiders' eyes, interpreting the context is a crucial component while determining an aggression label and it is important to develop more flexible context rationale representations in the future.

Take, for example, the post "I talk to alotta Da Guyz In jail Everyday On l'a Dese N***as Ain't Sending Bro Nem A Dime 😒 But Steady Yellin Free Em Goof ass". At face value, the words "😒", "goof", and "ass" per se do not capture the reason why this post is aggressive; the aggression label for this post in fact derives from the poster calling out the dishonesty of those who support incarcerated individuals in principle, without supporting them monetarily.

9.2 Controversial Labels

In the annotation procedure, it can be challenging to choose a single label when users express both anger and grief in a single post. In these instances, we aim to capture and annotate the tweet's dominant theme.

For example, the post "Fuck Da System Fuck Da State Fuck 12z 🖕😔" contains elements of aggression–the word "fuck" and the middle finger emoji–and loss–the sad frown emoji and the post's larger context. This post fits the *aggression* label, by challenging authority and insulting, and the *loss* label, by evoking incarceration. However, a *loss* label is more suitable, because: 1) though the anger seems to target specific players, the text as a whole reveals that the poster is highlighting

institutional violence; and 2) the sad frown emoji, paired with the context that one of the poster's loved ones was recently arrested on a drug charge ("12z" refers to law enforcement's drug unit), cements that the user is grieving in this post.

10 Conclusions and Future Directions

In this paper, we interpret the previous state-of-the-art model, find it is biased against stop words, create a dataset of rationales, develop metrics to measure the difference between how models and humans make predictions, design an adversarial approach to test the robustness of the model, and propose a neural network architecture to incorporate rationales. Our work has an important message to the broader NLP research community that develops tools for high stakes domains: the dominant evaluation methods in current research approaches, F-score and qualitative error analysis, are far from enough to develop good systems that might potentially lead to bad social consequences. We need various different approaches to evaluate and build a model, and each of them requires further research for improvement:

Interpretability: A solid understanding of model behavior can inform researchers of the potential weaknesses and guide the process of developing corresponding solutions. When trying to interpret Chang et al. (2018)'s deep learning model, we find it biased against many function words. Still, interpretation of neural network is an ongoing research topic; even though we verified "second order consistency", future work is needed for better and more faithful explanations.

Robustness under Adversary: It is better to break the system before it is broken when it is deployed. We find the previous model to be susceptible to insertions of certain function words, while our model is more robust against them. Nevertheless, the model is not winning every column in table 5, so there is still room for improvement.

Metrics Evaluating How Predictions are Made: We need to quantitatively evaluate the difference between how models and humans classify tweets. We develop the metrics "rationale rank" and "prediction flips under adversary", and verify that our model behaves more similar to domain experts. F-score does not reflect this important improvement. Additionally, uni-gram (lexical level) influence is only a shallow approximation of human reasoning - a process that involves understanding the semantics of a tweet as a whole and analyzing its pragmatics in the real-world context. Ideally we hope to find a formal language to approximate such a process and compare it against the model's interpretation.

Models that Incorporate Rationales: Our new model, though simple and straightforward, successfully makes use of the rationales and outperforms the previous model under most robustness metrics proposed in this paper; we believe that more sophisticated modeling of rationales can push the performances further, both in terms of accuracy and robustness.

Feature Evaluation: Performance improvement caused by additional features does not entail that they are used by the model in an expected way. We verify the claim of Chang et al. (2018) that the pairwise interaction feature does capture user retweet/mention interactions.

Domain Experts: In our domain, stakes are high and user behavior is frequently subject to biases and misinterpretations. Therefore, we ask domain experts rather than crowd workers to extend the annotation, and ask them to provide further insights about a domain that computer scientists are usually not at all familiar with. Furthermore, we should keep a critical eye on the labels and be aware of the limitations of our evaluation metrics for model accuracy. It is convenient for computer scientists to regard the labels as ground truth, the dataset as static and try different models to improve the f-score. However, as domain experts gained a deeper understanding about the twitter users, they marked 12% of the aggression labels as controversial (section 3); the annotation may evolve over time. Indeed, we need a consistent method and dataset to compare different models fairly, but we should also keep in mind that f-score is a proxy and might not necessarily reflect an improvement in the real-world.

CodeSwitch-Reddit: Exploration of Written Multilingual Discourse in Online Discussion Forums

Ella Rabinovich **Masih Sultani** **Suzanne Stevenson**
Dept. of Computer Science, University of Toronto, Canada
{ella,masih,suzanne}@cs.toronto.edu

Abstract

In contrast to many decades of research on oral code-switching, the study of written multilingual productions has only recently enjoyed a surge of interest. Many open questions remain regarding the sociolinguistic underpinnings of written code-switching, and progress has been limited by a lack of suitable resources. We introduce a novel, large, and diverse dataset of written code-switched productions, curated from topical threads of multiple bilingual communities on the Reddit discussion platform, and explore questions that were mainly addressed in the context of spoken language thus far. We investigate whether findings in oral code-switching concerning content and style, as well as speaker proficiency, are carried over into written code-switching in discussion forums. The released dataset can further facilitate a range of research and practical activities.

1 Introduction

Multilingual communities adopt various communicative strategies that navigate among multiple languages. One of the most notable of such strategies is *code-switching* (CS) – when a bilingual mixes two or more languages within a discourse, or even within a single utterance, as in:

εγώ θα το ήθελα, θα ήταν το guilty pleasure μου
[*I would like it, it would be my* guilty pleasure]

The sociolinguistic underpinnings of code-switching as an *oral* conversational strategy have been investigated extensively for many decades. The purposes of oral CS have been shown to range from practical considerations of domain-specific lexical knowledge, to indications of register and nuanced meanings (see Gardner-Chloros, 2009, for a recent review). Oral code-switching is thus known to be a multifaceted component of successful communication in a multilingual community, interacting with factors of speaker proficiency, and both style and content of utterances.

By contrast, the analysis of *written* code-switching has only recently enjoyed a surge of interest, and remains seriously under-studied (Sebba et al., 2012). Written text often differs greatly from conversation in its levels of both spontaneity and formality, and findings thus far have differed in their conclusions regarding the extent to which various genres of written text reflect the same communicative functions of CS as observed in oral conversation (e.g., McClure, 2001; Chan, 2009; Gardner-Chloros and Weston, 2015).

The growing popularity of social media and online discussion platforms poses both opportunities and new research questions regarding written code-switching. Global online forums, in which English is a lingua franca, not only draw on but create wide-reaching multilingual communities. The resulting communications lead to a wealth of data that potentially includes a large amount of code-switching across multiple language pairs (e.g., Solorio et al., 2014; Diab et al., 2016; Aguilar et al., 2018b). Moreover, communication on discussion platforms often resembles a hybrid between speech and more formal writing (Sebba, 2013). These differing characteristics lead to new research questions regarding the extent to which findings from oral CS carry over to these online interactions.

Research is only just beginning to grapple with these issues. Computational work on code-switching in online venues has largely focused on the practical challenges that multiple interleaved languages pose to the application of standard NLP tools (as reviewed in Çetinoğlu et al., 2016), rather than on the communicative purposes of CS. More broadly, computational investigation of the sociolinguistic aspects of written CS is dominated by studies conducted with a limited number of

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4776–4786,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

language-pairs and/or authors (e.g., Sebba et al., 2012), thereby constraining the nature of questions that can be addressed with this data.

Our work here seeks to address these gaps in the study of code-switching in online interactions. We begin by introducing the *CodeSwitch-Reddit* corpus:[1] a novel, large, and diverse dataset of written code-switched productions, carefully curated from topical threads of multiple (including understudied) bilingual communities on the Reddit discussion platform.[2] The main corpus comprises over 135K code-switched messages by over 20K unique authors, spanning five language-pairs, with average post length of 75 tokens.

The uniform nature of our data (written communication from a single online discussion platform), as well as its ample size, pose novel opportunities for large-scale empirical investigation of research questions on code-switching – questions that have thus far been mainly addressed in the context of oral language. As a first study, here we explore fundamental questions about both the content and style of code-switched posts, as well as about the English proficiency level of authors who frequently code-switch. Due to the size and breadth – yet homogeneity – of our corpus, we can explore these questions with appropriate comparisons to monolingual posts in the same genre and register, and by the same authors.

The contribution of this work is, therefore, twofold: First, we construct a novel code-switching corpus, whose size, number of language pairs, and diversity of content (consisting of posts of unrestricted length in a wide variety of topic areas) make it a desirable testbed for a range of research questions on code-switching in online discussion forums. Second, we demonstrate the usefulness of this dataset through an empirical investigation that sheds new light on postulated universals of code-switching – involving linguistic proficiency, style, and content – when inspected through the lens of online communication.

2 Compilation of CodeSwitch-Reddit

One of the contributions of this work is the CodeSwitch-Reddit corpus – a large and diverse corpus comprising multilingual posts from online discussion forums. We selected Reddit for construction of our corpus due to its size (over 200M unique users), its structure of content-focused subcommunities (over 100K active subreddits), and the unrestricted length of its posts (in contrast to Twitter, e.g.). This enabled us to extract a large amount of code-switching in natural contexts, within multiple language pairs and by numerous authors, and with access to much monolingual text by the same authors for comparative purposes. Because English is the lingua franca of Reddit, we restricted our focus to CS between English and another language, ensuring commonality in one language across all CS posts.

2.1 Initial Data Extraction

Effective use of CS relies on interactions between bilinguals, hence we needed to identify subreddits likely to contain posts in multiple languages. We observed that country-specific subreddits (e.g., r/greece and r/philippines) often contained posts both in English and in the language of the country specified (e.g., Greek and Tagalog, respectively). We thus restricted our extraction to all country-specific subreddits, except for countries with English as a national language, e.g., r/Australia.

We collected all posts (both initial submissions and subsequent comments/replies) from these subreddits using an API[3] designed for searching Reddit content. Among the properties collected for each post are the unique userid of the author, subreddit name, date of posting, and text of the message. Additional metadata properties include information regarding the full conversational chain of a post (e.g., links to 'parent' messages), facilitating planned further extension of our corpus with contextual information. This final raw dataset consisted of over 6.88M posts from 71 country-specific subreddits.

2.2 Identifying Code-switching Posts

We first identified posts that contained multiple languages, of which one was English, by using polyglot,[4] a probabilistic tool that identifies the languages present in a (multilingual) text, along with their approximate percentage of the total text. This yielded a set of posts where two languages – English and another one – were detected. At this stage, we removed posts shorter than five tokens and those containing weblinks (which misled the language identification tool).

[1] All data and code are available at https://github.com/ellarabi/CodeSwitch-Reddit

[2] https://www.reddit.com/

[3] https://github.com/pushshift/api

[4] https://polyglot.readthedocs.io

Second, we needed to automatically determine which of these multilingual posts actually contained code-switching. We followed a relatively strict notion of CS (Bullock and Toribio, 2009) as a fluid alternation between two languages in an author's own words. Due to the inherently conversational nature of Reddit discussions, authors may include in their own post (parts of) another message they are replying to. We did not consider a post CS if the author's own text was in a single language, but the 'reply-to' text contained another language. In addition, we aimed to exclude from our code-switching corpus any posts whose only alternation between two languages was a use of: named entities (e.g., 'Amazon'); quotes (from websites, books, movies, etc.; e.g., "Don't cry because it's over, smile because it happened."); or translations (text in one language along with its equivalent in the other language).

To enforce this definition of CS, we applied the following filters to our set of multilingual posts. Because our dataset was plentiful, we aimed at achieving high precision (occasionally at the cost of recall) to ensure that resulting posts were likely to have true examples of code-switching.

Replies: A reply-to section is typically preceded by a unique sequence of characters. We used a regular expression to remove all reply-to section(s).

Named entities: We removed all named entities identified by a multilingual Named-Entity Recognizer (NER) available in spaCy.[5]

Quotes: Quotation marks are used both to indicate actual quotes, as well as to convey emphasis of a word or phrase, so they are a clear but noisy cue. We used a regular expression to locate text within quotation marks, and remove it if longer than 5 tokens (since quotation marks around short phrases were often for emphasis). Other methods for quoting, such as copy and pasted text, could not be reliably identified; these are the largest source of false positives of CS in our corpus.

Translations: Here we sought to identify words that indicated that text in one language was likely a translation from the other language. Exploring lexical characteristics typical to r/translator, a subreddit for translation requests, we constructed a list of such words, and removed from our dataset all posts including any word on this set. The list of terms can be found in supplemental material (A.1).

After obtaining a set of 'clean' posts by removing sections/posts identified by these filters, we applied the polyglot tool once again. If two languages (English and another) were still present, we identified the posts as code-switched. In order to retain as much contextual information as possible, we reinserted back into the code-switched posts any named entities and quotes that were removed by the filters above. Table 1 presents some examples of code-switched utterances in the dataset, both intra- and inter-sentential.

2.3 Precision of CS Identification

The method above for identifying code-switched posts may lead to false positives, due to either polyglot errors or inadequacies in our filters. To evaluate the precision of the resulting corpus, we obtained manual annotations, as actual CS or not, of a random sample of the posts.[6]

For language pairs with a large amount of data in the compiled dataset – English plus each of Tagalog, Greek, Romanian, Indonesian, Russian, Spanish, and French – we used FigureEight,[7] a crowd sourcing platform designed to support large annotation tasks. The tasks were split by individual language-pairs, with each including 500 randomly sampled posts from that pair in our corpus. Aiming at reaching bilingual speakers, the tasks were released to countries where the non-English language of the pair was a national language of that country (e.g., Greece for English-Greek).

Annotators were provided with detailed instructions and plentiful examples to indicate precisely what we considered to be code-switching; sample guidelines can be found in supplemental material (A.2). Only those who successfully passed a (manually compiled) quiz were allowed to perform the task. We asked the annotators to indicate yes/no whether an utterance was code-switched or not. In the case of a 'no' answer, they were prompted to provide a reason from these options: (1) no second language present; or, the presence of a second language is due to (2) a named entity, (3) a quote, or (4) other.

Each post was annotated by three annotators, and 100% agreement (three 'yes' or three 'no')

[5] https://spacy.io/

[6] We did not evaluate recall, given that our goal here was to collect a large set of CS, not to detect all CS.

[7] https://www.figure-eight.com/

Not valid enough for me. 7 PM pa daw kasi out niya at hihintayin ko pa rin daw siya eh lagi ko namang ginagawa yun kapag magdidinner kami after work. So what's the difference this time?
Intreb pentru un prieten, care inca scrie SQL, si va scrie mult timp de acum inainte... FYI, relational databases ain't gonna go away any time soon...
Πράγματι, ήταν too good to be true.

Table 1: Examples of code-switched posts in English-Tagalog, English-Romanian, and English-Greek.

was achieved on 83.4% of the posts across all tasks. English-Indonesian and English-Tagalog had the highest percentage of unanimous annotation – 96% and 95%, respectively, followed by Greek (85%), Romanian (82%), and Russian (60%).[8] A majority of 'yes' answers indicated a true positive (actual CS post), and other patterns a false positive (not code-switching). The English-Tagalog and English-Indonesian tasks yielded 99% precision, the English-Romanian and English-Greek tasks 87%, and the English-Russian task 85%. The English-Spanish task had 70% of posts identified as code-switched, and the accuracy of English-French was extremely low; on manual inspection this appeared to be due to the high extent of shared lexical items, misleading the language identification tool.

Due to difficulty in securing bilingual workers on FigureEight, additional language pairs (with a smaller amount of data) were evaluated by an in-house team of annotators, with a relevant bilingual background where possible, or using an automatic translation tool. Five language pairs were identified as comprising between 70% and 85% code-switched posts.

2.4 Final Corpus and Additional Datasets

The final CodeSwitch-Reddit corpus includes the five language pairs that had 85% or higher precision. Table 2 (left) reports details on the corpus, which has over 135K posts, with an average of 75 tokens per post, thereby introducing a unique resource facilitating further research in this field. (A sample of English-Tagalog posts are in supplemental materials.) Table 2 (right) reports the details of the five additional language pairs that had at least 70% precision. Because of the lower quality, we omit these language-pairs from our experiments below. However, we recognize the potential usefulness of this additional data, and release it as an addendum to our main corpus, for possible further cleanup and preprocessing.

We also compiled an additional dataset of English *monolingual* posts from the same country-specific subreddits as our code-switched corpus. Here, as above, we excluded posts with weblinks and posts shorter than five words. This dataset serves as an appropriate comparison set for the code-switching corpus, and is used for some analyses in Section 3.

3 Sociolinguistic Aspects of Online CS

A large body of research has highlighted code-switching as a strategy used to shape the dynamics of the sociolinguistic situation, including aspects of identity, interpersonal relationships, and formality (e.g., Gardner-Chloros, 2009). In addition, studies have differed in their conclusions on whether those who code-switch in speech are highly adept bilinguals (e.g., Kootstra et al., 2012), or use code-switching to address lexical deficiencies (e.g., Poulisse, 1989). Using our new corpus, we aim to explore how such findings from the research on CS in oral communication apply in online written communication. Namely, we test whether code-switched text on the Reddit discussion platform is typified by unique topical and informality markers, and whether authors who frequently mix languages in their posts differ in their English proficiency level from those who do not. Our dataset, comprising communication in multiple language-pairs, as well as monolingual English writing by thousands of authors within the same register introduce an appropriate testbed for addressing these questions.

3.1 Topical Preferences in CS Text

We take a topic modeling approach to explore whether CS productions are characterized by a unique topical flavor, when compared to monolingual messages. Specifically, we compare two topic models, one created using English text from the CodeSwitch-Reddit corpus, and a second us-

[8] Manual inspection of English-Russian annotations revealed a wide range of (in part, subjective) usage cases employing CS; this sub-corpus accounts for 1.4% of our data.

language-pair	authors	posts	avg post len	language-pair	authors	posts	avg post len
English-Tagalog	12,159	88,038	74.6	English-Spanish	2,461	4,225	105.4

total	20,492	135,313	75.5		4,302	7,816	89.5

Table 2: Statistics of the main CodeSwitch-Reddit corpus (left) and the additional CS dataset (right).

ing the monolingual dataset from the same subreddits (see Section 2.4). We use only the text of each dataset from *a common set of authors* whose posts appear in both, thereby ensuring that any differences we find are likely due to the context of code-switching rather than individual differences in content between authors.

We identified a set of $4,843$ authors who posted both code-switched and monolingual messages in our datasets, resulting in $58,568$ CS posts and $58,603$ monolingual posts, having a minimum of 50 tokens and averaging 108.7 and 103.7 tokens per post, respectively. We tokenized and lemmatized texts, excluded English stopwords, and removed name entities and tokens other than nouns, verbs, adjectives and adverbs using python spaCy tools. We applied a dictionary-based approach in order to filter out non-English words; we removed all words ranked higher than $10,000$ in the word-rank list built from the English Wikipedia corpus.[9]

We used a publicly-available topic modeling tool (MALLET, McCallum, 2002) to identify the prevalent discussion topics in the CS and monolingual messages. Each topic is represented by a probability distribution over the entire vocabulary, where terms more characteristic of a topic are assigned a higher probability. A common way to evaluate a topic learned from a set of documents is by computing its *coherence score* – a statistical measure reflecting the quality of a topic (Newman et al., 2010). The quality of a learned model is then estimated by averaging the scores of its individual topics – the *model* coherence score. We selected the optimal number of topics for each set of posts by maximizing its model coherence score, resulting in 17 topics for CS posts (score of 0.58), and 21 topics for monolingual posts (score of 0.60).

Qualitative analysis: We first examine similarities and differences across the two topical distributions by extracting the top 5 topics – those with the highest individual coherence scores – in each of the code-switched and monolingual models. Table 3 presents the 15 most probable words for these top-five topics in each of the code-switched and monolingual models (on the left and right sides, respectively); topics within each are ordered by decreasing coherence score (left to right).

While both CS and monolingual posts include a topic expressing *sentiment about events* (topics CS-3 and M-1), CS posts have two further topics that particularly discuss *relationships* and *family* (CS-2, CS-4). This suggests that the choice to switch languages on Reddit can delineate social, personal, and emotional territory. Other topics typify both CS and monolingual posts, discussing *studies* (CS-1, M-4) and *shopping/travel* (CS-5, M-5). Discussions on *politics/issues* are prevalent only in monolingual communication (M-2, M-3), again indicating that CS posts are more focused on personal experiences.

Table 4 presents a few examples of code-switched posts associated most with the *relationship* topic in the model. It is worth noting that this is one of the subjects most prominently associated with code-switching in speech. The fluid and seamless interleaving of languages highlights the way that emotion, sentiment, and personal experience can guide lexical choice in written communication on the Reddit platform.

Quantitative analysis: We further assess the extent of topical distinctions between code-switched and monolingual posts by performing statistical significance analysis. Namely, we randomly partition the monolingual set of posts into two equal-sized subsets and test whether the two parts exhibit higher mutual similarity than (on average) with their code-switched counterpart.

Formally, given two topic models M_1 with topics $T_1^1, ..., T_1^N$, and M_2 with topics $T_2^1, ..., T_2^K$, where N and K are the number of topics in M_1 and M_2, respectively, we define the similarity be-

[9] https://dumps.wikimedia.org/enwiki

Topics with highest coherence scores in code-switched posts					Topics with highest coherence scores in monolingual posts				
CS-1	CS-2	CS-3	CS-4	CS-5	M-1	M-2	M-3	M-4	M-5
student	friend	make	give	phone	thing	vote	problem	learn	plan
exam	feel	thing	parent	check	person	power	change	student	price
study	girl	happen	live	driver	love	political	issue	study	cost
teacher	love	talk	chance	internet	call	support	reason	experience	cheap
grade	date	wrong	reason	price	wrong	rule	fact	teach	sell
graduate	close	word	plan	mall	happen	majority	deal	education	stay
pass	break	hate	late	shop	hate	politician	current	skill	travel
subject	relationship	joke	decide	traffic	understand	citizen	control	teacher	visit
program	happy	sense	child	store	kind	election	matter	research	expensive
review	meet	mind	baby	brand	accept	leader	point	test	compare

Table 3: Most coherent topics identified in code-switched and monolingual posts by the same set of authors.

tween two models as the average of their pairwise topic similarities:

$$sim(M_1, M_2) = \frac{1}{N \times K} \sum JSC(T_1^i, T_2^j) \quad (1)$$

where $i \in [1..N]$, $j \in [1..K]$, and the Jaccard similarity coefficient (JSC) is used to measure the extent of overlap between the top 100 terms associated with each of T_1^i and T_2^j.

Given model M_{cs} learned from the code-switched corpus, and models M_{en}^1 and M_{en}^2 from the two partitions of the monolingual posts, we can then compute two similarity metrics:

$$avg(sim(M_{cs}, M_{en}^1), sim(M_{cs}, M_{en}^2)) \quad (2)$$

and

$$sim(M_{en}^1, M_{en}^2) \quad (3)$$

We repeated the experiment with 30 random partitions of the monolingual corpus, resulting in mean *inter*-corpora similarity (Equation 2) of 0.030, and mean *intra*-corpus similarity (Equation 3) of 0.037.[10] A Wilcoxon rank-sum test for significance of the differences yielded a p-value of $2.87e$-11. Performing the same analysis with `max` instead of `average` topical similarity in Equation 1 (i.e., estimating sub-corpora topical similarity through two maximally similar topics), yields mean *inter*-corpora similarity of 0.384, and mean *intra*-corpus similarity of 0.470, with p-value of $4.99e$-7. We, therefore, conclude that significant differences can be observed in topical preferences in code-switched messages compared to monolingual texts in our datasets.

[10]The extremely low similarity scores reflect the (desirable) low average similarity between truly different topics.

3.2 (In)formality of code-switched content

Oral code-switching has been shown to be a marker of informality (Genesee, 1982; Myers-Scotton, 1995). While user-generated content on the Reddit discussion platform is by and large considered informal, in this section we test whether (presumably subtle) formality differences can be observed in CS posts compared to monolingual ones. In accord with findings in spoken language, we expect more informal context to stimulate more frequent language mixing.

We use the formal-informal GYAFC parallel dataset by Rao and Tetreault (2018) to extract a set of markers indicative of informal style. Originally collected from the Yahoo Answers platform, the corpus comprises over 50K sentence-pairs in the domain of Entertainment&Music and Family&Relationships, where each original *informal* sentence is paired with a manually generated *formal* counterpart. The parallel nature of the corpus facilitates extraction of a clean set of stylistic markers characteristic of informal text, while abstracting away from content. We use the *log-odds*

Entahlah, I'm self diagnosing, but maybe I'm on the spiral to depression... [*I've no idea*, I'm self diagnosing, but maybe I'm on the spiral to depression...]
If you somehow read this... Лена, я дурак. Мне очень жаль. Я очень по тебе скучаю. [If you somehow read this... *Lena, I'm a fool. I'm sorry. I miss you so much.*]
Lovely.... whataboutism at it's finest. Επισης κάνεις κάτι ατυχέστατες υποθέσεις. [Lovely.... whataboutism at it's finest. *You're also doing something wrong.*]

Table 4: Examples of CS posts (with *translations*) associated with emotion, sentiment, and relationships.

ratio informative Dirichlet prior (Monroe et al., 2008) to discover markers appearing more in informal style, by comparing the informal part of the GYAFC dataset to its formal part. We used the strict log-odds score of -5 as a threshold for collecting terms associated with informal writing. Among the markers identified by this procedure were {*!, ..., u, dont, n't, its, just, ur, im, thats, like, na, &, really, got, lol, cant, ya, coz, alot, but, yea, doesnt, so, kinda, hey, dude, 've, pretty*}.

Using the same sets of posts as in Section 3.1, we tested our hypothesis by inspecting these markers of informality in CS posts compared to monolingual posts by the same set of authors. Specifically, each author is assigned two measurements, reflecting the frequency of the informality markers in the entire collection of their code-switched posts and of their monolingual English posts. Frequency was computed by normalizing the total count of informality markers in an author's text (concatenation of individual posts) by its length.

The mean frequency of informality markers in CS posts was 0.160, while in monolingual posts by the same authors was 0.153. Figure 1 illustrates the kernel density estimation of these frequencies: the subtle deviation in formal style is mirrored by the slight right shift of the density function for code-switched texts. Moreover, a (paired difference) Wilcoxon signed-rank test for statistical significance of the difference in CS and monolingual posts resulted in a within-subjects effect size of 0.15 and a very low p-value ($1.01e$-23). Despite the generally high level of informality of Reddit postings, we see a small but reliably detected difference of even greater informality in CS utterances, mirroring the observations in oral CS being associated with informal speech.

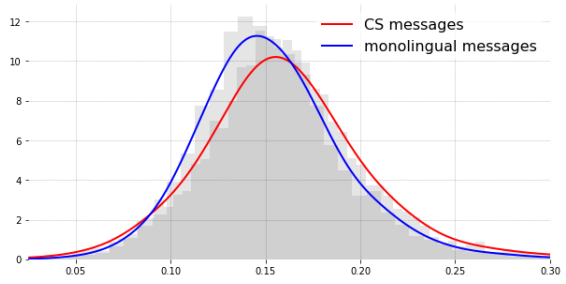

Figure 1: Kernel density estimate of informality markers' frequency in CS and monolingual messages.

3.3 Code-switching and language competence

Theoretical and experimental studies have differed in considering code-switching as a strategy of extremely proficient bilinguals, or as a coping mechanism of those with deficiencies in one of the languages (see Section 4). We address this issue in the context of written communication by computing a range of lexical and grammatical metrics from utterances of authors who tend to mix languages frequently, compared to those who do not.

We separated authors who were active contributors to bilingual subreddits into those who frequently code-switch vs. those who do not. We identified 288 authors as 'high code-switchers' – those who have over 100 messages in a country-specific subreddit, where at least 20% of these posts were code-switched. We further identified 262 authors as 'low code-switchers', having over 100 posts but mixing languages in less than 2% of their messages. Aiming at a reliable assessment of these authors' English linguistic skills, we gathered their entire monolingual English digital footprint from the Reddit platform, including their posts in all but country-specific subreddits. The collected set of messages contains an average of 1,060 and 856 posts per author, for high and low code-switchers, respectively.

We estimate linguistic competence by computing a set of lexical and grammatical measures commonly used for language proficiency assessment (Kyle and Crossley, 2015; Lu and Ai, 2015; Rabinovich et al., 2018). All posts were tokenized and lemmatized, and non-alphabetic tokens were excluded from the computation. We produce the following metrics:

Normalized type-to-token ratio (NTTR) – the ratio of the number of unique tokens and the total number of tokens, averaged over non-overlapping sliding windows of 1000 tokens.

Lexical density (lex. density) – the ratio of the number of content tokens (excluding function words) and the number of all tokens, using 426 function words from Koppel and Ordan (2011).

Mean average age of acquisition (mean AoA) – mean of the average AoA of tokens for over 30K English words (Kuperman et al., 2012).

Mean word concreteness (word conc.) – mean word concreteness of tokens, taken from ratings for 40K English words (Brysbaert et al., 2014).

Mean word length (word length) – the average

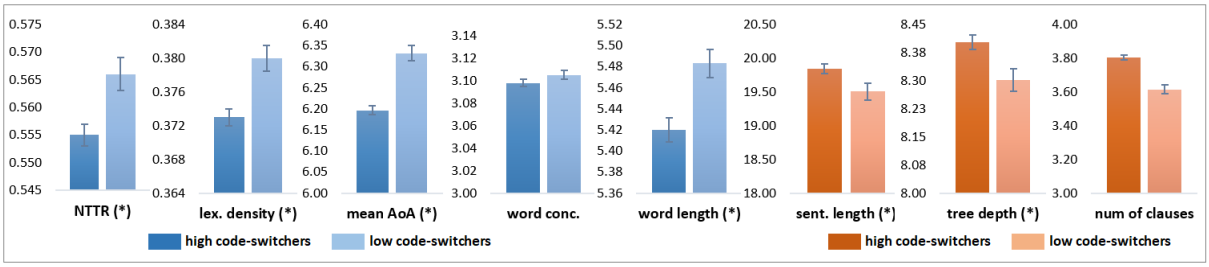

Figure 2: Linguistic proficiency metrics (mean and standard error; lexical on the left, grammatical on the right) of high and low code-switchers. '*' indicates significant difference in a Wilcoxon rank-sum test at the level of $p < .05$.

length in characters of a token.

Mean sentence length (sent. length) – the average length of a sentence (in tokens).

Mean parse tree depth (tree depth) – the average depth of a parse tree of a sentence, using the constituency parser of Kitaev and Klein (2018).

Mean number of clauses (num of clauses) – the average number of clauses in a sentence.

Figure 2 presents these metrics for high and low code-switchers. We find that high code-switchers exhibit statistically significant *lower* proficiency in the lexical metrics (with the exception of word concreteness level), but statistically significant *higher* proficiency for two of the grammatical metrics. Although the differences in both cases are small, they are reliably detected given the size of the corpora. Interestingly, while the lexical measures indicate less 'sophisticated' English words used by the high code-switchers, the distinctions in their grammatical complexity (reflected in longer sentences and greater parse tree depths) imply that mixing language in written communication may not necessarily be a manifestation of *overall* lower linguistic competence. These intriguing findings suggest that code-witching in online forums is a multi-faceted phenomenon: while bridging lexical deficiencies, it may require advanced grammatical capabilities in order to construct mixed sentences without distorting the 'grammaticality' of the target utterance. These results both demonstrate the value of studying code-switching at scale, and leave room for much further investigation. Our future plans include breaking down the data by individual native languages of the authors, in order to capture differences in proficiency stemming from various L1 backgrounds.

4 Related Work

Many studies have elucidated the communicative functions of oral code-switching. These include conveying nuanced attitudes through linguistic choices reflecting emotion and sentiment (Dewaele and Nakano, 2013), as well as establishing a level of (in)formality (Fishman, 1970; Genesee, 1982; Myers-Scotton, 1995). Other studies have focused more on the characteristics of code-switchers themselves: While CS has mostly been viewed as a deliberate choice of a proficient bilingual speaker, requiring adept control of two simultaneously-activated linguistic systems (Costa and Santesteban, 2004; Kootstra et al., 2012), mixing two languages may also serve as a strategy for bridging lexical inefficacy in a second language (Grosjean, 1982; Faerch and Kasper, 1983; Poulisse, 1989).

As noted earlier, written CS is much less studied and the extent to which these findings hold across various written genres is not clear (Sebba et al., 2012). Recent research from the sociolinguistic perspective has considered CS in an array of online genres: e.g., English-Jamaican Creole in email (Hinrichs, 2006), Malay-English language in online discussion forums (McLellan, 2005), English-Spanish bilingual blogging (Montes-Alcalá, 2007), and English-Chinese instant messaging (Lam, 2009). However, these studies have analyzed productions of a small number of authors (even a single person), and each is restricted to a single language-pair.

Most large-scale computational work on CS in social media has focused on essential prerequisites for various NLP tasks, such as POS tagging (Solorio and Liu, 2008; Soto et al., 2018), token-level language identification (Soto et al., 2018; Rijhwani et al., 2017), NER (Aguilar et al., 2018a), language modeling (Chandu et al., 2018), automatic speech recognition (Yılmaz et al., 2018),

etc. Almost no work has addressed theoretical and sociolinguistic aspects of written multilingual discourse computationally, at scale (for an exception, see Rudra et al., 2016).

Our work here addresses various gaps noted in the research above. We create (and make available) a novel dataset that enables investigation of research questions on written code-switching at scale, across multiple language pairs and a large number of speakers. Moreover, we use this dataset for computational, large-scale investigation of subtle issues of linguistic content and style, as well as speaker proficiency, that have been extensively studied in the context of spoken language, and enjoyed very limited attention in written communication.

5 Conclusion

Despite the presumed differences between code-switching in spoken and written communication, multilingual written discourse is understudied, partially due to the lack of adequate resources. In this work we introduced the CodeSwitch-Reddit corpus – a large, diverse and carefully curated dataset of code-switched posts collected from multiple multilingual discussions forums on Reddit. Computational investigation of this dataset reveals topical and stylistic distinctions between code-switched and monolingual communication, as well as differences in the proficiency level of authors who mix languages frequently, compared to those who do not. Our future plans include extending this dataset with conversational context and investigating additional aspects of online written multilingual discourse in richer contexts.

The released dataset suggests a wealth of both intra- and inter-sentential code-switched utterances, and investigation of sociolinguistic differences between the two introduces an interesting research question. As an example, while mixing languages within a sentence could be indicative of lexical deficiency, that may not necessarily be the case with inter-sentential code-switching.

Modeling Conversation Structure and Temporal Dynamics for Jointly Predicting Rumor Stance and Veracity

Penghui Wei, Nan Xu, Wenji Mao

{weipenghui2016,xunan2015,wenji.mao}@ia.ac.cn

Abstract

Automatically verifying rumorous information has become an important and challenging task in natural language processing and social media analytics. Previous studies reveal that people's stances towards rumorous messages can provide indicative clues for identifying the veracity of rumors, and thus determining the stances of public reactions is a crucial preceding step for rumor veracity prediction. In this paper, we propose a hierarchical multi-task learning framework for jointly predicting rumor stance and veracity on Twitter, which consists of two components. The bottom component of our framework classifies the stances of tweets in a conversation discussing a rumor via modeling the structural property based on a novel graph convolutional network. The top component predicts the rumor veracity by exploiting the temporal dynamics of stance evolution. Experimental results on two benchmark datasets show that our method outperforms previous methods in both rumor stance classification and veracity prediction.

1 Introduction

Social media websites have become the main platform for users to browse information and share opinions, facilitating news dissemination greatly. However, the characteristics of social media also accelerate the rapid spread and dissemination of unverified information, i.e., rumors (Shu et al., 2017). The definition of *rumor* is "*items of information that are unverified at the time of posting*" (Zubiaga et al., 2018). Ubiquitous false rumors bring about harmful effects, which has seriously affected public and individual lives, and caused panic in society (Zhou and Zafarani, 2018; Sharma et al., 2019). Because online content is massive and debunking rumors manually is time-consuming, there is a great need for automatic methods to identify false rumors (Oshikawa et al., 2018).

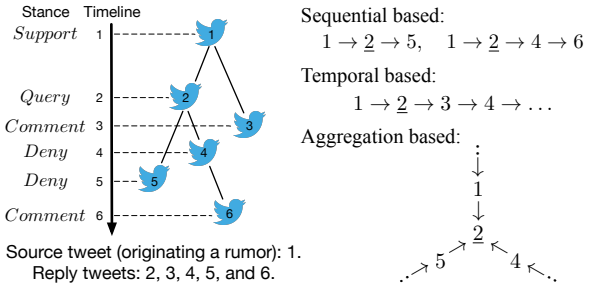

Figure 1: A conversation thread discussing the rumorous tweet "1". Three different perspectives for learning the stance feature of the reply tweet "2" are illustrated.

Previous studies have observed that public stances towards rumorous messages are crucial signals to detect trending rumors (Qazvinian et al., 2011; Zhao et al., 2015) and indicate the veracity of them (Mendoza et al., 2010; Procter et al., 2013; Liu et al., 2015; Jin et al., 2016; Glenski et al., 2018). Therefore, stance classification towards rumors is viewed as an important preceding step of rumor veracity prediction, especially in the context of Twitter conversations (Zubiaga et al., 2016a).

The state-of-the-art methods for rumor stance classification are proposed to model the sequential property (Kochkina et al., 2017) or the temporal property (Veyseh et al., 2017) of a Twitter conversation thread. In this paper, we propose a new perspective based on structural property: learning tweet representations through aggregating information from their neighboring tweets. Intuitively, a tweet's nearer neighbors in its conversation thread are more informative than farther neighbors because the replying relationships of them are closer, and their stance expressions can help classify the stance of the center tweet (e.g., in Figure 1, tweets "1", "4" and "5" are the one-hop neighbors of the tweet "2", and their influences on predicting the stance of "2" are larger than that of the two-hop neighbor "3"). To achieve this, we represent both

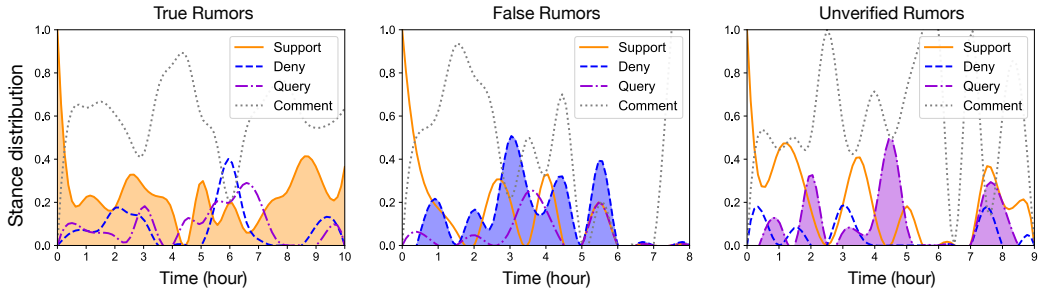

Figure 2: Stance distributions of tweets discussing $true$ rumors, $false$ rumors, and $unverified$ rumors, respectively (Better viewed in color). The horizontal axis is the spreading time of the first rumor. It is visualized based on SemEval-2017 task 8 dataset (Derczynski et al., 2017). All tweets are relevant to the event "Ottawa Shooting".

tweet contents and conversation structures into a latent space using a graph convolutional network (GCN) (Kipf and Welling, 2017), aiming to learn stance feature for each tweet by aggregating its neighbors' features. Compared with the sequential and temporal based methods, our aggregation based method leverages the intrinsic structural property in conversations to learn tweet representations.

After determining the stances of people's reactions, another challenge is how we can utilize public stances to predict rumor veracity accurately. We observe that the temporal dynamics of public stances can indicate rumor veracity. Figure 2 illustrates the stance distributions of tweets discussing $true$ rumors, $false$ rumors, and $unverified$ rumors, respectively. As we can see, $supporting$ stance dominates the inception phase of spreading. However, as time goes by, the proportion of $denying$ tweets towards $false$ rumors increases quite significantly. Meanwhile, the proportion of $querying$ tweets towards $unverified$ rumors also shows an upward trend. Based on this observation, we propose to model the temporal dynamics of stance evolution with a recurrent neural network (RNN), capturing the crucial signals containing in stance features for effective veracity prediction.

Further, most existing methods tackle stance classification and veracity prediction separately, which is suboptimal and limits the generalization of models. As shown previously, they are two closely related tasks in which stance classification can provide indicative clues to facilitate veracity prediction. Thus, these two tasks can be jointly learned to make better use of their interrelation.

Based on the above considerations, in this paper, we propose a hierarchical multi-task learning framework for jointly predicting rumor stance and veracity, which achieves deep integration between the preceding task (stance classification) and the subsequent task (veracity prediction). The bottom component of our framework classifies the stances of tweets in a conversation discussing a rumor via aggregation-based structure modeling, and we design a novel graph convolution operation customized for conversation structures. The top component predicts rumor veracity by exploiting the temporal dynamics of stance evolution, taking both content features and stance features learned by the bottom component into account. Two components are jointly trained to utilize the interrelation between the two tasks for learning more powerful feature representations.

The contributions of this work are as follows.

- We propose a hierarchical framework to tackle rumor stance classification and veracity prediction jointly, exploiting both structural characteristic and temporal dynamics in rumor spreading process.
- We design a novel graph convolution operation customized to encode conversation structures for learning stance features. To our knowledge, we are the first to employ graph convolution for modeling the structural property of Twitter conversations.
- Experimental results on two benchmark datasets verify that our hierarchical framework performs better than existing methods in both rumor stance classification and veracity prediction.

2 Related Work

Rumor Stance Classification Stance analysis has been widely studied in online debate forums (Somasundaran and Wiebe, 2009; Hasan and Ng, 2013), and recently has attracted increasing attention in different contexts (Mohammad et al., 2016; Augenstein et al., 2016; Ferreira and Vlachos, 2016; Mohtarami et al., 2018). After the pioneering studies on stance classification towards rumors in social media (Mendoza et al., 2010;

Qazvinian et al., 2011; Procter et al., 2013), linguistic feature (Hamidian and Diab, 2016; Zeng et al., 2016) and point process based methods (Lukasik et al., 2016, 2019) have been developed.

Recent work has focused on Twitter conversations discussing rumors. Zubiaga et al. (2016a) proposed to capture the sequential property of conversations with linear-chain CRF, and also used a tree-structured CRF to consider the conversation structure as a whole. Aker et al. (2017) developed a novel feature set that scores the level of users' confidence. Pamungkas et al. (2018) designed affective and dialogue-act features to cover various facets of affect. Giasemidis et al. (2018) proposed a semi-supervised method that propagates the stance labels on similarity graph. Beyond feature-based methods, Kochkina et al. (2017) utilized an LSTM to model the sequential branches in a conversation, and their system ranked the first in SemEval-2017 task 8. Veyseh et al. (2017) adopted attention to model the temporal property of a conversation and achieved the state-of-the-art performance.

Rumor Veracity Prediction Previous studies have proposed methods based on various features such as linguistics, time series and propagation structures (Castillo et al., 2011; Kwon et al., 2013; Wu et al., 2015; Ma et al., 2017). Neural networks show the effectiveness of modeling time series (Ma et al., 2016; Ruchansky et al., 2017) and propagation paths (Liu and Wu, 2018). Ma et al. (2018b)'s model adopted recursive neural networks to incorporate structure information into tweet representations and outperformed previous methods.

Some studies utilized stance labels as the input feature of veracity classifiers to improve the performance (Liu et al., 2015; Enayet and El-Beltagy, 2017). Dungs et al. (2018) proposed to recognize the temporal patterns of true and false rumors' stances by two hidden Markov models (HMMs). Unlike their solution, our method learns discriminative features of stance evolution with an RNN. Moreover, our method jointly predicts stance and veracity by exploiting both structural and temporal characteristics, whereas HMMs need stance labels as the input sequence of observations.

Joint Predictions of Rumor Stance and Veracity Several work has addressed the problem of jointly predicting rumor stance and veracity. These studies adopted multi-task learning to jointly train two tasks (Ma et al., 2018a; Kochkina et al., 2018; Poddar et al., 2018) and learned shared representations with parameter-sharing. Compared with such solutions based on "parallel" architectures, our method is deployed in a hierarchical fashion that encodes conversation structures to learn more powerful stance features by the bottom component, and models stance evolution by the top component, achieving deep integration between the two tasks' feature learning.

3 Problem Definition

Consider a Twitter conversation thread $\mathcal{C}$ which consists of a source tweet t_1 (originating a rumor) and a number of reply tweets $\{t_2, t_3, \ldots, t_{|\mathcal{C}|}\}$ that respond t_1 directly or indirectly, and each tweet t_i ($i \in [1, |\mathcal{C}|]$) expresses its stance towards the rumor. The thread $\mathcal{C}$ is a tree structure, in which the source tweet t_1 is the root node, and the replying relationships among tweets form the edges.[1]

This paper focuses on two tasks. The first task is rumor stance classification, aiming to determine the stance of each tweet in $\mathcal{C}$, which belongs to $\{supporting, denying, querying, commenting\}$. The second task is rumor veracity prediction, with the aim of identifying the veracity of the rumor, belonging to $\{true, false, unverified\}$.

4 Proposed Method

We propose a Hierarchical multi-task learning framework for jointly Predicting rumor Stance and Veracity (named *Hierarchical-PSV*). Figure 3 illustrates its overall architecture that is composed of two components. The bottom component is to classify the stances of tweets in a conversation thread, which learns stance features via encoding conversation structure using a customized graph convolutional network (named *Conversational-GCN*). The top component is to predict the rumor's veracity, which takes the learned features from the bottom component into account and models the temporal dynamics of stance evolution with a recurrent neural network (named *Stance-Aware RNN*).

4.1 Conversational-GCN: Aggregation-based Structure Modeling for Stance Prediction

Now we detail *Conversational-GCN*, the bottom component of our framework. We first adopt a bidirectional GRU (BGRU) (Cho et al., 2014) layer to learn the content feature for each tweet in the thread $\mathcal{C}$. For a tweet t_i ($i \in [1, |\mathcal{C}|]$), we run the

[1] We consider each replying relationship between two tweets in a conversation as an undirected edge in the tree.

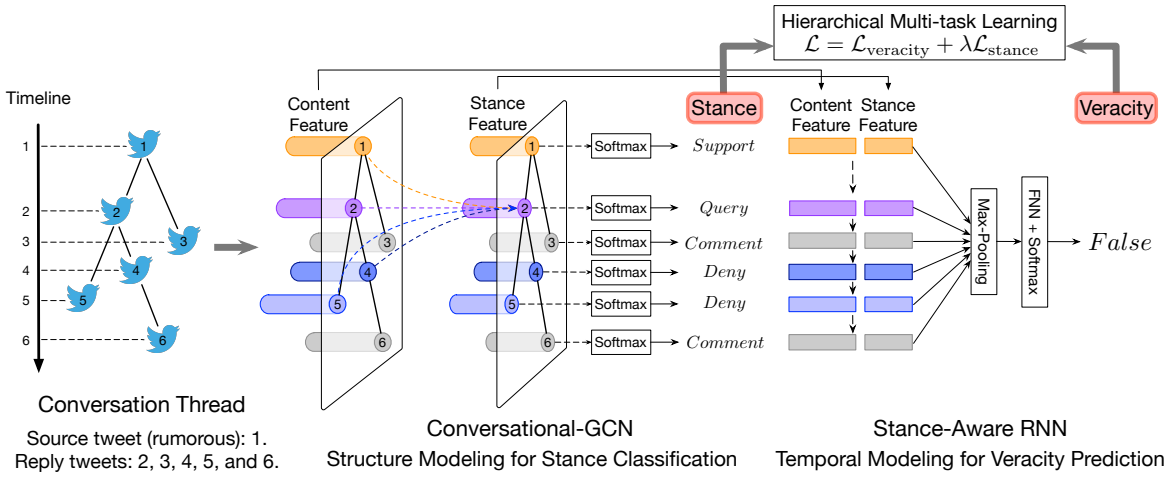

Figure 3: Overall architecture of our proposed framework for joint predictions of rumor stance and veracity. In this illustration, the number of GCN layers is one. The information aggregation process for the tweet t_2 based on original graph convolution operation (Eq. (1)) is detailed.

BGRU over its word embedding sequence, and use the final step's hidden vector to represent the tweet. The content feature representation of t_i is denoted as $\boldsymbol{c}_i \in \mathbb{R}^d$, where d is the output size of the BGRU.

As we mentioned in Section 1, the stance expressions of a tweet t_i's nearer neighbors can provide more informative signals than farther neighbors for learning t_i's stance feature. Based on the above intuition, we model the structural property of the conversation thread $\mathcal{C}$ to learn stance feature representation for each tweet in $\mathcal{C}$. To this end, we encode structural contexts to improve tweet representations by aggregating information from neighboring tweets with a graph convolutional network (GCN) (Kipf and Welling, 2017).

Formally, the conversation $\mathcal{C}$'s structure can be represented by a graph $\mathcal{C}_G = \langle \mathcal{T}, \mathcal{E} \rangle$, where $\mathcal{T} = \{t_i\}_{i=1}^{|\mathcal{C}|}$ denotes the node set (i.e., tweets in the conversation), and $\mathcal{E}$ denotes the edge set composed of all replying relationships among the tweets. We transform the edge set $\mathcal{E}$ to an adjacency matrix $\mathbf{A} \in \mathbb{R}^{|\mathcal{C}| \times |\mathcal{C}|}$, where $\mathbf{A}_{ij} = \mathbf{A}_{ji} = 1$ if the tweet t_i directly replies the tweet t_j or $i = j$. In one GCN layer, the graph convolution operation for one tweet t_i on $\mathcal{C}_G$ is defined as:

$$\boldsymbol{h}_i^{\text{out}} = \tanh\left(\sum_{j \in \{j | \hat{\mathbf{A}}_{ij} \neq 0\}} \hat{\mathbf{A}}_{ij} \boldsymbol{W}^\top \boldsymbol{h}_j^{\text{in}} + \boldsymbol{b} \right), \tag{1}$$

where $\boldsymbol{h}_i^{\text{in}} \in \mathbb{R}^{d_{\text{in}}}$ and $\boldsymbol{h}_i^{\text{out}} \in \mathbb{R}^{d_{\text{out}}}$ denote the input and output feature representations of the tweet t_i respectively. The convolution filter $\boldsymbol{W} \in \mathbb{R}^{d_{\text{in}} \times d_{\text{out}}}$ and the bias $\boldsymbol{b} \in \mathbb{R}^{d_{\text{out}}}$ are shared over all tweets in a conversation. We apply symmetric normalized transformation $\hat{\mathbf{A}} = \mathbf{D}^{-\frac{1}{2}} \mathbf{A} \mathbf{D}^{-\frac{1}{2}}$ to avoid the scale changing of feature representations, where $\mathbf{D}$ is the degree matrix of $\mathbf{A}$, and $\{j \mid \hat{\mathbf{A}}_{ij} \neq 0\}$ contains t_i's one-hop neighbors and t_i itself.

In this original graph convolution operation, given a tweet t_i, the receptive field for t_i contains its one-hop neighbors and t_i itself, and the aggregation level of two tweets t_i and t_j is dependent on $\hat{\mathbf{A}}_{ij}$. In the context of encoding conversation structures, we observe that such operation can be further improved for two issues. First, a tree-structured conversation may be very deep, which means that the receptive field of a GCN layer is restricted in our case. Although we can stack multiple GCN layers to expand the receptive field, it is still difficult to handle conversations with deep structures and increases the number of parameters. Second, the normalized matrix $\hat{\mathbf{A}}$ partly weakens the importance of the tweet t_i itself. To address these issues, we design a novel graph convolution operation which is customized to encode conversation structures. Formally, it is implemented by modifying the matrix $\hat{\mathbf{A}}$ in Eq. (1):

$$\hat{\mathbf{A}} \leftarrow \hat{\mathbf{A}}\hat{\mathbf{A}} + \mathbf{I}, \tag{2}$$

where the multiplication operation expands the receptive field of a GCN layer, and adding an identity matrix elevates the importance of t_i itself.

After defining the above graph convolution operation, we adopt an L-layer GCN to model conversation structures. The l^{th} GCN layer ($l \in [1, L]$) computed over the entire conversation structure can

be written as an efficient matrix operation:

$$\boldsymbol{H}^{(l)} = \tanh(\hat{\mathbf{A}}\boldsymbol{H}^{(l-1)}\boldsymbol{W}^{(l)} + \boldsymbol{b}^{(l)}), \quad (3)$$

where $\boldsymbol{H}^{(l-1)} \in \mathbb{R}^{|\mathcal{C}|\times d_{l-1}}$ and $\boldsymbol{H}^{(l)} \in \mathbb{R}^{|\mathcal{C}|\times d_l}$ denote the input and output features of all tweets in the conversation $\mathcal{C}$ respectively.

Specifically, the first GCN layer takes the content features of all tweets as input, i.e., $\boldsymbol{H}^{(0)} = (\boldsymbol{c}_1, \boldsymbol{c}_2, \ldots, \boldsymbol{c}_{|\mathcal{C}|})^\top \in \mathbb{R}^{|\mathcal{C}|\times d}$. The output of the last GCN layer represents the stance features of all tweets in the conversation, i.e., $\boldsymbol{H}^{(L)} = (\boldsymbol{s}_1, \boldsymbol{s}_2, \ldots, \boldsymbol{s}_{|\mathcal{C}|})^\top \in \mathbb{R}^{|\mathcal{C}|\times 4}$, where $\boldsymbol{s}_i$ is the unnormalized stance distribution of the tweet t_i.

For each tweet t_i in the conversation $\mathcal{C}$, we apply softmax to obtain its predicted stance distribution:

$$\hat{\boldsymbol{s}}_i = \mathrm{softmax}(\boldsymbol{s}_i) \in \mathbb{R}^4, \quad i \in [1, |\mathcal{C}|]. \quad (4)$$

The ground-truth labels of stance classification supervise the learning process of *Conversational-GCN*. The loss function of $\mathcal{C}$ for stance classification is computed by cross-entropy criterion:

$$\mathcal{L}_{\text{stance}} = \frac{1}{|\mathcal{C}|}\sum_{i=1}^{|\mathcal{C}|}\left(-s_i^\top \log \hat{\boldsymbol{s}}_i\right), \quad (5)$$

where s_i is a one-hot vector that denotes the stance label of the tweet t_i. For batch-wise training, the objective function for a batch is the averaged cross-entropy loss of all tweets in these conversations.

In previous studies, GCNs are used to encode dependency trees (Marcheggiani and Titov, 2017; Zhang et al., 2018) and cross-document relations (Yasunaga et al., 2017; De Cao et al., 2019) for downstream tasks. Our work is the first to leverage GCNs for encoding conversation structures.

4.2 Stance-Aware RNN: Temporal Dynamics Modeling for Veracity Prediction

The top component, *Stance-Aware RNN*, aims to capture the temporal dynamics of stance evolution in a conversation discussing a rumor. It integrates both content features and stance features learned from the bottom *Conversational-GCN* to facilitate the veracity prediction of the rumor.

Specifically, given a conversation thread $\mathcal{C} = \{t_1, t_2, \ldots, t_{|\mathcal{C}|}\}$ (where the tweets t_* are ordered chronologically), we combine the content feature and the stance feature for each tweet, and adopt a GRU layer to model the temporal evolution:

$$\boldsymbol{v}_i = \mathrm{GRU}([\boldsymbol{c}_i; \boldsymbol{s}_i], \boldsymbol{v}_{i-1}), \quad i \in [1, |\mathcal{C}|], \quad (6)$$

where $[\cdot;\cdot]$ denotes vector concatenation, and $(\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_{|\mathcal{C}|})$ is the output sequence that represents the temporal feature. We then transform the sequence to a vector $\boldsymbol{v}$ by a max-pooling function that captures the global information of stance evolution, and feed it into a one-layer feed-forward neural network (FNN) with softmax normalization to produce the predicted veracity distribution $\hat{\boldsymbol{v}}$:

$$\begin{aligned} \boldsymbol{v} &= \text{max-pooling}(\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_{|\mathcal{C}|}), \\ \hat{\boldsymbol{v}} &= \mathrm{softmax}(\mathrm{FNN}(\boldsymbol{v})). \end{aligned} \quad (7)$$

The loss function of $\mathcal{C}$ for veracity prediction is also computed by cross-entropy criterion:

$$\mathcal{L}_{\text{veracity}} = -v^\top \log \hat{\boldsymbol{v}}, \quad (8)$$

where v denotes the veracity label of $\mathcal{C}$.

4.3 Jointly Learning Two Tasks

To leverage the interrelation between the preceding task (stance classification) and the subsequent task (veracity prediction), we jointly train two components in our framework. Specifically, we add two tasks' loss functions to obtain a joint loss function $\mathcal{L}$ (with a trade-off parameter λ), and optimize $\mathcal{L}$ to train our framework:

$$\mathcal{L} = \mathcal{L}_{\text{veracity}} + \lambda\mathcal{L}_{\text{stance}}. \quad (9)$$

In our *Hierarchical-PSV*, the bottom component *Conversational-GCN* learns content and stance features, and the top component *Stance-Aware RNN* takes the learned features as input to further exploit temporal evolution for predicting rumor veracity. Our multi-task framework achieves deep integration of the feature representation learning process for the two closely related tasks.

5 Experiments

In this section, we first evaluate the performance of *Conversational-GCN* on rumor stance classification and evaluate *Hierarchical-PSV* on veracity prediction (Section 5.3). We then give a detailed analysis of our proposed method (Section 5.4).

5.1 Data & Evaluation Metric

To evaluate our proposed method, we conduct experiments on two benchmark datasets.

The first is **SemEval-2017 task 8** (Derczynski et al., 2017) dataset. It includes 325 rumorous conversation threads, and has been split into training, development and test sets. These threads cover ten

Dataset	# Thread	Depth	# Tweet	Stance Labels				Veracity Labels		
				# *support*	# *deny*	# *query*	# *comment*	# *true*	# *false*	# *unverified*
SemEval	325	3.5	5,568	1,004	415	464	3,685	145	74	106
PHEME	2,402	2.8	105,354	–				1,067	638	697

Table 1: Statistics of two datasets. The column "Depth" denotes the average depth of all conversation threads.

Method	Evaluation Metric					
	Macro-F_1	F_S	F_D	F_Q	F_C	Acc.
Affective Feature + SVM (Pamungkas et al., 2018)	0.470	**0.410**	0.000	0.580	**0.880**	0.795
BranchLSTM (Kochkina et al., 2017)	0.434	0.403	0.000	0.462	0.873	0.784
TemporalAttention (Veyseh et al., 2017)	0.482	–	–	–	–	**0.820**
Conversational-GCN (Ours, $L = 2$)	**0.499**	0.311	**0.194**	**0.646**	0.847	0.751

Table 2: Results of rumor stance classification. F_S, F_D, F_Q and F_C denote the F_1 scores of *supporting*, *denying*, *querying* and *commenting* classes respectively. "–" indicates that the original paper does not report the metric.

events, and two events of that only appear in the test set. This dataset is used to evaluate both stance classification and veracity prediction tasks.

The second is **PHEME** dataset (Zubiaga et al., 2016b). It provides 2,402 conversations covering nine events. Following previous work, we conduct leave-one-event-out cross-validation: in each fold, one event's conversations are used for testing, and all the rest events are used for training. The evaluation metric on this dataset is computed after integrating the outputs of all nine folds. Note that only a subset of this dataset has stance labels, and all conversations in this subset are already contained in SemEval-2017 task 8 dataset. Thus, PHEME dataset is used to evaluate veracity prediction task.

Table 1 shows the statistics of two datasets. Because of the class-imbalanced problem, we use macro-averaged F_1 as the evaluation metric for two tasks. We also report accuracy for reference.

5.2 Implementation Details

In all experiments, the number of GCN layers is set to $L = 2$. We list the implementation details in Appendix A.

5.3 Experimental Results

5.3.1 Results: Rumor Stance Classification

Baselines We compare our *Conversational-GCN* with the following methods in the literature:

• *Affective Feature + SVM* (Pamungkas et al., 2018) extracts affective and dialogue-act features for individual tweets, and then trains an SVM for classifying stances.

• *BranchLSTM* (Kochkina et al., 2017) is the winner of SemEval-2017 shared task 8 subtask A. It adopts an LSTM to model the sequential branches in a conversation thread. Before feeding branches into the LSTM, some additional hand-crafted features are used to enrich the tweet representations.

• *TemporalAttention* (Veyseh et al., 2017) is the state-of-the-art method. It uses a tweet's "neighbors in the conversation timeline" as the context, and utilizes attention to model such temporal sequence for learning the weight of each neighbor. Extra hand-crafted features are also used.

Performance Comparison Table 2 shows the results of different methods for rumor stance classification. Clearly, the macro-averaged F_1 of Conversational-GCN is better than all baselines.

Especially, our method shows the effectiveness of determining *denying* stance, while other methods can not give any correct prediction for *denying* class (the F_D scores of them are equal to zero). Further, Conversational-GCN also achieves higher F_1 score for *querying* stance (F_Q). Identifying *denying* and *querying* stances correctly is crucial for veracity prediction because they play the role of indicators for $false$ and $unverified$ rumors respectively (see Figure 2). Meanwhile, the class-imbalanced problem of data makes this a challenge. Conversational-GCN effectively encodes structural context for each tweet via aggregating information from its neighbors, learning powerful stance features without feature engineering. It is also more computationally efficient than sequential and temporal based methods. The information aggregations for all tweets in a conversation are worked in parallel and thus the running time is not sensitive to conversation's depth.

Setting	Method	SemEval dataset		PHEME dataset	
		Macro-F_1	Acc.	Macro-F_1	Acc.
Single-task	TD-RvNN (Ma et al., 2018b)	0.509	0.536	0.264	0.341
	Hierarchical GCN-RNN (Ours)	0.540	0.536	0.317	0.356
Multi-task	BranchLSTM+NileTMRG (Kochkina et al., 2018)	0.539	0.570	0.297	0.360
	MTL2 (Veracity+Stance) (Kochkina et al., 2018)	0.558	0.571	0.318	0.357
	Hierarchical-PSV (Ours, $\lambda = 1$)	**0.588**	**0.643**	**0.333**	**0.361**

Table 3: Results of veracity prediction. Single-task setting means that stance labels cannot be used to train models.

5.3.2 Results: Rumor Veracity Prediction

To evaluate our framework *Hierarchical-PSV*, we consider two groups of baselines: single-task and multi-task baselines.

Single-task Baselines In single-task setting, stance labels are not available. Only veracity labels can be used to supervise the training process.

• *TD-RvNN* (Ma et al., 2018b) models the top-down tree structure using a recursive neural network for veracity classification.

• *Hierarchical GCN-RNN* is the single-task variant of our framework: we optimize $\mathcal{L}_{\text{veracity}}$ (i.e., $\lambda = 0$ in Eq. (9)) during training. Thus, the bottom Conversational-GCN only has indirect supervision (veracity labels) to learn stance features.

Multi-task Baselines In multi-task setting, both stance labels and veracity labels are available for training.

• *BranchLSTM+NileTMRG* (Kochkina et al., 2018) is a pipeline method, combining the winner systems of two subtasks in SemEval-2017 shared task 8. It first trains a BranchLSTM for stance classification, and then uses the predicted stance labels as extra features to train an SVM for veracity prediction (Enayet and El-Beltagy, 2017).

• *MTL2 (Veracity+Stance)* (Kochkina et al., 2018) is a multi-task learning method that adopts BranchLSTM as the shared block across tasks. Then, each task has a task-specific output layer, and two tasks are jointly learned.[2]

Performance Comparison Table 3 shows the comparisons of different methods. By comparing single-task methods, Hierarchical GCN-RNN performs better than TD-RvNN, which indicates that our hierarchical framework can effectively model conversation structures to learn high-quality tweet representations. The recursive operation in TD-RvNN is performed in a fixed direction and runs over all tweets, thus may not obtain enough useful information. Moreover, the training speed of Hierarchical GCN-RNN is significantly faster than TD-RvNN: in the condition of batch-wise optimization for training one step over a batch containing 32 conversations, our method takes only 0.18 seconds, while TD-RvNN takes 5.02 seconds.

Comparisons among multi-task methods show that two joint methods outperform the pipeline method (BranchLSTM+NileTMRG), indicating that jointly learning two tasks can improve the generalization through leveraging the interrelation between them. Further, compared with MTL2 which uses a "parallel" architecture to make predictions for two tasks, our Hierarchical-PSV performs better than MTL2. The hierarchical architecture is more effective to tackle the joint predictions of rumor stance and veracity, because it not only possesses the advantage of parameter-sharing but also offers deep integration of the feature representation learning process for the two tasks. Compared with Hierarchical GCN-RNN that does not use the supervision from stance classification task, Hierarchical-PSV provides a performance boost, which demonstrates that our framework benefits from the joint learning scheme.

5.4 Further Analysis and Discussions

We conduct additional experiments to further demonstrate the effectiveness of our model.

5.4.1 Effect of Customized Graph Convolution

To show the effect of our customized graph convolution operation (Eq. (2)) for modeling conversation structures, we further compare it with the original graph convolution (Eq. (1), named Original-GCN) on stance classification task.

Specifically, we cluster tweets in the test set according to their depths in the conversation threads (e.g., the cluster "depth = 0" consists of all source

[2] Kochkina et al. (2018) also proposed *MTL3* that jointly trains three tasks (plus rumor detection (Zubiaga et al., 2017)). In our framework, we do not utilize data and labels from rumor detection task, and thus we choose *MTL2 (Veracity+Stance)* as the state-of-the-art method for comparison.

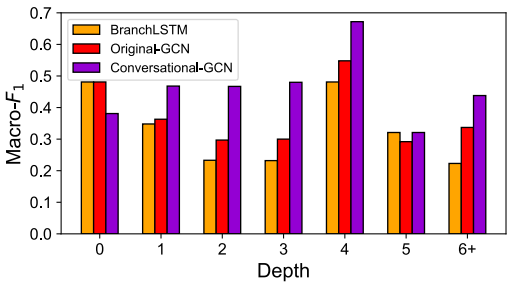

Figure 4: Stance classification results w.r.t. different depths (see Appendix B for exact numerical numbers).

Method	Macro-F_1	Acc.
Hierarchical-PSV (full model)	**0.333**	**0.361**
– stance features	0.299	0.338
– GRU, + CNN	0.312	0.328
– GRU	0.288	0.326

Table 4: Ablation tests of stance features and temporal modeling for veracity prediction on PHEME dataset.

tweets in the test set). For BranchLSTM, Original-GCN and Conversational-GCN, we report their macro-averaged F_1 on each cluster in Figure 4.

We observe that our Conversational-GCN outperforms Original-GCN and BranchLSTM significantly in most levels of depth. BranchLSTM may prefer to "shallow" tweets in a conversation because they often occur in multiple branches (e.g., in Figure 1, the tweet "2" occurs in two branches and thus it will be modeled twice). The results indicate that Conversational-GCN has advantage to identify stances of "deep" tweets in conversations.

5.4.2 Ablation Tests

Effect of Stance Features To understand the importance of stance features for veracity prediction, we conduct an ablation study: we only input the content features of all tweets in a conversation to the top component RNN. It means that the RNN only models the temporal variation of tweet contents during spreading, but does not consider their stances and is not "stance-aware". Table 4 shows that "– stance features" performs poorly, and thus the temporal modeling process benefits from the indicative signals provided by stance features. Hence, combining the low-level content features and the high-level stance features is crucial to improve rumor veracity prediction.

Effect of Temporal Evolution Modeling We modify the Stance-Aware RNN by two ways: (i) we replace the GRU layer by a CNN that only captures local temporal information; (ii) we remove the GRU layer. Results in Table 4 verify that replacing or removing the GRU block hurts the performance, and thus modeling the stance evolution of public reactions towards a rumorous message is indeed necessary for effective veracity prediction.

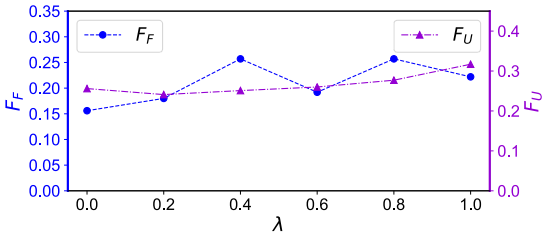

Figure 5: Veracity prediction results v.s. various values of λ on PHEME dataset. F_{F} and F_{U} denote the F_1 scores of $false$ and $unverified$ classes respectively.

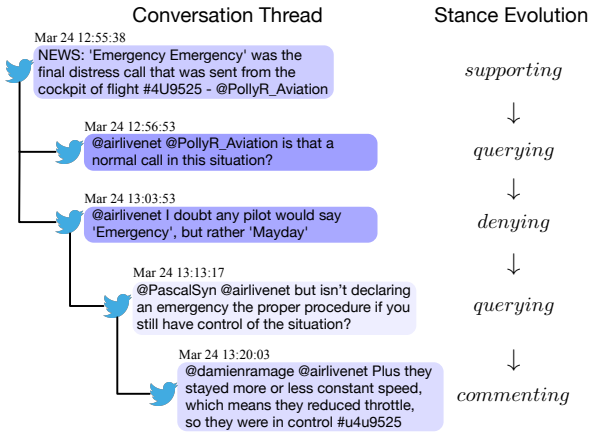

Figure 6: Case study: a $false$ rumor. Each tweet is colored by the number of dimensions it contributes to v in the max-pooling operation (Eq. (7)). We show important tweets in the conversation and truncate others.

5.4.3 Interrelation of Stance and Veracity

We vary the value of λ in the joint loss $\mathcal{L}$ and train models with various λ to show the interrelation between stance and veracity in Figure 5. As λ increases from 0.0 to 1.0, the performance of identifying $false$ and $unverified$ rumors generally gains. Therefore, when the supervision signal of stance classification becomes strong, the learned stance features can produce more accurate clues for predicting rumor veracity.

5.5 Case Study

Figure 6 illustrates a $false$ rumor identified by our model. We can observe that the stances of reply tweets present a typical temporal pattern "$supporting \rightarrow querying \rightarrow denying$". Our

model captures such stance evolution with RNN and predicts its veracity correctly. Further, the visualization of tweets shows that the max-pooling operation catches informative tweets in the conversation. Hence, our framework can notice salience indicators of rumor veracity in the spreading process and combine them to give correct prediction.

6 Conclusion

We propose a hierarchical multi-task learning framework for jointly predicting rumor stance and veracity on Twitter. We design a new graph convolution operation, Conversational-GCN, to encode conversation structures for classifying stance, and then the top Stance-Aware RNN combines the learned features to model the temporal dynamics of stance evolution for veracity prediction. Experimental results verify that Conversational-GCN can handle deep conversation structures effectively, and our hierarchical framework performs much better than existing methods. In future work, we shall explore to incorporate external context (Derczynski et al., 2017; Popat et al., 2018), and extend our model to multi-lingual scenarios (Wen et al., 2018). Moreover, we shall investigate the diffusion process of rumors from social science perspective (Vosoughi et al., 2018), draw deeper insights from there and try to incorporate them into the model design.

A Implementation Details

A.1 Hyperparameters

SemEval-2017 task 8 dataset We pretrain 200-dimensional word embeddings by Skip-gram with negative sampling (Mikolov et al., 2013), and they are fixed during the training process. We set the dimension of content feature to 200. We use a two-layer GCN, and the output sizes of two layers are 200 and 4, respectively. The max-pooling function in Eq. (7) is to select the maximum value of each dimension, and thus the size of $\boldsymbol{v}$ is equal to that of $\boldsymbol{v}_i$. The trade-off parameter λ is set to 1. We add dropout with 0.5 ratio to all but the last GCN layers and the FNN layer (used for veracity prediction). We train our model with 0.001 learning rate and 32 batch size using Adam (Kingma and Ba, 2015). For this dataset, after tuning hyperparameters on the development set, we merge the training and the development sets and re-train our model on the merged set.

PHEME dataset We set the learning rate to 0.005 for accelerating the training process. Other configurations are same to that of SemEval dataset. Because only a subset of PHEME dataset contains stance labels, if a training conversation does not have stance labels, we will not compute its loss function of rumor stance classification task during the training process.

A.2 The CNN Layer in Ablation Study

In Section 5.4.2, to demonstrate the effectiveness of modeling the temporal dynamics of stance evolution, we replace the GRU layer by a CNN layer that only captures local temporal information. Specifically, this CNN layer consists of a 1D convolution layer and a max-pooling function (Kim, 2014). We use three different filter windows: 2, 3 and 4. Each filter window has 100 feature maps. The output vector of this CNN layer is then fed into an FNN layer with softmax function to obtain the predicted veracity distribution.

Abstract

Intent classification is an important building block of dialogue systems. With the burgeoning of conversational AI, existing systems are not capable of handling numerous fast-emerging intents, which motivates zero-shot intent classification. Nevertheless, research on this problem is still in the incipient stage and few methods are available. A recently proposed zero-shot intent classification method, IntentCapsNet, has been shown to achieve state-of-the-art performance. However, it has two unaddressed limitations: (1) it cannot deal with polysemy when extracting semantic capsules; (2) it hardly recognizes the utterances of unseen intents in the generalized zero-shot intent classification setting. To overcome these limitations, we propose to reconstruct capsule networks for zero-shot intent classification. First, we introduce a dimensional attention mechanism to fight against polysemy. Second, we reconstruct the transformation matrices for unseen intents by utilizing abundant latent information of the labeled utterances, which significantly improves the model generalization ability. Experimental results on two task-oriented dialogue datasets in different languages show that our proposed method outperforms IntentCapsNet and other strong baselines.

1 Introduction

With the advent of conversational AI, task-oriented spoken dialogue systems are becoming ubiquitous, e.g., chatbots deployed on different applications, or modules integrated in the popular virtual personal assistants like Apple Siri or Microsoft Cortana (Chen et al., 2017). To improve business effectiveness and user satisfaction, accurately identifying the intents behind user utterances is indispensable. However, it is extremely challenging not only because user queries are sometimes short and expressed diversely, but also because it may continuously encounter new or unacquainted intents popped up quickly from various domains. Conventional intent classification methods (Hu et al., 2009; Tur et al., 2012; Xu and Sarikaya, 2013; Ravuri and Stolcke, 2015; Liu and Lane, 2016; Nam et al., 2016) typically train a supervised learning model on large amounts of labeled data, and are not effective in recognizing emerging unseen intents.

Several zero-shot learning approaches attempted to address the challenges for classifying intents whose instances are not present during training. One common idea is to utilize some external resources (Ferreira et al., 2015a,b; Yazdani and Henderson, 2015; Kumar et al., 2017; Zhang et al., 2019) such as label ontologies or manually defined attributes. However, such external resources are usually unavailable, as they require substantial extra time and expensive human labour to produce. To implement zero-shot intent classification more easily and intelligently, recent works rely more on the word embeddings of intent labels, which can be easily pretrained on text corpus. Methods proposed by Chen et al. (2016) and Kumar et al. (2017) utilize neural networks to project intent labels and data samples to the same semantic space and then measure their similarity. However, learning a good projection function is usually difficult due to the diversity of user expressions, especially in some complex domains such as medical queries (Zhang et al., 2016).

Unlike previous models, IntentCapsNet (Xia et al., 2018) employs capsule networks to extract high-level semantic features and then transfers the prediction vectors for seen intents to unseen intents. Although IntentCapsNet has achieved impressive performance in some zero-shot intent

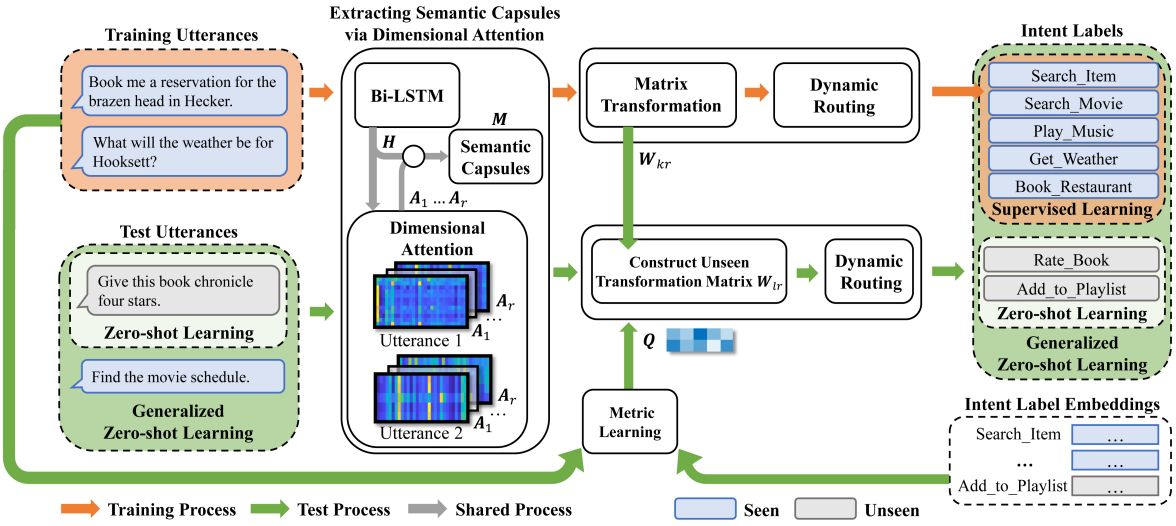

Figure 1: Illustration of our framework ReCapsNet-ZS. **In the training process**, labeled utterances are first encoded by Bi-LSTM. Then, a set of semantic capsules are extracted via the dimensional attention module. Finally, these semantic capsules are fed to a capsule network to train a model for predicting the seen intents. **In the testing process**, to predict the unseen intents, a metric learning method is trained on labeled utterances and intent label embeddings to learn the similarities between the unseen and seen intents. Then, the learned similarities and the transformation matrices for the seen intents trained by capsule networks are used to construct the transformation matrices for the unseen intents. When a test utterance arrives, it is first encoded into semantic capsules by the trained Bi-LSTM and dimensional attention module. There are two settings for intent classification. (1) Zero-shot intent classification: only utterances of the unseen intents participate in testing, so each utterance needs to be classified to one of the unseen intents. In this case, only the transformation matrices for the unseen intents are used for prediction. (2) Generalized zero-shot intent classification: test utterances may come from both the seen and unseen intents, so each utterance needs to be classified to either a seen or an unseen intent. In this case, the transformation matrices for the seen and unseen intents are all used for prediction.

classification tasks, it has two unaddressed limitations. (1) The self-attention module of IntentCapsNet cannot handle polysemy, which weakens the representation capacity of semantic capsules. (2) For the generalized zero-shot classification setting where newly arrived utterances come from both seen and unseen intents, the method of IntentCapsNet for constructing the prediction vectors can easily cause the model to completely fail in detecting unseen intents, which is clearly undesirable and inadequate for real dialogue systems.

In this paper, we propose to reconstruct capsule networks for zero-shot intent classification (ReCapsNet-ZS), which effectively addresses the limitations of IntentCapsNet and adapts well to the generalized zero-shot intent classification tasks. As illustrated in Figure 1, ReCapsNet-ZS consists of two components. First, it introduces a dimensional attention module to alleviate the polysemy problem, which helps to extract semantic features for capsule networks. Second, it computes the similarities between unseen and seen intents by utilizing the rich latent information of labeled utterances, and then constructs the transformation matrices for unseen intents with the computed similarities and the trained transformation matrices for seen intents, which greatly improves the generalization ability to unseen intents.

To verify the effectiveness of the proposed ReCapsNet-ZS for zero-shot intent classification, we conduct extensive experiments on two real task-oriented dialogue datasets in English and Chinese respectively. The empirical study validates our proposals and shows promising results of ReCapsNet-ZS, which are significantly better than state-of-the-art methods, especially on the generalized zero-shot intent classification tasks.

2 Related Works

Zero-shot Intent Classification. Zero-shot learning (Larochelle et al., 2008; Palatucci et al., 2009) aims to use the knowledge learned from seen classes, of which abundant labeled samples are typically available for training, to recognize unseen classes, of which no labeled samples are provided. It has been widely studied in computer

vision (Ba et al., 2015; Xian et al., 2016) and natural language processing (Sappadla et al., 2016; Zhang et al., 2019).

Zero-shot intent classification is an important and challenging task for many natural language understanding applications (Hu et al., 2009; Liu and Lane, 2016; Nam et al., 2016; Xu and Sarikaya, 2013), in which new intents emerge constantly and they cannot be easily recognized. Several methods have been proposed to tackle this problem. Ferreira et al. (2015a,b) and Yazdani and Henderson (2015) utilize external resources such as label ontologies or manually defined attributes to find the relationship between seen and unseen intent labels. However, the external resources are usually difficult to obtain, as collecting them is labor intensive and time consuming. Chen et al. (2016) and Kumar et al. (2017) project the utterances and intent labels to a same semantic space and then compute the similarities between utterances and intent labels (Chen et al., 2016; Kumar et al., 2017). However, diverse user expressions may make it difficult to learn a good projection function and thus affect the classification performance. Recently, Xia et al. (2018) extend capsule networks for zero-shot intent classification by transferring the prediction vectors from seen classes to unseen classes. However, there are some key issues left to be resolved, including how to deal with polysemy in word embeddings and how to improve the model generalization ability to unseen intents in the generalized zero-shot intent classification setting.

Capsule Networks. Capsule Networks (Sabour et al., 2017) were first proposed to address the shortcomings of convolutional neural networks (CNN) in the domain of computer vision. It allows the networks to learn part-whole invariant relationships consecutively. Recently, some studies have attempted to apply capsule networks in the domain of natural language processing (Yang et al., 2018; Geng et al., 2019; Xia et al., 2018) and obtained promising results. Yang et al. (2018) first extend capsule networks for text classification. Geng et al. (2019) successfully combine the dynamic routing algorithm with some meta-learning framework for few-shot text classification. However, their model still requires some labeled samples for each class. Xia et al. (2018) propose a model based on capsule networks for zero-shot intent classification and has achieved state-of-the-art performance, but as mentioned above, their model has some intrinsic limitations remained to be addressed.

3 Preliminaries

3.1 Problem Formulation

Given the set of all intent labels $Y = Y^s \bigcup Y^u$, where $Y^s = \{y_1^s, y_2^s, \ldots, y_K^s\}$ and $Y^u = \{y_1^u, y_2^u, \ldots, y_L^u\}$ are the sets of seen and unseen intent labels respectively. There is no overlap between Y^s and Y^u, i.e., $Y^s \bigcap Y^u = \emptyset$, and K and L are the numbers of seen and unseen intent labels respectively. The embeddings of the seen and unseen intent labels are denoted by $E^s = \{\boldsymbol{e}_1^s, \boldsymbol{e}_2^s, \ldots, \boldsymbol{e}_K^s\}$ and $E^u = \{\boldsymbol{e}_1^u, \boldsymbol{e}_2^u, \ldots, \boldsymbol{e}_L^u\}$ respectively. Each embedding is a d-dimensional vector. For all the seen and unseen intent labels, their associated embeddings are available. The sample (utterance) sets for the seen and unseen intent labels are denoted by $X^s = \{x_1^s, x_2^s, \ldots, x_{n_s}^s\}$ and $X^u = \{x_1^u, x_2^u, \ldots, x_{n_u}^u\}$ respectively, where n_s is the number of instances of the seen labels and n_u is the number of instances of the unseen labels.

Zero-shot Intent Classification. For this setting, the training set is $X^{tr} = \{X^s, Y^s\}$, and X^u is not available for training. In the test phase, the goal is to assign an unseen intent label $y \in Y^u$ to a given utterance.

Generalized Zero-shot Intent Classification. For this setting, the training procedure is the same as above, while the difference is in the test phase, where the goal is to assign an intent label $y \in Y^s \bigcup Y^u$ to a given utterance.

In this paper, we aim to reconstruct capsule networks for handling both of the two settings of zero-shot intent classification.

3.2 Limitations of IntentCapsNet

IntentCapsNet (Xia et al., 2018) is the first work to employ capsule networks for zero-shot intent classification. It exploits the self-attention mechanism to extract semantic features (capsules) of an utterance. For zero-shot intent classification, it utilizes the vote vectors of seen intents and the similarities between seen and unseen intents based on Euclidean distance to make predictions for unseen intents. Although IntentCapsNet has demonstrated strong performance, it has two fundamental limitations.

Limitation 1. The self-attention module of IntentCapsNet cannot handle the polysemy problem, which limits the representation capacity of semantic capsules.

Typically, a word is represented by a multi-dimensional embedding. Since a word can have different meanings in different contexts, some interesting recent studies (Shen et al., 2018; Şenel et al., 2018) suggest that different dimensions of a word embedding may tend to represent different semantic meanings. For example, the word "book" has different meanings in the two utterances: "Book a restaurant in Michigan for 4 people" and "Give 4 out of 6 points to this book". For the embedding of the word "book", it is hypothesized that some dimensions may be more indicative for the first meaning – "reserve", while some other dimensions may be more indicative for the second meaning. Apparently, the self-attention mechanism cannot pay more attentions to the dimensions that best describe the specific meaning of a word in a given context, as it assigns the same attention score for all the dimensions, which significantly limits the representation capacity of semantic capsules and undermines the performance of capsule networks.

Limitation 2. For the generalized zero-shot classification setting, the method of IntentCapsNet for constructing the prediction vectors is highly likely to cause the model to lose generalization ability to unseen intents.

Here, we provide an analysis of IntentCapsNet for predicting an unseen intent in the generalized zero-shot classification setting. In IntentCapsNet, the probability of a test utterance x belonging to a seen intent label k is computed as:

$$P_k = \|\sum_{r=1}^{R} c_{kr}\boldsymbol{p}_{k|r}\| = \|\sum_{r=1}^{R}\boldsymbol{g}_{k,r}\|, \quad (1)$$

where $\|\cdot\|$ is the L2-norm of a vector, R is the number of semantic capsules, $\boldsymbol{p}_{k|r}$ is the prediction vector for the r-th semantic capsule with respect to the seen intent k, and c_{kr} is the weight of the r-th semantic capsule with respect to the seen intent k, which is computed by the dynamic routing algorithm of capsule networks. $\boldsymbol{g}_{k,r} = c_{kr}\boldsymbol{p}_{k|r}$ is called the r-th vote vector for the seen intent k. By Eq. (1), we have a tight upper bound for P_k:

$$P_k \leqslant \sum_{r=1}^{R}\|\boldsymbol{g}_{k,r}\|. \quad (2)$$

IntentCapsNet computes the probability of x belonging to an unseen intent label l as:

$$P_l = \|\sum_{r=1}^{R} c_{lr}\boldsymbol{u}_{l|r}\| = \|\sum_{r=1}^{R} c_{lr}\sum_{k=1}^{K} q_{lk}\boldsymbol{g}_{k,r}\|, \quad (3)$$

where $\boldsymbol{u}_{l|r}$ is the prediction vector for the r-th semantic capsule with respect to the unseen intent l, and c_{lr} is the weight of the r-th semantic capsule with respect to the unseen intent l, which is determined by the dynamic routing algorithm. $\boldsymbol{u}_{l|r} = \sum_{k=1}^{K} q_{lk}\boldsymbol{g}_{k,r}$, where K is the number of seen intents, $\boldsymbol{g}_{k,r}$ is the r-th vote vector for the seen intent k, and q_{lk} is the similarity between an unseen intent $y_l^u \in Y^u$ and a seen intent $y_k^s \in Y^s$. $q_{lk} = \frac{exp(-d(\boldsymbol{e}_k^s, \boldsymbol{e}_l^u))}{\sum_{k=1}^{K} exp(-d(\boldsymbol{e}_k^s, \boldsymbol{e}_l^u))}$, where $\boldsymbol{e}_k^s$ and $\boldsymbol{e}_l^u$ are the embeddings of the seen and unseen intents respectively, and $d(\boldsymbol{e}_k^s, \boldsymbol{e}_l^u)$ is the scaled squared Euclidean distance between $\boldsymbol{e}_k^s$ and $\boldsymbol{e}_l^u$. Since $q_{lk} \in (0,1)$, $c_{lr} \in (0,1)$, $\sum_{k=1}^{K} q_{lk} = 1$ and $\sum_{r=1}^{R} c_{lr} = 1$, we have a tight upper bound for P_l:

$$P_l \leqslant \sum_{r=1}^{R} c_{lr}\sum_{k=1}^{K} q_{lk}\|\boldsymbol{g}_{k,r}\| \leqslant \|\boldsymbol{g}_{k,r}\|_{\max}, \quad (4)$$

where $\|\boldsymbol{g}_{k,r}\|_{\max}$ is the maximum among $\|\boldsymbol{g}_{k,r}\|$, $\forall r \in \{1, 2, \ldots, R\}$ and $\forall k \in \{1, 2, \ldots, K\}$.

By Eq. (2) & (4), it can be seen that the upper bound of P_k is much larger than P_l, indicating that for any utterance x, it is highly likely that $P(y \in Y^s|x)$ is larger than $P(y \in Y^u|x)$. Hence, for generalized zero-shot classification, with high probability IntentCapsNet will classify a test utterance to the seen intents, which is also verified by our experiments in section 5.

4 The Proposed Approach

To overcome the limitations of IntentCapsNet, we propose to reconstruct capsule networks for zero-shot intent classification. In particular, we introduce two modules to capsule networks: (1) a dimensional attention module that helps to extract more representative semantic capsules and (2) a new method for constructing the transformation matrices to improve the model generalization ability to unseen intents.

4.1 Dimensional Attention Capsule Networks

Pre-processing. An utterance with T words can be represented as $x = \{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_T\}$, where

$\boldsymbol{w}_t \in \mathbb{R}^{d_w}$ is the word embedding of the t-th word and can be pretrained by the skip-gram model (Mikolov et al., 2013). Each word can be further encoded sequentially using a recurrent neural network such as bidirectional LSTM (Hochreiter and Schmidhuber, 1997), i.e.,

$$\begin{aligned} \overrightarrow{\boldsymbol{h}}_t &= \text{LSTM}_{fw}(\boldsymbol{w}_t, \overrightarrow{\boldsymbol{h}}_{t-1}), \\ \overleftarrow{\boldsymbol{h}}_t &= \text{LSTM}_{bw}(\boldsymbol{w}_t, \overleftarrow{\boldsymbol{h}}_{t+1}), \end{aligned} \tag{5}$$

where LSTM_{fw} and LSTM_{bw} denote the forward and backward LSTM respectively, and $\overrightarrow{\boldsymbol{h}}_t \in \mathbb{R}^{d_h}$ and $\overleftarrow{\boldsymbol{h}}_t \in \mathbb{R}^{d_h}$ are the hidden states of the word $\boldsymbol{w}_t$ learned from LSTM_{fw} and LSTM_{bw} respectively. The entire hidden state of $\boldsymbol{w}_t$ is represented by concatenating $\overrightarrow{\boldsymbol{h}}_t$ and $\overleftarrow{\boldsymbol{h}}_t$, i.e., $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}}_t, \overleftarrow{\boldsymbol{h}}_t]$, and the hidden state matrix of the utterance is $\boldsymbol{H} = [\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_T] \in \mathbb{R}^{2d_h \times T}$.

4.1.1 Extracting Semantic Capsules with Dimensional Attention

In general, an utterance is composed of multiple semantic features, and these semantic features collectively contribute to a more abstract intent label. For example, an utterance "I want to know the temperature of Hong Kong" is composed by multiple semantic features such as get_action (want to know), weather (temperature), and city_name (Hong Kong), and these semantic features collectively reflect the intent label "Get_Weather". Capsule networks provide a hierarchical reasoning structure for modeling semantic features for intent classification. First, the primary capsules in capsule networks can properly match multiple semantic features of an utterance. Second, the dynamic routing mechanism of capsule networks can be used to automatically learn the importance weight of each semantic feature and aggregate them into a high-level intent label.

It is assumed that a high-level semantic feature of an utterance is largely generated by some of its words that have similar semantic meaning (Xia et al., 2018). To extract the semantic features of an utterance, the key problem is to learn the importance weight of each word for a semantic feature. IntentCapsNet (Xia et al., 2018) utilizes the self-attention mechanism to extract the semantic features (capsules) of each utterance. However, self-attention cannot effectively deal with polysemy. Inspired by the work of Shen et al. (2018), we propose to use the dimensional attention mechanism to alleviate the polysemy problem in extracting semantic features. Dimensional attention can automatically assign different attention scores to different dimensions of a word embedding, which not only helps to solve the polysemy problem to some extent, but also expands the search space of the attention parameters, thus improving model flexibility and effectiveness.

Assume each utterance has R semantic features. We propose to learn a dimensional attention matrix $\boldsymbol{A}_r \in \mathbb{R}^{2d_h \times T}$ that encodes the dimensional attentions of the T words with respect to the r-th semantic feature by:

$$\boldsymbol{A}_r = \text{softmax}\left(\boldsymbol{F}_2 \, \text{ReLU}\left(\boldsymbol{F}_1 \boldsymbol{H}\right)\right), \tag{6}$$

where $\boldsymbol{F}_1 \in \mathbb{R}^{d_a \times 2d_h}$ and $\boldsymbol{F}_2 \in \mathbb{R}^{2d_h \times d_a}$ are the trainable parameters, and $\boldsymbol{A}_r(i, j)$ (the element of $\boldsymbol{A}_r$ in the i-th row and j-th column) means the importance weight of the i-th dimension of the j-th word embedding to the r-th semantic feature. Compared with self-attention, dimensional attention can help to choose the appropriate dimensions of a word embedding that can best express the specific meaning of the word in a given context.

After obtaining $\boldsymbol{A}_r$, the r-th semantic feature $\boldsymbol{m}_r \in \mathbb{R}^{2d_h}$ is computed by:

$$\boldsymbol{m}_r = \sum\nolimits_{\text{row}} \left(\boldsymbol{A}_r \odot \boldsymbol{H}\right), \tag{7}$$

where $\odot$ is element-wise multiplication, and $\sum_{\text{row}}$ is an operator that sums up elements of each row. The entire semantic features for each utterance is $\boldsymbol{M} = [\boldsymbol{m}_1, \boldsymbol{m}_2, \ldots, \boldsymbol{m}_R] \in \mathbb{R}^{2d_h \times R}$.

4.1.2 Improved Max-margin Loss

The semantic features of the utterance can then be fed into a capsule network to learn the intent. First, we transform each semantic feature $\boldsymbol{m}_r$ of the utterance to a prediction vector with respect to each intent as:

$$\boldsymbol{p}_{k|r} = \boldsymbol{W}_{kr} \boldsymbol{m}_r, \tag{8}$$

where $\boldsymbol{p}_{k|r} \in \mathbb{R}^{d_p}$ is the prediction vector of the r-th semantic feature with respect to the k-th intent, and $\boldsymbol{W}_{kr} \in \mathbb{R}^{d_p \times 2d_h}$ is the associated transformation matrix.

In training, there are K output capsules, corresponding to K seen intents. The k-th output capsule $\boldsymbol{o}_k$ is the weighted sum of all the prediction vectors $\boldsymbol{p}_{k|r}$ ($r \in \{1, \ldots, R\}$),

$$\boldsymbol{o}_k = \sum_{r=1}^{R} c_{kr} \boldsymbol{p}_{k|r}, \tag{9}$$

Algorithm 1 Dynamic Routing Algorithm

Procedure Dynamic Routing($\boldsymbol{p}_{k|r}, n_{\text{route}}$)
  for all semantic capsule r and intent capsule k: $b_{kr} \leftarrow 0$.
  for n_{route} iterations **do**
    for all semantic capsule r: $\boldsymbol{c}_r \leftarrow \text{softmax}(\boldsymbol{b}_r)$.
    for all intent capsule k: $\boldsymbol{o}_k \leftarrow \sum_{r=1}^{R} c_{kr}\boldsymbol{p}_{k|r}$.
    for all intent capsule k: $\boldsymbol{v}_k \leftarrow \text{squash}(\boldsymbol{o}_k)$.
    for all semantic capsule r and intent capsule k:
      $b_{kr} \leftarrow b_{kr} + \boldsymbol{p}_{k|r} \cdot \boldsymbol{v}_k$.
  end for
  return $\boldsymbol{v}_k$.

where c_{kr} is the coupling coefficient representing the contribution degree of the r-th semantic feature to the k-th intent, which can be computed by the dynamic routing algorithm (Algorithm 1).

Then, a squashing function $\text{squash}(\cdot)$ is applied on $\boldsymbol{o}_k$, and the final output capsule of the k-th intent is:

$$\boldsymbol{v}_k = \text{squash}(\boldsymbol{o}_k) = \frac{\|\boldsymbol{o}_k\|^2}{1+\|\boldsymbol{o}_k\|^2}\frac{\boldsymbol{o}_k}{\|\boldsymbol{o}_k\|}. \quad (10)$$

Now, the probability of the existence of the k-th intent can be represented as the length of the output capsule $\boldsymbol{v}_k$. The computation procedure of $\boldsymbol{v}_k$ is shown in Algorithm 1, where $\boldsymbol{p}_{k|r} \cdot \boldsymbol{v}_k$ denotes the inner product between $\boldsymbol{p}_{k|r}$ and $\boldsymbol{v}_k$.

To train the dimensional attention capsule network, we propose an improved max-margin loss function consisting of two parts.

The first part is the max-margin loss on each labeled utterance, which is the original loss function of capsule networks (Sabour et al., 2017):

$$\begin{aligned} L_1 = \sum_{k=1}^{K} \{ & y_k \max(0, m^+ - \|\boldsymbol{v}_k\|)^2 \\ & + \lambda(1-y_k)\max(0, \|\boldsymbol{v}_k\| - m^-)^2\}, \end{aligned} \quad (11)$$

where $y_k = 1$ if the utterance is of intent label k and $y_k = 0$ otherwise, λ is a down-weighting parameter, and m^+ and m^- are the margins.

The second part is to ensure the diversity of the semantic capsules, i.e., different semantic capsules are likely to be generated by different words in an utterance. The importance weight of each word to the r-th semantic capsule can be represented by the average value of each column of the dimensional attention matrix $\boldsymbol{A}_r$, i.e.,

$$\boldsymbol{s}_r = \frac{1}{2d_h}\sum\nolimits_{\text{col}} \boldsymbol{A}_r, \quad (12)$$

where $\boldsymbol{s}_r \in \mathbb{R}^{1\times T}$ and $\sum_{\text{col}}$ is an operator that sums up elements of each column. Denote by $\boldsymbol{S} = [\boldsymbol{s}_1^\top, \boldsymbol{s}_2^\top, \ldots, \boldsymbol{s}_R^\top] \in \mathbb{R}^{T\times R}$ the importance weight matrix of each word to all the R semantic capsules. To ensure the diversity of the semantic capsules, a natural idea is to constrain the columns of $\boldsymbol{S}$ to be orthogonal with the following loss function:

$$L_2 = \|\boldsymbol{S}^\top\boldsymbol{S} - \boldsymbol{I}\|_F^2, \quad (13)$$

where $\|\cdot\|_F$ is the Frobenius norm of a matrix.

Combining Eq. (11) and Eq. (13), the overall loss function of the proposed dimensional attention capsule network is:

$$L_{total} = L_1 + \beta L_2, \quad (14)$$

where β is a trade-off parameter. By minimizing L_{total} with gradient descent methods, all model parameters including $\boldsymbol{F}_1$, $\boldsymbol{F}_2$ and $\boldsymbol{W}_{kr}$ can be learned.

4.2 Zero-shot Intent Classification

To solve zero-shot intent classification with capsule networks, two key problems need to be addressed. (1) How to find the relationship between unseen and seen intents? (2) How to make predictions for unseen intents?

Measuring Intent Relations. To tackle the first problem, we propose to learn a Mahalanobis distance metric to measure the relationship between unseen and seen intents. Specifically, given the embeddings of an unseen intent l and a seen intent k, their squared Mahalanobis distance is given by:

$$d_M(\boldsymbol{e}_l^u, \boldsymbol{e}_k^s) = (\boldsymbol{e}_l^u - \boldsymbol{e}_k^s)^\top \boldsymbol{\Omega}^{-1}(\boldsymbol{e}_l^u - \boldsymbol{e}_k^s), \quad (15)$$

where $\boldsymbol{\Omega}$ is a learnable covariance matrix which models the correlation between dimensions of the embedding. Note that IntentCapsNet (Xia et al., 2018) also tries to use Eq. (15) to model the relationship between unseen and seen intents, but it ignores the correlation between dimensions and simply sets $\boldsymbol{\Omega} = \sigma^2\boldsymbol{I}$ (σ is a scaling hyper-parameter), which is actually a scaled squared Euclidean distance.

As the number of intents is limited, it is difficult to learn a desirable covariance matrix $\boldsymbol{\Omega}$ with the intent embeddings only. Fortunately, we can leverage the word embeddings of the utterances, which come from the same semantic space as the intent embeddings (pre-trained by the same skip-gram model). Hence, we propose to learn the covariance matrix $\boldsymbol{\Omega}$ with the labeled utterances in the

training set. Inspired by the work of Ying and Li (2012), we propose to learn the Mahalanobis distance metric by optimizing the objective:

$$\max_{\mathbf{\Omega}} \min_{(i,j)\in\mathcal{D}} d_M(\boldsymbol{z}_i^s, \boldsymbol{z}_j^s), \quad s.t. \sum_{(i,j)\in\mathcal{S}} d_M(\boldsymbol{z}_i^s, \boldsymbol{z}_j^s) \leqslant 1, \tag{16}$$

where $\mathcal{D}$ and $\mathcal{S}$ respectively denote the pair sets in which utterances belong to different classes and the same class. For an utterance i, $\boldsymbol{z}_i^s$ denotes the average sum of all the word embeddings. As shown by Ying and Li (2012), optimizing Eq. (16) with respect to $\mathbf{\Omega}$ is equivalent to solving an efficient eigenvalue optimization problem. With the learned metric $\mathbf{\Omega}$, we can have the relationship between any unseen and seen intents by substituting it into Eq. (15). Furthermore, we can compute the similarity between them by $q_{lk} = \exp\left(-\alpha \cdot d_M(\boldsymbol{e}_l^u, \boldsymbol{e}_k^s)\right)$, where α is a scaling parameter.

Constructing Transformation Matrices. Intuitively, if an unseen intent is similar to a seen intent, their corresponding transformation matrices should also be similar. Based on this, to solve the second problem, we propose to derive the transformation matrices of unseen intents using the transformation matrices of seen intents and the similarities between unseen and seen intents, and then make predictions for unseen intents with the transformation matrices. Specifically, given a matrix $\boldsymbol{Q} \in \mathbb{R}^{L\times K}$ that encodes the similarities between unseen and seen intents, for an unseen intent l, we propose to construct the transformation matrix $\boldsymbol{W}_{lr}$ for the r-th semantic capsule with respect to the l-th unseen intent by:

$$\boldsymbol{W}_{lr} = \sum_{k=1}^{K} q_{lk} \boldsymbol{W}_{kr}, \tag{17}$$

where q_{lk} is the element in the l-th row and the k-th column of $\boldsymbol{Q}$, $\boldsymbol{W}_{kr}$ is the transformation matrix for the r-th semantic capsule with respect to the k-th seen intent. By Eq. (17), the transformation matrices for all unseen intents can be obtained. When a test utterance arrives, it can be directly fed into the trained dimensional attention capsule network for intent prediction.

Dataset	**SNIPS-NLU**	**SMP-2018**

5 Experiments

5.1 Datasets

We evaluate our model on two real task-oriented dialogue datasets in different languages. Table 1 summarizes the dataset statistics.

SNIPS-NLU. Following (Xia et al., 2018), we use the SNIPS-NLU (SNIPS Natural Language Understanding) benchmark dataset (Coucke et al., 2018). SNIPS-NLU is an open-source single-turn English corpus, which contains crowdsourced queries evenly distributed in 7 intents.

SMP-2018. It is a real Chinese dialogue corpus released in SMP 2018 (The China National Conference on Social Media Processing) for user intent classification tasks in Chinese (Zhang et al., 2017). The dataset is provided by the iFLYTEK Corporation, and it can be divided into two parts: chit-chat dialogues and task-oriented dialogues. Here, we only use the task-oriented dialogues.

Dataset Splitting. For zero-shot intent classification, we take all the samples of seen intents as the training set, and all the samples of unseen intents as the test set. For generalized zero-shot intent classification, we randomly take 70% samples of each seen intent as the training set, and the remaining 30% samples of each seen intent and all the samples of unseen intents as the test set.

5.2 Baselines

We compare ReCapsNet-ZS with the following state-of-the-art zero-shot learning methods: DeViSE (Frome et al., 2013), CMT (Socher et al., 2013), CDSSM (Chen et al., 2016), Zero-shot DNN (Kumar et al., 2017) and IntentCapsNet (Xia et al., 2018). To make DeViSE and CMT suit-

Table 3: Results of zero-shot intent classification.

able for intent classification, we use a multi-head self-attention Bi-LSTM model to encode the utterances and then feed the final hidden states to their zero-shot learning models. In addition, we conduct ablation study to evaluate the contribution of each module of our ReCapsNet-ZS. "ReCapsNet-ZS-Dim" refers to the model that only uses the dimensional attention mechanism, and "ReCapsNet-ZS-TM" refers to the one that only uses the proposed transformation matrix construction method.

5.3 Implementation Details

Parameter Settings. For SNIPS-NLU, we use 300-dim embeddings pre-trained on English Wikipedia (Bojanowski et al., 2017). For SMP-2018, we use 300-dim Chinese word embeddings pre-trained by Li et al. (2018). The main network structure hyperparameters are shown in Table 2. In addition, for the zero-shot classification setting, we set α to 1 for SNIPS-NLU and 10 for SMP-2018 respectively. For the generalized zero-shot classification setting, we set α to 1 for SNIPS-NLU and 5 for SMP-2018 respectively. To avoid overfitting, we use dropout with 0.5 dropout rate on the input of the attention layer. For the loss function, we set $\lambda = 0.5$, $m^+ = 0.9$, $m^- = 0.1$, $\beta = 0.001$, and use the Adam optimizer (Kingma and Ba, 2015) with initial learning rate 0.01.

Evaluation Metrics. We adopt two widely used metrics: accuracy (Acc) and micro-average F1-measure (F1) to evaluate the classification performance. Both metrics are computed with the average value weighted by the support of each class, where the support means the sample ratio of the corresponding class.

5.4 Result Analysis

Zero-shot Intent Classification. Table 3 summarizes the average results over 10 runs, where the top 2 results are highlighted in bold. The baseline results on SNIPS-NLU are taken from Xia et al. (2018). The results show that ReCapsNet-ZS outperforms all the baselines, demonstrating its superiority in tackling zero-shot intent classification. We can also see that ReCapsNet-ZS performs better than either ReCapsNet-ZS-Dim or ReCapsNet-ZS-TM, which shows the effectiveness of both of the dimensional attention mechanism and the transformation matrix construction method.

Generalized Zero-shot Intent Classification. Table 4 shows the average results over 10 runs, where the top 2 results are highlighted in bold. We can make the following observations. 1) The performances look much worse than the standard zero-shot setting, but it is not surprising since the seen intent labels are included in the test phase and it makes the problem harder. 2) ReCapsNet-ZS sometimes performs slightly worse than the baselines in detecting seen intents, which is because some baselines tend to classify the test utterances as seen intents, which on the other hand explain-

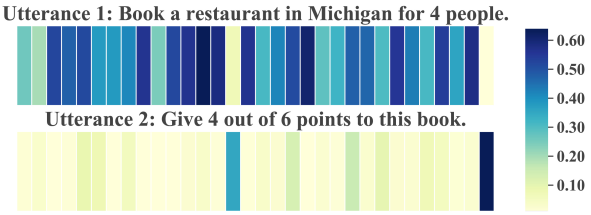

Figure 2: Comparison of the dimensional attentions of the word "book" in different contexts.

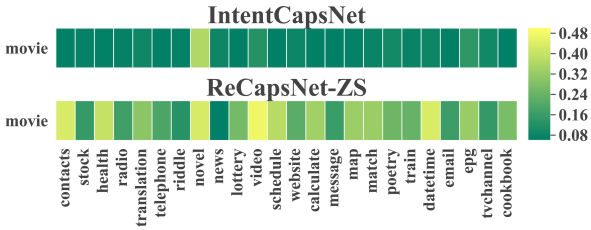

Figure 3: Comparison of the similarity scores between the unseen intent "movie" and the seen intents learned by IntentCapsNet and ReCapsNet-ZS (ours).

s why they perform much worse in detecting unseen intents. 3) ReCapsNet-ZS and ReCapsNet-ZS-TM perform much better than others in detecting unseen intents, whereas IntentCapsNet and ReCapsNet-ZS-Dim both have 0% Acc and F1. This verifies that the proposed transformation matrix construction method has much better generalization ability in detecting unseen intents. 4) Overall, ReCapsNet-ZS consistently performs the best, which further demonstrates the superiority of ReCapsNet-ZS on the generalized zero-shot intent classification tasks.

5.5 Visualization

Dimensional Attentions. Figure 2 visualizes the attention score for each dimension of the same word "book" in two different utterances (contexts) by heatmaps. The utterances are "Book a restaurant in Michigan for 4 people" and "Give 4 out of 6 points to this book", which are taken from SNIPS-NLU. It can be seen that for the two utterances the attention values of the word "book" exhibit completely different patterns, which makes sense as it contains different meanings in different contexts. Furthermore, for each utterance, the attention scores of "book" on different dimensions are also quite different. This shows that the dimensional attention mechanism can effectively capture the semantic differences of the same word in different contexts and encode more useful information than the traditional self-attention method, and thus helps to alleviate the polysemy problem.

Similarity Scores. Figure 3 visualizes the similarity scores between the unseen intent "movie" and the seen intents learned via metric learning by IntentCapsNet and ReCapsNet-ZS respectively on SMP-2018. It can be seen that IntentCapsNet can only discover few connections between the unseen and seen intents. In contrast, ReCapsNet-ZS can detect a lot more connections between them. Further, though the similarity scores of ReCapsNet-ZS may introduce some noise (e.g., "contacts"), they can capture many more positive relations between "movie" and the seen intents (e.g., "novel", "video", "schedule", and "datetime"), which is beneficial for detecting unseen intents.

6 Conclusion

In this paper, we have proposed a novel framework to reconstruct capsule networks for zero-shot intent classification and demonstrated empirically that it compares favourably with existing methods on some real dialogue datasets. The performance gains of our method come from two aspects: the introduction of a new dimensional attention module to capsule networks for feature extraction and the proposal of a new transformation scheme for detecting unseen intents.

There are several directions of the future works. One is to customize our model for few-shot intent classification. Another is to extend our framework to deal with multiple-intent classification. We also plan to apply our model in dialogue systems for low-resource languages such as Cantonese.

Abstract

Person-job fit has been an important task which aims to automatically match job positions with suitable candidates. Previous methods mainly focus on solving the match task in single-domain setting, which may not work well when labeled data is limited. We study the domain adaptation problem for person-job fit. We first propose a deep global match network for capturing the global semantic interactions between two sentences from a job posting and a candidate resume respectively. Furthermore, we extend the match network and implement domain adaptation in three levels, *i.e.,* sentence-level representation, sentence-level match, and global match. Extensive experiment results on a large real-world dataset consisting of six domains have demonstrated the effectiveness of the proposed model, especially when there is not sufficient labeled data.

1 Introduction

Recent years have witnessed the rapid growth of online recruitment platforms. According to (Iqbal, 2019), there were 590 million users and 11 million job listings in LinkedIn[1] from about over 200 countries and territories all over the world. With the increasing amount of online recruitment data, it has become an essential task that is able to automatically match jobs with suitable candidates, called *person-job fit* (Qin et al., 2018; Shen et al., 2018).

Due to the importance of person-job fit, many efforts have been devoted to improving the match algorithms (Xu et al., 2018; Malinowski et al., 2006; Paparrizos et al., 2011; Lee and Brusilovsky, 2007; Zhang et al., 2014). Among these studies, a typical approach is to casting the task as a supervised text match problem. Given a set of labeled data (*i.e.,* person-job match records), it aims to predict the match label based on the text content of job postings and candidate resumes. More recently, deep learning has shed light on person-job fit methods by learning more effective text representations or text match models (Qin et al., 2018; Zhu et al., 2018; Jiang et al., 2019).

Although these methods have achieved significant progress in person-job fit, they rely on a considerable amount of labeled data to learn the match models. When labeled data is insufficient, existing methods may not work well as expected. Therefore, the deficiency in labeled data has raised a significant challenge to the person-job fit algorithms. The availability of labeled data for different job categories is highly varying. A job position from a major category usually attracts hundreds of job applicants, while one from a minor category receives very few applications. Besides, due to the emergence of new positions, data accumulation under these new job categories is limited. For this purpose, we investigate domain adaptation for person-job fit, focusing on the text match between job postings and candidate resumes. We aim to utilize the acquired knowledge and information from a source domain with sufficient labeled data to improve the prediction performance in a target domain with limited or little labeled data.

Text-based domain adaptation has been extensively studied in the literature, such as text classification (Li et al., 2018; Glorot et al., 2011; Ziser and Reichart, 2017). However, these works mainly focus on how to model an individual document instead of the match for a document pair, which are not directly applicable to our task. As for existing person-job fit methods (Qin et al., 2018), they mainly learn an overall representation for both a job posting and a candidate resume. Then,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4810–4820, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the match score is measured via the similarity between the two overall representations, which is limited to extend for domain adaptation. A major reason is that job postings and resumes are written on top of basic semantic units (*e.g.,* sentences) related to skills, abilities or experiences, we have to model the global interaction between fine-grained semantic units for an accurate match. Such global match information is important to consider for effective domain adaptation.

To address these difficulties, we first design a deep global match network for modeling person-job fit in a single domain. This model can capture the comprehensive interaction information based on all pairwise sentence interactions given a job posting and a resume. Furthermore, we extend the match network for domain adaptation in three levels. First, to overcome the semantic gap or language variation across different domains, the sentence representations have been enhanced via structural correspondence learning. The derived sentence representations are more transferable across domains. Second, the sentence-level match function has been set to share parameters across domains for improving the match accuracy in target domains. We construct a match matrix to contain all the match results in sentence level. Third, we design a convolution based component to learn transferable match patterns and components across domains. Although different domains have varying semantic representations or match functions, the global match information reflected in the match matrix should share similar patterns.

To our knowledge, it is the first time that domain adaptation has been studied for the person-job fit task. To evaluate our proposed model, we construct a large real-world dataset containing two large and four small domains from an online recruitment platform. Extensive experiment results have demonstrated the effectiveness of the proposed model, especially when the labeled data is limited.

2 Related Work

As an important task in recruitment data mining (Li et al., 2017a; Xu et al., 2018; Oentaryo et al., 2018), person-job fit has been extensively studied in the literature. Early methods include treating person-job fit as a job/candidate recommendation problem (Lu et al., 2013; Diaby et al., 2013) and extending users' historical behavior by job application records for better match (Hong et al., 2013). Recently, deep learning methods have been utilized to design a hierarchical representation structure based on historical recruitment records (Qin et al., 2018; Zhu et al., 2018; Ramanath et al., 2018).

Domain adaptation is a hot topic in natural language processing, which has received much attention over the decades. Among the early works, Structural Correspondence Learning (SCL) (Blitzer et al., 2007, 2006) is a classic algorithm which learns transferable feature representations across domains. With the revival of deep learning, several studies focus on extending the neural network models for domain adaptation (Yu and Jiang, 2016; Ziser and Reichart, 2017). To further eliminate the distribution differences between source and target domains, the adversarial mechanism has been incorporated into domain adaptation (Li et al., 2017b, 2018; Ganin et al., 2016).

Besides, our work is also related to semantic text match (Mueller and Thyagarajan, 2016; Yin et al., 2016; Wang et al., 2017), specially the work which casts text match as image recognization (Pang et al., 2016) or captures both global and local interactions (Dai et al., 2018; Rao et al., 2018; Yang et al., 2018).

Our work is highly based on these related studies. To our knowledge, domain adaptation for person-job fit has seldom been studied before. We focus on how to transfer the match information between job postings and resumes across domains.

3 Problem Formulation

We assume text content of a job posting and a candidate resume are available as input. A job posting p is described as n_p sentences $\{\boldsymbol{w}_i^{(p)}\}_{i=1}^{n_p}$, and the i-th sentence $\boldsymbol{w}_i^{(p)}$ is a sequence of $n_{p,i}$ word tokens denoted by $\{w_{i,k}^{(p)}\}_{k=1}^{n_{p,i}}$, where $w_{i,k}^{(p)}$ denotes the k-th word of the i-th sentence in p. Each job posting sentence typically describes the skill or ability that is required for the position. Similarly, a resume r consists of n_r sentences $\{\boldsymbol{w}_i^{(r)}\}_{i=1}^{n_r}$, where $\boldsymbol{w}_i^{(r)}$ is a sequence of $n_{r,i}$ word tokens denoted by $\{w_{i,k}^{(r)}\}_{k=1}^{n_{r,i}}$. Each resume sentence typically describes the skills or experiences that a candidate has acquired. Let a binary label y denote the match result for a person-job pair based on the text of job posting p and

Symbols	Descriptions
p, r	the job posting and resume
n_p, n_r	the number of sentences in the p and r
$\boldsymbol{w}_i^{(p)}, \boldsymbol{w}_i^{(r)}$	the i-th sentence in the p and r
$\{w_{i,k}^{(p)}\}, \{w_{i,k}^{(r)}\}$	the k-th word of the i-th sentence in p and r
y	the match result for a person-job pair based on the p and r
$\mathcal{D}^t, \mathcal{D}^s$	the training set for the target domain t and source domain s
n_t, n_s	the number of target labeled instances and source labeled instances
$\boldsymbol{h}_{i,k}^{(p)}, \boldsymbol{h}_{i,k}^{(p)}$	the hidden states learned from BiGRU network for the k-th word of the i-th sentence in the p and r
L_P, L_R	the dimension size of hidden states for the p and r
$\mathbf{M}$	the match matrix ($\in \mathbb{R}^{n_p \times n_r}$) for the sentence similarity between the p and r
$\mathbf{W}$	the weight matrix ($\in \mathbb{R}^{K \times K}$) , K is the dimension size
$\boldsymbol{m}^{p,r}$	the match representation derived by stacked convolutional layers with max-pooling layers
Θ	all the involved parameters
$\boldsymbol{h}^p, \boldsymbol{h}^r$	the representations of the p and r
$\hat{y}$	the output score calculated by the Multi-Layer Perceptron
$\boldsymbol{x}_{i,\text{SCL}}^p, \boldsymbol{x}_{i,\text{SCL}}^r$	the transferable representation transformed by the original feature in the p and r
$\widetilde{\boldsymbol{h}_i^p}, \widetilde{\boldsymbol{h}_i^r}$	the enhanced job posting and resume sentence representation
$\mathbf{A}$	the shared weight matrix by all the domains
$\mathbf{B}^d$	the specific weight matrix to the domain d
$\hat{\Theta}^s$	the learned parameters for the auxiliary domain s
$\hat{\Theta}^t$	the domain-specific parameters for the target domain t
$\widetilde{\boldsymbol{m}^{p,r}}$	the new representation by the concatenation of the output from both components with the parameters $\hat{\Theta}^s$ and $\hat{\Theta}^t$

Table 1. The notations used in this paper.

candidate resume r.

Following (Qin et al., 2018; Zhu et al., 2018), we cast the person-job fit problem into a text match task based on the text information of job postings and candidate resumes. The *Person-Job Fit* task aims to learn a match function that is able to predict the actual label for a new job-person pair from the target domain.

Furthermore, we consider a domain adaptation setting for such an match task. Given a target domain t, a training set $\mathcal{D}^t = \{\langle p_j^t, r_j^t, y_j\rangle\}_{j=1}^{n_t}$ of n_t labeled instances is given. Considering the target domain to be new or minor, there is very little labeled data. We assume an auxiliary training set $\mathcal{D}^s = \{\langle p_j^s, r_j^s, y_j\rangle\}_{j=1}^{n_s}$ from another source domain s is given, consisting of n_s labeled instances. The source domain (or auxiliary domain) is selected from an existing domain with sufficient match records. In this case, we have $n_t \ll n_s$. For simplicity, we will drop the domain index unless needed, which is the target domain by default. The notations used in this paper are summarized in Table 1.

4 The Proposed Model

In this section, we first present a deep global match network for person-job fit using only target domain data. Then, we extend the match network by leveraging the labeled data of an auxiliary domain.

4.1 A Deep Global Match Network for Single-Domain Person-Job Fit

Previous studies (Shen et al., 2018; Zhu et al., 2018) mainly focus on modeling the overall interaction between the representations of a job and a candidate. They cannot explicitly capture global match information in terms of fine-grained semantic units. In this section, we propose a deep global match network which is able to characterize global sentence-level interaction for semantic match between a job posting and a candidate resume.

Hierarchical Attention-based RNN Encoder. First, we employ the bi-directional recurrent neural networks with gated recurrent unit (BiGRU) to model both sentences and documents (*i.e.,* a job posting or a resume).

Formally, let $\overleftarrow{\boldsymbol{h}_{i,k}^{(p)}}$ and $\overrightarrow{\boldsymbol{h}_{i,k}^{(p)}}$ denote the forward and backward states learned from the BiGRU network for the k-th word of the i-th sentence in job posting p. We concatenate the two directional representations as the representation of a word, *i.e.,* $\boldsymbol{h}_{i,k}^{(p)} = [\overleftarrow{\boldsymbol{h}_{i,k}^{(p)}}, \overrightarrow{\boldsymbol{h}_{i,k}^{(p)}}]$. Since some words in a sentence are important than others, we apply the attention mechanism (Qin et al., 2018) to derive the sentence representation $\boldsymbol{h}_i^{(p)} \in \mathbb{R}^{L_P}$ in a job posting:

$$\boldsymbol{h}_i^{(p)} = \sum_{k=1}^{n_{p,i}} \alpha_k \cdot \boldsymbol{h}_{i,k}^{(p)}, \tag{1}$$

where the attention weight α_k is calculated as

$$\begin{aligned} \alpha_k &= \text{softmax}(a_k), \\ a_k &= \boldsymbol{v}_1^\top \cdot \tanh(\mathbf{W}_1 \boldsymbol{h}_{i,k}^{(p)} + \boldsymbol{b}_1). \end{aligned} \tag{2}$$

Similarly, we can derive the sentence representations for a resume, denoted by $\boldsymbol{h}_i^{(r)} \in \mathbb{R}^{L_R}$. Based on the learned sentence representations, we apply the similar attentional BiGRU network to derive the overall representations for a job posting and a

resume, denoted by $\boldsymbol{h}^p$ and $\boldsymbol{h}^r$:

$$\boldsymbol{h}^{(p)} = \sum_{i=1}^{n_p} \beta_i^{(p)} \cdot \boldsymbol{h}_i^{(p)}, \quad (3)$$

$$\boldsymbol{h}^{(r)} = \sum_{i=1}^{n_p} \beta_i^{(r)} \cdot \boldsymbol{h}_i^{(r)}, \quad (4)$$

where $\beta_i^{(p)}$ and $\beta_i^{(r)}$ are the attention weights defined in a similar way as Eq. 2.

Global Match Representation. After encoding the sentences, we further model global semantic interactions between sentence representations of a job and a resume. In specific, we compute the similarities between each sentence in a job posting and each sentence in a candidate resume. Assume that a job posting p has n_p sentences and a resume r has n_r sentences. We can derive a match matrix $\mathbf{M} \in \mathbb{R}^{n_p \times n_r}$ for modeling the global semantic interactions. Formally, to calculate the sentence similarity in $\mathbf{M}$, we apply a linear form as

$$M_{i,i'} = \boldsymbol{h}_i^{(p)\top} \cdot \mathbf{W} \cdot \boldsymbol{h}_{i'}^{(r)}, \quad (5)$$

where $\mathbf{W} \in \mathbb{R}^{K \times K}$ is the match matrix, $\boldsymbol{h}_i^{(p)}$ is the representation of the i-th sentence for a job posting p, and $\boldsymbol{h}_{i'}^{(r)}$ is the representation of the i'-th sentence for resume r. Inspired by the recent work on image-based text match models (Pang et al., 2016), we propose to use the convolution based method to model the match information. Formally, we stack two 2-D convolutional layers with two 2-D max-pooling layers in an interleaving way, and derive a match representation $\boldsymbol{m}^{p,r}$ as

$$\boldsymbol{m}^{p,r} = \text{ConvNet}(\mathbf{M}; \Theta), \quad (6)$$

where $\boldsymbol{m}^{p,r}$ summarizes the match information from global sentence interactions, and "Θ" denote all the involved parameters.

Predicting the Match Label. With the learned match representation $\boldsymbol{m}^{p,r}$, we concatenate it with the representations of the job posting and the resume as the input for the predictor,

$$\hat{y} = \text{MLP}([\boldsymbol{m}^{p,r}; \boldsymbol{h}^p; \boldsymbol{h}^r]), \quad (7)$$

where we $\boldsymbol{h}^p$ and $\boldsymbol{h}^r$ are the representations of job posting p and resume r defined in Eq. 3 and Eq. 4 respectively, and $\text{MLP}(\cdot)$ is the Multi-Layer Perceptron with a nonlinear layer and a sigmoid layer. Compare with previous work (Qin et al., 2018; Zhu et al., 2018), a major novelty of this match model lies in the fact it has explicitly modeled the match information between a job posting and a resume. It is able to model sentence-level interactions between two text documents.

4.2 Domain Adaptation by Transferring Local and Global Match Information

In this part, we study how to extend the proposed deep global match network for domain adaptation. Instead of directly enriching the overall representation of a training instance, we seek a way to transfer local and global match information.

Enhanced Sentence Representation with Structural Correspondence. Different domains may have significant language variation or semantic gap, which makes it difficult to derive transferable sentence representations across domains. Inspired by the classic SCL algorithm (Blitzer et al., 2007), we propose to model the structural correspondence of sentences in different domains by using pivot keywords. Consider an example of two snippets from two different job domains:

S_1: *grasp* C programming skills
S_2: *grasp* picture editing skills

Although the semantics of computer programming and picture editing are very different, they are aligned skill requirements for the two domains via the pivot word *grasp*. By pre-selecting a number of high-quality pivot words, SCL algorithm is able to learn such semantic alignment via large-scale co-occurrence data. In specific, the SCL algorithm is able to learn a mapping function $f_{\text{SCL}}(\cdot)$ that transforms an original into a more transferable representation:

$$\boldsymbol{x}_{i,\text{SCL}}^p = f_{\text{SCL}}(\boldsymbol{h}_i^p). \quad (8)$$

For the i-th sentence of a job posting, we derive its representation by concatenating the original representation in Eq. 1 and the transformed representation using SCL algorithm:

$$\widetilde{\boldsymbol{h}_i^p} = \boldsymbol{h}_i^p \oplus \boldsymbol{x}_{i,\text{SCL}}^p, \quad (9)$$

where "$\oplus$" is the vector concatenation operation. Similarly, we can obtain the enhanced resume sentence representation, denoted by $\widetilde{\boldsymbol{h}_i^r}$. With the $\widetilde{\boldsymbol{h}_i^p}$ and $\widetilde{\boldsymbol{h}_i^r}$, we can update the overall representations of $\boldsymbol{h}^p$ and $\boldsymbol{h}^r$ in Eq. 3 and 4.

Transferring Sentence-level Match Information. After obtaining the new sentence representations, we study how to transfer the parameters

for modeling sentence-pair match. As shown in Eq. 5, we incorporate a transformation matrix $\mathbf{W}$ to compute sentence similarities. A simple transfer strategy is to share the whole matrix in both target and source domains. However, such a method will make it less flexible to capture domain-specific match information, since the local match information is likely to be varied across domains. Hence, we propose to factorize the matrix $\mathbf{W}$ into a product of two smaller matrices $\mathbf{A} \in \mathbb{R}^{l \times K}$ and $\mathbf{B}^d \in \mathbb{R}^{l \times K}$:

$$\mathbf{W}^d = \mathbf{A}^\top \cdot \mathbf{B}^d, \tag{10}$$

where $\mathbf{A}$ is shared by all the domains, while $\mathbf{B}^d$ is specific to domain d. In this factorization, we share the parameters across domains and meanwhile set domain-specific parameters to better capture domain-specific information.

Transferring Global Match Information. As shown in Eq. 5, we have constructed a match matrix consisting of pairwise sentence similarities between a job posting and a resume. Our idea is that although sentence-level representation or match is different across domains, global semantic interactions are likely to show the similar patterns. For example, the majority of required skills or abilities in the job posting should be well covered for a good candidate, corresponding to large entries in the match matrix $\mathbf{M}$. Based on this idea, we propose to transfer the parameters of the convolution module across domains. In specific, we first use the rich training data of the auxiliary domain s to train the parameters in Eq. 6, and obtain the learned parameters $\hat{\Theta}^s$. We assume the mapping process from the match matrix to the final match representation (*i.e.,* $\mathbf{M} \rightarrow \boldsymbol{m}^{p,r}$) is transferable. Hence, we directly reuse $\hat{\Theta}^s$ trained from the source domain. For enhancing the modeling capacity, we also train a domain-specific convolution component with the parameters $\hat{\Theta}^t$. For the target domain, we derive the new match representation by using the concatenation of the output from both components with the parameters $\hat{\Theta}^s$ and $\hat{\Theta}^t$:

$$\widetilde{\boldsymbol{m}^{p,r}} = \text{ConvNet}(\mathbf{M}; \hat{\Theta}^s) \oplus \text{ConvNet}(\mathbf{M}; \hat{\Theta}^t). \tag{11}$$

4.3 The Final Model and Training

To predict the match label for domain adaptation, we replace $\boldsymbol{h}^p$, $\boldsymbol{h}^r$ and $\boldsymbol{m}^{p,r}$ in Eq. 7 with $\widetilde{\boldsymbol{h}^p}$, $\widetilde{\boldsymbol{h}^r}$, and $\widetilde{\boldsymbol{m}^{p,r}}$ respectively. We present an overview sketch of the proposed model in Fig. 1. We have highlighted the three points for transferring information across domain. Different from previous text-based domain adaption methods, we focus on the transfer of match information, including both local and global semantic interactions.

To optimize our model, we adopt the the binary cross-entropy loss over the entire training data as the total loss. To learn the model parameters, we adopt the Adam optimizer (Kingma and Ba, 2014). In order to avoid overfitting, we adopt the dropout strategy with a rate of 0.1. More parameter settings can be found in Table 2.

Modules	Settings
HA-RNN	$L_R = L_P = 200$, #GRU-layer=2, batch-size=512,init.-learning-rate=0.001
SCL	#pivots = 200, init.-learning-rate=0.01
$\mathbf{W}, \mathbf{A}, \mathbf{B}^d$	$K = 100, l = 50$
Global Matching	kernel sizes = $\{4 \times 4, 6 \times 6\}$, init.-learning-rate=0.001, batch-size=512

Table 2. Parameter settings of our model.

Domain	#instances	#ASPJ	#ASPR

Journey	3,000	9.5	7.0

Table 3. Statistics of the datasets. #ASPJ means the average number of sentences per job posting, and #ASPR means the average number of sentences per resume.

5 Experiments

In this section, we first set up the experiments, and then report the results and analysis.

5.1 Experimental Setup

We evaluate our model on a large real-world dataset provided by the largest online recruiting platform named "BOSS Zhipin" (the BOSS Recruiting)[2] in China. To protect the privacy of candidates, all the records have been anonymized by deleting identity information. Since the original amount of recruitment data is huge, we randomly sample a fraction of the entire data, containing job postings and resumes within a time period of six months. Specifically, the dataset has covered six job domains: two major domains have a large number person-job pairs and four

Table 4. Performance comparisons on single domain evaluation for person-job fit.

minor domains have a limited number of person-job pairs. The match label information is obtained according to the acceptance status of the candidates, provided by the online recruiting platform. In our dataset, the ratio between matched and unmatched instances is 1:1[3]. We perform the basic preprocessing steps on the text data, including tokenization and stopword removal. The statistics of the dataset are summarized in Table 3. Our code and data are available at https://github.com/RUCAIBox/Person-Job-Fit.

We consider two evaluation settings, namely single domain evaluation and domain adaptation evaluation. For all domains, we first split the entire data set with a ratio of 1:1 into a training set and a test set. Single domain evaluation examines the performance of a model model trained with domain-specific training data respectively for each of all six domains, while domain adaptation evaluation examines the performance of a model trained with the data from both the source and target domains. For domain adaptation, we consider the four minor domains as target domains, and the major domains as source domains.

Since our task is casted as a classification task, we adopt four commonly used evaluation metrics, including Accuracy, Precision, Recall and F1.

5.2 Comparison Methods

Single Domain. For single domain evaluation, we consider three latest methods as baselines:

• DSSM (Huang et al., 2013): it utilizes a deep neural network (DNN) to map high-dimensional sparse features into low-dimensional dense features, and calculates the semantic similarity of the text pair.

• BPJFNN (Qin et al., 2018): It applies BiLSTMs to obtain the semantic representation of each word in job postings and resumes, and considers the text content as a single sequence.

• PJFNN (Zhu et al., 2018): It proposes a bipartite Convolutional Neural Networks that can effectively learn the joint representation of Person-Job fitness from historical job applications.

• APJFNN (Qin et al., 2018): It learns a word-level semantic representation for both job requirements and resumes based on RNN and four

[3]There were more negative instances in original data. we randomly sample an equal number of negative instances to reduce the data bias.

hierarchical ability-aware attention strategies.

Domain Adaptation. For domain adaptation evaluation, we consider three baseline methods:

• SCL-MI (Blitzer et al., 2007): It proposes the SCL algorithm where pivot features are seleced based on mutual information in the unlabeled data of both the source and target domains.

• AE-SCL-SR (Ziser and Reichart, 2017): It proposes to find a shared low dimensional representation in order to overcome the domain adaptation problem.

• ASP-MTL (Liu et al., 2017): It proposes an adversarial multi-task learning framework, alleviating the shared and private latent feature spaces from interfering with each other.

For our deep match network, we also prepare three simple single-domain variants, include (1) *Tgt-Only* trains the model with only target domain data, (2) *Src-Only* trains the model with only source domain data, and (3) *Mixed* trains the model with a simple mixture of source and target domain data.

5.3 Results and Analysis

In this part, we construct a series of experiments on the effectiveness of the proposed model for the person-job fit task.

Single Domain Results. We first report the results on single domain evaluation, where we only use the training data from the target domain. In Table 4, we compare our model with three recently proposed methods for person-job fit. Among the three baselines, the APJFNN method performs better than the other two methods. It adopts fine-grained attention mechanism based on skills and abilities. Our (single domain) model outperforms all the baselines. The proposed deep global match network extends the APJFNN by explicitly modeling the global match information for the sentence representations of job postings and resumes. These results indicate the global match information is useful to improve the performance of the person-job fit task.

Domain Adaptation Results. We select the domains of *technology* and *sales* as the source domains, since both contain much more training data, while the rest domains are selected as the target domains. Table 5 presents the performance of different comparison methods for domain adaptation. First, for the three variants for our single-domain model, the performance order is *Src-Only* $<$ *Mixed* $<$ *Tgt-Only*. The result indicates that directly incorporating the source domain data as training data may hurt the performance for the target domain. Second, ASP-MTL performs best among the three baselines. It sets up both shared and private feature representations, and apply the adversarial mechanism to alleviate the shared and private latent feature spaces from interfering with each other. Finally, our model outperforms all the baselines with a large margin. Previous methods (*e.g.,* ASP-MTL) learns an overall representation for a document, which cannot characterize global semantic interaction in fine-grained semantic units. As a comparison, our deep global match network is able to transfer information in three levels, namely sentence representation, sentence-level match and global match. Different from existing text-based domain adaption methods, our model is tailored to transfer the match information between a document pair.

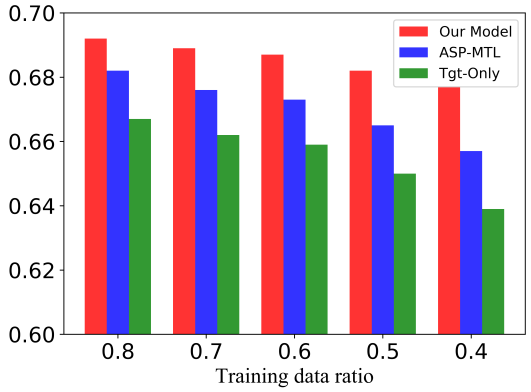

Figure 2. Domain adaptation with different train/test splitting ratios in the target domain for "Technology→Car".

Ablation Analysis. Recall we proposed three transfer techniques to improve the performance for domain adaptation in Section 4.2, including sentence representation (denoted by *SR*), sentence-level match (denoted by *SM*) and global match (denoted by *GM*). Now we examine the effect of each factor on the prediction performance. At each time, we remove an individual factor while keep the rest. Due to space limit, we only report the results with the cases "Technology→Cars" and "Sales→Product". As shown in Table 6, all the three factors are useful to improve the performance of our model. Especially, the transferred information in sentence representation

and global match bring more improvement to our model.

Varying the Amount of Training Data. An important consideration for domain adaptation is the amount of training data in the target domain. Here, we vary the ratio of training data in the target domain with the case "Technology→Car". We re-split the dataset of the *Car* domain according to different training data ratios. We select the single domain variant of our model and the best baseline ASP-MTL as comparisons. Fig. 2 presents the varying results. With the decreasing of training data, the performance of all the methods drops accordingly. While, domain adaption techniques are useful to alleviate the deficiency of training data, since ASP-MTL and our model yield less performance drop. Especially, the performance of our model is relatively stable, which indicates its robustness for domain adaption.

Parameters Sensitivity Analysis. In our model, we have two important parameters, namely the dimension number K of the matrix $\mathbf{W}$ in Eq. 10 and the number of pivot words in the SCL algorithm. We vary the two parameters and present the tuning results in Fig. 3. We select the best baseline ASP-MTL as a comparison. As we can see, the performance of our model is relatively stable *w.r.t.* the varying of the two parameters. A dimension number of 100 and a number of 200 pivot words lead to the best performance.

(a) Varying the dimension number K.

(b) Varying the number of pivot words.

Figure 3. Parameter tuning for our model with the case "Technology→Car".

5.4 Qualitative Analysis

A key point of our model is that it can transfer the global match information derived by computing the pairwise similarities between two sentence respectively from a job posting and a resume. Recall that we reuse the convolution-based component

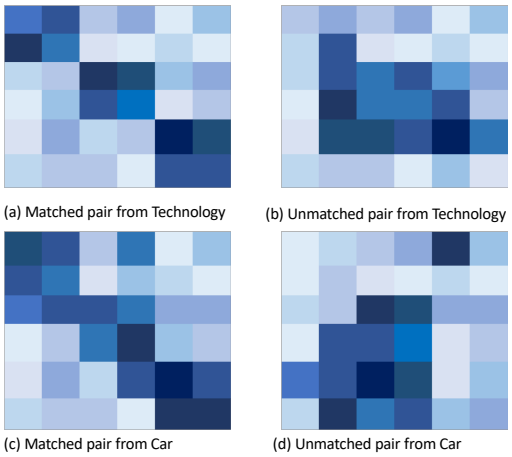

Figure 4. An illustrative example for the effect of the global match in our model. Here, “matched" and “unmatched" indicates the candidate person has been or not been accepted by the job position, respectively.

trained with the source domain data. Now, we study how such a mechanism work and why it is useful to improve the performance.

In Fig. 4, we present four person-job pairs from our dataset containing two matched pairs and two unmatched pairs. In a subfigure, each row corresponds to a sentence in a job posting, while a column corresponds to a sentence in a resume. Due to space limit, we only select six sentences for each document. We follow the method in Eq. 5 to construct the match matrix $\mathbf{M}$. We use the darkness degree to indicate the similarity between two sentences. For ease of understanding, we further perform the row and column permutation to make the large entries distributed in blocks.

From Fig. 4, we can make the following observations. First, global match matrices have a significant difference between a matched and an unmatched case. Although the match matrix for an unmatched pair also contains many large values, they are usually located in off-diagonal entries. Comparing Fig. 4(a) and Fig. 4(c), it is interesting to see that they share a similar distribution pattern, *i.e.,* large values are mainly distributed along the diagonal line and these values are also aggregated in small blocks. Such a phenomenon indicates that the majority of the required skills have been well covered by a candidate in a matched pair. Without considering global semantic interactions, it is difficult to correctly predict the label for the unmatched pairs in Fig. 4(b) and Fig. 4(d), since they are likely to have a large similarity measured by the overall representations.

6 Conclusion

This paper studied the domain adaptation for person-job fit. We first proposed a deep global match network for the single-domain match setting. Then, we extended the proposed model for domain adaptation in three aspects. We constructed extensive experiments on a large real-world recruitment dataset, containing six job domains. The results have demonstrated the effectiveness of our model in terms of the prediction accuracy for person-job fit, especially when the training data is limited. Our current characterization with global match information provides a good form to develop interpretable domain adaptation models, *i.e.,* what kind of information has been transferred across domains. As future work, we will work along this line and investigate the design interpretable solutions to domain adaptation for person-job fit. We will also consider how to model the domain relationship for effectively transferring information across domains.

Abstract

Short text classification has found rich and critical applications in news and tweet tagging to help users find relevant information. Due to lack of labeled training data in many practical use cases, there is a pressing need for studying semi-supervised short text classification. Most existing studies focus on long texts and achieve unsatisfactory performance on short texts due to the sparsity and limited labeled data. In this paper, we propose a novel heterogeneous graph neural network based method for semi-supervised short text classification, leveraging full advantage of few labeled data and large unlabeled data through information propagation along the graph. In particular, we first present a flexible HIN (heterogeneous information network) framework for modeling the short texts, which can integrate any type of additional information as well as capture their relations to address the semantic sparsity. Then, we propose **H**eterogeneous **G**raph **AT**tention networks (HGAT) to embed the HIN for short text classification based on a dual-level attention mechanism, including node-level and type-level attentions. The attention mechanism can learn the importance of different neighboring nodes as well as the importance of different node (information) types to a current node. Extensive experimental results have demonstrated that our proposed model outperforms state-of-the-art methods across six benchmark datasets significantly.

1 Introduction

With the rapid development of online social media and e-commerce, short texts, such as online news, queries, reviews, tweets, are increasingly widespread on the Internet (Song et al., 2014). Short text classification can be widely applied in many domains, ranging from sentiment analysis to news tagging/categorization and query intent classification (Aggarwal and Zhai, 2012; Meng et al., 2018). In many practical scenarios, the labeled data is scarce, while human labeling is time-consuming and may require expert knowledge (Aggarwal and Zhai, 2012). As a consequence, there is a pressing need for studying semi-supervised short text classification with a relatively small number of labeled training data.

Nevertheless, semi-supervised short text classification is nontrivial due to the following challenges. Firstly, short texts are usually semantically sparse and ambiguous, lacking contexts (Phan et al., 2008). While some methods have been proposed to incorporate additional information such as entities (Wang et al., 2013, 2017), they are unable to consider the relational data such as the semantic relations among entities. Secondly, the labeled training data is limited, which leads to traditional and neural supervised methods (Wang and Manning, 2012; Kim, 2014; Zhang et al., 2015) ineffective. As such, how to make full use of the limited labeled data and large number of unlabeled data has become a key problem for short text classification (Aggarwal and Zhai, 2012). Finally, we need to capture the importance of different information that is incorporated to address sparsity at multiple granularity levels and reduce the weights of noisy information to achieve more accurate classification results.

In this work, we propose a novel *heterogeneous graph neural network based method* for semi-supervised short text classification, which makes full use of both limited labeled data and large unlabeled data by allowing information propagation through our automatically constructed graph. Particularly, we first present a flexible HIN framework for modeling the short texts, which is able to incorporate any additional information (e.g., entities and topics) as well as capture the rich relations among the texts and the additional information. Then, we propose Heterogeneous Graph Attention

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4821–4830,

networks (HGAT) to embed the HIN for short text classification based on a new dual-level attention mechanism including node-level and type-level attentions. Our HGAT method considers the heterogeneity of different node types. Additionally, the dual-level attention mechanism captures both the importance of different neighboring nodes (reducing the weights of noisy information) and the importance of different node (information) types to a current node. The main contributions of this paper can be summarized as follows:

1) To the best of our knowledge, *this is the first attempt* to model short texts as well as additional information with an HIN and adapt graph neural networks on the HIN for semi-supervised classification.

2) We propose novel *heterogeneous graph attention networks* (HGAT) for the HIN embedding based on a new dual-level attention mechanism which can learn the importance of different neighboring nodes and the importance of different node (information) types to a current node.

3) Extensive experimental results have demonstrated that our proposed HGAT model significantly outperforms seven state-of-the-art methods across six benchmark datasets.

2 Related Work

2.1 Traditional Text Classification

Traditional text classification methods such as SVM (Drucker et al., 1999) need a feature engineering step for text representation. The most commonly used features are BoW and TF-IDF (Blei et al., 2003). Some recent studies (Rousseau et al., 2015; Wang et al., 2016) model texts as graphs and extract path based features for classification. Despite its initial success on formal and well-edited texts, all these methods fail to achieve satisfactory performance on short text classification, due to the insufficient features incurred by short texts. To address the problem, efforts have been made to enrich the semantics of *short texts*. For example, Phan et al. (2008) extracted the latent topics of the short texts with the help of an external corpus. Wang et al. (2013) introduced external entity information from Knowledge Bases, etc. However, these methods are not able to achieve good performance as the feature engineering step relies on domain knowledge.

2.2 Deep neural networks for Text Classification

Deep neural networks which automatically represent texts as embeddings, have been widely used for text classification. Two representative deep neural models, such as RNNs (Liu et al., 2016; Sinha et al., 2018) and CNNs, (Kim, 2014; Shimura et al., 2018) have shown their power in many NLP tasks, including text classification. To adapt it to *short text classification*, several methods have been proposed. For example, Zhang et al. (2015) designs a character-level CNN which alleviates the sparsity by mining different levels of information within the texts. Wang et al. (2017) incorporates the entities and concepts from KBs to enrich the semantics of short texts. However, these methods cannot capture the semantic relations (e.g., entity relations) and rely heavily on the number of training data. Clearly, lacking of training data is still a key bottleneck that prohibits them from successful practical applications.

2.3 Semi-supervised Text Classification

Considering the cost of human labeling and the fact that unlabeled texts also provide valuable information, semi-supervised methods have peen proposed. They can be categorized into two classes: (1) latent variable models (Lu and Zhai, 2008; Chen et al., 2015); and (2) embedding-based models (Meng et al., 2018). The former mainly extend topic model by user-provided seed information and then infer the documents' labels based on posterior category-topic assignment. The latter use seed information to derive embeddings for documents and label names for text classification. For example, PTE (Tang et al., 2015) models the documents, words and labels with graphs and learns text (node) embeddings for classification. Meng et al. (2018) leveraged seed information to generate pseudo-labeled documents for pre-training. Yin et al. (2015) used a semi-supervised learning method based on SVM to label the unlabeled documents in an iterative way. Recently, graph convolutional networks (GCN) have received wide attention for semi-supervised classification (Kipf and Welling, 2017). TextGCN (Yao et al., 2019) models the whole text corpus as a document-word graph and applies GCN for classification. However, all these methods focus on long texts. In addition, they fail to use attention mechanisms to capture important information.

3 Our Proposed Method

In this paper, we propose a novel heterogeneous graph neural network based method for semi-supervised short text classification, which takes full advantage of both limited labeled data and large unlabeled data by allowing information propagation along the graph. Our method includes two steps. Particularly, to alleviate the sparsity of short texts, we first present a flexible HIN framework for modeling the short texts, which can incorporate any additional information as well as capture the rich relations among the short texts and the added information. Then, we propose a novel model HGAT to embed the HIN for short text classification based on a new dual-level attention mechanism. HGAT considers the heterogeneity of different types of information. In addition, the attention mechanism can learn the importance of different nodes (reducing the weights of noisy information) as well as the importance of different node (information) types.

3.1 HIN for Short Texts

We first present the HIN framework for modeling the short texts, which enables integration of any additional information and captures the rich relations among the texts and the added information. In this way, the sparsity of the short texts is alleviated.

Previous studies have exploited latent topics (Zeng et al., 2018) and external knowledge (e.g., entities) from Knowledge Bases to enrich the semantics of the short texts (Wang et al., 2013, 2017). However, they fail to consider the semantic relation information, such as entity relations. Our HIN framework for short texts is flexible for integrating any additional information and modeling their rich relations.

Here, we consider two types of additional information i.e., topics and entities. As shown in Figure 1, we construct the HIN $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ containing the short texts $D = \{d_1, ..., d_m\}$, topics $T = \{t_1, ..., t_K\}$, and entities $E = \{e_1, ..., e_n\}$ as nodes, i.e., $\mathcal{V} = D \cup T \cup E$. The set of edges $\mathcal{E}$ represent their relations. The details of constructing the network are described as follows.

First, we mine the latent topics T to enrich the semantics of short texts using LDA (Blei et al., 2003). Each topic $t_i = (\theta_1, ..., \theta_w)$ (w denotes the vocabulary size) is represented by a probability distribution over the words. We assign each

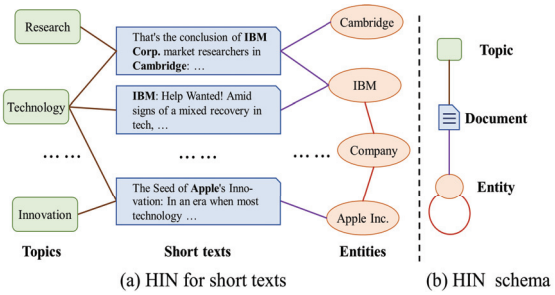

Figure 1: An example of HIN for short texts on AGNews.

document to the top P topics with the largest probabilities. Thus, the edge between a document and a topic is built if the document is assigned to the topic.

Second, we recognize the entities E in the documents D and map them to Wikipedia with the entity linking tool TAGME[1]. The edge between a document and an entity is built if the document contains the entity. We take an entity as a whole word and learn the entity embeddings using word2vec[2] based on the Wikipedia corpus. To further enrich the semantics of short texts and advance the information propagation, we consider the relations between entities. Particularly, if the similarity score (cosine similarity) between two entities, computed based on their embeddings, is above a predefined threshold δ, we build an edge between them.

By incorporating the topics, entities and the relations, we enrich the semantics of the short texts and thus greatly benefit the following classification task. For example, as shown in Figure 1, the short text "the seed of Apple's Innovation: In an era when most technology..." is semantically enriched by the relations with the entities "Apple Inc." and "company", as well as the topic "technology". Thus, it can be correctly classified into the category of "business" with high confidence.

3.2 HGAT

We then propose HGAT model (shown in Figure 2) to embed the HIN for short text classification based on a new dual-level attention mechanism including node level and type level. HGAT considers the heterogeneity of different types of information with heterogeneous graph convolution. In addition, the dual-level attention mechanism

[1]https://sobigdata.d4science.org/group/tagme/
[2]https://code.google.com/archive/p/word2vec/

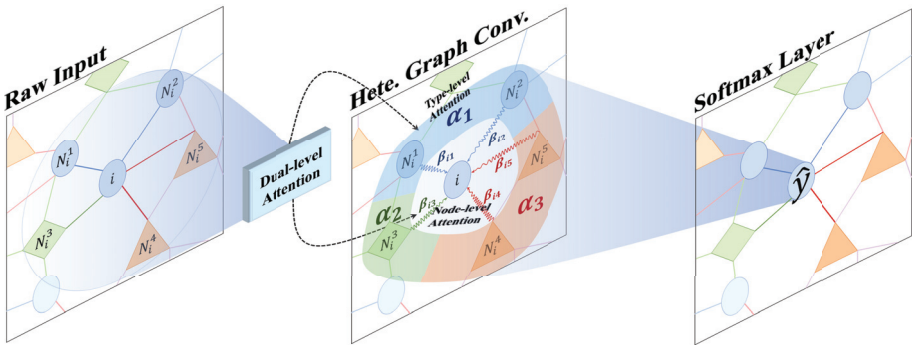

Figure 2: Illustration of our model HGAT.

captures the importance of different neighboring nodes (reducing the weights of noisy information) and the importance of different node (information) types to a specific node. Finally, it predicts the labels of documents through a softmax layer.

3.2.1 Heterogeneous Graph Convolution

We first describe the heterogeneous graph convolution in HGAT, considering the heterogeneous types of nodes (information).

As known, GCN (Kipf and Welling, 2017) is a multi-layer neural network that operates directly on a homogeneous graph and induces the embedding vectors of nodes based on the properties of their neighborhoods. Formally, consider a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ and $\mathcal{E}$ represent the set of nodes and edges respectively. Let $X \in \mathbb{R}^{|\mathcal{V}| \times q}$ be a matrix containing the nodes with their features $x_v \in \mathbb{R}^q$ (each row x_v is a feature vector for a node v). For the graph $\mathcal{G}$, we introduce its adjacency matrix $A' = A + I$ with added self-connections and degree matrix M, where $M_{ii} = \sum_j A'_{ij}$. Then the layer-wise propagation rule is as follows:

$$H^{(l+1)} = \sigma(\tilde{A} \cdot H^{(l)} \cdot W^{(l)}). \quad (1)$$

Here, $\tilde{A} = M^{-\frac{1}{2}} A' M^{-\frac{1}{2}}$ represents the symmetric normalized adjacency matrix. $W^{(l)}$ is a layer-specific trainable transformation matrix. $\sigma(\cdot)$ denotes an activation function such as ReLU. $H^{(l)} \in \mathbb{R}^{|\mathcal{V}| \times q}$ denotes the hidden representations of nodes in the l^{th} layer. Initially, $H^{(0)} = X$.

Unfortunately, GCN cannot be directly applied to the HIN for short texts due to the node heterogeneity issue. Specifically, in the HIN, we have three types of nodes: documents, topics and entities with different feature spaces. For a document $d \in D$, we use the TF-IDF vector as its feature vector x_d. For the topic $t \in T$, the word distribution is used to represent the topic $x_t = \{\theta_i\}_{i=[1,w]}$. For each entity, to make full use of relevant information, we represent the entity x_v by concatenating its embedding and TF-IDF vector of its Wikipedia description text.

A straightforward way to adapt GCN for the HIN containing different types of nodes $\mathcal{T} = \{\tau_1, \tau_2, \tau_3\}$ is to construct a new large feature space by concatenating together the feature spaces of different types of nodes. For example, each node is denoted as a feature vector with 0 values for the irrelevant dimensions for other types. We name this basic method for adapting GCN to HIN as *GCN-HIN*. However, it suffers from reduced performance since it ignores the heterogeneity of different information types.

To address the issue, we propose the heterogeneous graph convolution, which considers the difference of various types of information and projects them into an implicit common space with their respective transformation matrices.

$$H^{(l+1)} = \sigma(\sum_{\tau \in \mathcal{T}} \tilde{A}_\tau \cdot H_\tau^{(l)} \cdot W_\tau^{(l)}), \quad (2)$$

where $\tilde{A}_\tau \in \mathbb{R}^{|\mathcal{V}| \times |\mathcal{V}_\tau|}$ is the submatrix of $\tilde{A}$, whose rows represent all the nodes and columns represent their neighboring nodes with the type τ. The representation of the nodes $H^{(l+1)}$ is obtained by aggregating information from the features of their neighboring nodes $H_\tau^{(l)}$ with different types τ using different transformation matrix $W_\tau^{(l)} \in \mathbb{R}^{q^{(l)} \times q^{(l+1)}}$. The transformation matrix $W_\tau^{(l)}$ considers the difference of different feature spaces and projects them into an implicit common space $\mathbb{R}^{q^{(l+1)}}$. Initially, $H_\tau^{(0)} = X_\tau$.

3.2.2 Dual-level Attention Mechanism

Typically, given a specific node, different types of neighboring nodes may have different impacts on it. For example, the neighboring nodes of the same

type may carry more useful information. Additionally, different neighboring nodes of the same type could also have different importance. To capture both the different importance at both node level and type level, we design a new dual-level attention mechanism.

Type-level Attention. Given a specific node v, the type-level attention learns the weights of different types of neighboring nodes. Specifically, we first represent the embedding of the type τ as $h_\tau = \sum_{v'} \tilde{A}_{vv'} h_{v'}$, which is the sum of the neighboring node features $h_{v'}$ where the nodes $v' \in \mathcal{N}_v$ and are with the type τ. Then, we calculate the type-level attention scores based on the current node embedding h_v and the type embedding h_τ:

$$a_\tau = \sigma(\mu_\tau^T \cdot [h_v || h_\tau]), \tag{3}$$

where μ_τ is the attention vector for the type τ, $||$ means "concatenate", and $\sigma(\cdot)$ denotes the activation function, such as Leaky ReLU.

Then we obtain the type-level attention weights by normalizing the attention scores across all the types with the softmax function:

$$\alpha_\tau = \frac{\exp(a_\tau)}{\sum_{\tau' \in \mathcal{T}} \exp(a_{\tau'})}. \tag{4}$$

Node-level Attention. We design the node-level attention to capture the importance of different neighboring nodes and reduce the weights of noisy nodes. Formally, given a specific node v with the type τ and its neighboring node $v' \in \mathcal{N}_v$ with the type τ', we compute the node-level attention scores based on the node embeddings h_v and $h_{v'}$ with the type-level attention weight $\alpha_{\tau'}$ for the node v':

$$b_{vv'} = \sigma(\nu^T \cdot \alpha_{\tau'} [h_v || h_{v'}]), \tag{5}$$

where ν is the attention vector. Then we normalize the node-level attention scores with the softmax function:

$$\beta_{vv'} = \frac{\exp(b_{vv'})}{\sum_{i \in \mathcal{N}_v} \exp(b_{vi})}. \tag{6}$$

Finally, we incorporate the dual-level attention mechanism including type-level and node-level attentions into the heterogeneous graph convolution by replacing Eq. 2 with the following layer-wise propagation rule:

$$H^{(l+1)} = \sigma(\sum_{\tau \in \mathcal{T}} \mathcal{B}_\tau \cdot H_\tau^{(l)} \cdot W_\tau^{(l)}). \tag{7}$$

Here, $\mathcal{B}_\tau$ represents the attention matrix, whose element in the v^{th} row v'^{th} column is $\beta_{vv'}$ in Eq. 6.

3.3 Model Training

After going through an L-layer HGAT, we can get the embeddings of nodes (including short texts) in the HIN. The short text embeddings $H^{(L)}$ are then fed to a softmax layer for classification. Formlly,

$$Z = \text{softmax}(H^{(L)}), \tag{8}$$

During model training, we exploit the cross-entropy loss over training data with the L2-norm. Formally,

$$\mathcal{L} = -\sum_{i \in D_{\text{train}}} \sum_{j=1}^{C} Y_{ij} \cdot \log Z_{ij} + \eta \, \|\Theta\|_2, \tag{9}$$

where C is the number of classes, D_{train} is the set of short text indices for training, Y is the corresponding label indicator matrix, Θ is model parameters, and η is regularization factor. For model optimization, we adopt the gradient descent algorithm.

4 Experiments

In this section, we evaluate the empirical performance of different methods for semi-supervised short text classification.

4.1 Experimental Setup

4.1.1 Datasets

We conduct extensive experiments on 6 benchmark short text datasets: AGNews, Snippets, Ohsumed, TagMyNews, MR and Twitter.

AGNews: This dataset is adopted from Zhang et al. (2015). We randomly select 6,000 pieces of news from AGNews, evenly distributed into 4 classes.

Snippets: This dataset is released by Phan et al. (2008). It is composed of the snippets returned by a web-search engine.

Ohsumed[3]: We use the benchmark bibliographic classification dataset released by Yao et al. (2019), where the documents with multiple labels are removed. We use the titles for short text classification.

TagMyNews: We use the news titles as instances from the benchmark classification dataset

[3]http://disi.unitn.it/moschitti/corpora.htm

	#docs	#tokens	#entities	#classes
AGNews	6,000	18.4	0.9 (72%)	4
Snippets	12,340	14.5	4.4 (94%)	8
Ohsumed	7,400	6.8	3.1 (96%)	23
TagMyNews	32,549	5.1	1.9 (86%)	7
MR	10,662	7.6	1.8 (76%)	2
Twitter	10,000	3.5	1.1 (63%)	2

Table 1: Statistics of the datasets.

released by Vitale et al. (2012), which contains English news from really simple syndication (RSS) feeds.

MR: It is a movie review dataset, in which each review only contains one sentence (Pang and Lee, 2005). Each sentence is annotated with positive or negative for binary sentiment classification.

Twitter: This dataset is provided by NLTK[4], a library of Python, which is also a binary sentiment classification dataset.

For each dataset, we randomly select 40 labeled documents per class, half of which for training and the other half for validation. Following Kipf and Welling (2017), all the left documents are for testing, which are also used as unlabeled documents during training.

We preprocess all the datasets as follows. We remove non-English characters, the stop words, and low-frequency words appearing less than 5 times. Table 1 shows the statistics of the datasets, including the number of documents, the number of average tokens and entities, the number of classes, and the proportion of texts containing entities in parentheses. In our datasets, most of the texts (around 80%) contain entities.

4.1.2 Baselines

To comprehensively evaluate our proposed method for semi-supervised short text classification, we compare it with the following nine state-of-the-art methods:

SVM: SVM classifiers using TF-IDF features and LDA features (Blei et al., 2003), are denoted as SVM+TFIDF and SVM+LDA, respectively.

CNN: CNN (Kim, 2014) with 2 variants: 1) CNN-rand, whose word embeddings are randomly initialized, and 2) CNN-pretrain, whose word embeddings are pre-trained with Wikipedia Corpus.

LSTM: LSTM (Liu et al., 2016) with and without pre-trained word embeddings, named LSTM-rand and LSTM-pretrain, respectively.

[4]https://www.nltk.org/

PTE: A semi-supervised representation learning method for text data (Tang et al., 2015). It firstly learns word embedding based on the heterogeneous text networks containing three bipartite networks of words, documents and labels, then averages word embeddings as document embeddings for text classification.

TextGCN: Text GCN (Yao et al., 2019) models the text corpus as a graph containing documents and words as nodes, and applies GCN for text classification.

HAN: HAN (Wang et al., 2019) embeds HINs by first converting an HIN to several homogeneous sub-networks through pre-defined meta-paths and then applying graph attention networks.

For fair comparison, all of the above baselines, such as SVMs, CNN and LSTM, have used entity information.

4.1.3 Parameter Settings

We choose the parameter values of K, T and δ that achieve the best results on the validation set. To construct HIN for short texts, we set the number of topics $K = 15$ in LDA for the datasets AGNews, TagMyNews, MR and Twitter. We set $K = 20$ for Snippets and $K = 40$ for Ohsumed. For all the datasets, each document is assigned to top $P = 2$ topics with the largest probabilities. The similarity threshold δ between entities is set $\delta = 0.5$.

Following previous studies (Vaswani et al., 2017), we set the hidden dimension of our model HGAT and other neural models to $d = 512$ and the dimension of pre-trained word embeddings to 100. We set the layer number L of HGAT, GCN-HIN and TextGCN as 2. For model training, we set the learning rate as 0.005, dropout rate as 0.8 and the regularization factor $\eta = 5e$-6. Early stopping is applied to avoid overfitting.

4.2 Experimental Results

Table 2 shows the classification accuracy of different methods on 6 benchmark datasets. We can see that our methods significantly outperform all the baselines by a large margin, which shows the effectiveness of our proposed method on semi-supervised short text classification.

The traditional method SVMs based on the human-designed features, achieve better performance than the deep models with random initialization, i.e., CNN-rand and LSTM-rand in most cases. While CNN-pretrain and LSTM-pretrain using the pre-trained vectors achieve significant

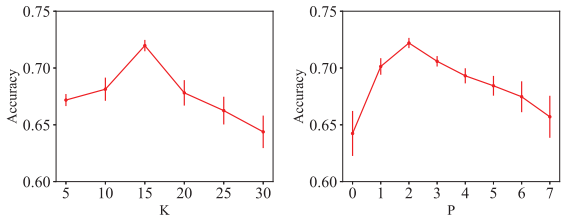
improvements and outperform SVMs. The graph based model PTE achieves inferior performance compared to CNN-pretrain and LSTM-pretrain. The reason may be that PTE learns text embeddings based on word co-occurrences, which, however, are sparse in short text classification. Graph neural network based models TextGCN and HAN achieve comparable results with the deep models CNN-pretrain and LSTM-pretrain. Our model HGAT consistently outperforms all the state-of-the-art models by a large margin, which shows the effectiveness of our proposed method. The reasons include that 1) we construct a flexible HIN framework for modeling the short texts, enabling integration of additional information to enrich the semantics and 2) we propose a novel model HGAT to embed the HIN for short text classification based on a new dual-level attention mechanism. The attention mechanism not only captures the importance of different neighboring nodes (reducing the weights of noisy information) but also the importance of different types of nodes.



4.2.1 Comparison of Variants of HGAT

We also compare our model HGAT with some variants to validate the effectiveness of our model. As shown in Table 3, we compare our HGAT with four variant models. The basic model GCN-HIN directly applies GCN on our constructed HIN for short texts by concatenating the feature spaces of different types of information. It does not consider the heterogeneity of various information types. HGAT w/o ATT considers the heterogeneity through our proposed heterogeneous graph convolution, which projects different types of information to an implicit common space with respective transformation matrices. HGAT-Type and HGAT-Node respectively consider only type-level attention and node-level attention.

We can see from Table 2, HGAT w/o ATT consistently outperforms GCN-HIN on all datasets, demonstrating the effectiveness of our proposed heterogeneous graph convolution which considers the heterogeneity of various information types. HGAT-Type and HGAT-Node further improve HGAT w/o ATT by capturing the importance of different information (reducing the weights of noisy information). HGAT-Node achieves better performance than HGAT-Type, indicating that node-level attention is more important. Finally, HGAT significantly outperforms all the variants by considering the heterogeneity and applying dual-level attention mechanism including node-level and type-level attentions.

4.2.2 Impact of Number of Labeled Docs

We choose 6 representative methods with the best performance: SVM+LDA, CNN-pretrain, LSM-

(a) K: Number of topics. (b) P: Top P relevant topics.

Figure 4: The average accuracy with different number of topics and top relevant topics on AGNews.

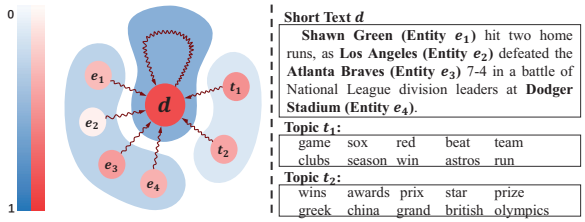


Figure 5: Visualization of the dual-level attention including node-level attention (shown in red) and type-level attention (shown in blue). Each topic t is represented by top 10 words with highest probabilities.

pretrain, GCN-HIN, TextGCN and HGAT, to study the impact of the number of labeled documents. Particularly, we vary the number of labeled documents per class and compare their performance on the AGNews dataset. We run each method 10 times and report the average performance. As shown in Figure 3, with the increase of labeled documents, all the methods achieve better results in terms of accuracy. Generally, the graph based methods GCN-HIN, TextGCN and HGAT achieve better performance, indicating that graph-based methods can make better use of limited labeled data through information propagation. Our method outperforms all the other methods consistently. When fewer labeled documents are provided, the baselines exhibit obvious performance drop, while our model still achieves relatively high performance. It demonstrates that our method can more effectively take advantage of the limited labeled data for short text classification. We believe our method benefits from the flexible HIN and the proposed heterogeneous graph attention networks with dual-level attention.

4.2.3 Parameter Analysis

Figure 4 (a) and (b) show the test accuracy of our HGAT model on the AGNews dataset with different number of topics K and Top P relevant topics assigned to a document. As we can see clearly, for the number of topics, the test accuracy first increases with the increase of the number of topics, reaching the highest value at 15; it falls when its number is larger than 15. We also tried the different numbers of topics for baselines, and have observed that the best K is the same as in our model. This is consistent with the intuition that the number of topics should fit the dataset, i.e., it should be model free. For the number of top relevant topics P assigned to the documents, the test accuracy first increases with the increase of P and then decreases when P is larger than 2. In our experiments, the two parameters are set based on the validation set of each dataset.

4.2.4 Case Study

As Figure 5 shows, we take a short text from AGNews as an example (which is classified to the class of sports correctly) to illustrate the dual-level attention of HGAT. The type-level attention assigns high weight (0.7) to the short text itself, while lower weights (0.2 and 0.1) to entities and topics. It means that the text itself contributes more for classification, than the entities and topics. The node-level attention assigns different weights to neighboring nodes. The node-level weights of nodes belonging to a same type sum to 1. As we see, the entities e_3 (Atlanta Braves, a baseball team), e_4 (Dodger Stadium, a baseball gym), e_1 (Shawn Green, a baseball player) have higher weights than e_2 (Los Angeles, referring to a city at most time). The topics t_1 (game) and t_2 (win) have almost the same importance for classifying the text to the class of sports. The case study shows that our proposed dual-level attention can capture key information at multiple granularities for classification and reduce the weights of noisy information.

5 Conclusion

In this paper, we propose a novel heterogeneous graph neural network based method for semi-supervised short text classification, which takes full advantage of both limited labeled and large unlabeled data by information propagation. Particularly, we first present a flexible HIN framework for modeling the short texts, which can integrate any additional information and capture their rich relations to address the semantic sparsity of short texts. Then, we propose a novel model HGAT to embed the HIN based on a dual-level attention mechanism including node-level and type-level at-

tentions. HGAT considers the heterogeneity of various information types by projecting them into an implicit common space. Additionally, the dual-level attention captures the key information at multiple granularity levels and reduces the weights of noisy information. Extensive experimental results demonstrated that our proposed model significantly outperforms the state-of-the-art methods across six benchmark datasets consistently.

As our model HGAT is a general HIN embedding approach, it would be interesting to apply it to other tasks, e.g., HIN based recommendation.

Abstract

The readability of a digital text can influence people's ability to learn new things about a range topics from digital resources (e.g., Wikipedia, WebMD). Readability also impacts search rankings, and is used to evaluate the performance of NLP systems. Despite this, we lack a thorough understanding of how to validly measure readability at scale, especially for domain-specific texts.

In this work, we present a comparison of the validity of well-known readability measures and introduce a novel approach, *Smart Cloze*, which is designed to address shortcomings of existing measures. We compare these approaches across four different corpora: crowdworker-generated stories, Wikipedia articles, security and privacy advice, and health information. On these corpora, we evaluate the convergent and content validity of each measure, and detail tradeoffs in score precision, domain-specificity, and participant burden. These results provide a foundation for more accurate readability measurements and better evaluation of new natural-language-processing systems and tools.

1 Introduction

Readability metrics are used in a variety of computational contexts, including to evaluate the quality of novel natural language processing (NLP) systems (Sugawara et al., 2017; Kandula et al., 2010) or machine generated translations (House, 2014), or to rank search results (Slegg, 2018). A variety of readability metrics are available for assessing comprehensibility of texts: human-expert-written comprehension questions, automatically generated readability tests, and computed metrics requiring no human/agent input (Bormuth, 1968; Flesch, 1948; Taylor, 1953; Graesser et al., 2004).

Despite being used frequently in computational contexts, the majority of readability assessments were developed for grade-school texts and validated with grade-school readers. Online texts are generally targeted toward adult readers, leading to differences in text structure (e.g., bullet points), word abstraction (Graesser et al., 2004), and domain-specificity (e.g., medical advice, digital-security advice). Such differences may affect the accuracy of computed metrics and automatically generated readability tests, which are increasingly used to scale readability measurements in the digital world (Friedman and Hoffman-Goetz, 2006; Eysenbach et al., 2002; Bernstam et al., 2005). Despite this use, the validity of readability assessment techniques has rarely been re-evaluated for online contexts.

In this work, we make three contributions: **First**, we evaluate the most commonly used methods for measuring readability in terms of *content validity* (the degree to which different measures relate to theoretically-grounded linguistic components like text cohesion or syntactic complexity), *convergent validity* (the degree to which these measures correspond to each other), *redundancy* (the degree to which one measure is subsumed by another), and *score precision* (the shape of the distribution of score from a given measure, and how well it distinguishes among documents). **Second**, we identify a need for domain-specific automatically generated readability tests. To address this, we develop and evaluate a novel technique for automatically generating readability tests specifically for domain-specific texts: *Smart Cloze*. We find that Smart Cloze offers some benefits for domain-specific applications compared to existing measures. **Third**, we contribute two open-science resources: our open-source Smart Cloze tool, as well as a *Digital Readability* evaluation corpus of 100 documents, including 300 comprehension questions written by human experts, that we use in our evaluation.

2 Related Work

Human-written comprehension questions are the gold standard for measuring readability (Duke and Pearson, 2009; Sarroub and Pearson, 1998), but developing such questions is costly and difficult to scale. As such, prior work has explored various automated, scalable approaches to generating comprehension questions. One such approach is automatic reading test generation, typically using the Cloze (Taylor, 1953) procedure, which involves removing every *n*th word in a given document and requiring the reader to "fill-in-the-blank" with the correct word. The Cloze procedure was validated as a scalable method of comprehension assessment through comparison with expert-written comprehension questions for grade-school texts (Bormuth, 1967; Heilman, 2011; Rankin and Culhane, 1969; Oller et al., 1972).

Recently, researchers have explored approaches to adjusting the construction of Cloze tests: selecting particular key sentences or parts of speech to use as blanks, often to assess retention of factual knowledge or awareness of vocabulary (Goto et al., 2010; Chen et al., 2006; Gates, 2011; Lin and Ji, 2010; Lee and Seneff, 2007), and multiple-choice Cloze tests in which test-takers select from a set of distractors rather than filling in an open blank, avoiding potential scoring issues with typos and equally-correct synonyms (Goto et al., 2010; Narendra et al., 2013; Brown et al., 2005; Mostow and Jang, 2012; Gates, 2011; Pino et al., 2008; Hoshino and Nakagawa, 2007). Our Smart Cloze tool builds on this prior work by choosing distractors from a domain-specific rather than a general dictionary, answering the call from Collins-Thompson's 2014 review of readability measures for more domain-specific tool options.

The second scalable alternative consists of readability metrics that take no reader input. The first such metrics were readability formulae, the most popular of which is the Flesch reading ease score (FRES) (Tekfi, 1987; Flesch, 1948, 1943). FRES assumes that longer sentences and words — which often co-occur with complex syntax — indicate greater reading difficulty (Dale and Tyler, 1934; Feng et al., 2009). More recently, linguistic feature-based (McNamara et al., 2014; François and Miltsakaki, 2012; Collins-Thompson and Callan, 2004) and machine learning approaches have also been used to predict the readability of text (Kate et al., 2010; De Clercq and Hoste, 2016; Collins-Thompson, 2014). Finally, there has also been recent work that goes beyond readability to assess the overall *quality* of text, including factors such as topical interest, persuasiveness, or grammatical correctness (Louis and Nenkova, 2013; Pitler et al., 2010; Tan et al., 2016). In this work, we focus strictly on readability and exclude other quality measures from our comparative evaluation.

All but one of the new approaches to measuring readability (modified Cloze and linguistic metric/ML approaches) were evaluated only through comparison with annotator judgements of perceived readability or correlation with FRES-style formulae, rather than the gold standard of human comprehension questions (Benjamin, 2012), the exception being Mostow et al. (2004). Further, these evaluations were conducted strictly with grade-school texts, leaving a significant gap around online, adult texts (Benjamin, 2012). Our work fills this gap in evaluation (Benjamin, 2012; Collins-Thompson, 2014) by systematically evaluating the validity of currently used readability metrics through comparison with each other and with results from expert written comprehension tests on a wide set of both general and domain-specific documents.

3 Methods

In our evaluation, we compare readability scores from five sources: human-written comprehension questions; automatically generated readability tests including both traditional Cloze and our Smart Cloze domain-specific variant; annotator perceived ease (Sauro and Dumas, 2009; Rello et al., 2016), which has been used to evaluate readability metrics in the past; and the Flesch Reading Ease Score (FRES) (Flesch, 1948). We compared these metrics across our *Digital Readability* evaluation corpus. Here we describe our corpus, how we generated each of the readability metrics, and how we conducted our validity analysis.

3.1 Digital Readability Corpus

We draw our final evaluation corpus from four source corpora, as follows:

Story corpus. We drew our crowd-worker-created stories from the MCTest (Richardson et al., 2013) dataset, which consists of 500 simple stories created by Amazon Mechanical Turk crowdworkers and validated manually for quality.

Wikipedia corpus. We drew our Wikipedia articles from a corpus of 20,000 Wikipedia articles scraped from Wikipedia and cleaned for quality by Shaoul (2010). We selected Wikipedia articles as a baseline of adult texts against which to compare the domain-specific texts. Wikipedia articles have a mean FRES similar to our domain-specific texts (mean FRES for the wikipedia sample = 47.9; for the health documents = 53.7; and for the security documents = 48.7), suggesting that, at least by one measure, the texts should be similar in readability.

Health corpus. We drew health articles from the 500-document Health Text Readability Corpus (Morales and Wacholder, 2018). This corpus includes consumer health-information documents made available for public use by the CDC, NIH, American Heart Association, American Diabetes Association, and the National Library of Medicine's Medline Plus resource. Worksheets, posters, infographics, and websites are not included. More than half (N=293) of the documents were found in "Easy to Read" collections; that is, the document has been designated by its source agency as appropriate for adults who read at or below a 7th-8th grade reading level.

Security corpus. We collected security advice documents through two methods: (a) asking MTurk workers to create Google search queries for computer security advice, then scraping the top 20 Google results of each query, using the DiffBot API[1] to parse and sanitize HTML body elements within each identified site, and (b) by asking 10 security experts and librarians to recommend digital security advice sources and scraping those websites. These two approaches, along with a manual cleaning process in which we performed spot checks and also manually reviewed 144 documents identified as outliers by FRES or length, generated 1,878 security advice documents.

The last two corpora – health and security advice – are domain-specific: focused on a singular domain and often containing jargon or topics not typically encountered in daily life.

Final evaluation corpus. To ensure comparability of results, we used a standardized subsampling procedure to select 25 documents from each corpus. To ensure that our evaluation captured some variance in documents, we subsampled by length. We first remove the shortest and longest 5% of documents, then we then divide the documents into five bins by length, based on how many standard deviations the length of a given document is from the mean length for that corpus. We manually reviewed all selected documents to ensure that they were on-topic and appropriately clean.[2]

3.2 Readability Metrics

We created three **comprehension questions** for each of the documents in our evaluation corpus: one True/False question and two multiple choice questions with four answer options each, per comprehension question best practices (Anderson, 1972; Day and Park, 2005). Domain-specific questions were written by three co-authors who were domain experts in digital security or in health; the general questions were written by two other co-authors. All 300 comprehension questions were reviewed and edited by a paid comprehension question specialist, who had experience writing and evaluating comprehension questions for the SAT, Discovery Science, and similar organizations; the specialist spent more than 10 hours editing and refining the questions.[2]

We selected the FRES as our **computed measure**, as it is the most-used by number of citations, and anecdotally, by wide-spread application. We computed the FRES for each document using the Python `textstat` package [3].

For our **annotator perception of ease** measurement, we use a single-item question "How easy is this document to read?" with 5-point Likert-item response choices ranging from "Very Easy" to "Very Hard."

Finally, for our **automatically generated readability tests** we used both the traditional Cloze Procedure and our Smart Cloze procedure. Prior work suggests that the frequency of blanks does not significantly affect results (Taylor, 1953). We select set $n = 5$, up to a maximum of 35 target words, for both our traditional Cloze implementation and our Smart Cloze tests, as was done in the original Cloze implementation (Taylor, 1956).

Smart Cloze tool. Prior work to improve Cloze tests offered a multiple-choice variant of the traditional Cloze procedure in which distractors (incorrect answer choices) are randomly drawn from a general dictionary containing other words with the

[2] You can find the documents in our corpus, the 300 comprehension questions, and the code for generating traditional Cloze and Smart Cloze tests at: https://github.com/SP2-MC2/Readability-Resources.

[3] https://pypi.org/project/textstat/

same part of speech. While such multiple-choice variants offer improvements in test-taker time, they are potentially inappropriate for domain-specific applications. For example, replacing the word "encryption" in a cybersecurity text with "dog" creates a very easy test. As such, we implemented a novel approach that we call Smart Cloze: we construct a domain-specific dictionary from the same corpus for which we are generating tests and draw distractors from it. The goal is to offer relevant alternatives such as "antivirus" and "key" as distractors for "encryption."

To construct a Smart Cloze test for some document d selected from a domain-specific corpus c, our tool follows the following procedure. First, we bin all of the words in c by part of speech (tagged using Spacy[4]) to create a domain-specific dictionary. We then construct a similar part-of-speech-tagged *document-specific dictionary* using only the words in d. Third, we identify *target words* in d to be replaced by multiple-choice questions. Fourth, we generate distractors for each target. We randomly select up to 14 potential distractors with the same part of speech as the target word from each of the domain-specific and document-specific dictionaries. We then process these distractors in random order, optimizing to obtain two from each dictionary, until we have found four satisfactory distractors.

We measure whether a potential distractor is satisfactory by examining how probable it is that the distractor might substitute for the target word within d. To do this, we first look up the bigram probabilities of the target word (w_c) with its preceding (w_{c-1}) and following (w_{c+1}) words in Google's n-gram corpus. This gives us a baseline for how probable the correct answer is. We then look up bigram probabilities of the potential distractor (say w_d) in combination with the same preceding (w_{c-1}) and following (w_{c+1}) words. Satisfactory distractors have both preceding-distractor and distractor-following bigram probabilities within two orders of magnitude of those for the correct target word. [5] More precisely, a distractor w_d will be accepted if:

$$[P(w_d|w_{c+1}) \geq P(w_c|w_{c+1})] \wedge [P(w_{c-1}|w_d) >= P(w_{c-1}|w_c)]$$

If we do not find four satisfactory distractors (by this definition) within the candidate 28, we instead select the potential distractors with the highest bigram probabilities until we obtain the desired four distractors. Finally, to avoid very small lists of distractor options for certain part of speech (e.g., `TO` only contains to'), we merge parts of speech with small wordlists with larger, related parts of speech until enough unique distractors can be found.

3.3 Validity Evaluation

To evaluate the validity of these readability metrics and compare them, we needed readers to answer the comprehension questions, Cloze tests, and ease question for our documents. We recruited U.S. Amazon Mechanical Turk workers (MTurkers) with a 95% approval rating or above to complete these tasks. Each worker completed one randomly selected readability measure for four documents, including one randomly selected from each of the four corpora. MTurkers were compensated with $1.50 for completing the task. We recruited at least five distinct MTurkers for each type of measure and each document (n=841).

We compare our five readability metrics by examining their construct validity (Cronbach and Meehl, 1955): the degree to which it appears that the measures are accurately measuring readability. To do so, we examine:

- *Content validity:* the degree to which the measures relate to concepts that have been theorized to be relevant to readability; and
- *Convergent validity:* the degree to which related measures (e.g., multiple measures of the same construct) are correlated.

We also explore three factors that are relevant to selecting an appropriate readability measure:

- *Redundancy:* the degree to which any measure is fully, and redundantly, covered by another measure;
- *Score precision:* the precision with which the measure distinguishes between different documents; and
- *Participant burden:* the cost of the measure to the participant (and the researcher) in time to complete.

To assess **content validity**, we examine the degree to which five core linguistic components (narrativity, syntactic simplicity, word concreteness, referential cohesion, and deep cohesion) theorized to be related to readability (Graesser et al., 2004) can *explain the variance* in the measure scores. We

[4] https://spacy.io

[5] We selected two orders of magnitude heuristically to narrow the search space for faster computation while obtaining an appropriate difficulty for the test. Future work could explore alternative heuristics in more detail.

measure these components using the Cohmetrix tool (Graesser et al., 2004). We construct linear regression models, in which the mean measure score for a document is the outcome variable and the input variables are the five linguistic components.

As we wish to understand *which* components are related to which measures, we seek to ensure that we construct a model of best fit. To do so, we perform feature selection via stepwise backward selection, minimizing AIC (Bursac et al., 2008). We further measure applicability to domain-specific texts by including the source corpora of the document as a sixth covariate in the regression model. We set Wikipedia as the baseline for corpora source, as it represents a broad set of non-domain-specific documents with similar FRES to the domain-specific documents.

To assess **convergent validity**, we compute the Pearson correlation between the scores for each readability method in our evaluation dataset. We report the ρ value (strength of the correlation) for correlations significant at $\alpha < 0.05$; Holm-Bonferonni (Abdi, 2010) correction is applied to account for multiple testing.

We also assess **redundancy**, which is not strictly a property of convergent validity, but is relevant when comparing multiple measures that attempt to assess the same construct. Demonstrating that two related measures are correlated establishes convergent validity, but if they are perfectly correlated, then it is unlikely both are needed (Quinn et al., 2010). For this analysis, we construct linear regression models in which the mean score from a given measure for a given document is the outcome variable and the input variables are the three other types of measures (note that we do not include both Cloze measures in any model, but instead construct separate, three-variable models, each with FRES, comprehension questions, ease, and one of the Cloze measures). We consider the degree of redundancy to be the proportion of variance in measure scores explained by the other measures (that is, the R^2 value of this regression model).

To assess **score precision**, we examine the shape of the distribution of scores for a given measure. Per best practice for observing distributions, we do so both through visual inspection and by measuring kurtosis (a statistical measure of the 'tailness' of a distribution) (DeCarlo, 1997).

Finally, we assess **participant burden** in terms of time to complete the task (which also proxies for researcher cost). We compare time by bootstrapping confidence intervals for the mean time for completion of a readability assessment for a given document. Non-overlapping confidence intervals indicate a significant difference in completion time.

3.4 Limitations

Our work is subject to four primary limitations. First, automatic selection of distractors means that there may be differences in the difficulty of different distractors (or variances in difficulty of tests generated by the method when used repeatedly). Based on a manual review of the Cloze tests we conducted before deployment, we did not find trivial distractors to be highly prevalent, given the breadth of words available in each dictionary. However, future work may wish to explore methods for measuring and ensuring consistency in distractor difficulty. Second, MTurk respondents are known to be more educated than the general population, and thus the results of our work may not generalize to low-literacy populations, second-language learners, and others (Redmiles et al., 2019; Ipeirotis, 2010). Third, while we attempted to cover a relatively broad space of online documents, other types of documents (e.g., news articles, Facebook posts) may perform differently. Finally, it is possible that MTurkers were inattentive to our tasks, limiting the validity of our data. We mitigate this possibility by restricting our sample to workers with 95% approval rates on past tasks, as shown in prior work to ensure participant attention to surveys as well as gold-standard 'test' questions (Peer et al., 2014).

4 Results

In this section we summarize our results for content validity (including domain sensitivity of measurements), convergent validity, redundancy, score precision, and participant burden (Table 1).

4.1 Content Validity

We find that comprehension question scores are significantly related to the narrativity ($p = 0.003$) and syntactic complexity ($p = 0.035$) of the document, while performance on comprehension questions is not significantly related to the other three linguistic factors we examined (word concreteness, referential cohesion, deep cohesion) or to

	Linguistic Components (Content Validity)					Additional Considerations			
	Narrativity	Syntactic Simplicity	Word Concreteness	Referential Cohesion	Deep Cohesion	Burden (Mean Time)	Mean Score	Score Precision (Distribution Trend)	Domain Sensitivity
Comprehension	✓	✓				2.86 min	75.7%	exponential	
Traditional Cloze	✓			✓		5.05 min	34.1%	normal	
Smart Cloze	✓	✓		✓		4.55 min	52.4%	normal	✓
Ease			✓			1.67 min	67.1%	uniform	✓
FRES	✓	✓	✓			—	61.0%	uniform	✓

Table 1: Summary of our results on content validity (significant relationships between readability measure and linguistic components theorized to explain comprehension) and other considerations for selecting a readability measure (time for participants to complete a test for a given measure on an average document, average score achieved across documents, trend in the shape of the distribution of scores achieved with a measure, and whether the measure exhibits variation by document domain.

type of document (source corpus).

Traditional and Smart Cloze scores are significantly related to the narrativity (Traditional: $p < 0.001$; Smart: $p = 0.040$) and referential cohesion (Traditional: $p = 0.035$; Smart: $p = 0.008$) of the document. Smart Cloze scores were significantly related to the syntactic complexity ($p = 0.005$) of the document; traditional Cloze scores were not significantly related to syntactic complexity. Finally, neither type of Cloze score was significantly related to deep cohesion or to word concreteness. Smart Cloze scores vary significantly by document domain, while traditional Cloze scores do not. Specifically, Smart Cloze scores are significantly higher for domain-specific documents: those from the health ($p < 0.001$) and security (0.031) source corpora, than for Wikipedia documents. We hypothesize that this is the case because the topics of domain-specific documents are narrower — there are fewer reasonable options for any given blank space — than in the Wikipedia documents, resulting in easier multiple-choice questions. (Anecdotal observation of the generated questions seems to align with this theory.)

Ease perceptions are significantly related only to word concreteness ($p = 0.015$) and document domain: stories ($p = 0.027$) and security ($p = 0.015$) documents are perceived as significantly easier to read than Wikipedia articles. The relationship between ease perceptions and concreteness (and lack of relationship with the other linguistic features we examined) is worth remark. Concreteness of words appears to be easy for readers to assess with a quick glance at an article. This assessment, and their overall perception of ease, may in turn determine whether readers are willing to further read a document they encounter "in the wild," at which point other readability factors may become more relevant. We therefore hypothesize that ease and other measures may complement

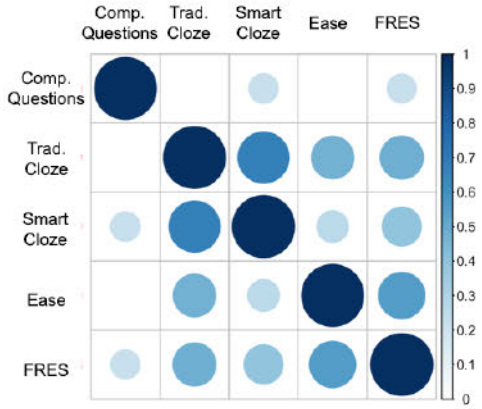

Figure 1: Correlation matrix showing the convergent validity of the measures. That is, the correlation between readability measurement methods. Non-significant correlations ($p > 0.05$) are not shown.

each other. Finally, FRES scores are significantly related to narrativity ($p < 0.001$), word concreteness ($p < 0.001$), and syntactic complexity ($p < 0.001$); but not to either referential or deep cohesion. Perhaps unsurprisingly, FRES scores were significantly higher for stories than for Wikipedia ($p < 0.001$). FRES scores were also higher for security than for Wikipedia ($p = 0.015$), but the health and Wikipedia documents in our sample did not differ in FRES.

While the regression models we constructed explained a significant portion of the variance in scores for ease [6] ($R^2 = 0.504$), FRES ($R^2 = 0.758$), Smart Cloze ($R^2 = 0.389$) and traditional Cloze ($R^2 = 0.334$), these factors explained much less of the variance for comprehension question scores ($R^2 = 0.132$).

[6] This result closely parallels prior work, which predicted perceived ease of Wall Street Journal articles using discourse, vocabulary and length, resulting in an R^2 of 0.503 (Pitler and Nenkova, 2008).

4.2 Convergent Validity

To examine **convergent validity**, we examine the correlation between scores from different measures (Figure 1). Comprehension question scores have the least correlation with scores from the other methods: no correlation with traditional Cloze or ease ratings, and small correlation with FRES ($\rho = 0.22$) and Smart Cloze ($\rho = 0.23$).

This low correlation between comprehension questions and the other methods of measuring readability, together with the low explanation of variance noted above, suggest that comprehension questions assess a combination of the readability of the text and the reader's cognitive abilities, different from the other metrics, which may be more specific to just the text itself (Sarroub and Pearson, 1998). Traditional Cloze, on the other hand, correlates relatively well with all other methods. Perhaps unsurprisingly, there is high correlation ($\rho = 0.71$) between traditional and Smart Cloze scores. Traditional Cloze also correlates well with ease ($\rho = 0.47$) and FRES ($\rho = 0.48$). Smart Cloze correlates less with ease than does traditional Cloze (ease: $\rho = 0.264$, FRES: $\rho = 0.44$). Finally, ease and FRES correlate relatively strongly with each other ($\rho = 0.56$).

4.3 Redundancy

By constructing regression models with the mean score from a given measure on a given document as the outcome variable, and the other measures as the input variables, we find that 4.02% of the variance in the comprehension question scores can be explained by ease perception, FRES, and traditional Cloze (7.92% with Smart Cloze). 20.1% of the variance in traditional Cloze is explained by the other measures, while 22.1% of the variance in Smart Cloze is explained by these measures. 36.0% of the variance in ease perception is explained by mean comprehension question scores, FRES, and traditional Cloze (31.8% with Smart Cloze), while 35.8% of the variance in FRES measurements is explained by scores on comprehension questions, ease perception, and traditional Cloze (37.8% Smart Cloze). Thus, none of the measures are redundant, as the variance in no measure is fully (or even more than 50%) explained by the others.

4.4 Score Precision

Researchers selecting a readability measurement method may also wish to consider the **score precision**: that is, are you trying to find a few bad outliers in a corpus of highly readable documents, or are you expecting a relatively normal distribution of document quality? Figure 2 shows the score distributions by method across all documents and for each document type.

Across domains, the Cloze tests provide the most normal distributions of scores (average traditional Cloze kurtosis = 2.34, average Smart Cloze kurtosis = 3.08)[7]. Cloze scores are thus useful in cases where the relative readability of documents is of interest and where you hypothesize that a normal distribution of readability may be appropriate. The distribution of traditional Cloze scores is transposed left, with a mean of 0.341 (95% confidence interval: [0.329, 0.353]), while the Smart Cloze distribution is centered, with a mean of 0.524 (95% confidence interval: [0.510, 0.537]). Traditional Cloze scores may thus need to be scaled (considered relative to each other rather than as absolute values) to account for this observed ceiling effect.

Ease ratings and FRES, on the other hand, have a more platykurtic distribution (ease: average kurtosis 1.91; FRES: average kurtosis 1.94; fully uniform or platykurtic distribution is 1). A platykurtic distribution has fewer outliers than a normal distribution. Thus, these methods may be more useful in corpora where you expect few readability outliers. Further, ease ratings and FRES both have means higher than 0.5: ease has a mean across domains of 0.671 (95% CI: [0.657, 0.685]) and FRES has a mean of 0.610 (95% CI: [0.594, 0.625]). Given these relatively high means, these methods may also need to be scaled, or may be most useful in cases where you anticipate that an average document in your corpus will be fairly readable. Comprehension questions provide a similarly platykurtic distribution (average kurtosis: 2.06), but with a very high mean (0.757, 95% CI:[0.739, 0.778]).

4.5 Participant Burden

Finally, research is often constrained by resources, including time and budget, and ethically we must be mindful of the burden we impose on our partici-

[7]The kurtosis of a normal distribution is 3; the kurtosis of a unifom distribution is 1.

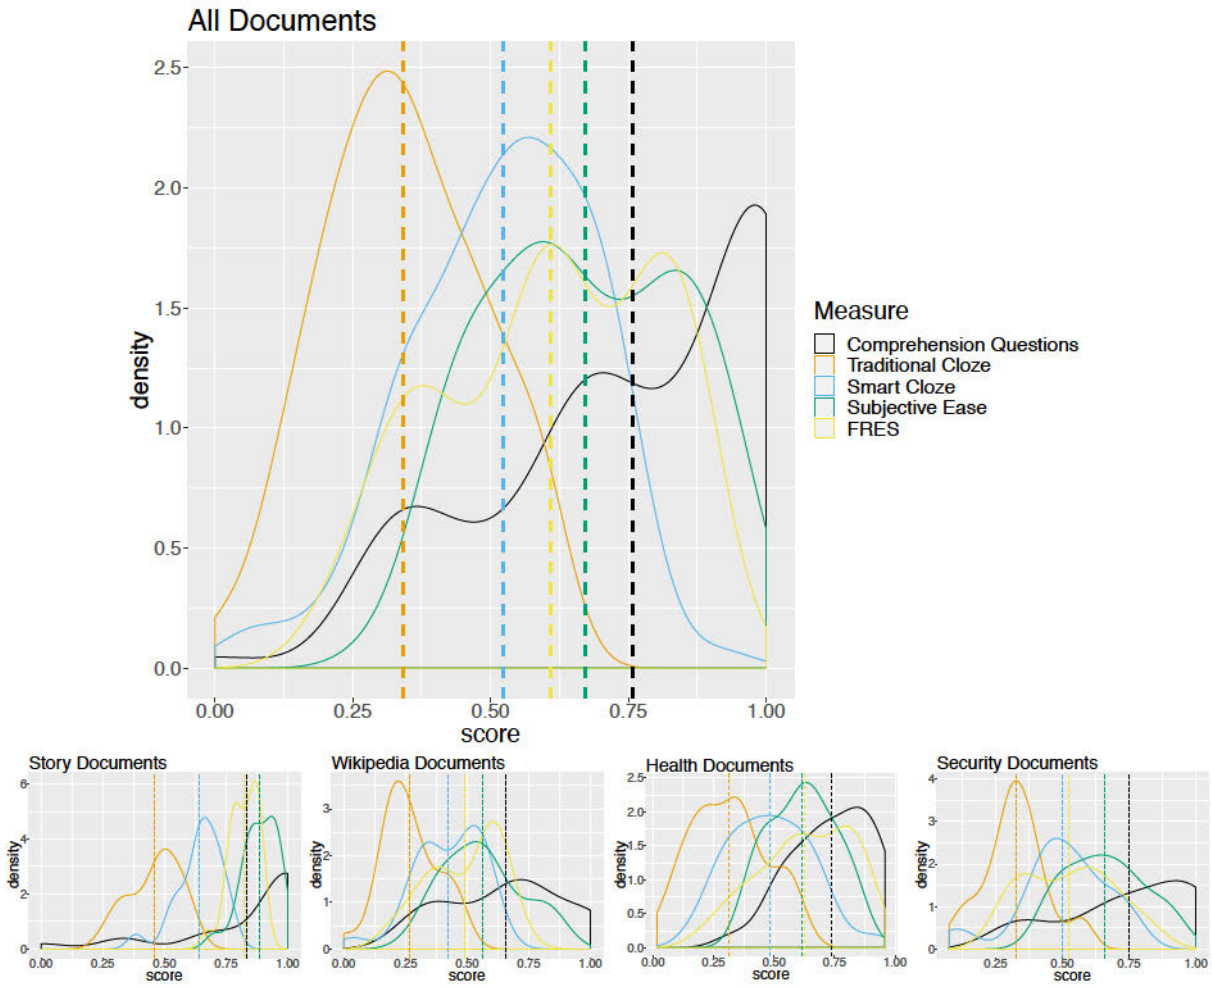

Figure 2: Score distributions by method, across all corpora (top) and by corpus (bottom).

pants. Ease perception (one question) is the fastest test for a worker to complete, with participants spending an average of 1.67 minutes (95% CI: [1.56, 1.78]) per document. Comprehension questions (three questions) took a significantly longer period of time, averaging 2.86 minutes ([2.64, 3.12]) per document, followed by Smart Cloze with an average of 4.55 minutes ([4.08, 4.60]) per document. Finally, traditional Cloze took significantly longer than Smart Cloze, averaging 5.05 minutes per document ([4.72, 5.42]).

5 Moving Forward

In sum, no single readability metric outperformed all the others. Each metric offers different benefits and tradeoffs, and human-written comprehension questions differ the most from the other metrics. We summarize the relevant considerations for selecting a readability metric in Figure 3 and encourage the use of multiple metrics in cases where creating comprehension questions is not scalable.

We find that comprehension questions and Smart Cloze both relate significantly to syntactic complexity, perhaps because they require selection among different possible answer choices. Traditional and Smart Cloze relate to referential cohesion, which makes logical sense, as filling-in-the-blank questions require context from prior sentences. Finally, ease and FRES relate to word concreteness, potentially providing relevant assessments of "first glance" readability reactions. The readability metrics examined also exhibit convergent validity, with the three traditional methods (traditional Cloze, subjective ease, and FRES exhibiting the strongest correlation in scores. Finally, the measures are not redundant: a significant portion of the variance in each remains unexplained by the others.

These different methods offer different levels of precision: the Cloze methods trend toward normal distributions with low (traditional) and centered (Smart) means. On the other hand, ease

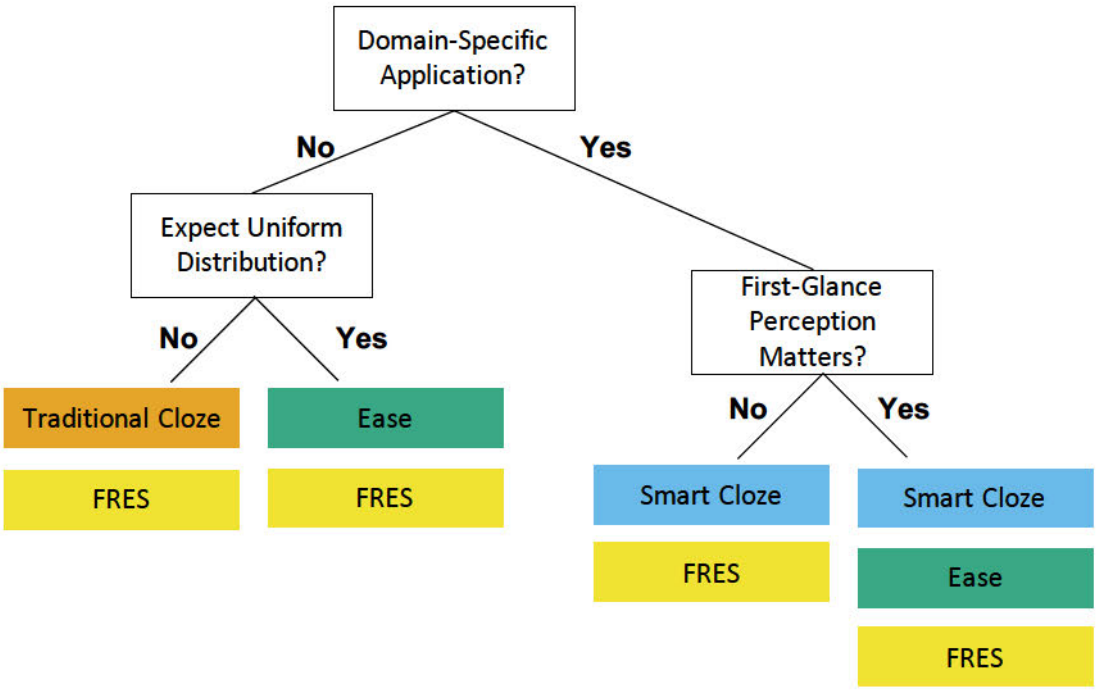

Figure 3: Flow chart for selecting readability measures.

and FRES assessments are more uniformly distributed, with higher means (near 60 and 70%, respectively). Further, Smart Cloze, FRES, and ease measurements all significantly co-varied with document type: Smart Cloze scores were significantly higher for the domain-specific documents (health, security) than for Wikipedia articles, while FRES and ease scores were significantly higher for the story and security documents than for Wikipedia.

While it may be tempting to exclusively use linguistic features because they are cheap and easy to obtain, we find that for the five linguistic factors we explored in this work, these factors explain only 30-50% of the variance in the reader-input readability metrics. Future work may wish to explore additional linguistic factors (Tham, 1987; Hancke et al., 2012; Vajjala and Meurers, 2013; Kate et al., 2010), beyond those covered in this work. In the mean time, our results suggest that when possible, researchers should still consider augmenting these factors with a human-input method. The Smart Cloze tool we propose offers improvements in participant burden, especially for domain-specific documents: scores are higher on average than for traditional Cloze, and tests are 30 seconds faster on average (54 seconds faster for domain-specific documents). However, Smart Cloze is less correlated with perceived ease than traditional Cloze, possibly because the multiple choice option makes the test easier to complete, lessening the chance that participants will "give up." Thus, Smart Cloze is best used in cases where cursory or first glance assessment of readability is less relevant, or in combination with an ease assessment.

Acknowledgements

We are grateful to all reviewers for their thoughtful feedback. We also thank Hanna Wallach introducing us to the ideas of measurement modeling, as well as in depth discussions on the topic, as well as sharing her work with Abigail Jacobs on this topic in their in-preparation paper (Jacobs and Wallach).

Abstract

With the development of NLP technologies, news can be automatically categorized and labeled according to a variety of characteristics, at the same time be represented as low dimensional embeddings. However, it lacks a systematic approach that effectively integrates the inherited features and inter-textual knowledge of news to represent the collective information with a dense vector. With the aim of filling this gap, the News2vec model is proposed to allow the distributed representation of news taking into account its associated features. To describe the cross-document linkages between news, a network consisting of news and its attributes is constructed. Moreover, the News2vec model treats the news node as a bag of features by developing the Subnode model. Based on the biased random walk and the skip-gram model, each news feature is mapped to a vector, and the news is thus represented as the sum of its features. This approach offers an easy solution to create embeddings for unseen news nodes based on its attributes. To evaluate our model, dimension reduction plots and correlation heat-maps are created to visualize the news vectors, together with the application of two downstream tasks, the stock movement prediction and news recommendation. By comparing with other established text/sentence embedding models, we show that News2vec achieves state-of-the-art performance on these news-related tasks.

1 Introduction

News, carrying a large amount of information, can often guide public opinions, affect people's behavior and drive the evolution of social events. In the era of information, news text is considered to be a part of big data that is continuously updated. In order to facilitate the performance of downstream NLP tasks, it is rather essential to find an efficient way to represent news as continuous vectors that contain the collective information of its inherited features and the inter-textual knowledge between different news.

The most straightforward approach to embed news is to directly treat it as textual data and apply text/sentence embedding models. To represent texts/sentences as vectors, one of the classic techniques is to perform numerical operations on the word vectors (Mikolov et al., 2013b), which is recognized as a simple but powerful baseline (Conneau et al., 2018). SDAE (Vincent et al., 2010) uses an auto-encoder to compress texts into a low-dimensional vector. Paragraph Vector (Le and Mikolov, 2014) learns the distributed representation of sentences and documents by predicting their contexts, *i.e.*, words in the sentence/document. Additionally, Skip-Thought (Li and Hovy, 2014), FastSent (Hill et al., 2016) and Quick-Though (Logeswaran and Lee, 2018) learn distributed sentence-level representations through the coherence between sentences. BERT (Devlin et al., 2018) proposes a powerful pre-trained sentence encoder which is trained on unsupervised datasets based on the masked language model and next sentence prediction. The major limitation of embedding approaches discussed above is that they produce representations and features that solely describe the contextual information at the document level. In the case of news representation, the connection between different news events is also considered as crucial information that should be incorporated into the news embedding, as well as other labeled features such as the topic category and the polarity of the news.

With the argument that news stories describe events, news event embedding models are developed to offer an alternative solution for the vector representation of news. It is suggested to extract event tuples $E = (Actor, Predicate, Object)$ from headlines and learn vector representations

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4843–4852,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

by scoring the correct tuples higher than the corrupted ones (Ding et al., 2015, 2016). Event2vec (Setty and Hose, 2018) is constructed on a classified news event database from Wikipedia[1], where an event network is created by considering events, entities, event types and years as nodes of different types. The Event2vec model thus produces distributed vector representations of news events based on the network embedding mechanisms, which lacks the flexibility of generating vectors for nodes outside the trained network. In addition, the weights of some edges in the event network are determined by objective assumptions since types and years are not comparable.

In this study, the News2vec model is proposed to learn distributed representations of news, with the embedded vectors containing not only the semantic and labeled information, but also the latent connections between different news events. We start by building the news network that connects the news nodes with their corresponding event element nodes in order to create the aggregated news context that describes both the semantic information and the background linkages between different news events (See Figure 1 for a simplified example of the news network). According to Figure 1, the two pieces of news $Alibaba\ reinvested\ Suning\ after\ three\ years$ and $Suning's\ second-half\ profit\ rose\ by\ 5\%$ are connected by sharing the same contextual element $Suning$. The verbal keywords $reinvest$ and $rise$ of the two different news are thus connected through their common node $Suning$ and become the latent contextual element of the other news. Based on the constructed news network, the biased random walk approach (Grover and Leskovec, 2016) is adopted to generate adequate number of connected node sequences which are later used in the network embedding. Inspired by the Subword model (Bojanowski et al., 2016), we further represent each news node as a bag of news features including semantic features, categorical features, time features, *etc.*. The vector representation of the news feature is thus obtained based on the skip-gram architecture (Mikolov et al., 2013a), and the news vectors are computed as the sum of its feature embeddings.

The advantages of the proposed News2vec model are twofold. First, the News2vec embeddings capture both the semantic features and the potential connections between news by constructing the news network. Second, the Subnode model offers an easy solution to create embeddings for unseen (news) nodes outside the trained network, at the same time enriches the node vector with its node attributes (news features). As the experiments suggest, the News2vec model achieves state-of-the-art performance on the news-related downstream tasks, namely the stock movement prediction and news recommendation.

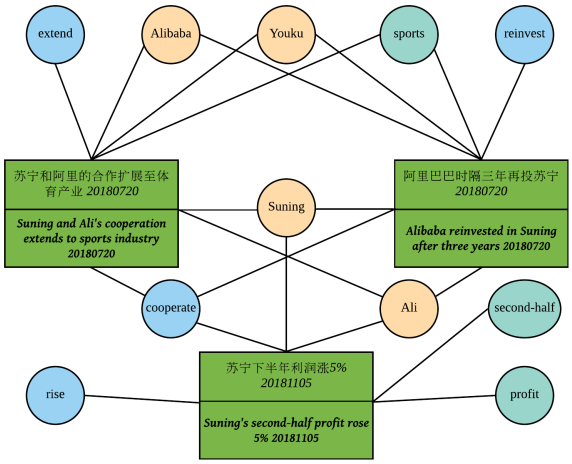

Figure 1: Simplified sample of the news network

2 The News2vec Model

In this section, the formation of the News2vec model is discussed in terms of the news network construction and news embedding based on the Subnode model. According to Figure 2, news elements including entities, actions and nouns, are first extracted from the news titles and texts. Based on these elements and their term frequencyinverse document frequency (tf-idf), the news network is built and sequences of nodes are sampled by the biased random walk. News nodes in these sequences are then represented as bags of extracted news features. The associated vector is thus assigned to each feature by the Subnode model.

2.1 News Network

The News2vec model creates news embeddings based on the news network that connects news with their elements. With the argument that a piece of news often describes one or several events which could be represented as a collection of elements, this study extracts news elements as enti-

[1] https://en.wikipedia.org/wiki/Portal:Currentevents

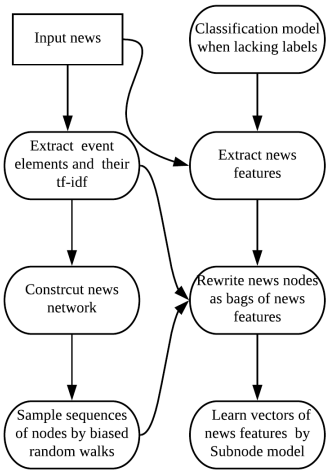

Figure 2: Flow chart of creating news embeddings with News2vec

ties, actions and nouns from news titles and texts, with respect to their tf-idf scores. Specifically, the tf-idf is a well recognized tool to measure the importance of a word/phrase inside the document and to extract the representative elements at the document level. The tf-idf score is formulated as:

$$tfidf_{k,e} = \frac{n_{k,e}}{\sum_w n_{w,e}} \times \log \frac{|D|}{|e : k \in d_e|}, \quad (1)$$

where $n_{k,e}$ denotes the number of the news element k in the news story e, whereas its denominator is the total number of words/phrases in the news document. $|D|$ is the total number of documents, the denominator represents the number of stories containing the element k. In a nutshell, the tf-idf assigns a higher score to the element which appears more frequently in the news story than in others.

After determining the elements of news, the news network is hence constructed by connecting the news nodes $e \in V_e$ of the news title and published time with its element nodes $k \in V_k$. The weights of connective edges (e, k) are computed based on the importance of the element to the news, which is determined by their tf-idf scores. The weight of an edge (e, k) is computed as:

$$W_{e,k} = \frac{tfidf_{k,e}(title)}{Z_1} + \frac{tfidf_{k,e}(content)}{Z_2}, \quad (2)$$

where Z is a normalization constant.

2.2 Network Embedding with Subnode Information

Network embedding

The New2vec network embedding is based on the Node2vec (Grover and Leskovec, 2016) model, with the objective to learn a latent feature vector $F(v)$ for each node $v \in V$ that maximizes the probability of predicting the node $v's$ network neighborhood $N(v)$. The objective function is written as:

$$\max \sum_{v \in V} \log Pr(N(v)|F(v)). \quad (3)$$

Given the feature vector of node v, it is assumed that the prediction probabilities of its neighborhoods are independent from each other, which leads to:

$$Pr(N(v)|F(v)) = \prod_{u \in N(v)} Pr(u|F(v)). \quad (4)$$

To solve the objective function and obtain the optimized node representations, the skip-gram architecture (Mikolov et al., 2013a) is adopted on the basis of network neighboring sequences sampled by the biased random walk. To reduce the computational cost, negative sampling (Mikolov et al., 2013b) is used to replace the softmax classifier by multiple logistic binary classifiers. The optimizer is the Stochastic Gradient Descent (SGD).

Different from the uniform random walk of DeepWalk (Perozzi et al., 2014), News2vec uses the Breadth-first Search (BFS) and the Depth-first Search (DFS) as its search strategies. Suppose that the walk just transitioned from t to v and is now walking to its next step node x, BFS determines the next step with a greater chance of revisiting t, *i.e.*, $d_{tx} = 0$, whilst DFS drives the walk to go deeper and further away from the node t, *i.e.*, $d_{tx} = 2$. In line with the Node2vec model, News2vec defines a search bias α to control the search preference.

$$\alpha_{vx} = \begin{cases} \frac{1}{p}, & if\ d_{tx} = 0 \\ \frac{1}{q}, & if\ d_{tx} = 2 \end{cases} \quad (5)$$

Next, the transition probability of edge (v, x) is defined as the product of the weight of the edge and the bias, *i.e.*, $\frac{\alpha_{vx} \times w_{vx}}{Z}$ where Z is a normalization constant. Explicitly, if $p < q$, the walk is width-first which indicates that there is a greater chance to revisit the original node and sample the

nodes around it, that is, semantically similar news. If $p > q$, the walk is depth-first and tends to go to nodes that are not passed before, which leads to the exploration of news with latent relations. During the random walk, each node is used as a starting vertex for a fixed-length walk to produce a group of sequences. Based on the skip-gram model, we can train vector representations of nodes on these sequences.

Subnode model

Classic skip-gram model assigns a distinct vector to each word, neglecting the morphology information of words. With the purpose of addressing this problem, the Subword (Bojanowski et al., 2016) model represents each word using a bag of character $n-$grams, and the word vector is thus the summation of its character $n-$grams. The major advantage of the Subword model is that it allows the computation of word vectors that are not in the trained corpus by using their character $n-$gram vectors. Inspired by the Subword model, we introduce the Subnode model to solve network embedding problems by offering a solution to create inferential vectors of unseen news nodes outside the trained network, at the same time incorporate node attributes to the node vectors.

The biased random walk produces sequences of news and event element nodes from the news network. The proposed Subnode model expresses each of the news node as a bag of subnode information of its associated features including semantic features such as event elements with high tf-idf scores, text structure features such as words count and paragraphs count, and side information such as published date, news type and emotion. As a result, each news vertex $e \in V_e$ is represented as:

$$G =< entity_A, entity_B, action, \cdots,$$

$$words\ count, paragraph\ count,$$

$$month, day, week, type, sentiment, \cdots >$$

where word count, paragraph count and sentiment are ordinal data rather than real values. Further, the Subnode model represents a news node as the sum of its features, instead of a distinct vector obtained from the other network embedding models. Therefore, the objective function of news network embedding is expressed as:

$$max \sum_{e \in V_e} \log Pr(N(e) | \sum_{g \in G_e} f(g)) \qquad (6)$$

where $f(g)$ denotes the vector representation of a news feature. In addition, we remove nodes with only one edge to reduce the sparsity of the network. As it is mentioned in the previous section, the Subnode vector representations of news features are learned based on the skip-gram architecture by optimizing the updated objective function using SGD with negative sampling (Mikolov et al., 2013b). With an adequately large news network that contains a wide range of features, the Subnode mechanism of News2vec allows the vector representation of an unseen news node directly computed by extracting news features and summing up their corresponding vectors according to the $feature\ to\ vector$ dictionary. See Github[2] for the codes and examples of News2vec.

3 Experiments

Four experiments are implemented and explored in this section. In particular, we first visualize the News2vec embeddings in terms of the news vectors and feature vectors with the dimension reduction plot and the correlation heat maps. Two downstream experiments, *i.e.* the stock movement prediction and news recommendation, are then conducted to examine the News2vec model in comparison with other established text/sentence embedding models. Overall, News2vec achieves state-of-the-art performances in these news-related tasks which demonstrates its validity of addressing potential relevance of news via the network, as well as the integrated consideration of the news features.

3.1 Visualization of News Vectors

In this section, the THUCTC[3] (THU Chinese Text Classification) news data set is used to train the vectors of news features, including the semantic features and four additional features, namely $type$, $words\ count$, $paragraph\ count$ and $sentiment$. We determine the sentiment by counting positive words over negative words. There are 14 types of news in the news corpus and we randomly take 6,000 pieces of news from each type as the training set. In the test set, we additionally extract 1,000 pieces of news from each type. Based on these 84,000 pieces of news in the training set, we learn a vector representation of 128 dimensions for each news feature. The news vectors in the test set are

[2] https://github.com/yema2018/News2vec
[3] http://thuctc.thunlp.org

then computed, whereas their dimension reduction plots are produced using the t-Distributed Stochastic Neighbor Embedding (t-SNE).

Figure 3 shows the dimension reduction results of news vectors in the test set. According to the right panel, a high level of clustering is observed, indicating that News2vec allows the embedding of type information into news vectors after incorporating the type feature. Moreover, the distance between two clusters is in-line with the relevancy between the clustered topics in reality. In particular, neighboring relationships are exhibited between similar topics such as sports & lottery ticket, current affairs & society, stock & finance, and fashion & entertainment, whilst the distance between less relevant clusters, such as constellation & finance, game & education, is relatively larger. Nevertheless, the left panel of Figure 3 shows that news embeddings significantly lose classification information once vectors of the type feature are removed from the news vector, which shows that News2vec enriches the news vector representation by the news network and the Subnode information.

3.2 Correlations of News Features

In this section, we further investigate the vector correlation between three news features, namely the $type$, the $words\ count$ and the $sentiment$. The correlation coefficients (*i.e.*, normalized cosine similarity) heat maps for each feature are displayed in Figure 4.

The correlation heat map of news type features (upper panel) supports the conclusion in Section 3.1. It is observed that vector pairs of close topics such as $type : Stock$ and $type : Finance$ are highly correlated, indicating stock news and financial news share similar contextual elements. Other highly correlated pairs include sports and lottery ticket news, game and technology news, fashion and entertainment news, etc., whilst less relevant topics show low correlations, such as real estate and constellation, sports and real estate. According to the bottom left panel of Figure 4, a significant number of dark blocks are observed in the area from $wc200$ to $wc3000$ ($wc200$ means the news is less than 200 words and $wc2000$ means the news is between 1000 and 2000 words), and there is a clear reduction of correlation once the news exceeds 3,000 words. As it is indicated by the word count correlation heat map, news that has similar numbers of words is more likely to have similar content. The correlation reduction from $wc3000$ to $wc5000$ suggests that there is a group of news with specific content, that is often discussed in long articles. Meanwhile, the right bottom of Figure 4 shows that news with close sentiment levels tends to have higher correlations. As the sentiment moves from more positive to more negative, the correlation decreases. Overall, the correlation heat maps show that the News2vec feature vectors are reliable in terms of expressing Subnode information.

3.3 Stock Movement Prediction

Experimental settings

We use financial news (2009.10.19 to 2016.10.31) from Sohu [4] to predict the daily movement of Shanghai securities composite index. The news feature vectors are trained based on news from 2009.10.19 to 2015.12.31 and news vectors are computed by summing up these feature vectors. There are five additional news features, namely $month$, $week$, $sentiment$, $words\ count$ and day.

The length of the walk is fixed at 100, the context size is 10, return hyper-parameter (p in Equation (5)) and input hyper-parameter (q in Equation (5)) are both set to 1.

Predictive model

The predictive model is the long short term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) with self-attention mechanism (Yang et al., 2016). As shown in 5, the LSTM model has T time steps (*i.e.*, T days) in total. At each time step, the input is the weighted average of news vectors in that day. Weights are initialized at the beginning and updated by the gradient descent. Based on the attention model, news that is closely related to the stock price movement is assigned with higher weights.

In this paper, we use the previous 20 days' ($T = 20$) news to predict the next day's stock index movement. The output layer is a Softmax classfier that indicates whether the index goes UP (rise percent $> 0.33\%$), DOWN (rise percent $< -0.29\%$) or PRESERVE ($-0.29\% <$ rise percent $< 0.33\%$). We employ a rolling window with $size = 20$ and $strider = 1$ to augment the sample. News before 2016 is used as the training set, whilst news after 2016 is used as the test-validation set.

[4] https://www.jianshu.com/p/370d3e67a18f

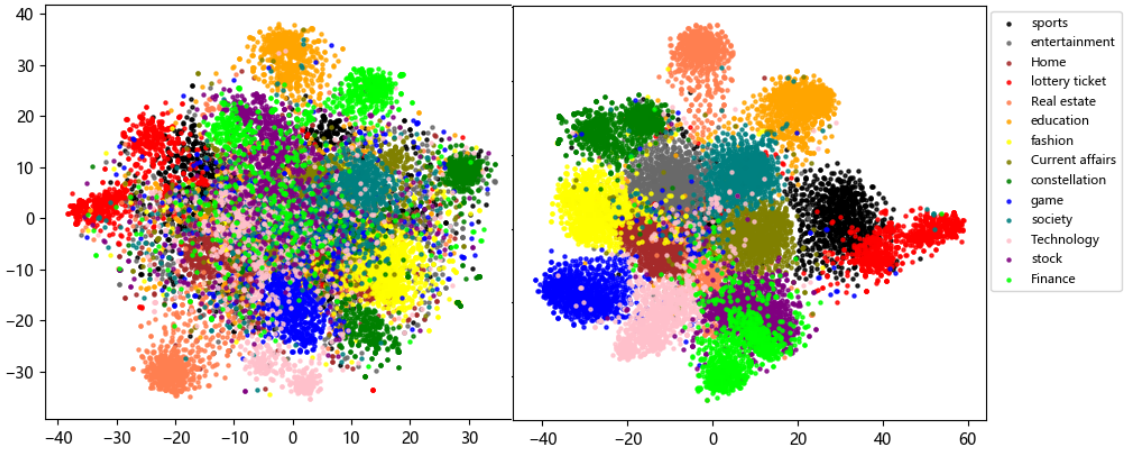

Figure 3: Dimension reduction plots of test set news without and with the type feature

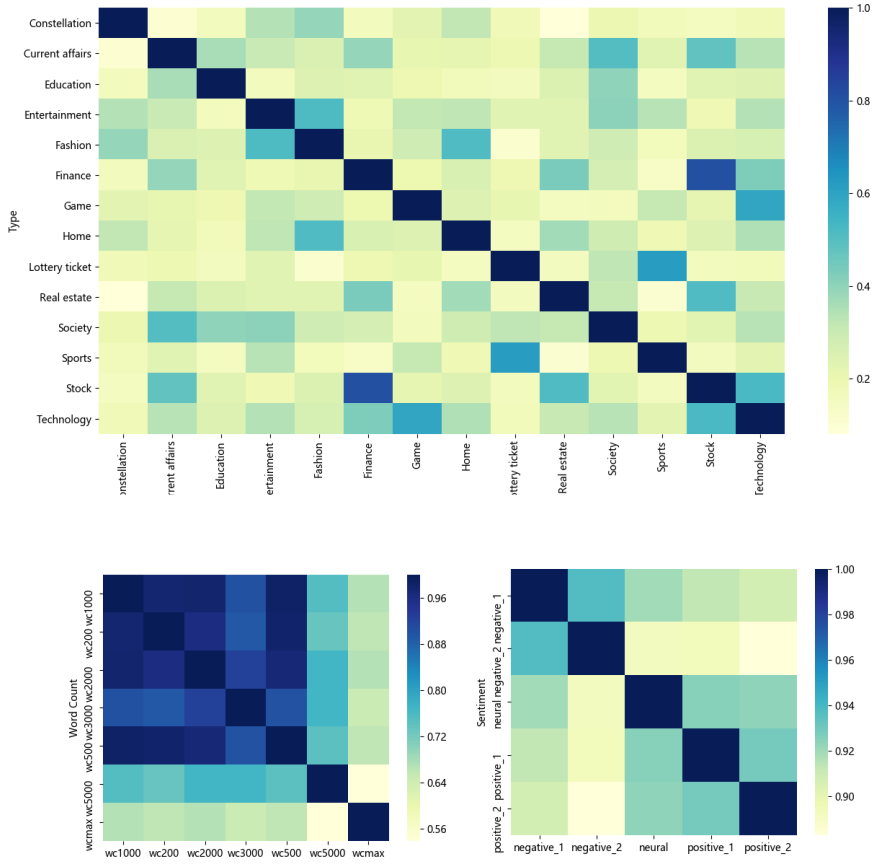

Figure 4: Correlations of news features (Upper panel: news type. Lower left: word count. Lower right: sentiment.

Results

As for the baseline models, we include several established embedding approaches to compute news vectors in the experiment of the stock movement prediction:

Average BOW: News embedding is represented as the average of word vectors in the news titles and bodies (Hu et al., 2018). Word embedding is obtained by training the skip-gram Word2vec model (Mikolov et al., 2013a).

Doc2vec: Paragraph Vector (Le and Mikolov, 2014): News texts are represented as dense vectors by the Paragraph Vector model(Akita et al., 2016).

Event embedding (Ding et al., 2015, 2016): Event tuples are extracted from headlines and represented as vector representations by scoring the correct tuples higher than the corrupted tuples.

In addition, we apply a sentence-level encoder

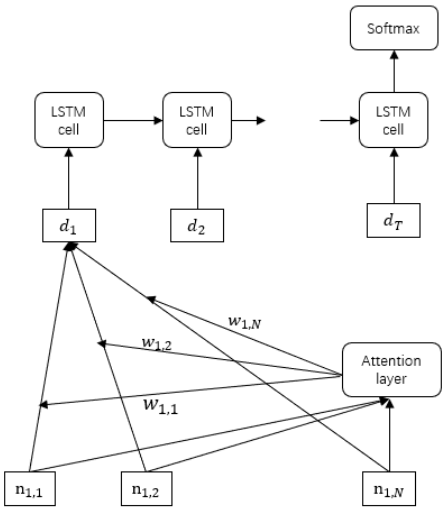

Figure 5: LSTM model with attention mechanism

BERT to encode news headlines as another baseline model:

BERT (Devlin et al., 2018): Average pooling is used to get a fixed representation of a headline based on the Chinese pre-trained model[5].

The proposed News2vec model is implemented separately with and without the five additional features (*i.e.* $month$, $week$, $sentiment$, $words\ count$ and day):

News2vec-: News vectors are the summation of solely the semantic features (*i.e.*, event elements).

News2vec+: News vectors are the summation of all news features including the semantic and the five additional features.

	Acc	MCC
Average BOW($d = 128$)	41.91%	0.1137
Doc2vec($d = 128$)	43.90%	0.1484
Event embedding($d = 128$)	43.76%	0.1439
BERT($d = 764$)	45.83%	0.1442
News2vec-($d = 128$)	44.68%	0.1664
News2vec+($d = 128$)	**46.24%**	**0.1936**

Table 1: Acc and MCC Results of stock movements in the test set

In Table 1, test results are presented according to two measurements, namely the accuracy (Acc) and the Matthews Correlation Coefficient (MCC). We find the News2vec model outperforms BERT and all the other baseline models both in terms of the Acc and MCC, with a lower dimension of 128 (The dimension of BERT embeddings is 764). As the MCC suggests, Doc2vec, Event embedding and BERT produce stock movement predictions of similar qualities as the news vectors generated by the three approaches uniformly limit to the semantic information of news articles. As for news-driven stock price prediction, it is more reasonable to take into account the potential connections between news, such as having similar background story or leading to the same event, and reflect the connection by embed similar values in certain dimensions of the news vectors. In the case of the New2vec+ model, we find that extra features contribute to the improvement of the MCC, indicating the New2vec representations are able to capture the latent connections between news events. After considering all news features, the results are improved by 0.028, showing their positive effect on stock movement predictions. It is worth-mentioning that the New2vec model is performed in an unsupervised manner as all features are extracted from common news text without any artificial label or trained classifier. We believe that there is a large chance to further improve the result once artificial labels such as the polarity are incorporated.

3.4 News Recommendation

Experiment settings

In this section, a news recommendation task is implemented based on the data of news browsing records (2014.2 to 2014.3) using the news embedding models [6]. The obtained data set contains 16214 news browsing sequences in total, which is split into halfs for testing and fine-tuning, respectively. The overall objective is to recommend news based on the content by computing the cosine similarities of the news vectors.

News recommendations are made for each news by selecting the top ten news with the highest vector similarities. The recommendation is considered to be successful as long as the next browse in the sequence belongs to the ten news articles selected. We compute the success rate for each sequence. The average success rate of all sequences is the final evaluation result for the embedding model.

Since the news titles are absent in the data set, event elements are only extracted from news bodies. As a result, we only use the text-level em-

[5] https://github.com/google-research/bert#pre-trained-models

[6] https://github.com/YLonely/web-data-mining

bedding models (*i.e.*, Paragraph Vector and Average BOW) as the baselines to compare with the News2vec model. We use the trained news feature vectors in the previous section as the initial inputs of the new news network (Sohu+rec). Moreover, half of the news sequences are employed to fine-tune these vectors (Sohu+rec+seq). Due to the lack of information, only $sentiment$ and $word\ counts$ are included as the extra news features together with the existing semantic features.

Evaluation of news recommendation

	Success rate
Paragraph Vector	4.31%
Average BOW	3.09%
Sohu (no extra features)	3.36%
Sohu+rec (no extra features)	3.69%
Sohu+rec+seq (no extra features)	6.73%
Sohu	2.95%
Sohu+rec	3.61%
Sohu+rec+seq	**7.53%**

Table 2: Evaluation results of news recommendation

From Table 2, it is observed that the success rate improves significantly after fine-tuning the news vectors with respect to the news browsing sequences. In comparison with Paragraph Vector, News2vec (Sohu+rec) demonstrates no significant advantage without sequence fine-tuning (Sohu+rec+seq), indicating potential connections between news have limited effect on this task. Nonetheless, News2vec achieves state-of-art performance after sequence fine-tuning. On the other hand, the result of Paragraph Vector cannot be further improved by fine-tuning. A possible explanation is that the Paragraph Vector model assigns a distinct vector to each of the news articles, thus inconsistency between news in different news browsing sequences is easily created by the sequence-level fine-tuning. On the other hand, fine-tuned News2vec embeddings carry the information of both the news network and the browsing sequences by treating the browsing sequence as a special sequence generated by the biased random walk. In addition, it is found that with fine-tuning, the additional features tend to have positive effects on the recommendation task (see Sohu to Sohu+rec+seq without extra features and Sohu to Sohu+rec+seq with extra features). As a matter of fact, additional news features, such as the release time and type, are considered to contain important information for news recommendation tasks. Unfortunately, due to the lack of data, only two extra features are included in this experiment.

4 Related Work

In most cases, news embeddings are directly created by sentence/text embedding approaches (Ding et al., 2015; Hu et al., 2018; Vargas et al., 2017; Akita et al., 2016), that are often divided into two groups: the unsupervised and the supervised models. For unsupervised learning, the auto-encoder model is an early solution to compress text data (Vincent et al., 2010). Inspired by word embedding, Paragraph Vector (Le and Mikolov, 2014; Li et al., 2016) represents texts or sentences as vectors based on the co-occurrence relation between words and documents, whilst Skip-Thought (Li and Hovy, 2014), FastSent (Hill et al., 2016) and Quick-Though (Logeswaran and Lee, 2018) are based on the coherence between sentences. For supervised learning-based models, most methods use sentence encoder such as LSTM or Transformer (Vaswani et al., 2017) to encode word vectors into sentence vectors and train the encoder on various NLP tasks (Conneau et al., 2017; Cer et al., 2018).

5 Conclusions

In this paper, we develop the News2vec model that learns the vector representation of news articles by constructing a news network. The Subnode model is further proposed to allow the embedding of unseen (news) nodes outside the existing network, at the same time to enrich the news vector with its associated feature vectors. Compared to other established text embedding models, the News2vec embedding contains not only the information of the contextual relationship between news and its event elements, but also potential connections as the network goes deeper. According to the dimension reduction plots and correlation heat-maps, it is suggested that the news/feature vectors contain adequate information as expected. Two downstream tasks, the news-driven stock movement prediction and news recommendation, show the News2vec embeddings demonstrate the latent connections between news articles, and the integration of news features enhances the model's performance in comparison to the baseline models.

Abstract

This paper presents a novel architecture for recursive context-aware lexical simplification, REC-LS, that is capable of (1) making use of the wider context when detecting the words in need of simplification and suggesting alternatives, and (2) taking previous simplification steps into account. We show that our system outputs lexical simplifications that are grammatically correct and semantically appropriate, and outperforms the current state-of-the-art systems in lexical simplification.

1 Introduction

Text simplification (TS) is aimed at reducing the reading and grammatical complexity of text while retaining the meaning and grammaticality (Chandrasekar and Bangalore, 1997). This is usually achieved by a series of transformations at the lexical and syntactic level. A number of systems in the recent years have approached this task in an integral manner (Zhu et al., 2010; Kauchak, 2013; Zhang and Lapata, 2017). Such comprehensive systems can perform a number of simplification operations at once, but the results are sometimes ungrammatical and meaning can be changed, arguably making the original text less clear and more complex (Siddharthan, 2014).

In this paper, we assume the lexical and syntactic components of a TS system to be independent and complementary to each other, and focus on the *lexical simplification* (LS) component for a number of reasons. First, it has been shown that *lexical simplification* techniques positively impact the readability of text and improve reader understanding and information retention (Leroy et al., 2012). Secondly, it has been argued that a large number of people with reading difficulties, including those with disabilities, low-literacy, non-native backgrounds or non-expert knowledge benefit from LS (Xu et al., 2015). For instance, James (1998) shows that vocabulary of the non-native language plays central role in second language acquisition. As we aim to make information more accessible to such readers, the quality of the simplified text is of a paramount importance.

We stress the importance of three key points of quality assessment in LS: it is vital for the simplified text to be *of a lower complexity*, while being *semantically equivalent* to the original, and *grammatically correct*. Context plays a central role in fulfilling these requirements. For instance, consider the different uses of *situation* in the complex word dataset collected by Yimam et al. (2017):

(1) the gravity of the **economic *situation***

(2) the *situation* has remained unchanged

This example demonstrates two types of contextual effects: first of all, in (1) both *economic* and *situation* are marked as complex in mutual context, but when *situation* occurs in a different context it is not annotated as complex. Secondly, this example illustrates the impact of the context on the choice of the appropriate substitution: substituting *climate* for *situation* will work for (1), but will result in a semantically different expression in (2).

In addition, we argue that as word complexity depends on context, the order and choice of applied simplifications matters. For instance, consider the following simplifications for the sentence '*This is a problem in the contemporary world*':

(3) This is a problem in the *modern earth*

(4) This is a problem in the *modern* world

Example (3) shows an output of a system that tries to simplify all words, which results in a nonsensical sentence, while (4) exemplifies the result of recursive word replacement in context.

Context effects in LS have not been thoroughly investigated before. In this paper, we introduce a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4853–4863,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

novel approach to LS that addresses these issues. In particular, we make the following contributions:

1. As each simplification step changes the complexity of the output sentence, our LS algorithm applies simplification *recursively taking word complexity in context into account*;
2. To ensure grammaticality and meaning equivalence to the input in the output, our algorithm *takes context both at the complex word identification and substitution selection steps into account*. We use a novel sequence labelling component for the former step, and assess semantic equivalence at the latter using deep contextualized word representations provided by ELMo (Peters et al., 2018).
3. To facilitate reproducibility, we release the code and the output of our system at `github.com/siangooding/lexical_simplification`.

2 Previous work

2.1 Approaches

Early approaches to TS have mostly relied on rule-based systems (Carroll et al., 1998; Canning et al., 2000; Siddharthan, 2006), with many of the earlier systems prioritising syntactic operations, such as sentence splitting, deletion or reordering. Some work combined lexical simplification with syntactic operations (Zhu et al., 2010; Coster and Kauchak, 2011a; Kauchak, 2013). The availability of parallel corpora of "normal" and simplified text has inspired a number of approaches that treated TS as a monolingual machine translation problem (Zhu et al., 2010; Coster and Kauchak, 2011a,b) or allowed the researchers to apply language modelling (Kauchak, 2013).

Building on this line of work, Zhang and Lapata (2017) combine a novel sequence-to-sequence encoder-decoder model with a deep reinforcement learning framework that rewards the system for providing simple, fluent output, similar in meaning to the input. However, one of the main challenges for such comprehensive end-to-end systems is the ability to address specific types of errors independently. For instance, the DRESS-LS model (Zhang and Lapata, 2017) sometimes changes the meaning of the input to the opposite as in "*Inspections, she said,* **rarely** *cost more than $ 1,400*" → "*Inspections, she said,* **often** *cost more than $ 1,400*", or produces nonsensical output as in "*Archaeologists digging on the* **grounds**" → *Archaeologists digging on the* **zebras**".

A number of approaches focused on generation and assessment of *lexical simplification* (Yatskar et al., 2010; Biran et al., 2011; Horn et al., 2014; Glavaš and Štajner, 2015). Paetzold and Specia (2016a) note the lack of consistent evaluation for text simplification, and in particular lexical simplification, and introduce an evaluation dataset BENCHLS, on which they perform benchmarking of several LS systems. They argue that lexical simplification consists of a number of steps, including substitution generation, substitution selection and ranking. They show that the unsupervised system of Paetzold and Specia (2016b) outperforms a range of other systems in all steps, with the only exception of the feature-based system by Horn et al. (2014), which performs better in terms of precision in a round-trip system evaluation.

Finally, Shardlow (2013) introduced complex word identification (CWI) as the first step in an LS pipeline to detect words within text that require simplification. He showed that systems' performance on this stage is crucial for the overall performance, as low recall of this component might result in an overly difficult text with many missed complex words, while low precision might result in meaning distortions. The recent shared task on CWI shows that most systems rely on classification approaches using features that pertain to individual words, not taking wider context into account (Yimam et al., 2018).

2.2 Datasets

Until recently, parallel Wikipedia and Simple Wikipedia datasets have been the most widely used data for training and evaluating TS systems (Zhu et al., 2010; Yatskar et al., 2010; Coster and Kauchak, 2011a,b; Biran et al., 2011; Kauchak, 2013; Horn et al., 2014). Wikipedia allows free access to large quantities of data, and Simple Wikipedia represents a simplified version of original articles that uses simpler vocabulary and syntactic structures (Coster and Kauchak, 2011a). Researchers in the past applied monolingual alignment techniques to construct parallel versions of the two Wikipedias and learn the transformations from these parallel versions using such tools as GIZA++ (Och and Ney, 2000).

Despite the popularity of the Wikipedia-based

datasets for TS research, Xu et al. (2015) argue that focusing on Wikipedia limits simplification research and propose using a dataset based on news articles. They use a dataset from Newsela as an example, where the texts are simplified by professional editors at 4 levels of simplificity in accordance with the grade levels defined by the Common Core Standards (Porter et al., 2011).

In their benchmarking study, Paetzold and Specia (2016a) introduce an evaluation dataset BENCHLS that combines two previously released datasets for TS – LexMTurk (Horn et al., 2014) and LSeval (De Belder and Moens, 2012). This dataset contains 929 instances with an original sentence, a target complex word, and several candidate substitutions ranked by English speakers from the U.S. according to their simplicity. Paetzold and Specia (2016a) additionally filter out misspelled candidates and inflect all candidates to the grammatical form of the target word. The dataset contains an average of 7.37 candidate substitutions per complex word.

Finally, the CEFR-LS dataset (Uchida et al., 2018) contains simplifications, which not only represent a semantically good fit and are grammatically correct, but are also at different levels of simplicity annotated with respect to non-native speakers. Simpler candidates at lower levels of language proficiency (A1-B1) according to the Common European Framework of Reference for Languages (CEFR) (Council of Europe, 2011) are provided for the original words that are at higher levels of language proficiency (B2-C2). The dataset contains 406 target words and 4912 possible substitutions. Unlike BENCHLS, substitute candidates within this dataset may not be correct for the given context, and if a substitute candidate is not appropriate in context it is labelled as such. The dataset contains an average of 2.35 candidate substitutions per complex word.

3 Data

In this study we implement an LS system that includes complex word identification, substitute generation, filtering and ranking as steps in a simplification pipeline. To train our CWI system, we use the CWI 2018 shared task dataset (Yimam et al., 2017), which contains texts on three genres – professionally written NEWS, amateurishly written WIKINEWS, and WIKIPEDIA articles. The words in the dataset are annotated as complex or not by 10 native and 10 non-native speakers of English.

We evaluate each step of the LS pipeline on two datasets – BENCHLS and CEFR-LS. We select the BENCHLS dataset because it contains multiple simplification alternatives ranked with respect to their simplicity by a number of human annotators. The CEFR-LS dataset is a useful resource for evaluation because, in addition to contextually suitable, grammatically correct, simpler alternatives, it also contains substitution candidates that do not fit the context. Furthermore, this dataset is aimed at non-native speakers of English which we view as the future target group for our LS system. For further details on datasets collection and annotation, we refer the readers to the original papers.

Finally, we evaluate our LS system in an end-to-end manner and compare its performance to that of the current state-of-the-art systems, including those reported in Paetzold and Specia (2016a) and the DRESS-LS system of Zhang and Lapata (2017). In contrast to Zhang and Lapata (2017), we perform lexical simplification only. For fair comparison of the two systems, we extract only lexical simplifications from the parallel "normal" to simplified versions of the data used in Zhang and Lapata (2017), as well as from the original "normal" text and the DRESS-LS system output.

To extract the lexical transformations from the data, we use GIZA++ (Och and Ney, 2000) similarly to previous research (Coster and Kauchak, 2011b; Xu et al., 2015). Following Horn et al. (2014), we extract the examples that constitute one-to-one word correspondences between the two sides identified by the automatically induced word alignment, where the part-of-speech tag of the two words is the same while the lemmas are different. In addition, we filter out the instances involving modification of stopwords on the original, "normal" side as well as rewrites involving proper nouns. All preprocessing steps for our algorithm are performed using the RASP parser (Briscoe et al., 2006).

4 Lexical Simplification Pipeline

Lexical simplification can be viewed as a multi-stage process involving complex word identification, substitute generation, filtering and substitute ranking. In this section we outline each step of the simplification process as presented in Figure 1.

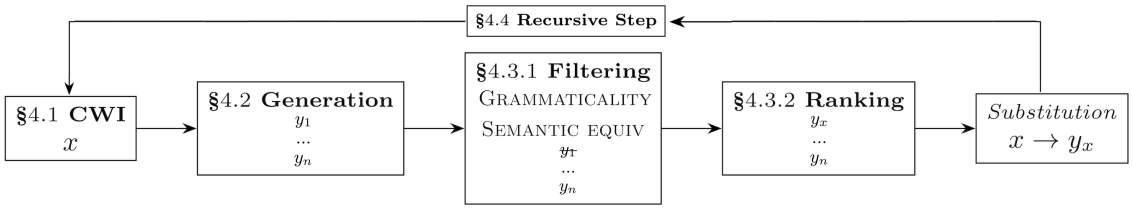

Figure 1: Recursive Simplification (REC-LS) pipeline: x is a complex word and y_i are the generated substitutes

4.1 Complex Word Identification (CWI)

The first stage of the algorithm is complex word identification (CWI), which aims to identify which words should be simplified within the text and, thus, allows for a personalisable and targeted approach to LS. Furthermore, it helps to reduce the number of unnecessary and potentially "harmful" simplifications performed by a 'simplify all words' approach. To train and test our CWI component we use the dataset by Yimam et al. (2017).

Word complexity depends on the surrounding context: for instance, between 3% and 10% of lexical items (depending on genre) in the Yimam et al. (2017) dataset receive different annotations in different contexts. However, most CWI systems to date have approached this task on an individual word basis (Yimam et al., 2018). For instance, the 2018 CWI shared task winning system CAMB uses a classification-based approach with 27 word-level features (Gooding and Kochmar, 2018). As context impacts the perceived complexity of text, we argue that CWI should be framed as a sequence labelling task and propose a novel architecture SEQ based on this idea (Gooding and Kochmar, 2019). We extend the implementation of a sequence labeller by Rei (2017),[1] which achieves state-of-the-art results on a number of NLP tasks. The design of this architecture is highly suitable for CWI as: (1) it uses bi-directional long short-term memory units (BiLSTM) (Hochreiter and Schmidhuber, 1997), which allow the system to learn about both the left and right context of a target word; (2) the context is combined with both word and character-level representations (Rei et al., 2016) which helps capture complexity due to rare character sequences as well as morphological structure; (3) this architecture uses a language modelling objective, which enables the model to take one of the highly informative complexity factors of word frequency into account.

Test Set	Macro F-Score	
	CAMB	SEQ
NEWS	0.8633	**0.8763**
WIKINEWS	0.8317	**0.8540**
WIKIPEDIA	0.7780	**0.8140**

Table 1: SEQ vs. CAMB system results on CWI

DATASET	Precision	Recall	F-Score
CEFR-LS	0.9327	0.7936	0.8575
BENCHLS	0.5000	0.4025	0.4460

Table 2: SEQ results for CWI on the two datasets

SEQ uses 300-dimensional GloVe embeddings as word representations (Pennington et al., 2014). The model is trained to predict the binary complexity of words as annotated in the dataset of Yimam et al. (2017). Training is performed over 20 iterations on randomly shuffled sentences from all genres included within the dataset. To test this novel architecture on CWI, we apply it to the CWI 2018 shared task test data (Yimam et al., 2018) and compare the results to the current state-of-the-art (SOTA) CAMB system. Table 1 shows that the SEQ model outperforms the current SOTA system on all three text genres for binary CWI (statistically significant using McNemar's test, p=0.0016, χ^2=9.95).

The proposed SEQ model (Gooding and Kochmar, 2019) has a number of additional advantages: it takes context into account, helps avoid the necessity of extensive feature engineering relying on word embeddings as the only input information at run time, and generalises well across all three datasets. To further assess generalisability of the model, we test it on CEFR-LS, as well as BENCHLS for consistency (see Table 2). However, as the words in BENCHLS dataset were selected at random rather than according to their complexity (Paetzold and Specia, 2016a), the results as expected are lower.

4.1.1 Lexical Complexity Threshold

The SEQ system labels each word with a lexical complexity score. This score represents the likelihood (p) of each word belonging to the complex class. Whether a word is considered as complex is set according to a predefined threshold for p, which allows the 'aggressiveness' of the algorithm to be tailored according to the application. For instance, consider the following example:

(5) I believe that ignoring public opinion ***discredits***$_{0.89}$ the *authorities*$_{0.79}$ and ***destabilises***$_{0.84}$ the situation.

The SEQ labeller assigns complexity probability p>0.80 to the words ***discredits*** and ***destabilises***, whereas for *authorities* p=0.79. If the complexity threshold in the simplification pipeline is set to 0.80, the word *authorities* would not be a candidate for lexical simplification. Our simplification pipeline will attempt to simplify words one at a time, starting with the highest p values above this predefined threshold.

4.2 Substitute Generation

Substitute generation refers to the process of generating candidates that can be used as simpler alternatives to the target word. The goal of the system at this stage is to generate a diverse set of potential substitutions that can be filtered and ranked according to different criteria at later steps. We note that the use of multiple resources for substitute generation at this step is crucial as each individual resource has only a limited coverage. To this end, we first use traditional approaches, which do not take the context of the target word or the simplicity of substitutes into account. In summary, we rely on the following resources:

- we extract synonyms from WordNet (Fellbaum, 2012), following Devlin (1998);
- we use Big Huge Thesaurus[2] to find candidates by querying for the word form and lemma;
- following Glavaš and Štajner (2015), we use word embeddings to create substitutions. Synonyms are identified by finding 10 words with the highest cosine similarity to the target word in the vector space. These are obtained for both GloVe (Pennington et al., 2014) and Word2Vec embeddings (Mikolov et al., 2013), using the Gensim library.[3]

The candidate lemmas retrieved using these resources are added to the candidate substitutions set. To match the grammatical form of the original word, we convert all candidates to the appropriate word forms using NodeBox English Linguistics library.[4]

4.3 Substitution Filtering and Ranking

Following substitute generation, the next step in the LS pipeline is to choose one of the generated candidates to replace the original target word. This is done by filtering and ranking the candidates using a set of criteria, and choosing the top candidate. Previous work has framed this task as ranking words according to simplicity (Paetzold and Specia, 2016a). However, a system that is only aimed at selecting the simplest candidate may return a substitution that does not fit the surrounding context, is ungrammatical or not semantically equivalent to the original. Therefore, we consider all three aspects of high-quality substitution selection: *contextual simplicity*, *semantic equivalence* and *grammaticality*, which are outlined below.

Contextual Simplicity: The complexity of each candidate is calculated using our sequential CWI model from Section 4.1. We calculate the complexity for each substitution within context and refer to this as the simplicity score S. Table 3 shows 2 possible substitutions for *engulfed*, with their respective simplicity scores.

Contextual Semantic Equivalence: To assess whether a substitution is semantically equivalent to the original we use ELMo embeddings (Peters et al., 2018), which to the best of our knowledge have not been used for LS before. ELMo provides deep contextualized word representations, which are learned from the internal states of a deep bidirectional language model. As a result, these embeddings are able to model complex syntactic and

Table 4: Contextual semantic equivalence scores for 3 candidate substitutions (S_1-S_3) for the original O

O	Oak is strong and also *gives* shade
g.c.	Oak *gives* shade

Table 5: Original sentence O and the grammatical context (g.c.) used to calculate C_G for the word *gives*

semantic characteristics of word use, as well as how these word uses vary across linguistic contexts. In addition, contextualised embeddings help filter out antonyms that might be included in the set of potential substitutes by the previous step.

The similarity of words in a given sentential context is calculated using the ELMo embeddings associated with the target word and each of the substitutes. The contextual similarity score (C_S) is calculated by taking the cosine distance between the ELMo word vectors associated with the original word v_o and the substitute v_s. This allows us to reason about the likelihood that the substitution is semantically equivalent to the original in the given context: the *smaller* the distance the *more likely* this word fits the context. Table 4 provides some examples for this score.

This technique works particularly well when the target word appears in the immediate context of the words grammatically related to it, for example when a verb is surrounded by its subject and object. To counteract the effect of long range dependencies in sentences, we constrain the context to the grammatical dependents and calculate a second contextual score C_G using cosine distance. Table 5 provides an example of a full sentence O and the grammatical context for the word *gives*.

Grammaticality: To assess whether a substitution results in a grammatically correct sentence, we calculate bigram frequencies of the candidate substitute and one word to the left and to the right of it using the 520 million word COCA corpus (Davies, 2014). If either of these frequencies equals 0, it is assumed that the substitute is not a valid grammatical fit or is extremely rare, making it a poor candidate for simplification. Table 6 shows one such example.

	left	*right*
He was **capable** of [...]		
bigram	was capable	capable of
freq	778	12341
He was **able** of [...]		
bigram	was able	able of
freq	10281	0

Table 6: Bigram frequencies for left and right contexts of a candidate substitute

Here, we use the bigram frequencies as a proxy for grammaticality: although "able" and "capable" are semantically similar, it is the grammatical constraints, captured by the bigram frequencies, that rule one of the alternatives out.

4.3.1 Threshold-based filtering

Threshold-based filtering is performed by removing all substitutes that are unlikely to be grammatical or do not fit the target context. First, substitutes are removed from consideration if their right or left bigram frequency equals 0. Then, we remove substitutes if either of their contextual ELMo scores is below a given threshold t ($C_S \vee C_G < t$), as this implies the substitute is not equivalent in this context. We test our filtering approach on the CEFR-LS dataset as it contains annotations for contextually suitable (value 1) as well as unsuitable (value 0) substitutions. We empirically find the optimal threshold value on the CEFR-LS dataset to be 0.175. With this optimal value, we can identify contextually suitable and grammatically correct substitutes on CEFR-LS with the *precision* of 0.7968, *recall* of 0.8081 and F_1=0.8014. As we show in Section 5, this filtering technique generalises well to other datasets.

4.3.2 Ranking Algorithm

Once filtering has been performed we then rank substitutes. In order to rank substitutes, the simplicity and contextual semantic equivalence scores are combined to produce an overall suitability score. We evaluate our ranking techniques on the BENCHLS and CEFR-LS datasets.

We perform ranking using the sum of the contextual simplicity score (S) and the average contextual semantic equivalence score $\bar{C} = avg(C_S, C_G)$, and evaluate the results using the *TRank-at-n* measure introduced in Paetzold and Specia (2016a), which estimates the proportion of times a candidate with a gold-standard rank

BENCHLS		n=1	n=2	n=3	MRR
$full_{(929)}$	S	0.4974	0.7381	0.8899	0.6648
	$\bar{C}$	0.3509	0.5885	0.7877	0.5998
	S+$\bar{C}$	**0.5602**	**0.8064**	**0.9428**	**0.7219**
$test_{(464)}$	S	0.5839	0.7546	0.9302	0.7083
	$\bar{C}$	0.4086	0.7142	0.8950	0.6563
	S+$\bar{C}$	**0.6774**	**0.7857**	**0.9308**	**0.8218**
	P&S	0.4841	0.5596	0.7004	0.6615

Table 7: Ranking results on BENCHLS dataset

CEFR-LS	n=1	n=2	n=3	MRR
S	0.2166	0.3357	0.5271	0.4182
$\bar{C}$	0.3754	**0.6137**	**0.7689**	0.5857
S+$\bar{C}$	**0.4624**	0.5906	0.7314	**0.6582**
P&S	0.2129	0.4339	0.5760	0.4736

Table 8: Ranking results on CEFR-LS dataset

$r \leq n$ is ranked first by the system. For instance, our best performing ranking technique on the full BENCHLS dataset for n=1 is based on the combination of S+$\bar{C}$ scores and achieves *TRank-at-n*=0.5602. This means that for approximately 56% of the test instances the top ranked substitute in the gold standard is correctly ranked first. In addition, we report the *mean reciprocal rank (MRR)* (Voorhees, 1999), which takes into account the rank of the substitutes proposed by each ranking technique.

We report the results on the full BENCHLS dataset in the upper half of Table 7. In the lower half, we compare our results on the test set of 464 instances to those running the Paetzold and Specia (2016a) system (P&S) on the same test splits. Since the P&S system was trained on half of BENCHLS we cannot run it on the full dataset. Table 7 shows that ranking with S+$\bar{C}$ works best according to all measures and across both sets.

Table 8 reports the ranking results on the CEFR-LS data. We observe a decrease in performance, however this is expected: as all substitutes within the BENCHLS dataset are valid, ranking by simplicity is more informative; in contrast, the CEFR-LS dataset contains irrelevant substitutes, so contextual fit has more pronounced effects.

4.4 Recursive Step

Following CWI, substitute generation, filtering and substitute ranking steps, the system is able to perform a simplification. As outlined in Section 4.1.1, our system attempts to simplify one word at a time, starting with the word considered most complex. Since word complexity depends on the context, each individual lexical simplification made to a sentence has a subsequent impact on the perceived complexity of the surrounding words. Such sequential effects cannot be modelled by systems that apply several simplification steps at once. For instance, when considering examples (6) and (7) we see that the word *situation* is given a high likelihood of being complex in the context of another complex word *hazardous*. However, once *dangerous* is substituted for *hazardous*, the subsequent complexity of *situation* is reduced as well.

(6) It was a **hazardous**$_{0.90}$ **situation**$_{0.87}$

(7) It was a dangerous$_{0.30}$ situation$_{0.35}$

Our lexical simplification algorithm is applied to a sentence recursively: it starts by identifying and simplifying the most complex words in the sentence. Once the simplification is applied in step n, the algorithm reassesses word complexity in step n+1, which, in light of the simplifications applied in previous steps, might have changed. This prevents unnecessarily simplifying *situation* in example (7), which is no longer necessary after simplifying *hazardous* → *dangerous*. The simplification algorithm stops when there are no words with the complexity score above the predefined threshold left within the sentence, set to 0.5.

Table 9 exemplifies the benefit of using the recursive simplification approach REC-LS. We see that both the 'Simplify CW', aimed at individually identified complex words, and 'Simplify all' approaches result in unnecessary simplifications, whilst REC-LS stops when it recognises that the surrounding words are no longer complex.

Original	*prepare*$_{0.32}$ *for a* *hazardous*$_{0.81}$ *journey*$_{0.52}$
REC-LS	prepare for a **dangerous**$_{0.35}$ journey$_{0.45}$
Simplify CW	prepare for a **dangerous trip**
Simplify all	**arrange** for a **dangerous trip**

Table 9: Recursive simplification compared with simplifying only complex words and simplifying all words

We note that the only consequence of performing simplification recursively is that fewer words, or potentially different words, are simplified, and highlight that it does not lead to any error propagation. Table 10 presents the entire REC-LS algorithm including the recursive simplification step.

5 End-to-end System Performance

Finally, we test the full LS pipeline, visualised in Figure 1, on the BENCHLS and CEFR-LS

Result: Lexically simplified sentence
$S \leftarrow$ Input Sentence
$c \leftarrow$ Complexity threshold
REC-LS($S, c, ignore_list$)
while *complexity(S)* $> c$ **do**
  complex_words $\leftarrow$ CWI(S) - *ignore_list*
  SORT(complex_words)
  for *word in complex_words* **do**
    subs $\leftarrow$ SUB_GENERATION($word$);
    subs $\leftarrow$ MORPH($substitutes$);
    subs $\leftarrow$ SUB_RANK($substitutes$);
    top_substitute $\leftarrow$ $head(substitutes)$;
    if *top_substitute == word or []* **then**
      ignore_list.add(*word*)
      REC-LS($S, c, ignore_list$)
    else
      REPLACE($S, word, top_substitute$)
      REC-LS($S, c, ignore_list$)
  end
end

Table 10: REC-LS Algorithm Steps

(4)	Check if complexity of any word in S is above the threshold c
(5)	Check sentence for complex words minus those which are in *ignore_list*
(6)	Sort complex words according to confidence score
(8)	Generate substitutes for the top complex word
(9)	Convert substitutions to correct word form (e.g., tense for verbs)
(10)	Rank substitutes according to grammaticality, contextual semantic equivalence and simplicity
(11)	Take the top substitute
(13)	If no appropriate substitutes found, or best fit is original word, then retain original word and add word to *ignore_list*
(15)	Otherwise replace word and call function with new sentence

datasets. The CWI step of our recursive LS algorithm identifies 77% of the target complex words in the BENCHLS and 86% of the target complex words in the CEFR-LS dataset. Next, the substitution generation and ranking produce lists of simplification candidates. We evaluate these steps using *precision* and measuring the percentage of times that our system ranks one of the gold standard candidates as its top choice for substitution.

The best precision P=0.7945 on BENCHLS is achieved with threshold-based filtering of the unsuitable candidates and ranking of the candidates according to the combination of contextual simplicity (S) and contextual fit ($\bar{C}$) scores. We note that this result outperforms the previous SOTA system by Horn et al. (2014), which is reported to have P=0.5460 (Paetzold and Specia, 2016a), by a large margin.

With a similar approach, we achieve P=0.4628 on the CEFR-LS, and to the best of our knowledge, this is the first time an LS system is benchmarked on this dataset. We note that the precision on this dataset is lower, which can be attributed to the smaller set of gold standard substitutes per word (an average of 2.35 in CEFR-LS vs 7.37 in BENCHLS). We also note that in a number of cases our system generates valid substitutes, which are not included in the gold standard. For example, *wealthy* → *rich* in "could participate in government just as **wealthy** men could". We present more examples of such cases in the Appendix.

We also run our entire recursive simplification system REC-LS on the three simplification datasets: WikiSmall, WikiLarge and Newsela, used in Zhang and Lapata (2017). We then compare the results to the SOTA simplification systems DRESS-LS by Zhang and Lapata (2017), which contains a specialised LS model, and the P&S simplification system (Paetzold and Specia, 2016a). As DRESS-LS is trained using the above datasets, we test using the 649 sentences that are reserved for testing only. Simplifications are assessed using the gold standard for lexical substitutions. For each dataset, the number of lexical simplifications performed by the systems is recorded. We then compare the simplifications performed by the system with the gold standard simplifications and calculate the *recall*, *precision* and *correct* proportion as follows:

- For *recall* we estimate the number of simplifications present in the gold standard $|G|$, and the total number produced by the system S, which are in the gold standard $|S \cap G|$. Recall is then calculated as $|S \cap G| / |G|$.
- For *precision*, we identify the proportion of simplifications out of the total $|S|$, which are also in the gold standard: $|S \cap G| / |S|$.

	Newsela			*WikiSmall*			*WikiLarge*		
	DRESS-LS	P&S	REC-LS	DRESS-LS	P&S	REC-LS	DRESS-LS	P&S	REC-LS
Precision	0.1673	0.0836	**0.3000**	0.0000	0.0602	**0.1275**	0.2258	0.0697	**0.2778**
Recall	0.2389	**0.9721**	0.2393	0.0000	**0.9743**	0.4815	0.0004	**0.9763**	0.1856
Correct	0.3256	0.0402	**0.5238**	0.0000	0.0526	**0.4615**	**0.4286**	0.0787	0.4001

Table 11: Lexical substitution results for DRESS-LS, P&S and our system (REC-LS) on three genres

- Finally, *correct* stands for the proportion of instances where the top lexical substitution returned by the system is exactly the same as the gold standard one.

The results show that the recall for REC-LS is higher than that of DRESS-LS across all datasets, while the P&S system performs the best in terms of recall as it applies a 'simplify all' approach. The difference is especially pronounced in the WikiSmall dataset, where the DRESS-LS system does not perform any required lexical substitutions. REC-LS outperforms both DRESS-LS and P&S systems across all datasets in terms of precision, which indicates that the CWI stage of the algorithm is able to narrow down simplifications to relevant words. Finally, the three systems show different results in terms of correct proportion: REC-LS outperforms other systems on Newsela and WikiSmall, and DRESS-LS has a higher correct proportion on WikiLarge.

Finally, we note that there are many instances where the REC-LS system performs substitutions with valid alternatives that are not contained within the gold standard. For instance, consider the word "*separated*" in the following context:

(8) The island chain forms part of the Hebrides, *separated* from the Scottish mainland.

The gold standard substitution suggested by the human annotators in this context is "demarcated", whereas REC-LS substitutes this word with "split". We argue that, in this context, "split" would be both grammatically correct and semantically appropriate, while also being simpler than the original word and, arguably, the substitute suggested by the human annotators. However, as it is not an exact match with the gold standard substitution in the dataset, cases like this negatively impact precision of our system. We provide more examples of the system's output and compare the simplifications from the three systems in the Appendix.

6 Conclusions

In this paper, we have presented a novel recursive context-aware lexical simplification architecture REC-LS.[5] We summarise the main contributions of this work as follows:

1. our model takes the surrounding context into account at the complex word identification step, using a novel sequence labelling approach;
2. it filters and ranks the substitution alternatives taking contextual fit and grammaticality of the output into account;
3. the novel architecture performs simplification recursively and can be adapted to different levels of language complexity in the future;
4. as a result, REC-LS outperforms the current state-of-the-art systems in lexical simplification on various datasets.

We note that REC-LS can be used as a stand-alone lexical simplification system as well as an LS component as part of an integral TS system.

In this paper, we focus on intrinsic evaluation of our system, and we show that it outperforms SOTA in terms of the widely accepted set of measures, which we believe to be important for benchmarking purposes. In the future, we plan to extend this work with a syntactic simplification component and test the architecture extrinsically with non-native readers.

Abstract

Electronic Health Records (EHRs) contain both structured content and unstructured (text) content about a patient's medical history. In the unstructured text parts, there are common sections such as *Assessment and Plan*, *Social History*, and *Medications*. These sections help physicians find information easily and can be used by an information retrieval system to return specific information sought by a user. However, it is common that the exact format of sections in a particular EHR does not adhere to known patterns. Therefore, being able to predict sections and headers in EHRs automatically is beneficial to physicians. Prior approaches in EHR section prediction have only used text data from EHRs and have required significant manual annotation. We propose using sections from medical literature (e.g., textbooks, journals, web content) that contain content similar to that found in EHR sections. Our approach uses data from a different kind of source where labels are provided without the need of a time-consuming annotation effort. We use this data to train two models: an RNN and a BERT-based model. We apply the learned models along with source data via transfer learning to predict sections in EHRs. Our results show that medical literature can provide helpful supervision signal for this classification task.

1 Introduction

Electronic Health Records (EHRs) are an important tool used by physicians that contain an abundance of information about each patient. In addition to aiding the physician in providing patient care, EHRs can be used for downstream tasks such as predicting patient outcome, representation learning, and information extraction (Shickel et al., 2017). All of these tasks can be applied to the unstructured text parts of an EHR. Furthermore, they would benefit from the section structure to pinpoint the likely location where the information should be found (e.g. drug codes are more likely to be in the *Medication* section). However, when physicians edit the unstructured text parts of an EHR, there are no set rules for indicating sections and format is not strictly enforced, nor is there any markup (e.g. XML). An added difficulty is that the formatting is not uniform across EHRs. This is even more common when the EHRs come from different hospitals. For example, one EHR may have the section heading "Assessment and Plan" where another may use "A&P". As an added challenge there may also be nested sections, such as information about a specific medication. Being able to predict sections and headers in EHRs automatically is beneficial to physicians. It allows them to find information easily as well as discover errors and omissions in an EHR.

Consider the publicly available EHR note[1] in Figure 1. The note is divided into the 10 sections found in that EHR (*Problems*, *Medications*, *History*, etc.). This example provides insight into why section prediction can be a difficult task. Although most of the headers appear to be bold, there is also plenty of bold text which is not the main header (e.g. see the *History* section). Additionally, in some cases (e.g. *Allergies* section) there is no text under the header at all. This makes it difficult to segment the data appropriately. Finally, although

Review of systems

a psychiatric review of systems may include screening questions directed at identifying or exploring co morbid psychiatric illnesses or issues e g sigecaps mnemonic or phq 9 for depression generalized anxiety disorder 7 for anxiety digfast mnemonic for mania or specific questioning around psychoses or other psychiatric complaints a full review of systems should attempt to identify and list all of the relevant stressors that may be impacting a patient s function and overall health

Diagnosis

ultrasound remains as one of the only effective ways of prenatally diagnosing larsen syndrome prenatal diagnosis is extremely important as it can help families prepare for the arrival of an infant with several defects ultrasound can capture prenatal images of multiple joint dislocations abnormal positioning of legs and knees depressed nasal bridge prominent forehead and club feet these symptoms are all associated with larsen syndrome so they can be used to confirm that a fetus has the disorder

Medical History

kniest dysplasia is an autosomal dominant condition this means that the person only needs to have one copy of the mutated gene in order to have the condition people with a family history are at a higher risk of having the disease than people with no family history a random mutation in the gene can cause a person with no family history to also have the condition

Physical Examination

the general appearance of patients may vary according to the experienced symptoms the patient may be comfortable or restless and in severe distress with an increased respiratory rate a cool and pale skin is common and points to vasoconstriction some patients have low grade fever 38 39°c blood pressure may be elevated or decreased and the pulse can become irregular if heart failure ensues elevated jugular venous pressure and hepatojugular reflux or swelling of the legs due to peripheral edema may be found on inspection rarely a cardiac bulge with a pace different from the pulse rhythm can be felt on precordial examination various abnormalities can be found on auscultation such as a 3rd and 4th heart sound systolic murmurs paradoxical splitting of the second heart sound a pericardial friction rub and rales over the lung

Figure 2: Sections from Wikipedia articles (*Psychiatric history*, *Larsen syndrome*, *Kniest dysplasia*, and *Myocardial infarction diagnosis*) that are similar to sections that occur in EHRs. Colors match sections types from Figure 1. The four headers map to the classes *ROS, Find, PMH, and Exam.*

medications have their own section, they also appear in the *Plan* section. Other issues that are not exposed in this example include: 1) Section order is not consistent across EHRs, 2) Headers may be missing, 3) Common features of headers (e.g. bold or colon) are not guaranteed to appear.

Prior approaches in EHR section prediction have been specific to one source and have required significant annotation effort. We propose to reduce the annotation burden by augmenting training data using sections in medical literature (journals, textbooks, web content). Section headers in medical literature are often much more consistent than in EHRs, allowing us to identify with high precision a large number of training example sections using a small number of simple patterns. And although the style and content of sections is different from EHRs, our hypothesis is that there is enough similarity in language to help train models to detect sections in EHRs. Figure 2 shows paragraphs from Wikipedia articles whose sections are similar to those found in EHRs. The text tends to be more descriptive of the kinds of things that could be found in an EHR, but there is semantic overlap.

Our approach is not specific to one hospital or software system and uses data where labels are easy to infer without the need of a time-consuming annotation effort. Furthermore, the large amount of data allows us to explore state of the art neural classification approaches. Finally, training from medical literature can aid in identification of common sections in EHRs from different sources, making it possible to share EHR information more easily across medical facilities and insurance companies which may have access to EHRs from multiple providers.

Our work has two main contributions, demonstrating that augmenting automatically labeled

data from medical literature with:

1. a *small amount* of labeled in-domain EHR training data significantly improves prediction in the EHR dataset.

2. labeled EHR data from a *different source* (out-of-domain) significantly improves the transferability of models trained when there is *no labeled* data in the in-domain EHR dataset.

2 Related Work

Prior work in EHR section prediction has focused on the following tasks:

1. *Section detection:* detecting the boundaries of sections; detecting section header text.

2. *Section classification:* assigning a class label to a section or to sentences (a section class label on a sentence indicates the section to which a sentence likely belongs).

Research may concentrate on section detection only (Ganesan and Subotin, 2014; Dai et al., 2015), section classification (with section boundaries assumed to be known) (Li et al., 2010; Haug et al., 2014) or both (Apostolova et al., 2009; Denny et al., 2009; Tepper et al., 2012). In this paper we focus on section-level classification and section classification at the sentence level.

Prior approaches to section prediction include Support Vector Machines leveraging features computed by bi-gram tf-idf vector representations (Apostolova et al., 2009), Hidden Markov Models (HMM) with sections regarded as part of a sequence (Li et al., 2010), Maximum Entropy Classifiers (Tepper et al., 2012), ℓ1-Regularized Logistic Regression (Ganesan and Subotin, 2014), Bayesian models using N-gram features (Haug et al., 2014), and linear-chain Conditional Random Fields (CRF) to determine section headers (Dai et al., 2015). Most of these approaches rely heavily on hand-crafted features that are time consuming to develop and may not easily generalize across EHRs from different sources. To the best of our knowledge no prior work has explored deep learning or transfer learning. Given enough data, deep neural networks can extract useful features automatically. Some prior work is able to capture regularities in section ordering, either by using the Viterbi Algorithm (Ganesan and Subotin, 2014; Li et al., 2010) or beam search (Tepper et al., 2012) during the final section labeling phase, or by incorporating section ordering features (e.g. the class of the section preceding the section to be classified) into the model (Tepper et al., 2012). In this paper, since we mainly focus on transfer learning based on deep learning models, we predict labels for each section or sentence independently, leaving section sequence considerations to future work.

Two previous efforts have explored more than one dataset (Tepper et al., 2012; Ganesan and Subotin, 2014). Both evaluated domain adaptability and found significant reduction in performance across domains. The largest dataset, *i2b2*, has 13,962 expert-labeled sections (Dai et al., 2015). We use this dataset in our experiments as well. Because of the difficulty of annotating training data, some prior work adopts a semi-automated labeling approach (Apostolova et al., 2009; Denny et al., 2009; Li et al., 2010; Ganesan and Subotin, 2014) as we do for our medical literature dataset.

With the exception of the approaches using i2b2, all prior work uses proprietary datasets that are not available publicly making it difficult to compare to earlier approaches. We make our MedLit dataset as well as our extension of the labels for the i2b2 dataset available for research.

3 Data

We chose a set of 11 section class labels based on those used in the prior work discussed in Section 2 and on the most common sections from EHRs in our sources. The 11 classes are:

Allergies (Alrg)
Assessment and Plan (A&P)
Chief Complaint (CC)
Examination (Exam)
Family History (FHX)
Diagnostic Findings (Find)
Medications (Meds)
Past Medical History (PMH)
Personal and Social History (PSH)
Procedures (Proc)
Review of Systems (ROS)

For our experiments we use three datasets: Medical Literature (MedLit), Cleveland Clinic EHRs (ClvC), and i2b2 EHRs (i2b2).

Source	# Sections	# Sentences
Textbooks	807	7,407
Guidelines	4,781	53,013
Wikipedia	2,658	24,830

Table 1: Sections and sentences in each MedLit source.

3.1 Medical Literature (MedLit)

The medical literature dataset consists of passages from textbooks, guidelines, and a subset of medically relevant Wikipedia articles[2]. The number of sentences per source type is shown in Table 1. In total there are four sources in this dataset: Wikipedia and licensed content from DynaMed, Elsevier, and Wiley publishers.

To generate training data, we created a short list of common phrases for each of the 11 section classes by looking at labels used in prior work as well as section headers labeled in our annotated EHR datasets. We extracted sections in the MedLit corpus whose headers (indicated by XML markup) matched these phrases. For example, any section whose header matched "Chief Complaint", "Reason for Admission", "CC", "Signs and Symptoms", "History of Present Illness", or "SUBJ" was extracted as a positive example of the *Chief Complaint* class[3]. We experimented with partial phrase matches but ultimately decided to use exact match with stemming for higher precision on the common classes. For less frequent classes (e.g. *Allergies, Family History, Personal and Social History*), we allowed additional words to be present in the title. We make the 2,658 sections and labels for the Medical Wikipedia dataset available publicly for research purposes. Examples of sections and their headers are shown in Figure 2, with corresponding class labels indicated in the caption. In the discussion section (Section 5.3) we analyze the quality of the MedLit dataset as a cheaply labeled resource.

3.2 I2b2 EHRs (i2b2)

We use the i2b2 Risk Factors dataset (Stubbs and Uzuner, 2015; Stubbs et al., 2015) which was annotated for section header boundaries (Dai et al., 2015). The annotations do not indicate section

[2]Articles under the 'Clinical Medicine' category (https://en.wikipedia.org/wiki/Category:Clinical_medicine).

[3]It is common for *History of Present Illness* to be its own section but it is often part of or interchangeable with *Chief Complaint* so we opted to combine these two sections.

	Source	# Sections	# Sentences	Ratio
Train	MedLit	7042	72191	10
	i2b2	1680	10093	6
	ClvC	294	3467	12
Dev	MedLit	1204	13059	11
	i2b2	1591	9373	6
	ClvC	404	3282	8
Test	i2b2	3098	19110	6
	ClvC	404	4046	10

Table 2: The number of sections and sentences as well as the ratio of sentences to sections in each of the three datasets for train, dev, and test sets.

class so we matched the headers to our 11 classes. We used partial matches for this data due to the variability of EHR header text. There were 743 unique headers in the Dai et al. (2015) dataset that map to our 11 headers.

3.3 Cleveland Clinic EHRs (ClvC)

The Cleveland Clinic dataset consists of 178 deidentified patient notes from 54 patients acquired through a research collaboration agreement with Cleveland Clinic. The notes were annotated by two medical students in prior work. Inter-annotator agreement was computed on the first 34 notes (containing 106 sections) annotated by both annotators. The κ score was 0.86 for the sections and 0.80 at the note level. Due to the high agreement between the annotators, the remaining notes were annotated by one annotator each. We manually mapped the section class labels from those annotations to our 11.

3.4 Data Splits

The MedLit dataset was split 80/20 by section for training and tuning. We do not test on MedLit as our goal is finding sections in EHRs. The ClvC EHR dataset was split by patient into 60% for training and tuning, and 40% for testing. For i2b2 (Stubbs and Uzuner, 2015; Stubbs et al., 2015) we use Set 1 and 2 for training and development, and the i2b2 Test Set for testing. The distribution of the train, development/tuning (dev), and test is shown in Table 2. MedLit is the largest dataset. It has more than twice as many sentences as i2b2 and 8 times as many as ClvC. For some of the classes (e.g. *Allergies* and *Personal and Social History*) MedLit data is harder to find. *Procedures* is the smallest category in i2b2 (102 sentences) and *Allergies* is the smallest category in ClvC with

only 35 sentences in the training data.

4 Method and Results

Our work addresses the scenario of an EHR dataset (a *target* dataset) with little or no training data for section classification. We would like to measure how well models trained on a different EHR dataset and/or on medical literature (*source* datasets) can be transferred to classify the target dataset. We use each of the ClvC and i2b2 datasets in turn as target, with the other as source. We also experiment with using the MedLit dataset as source, both alone and together with data from a source EHR dataset. Specifically, for each target EHR dataset we compare the following models:

- ***ClvC:*** train on labeled data from ClvC EHRs
- ***i2b2:*** train on labeled data from i2b2 EHRs
- ***MedLit:*** train on medical literature data only
- ***MedLit + TR ClvC:*** take the MedLit model, then continue to train (transfer) on labeled ClvC data
- ***MedLit TR i2b2:*** take the MedLit model, then continue to train (transfer) on labeled i2b2 data

In all cases we evaluate our model on our two test sets: ClvC and i2b2. The data used in the test set is considered the **target**, or **in-domain** dataset. The other dataset(s) are considered **source**, or **out-of-domain**, for that experiment and will differ depending on the experiment. We consider the model that trains and tests on the same dataset to be an upper bound (UB). Given enough data[4], we would expect this configuration to perform the best.

We show our results with two different approaches. The first is a Recurrent Neural Network (RNN) using Gated Recurrent Unit (GRU) cell (Cho et al., 2014) and attention mechanism (Bahdanau et al., 2015). GRU aims to solve the vanishing gradient problem revealed in standard RNNs. In our model, attention is used to generate a weighted sum of GRU cell outputs for each word in the input text, for predicting the classification label (rather than only using the output from the last cell). The motivation is to let the model focus on those words that are the most useful for prediction, especially for long input text. The weights are computed by the soft alignment scores between each of the outputs and the last output of the RNN.

The second approach is based on BERT (Devlin et al., 2019), a state-of-the-art language representation model that pre-trains bidirectional representations by jointly conditioning on both left and right context. Once pre-trained, a BERT model can be fine-tuned to specific tasks. In our setting, we take the output of the transformer for the first token in the input, i.e., the special `[CLS]` word embedding, as the representation of the input, which is then used for label prediction by feeding into a classification layer.

We also experimented with a Convolutional Neural Network text classification model (Kim, 2014) as well as traditional machine learning models (Naive Bayes and SVM) using n-gram features, but all performed worse than our GRU RNN and BERT.

For the GRU RNN, we use the Adam optimizer, a batch size of 32, dropout of 0.2, and embedding size 300. We experimented with other parameter values on the development set, but these worked best. We ran each model for 50 epochs—enough for the training loss to converge. For our BERT experiments we use a PyTorch implementation[5] with the bert-base-uncased model. We use the default BERT parameters including the BERT Adam optimizer, a batch size of 32, dropout of 0.1, and embedding size 768. All text is cut off to the first 128 word-pieces. We experimented with different numbers of epochs, and chose the model that performed best on the dev set (usually one tuned at 10 epochs or fewer). Statistical significance was computed using McNemar's test. We experimented with both section classification and sentence classification as described in the following subsections.

Our transfer setting follows the pre-training and fine-tuning approach: after training on the large source domain (MedLit), we continue to tune the model on a small amount of labeled data from the target domain. We follow this approach using our RNN as well as the BERT model where we first tune BERT to the MedLit data and then continue to tune that model on the EHR data. We also experimented with using subsets of the MedLit dataset, downsampling, and class balancing. These exper-

[4] In the case of ClvC we do not have enough annotated data to train a model that would be considered a good upper bound

The results are grouped by MedLit, in-domain ((a) ClvC, (b) i2b2), and out-of-domain ((a) i2b2, (b) ClvC) training. * is significantly higher than + at $p <= .01$.

iments resulted in no significant change or a negative change to the results[6], so we report results using the complete, raw MedLit dataset. We expect that the models learn which data sources are more useful.

4.1 Section Classification

Our first set of experiments follow the approach of prior work (Li et al., 2010; Haug et al., 2014) in classifying sections of the EHR. The section header is included in the data if it exists. As noted in prior work, this task is easier than sentence classification as it is common for the header to be discoverable with accuracy $>$ 90% for most categories. We find similar trends in the i2b2 data with the upper bound (train on i2b2, test on i2b2) achieving an average 95% F-score with the RNN and near perfect F-score of 99% with BERT.

Results of experiments using the Cleveland Clinic (ClvC) test set as target are shown in Table 3a. The ClvC upper bound using the RNN (59% average F-score) is much lower than is typical in prior work, underlining the difficulty of even section-level classification with small amounts of training data (294 sections). Using the RNN model trained on MedLit alone does quite poorly, but tuning on MedLit prior to training on ClvC improves results very significantly over ClvC training alone (average F-score of 78%). BERT improves the results significantly here with 89% F-score, but the 90% F-score when tuning on the MedLit data is not significantly better. The bottom rows of the table show the scenario where no in-domain (ClvC) data exists, so we train on out-of-domain (i2b2) data. In this case, training on i2b2 alone is better than pre-training first on MedLit. When there is enough EHR data (even from a different source), the MedLit data does not help.

Table 3b shows results using the i2b2 test set as target. With the large amount of in-domain i2b2 training data available, using MedLit does not help. The bottom rows of Table 3b shows performance if we did not have i2b2 training data. Using the out-of-domain (ClvC) training data performs poorly. Transferring MedLit with a very small amount of out-of-domain (ClvC) data significantly outperforms using just the ClvC data for both the RNN and BERT, improving average F-score from 53% to 81% for the RNN and from 84% to 92% for BERT.

4.2 Sentence Classification

Prior work on section-level classification assumes that the section segmentation and header are known. In practice, this is not always the case. It is common for headers to be missing or unclear. In our experiments, therefore, we don't assume to know where the header is and instead of trying to classify a section we classify all sentences in the EHR. For training data for this task we take the class label annotated on each section in our datasets and attach it to each sentence in the section. So each sentence in the section (including the header) is considered an instance of the class. The sentence predictions could be combined to provide section level boundaries. We discuss this further as future work in Section 6. In the MedLit training data, we exclude sentences that are too small (fewer than 15 characters) or too large (more than 400 characters). As with our section-level experiments (Section 4.1), we evaluate our performance with the ClvC and i2b2 test sets. We first tuned the MedLit model using the MedLit development set as described in Section 4. We found that with BERT, only one epoch was necessary, with more epochs resulting in over-fitting.

[6]There is some change in the performance when using Wikipedia only, but not in the overall trends

Experiment	RNN F1	BERT F1
MedLit	0.30	0.37
ClvC (UB)	0.61^{+}	0.73^{+}

(b) Testing on i2b2

Table 4: Sentence-Level results for testing on the (a) ClvC and (b) i2b2 EHRs in Micro Avg F1-score. The best results in each column are highlighted in bold. The results are grouped by MedLit, in-domain ((a) ClvC, (b) i2b2) and out-of-domain ((a) i2b2, (b) ClvC) training. * is significantly higher than + at $p <= .01$.

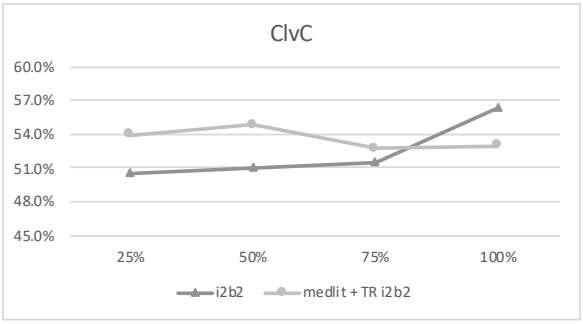

Figure 3: F-score trends of our RNN model training on smaller portions of the i2b2 data for the i2b2 and MedLit + TR i2b2 experiments and testing on ClvC

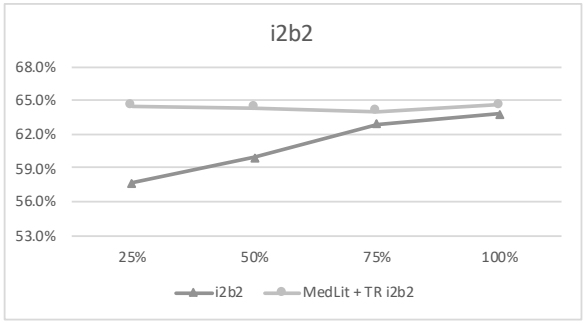

Figure 4: F-score trends of our RNN model training on smaller portions of the i2b2 data for the i2b2 and MedLit + TR i2b2 experiments and testing on i2b2

The results for testing on the ClvC data are shown in Table 4a. Although we call the configuration where we train and test on ClvC data the "upper bound", the MedLit + TR ClvC performs significantly ($p <= .01$) better for the RNN (62% vs 61%) and BERT models (74% vs 73%). We believe that this is because the ClvC dataset is small so the upper bound is not achieved. On the other hand, because the i2b2 training dataset is large, training on the MedLit data first does not provide a significant improvement with either model. We analyzed this result further by experimenting on training with subsets (25%, 50%, and 75%) of the i2b2 training data and testing on ClvC for the i2b2 and MedLit + TR i2b2 experiments. Figure 3 shows that with less out-of-domain EHR training data, transfer learning does help significantly (p-value $<= .01$) in all cases for the RNN model. In fact, there is no significant difference between using 25% or 100% of the i2b2 training data in the MedLit + TR i2b2 experiment.

The sentence-level results for testing with i2b2 as target are shown in Table 4b. Using the MedLit data in the RNN provides a significant improvement (65% vs 64%). However, there is no difference in the BERT models, likely because of the a large amount of i2b2 training data. Here again, we explored how having a smaller subset of the in-domain training data would impact the results. We found that running the MedLit + TR i2b2 experiment with just 25% of the i2b2 dataset with the RNN model performs as well (no significant difference) as training on the full i2b2 dataset (Figure 4), and 12% better than the model using 25% of the i2b2 data alone. In contrast, when using the BERT model, MedLit + TR i2b2 only performs better than i2b2 alone if less than 25% of the training data is available. This indicates that BERT can compensate for the lack of data while the RNN cannot, and MedLit is needed to improve the model. In the scenario where no in-domain training data is available we show that MedLit + TR ClvC does significantly better than just ClvC when testing on i2b2 for the RNN model (52% vs 48%) and BERT (60% vs 59%). We discuss these results further in the next section

Experiment	F1@1	F1@2	F1@3
RNN ClvC	0.48	0.66	0.75
RNN MedLit + TR ClvC	0.52	0.69	0.79
BERT ClvC	0.59	0.75	0.82
BERT MedLit + TR ClvC	0.60	0.75	0.83

Table 5: Average F1 score for training on ClvC and testing on i2b2 when examining the top 3 predictions.

5 Discussion

5.1 How much do out-of-domain EHRs help?

One of our most interesting results using the full datasets is the improvement we are able to achieve training with a small amount of ClvC (out-of-domain) EHR data and testing on i2b2 as the target domain (the last two rows of Table 3b and Table 4b). All of these results on the sentence level are quite low due to similar text that may be found in multiple sections. For example, the text found for *Chief Complaint* and *Past Medical History* can be quite similar with the only difference being *when* the problems occurred. To determine if this kind of misclassification was common we looked at our performance based on whether the correct class was in the top 1, 2, or 3 predictions (F1@3). Both ClvC and MedLit+TR ClvC showed large improvements for the RNN and BERT models as shown in Table 5 with roughly a 27 point improvement for the RNN models and a 22 point improvement for the BERT models. We analyzed the confusion matrix and the most common misclassifications were to the majority MedLit and ClvC classes (*Assessment and Plan* and *Chief Complaint*).

5.2 Do models impact sections differently?

We also compared performance on the individual classes when transferring from MedLit. To do this, we explored the training on i2b2 and testing on BERT i2b2, and BERT MedLit + TR i2b2 experiments (See the middle rows in Table 4b) where both models performed the same. We found the BERT i2b2 performed better for *Allergies* (6.8%), but BERT MedLit + TR i2b2 performed better for *Family History* (5.8%), and *Procedures* (7.9%). This suggests that it may be worth exploring an ensemble approach.

5.3 What is the quality of the MedLit data?

How well our approach performs on EHR section classification relies on the MedLit data. The MedLit dataset is cheaply labeled data of a different genre than the target data, so we would not expect the MedLit model to perform particularly well on its own on EHR data. To judge the quality of the MedLit-trained model in *its own genre*, we analyzed its performance on the dev set made up solely of medical literature. The best average F-score was 65.2% using the RNN and 71.2% for BERT on the sentence classification task. In particular, we found that *Assessment and Plan* performs quite poorly. We examined the confusion matrix and the predictions are distributed among the other classes indicating that it is more vague. Looking to see if the correct label is at the second- or third-highest scoring predictions, we find the F1@3 is 88.9% for the RNN model and 92.6% for the BERT model. This is significantly better, but still shows that it is weakly labeled data. We also analyzed the performance from our different medical literature sources. This analysis caused us to drop one of our initial guideline sources because it had few useful labels. The two relevant labels it did have were easy to predict correctly causing a bias toward the source. Finally, we inspected the text for the section headers. There were 66 unique headers in the medical literature dev set ranging over the 11 classes. "Physical", which maps to the *Examination* class was the most common section header and was predicted correctly 74% and 79% of the time for the RNN and BERT models respectively. Some other good strings include "History of Present Illness" and "signs and symptoms" for the *Chief Complaint* class and "medication" for the *Medications* class. Our *Review of Systems* headers included common subsections found in this area of the EHR such as "eye", "neurology", and "genitourinary". Some of these did not perform as well, probably because they are likely to appear in many different sections. We also analyzed the confusion matrix to determine the common misclassifications. In most cases the common misclassifications were to *Chief Complaint*, the majority class. We also found that *Past Medical History* was often incorrectly labeled as *Medications*. We found this analysis to be consistent across both models indicating that the data is not model dependent.

6 Conclusion

In this paper we describe a novel approach to classifying sections in Electronic Health Records

when a limited amount of in-domain training data is available. We present a new dataset for EHR section prediction from Medical Literature, of which the Wikipedia part is available to the public for research purposes. We show that combining a very small amount of in-domain EHR data with a large amount of automatically labeled, out-of-domain, out-of-genre Medical Literature data can perform as well as using a large amount of in-domain EHR data at the section and sentence level. We also show that combining out-of-domain, out-of-genre Medical Literature data with out-of-domain EHRs can provide significant improvement over using just out-of-domain EHRs at the section and sentence level, depending on training data size. These results indicate that even though the data in Medical Literature is very different in style, the content can bridge between the domain-specific vocabularies of different EHR systems. We show that our approach can be used to achieve good results on *new unseen EHR datasets* with minimal or even no training data. In the future we would also like to explore using both i2b2 and ClvC together to see if a multi-task learning approach would provide additional improvements. In addition to BERT, we also briefly explored BioBERT (Lee et al., 2019), a BERT model pre-trained on a medical corpus. In our initial experiments BioBERT performed worse than BERT, but we would like to explore this further.

Finally, in this work we focus on individual sentence and section classification and show that we can achieve improvements in this regard. In addition, we could also exploit the structure of the document to provide additional improvements. The structure often follows a pattern in EHRs (for example, *Chief Complaint* tends to be the first section). Prior work has looked at CRFs and HMMs (Li et al., 2010; Dai et al., 2015) to exploit this property. We would like to explore whether we can improve our model by combining it with a model that takes into account trends at the document level. Using LSTM-CRFs (Lample et al., 2016; Huang et al., 2015) as a second level with BERT as pre-training on our model may provide such an improvement.

Abstract

News recommendation is important for online news platforms to help users find interested news and alleviate information overload. Existing news recommendation methods usually rely on the news click history to model user interest. However, these methods may suffer from the data sparsity problem, since the news click behaviors of many users in online news platforms are usually very limited. Fortunately, some other kinds of user behaviors such as webpage browsing and search queries can also provide useful clues of users' news reading interest. In this paper, we propose a neural news recommendation approach which can exploit heterogeneous user behaviors. Our approach contains two major modules, i.e., news representation and user representation. In the news representation module, we learn representations of news from their titles via CNN networks, and apply attention networks to select important words. In the user representation module, we propose an attentive multi-view learning framework to learn unified representations of users from their heterogeneous behaviors such as search queries, clicked news and browsed webpages. In addition, we use word- and record-level attentions to select informative words and behavior records. Experiments on a real-world dataset validate the effectiveness of our approach.

1 Introduction

Online news platforms such as Google News[1] and MSN[2] News have gained huge popularity for online digital news reading (Das et al., 2007). Tens of thousands of news articles are streamed from various sources every day, making it very difficult for users to read all news to find their interested content (Phelan et al., 2011). Thus, personalized news recommendation is critical for online news platforms to target user interests and alleviate information overload (IJntema et al., 2010).

Figure 1: An illustrative example of news recommendation based on heterogeneous user behaviors.

News and user representation learning is critical for news recommendation. Many deep learning based methods have been proposed for this task (Okura et al., 2017; Wang et al., 2018). For example, Okura et al. (2017) proposed to learn news representations from news bodies via auto-encoders, and learn user representations from their clicked news via a gated recurrent unit (GRU) network. Wang et al. (2018) proposed to learn news representations from news titles via a knowledge-aware convolutional neural network (CNN), and learn user representations from their clicked news using the similarities between candidate news and clicked news. These methods rely on the news click histories to model users' news reading interest. However, these methods usually suffer from the data sparsity problem, since the news click behaviors of many users on news platforms are very limited, making it difficult for these methods to learn accurate representations of these users.

Luckily, there are several other kinds of user

behaviors such as search queries and webpage browsing which are useful for news recommendation. Many online users frequently use search engines such as Google and Bing to search for desired information (Wu et al.). In addition, they may browse related webpages to get more detailed information. Thus, the search and browsing data accumulated by commercial search engines can cover a large number of online users. In addition, the search and browsing behaviors of users can provide rich information for inferring user interests. For example, in Fig. 1, since the user posts the search query "toyota crown", and browses the webpage of "Pros and Cons of Toyota" for detailed information, she may have high interest in Toyota cars and is likely to read news articles related to Toyota cars. However, this user may click only a few news articles, and her interest in toyota cars cannot be mined from the news click history. Thus, incorporating the heterogeneous behaviors of online users such as search queries and webpage browsing has the potential to improve the performance of news recommendation.

Our work is motivated by following observations. First, the characteristics of search queries, webpage titles and news have huge differences. For example, in Fig. 1, search queries are usually phrase pieces with a few words, while news and webpage titles are usually complete sentences. Thus, they should be handled differently. Second, different words usually have different importance in representing behavior records. For example, in Fig. 1 the word "NFL" is more informative than "Today". Third, different behavior records may also have different importance for representing users. For instance, the search query "safe cars" in Fig. 1 is more informative than the query "google map" in modeling user interest. Fourth, different kinds of user behaviors usually have different informativeness for user representation learning. For example, in Fig. 1 since the user clicks very few news articles, her news click behaviors are not very informative for modeling this user.

In this paper, we propose a neural news recommendation approach with heterogeneous user behavior (NRHUB). The core of our approach is a news representation module and a user representation module. In the news representation module, we learn news representations from news titles via a CNN network with word-level attentions to select important words. In the user representation module, we propose an attentive multi-view learning framework to incorporate the different kinds of user behavior data into our model to learn unified user representations. In each view, we propose to use hierarchical user encoders to first learn record representations from words, and then learn user representations from different kinds of behavior records. Since different views may have different informativeness for modeling users, we propose to use a view-level attention network to select important views for learning informative user representations. In addition, since different words and records may also have different informativeness, we apply word-level and record-level attention networks to select important words and records. Extensive experiments are conducted on a real-world news recommendation dataset. The results show that our approach can effectively improve the performance of news recommendation, especially in the cold-start scenario.

2 Related Work

News recommendation is an important task in both natural language processing and data mining fields, and has wide applications (Okura et al., 2017; Zheng et al., 2018). Learning accurate news and user representations is critical for news recommendation. Many of existing methods for news recommendation rely on manual feature engineering to build news and user representations (Liu et al., 2010; Son et al., 2013; Bansal et al., 2015). For example, Liu et al. (2010) proposed to use topic categories and interest features generated by a Bayesian model to build news and user representations. Son et al. (2013) proposed an Explicit Localized Semantic Analysis (ELSA) model for location-based news recommendation. They proposed to extract topic and location features from Wikipedia pages to build news representations. Lian et al. (2018) proposed a deep fusion model (DMF) to learn news representations from various handcrafted features such as title length, entities and news topics, and learn user representations from features extracted from the news reading, web browsing, and searching behaviors of users. However, these methods usually rely on manual feature engineering, which necessities massive domain knowledge and time to design. In addition, these methods cannot exploit contextual information in the behavior records of users, which may be insufficient to learn accurate user representations.

In recent years, several deep learning based methods are proposed for news recommendation (Okura et al., 2017; Wang et al., 2018; Khattar et al., 2018; Kumar et al., 2017; Zheng et al., 2018; Wu et al., 2019b; An et al., 2019; Wu et al., 2019c,a; Zhu et al., 2019). For example, Okura et al. (2017) proposed to learn news representations from news bodies via denoising autoencoders, and learn user representations from the news browsing sequence via a GRU network. Wang et al. (2018) proposed to learn news representations from news titles via a knowledge-aware CNN network, which can incorporate useful entity information from knowledge graphs. Wu et al. (2019b) proposed to learn news representations from news titles, and apply personalized attention mechanism at both word- and news-level to generate representations of news and users according to user preferences. However, these methods only learn user representations from a single kind of user behavior, i.e., news click, which may be insufficient. Different from these methods, our approach can learn unified user representations by incorporating heterogeneous user behaviors via an attentive multi-view learning framework. Extensive experiments on real-world dataset validate our approach can learn better news and user representations, and achieve better performance on news recommendation than existing methods.

3 Our Approach

In this section, we introduce our neural news recommendation approach with heterogeneous user behavior (NRHUB) in detail. The architecture of our *NRHUB* approach is shown in Fig. 2. Our approach has three major modules, i.e., *news representation*, *user representation* and *click predictor*. Next, we introduce the details of each module.

3.1 News Representation Learning

The *news representation* module is used to learn representations of news articles from their titles. It contains three layers.

The first one is a word embedding layer, which is used to convert a news title from a sequence of words into a sequence of low-dimensional semantic vectors. Denote a news title with M words as $[w_1, w_2, ..., w_M]$. It is converted into a vector sequence $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M]$ via a pre-trained embedding matrix.

The second one is a CNN layer (Kim, 2014). Usually, local contexts are very important in representing the news titles. For example, in the news title "Toyota Crown Classics for Sale", local contexts of "Crown" such as "Toyota" are useful for inferring the topic of this news, i.e., cars. Thus, we apply a CNN network to learn contextual representations of words within news titles by capturing their contexts. The CNN layer computes the contextual representations of each word, and outputs a vector sequence $[\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_M]$.

The third one is a word-level attention network. Different words in the same news title may have different importance in representing this news. For example, in the second news in Fig. 1, the word "NFL" is more informative than "Today" for representing this news. Thus, we propose to use attention mechanism to select important words in news titles for learning informative news representations. Denote the attention weight of the i-th word in a news title as α_i^w:

$$
\begin{aligned}
a_i^w &= \mathbf{v}_w^n \times \tanh(\mathbf{V}_w \times \mathbf{c}_i + \mathbf{v}_w), \\
\alpha_i^w &= \frac{\exp(a_i^w)}{\sum_{j=1}^{M} \exp(a_j^w)},
\end{aligned} \tag{1}
$$

where $\mathbf{V}_w$ and $\mathbf{v}_w$ are projection parameters, $\mathbf{v}_w^n$ is the query vector in this attention network. The final contextual representation of a news title is the summation of its word representations weighted by their attention weights as follows:

$$
\mathbf{r}^n = \sum_{i=1}^{M} \alpha_i^w \mathbf{c}_i. \tag{2}
$$

3.2 User Representation Learning

The *user representation* module is used to learn the representations of users from different kinds of user behaviors, e.g., web searching, news click and webpage browsing. Since these user behaviors usually have different characteristics, simply aggregate them together into a long document may not be optimal for news representation. Thus, we propose an attentive multi-view learning framework to learn unified user representations by incorporating these three kinds of user behavior information as different views of news.

The first view is *news encoder*, which is used to learn user representations from his/her clicked news. There are two major submodules in this view. The first one is news representation, as described in section 3.1. Denote the sequence of news clicked by a user as $[D_1, D_2, ..., D_N]$, where

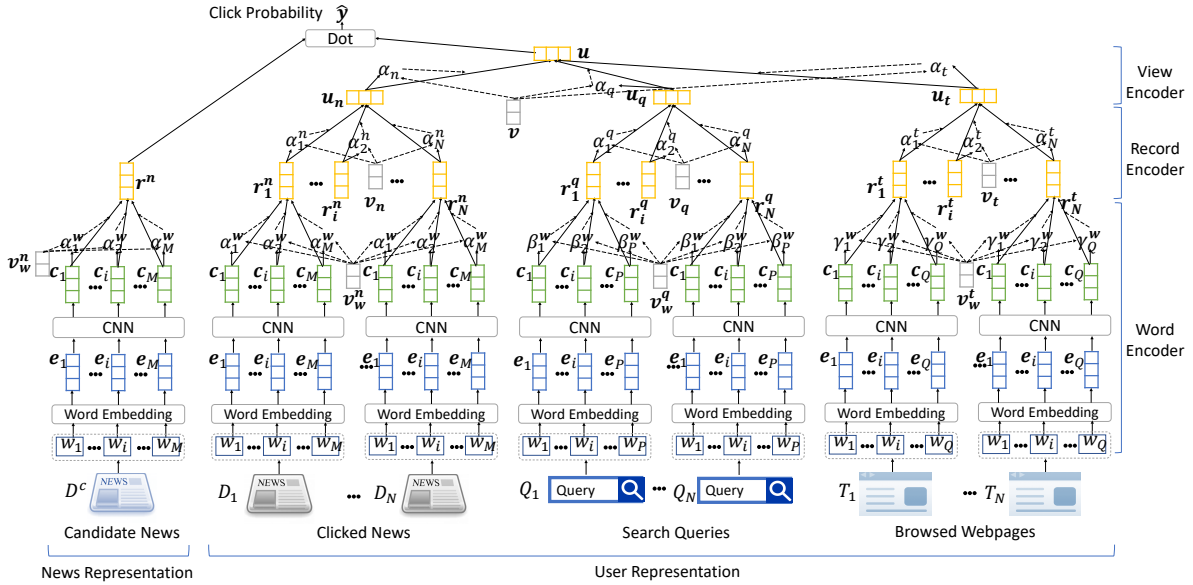

Figure 2: The framework of our *NRHUB* approach.

N is the number of clicked news articles. It is transformed into a sequence of hidden news representations, denoted as $[\mathbf{r}_1^n, \mathbf{r}_2^n, ..., \mathbf{r}_N^n]$.

The second one is a news-level attention network. Different news clicked by the same user may have different informativeness for representing this user. For example, in Fig. 1, the second news is more informative than the first news in modeling user preferences, since the first one is usually not audience sensitive. Thus, we use a news-level attention network to select important news for learning informative user representations. Denote the attention weight of the i-th news clicked by a user as α_i^n, which is computed as:

$$a_i^n = \mathbf{v}_n \times \tanh(\mathbf{V}_n \times \mathbf{r}_i + \mathbf{b}_n),$$
$$\alpha_i^n = \frac{\exp(a_i^n)}{\sum_{j=1}^{N} \exp(a_j^n)}, \tag{3}$$

where $\mathbf{V}_n$ and $\mathbf{b}_n$ are parameters, $\mathbf{v}_n$ is the attention query vector. The news based representation of a user u is the summation of the representations of clicked news articles weighted by their attention weights as follows:

$$\mathbf{u}_n = \sum_{i=1}^{N} \alpha_i^n \mathbf{r}_i^n. \tag{4}$$

The second view is *query encoder*, which is used to learn representations of users from their search queries. There are two submodules in this view. The first module is query representation, which is used to learn query representations from words. It also has three layers.

The first one is a word embedding layer, which is shared with the news representation view. Denote a search query q with P words as $q = [w_1, w_2, ..., w_P]$. It is converted into a sequence of hidden word representations, denoted as $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_P]$.

The second one is a CNN layer. Local contexts are very important in learning query representations. For example, in the query "xbox one player", the local contexts of "one", i.e., "xbox" and "player" are important in representing this query. Thus, we apply CNN to capture the local contexts within queries, and compute the contextual representations of each word. The outputs of this CNN layer is denoted as $[\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_P]$.

The third one is a word-level attention network. Different words in the same search query usually have different informativeness for representation learning. For example, in the query "hot movies this week" "movies" is more informative than "week" in modeling this query. Thus, we propose to use a word-level attention network to recognize important words in search queries for learning informative query representations. The attention weight β_i^w of the i-th word in a search query is computed as:

$$b_i^w = \mathbf{v}_w^q \times \tanh(\mathbf{V}_q \times \mathbf{c}_i + \mathbf{v}_q),$$
$$\beta_i^w = \frac{\exp(b_i^w)}{\sum_{j=1}^{P} \exp(b_j^w)}, \tag{5}$$

where $\mathbf{V}_q$, $\mathbf{v}_q$ and $\mathbf{v}_w^q$ are parameters in the attention network. The contextual representation of this query is the summation of its word representations weighted by their attention weights, as follows:

$$\mathbf{r}^q = \sum_{i=1}^{P} \beta_i^w \mathbf{c}_i. \tag{6}$$

The second module is a query-level attention network, which is used to learn user representations from query representations. Different queries posted by the same user usually have different importance in characterizing this user. For example, the query "toyota cars" is more informative than the query "google mail", since the later one does not contain information of user preference. To select important search queries for learning informative user representations, we propose to incorporate a query-level attention network. The attention weight α_i^q of the query Q_i is computed as:

$$\begin{aligned} a_i^q &= \mathbf{v}_q \times \tanh(\mathbf{U}_q \times \mathbf{r}_i + \mathbf{u}_q), \\ \alpha_i^q &= \frac{\exp(a_i^q)}{\sum_{j=1}^{N} \exp(a_j^q)}, \end{aligned} \tag{7}$$

where $\mathbf{U}_q$, $\mathbf{u}_q$ and $\mathbf{v}_q$ are attention parameters. The user representation learned from queries is the summation of the query representations weighted by their attention weights as:

$$\mathbf{u}_q = \sum_{i=1}^{N} \alpha_i^q \mathbf{r}_i^q. \tag{8}$$

The third view is *webpage encoder*. It is used to learn representations of users from the titles of their browsed webpages. There are two submodules in this view. The first one is *webpage representation*, which is used to learn the representations of webpage titles from their words, and the second one is a webpage-level attention network which learns user representation from webpages. In the *webpage representation* module, we first use a CNN network to learn contextual representations of the words in webpage titles, and then we use a word-level attention network to highlight important words. The hidden representation of each webpage is the summation of the contextual representations of words weighted by their attention weights, which is similar to the search query and news views described previously. The webpage-level attention network is used to select informative webpages for user representation learning, and the final webpage based user representation $\mathbf{u}_t$ is the summation of the webpage representations weighted by their attention weights.

The last component in the *user representation* module is a view encoder. Usually, different views may have different informativeness for modeling users. For example, a user may never or rarely cl news, and his/her news click data may be uninformative for representing this user. Thus, modeling the informativeness of different views may benefit user representation learning. Motivated by these observations, we propose a view-level attention network to select important views for learning informative user representations. Denote the attention weights of the news, query and webpage views as α_n, α_q and α_t, respectively. For instance, the attention weight of the news title view is computed as follows:

$$\begin{aligned} a_n &= \mathbf{v} \times \tanh(\mathbf{U}_v \times \mathbf{u}_n + \mathbf{u}_v), \\ \alpha_n &= \frac{\exp(a_n)}{\exp(a_n) + \exp(a_q) + \exp(a_t)}, \end{aligned} \tag{9}$$

where $\mathbf{v}$, $\mathbf{U}_v$ and $\mathbf{u}_v$ are parameters. The attention weights of the search query and webpage title views are computed similarly. The unified user representation is the summation of the user representations from different views weighted by their attention weights, which is formulated as

$$\mathbf{u} = \alpha_n \mathbf{u}_n + \alpha_q \mathbf{u}_q + \alpha_t \mathbf{u}_t. \tag{10}$$

3.3 Click Predictor

The *click predictor* module is used to predict the probability of a user clicking a candidate news article from their representations. Denote the representation of the candidate news D^c as $\mathbf{r}^n$. Following (Okura et al., 2017), the click probability score $\hat{y}$ is computed by the inner product of the user and candidate news representations, i.e., $\hat{y} = \mathbf{u}^T \mathbf{r}^n$.

3.4 Model Training

Motivated by (Huang et al., 2013), we propose to use the negative sampling technique for model training. For each news clicked by a user which is regarded as a positive sample, we randomly sample K news in the same impression but not clicked by this user as the negative samples. Denote the click probability score of the positive news as $\hat{y}^+$, and scores of the K negative news as $[\hat{y}_1^-, \hat{y}_2^-, ..., \hat{y}_K^-]$. We normalize these scores using the softmax function to compute the posterior

# users	10,000	**avg. # words per new title**	11.29
# news	42,255	**avg. # displays per news**	247.89
# queries	923,041	**# user w/ queries**	5,282
# webpage titles	813,852	**# user w/ webpages**	6,134
# impressions	360,428	**avg. # words per query**	3.25
# samples	10,474,493	**avg. # words per webpage title**	9.01
# positive samples	503,698	**# negative samples**	9,970,795

Table 1: Statistics of our dataset.

click probability of a positive sample as follows:

$$p_i = \frac{\exp(\hat{y}_i^+)}{\exp(\hat{y}_i^+) + \sum_{j=1}^{K} \exp(\hat{y}_{i,j}^-)}. \quad (11)$$

The loss function for model training is the negative log-likelihood of all positive samples:

$$\mathcal{L} = -\frac{1}{|\mathcal{S}|} \sum_{i \in \mathcal{S}} \log(p_i), \quad (12)$$

where $\mathcal{S}$ is the set of positive training samples.

4 Experiments

4.1 Datasets and Experimental Settings

We conducted experiments on a real-world news recommendation dataset[3] collected from MSN News[4] logs during Dec. 13, 2018 and Jan. 12, 2019. In addition, we crawled the search queries and titles of browsed webpages from the logs of the Bing search engine. The detailed statistics of this dataset are summarized in Table 1. The news data in the last week is used for test, and the rest is used for model training. In addition, we randomly sampled 10% of the training data for validation.

In our experiments, the word embeddings were 300-dimensional and we used the pre-trained Glove embedding for initialization (Pennington et al., 2014). All CNN networks had 400 filters, and their window size was set to 3. The dimension of attention query vectors was 200. Following (Wu et al., 2019b), the negative sampling ratio K was set to 4. Adam (Kingma and Ba, 2014) was used as the optimization algorithm. We applied 30% dropout to the word embedding and CNN networks to mitigate overfitting. The training batch size was 64. These hyperparameters were all tuned on the validation set. We independently repeated each experiment 10 times and reported the average results in AUC, MRR, nDCG@5 and nDCG@10 of all impressions.

4.2 Performance Evaluation

We evaluate the performance of our *NRHUB* approach by comparing it with many baseline methods, including: (1) *LibFM* (Rendle, 2012), a matrix factorization method for recommendation; (2) *DSSM* (Huang et al., 2013), deep structured semantic model; (3) *Wide&Deep* (Cheng et al., 2016), a popular neural recommendation method with a wide linear model and a deep neural network; (4) *DeepFM* (Guo et al., 2017), a famous neural recommendation method with a factorization machine and a deep neural network; (5) *DFM* (Lian et al., 2018), a deep fusion model for news recommendation; (6) *GRU* (Okura et al., 2017), a neural news recommendation method based on autoencoder and GRU to learn news and user representations; (7) *DKN* (Wang et al., 2018), a deep knowledge-aware news recommendation method; (8) *Conv3D* (Kumar et al., 2017; Khattar et al., 2018), a nerual news recommendation method based on a 3-D convolutional neural network to learn user representations from the sequence of clicked news[5]; (9) *NRHUB*, our neural new recommendation approach with heterogeneous user behavior; (10) *NRHUB-basic*, a variant of our approach with only news click behavior; (11) *NRHUB-concat*, a variant of our approach which aggregates different kinds of user behaviors as a single view. Following (Wang et al., 2018), in methods (1, 3-5), we use one-hot encoded user ID, news ID and the TF-IDF features of news titles as the input features. The results are summarized in Table 2.

From Table 2, we have several observations. First, deep learning based news recommendation methods (e.g., *DSSM* and *NRHUB*) can outperform *LibFM*. This is because neural networks can

[3]Some publicly available resources can be found at https://github.com/wuch15/NRHUB.

NRHUB*	**0.6317**	**0.3020**	**0.3260**	**0.4076**

Table 2: The results of different methods. *The improvement is significant at $p < 0.01$.

learn better news and user representations than traditional matrix factorization methods, which is beneficial for more accurate news recommendation. Second, among deep learning based methods, both *NRHUB-basic* and *NRHUB* can outperform all baseline methods. This is because our approaches incorporate both word- and news-level attention networks to simultaneously select important words and news for learning more informative news and user representations. Thus, our approaches can outperform baseline methods. Third, *NRHUB* and *NRHUB-concat* methods outperform *NRHUB-basic*. This is because search queries and browsed webpage can provide rich information of user interests, which is useful for learning user representation for news recommendation. Fourth, *NRHUB* consistently outperforms *NRHUB-concat*. This is because the characteristics of news titles, search queries and webpage titles are quite different, and they should be handled differently. Thus, simply merging them together is not the optimal way to exploit them. These results validate the effectiveness of our *NRHUB* approach in incorporating heterogeneous user behaviors for news recommendation.

4.3 Effectiveness of Attentive Multi-view Learning

In this section, we explore the effectiveness of the attentive multi-view learning framework in our approach. First, we want to verify the effectiveness of incorporating heterogeneous user behaviors as different views. We compare the performance of our *NRHUB* approach with its variants with different combinations of views, and the results are shown in Fig. 3. From Fig. 3, we have several observations. First, both search queries and browsed webpage titles are useful for improving the performance of news recommendation. This may be because users usually use post search queries to search engines to seek for interested content, and may browse several related webpages for detailed information. Thus, search queries and browsed webpage titles contain rich information of user preferences, which is useful for learning accurate user representations. Second, webpage titles are more important than search queries. This may be because webpage titles have larger coverage in our dataset. In addition, search queries are usually very short with a few words, while webpage titles are often like complete sentences with much more words. Thus, webpage titles are more informative for learning user representations. Third, incorporating both kinds of user behaviors can further improve the performance of our approach. These results validate the effectiveness of incorporating heterogeneous user behaviors via multi-view learning.

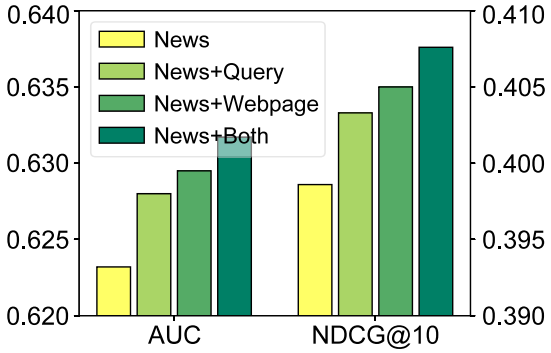

Figure 3: Effect of heterogeneous user behaviors.

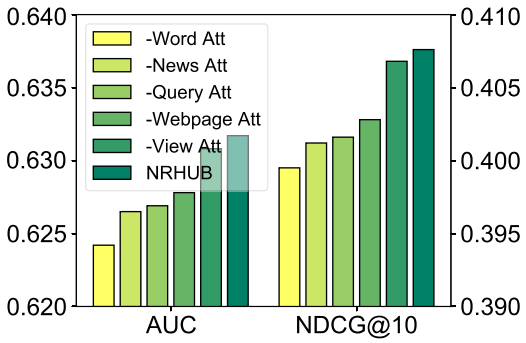

Figure 4: Influence of different attention networks.

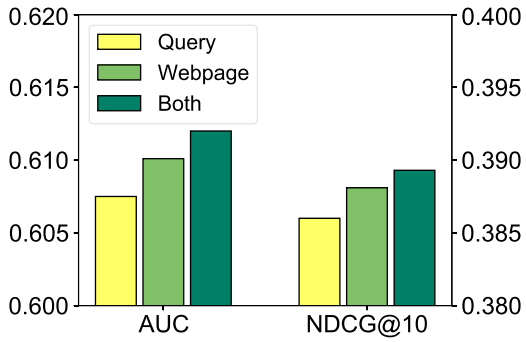

Figure 5: Cold-start performance of our approach.

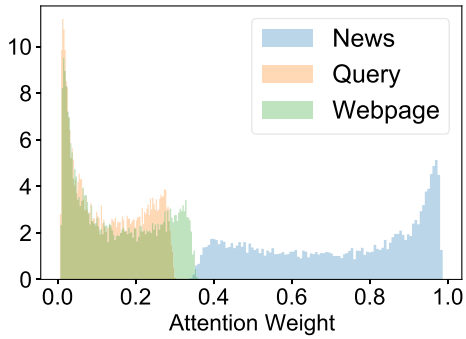

Figure 6: Distributions of view-level attention weights. The left, middle and right curves respectively denote search query, browsed webpage and clicked news.

Next, we explore the effectiveness of different attention networks in our approach. We conduct experiments using the leave-one-out scheme to evaluate the contribution of each attention network. The results are shown in Fig. 4. From Fig. 4, we find the word-level attention network can effectively improve the performance of our approach. This is because different words in the same news, query or webpage title may have different importance for learning user representations. Thus, selecting important words can help learn more informative news, query and webpage representations. In addition, the news-, query- and webpage-level attention networks are also important to our approach. This is because different news articles, search queries or webpages usually have different importance in representing users, and selecting important news, queries and webpages is beneficial for learning accurate user representations. Besides, the view-level attention network is also useful. This is because different views also have different informativeness in modeling user preferences. Thus, evaluating the informativeness of different views via a view-level attention network can learn better user representations. Moreover, combining all these kinds of attention networks can further improve the performance of our approach. These results validate the effectiveness of the attentive multi-view learning framework in our approach.

4.4 Cold-start Performance

In this section, we explore the cold-start performance of our approach. In practical use, massive users may rarely or have never clicked news articles on the target news platform, making it difficult to effectively recommend news to these users. Luckily, the search and browsing behaviors can cover many of these users. These user behaviors usually contain rich information of user preferences, and have the potential to address the cold-start problem. To validate the effectiveness of our approach, we compare the performance of several variants of our approach without the news encoder view to simulate the cold-start situation. The results are shown in Fig. 5. According to the results, we find our approach can still achieve satisfactory performance in the cold-start situation. This may be because search queries and webpage titles are important clues of user interests, which are very useful for news recommendation. Thus, our approach can recommend news effectively to the users with very limited or even no news browsing histories, which can effectively improve their experiences. In addition, combining the information of queries and webpage titles can further improve the performance of our approach. These results validate the effectiveness of our approach.

4.5 Case Study

In this section, we conduct several case studies to visually explore the effectiveness of different at-

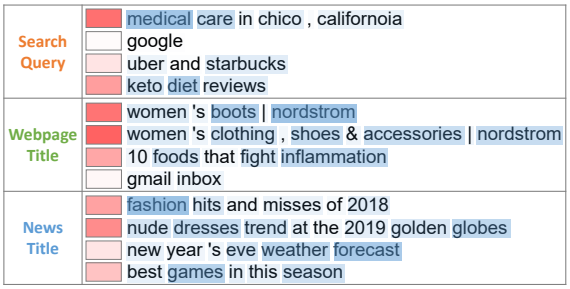

Figure 7: Visualization of the word-level and record-level attention weights from a randomly selected user.

tention networks in our approach. First, we visualize the distributions of the view-level attention weights in our *NRHUB* approach, and the results are shown in Fig. 6. According to the results, we find the attention weights of the news encoder view can be relatively low. This may be because the news browsing histories of some users are less informative for modeling these users. In addition, we find the attention weight of the webpage encoder view is higher than the query encoder view. This may be because webpage titles are usually complete sentences, while search queries are usually pieces of words. Thus, webpage titles contain richer information of user interests than search queries, which are more informative for representing users.

Next, we illustrate the attention weights in the word-level and record (news, query and webpage)-level attention networks. The results are shown in Fig. 7. From Fig. 7, we have several observations. First, we find search queries and webpage titles can provide much information of user interests which is not covered by the news browsing histories of users. For example, we can infer that this user is interested in the health topic from her queries and browsed webpages, which is not revealed by her clicked news. Thus, incorporating heterogeneous behaviors of users are useful for learning more accurate user representations. Second, we find that our approach can effectively select important words in queries, news and webpage titles. For example, the word "medical" gains high attention weight since it is informative for learning query representations, while the word "in" receives low attentions. In addition, our approach can effectively select important queries, news and webpages. For example, the query "deto diet reviews" and the webpage of "10 foods that fight inflammation" are assigned high attention weights since they are informative for learning user representations, but the query "google" and the webpage of "gmail inbox" are assigned low attention weights since they are uninformative. These results validate the effectiveness of the attention networks in our approach.

5 Conclusion and Furture Work

In this paper, we propose a neural news recommendation approach which can exploit heterogeneous user behaviors. In our approach, we propose an attentive multi-view learning framework to learn unified user representations from their search queries, clicked news, and browsed webpages by regarding them as different views. We propose to apply a view-level attention network to select important views for informative user representation learning. Besides, we propose to employ both word- and record-level attention networks to learn more informative news and user representations. Extensive experiments on a real-world dataset collected from MSN News show our approach can effectively improve the performance of neural news recommendation, and can achieve satisfactory results in cold-start scenarios.

In our future work, we will explore three potential directions. The first one is how to incorporate the interactions between different kinds of user behaviors, since the relatedness of them may be useful for modeling the interest evolution of users. The second one is how to incorporate the activities of users on social media platforms, since the opinions, experiences and events shared by users on social media are usually useful clues to indicate their interests. The third one is how to incorporate language models to generate context-aware word embeddings, which may enhance the representation learning of contexts in news and other kinds of user generated content.

Abstract

User and item representation learning is critical for recommendation. Many of existing recommendation methods learn representations of users and items based on their ratings and reviews. However, the user-user and item-item relatedness are usually not considered in these methods, which may be insufficient. In this paper, we propose a neural recommendation approach which can utilize useful information from both review content and user-item graphs. Since reviews and graphs have different characteristics, we propose to use a multi-view learning framework to incorporate them as different views. In the review content-view, we propose to use a hierarchical model to first learn sentence representations from words, then learn review representations from sentences, and finally learn user/item representations from reviews. In addition, we propose to incorporate a three-level attention network into this view to select important words, sentences and reviews for learning informative user and item representations. In the graph-view, we propose a hierarchical graph neural network to jointly model the user-item, user-user and item-item relatedness by capturing the first- and second-order interactions between users and items in the user-item graph. In addition, we apply attention mechanism to model the importance of these interactions to learn informative user and item representations. Extensive experiments on four benchmark datasets validate the effectiveness of our approach.

1 Introduction

Precisely learning user and item representations is critical for recommendation (Tay et al., 2018). Many existing recommendation methods learn user and item representations from their rating matrix (Koren et al., 2009; Mnih and Salakhutdinov, 2008; Berg et al., 2017). For example, Koren et al. (2009) proposed to use singular value decomposition (SVD) to learn latent user and item representations based on the review ratings that users gave to items. However, there are massive users and items in online platforms, making the rating matrix between users and items very sparse. Thus, it is difficult for these methods to learn accurate user and item representations (Zheng et al., 2017).

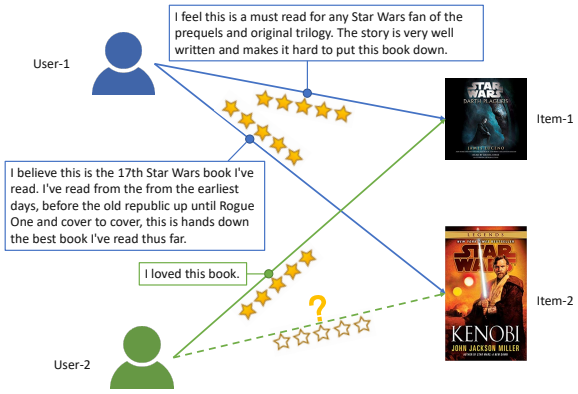

Figure 1: Two example users and items.

In recent years, several deep learning based recommendation methods are proposed to learn user and item representations from review texts (Zheng et al., 2017; Catherine and Cohen, 2017). For example, Zheng et al. (2017) proposed a DeepCoNN approach to learn the representations of users and items from their reviews via convolutional neural networks (CNN). However, these methods only consider the interactions of user-item pairs, while the relatedness between users or items are ignored, which may be insufficient for learning accurate user and item representations.

Our work is motivated by several observations. First, users who write reviews on the same products may have some relatedness. For example, in Fig. 1 both User-1 and User-2 give 5 stars to Item-1, and we can infer that both users are interested in Star Wars. Second, items that commented by the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4884–4893,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

same user may also have relatedness. For example, in Fig. 1 both items are commented by User-1, and they share the same topics on Star Wars. Third, modeling the user-user and item-item interactions is useful for recommendation. For example, in Fig. 1 both users may have similar interests on Star Wars, and both books have related topics. Thus, it may be effective to recommend Item-2 to User-2. Fourth, the interactions between users and items, e.g., reviews, may have different importance for representing users and items. For example, in Fig. 1 the interaction between User-1 and Item-1 is more important than that between User-2 and Item-1 in representing this item, since the review of User-1 contain more details about item properties. In addition, different words and sentences in the same review may also have different importance. For instance, the sentence "this is the best book I've read thus far" is more important than "I've read from the earliest days", and the word "best" is more important than "read" in the former sentence.

In this paper, we propose a reviews meet graphs approach (*RMG*) to combine reviews and the information of user-item graphs via a multi-view learning framework. In the review content-view, we use a hierarchical model to learn user and item representations. It first learns sentence representations from words, then learn review representations from sentences, and finally learn user/item representations from reviews. In addition, we propose to apply a three-level attention network to select important words, sentences and reviews to learn informative user and item representations. In the graph-view, we propose to use a graph neural network to capture the user-item, user-user, and item-item relatedness in the user-item bipartite graphs by modeling the first-order and second-order interactions between different users and items. In addition, we propose to incorporate attention mechanism into the graph neural network to model the importance of these interactions for informative user and item representation learning. Extensive experiments on four benchmark datasets validate that our approach can effectively improve the performance of recommendation and outperform many baseline methods.

2 Related Work

Many previous works have studied the problem of learning user and item representations from reviews for recommendation (Zhang et al., 2014; Diao et al., 2014; He et al., 2015; Tan et al., 2016; Ren et al., 2017). Many of existing methods rely on topic models to extract topics from reviews for user and item representation (McAuley and Leskovec, 2013; Ling et al., 2014; Bao et al., 2014). For example, McAuley and Leskovec (2013) proposed a Hidden Factors as Topics (HFT) method to learn latent user and item factors from review content via a latent Dirichlet allocation (LDA) model. Ling et al. (2014) proposed a Ratings Meet Reviews (RMR) approach to represent users and items by first extracting topics from reviews and then aligning the dimensions of these topics with the latent user factors learned from review ratings via matrix factorization. Bao et al. (2014) proposed a TopicMF method to represent users and items by incorporate the topics extracted from review texts to enhance the learning of latent user and item factors from the rating matrix via non-negative matrix factorization (NMF). However, these methods only extract topics from reviews, and cannot effectively utilize the contexts and word orders in reviews, both of which are important for learning accurate user and item representations.

In recent years, several deep learning based methods proposed to learn user and item representations from original review texts (Zhang et al., 2016; Zheng et al., 2017; Catherine and Cohen, 2017; Seo et al., 2017b,a; Chen et al., 2018; Tay et al., 2018; Wu et al., 2019). For example, Zheng et al. (2017) proposed a DeepCoNN approach to learn user and item representations from reviews via CNN networks. Catherine and Cohen (2017) proposed a TransNets approach to use CNNs to learn user and item representations. In their approach, these representations are regularized to be close to the representations of reviews from the target user-item pairs. Seo et al. (2017b) proposed to use CNN networks to learn user and item representations, and applied a word-level attention network to select important words. Chen et al. (2018) proposed to learn review representations using CNNs and they modeled the usefulness of reviews via a review-level attention network to learn informative user and item representation learning. However, these methods can only model the user-item interactions, while the user-user and item-item relatedness is not considered. In addition, these methods usually aggregate reviews or

their texts together, and cannot fully model their informativeness. Different from these methods, in our approach we propose a review meet graph approach which can combine reviews with user-item graphs via a multi-view learning framework to enhance user and item representation learning. In the review text-view, we use a hierarchical framework to learn sentence representations from words first, then learn review representations form sentences, and finally learns user/item representations from their reviews. In addition, we apply attention network at each level to select important words, sentences and reviews. In the graph-view, our approach uses a hierarchical graph neural network to mine the user-item, user-user and item-item relatedness from user-item graphs, and attentively selects the interactions between users and items. Experiments on four benchmark datasets validate the effectiveness of our approach in recommendation.

3 Our Approach

In this section, we will introduce our reviews meet graphs approach for recommendation (denoted as *RMG*). The architecture of our basic *RMG* approach is shown in Fig. 2. Our approach consists of two different views, i.e., a *review content-view* and a *graph-view*.

3.1 Review Content View

The *review content-view* module is used to learn representations of users and items from their review texts. It contains three modules, i.e, *sentence encoder*, *review encoder* and *user/item encoder*.

There are three layers in the *sentence encoder*. The first one is word embedding. It is used to convert a sentence s into a low-dimensional semantic vector sequence. Denote the word sequence of s as $[w_1, w_2, ..., w_M]$, where M is its length. It is converted into a vector sequence $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M]$ via a pre-trained embedding matrix.

The second one is a convolutional neural network (CNN). Local contexts are important for review representation learning. For example, in the sentence "I am a star wars fan", the local contexts of "wars" such as "star" and "fan" are useful for inferring this sentence is about a famous movie series. Thus, we employ a CNN over word embeddings to learn contextual word representations by capturing local contexts. It takes the embedding sequence $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M]$ as input, and outputs a sequence of word contextual representation vectors $[\mathbf{c}_1^w, \mathbf{c}_2^w, ..., \mathbf{c}_M^w]$.

The third layer is a word-level attention network. Different words in the same sentence may have different informativeness in representing users and items. For example, in the sentence "This story book is very interesting" , the word "interesting" is more important than the word "story" in representing this book. Thus, we use an attention network over word representations to learn informative sentence representations by selecting important words. The attention weight of the i-th word w_i is computed as follows:

$$a_i^w = \tanh(\mathbf{w}_w \times \mathbf{c}_i^w + \mathbf{b}_w), \tag{1}$$

$$\alpha_i^w = \frac{\exp(a_i^w)}{\sum_{j=1}^{M} \exp(a_j^w)}, \tag{2}$$

where $\mathbf{w}_w$ and $\mathbf{b}_w$ are parameters. The final representation of the sentence s is the summation of the contextual word representations weighted by their attention weights, i.e., $\mathbf{s} = \sum_{i=1}^{M} \alpha_i^w \mathbf{c}_i^w$.

The *review encoder* module is used to learn representations of reviews from their sentence representations. There are two layers in the *review encoder* module. The first layer is a sentence-level CNN network. Neighboring sentences usually have some relatedness in their content. For example, in the book review "The book is very well written. I will recommend it to others", the two neighboring sentences have close relatedness and they both express positive opinion towards the book. Thus, we use a sentence-level CNN network to learn contextual sentence representations by capturing sentence-level local contexts. We denote the representation sequence of the sentences in a review r as $[\mathbf{s}_1, \mathbf{s}_2, ..., \mathbf{s}_N]$. The CNN layer takes the representation sequence as input, and outputs a sequence of contextual sentence representations, denoted as $[\mathbf{c}_1^s, \mathbf{c}_2^s, ..., \mathbf{c}_N^s]$.

The second layer is a sentence-level attention network. Different sentences in the same review may have different informativeness for modeling users and items. For example, the sentence "The book tells a good story" is more informative than the sentence "I read this book today" in representing this book. Thus, we use a sentence-level attention network to select important sentences to learn informative representations of reviews for recommendation. The attention weight α_i^s of the i-th sentence is formulated as follows:

$$a_i^s = \tanh(\mathbf{w}_s \times \mathbf{c}_i^s + \mathbf{b}_s), \tag{3}$$

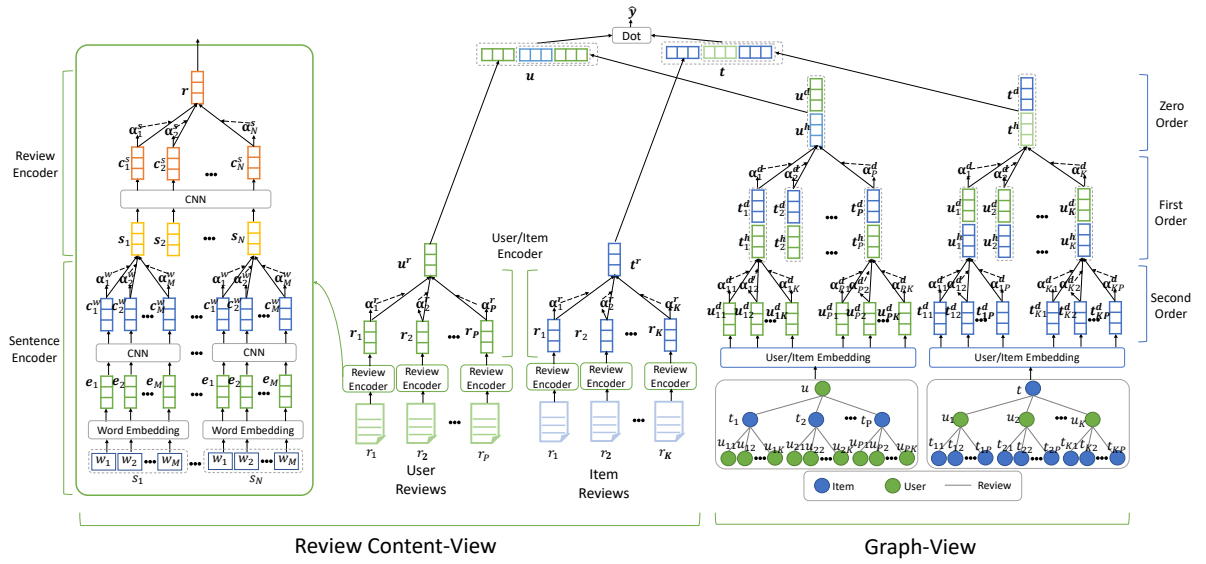

Figure 2: The framework of our *RMG* approach.

$$\alpha_i^s = \frac{\exp(a_i^s)}{\sum_{j=1}^{N} \exp(a_j^s)}, \tag{4}$$

where $\mathbf{w}_s$ and $\mathbf{b}_s$ are parameters in the attention network. The final contextual representation of the review r the summation of the contextual sentence representations weighted by their attention weights, i.e., $\mathbf{r} = \sum_{i=1}^{N} \alpha_i^s \mathbf{c}_i^s$. We apply the *review encoder* to encode the reviews of users and items into their representation vectors.

The *user/item encoder* is used to learn representations of users and items from the their review representations. Different reviews usually have different informativeness in characterizing users and items. For example, in Fig. 1, the first review of Item-1 is more informative than its second review. Thus, we use a review-level attention network to recognize informative reviews and attend to them. Denote the reviews written by a user as $[r_1, r_2, ..., r_P]$, where P is the number of reviews. The attention weight of the review r_i is formulated as follows:

$$a_i^r = \tanh(\mathbf{w}_r \times \mathbf{r}_i + \mathbf{b}_r), \tag{5}$$

$$\alpha_i^r = \frac{\exp(a_i^r)}{\sum_{j=1}^{P} \exp(a_j^r)}, \tag{6}$$

where $\mathbf{w}_r$ and $\mathbf{b}_r$ are parameters. The user representation learned from reviews is the summation of the review representations weighted by their attention weights, i.e., $\mathbf{u}^r = \sum_{i=1}^{P} \alpha_i^r \mathbf{r}_i$. Denote the K reviews commented on an item as $[r_1, r_2, ..., r_K]$. The item representation $\mathbf{t}^r$ learned from these reviews is computed similarly, i.e., $\mathbf{t}^r = \sum_{i=1}^{K} \alpha_i^r \mathbf{r}_i$, where α_i^r is the attention weight of the review r_i.

3.2 User-Item Graph View

The *graph-view* module is used to learn representations of users and items by modeling their interactions in the user-item bipartite graph, as shown in Fig. 2. In this bipartite graph, users and items are represented as nodes, and the interactions of user-item pairs are regarded as edges. However, different from typical graph neural networks (Veličković et al., 2017), the input of typical review-based recommender systems is only a user-item pair (two nodes with an edge) rather than the entire user-item graph. Therefore, it is difficult to directly capture high-order interactions between users and items via a stacked graph neural networks. To solve this problem, in our approach we propose a hierarchical attentive graph neural network for recommendation which can model high-order user-item interactions. It contains three core components, i.e., *second-order* encoder, *first-order* encoder, and *zero-order* encoder. We will introduce each one as follows.

The first one is a *second-order* encoder. Since a user-item graph is bipartite, there are no edges among users (or items). Thus, it is difficult to directly model their relatedness. Luckily, users bought the same items may have some relatedness, as well as the items bought by the same users. Thus, we propose to indirectly mine the user-

user and item-item relatedness by modeling the second-order interactions in the user-item graph, as shown in Fig. 2. For each user-item pair (u, t) in the training set, we denote the items that this user gave ratings to as $[t_1, t_2, ..., t_P]$. Among these items, we denote the users who commented the i-th item as $[u_{i1}, u_{i2}, ..., u_{iK}]$. Motivated by typical graph neural networks (Veličković et al., 2017), we incorporate the embedding of user and item IDs as the node representation in the user-item graph, and then learn the representations of each item from the representations of the users who has commented this item. Usually different users who bought the same item may have different informativeness in representing this item. For example, in Fig. 1, the first user is more important than second user in representing the first item. Thus, we propose to use an attentive graph neural network to model the importance of the users that connected to the item node. Denote the representations of these users as $[\mathbf{u}_{i1}, \mathbf{u}_{i2}, ..., \mathbf{u}_{iK}]$. The attention weight a_{ij}^d of the j-th user who comments the item t_i is computed as:

$$a_{ij}^d = \tanh(\mathbf{w}_2 \times \mathbf{u}_{ij} + b_2), \tag{7}$$

$$\alpha_{ij}^d = \frac{\exp(a_{ij}^d)}{\sum_{k=1}^{K} \exp(a_{ik}^d)}, \tag{8}$$

where $\mathbf{w}_2$ and b_2 are parameters in this network. The user-based representation $\mathbf{t}_i^h$ of the item t_i is the summation of the embeddings of its related user weighted by their attention weights, which is formulated as:

$$\mathbf{t}_i^h = \sum_{k=1}^{K} \alpha_{ik}^d \mathbf{u}_{ik}, \tag{9}$$

The second one is a *first-order* encoder. Since some latent properties of this item may not be revealed by the interactions with users, we incorporate the embedding of item IDs to enhance representation learning. The final representation of node t_i is the concatenation of the item node representation $\mathbf{t}_i^h$ learned from user node representations and the item ID embedding $\mathbf{t}_i^d$, i.e., $\mathbf{t}_i = [\mathbf{t}_i^h, \mathbf{t}_i^d]$. The representations of the users (denoted as $[\mathbf{u}_1, \mathbf{u}_2, ..., \mathbf{u}_K]$) who interact with the item t are computed similarly. Similar with the *second-order* encoder, we first learn the item-based representation $\mathbf{u}^h$ of the user u from the representations of its neighbor item nodes in an attentive manner. Denote the attention weight of the i-th item that the user u commented as a_i^d, which is computed as:

$$a_i^d = \tanh(\mathbf{w}_1 \times \mathbf{t}_i + b_1), \tag{10}$$

$$\alpha_i^d = \frac{\exp(a_i^d)}{\sum_{p=1}^{P} \exp(a_p^d)}, \tag{11}$$

where $\mathbf{w}_1$ and b_1 are parameters. The item-based representation $\mathbf{u}^h$ of the user u is the summation of the item representations associated with this user weighted by their attention weights, which is formulated as:

$$\mathbf{u}^h = \sum_{p=1}^{P} \alpha_p^d \mathbf{t}_p, \tag{12}$$

The third one is *zero-order* encoder. It learns the graph-based representation of user u by using the concatenation of the user node representation $\mathbf{u}^h$ and the user ID embedding $\mathbf{u}^d$, i.e., $\mathbf{u}^g = [\mathbf{u}^h, \mathbf{u}^d]$. The representation of the item t is computed similarly. Denote the representation of the item t learned from user-item interactions as $\mathbf{t}^h$, and the embedding of its ID as $\mathbf{t}^d$. Then its graph-based representation $\mathbf{t}^g$ is calculated as $\mathbf{t}^g = [\mathbf{t}^h, \mathbf{t}^d]$.

3.3 Rating Scoring

In our approach, the final representations of users and items are the concatenation of the representations learned from the review content-view and graph-view, i.e., $\mathbf{u} = [\mathbf{u}^g, \mathbf{u}^r]$ and $\mathbf{t} = [\mathbf{t}^g, \mathbf{t}^r]$. The rating score of a user-item pair is predicted by the inner product of user and item representations, i.e., $\hat{y} = \mathbf{u}^T \mathbf{t}$.

3.4 Model Training

For model training, mean squared error is used as the loss function:

$$\mathcal{L} = \frac{1}{T} \sum_{i=1}^{T} (\hat{y}_i - y_i)^2, \tag{13}$$

where T denotes the number of user-item pairs for training, $\hat{y}_i$ and y_i respectively denote the predicted and gold rating score of the i-th user-item pair. By optimizing the loss function, all parameters can be tuned via backward propagation.

4 Experiments

4.1 Datasets and Experimental Settings

We conducted experiments on four widely used benchmark datasets in different domains and

Dataset	#users	#items	#reviews
Toys	19,412	11,924	167,597
Kindle	68,223	61,935	982,619
Movies	123,960	50,052	1,679,533
Yelp	199,445	119,441	3,072,129

Table 1: Statistics of the benchmark datasets.

scales to validate the effectiveness of our approach. Following (Chen et al., 2018), we used three datasets from the Amazon collection[1](He and McAuley, 2016), i.e., *Toys_and_Games*, *Kindle_Store*, and *Movies_and_TV* (respectively denoted as *Toys*, *Kindle* and *Movies*). Another dataset is from Yelp Challenge 2017[2] (denoted as **Yelp**), which is a large collection of restaurant reviews. Following (Chen et al., 2018), we only kept the users and items which have at least 5 reviews. The detailed statistics of the four datasets are summarized in Table 1. The ratings in these datasets are ranged in [1, 5].

In our experiments, the word embeddings were 300-dimensional. We used the pre-trained Google embedding (Mikolov et al., 2013) for initialization. The CNNs had 150 filters and their window sizes were set to 3. The user and item embedding vector was 100-dimensional. We applied 25% dropout (Srivastava et al., 2014) to each layer in our model to mitigate overfitting. Adam (Kingma and Ba, 2014) was used as the optimization algorithm. The batch size was set to 20. We randomly selected 80% of the user-item pairs in each dataset for training, 10% for validation and 10% for test. All hyperparameters were tuned according to the validation set. We independently repeated each experiment 5 times and reported the average Root Mean Square Error (RMSE).

4.2 Performance Evaluation

We evaluate the performance of our approach by comparing it with several baseline methods[3]. The methods to be compared include:

- *PMF*: Probabilistic Matrix Factorization, which models users and items based on ratings via matrix factorization (Mnih and Salakhutdinov, 2008).
- *NMF*: Non-negative Matrix Factorization for recommendation based on rating scores (Lee and Seung, 2001).
- *SVD++*: The recommendation method based on rating matrix via SVD and similarities between items (Koren, 2008).
- *HFT*: Hidden Factor as Topic (HFT), a method to combine reviews with ratings via LDA (McAuley and Leskovec, 2013).
- *DeepCoNN*: Deep Cooperative Neural Networks, a neural method to jointly model users and items from their reviews via CNN (Zheng et al., 2017).
- *Attn+CNN*: Attention-based CNN, which uses both CNN and attention over word embeddings to learn user and item representation from reviews (Seo et al., 2017b).
- *NARRE*: Neural Attentional Rating Regression with Review-level Explanations, which uses attention mechanism to model the informativeness of reviews for recommendation (Chen et al., 2018).
- *RMG-review*: A variant of our approach with the review content-view only.
- *RMG*: Our reviews meet graphs approach.

In Table 2, we present a simple comparison of different methods by summarizing the information they incorporated. Traditional matrix factorization methods such as *PMF*, *NMF* and *SVD++* learn user and item representations based on review ratings only, while other methods can exploit both rating scores and reviews texts to learn representations for recommendation. Among these methods, *HFT* is based on topic models and cannot effectively utilize the contexts and word orders of words. *DeepCoNN* and *Attn+CNN* simply concatenate all reviews into a long document, and cannot model the informativeness of different reviews. Although *NARRE* can model review informativeness using a review-level attention network, it simply aggregates all sentences and cannot model the informativeness of words and sentences. *RMG-review* can simultaneously recognize important word, sentences and reviews, but does not consider the information in user-item graphs. Different from these methods, our *RMG*

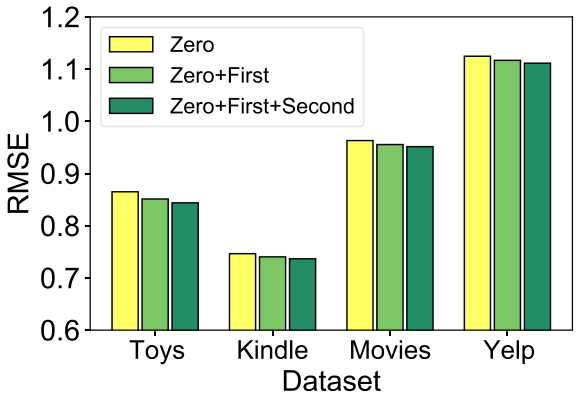

Figure 3: The influence of the depth of the hierarchical attentive graph neural network.

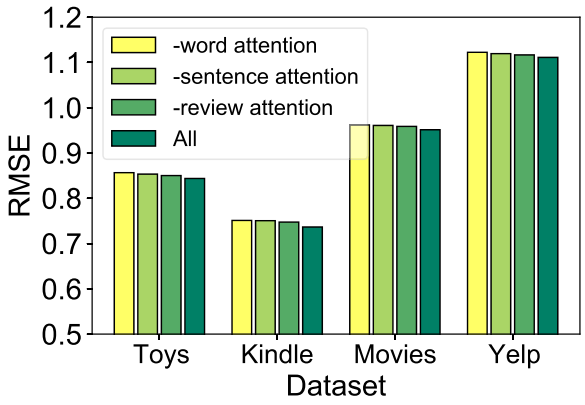
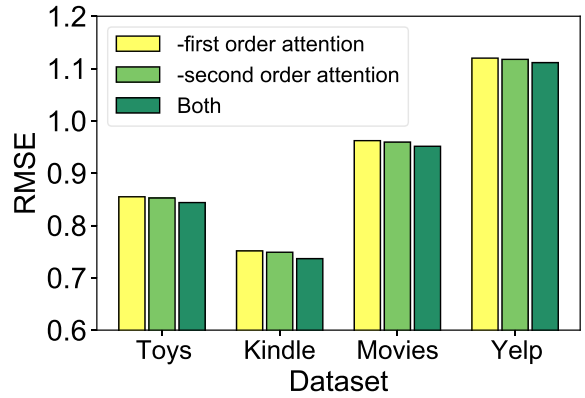
approach can learn user and item representations from both reviews and graphs, which has the potential to learn more informative user and item representations.

The performance of different methods is summarized in Table 3. The results lead to several observations. First, the methods which combine reviews and ratings (e.g., *HFT*, *DeepCoNN*, *NARRE* and *RMG*) usually outperform the methods based on ratings only (*PMF*, *NMF* and *SVD++*). This is probably because reviews usually contain rich clues on user preferences and item properties, which is useful for user and item representation learning for recommendation.



Second, among the methods considering the content information of reviews, neural network based methods (e.g., *DeepCoNN*, *Attn+CNN*, *NARRE* and *RMG*) usually outperform *HFT*, which is based on topic models. This is probably because *HFT* rely on bag-of-words features to extract topics from reviews, and cannot utilize the contexts and orders of words. Different from topic model based methods, neural methods can better model user preferences and item properties by utilizing the rich semantic information in reviews, which is beneficial for recommendation.

Third, among the methods based on deep learning, *RMG-review* and *RMG* can consistently outperform other baseline methods. This is because different words, sentences and reviews usually have different informativeness for modeling users and items. Different from *Attn+CNN*, *NARRE* and *DeepCoNN*, both *RMG-review* and *RMG* use a hierarchical model to learn user and item representations. In addition, our approach can select important words, sentences and reviews via a three-level attention network to help learn more accurate user and item representations for recommendation.



Fourth, our *RMG* approach which incorporates information of user-item graph outperforms other methods based on reviews only (e.g., *RMG-review*), and further hypothesis test results show that the advantage over *RMG-review* is significant. This is because the information of user-item graphs is useful for recommendation, and modeling the interactions between users amd items in graphs can help learn more accurate user and item representations. This result validates the effectiveness of our approach.

4.3 Influence of the Depth of Graph Neural Network

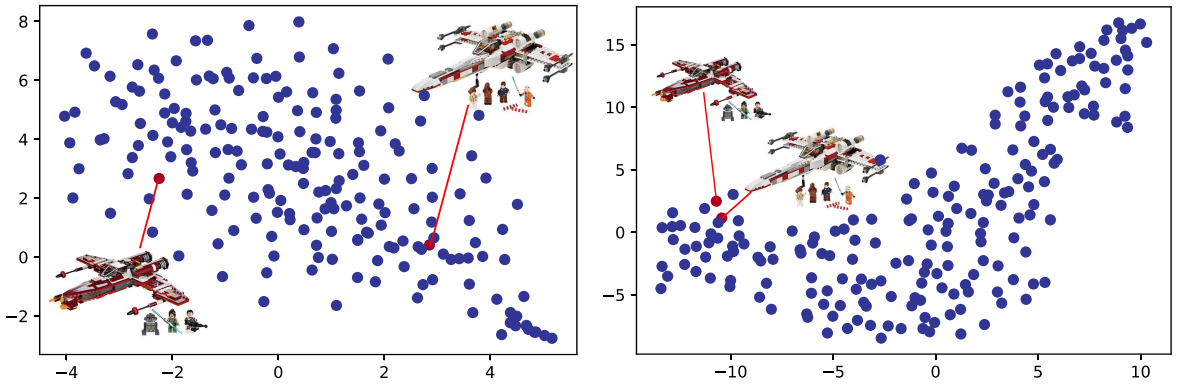
In this section, we conducted several experiments to explore the influence of the depth of the graph neural network on our approach. We compare the performance of our approach with its variants

(a) Attentions in the review content-view.

(b) Attentions in the graph-view.

Figure 4: The effectiveness of different attentions.

with the zero-order encoder only or with both the zero- and first-order encoder. The results are illustrated in Fig. 3. According to the results, we find the performance of our approach can be consistently improved as the depth increases. This is because the first-order information of graph contains the interactions between users and items, and the second-order information can reveal the user-user and item-item relatedness. Thus, more information can be incorporated as the depth increases, which can benefit user and item representation learning. Although the performance may be further improved when the depth gets deeper, in our approach we only set the depth of the graph neural network to 2. This is because the user-item, user-user and item-item interactions are usually sufficient for modeling users and items, and their high-order relatedness is usually weak. In addition, the computational cost is huge when higher-order information is considered. Thus, a moderate depth of the graph neural network (i.e., 2) is the most appropriate for our approach.



4.4 Effectiveness of Attention Mechanism

In this section, we conducted experiments to explore the effectiveness of the attention networks in our approach. First, we want to validate the effectiveness of the attention network in the review content-view. We compare the performance of several variants of our approach with one kind of attention network removed to evaluate the contribution of different attentions. The results are shown in Fig. 4(a). From Fig. 4(a), the word-level attention can effectively improve the performance of our approach. This is because different words in the same review have different importance in representing this review. Therefore, selecting important words via a word-level attention network can learn more informative sentence representations. In addition, the sentence-level attention is also useful. This is because different sentences also have different informativeness, and selecting important sentences using a sentence-level attention network can benefit review representation learning. Besides, the review-level attention is also useful in our approach. This is because different reviews have different informativeness for learning user and item representations, and distinguishing informative reviews from the uninformative ones can help learn more accurate user and item representations. Moreover, combining all three kinds of attentions can further improve our approach, which validates the effectiveness of our hierarchical attention framework.

Then, we want to validate the effectiveness of the attention network in the graph-view. We compare our approach with its variants by removing the attention networks in the first-order or second-order encoder to validate the effectiveness of them. The results are shown in Fig. 4(b). According to Fig. 4(b), we find the attention networks in both first- and second-order encoders are important in our approach. This may be because the interactions between users and items usually have different importance in representing them, and distinguish informative interactions from uninformative ones is useful for learning better user and item representations. These results validate the effectiveness of the attention networks in the graph-view.

4.5 Case Study

In this section, we conducted several case studies to visually explore our *RMG* approach can learn better user and item representations. For instance,

(a) *RMG-review* (b) *RMG*

Figure 5: Visualization of the item representations learned by *RMG-review* and *RMG* via t-SNE. Each point represents an item. The red points represent two similar items.

we use t-SNE to visualize the representations of several randomly selected items in the *Toys* dataset learned by *RMG-review* and *RMG*. Among these items there are two very similar items, both of which are Lego toys of the planes in Star Wars. The results are respectively shown in Fig. 5(a) and 5(b)[4]. From the results, we find the distance between the representations of these two items learned by *RMG-review* is large, which usually indicates their similarity is low. This may be because the reviews of both items are insufficient (only 3 reviews appeared in the training set), making it difficult for *RMG-review* to learn accurate representations of them. Different from *RMG-review*, our *RMG* approach can correctly recognize that both items are very similar. This is probably because our approach can mine the user-user and item-item relatedness by modeling the first-order and second-order interactions between users and items. Thus, our *RMG* approach can learn better user and item representations.

5 Conclusion and Future Work

In this paper, we propose a reviews meet graphs approach for recommendation which can exploit information of user-item graphs. In our approach, we use a multi-view framework to incorporate review texts and user-item graphs as different views. In the review content-view, we use a hierarchical model to first learn sentence representations from words, then learn review representations from sentences, and finally learn user/item representations from reviews. In addition, we apply a three-level attention network to select important words, sentences and reviews for informative representation learning. In the graph-view, we propose to use a graph neural network to jointly mine user-item, user-user and item-item relatedness by modeling the first- and second-order interactions between users and items in graphs. In addition, we propose to apply attention mechanism to model the importance of these interactions to learn more accurate user and item representations. Experiments on four benchmark datasets validate the effectiveness of our approach.

In our future work, we will explore several potential directions. First, since we only use the local neighbors of nodes in the user-item graph, we will explore the use of other kinds of graph neural networks to further enhance the learning of users and items. Second, since there are also other kinds of user and item information, we will explore how to incorporate heterogeneous user and item information to benefit recommendation. Third, we will work on how to reduce the computational cost of our approach, which can improve the applicability of our approach.

Event Representation Learning Enhanced with External Commonsense Knowledge

Xiao Ding, Kuo Liao, Ting Liu*, Zhongyang Li, Junwen Duan

{xding, kliao, tliu, zyli, jwduan}@ir.hit.edu.cn

Abstract

Prior work has proposed effective methods to learn event representations that can capture syntactic and semantic information over text corpus, demonstrating their effectiveness for downstream tasks such as script event prediction. On the other hand, events extracted from raw texts lacks of commonsense knowledge, such as the intents and emotions of the event participants, which are useful for distinguishing event pairs when there are only subtle differences in their surface realizations. To address this issue, this paper proposes to leverage external commonsense knowledge about the intent and sentiment of the event. Experiments on three event-related tasks, i.e., event similarity, script event prediction and stock market prediction, show that our model obtains much better event embeddings for the tasks, achieving 78% improvements on hard similarity task, yielding more precise inferences on subsequent events under given contexts, and better accuracies in predicting the volatilities of the stock market[1].

1 Introduction

Events are a kind of important *objective* information of the world. Structuralizing and representing such information as machine-readable knowledge are crucial to artificial intelligence (Li et al., 2018b, 2019). The main idea is to learn distributed representations for structured events (i.e. event embeddings) from text, and use them as the basis to induce textual features for downstream applications, such as script event prediction and stock market prediction.

Parameterized additive models are among the most widely used for learning distributed event representations in prior work (Granroth-Wilding and Clark, 2016; Modi, 2016), which passes the concatenation or addition of event arguments' word embeddings to a parameterized function. The function maps the summed vectors into an event embedding space. Furthermore, Ding et al. (2015) and Weber et al. (2018) propose using neural tensor networks to perform semantic composition of event arguments, which can better capture the interactions between event arguments.

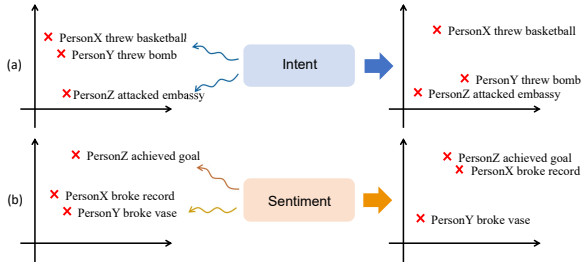

Figure 1: Intent and sentiment enhanced event embeddings can distinguish distinct events even with high lexical overlap, and find similar events even with low lexical overlap.

This line of work only captures shallow event semantics, which is not capable of distinguishing events with subtle differences. On the one hand, the obtained event embeddings cannot capture the relationship between events that are syntactically or semantically similar, if they do not share similar word vectors. For example, as shown in Figure 1 (a), "*PersonX threw bomb*" and "*PersonZ attacked embassy*". On the other hand, two events with similar word embeddings may have similar embeddings despite that they are quite unrelated, for example, as shown in Figure 1 (b), "*PersonX broke record*" and "*PersonY broke vase*". Note that in this paper, similar events generally refer to events with strong semantic relationships rather than just the same events.

One important reason for the problem is the lack

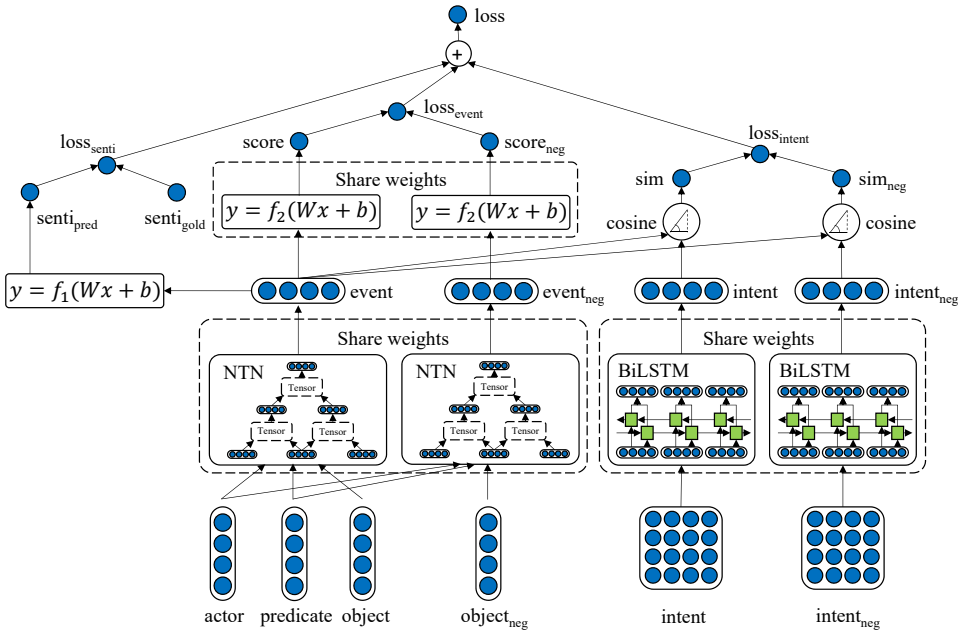

Figure 2: Architecture of the joint embedding model. $event_{neg}$ refers to the corrupted event tuple, which is derived by replacing each word of the event object with a random word in our dictionary. $intent_{neg}$ is the incorrect intent for the given event, which is randomly selected from the annotated dataset.

of the external commonsense knowledge about the mental state of event participants when learning the *objective* event representations. In Figure 1 (a), two event participants "*PersonY*" and "*PersonZ*" may carry out a terrorist attack, and hence, they have the same intent: "*to bloodshed*", which can help representation learning model maps two events into the neighbor vector space. In Figure 1 (b), a change to a single argument leads to a large semantic shift in the event representations, as the change of an argument can result in different emotions of event participants. Who "*broke the record*" is likely to be happy, while, who "*broke a vase*" may be sad. Hence, intent and sentiment can be used to learn more fine-grained semantic features for event embeddings.

Such commonsense knowledge is not explicitly expressed but can be found in a knowledge base such as Event2Mind (Rashkin et al., 2018) and ATOMIC (Sap et al., 2019). Thus, we aim to incorporate the external commonsense knowledge, i.e., **intent** and **sentiment**, into the learning process to generate better event representations. Specifically, we propose a simple and effective model to jointly embed events, intents and emotions into the same vector space. A neural tensor network is used to learn baseline event embeddings, and we define a corresponding loss function to incorporate intent and sentiment information.

Extensive experiments show that incorporating external commonsense knowledge brings promising improvements to event embeddings, achieving 78% and 200% improvements on hard similarity small and big dataset, respectively. With better embeddings, we can achieve superior performances on script event prediction and stock market prediction compared to state-of-the-art baseline methods.

2 Commonsense Knowledge Enhanced Event Representations

The joint embedding framework is shown in Figure 2. We begin by introducing the baseline event embedding learning model, which serves as the basis of the proposed framework. Then, we show how to model intent and sentiment information. Subsequently, we describe the proposed joint model by integrating intent and sentiment into the original objective function to help learn high-quality event representations, and introduce the training details.

2.1 Low-Rank Tensors for Event Embedding

The goal of event embedding is to learn low-dimension dense vector representations for event tuples $E = (A, P, O)$, where P is the action or predicate, A is the actor or subject and O is the object on which the action is performed. Event

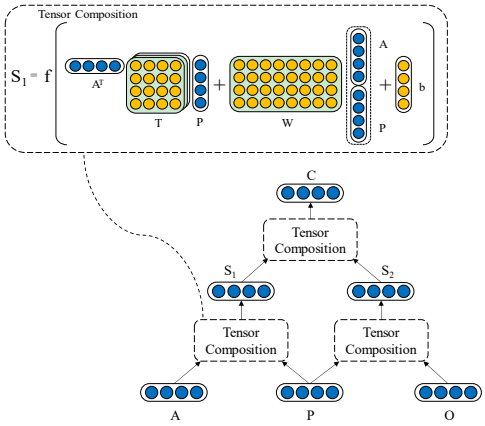

Figure 3: Baseline event-embedding model.

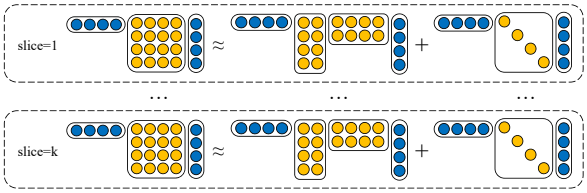

Figure 4: An illustration of low-rank neural tensor network for learning event embeddings.

embedding models compound vector representations over its predicate and arguments representations. The challenge is that the composition models should be effective for learning the interactions between the predicate and the argument. Simple additive transformations are incompetent.

We follow Ding et al. (2015) modelling such informative interactions through tensor composition. The architecture of neural tensor network (NTN) for learning event embeddings is shown in Figure 3, where the bilinear tensors are used to explicitly model the relationship between the actor and the action, and that between the object and the action.

The inputs of NTN are the word embeddings of A, P and O, and the outputs are event embeddings. We initialized our word representations using publicly available d-dimensional ($d = 100$) GloVe vectors (Pennington et al., 2014). As most event arguments consist of several words, we represent the actor, action and object as the average of their word embeddings, respectively.

From Figure 3, $S_1 \in \mathbb{R}^d$ is computed by:

$$S_1 = f\left(A^T T_1^{[1:k]} P + W \begin{bmatrix} A \\ P \end{bmatrix} + b\right)$$
$$g(S_1) = g(A, P) = U^T S_1 \quad (1)$$

where $T_1^{[1:k]} \in \mathbb{R}^{d \times d \times k}$ is a tensor, which is a set of k matrices, each with $d \times d$ dimensions. The bilinear tensor product $A^T T_1^{[1:k]} P$ is a vector $r \in \mathbb{R}^k$, where each entry is computed by one slice of the tensor ($r_i = A^T T_1^{[i]} P, i = 1, \cdots, k$). The other parameters are a standard feed-forward neural network, where $W \in \mathbb{R}^{k \times 2d}$ is the weight matrix, $b \in \mathbb{R}^k$ is the bias vector, $U \in \mathbb{R}^k$ is a hyper-parameter and $f = tanh$ is a standard nonlinearity applied element-wise. S_2 and C in Figure 3 are computed in the same way as S_1.

One problem with tensors is *curse of dimensionality*, which limits the wide application of tensors in many areas. It is therefore essential to approximate tensors of higher order in a compressed scheme, for example, a low-rank tensor decomposition. To decrease the number of parameters in standard neural tensor network, we make low-rank approximation that represents each matrix by two low-rank matrices plus diagonal, as illustrated in Figure 4. Formally, the parameter of the i-th slice is $T_{appr}^{[i]} = T^{[i_1]} \times T^{[i_2]} + diag(t^{[i]})$, where $T^{[i_1]} \in \mathbb{R}^{d \times n}$, $T^{[i_2]} \in \mathbb{R}^{n \times d}$, $t^{[i]} \in \mathbb{R}^d$, n is a hyper-parameter, which is used for adjusting the degree of tensor decomposition. The output of neural tensor layer is formalized as follows.

$$S_1 = f\left(A^T [T_{appr}]_1^{[1:k]} P + W \begin{bmatrix} A \\ P \end{bmatrix} + b\right), \quad (2)$$

where $[T_{appr}]_1^{[1:k]}$ is the low-rank tensor that defines multiple low-rank bilinear layers. k is the slice number of neural tensor network which is also equal to the output length of S_1.

We assume that event tuples in the training data should be scored higher than corrupted tuples, in which one of the event arguments is replaced with a random argument. Formally, the corrupted event tuple is $E^r = (A^r, P, O)$, which is derived by replacing each word in A with a random word w^r in our dictionary $\mathcal{D}$ (which contains all the words in the training data) to obtain a corrupted counterpart A^r. We calculate the *margin loss* of the two event tuples as:

$$\mathcal{L}_\mathcal{E} = loss(E, E^r) = \max(0, 1 - g(E) + g(E^r)) + \lambda \|\Phi\|_2^2, \quad (3)$$

where $\Phi = (T_1, T_2, T_3, W, b)$ is the set of model parameters. The standard L_2 regularization is used, for which the weight λ is set as 0.0001. The

algorithm goes over the training set for multiple iterations. For each training instance, if the loss $loss(E, E^r) = \max(0, 1-g(E)+g(E^r))$ is equal to zero, the online training algorithm continues to process the next event tuple. Otherwise, the parameters are updated to minimize the loss using back-propagation (Rumelhart et al., 1985).

2.2 Intent Embedding

Intent embedding refers to encoding the event participants' intents into event vectors, which is mainly used to explain why the actor performed the action. For example, given two events "*PersonX threw basketball*" and "*PersonX threw bomb*", there are only subtle differences in their surface realizations, however, the intents are totally different. "*PersonX threw basketball*" is just for fun, while "*PersonX threw bomb*" could be a terrorist attack. With the intents, we can easily distinguish these superficial similar events.

One challenge for incorporating intents into event embeddings is that we should have a large-scale labeled dataset, which annotated the event and its actor's intents. Recently, Rashkin et al. (2018) and Sap et al. (2019) released such valuable commonsense knowledge dataset (ATOMIC), which consists of 25,000 event phrases covering a diverse range of daily-life events and situations. For example, given an event "*PersonX drinks coffee in the morning*", the dataset labels *PersonX*'s likely intent is "*PersonX wants to stay awake*".

We notice that the intents labeled in ATOMIC is a sentence. Hence, intent embedding is actually a sentence representation learning task. Among various neural networks for encoding sentences, bi-directional LSTMs (BiLSTM) (Hochreiter and Schmidhuber, 1997) have been a dominant method, giving state-of-the-art results in language modelling (Peters et al., 2018) and syntactic parsing (Dozat and Manning, 2016).

We use BiLSTM model to learn intent representations. BiLSTM consists of two LSTM components, which process the input in the forward left-to-right and the backward right-to-left directions, respectively. In each direction, the reading of input words is modelled as a recurrent process with a single hidden state. Given an initial value, the state changes its value recurrently, each time consuming an incoming word.

Take the forward LSTM component for example. Denoting the initial state as $\overrightarrow{\boldsymbol{h}}^0$, which is a model parameter, it reads the input word representations $\boldsymbol{x}_0, \boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$, and the recurrent state transition step for calculating $\overrightarrow{\boldsymbol{h}}^1, \ldots, \overrightarrow{\boldsymbol{h}}^{n+1}$ is defined as Graves and Schmidhuber (2005).

The backward LSTM component follows the same recurrent state transition process as the forward LSTM component. Starting from an initial state $\overleftarrow{\boldsymbol{h}}^{n+1}$, which is a model parameter, it reads the input $\boldsymbol{x}_n, \boldsymbol{x}_{n-1}, \ldots, \boldsymbol{x}_0$, changing its value to $\overleftarrow{\boldsymbol{h}}^n, \overleftarrow{\boldsymbol{h}}^{n-1}, \ldots, \overleftarrow{\boldsymbol{h}}^0$, respectively.

The BiLSTM model uses the concatenated value of $\overrightarrow{\boldsymbol{h}}^t$ and $\overleftarrow{\boldsymbol{h}}^t$ as the hidden vector for w_t:

$$\boldsymbol{h}^t = [\overrightarrow{\boldsymbol{h}}^t; \overleftarrow{\boldsymbol{h}}^t] \quad (4)$$

A single hidden vector representation $\boldsymbol{v}_i$ of the input intent can be obtained by concatenating the last hidden states of the two LSTMs:

$$\boldsymbol{v}_i = [\overrightarrow{\boldsymbol{h}}^{n+1}; \overleftarrow{\boldsymbol{h}}^0] \quad (5)$$

In the training process, we calculate the similarity between a given event vector $\boldsymbol{v}_e$ and its related intent vector $\boldsymbol{v}_i$. For effectively training the model, we devise a ranking type loss function as follows:

$$\mathcal{L}_{\mathcal{I}} = max(0, 1 - cosine(\boldsymbol{v}_e, \boldsymbol{v}_i) + cosine(\boldsymbol{v}_e, \boldsymbol{v}_i')) \quad (6)$$

where $\boldsymbol{v}_i'$ is the incorrect intent for $\boldsymbol{v}_e$, which is randomly selected from the annotated dataset.

2.3 Sentiment Embedding

Sentiment embedding refers to encoding the event participants' emotions into event vectors, which is mainly used to explain how does the actor feel after the event. For example, given two events "*PersonX broke record*" and "*PersonX broke vase*", there are only subtle differences in their surface realizations, however, the emotions of *PersonX* are totally different. After "*PersonX broke record*", *PersonX* may be feel happy, while after "*PersonX broke vase*", *PersonX* could be feel sad. With the emotions, we can also effectively distinguish these superficial similar events.

We also use ATOMIC (Sap et al., 2019) as the event sentiment labeled dataset. In this dataset, the sentiment of the event is labeled as words. For example, the sentiment of "*PersonX broke vase*" is labeled as "(*sad, be regretful, feel sorry, afraid*)". We use SenticNet (Cambria et al., 2018) to normalize these emotion words ($W = \{w_1, w_2, \ldots, w_n\}$) as the positive (labeled as 1) or

the negative (labeled as -1) sentiment. The sentiment polarity of the event P_e is dependent on the polarity of the labeled emotion words P_W: $P_e = 1$, if $\sum_i P_{w_i} > 0$, or $P_e = -1$, if $\sum_i P_{w_i} < 0$. We use the softmax binary classifier to learn sentiment enhanced event embeddings. The input of the classifier is event embeddings, and the output is its sentiment polarity (positive or negative). The model is trained in a supervised manner by minimizing the cross entropy error of the sentiment classification, whose loss function is given below.

$$\mathcal{L}_{\mathcal{S}} = -\sum_{x_e \in C} \sum_{l \in L} p_l^g(x_e) \cdot log(p_l(x_e)) \quad (7)$$

where C means all training instances, L is the collection of sentiment categories, x_e means an event vector, $p_l(x_e)$ is the probability of predicting x_e as class l, $p_l^g(x_e)$ indicates whether class l is the correct sentiment category, whose value is 1 or -1.

2.4 Joint Event, Intent and Sentiment Embedding

Given a training event corpus with annotated intents and emotions, our model jointly minimizes a linear combination of the loss functions on events, intents and sentiment:

$$\mathcal{L} = \alpha\mathcal{L}_{\mathcal{E}} + \beta\mathcal{L}_{\mathcal{I}} + \gamma\mathcal{L}_{\mathcal{S}} \quad (8)$$

where $\alpha, \beta, \gamma \in [0, 1]$ are model parameters to weight the three loss functions.

We use the New York Times Gigaword Corpus (LDC2007T07) for pre-training event embeddings. Event triples are extracted based on the Open Information Extraction technology (Schmitz et al., 2012). We initialize the word embedding layer with 100 dimensional pre-trained GloVe vectors (Pennington et al., 2014), and fine-tune initialized word vectors during our model training. We use Adagrad (Duchi et al., 2011) for optimizing the parameters with initial learning rate 0.001 and batch size 128.

3 Experiments

We compare the performance of intent and sentiment powered event embedding model with state-of-the-art baselines on three tasks: event similarity, script event prediction and stock prediction.

3.1 Baselines

We compare the performance of our approach against a variety of event embedding models developed in recent years. These models can be categorized into three groups:

- **Averaging Baseline (Avg)** This represents each event as the average of the constituent word vectors using pre-trained GloVe embeddings (Pennington et al., 2014).
- **Compositional Neural Network (Comp. NN)** The event representation in this model is computed by feeding the concatenation of the subject, predicate, and object embedding into a two layer neural network (Modi and Titov, 2013; Modi, 2016; Granroth-Wilding and Clark, 2016).
- **Element-wise Multiplicative Composition (EM Comp.)** This method simply concatenates the element-wise multiplications between the verb and its subject/object.
- **Neural Tensor Network** This line of work use tensors to learn the interactions between the predicate and its subject/object (Ding et al., 2015; Weber et al., 2018). According to the different usage of tensors, we have three baseline methods: **Role Factor Tensor** (Weber et al., 2018) which represents the predicate as a tensor, **Predicate Tensor** (Weber et al., 2018) which uses two tensors learning the interactions between the predicate and its subject, and the predicate and its object, respectively, **NTN** (Ding et al., 2015), which we used as the baseline event embedding model in this paper, and **KGEB** (Ding et al., 2016), which incorporates knowledge graph information in NTN.

3.2 Event Similarity Evaluation

3.2.1 Hard Similarity Task

We first follow Weber et al. (2018) evaluating our proposed approach on the hard similarity task. The goal of this task is that similar events should be close to each other in the same vector space, while dissimilar events should be far away with each other. To this end, Weber et al. (2018) created two types of event pairs, one with events that should be close to each other but have very little lexical overlap (e.g., police catch robber / authorities apprehend suspect), and another with events that should be farther apart but have high overlap (e.g., police catch robber / police catch disease).

Method	Hard Similarity (*Accuracy* %) Small Dataset	Big Dataset	Transitive Sentence Similarity (ρ)
Avg	5.2	13.7	0.67
Comp. NN	33.0	18.9	0.63
EM Comp.	33.9	18.7	0.57
Role Factor Tensor	43.5	20.7	0.64
Predicate Tensor	41.0	25.6	0.63
KGEB	52.6	49.8	0.61
NTN	40.0	37.0	0.60
NTN+Int	65.2	58.1	0.67
NTN+Senti	54.8	52.2	0.61
NTN+Int+Senti	**77.4**	**62.8**	**0.74**

Table 1: Experimental results on hard similarity dataset and transitive sentence similarity dataset. The small dataset (230 event pairs) of hard similarity task from Weber et al. (2018), and the big dataset (2,000 event pairs) is annotated by us. The best results are in bold.

The labeled dataset contains 230 event pairs (115 pairs each of similar and dissimilar types). Three different annotators were asked to give the similarity/dissimilarity rankings, of which only those the annotators agreed upon completely were kept. For each event representation learning method, we obtain the cosine similarity score of the pairs, and report the fraction of cases where the similar pair receives a higher cosine value than the dissimilar pair (we use *Accuracy* $\in [0, 1]$ denoting it). To evaluate the robustness of our approach, we extend this dataset to 1,000 event pairs (similar and dissimilar events each account for 50%), and we will release this dataset to the public.

3.2.2 Transitive Sentence Similarity

Except for the hard similarity task, we also evaluate our approach on the transitive sentence similarity dataset (Kartsaklis and Sadrzadeh, 2014), which contains 108 pairs of transitive sentences: short phrases containing a single subject, object and verb (e.g., agent sell property). It also has another dataset which consists of 200 sentence pairs. In this dataset, the sentences to be compared are constructed using the same subject and object and semantically correlated verbs, such as 'spell' and 'write'; for example, 'pupils write letters' is compared with 'pupils spell letters'. As this dataset is not suitable for our task, we only evaluate our approach and baselines on 108 sentence pairs.

Every pair is annotated by a human with a similarity score from 1 to 7. For example, pairs such as (design, reduce, amount) and (company, cut, cost) are annotated with a high similarity score, while pairs such as (wife, pour, tea) and (worker, join, party) are given low similarity scores. Since each pair has several annotations, we use the average annotator score as the gold score[2]. To evaluate the cosine similarity given by each model and the annotated similarity score, we use the Spearman's correlation ($\rho \in [-1, 1]$).

3.2.3 Results

Experimental results of hard similarity and transitive sentence similarity are shown in Table 1. We find that:

(1) Simple averaging achieved competitive performance in the task of transitive sentence similarity, while performed very badly in the task of hard similarity. This is mainly because hard similarity dataset is specially created for evaluating the event pairs that should be close to each other but have little lexical overlap and that should be farther apart but have high lexical overlap. Obviously, on such dataset, simply averaging word vectors which is incapable of capturing the semantic interactions between event arguments, cannot achieve a sound performance.

(2) Tensor-based compositional methods (NTN, KGEB, Role Factor Tensor and Predicate Tensor) outperformed parameterized additive models (Comp. NN and EM Comp.), which shows that tensor is capable of learning the semantic composition of event arguments.

(3) Our commonsense knowledge enhanced event representation learning approach outperformed all baseline methods across all datasets (achieving 78% and 200% improvements on hard similarity small and big dataset, respectively, compared to previous SOTA method), which indicates that commonsense knowledge is useful for distinguishing distinct events.

[2]To directly compare with baseline methods (Weber et al., 2018), this paper compares with averaged annotator scores, other than comparing with every annotator scores.

Event1	Event 2	oScore	mScore	Event1	Event 2	oScore	mScore
man clears test	he passed exam	-0.08	0.40	man passed car	man passed exam	0.81	0.12
he grind corn	cook chops beans	0.31	0.81	he grind corn	he grind teeth	0.89	0.36
he made meal	chef cooked pasta	0.51	0.85	chef cooked pasta	chef cooked books	0.89	0.45
farmer load truck	person packs car	0.58	0.83	farmer load truck	farmer load gun	0.93	0.55
player scored goal	she carried team	0.19	0.44	she carried bread	she carried team	0.59	0.09

Table 2: Case study of the cosine similarity score changes with incorporating the intent and sentiment. oScore is the original cosine similarity score without intent and sentiment, and mScore is the modified cosine similarity score with intent and sentiment.

Methods	**Acc (%)**
SGNN	52.45
SGNN+Int	**53.93**
SGNN+Senti	53.57
SGNN+Int+Senti	53.88
SGNN+PairLSTM	52.71
SGNN+EventComp	54.15
SGNN+EventComp+PairLSTM	54.93
SGNN+PairLSTM+Int+Senti	54.14
SGNN+EventComp+Int+Senti	55.08
SGNN+EventComp+PairLSTM+Int+Senti	**56.03**

Table 3: Results of script event prediction on the test set. The improvement is significant at $p < 0.05$. Acc is short for Accuracy.

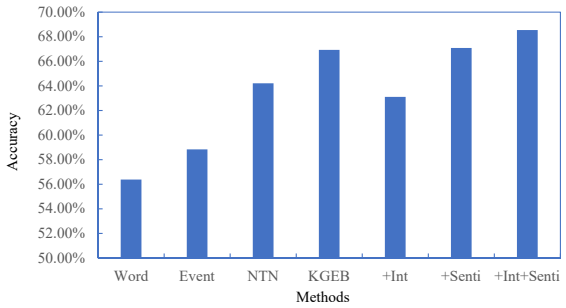

Figure 5: Experimental results on S&P 500 index prediction. "+Int" means that we encode the intent information into the original event embeddings.

3.2.4 Case Study

To further analyse the effects of intents and emotions on the event representation learning, we present case studies in Table 2, which directly shows the changes of similarity scores before and after incorporating intent and sentiment. For example, the original similarity score of two events "*chef cooked pasta*" and "*chef cooked books*" is very high (0.89) as they have high lexical overlap. However, their intents differ greatly. The intent of "*chef cooked pasta*" is "*to hope his customer enjoying the delicious food*", while the intent of "*chef cooked books*" is "*to falsify their financial statements*". Enhanced with the intents, the similarity score of the above two events dramatically drops to 0.45. For another example, as the event pair "*man clears test*" and "*he passed exam*" share the same sentiment polarity, their similarity score is boosted from -0.08 to 0.40.

3.3 Script Event Prediction

Event is a kind of important real-world knowledge. Learning effective event representations can be benefit for numerous applications. Script event prediction (Chambers and Jurafsky, 2008) is a challenging event-based commonsense reasoning task, which is defined as giving an existing event context, one needs to choose the most reasonable subsequent event from a candidate list.

Following Li et al. (2018a), we evaluate on the standard multiple choice narrative cloze (MCNC) dataset (Granroth-Wilding and Clark, 2016). As SGNN proposed by Li et al. (2018a) achieved state-of-the-art performances for this task, we use the framework of SGNN, and only replace their input event embeddings with our intent and sentiment-enhanced event embeddings.

Wang et al. (2017) and Li et al. (2018a) showed that script event prediction is a challenging problem, and even 1% of accuracy improvement is very difficult. Experimental results shown in Table 3 demonstrate that we can achieve more than 1.5% improvements in single model comparison and more than 1.4% improvements in multi-model integration comparison, just by replacing the input embeddings, which confirms that better event understanding can lead to better inference results. An interesting result is that the event embeddings only incorporated with intents achieved the best result against other baselines. This confirms that capturing people's intents is helpful to infer their next plan. In addition, we notice that the event embeddings only incorporated with sentiment also achieve better performance than SGNN. This is mainly because the emotional consistency does also contribute to predicate the subsequent event.

3.4 Stock Market Prediction

It has been shown that news events influence the trends of stock price movements (Luss and d'Aspremont, 2012). As news events affect human decisions and the volatility of stock prices is influenced by human trading, it is reasonable to say that events can influence the stock market.

In this section, we compare with several event-driven stock market prediction baseline methods: (1) **Word**, Luss and d'Aspremont (2012) use bag-of-words represent news events for stock prediction; (2) **Event**, Ding et al. (2014) represent events by subject-predicate-object triples for stock prediction; (3) **NTN**, Ding et al. (2015) learn continues event vectors for stock prediction; (4) **KGEB**, Ding et al. (2016) incorporate knowledge graph into event vectors for stock prediction.

Experimental results are shown in Figure 5. We find that knowledge-driven event embedding is a competitive baseline method, which incorporates world knowledge to improve the performances of event embeddings on the stock prediction. Sentiment is often discussed in predicting stock market, as positive or negative news can affect people's trading decision, which in turn influences the movement of stock market. In this study, we empirically show that event emotions are effective for improving the performance of stock prediction (+2.4%).

4 Related Work

Recent advances in computing power and NLP technology enables more accurate models of events with structures. Using open information extraction to obtain structured events representations, we find that the actor and object of events can be better captured (Ding et al., 2014). For example, a structured representation of the event above can be (Actor = *Microsoft*, Action = *sues*, Object = *Barnes & Noble*). They report improvements on stock market prediction using their structured representation instead of words as features.

One disadvantage of structured representations of events is that they lead to increased sparsity, which potentially limits the predictive power. Ding et al. (2015) propose to address this issue by representing structured events using *event embeddings*, which are dense vectors. The goal of event representation learning is that similar events should be embedded close to each other in the same vector space, and distinct events should be farther from each other.

Previous work investigated compositional models for event embeddings. Granroth-Wilding and Clark (2016) concatenate predicate and argument embeddings and feed them to a neural network to generate an event embedding. Event embeddings are further concatenated and fed through another neural network to predict the coherence between the events. Modi (2016) encodes a set of events in a similar way and use that to incrementally predict the next event – first the argument, then the predicate and then next argument. Pichotta and Mooney (2016) treat event prediction as a sequence to sequence problem and use RNN based models conditioned on event sequences in order to predict the next event. These three works all model narrative chains, that is, event sequences in which a single entity (the protagonist) participates in every event. Hu et al. (2017) also apply an RNN approach, applying a new hierarchical LSTM model in order to predict events by generating descriptive word sequences. This line of work combines the words in these phrases by the passing the concatenation or addition of their word embeddings to a parameterized function that maps the summed vector into event embedding space. The additive nature of these models makes it difficult to model subtle differences in an event's surface form.

To address this issue, Ding et al. (2015), and Weber et al. (2018) propose tensor-based composition models, which combine the subject, predicate and object to produce the final event representation. The models capture multiplicative interactions between these elements and are thus able to make large shifts in event semantics with only small changes to the arguments.

However, previous work mainly focuses on the nature of the event and lose sight of external commonsense knowledge, such as the intent and sentiment of event participants. This paper proposes to encode intent and sentiment into event embeddings, such that we can obtain a kind of more powerful event representations.

5 Conclusion

Understanding events requires effective representations that contain commonsense knowledge. High-quality event representations are valuable for many NLP downstream applications. This paper proposed a simple and effective framework to incorporate commonsense knowledge into the learn-

ing process of event embeddings. Experimental results on event similarity, script event prediction and stock prediction showed that commonsense knowledge enhanced event embeddings can improve the quality of event representations and benefit the downstream applications.

Abstract

Adversarial attacks against machine learning models have threatened various real-world applications such as spam filtering and sentiment analysis. In this paper, we propose a novel framework, learning to discriminate perturbations (DISP), to identify and adjust malicious perturbations, thereby blocking adversarial attacks for text classification models. To identify adversarial attacks, a perturbation discriminator validates how likely a token in the text is perturbed and provides a set of potential perturbations. For each potential perturbation, an embedding estimator learns to restore the embedding of the original word based on the context and a replacement token is chosen based on approximate kNN search. DISP can block adversarial attacks for any NLP model without modifying the model structure or training procedure. Extensive experiments on two benchmark datasets demonstrate that DISP significantly outperforms baseline methods in blocking adversarial attacks for text classification. In addition, in-depth analysis shows the robustness of DISP across different situations.

1 Introduction

Deep learning techniques (Goodfellow et al., 2016) have achieved enormous success in many fields, such as computer vision and NLP. However, complex deep learning models are often sensitive and vulnerable to a tiny modification. In other words, malicious attackers can destroy the models by adding a few inconspicuous perturbations into input data, such as masking images with unrecognizable filters and making low-key modifications for texts. Therefore, developing techniques to equip models against adversarial attacks becomes a prominent research problem.

Existing studies on adversarial attacks can be classified into two groups, generation of adversarial examples and defense against adversarial attacks (Yuan et al., 2019). In the field of NLP, most of the existing studies focus on the former. For example, Ebrahimi et al. (2017); Alzantot et al. (2018) replace a word with synonyms or similar words while Gao et al. (2018); Liang et al. (2017); Ebrahimi et al. (2017) conduct character-level manipulations to fool the models. Moreover, it is not straightforward to adapt existing approaches for blocking adversarial attacks, such as data augmentation (Krizhevsky et al., 2012; Ribeiro et al., 2018; Ren et al., 2019) and adversarial training (Goodfellow et al., 2015; Iyyer et al., 2018; Marzinotto et al., 2019; Cheng et al., 2019; Zhu et al., 2019), to NLP applications. Hence, the defense against adversarial attacks in NLP remains a challenging and unsolved problem.

Recognizing and removing the inconspicuous perturbations are the core of defense against adversarial attacks. For instance, in computer vision, denoising auto-encoders (Warde-Farley and Bengio, 2017; Gu and Rigazio, 2015) are applied to remove the noises introduced by perturbations; Prakash et al. (2018) manipulate the images to make the trained models more robust to the perturbations; Samangouei et al. (2018) apply generative adversarial networks to generate perturbation-free images. However, all of these approaches cannot straightforwardly apply to the NLP tasks for the following two reasons. First, images consist of continuous pixels while texts are discrete tokens. As a result, a token can be replaced with another semantically similar token that drops the performance, so perturbations with natural looks cannot be easily recognized compared to previous approaches that capture unusual differences between the intensities of neighboring pixels. Second, sentences consist of words with an enormous

*Equal contribution. Listing order is random.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4904–4913, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

vocabulary size, so it is intractable to enumerate all of the possible sentences. Therefore, existing defense approaches in computer vision that rely on pixel intensities cannot be directly used for the NLP tasks.

After recognizing the perturbed tokens, the naïve way to eliminate the perturbations for blocking adversarial attacks is to remove these perturbed tokens. However, removing words from sentences results in fractured sentences, causing the performance of NLP models to degrade. Therefore, it is essential to recover the removed tokens. Nevertheless, training a satisfactory language model requires myriad and diverse training data, which is often unavailable. An inaccurate language model that incoherently patches missing tokens can further worsen the prediction performance. To tackle this difficult challenge, we propose to recover the tokens from discriminated perturbations by a masked language model objective with contextualized language modeling.

In this paper, we propose *Learning to Discriminate Perturbations* (DISP), as a framework for blocking adversarial attacks in NLP. More specifically, we aim to defend the model against adversarial attacks without modifying the model structure and the training procedure. DISP consists of three components, perturbation discriminator, embedding estimator, and hierarchical navigable small world graphs. Given a perturbed testing data, the perturbation discriminator first identifies a set of perturbed tokens. For each perturbed token, the embedding estimator optimized with a corpus of token embeddings infers an embedding vector to represent its semantics. Finally, we conduct an efficient kNN search over a hierarchical taxonomy to translate each of the embedding vectors into appropriate token to replace the associated perturbed word. We summarize our contributions in the following.

- To the best of our knowledge, this paper is the first work for blocking adversarial attacks in NLP without retraining the model.
- We propose a novel framework, DISP, which is effective and significantly outperforms other baseline methods in defense against adversarial attacks on two benchmark datasets.
- Comprehensive experiments have been conducted to demonstrate the improvements of DISP. In addition, we will release our implementations and the datasets to provide a testbed and facilitate future research in this direction.

2 Related Work

Adversarial examples crafted by malicious attackers expose the vulnerability of deep neural networks when they are applied to down-streaming tasks, such as image recognition, speech processing, and text classifications (Wang et al., 2019; Goodfellow et al., 2015; Nguyen et al., 2015; Moosavi-Dezfooli et al., 2017).

For adversarial attacks, white-box attacks have full access to the target model while black-box attacks can only explore the models by observing the outputs with limited trials. Ebrahimi et al. (2017) propose a gradient-based white-box model to attack character-level classifiers via an atomic flip operation. Small character-level transformations, such as swap, deletion, and insertion, are applied on critical tokens identified with a scoring strategy (Gao et al., 2018) or gradient-based computation (Liang et al., 2017). Samanta and Mehta (2017); Alzantot et al. (2018) replace words with semantically and syntactically similar adversarial examples.

However, limited efforts have been done on adversarial defense in the NLP fields. Texts as discrete data are sensitive to the perturbations and cannot transplant most of the defense techniques from the image processing domain such as Gaussian denoising with autoencoders (Meng and Chen, 2017; Gu and Rigazio, 2014). Adversarial training is the prevailing counter-measure to build a robust model (Goodfellow et al., 2015; Iyyer et al., 2018; Marzinotto et al., 2019; Cheng et al., 2019; Zhu et al., 2019) by mixing adversarial examples with the original ones during training the model. However, these adversarial examples can be detected and deactivated by a genetic algorithm (Alzantot et al., 2018). This method also requires retraining, which can be time and cost consuming for large-scale models.

Spelling correction (Mays et al., 1991; Islam and Inkpen, 2009) and grammar error correction (Sakaguchi et al., 2017) are useful tools which can block editorial adversarial attacks, such as swap and insertion. However, they cannot handle cases where word-level attacks that do not cause spelling and grammar errors. In our paper, we propose a general schema to block both word-level and character-level attacks.

3 DISP for Blocking Adversarial Attacks

In this section, we first formally define the goal of adversarial defense and then introduce the proposed framework DISP, learning to discriminate perturbations, for blocking adversarial attacks.

Problem Statement. Given an NLP model $F(X)$, where $X = \{t_1, \ldots, t_N\}$ is the input text of N tokens while t_i indicates the i-th token. A malicious attacker can add a few inconspicuous perturbations into the input text and generate an adversarial example X_a so that $F(X) \neq F(X_a)$ with unsatisfactory prediction performance. For example, a perturbation can be an insertion, a deletion of a character in a token, a replacement of a token with its synonym. In this paper, we aim to block adversarial attacks for general text classification models. More specifically, we seek to preserve the model performances by recovering original input text and universally improve the robustness of any text classification model.

3.1 Framework Overview

Figure 1 illustrates the overall schema of the proposed framework. DISP consists of three components, (1) a perturbation discriminator, (2) an embedding estimator, and (3) a token embedding corpus with the corresponding small world graphs G. In the training phase, DISP constructs a corpus D from the original corpus for training the perturbation discriminator so that it is capable of recognizing the perturbed tokens. The corpus of token embeddings C is then applied to train the embedding estimator to recover the removed tokens after establishing the small world graphs G of the embedding corpus. In the prediction phase, for each token in testing data, the perturbation discriminator predicts if the token is perturbed. For each potential perturbation that is potentially perturbed, the embedding estimator generates an approximate embedding vector and retrieve the token with the closest distance in the embedding space for token recovery. Finally, the recovered testing data can be applied for prediction. Note that the prediction model can be any NLP model.Moreover, DISP is a general framework for blocking adversarial attacks, so the model selection for the discriminator and estimator can also be flexible.

3.2 Perturbation Discrimination

Perturbation Discriminator. The perturbation discriminator plays an important role to classify whether a token t_i in the input X_a is perturbed based on its neighboring tokens. We adopt contextualized language modeling, such as BERT (Devlin et al., 2018), to derive d-dimension contextualized token representation T_i^D for each token t_i and then cascade it with a binary logistic regression classifier to predict if the token t_i is perturbed or not. Figure 2 illustrates the perturbation discriminator based on a contextualized word encoder. The discriminator classifies a token t_i into two classes $\{0, 1\}$ with logistic regression based on the contextual representation T_i^D to indicate if the token is perturbed. More formally, for each token t_i, the discriminator predictions r_i can then be derived as:

$$r_i = \underset{c}{\operatorname{argmax}}\, y_i^c = \underset{c}{\operatorname{argmax}} \left(\boldsymbol{w_c} \cdot T_i^D + b_c \right),$$

where y_i^c is the logit for the class c; $\boldsymbol{w_c}$ and b_c are the weights and the bias for the class c. Finally, the potential perturbations R is the set of tokens with positive discriminator predictions $R = \{t_i \mid r_i = 1\}$.

3.3 Efficient Token-level Recovery with Embedding Estimator

After predicting the perturbations R, we need to correct these disorders to preserve the prediction performance. One of the most intuitive approaches to recover tokens with context is to exploit language models. However, language models require sufficient training data while the precision to exact tokens can be dispensable for rescuing prediction performance. Moreover, over-fitting limited training data can be harmful to the prediction quality. To resolve this problem, we assume that replacing the perturbed word with a word with similar meanings to the original word is sufficient for the downstream models to make the correct prediction. Based on the assumption, DISP first predicts the embeddings of the recovered tokens for the potential perturbations with an embedding estimator based on context tokens. The tokens can then be appropriately recovered by an efficient k-nearest neighbors (kNN) search in the embedding space of a token embedding corpus C.

Embedding Estimator. Similar to the perturbation discriminator, any regression model can be employed as an embedding estimator based on the proposed concept. Here we adopt the contextualized language modeling again as an example of the embedding estimator. For each token t_i, the

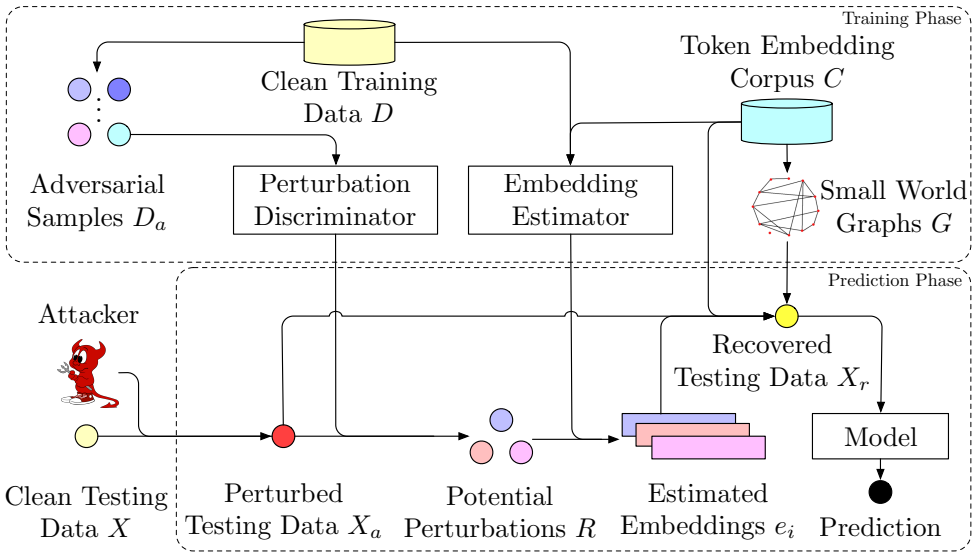

Figure 1: Schema of the proposed framework DISP.

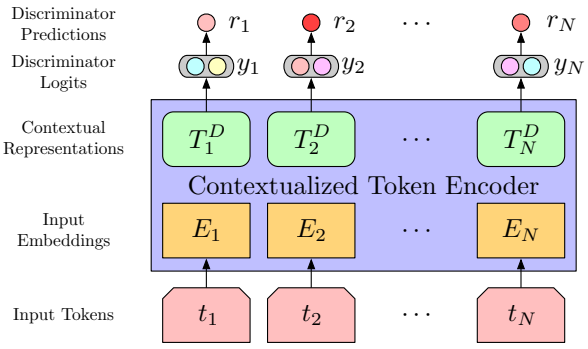

Figure 2: The illustration of the perturbation discriminator in DISP.

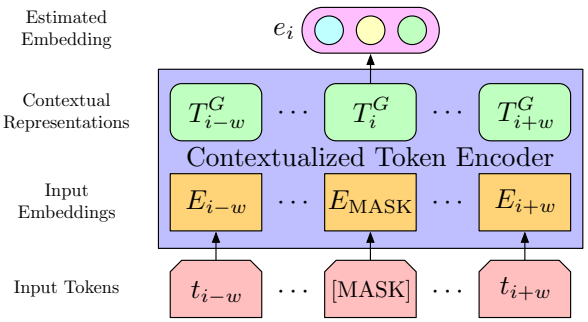

Figure 3: The illustration of the embedding estimator in DISP with a window size $2w+1$ for the token at the position i.

contextualized token embedding can be derived as a d-dimensional contextual representation vector T_i^G to be features for estimating appropriate embeddings.

Figure 3 shows the embedding estimator based on BERT. For each potential perturbation $t_i \in R$, $2w$ neighboring tokens are selected as the context for estimating the appropriate embedding, where w decides the window size. More precisely, a segment of tokens with a window size $2w+1$ from t_{i-w} to t_{i+w} is the input tokens for BERT, where t_i is replaced with a `[MASK]` token as the perturbed position. Finally, for the target t_i, a weight matrix $W^G \in \mathbb{R}^{d \times k}$ projects the contextual representation T_i^G to a k-dimensional estimated embedding e_i as follows:

$$e_i = T_i^G W^G,$$

where the dimension size k is required to be consistent with the embedding dimension in the token embedding corpus C.

Efficient Token-level Recovery. Finally, we recover the input sentence based on the predicted recover embeddings from the embedding estimator. Specifically, the input text X needs to be recovered from the perturbed text X_a by fixing token-level perturbations based on its approximate embeddings.

Given the token embedding corpus C, it is simple to transform an embedding to a token by finding the nearest neighbor token in the embedding space. However, a naïve kNN search query can take $O(kn)$ time complexity, where n is the number of embeddings in C; k is the embedding dimension. To accelerate the search process, we apply hierarchical navigable small world graphs (SWGs) (Malkov and Yashunin, 2018) for fast approximate kNN search. More precisely, em-

Algorithm 1: Efficient Token-level Recovery

Input: Perturbed text X_a, potential perturbations R, estimated embeddings $\{e_i\}$, small world graphs G, token embedding corpus C.
Output: Recovered text X_r.

```
X_r = X_a;
for t_i ∈ R do
    index = QuerySmallWorldGraph(G, e_i);
    z = C[index].token;
    Replace t_i in X_r with z;
return X_r;
```

beddings are transformed into a hierarchical set of SWGs based on the proximity between different embeddings. To conduct kNN searches, the property of degree distributions in SWGs significantly reduces the search space of each kNN query from $O(n)$ to $O(\log n)$ by navigating on the graphs, so a kNN query can be efficiently completed in $O(k \log n)$ time complexity. Finally, the recovered text X_r can be obtained by replacing the perturbations R in X_a as shown in Algorithm 1.

3.4 Learning and Optimization

To learn a robust discriminator, we randomly sample adversarial examples from both character-level and word-level attacks in each training epoch. The loss function optimizes the cross-entropy between the labels and the probabilistic scores computed by the logits y_i and the softmax function.

The learning process of embedding estimator is similar to masked language models. The major difference is that language models optimize the likelihood to generate the same original token while the embedding estimator minimizes the distance between the derived embedding and the original token embedding. To learn the embedding estimator, a size-$(2w+1)$ sliding window is applied to enumerate $(2w+1)$-gram training data for approximating embeddings with context tokens. For optimization, the embedding estimator is learned to minimize the mean square error (MSE) from the inferred embeddings to the original token embeddings.

To take advantage of hierarchical navigable SWGs for an efficient recovery, although a preprocess to construct SWGs G is required, the preprocess can be fast. The established SWGs can also be serialized in advance. More precisely, the time complexity is $O(kn \log n)$ for one-time construction of reusable SWGs, where n is the number of embeddings in the embedding corpus C.

Dataset	Train	Test	Length

4 Experiments

In this section, we conduct extensive experiments to evaluate the performance of DISP in improving model robustness.

4.1 Experimental Settings

Experimental Datasets. Experiments are conducted on two benchmark datasets: (1) Stanford Sentiment Treebank Binary (SST-2) (Socher et al., 2013) and (2) Internet Movie Database (IMDb) (Maas et al., 2011). SST-2 and IMDb are both sentiment classification datasets which involve binary labels annotating sentiment of sentences in movie reviews. Detailed statistics of two datasets are listed in Table 1.

Attack Generation. We consider three types of character-level attacks and two types of word-level attacks. The character-level attacks consist of *insertion*, *deletion*, and *swap*. *Insertion* and *deletion* attacks inject and remove a character, respectively, while a *swap* attack flips two adjacent characters. The word-level attacks include *random* and *embed*. A *random* attack randomly samples a word to replace the target word while a *embed* attack replaces the word with a word among the top-10 nearest words in the embedding space. The examples of each attack type are illustrated in Table 2. To obtain strong adversarial attack samples,w we consider to leverage oracle to identify the perturbations that cause prediction changes. Specifically, for each test sample we construct 50 adversarial examples by perturbing the test data. We sample one example in which model prediction changes after perturbing. If none of them can

Table 3: Performance of SC and DISP on identifying perpetuated tokens.

change the prediction, the sample with the least confidence is selected.

Base Model and Baselines. We consider BERT (Devlin et al., 2018) as the base model as it achieves strong performance in these benchmarks. To evaluate the performance of DISP, we consider the following baseline methods: (1) Adversarial Data Augmentation (ADA) samples adversarial examples to increase the diversity of training data; (2) Adversarial Training (AT) samples different adversarial examples in each training epoch; (3) Spelling Correction (SC) is used as a baseline for discriminating perturbations and blocking character-level attacks. Note that ADA and AT require to re-train BERT with the augmented training data, while DISP and SC modify the input text and then exploit the original model for prediction. SC is also the only baseline for evaluating discriminator performance. In addition, we also try to ensemble DISP and SC (DISP+SC) by conducting DISP on the spelling corrected input.

Evaluation Metrics. We evaluate the performance of the perturbation discriminator by precision, recall and F1 scores, and evaluate the overall end-to-end performance by classification accuracy that the models recover.

Implementation Details. The model is implemented in PyTorch (Paszke et al., 2017). We set the initial learning and dropout parameter to be 2×10^{-5} and 0.1. We use crawl-300d-2M word embeddings from *fastText* (Mikolov et al., 2018) to search similar words. The dimensions of word embedding k and contextual representation d are set as 300 and 768. w is set as 2. We follow $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2018) to set the numbers of layers (i.e., Transformer blocks) and self-attention heads as 12.

4.2 Experimental Results

Performance on identifying perpetuated tokens. Table 3 shows the performance of DISP and SC in discriminating perturbations. Compared to SC, DISP has an absolute improvement by 35% and 46% on SST-2 and IMDb in terms of F1-score, respectively. It also proves that the context information is essential when discriminating the perturbations. An interesting observation is that SC has high recall but low precision scores for character-level attacks because it is eager to correct misspellings while most of its corrections are not perturbations. Conversely, DISP has more balances of recall and precision scores since it is optimized to discriminate the perturbed tokens. For the word-level attacks, SC shows similar low performance on both *random* and *embed* attacks while DISP behaves much better. Moreover, DISP works better on the *random* attack because the embeddings of the original tokens tend to have noticeably greater Euclidean distances to randomly-picked tokens than the distances to other tokens.

Defense Performance. Table 4 reports the accuracy scores of all methods with different types of adversarial attacks on two datasets. Compared to the baseline BERT model, all of the methods alleviate the performance drops. All methods perform better on blocking character-level attacks than word-level attacks because word-level attacks eliminate more information. For the base-

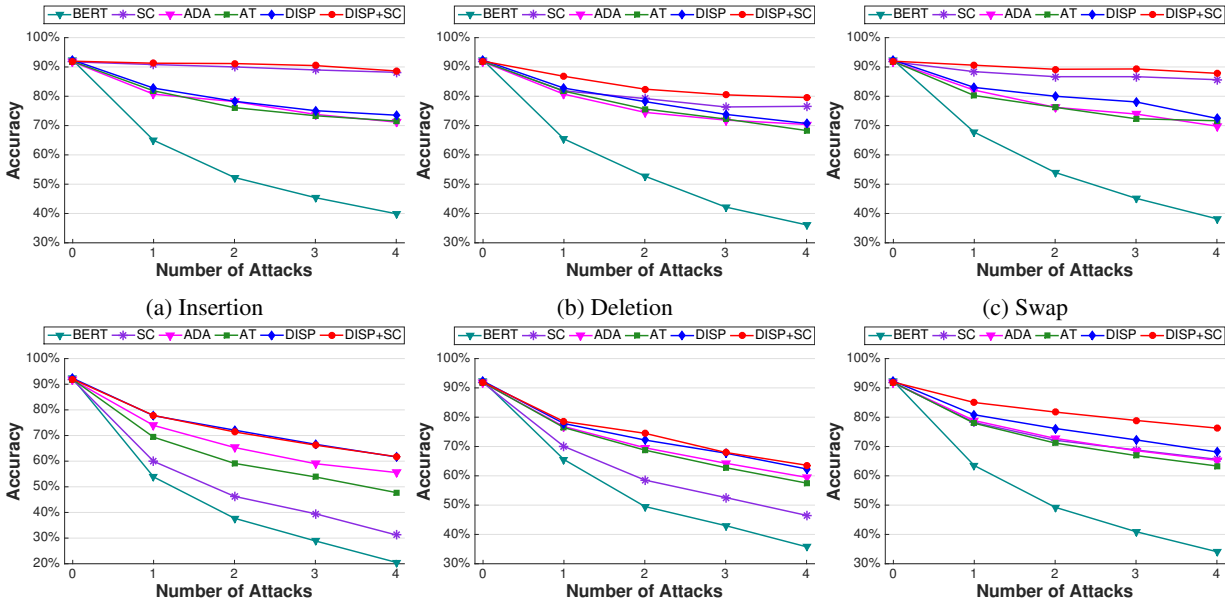
IMDb	BERT	**0.9431**	0.8586	0.8599	0.8568	0.8468	0.8615	0.8567
	SC	0.9193	0.8834	0.8794	0.8825	0.8695	0.8753	0.8780
	ADA	0.9393	0.8766	0.8765	0.8754	0.8722	0.8755	0.8752
	AT	0.8998	0.8958	0.8822	0.8787	0.8886	0.8822	0.8855
	DISP	0.9378	**0.9310**	**0.9297**	**0.9301**	**0.9281**	**0.9347**	**0.9307**
	DISP+SC	0.9395	**0.9316**	0.8772	**0.9313**	0.8755	0.9292	0.9090

Table 4: The accuracy scores of methods with different adversarial attacks on two datasets.

lines, consistent with Table 3, SC performs the best for character-level attacks and the worst for word-level attacks. In contrast, ADA and AT are comparably more stable across different types of attacks. The differences between performance for character- and word-level attacks are less obvious in IMDb because documents in IMDb tend to be longer with more contexts to support the models. DISP works well to block all types of attacks. Compared with the best baseline models, DISP significantly improves the classification accuracy by 2.51% and 5.10% for SST-2 and IMDb, respectively. By ensembling SC and DISP, DISP+SC achieves better performance for blocking all types of attacks. However, the improvements are not consistent in IMDb. In particular, SC performs worse with lower discrimination accuracy and over-correcting the documents. In addition, DISP has a stable defense performance across different types of attacks on IMDb because richer context information in the documents benefits token recovery.



Number of Attacks. Figure 4 shows the classification accuracy of all methods over different numbers of attacks, i.e., perturbations, for different types of adversarial attacks. Without using a defense method, the performance of BERT dramatically decreases when the number of attacks increases. With defense approaches, the performance drops are alleveated. Moreover, the relations between the performance of methods are consistent across different perturbation numbers. DISP+SC consistently performs the best for all of the cases when DISP outperforms all of the single methods for most of the situations. These results demonstrate the robustness of the proposed approach.

Method	Insertion	Delete	Swap

$\text{DISP}_{\text{SST-2}}$	0.7773	0.7784	0.8083
$\text{DISP}_{\text{IMDb}}$	0.7623	0.7681	0.8005

Table 5: The accuracy of DISP over different types of attacks on the SST-2 dataset with the tokens recovered by the perturbation discriminator and the embedding estimator trained on the IMDb dataset for robust transfer defense. Note that DISP_x indicates the framework is established on the dataset x.

Robust Transfer Defense. In practice, we may not have access to the original training corpus of a prediction model. In the following, we investigate if the perturbation discriminator can transfer across different corpora. We first train the discriminator and the estimator on IMDb denoted as $\text{DISP}_{\text{IMDb}}$ and then apply it to defend the prediction model on SST-2. Table 5 shows the experimental results of robust transfer defense. $\text{DISP}_{\text{IMDb}}$ achieves similar performance as the performance of $\text{DISP}_{\text{SST-2}}$ trained on the same training set. Hence, it shows that DISP can transfer the ability to recover perpetuated token across different sentiment copora.

4	a **painfulily funtny** ode to **g**bad behavior.	painfully; silly; one	positive	negative

Table 6: A case study of recovered tokens in SST-2. Note that Label and Pred represent the ground-truth label and the predicted label.

documents from SST-2 for a case study. We successfully recovered the attacked words from "original" and "bet" in the cases 1 and 2 to "imaginative" and "best". It demonstrates that embeddings generated by the embedding estimator are robust to recover the appropriate tokens and block adversarial attacks. However, DISP performs worse when the remaining sentence is lack of informative contexts as case 3. When multiple attacks exist, the incorrect context may also lead to unsatisfactory recoveries, e.g., DISP converts "funny" to "silly" in case 4, thus flipping the prediction. This experiment depicts a disadvantage of DISP and demonstrates that DISP+SC can gain further improvements.

Embedding Estimator. Although DISP is not required to recover the ground-truth perturbed tokens, the embedding estimator plays an important role to derive appropriate embedding vectors that obtain the original semantics. We first evaluate the performance of embedding estimator as a regression task. The RMSE scores of estimated embeddings are 0.0442 and 0.1030 in SST-2 and IMDb datasets, which are small enough to derive satisfactory tokens. To further demonstrate the robustness of the embedding estimator and estimated embeddings, we identify the perturbations with our discriminator and replace them with the ground-truth tokens. Table 7 shows the accuracy scores over different types of attacks in the SST-2 dataset. DISP and DISP$_G$ denotes the recovery performance with our estimator and gound-truth tokens, respectively. More specifically, the accuracy of DISP$_G$ presents the upperbound performance gained by the embedding estimator. The experimental results demonstrate the robustness of

Method	Insertion	Delete	Swap
DISP$_G$	0.8773	0.8681	0.8796
DISP	0.8278	0.8278	0.8301
Method	Random	Embed	Overall
DISP$_G$	0.7970	0.7924	0.8429
DISP	0.7773	0.7784	0.8083

Table 7: The performance of DISP using ground-truth and recovered tokens over different types of attacks in SST-2. Result are in accuracy. Note that DISP$_G$ denotes DISP using ground-truth tokens.

Method	Insertion	Delete	Swap
BERT	0.1160	0.1407	0.1806
DISP	0.5856	0.5684	0.6008
Method	Random	Embed	Overall
BERT	0.0855	0.0817	0.1209
DISP	0.4848	0.5114	0.5502

Table 8: The accuracy scores of BERT and DISP over different types of attacks on the CoLA dataset for the task of linguistic acceptability classification. The accuracy score of BERT without any attack is 0.8519.

the embedding estimator while the estimated embeddings only slightly lower the accuracy of DISP.

Linguistic Acceptability Classification. In addition to the task of sentiment analysis, we also evaluate the performance of DISP in linguistic acceptability classification. The Corpus of Linguistic Acceptability (CoLA) is a binary classification task. The goal of this task is to predict whether an English sentence is linguistically acceptable or not (Warstadt et al., 2018). Table 8 presents the accuracy scores of BERT and DISP on the CoLA dataset with one adversarial attack of each type. It is interesting that the original BERT is extremely vulnerable to the adversarial attacks. This is because the linguistic acceptability can be easily affected by perturbations. The experimental results also depict that DISP can significantly alleviate the performance drops. DISP is capable of blocking adversarial attacks across different NLP tasks.

5 Conclusions

In this paper, we propose a novel approach to discriminate perturbations and recover the text semantics, thereby blocking adversarial attacks in NLP. DISP not only correctly identifies the perturbations but also significantly alleviates the performance drops caused by attacks.

Abstract

Citation count prediction (CCP) has been an important research task for automatically estimating the future impact of a scholarly paper. Previous studies mainly focus on extracting or mining useful features from the paper itself or the associated authors. An important kind of data signals, *i.e.,* peer review text, has not been utilized for the CCP task. In this paper, we take the initiative to utilize peer review data for the CCP task with a neural prediction model. Our focus is to learn a comprehensive semantic representation for peer review text for improving the prediction performance. To achieve this goal, we incorporate the abstract-review match mechanism and the cross-review match mechanism to learn deep features from peer review text. We also consider integrating hand-crafted features via a wide component. The deep and wide components jointly make the prediction. Extensive experiments have demonstrated the usefulness of the peer review data and the effectiveness of the proposed model. Our dataset has been released online.

1 Introduction

In recent years, the number of scientific publications has been growing in a dramatic rate. For example, the numbers of submissions and accepted papers of EMNLP 2019 have increased to 2,877 and 684 respectively[1]. Given the huge volume of scholarly papers, a long-standing research challenge is how to effectively evaluate the impact of scientific literature (Garfield, 1999; Saha et al., 2003; Bornmann, 2013). A typical way to measure the impact of a scholarly paper is through the number of citations received after publication (Garfield, 1979; Aksnes, 2006), reflecting the influence in the research community.

Since citation count is an important evaluation measure for scientific impact, many researchers aim to develop automatic ways to predict the future citation of a paper (Castillo et al., 2007; Ibáñez et al., 2009; Davletov et al., 2014; Xiao et al., 2016). A typical approach is to casting the problem into a classification or regression task, focusing on extracting useful feature information (Yan et al., 2011; Chen and Zhang, 2015; Singh et al., 2015; Park et al., 2017) (*e.g.,* h-index and topic distribution). Although these studies have achieved important progress on this task, they mainly utilize information from the papers themselves or their associated authors. They have neglected an important kind of data signal for the prediction task, *i.e.,* peer review data.

Peer review is a widely adopted paper evaluation mechanism, in which three or more reviewers would be assigned to decide whether to accept or reject a paper. During the review process, the reviewers should assess the paper quality in terms of several important factors, including originality, correctness, substance and readability[2]. Intuitively, peer review data should be useful to predict future impact of a paper, since the review text contains assessment comments from domain experts. Fortunately, the mechanism of open review (Soergel et al., 2013) has made it possible to obtain peer review data for the citation count prediction (CCP) task.

Although it is appealing to leverage peer reviews for the CCP task, it is difficult to effectively extract supporting evidence and learn comprehensive semantic representations from peer review data. Reviews are usually written in natural language text, covering the assessment comments of a paper in multiple aspects. Some comments may not focus on the main contribution of a paper. For

example, a review typically contains the reminders for minor spelling errors or format problems. Another interesting observation is that different reviewers may focus on different aspects in their comments, and even raise divergent attitudes on the same aspect. Hence, it is important to consider both coverage and divergence of review comments for making a comprehensive decision on the paper impact.

In this paper, we take the initiative to study how to utilize the peer review data in the CCP task. We focus on how to learn a comprehensive semantic representation from peer review text for improving the prediction performance. To identify relevant evidence from long text, we utilize the abstract-review match method to learn abstract-aware review representations by using abstract text as an attentive query. In this way, we can reduce the influence of irrelevant content or noise. To further characterize the interaction among multiple reviews, we propose a novel cross-review match mechanism. With such a mechanism, a review representation will be decomposed into a parallel representation and an orthogonal representation by referring to the rest of the reviews. Our model can derive an effective semantic representation for capturing the comprehensive semantics of all the reviewers.

To evaluate our model, we have constructed two peer review datasets with citation counts. Extensive experiments have demonstrated the superiority of the proposed model over several competitive baselines. To our knowledge, it is the first time that peer review data has been utilized in the CCP task. Our work has shown that peer review data is important to improve the prediction performance. Our code and dataset have been released at `https://github.com/RUCAIBox/Citation-Count-Prediction`.

2 Related Work

Citation count prediction has been a hot research topic in the literature (Castillo et al., 2007; Ibáñez et al., 2009; Chakraborty et al., 2014). Early studies casted this task as a classification or regression task (Fu and Aliferis, 2008). Their focus was to identify features in a certain aspect to explore the factors of the impact of papers. Following works formally defined this task and thoroughly examined various possible factors correlated with citation counts (Yan et al., 2011; Bhat et al., 2015; Chen and Zhang, 2015; Singh et al., 2015; Chen and Zhang, 2015; Park et al., 2017). These studies mainly model the long-term scientific impact (Wu et al., 2019; Abrishami and Aliakbary, 2018; Yuan et al., 2018). Furthermore, some researchers casted the problem as a time series task, and focused on analyzing temporal features or patterns in the process of citation growth (Davletov et al., 2014; Xiao et al., 2016; Yuan et al., 2018). However, to the best of our knowledge, no work has utilized peer review data of scholarly papers for citation count prediction.

As an important paper evaluation mechanism, peer review has been widely adopted in various journals and conferences (Ross et al., 2006; Fisher et al., 1994). Based on private review data, researchers have explored the usefulness of peer reviews in several aspects, such as issue localization (Xiong et al., 2010), review utility (Xiong and Litman, 2011) and quality/tone (Ramachandran and Gehringer, 2011). More recently, to lower the barrier to studying peer reviews for the scientific community, a public dataset of peer reviews has been released for research purpose (Kang et al., 2018). Based on this dataset, Wang and Wan (2018) have employed peer review text to predict the overall decision status for a paper submission. Compared with (Wang and Wan, 2018), we focus on a different task by studying how to leverage peer review for future impact estimation instead of paper acceptance, which has its own technical challenges. Besides, we have released our dataset with citation counts online.

Our work is also related to the studies that analyze scientific literature or citation data, including concept or keyphrase extraction (Shen et al., 2018; Gordon et al., 2016; Luan et al., 2017; Caragea et al., 2014), citation or influence analysis (Lauscher et al., 2018; Chakraborty and Narayanam, 2016; Bonab et al., 2018; Chen et al., 2018), context modeling (Cohan and Goharian, 2017; Jin and Szolovits, 2018) and automatic paper rating (Yang et al., 2018).

3 Problem Formulation

Let d denote a scientific paper from a literature corpus $\mathcal{D}$. Following (Ibáñez et al., 2009), we only consider the abstract text for modeling paper content, which summarizes the main contributions of a paper. Let $\boldsymbol{a}_d$ denote the abstract text of d, which consists of multiple abstract sentences.

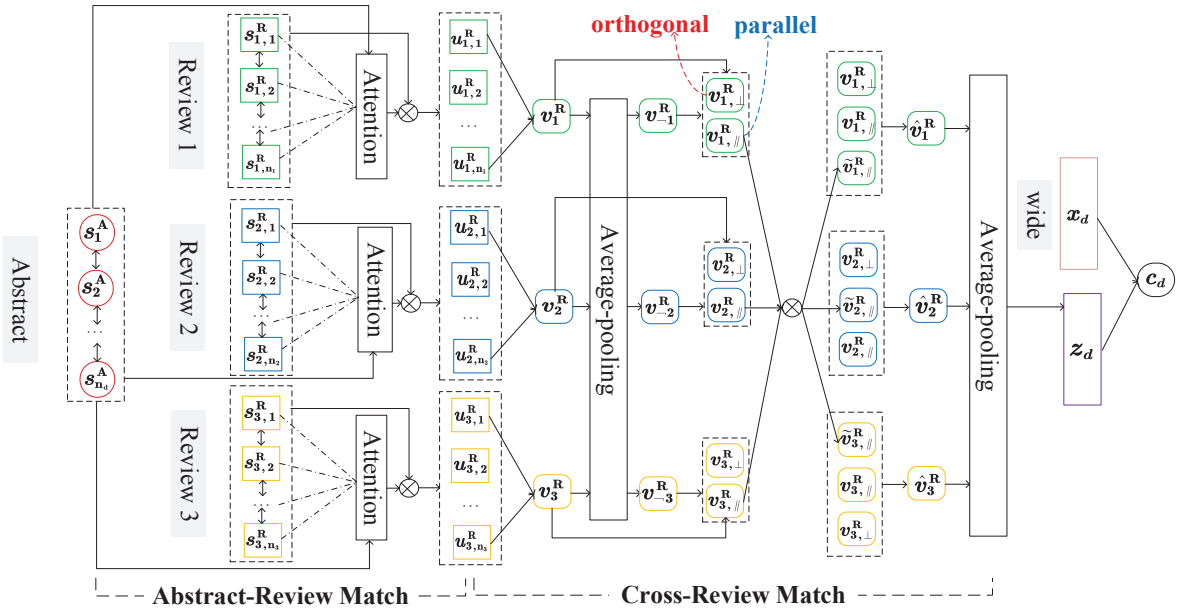

Figure 1: The overview of the proposed citation count prediction model.

We also assume that K peer reviews are available for paper d, characterized by $\{\boldsymbol{r}_k\}_{k=1}^{K}$, where $\boldsymbol{r}_k$ denotes the k-th review consisting of multiple review sentences. We assume that both abstract and review text share the same vocabulary $\mathcal{V}$. Besides these features, we also assume other types of information (*e.g.,* authors' h-index) are also available for our task. We use a vectorized representation $\boldsymbol{x}_d$ to encode all non-review features.

Based on the above preliminaries, we now define the Citation Count Prediction (CCP) task. We aim to learn an effective predictive function that takes as input the abstract text, review text and other available information and estimates the future citation count after a given time period:

$$f(\boldsymbol{x}_d, \boldsymbol{a}_d, \{\boldsymbol{r}_k\}_{k=1}^{K}) \rightarrow \hat{c}_d, \tag{1}$$

where $\hat{c}_d$ is the estimated citation count for d. To make the citation number more predictable, we normalize the value range of c_d within the interval $(0, 1)$. Here, we consider long-term citation count prediction in terms of years.

4 The Proposed Model

In this section, we present a neural citation count prediction model based on peer review text. Our model consists of two major components, namely the deep component and wide component, which model review-based text features and other hand-crafted features, respectively. Figure 1 presents an illustrative sketch for our model architecture. The notations and the descriptions are shown in Table 1.

Symbols	Descriptions
$\boldsymbol{x}_d$	the non-review features of paper d
$\boldsymbol{z}_d$	the final review representation of paper d
$\boldsymbol{c}_d$	the citation count of paper d
$\boldsymbol{a}_d$	the abstract text of paper d
$\boldsymbol{r}_k$	the k-th review consisting of multiple review sentences
$\boldsymbol{s}_j^A$	the learned representations of the j-th sentence in the abstract text
$\boldsymbol{s}_{k,j}^R$	the learned representations of the j-th sentence in the k-th review text
h_S	the dimension of sentence vectors
n_d	the number of sentences in abstract of paper d
n_k	the number of sentences in the k-th review of paper d
$\boldsymbol{u}_t^R$	the updated representation of the t-th sentence in a review after abstract-review match
h_H	the GRU hidden size
$\boldsymbol{v}_k^R$	the representation of the k-th review
$\boldsymbol{v}_{k,\parallel}^R$	the parallel representation of the k-th review
$\boldsymbol{v}_{k,\perp}^R$	the orthogonal representation of the k-th review
$\boldsymbol{v}_{\neg k}^R$	the representation of other reviews excluding the k-th review
$\hat{\boldsymbol{v}}_k^R$	the refined representation of the k-th review after cross-review match

Table 1: Notations used in the paper.

4.1 The Deep Component

The deep component is the core part of our model, which aims to extract important semantic charac-

teristics from peer review text for the CCP task. We first encode abstract and review sentences into embedding vectors, and then distill the relevant evidence from review text by referring to the abstract. To characterize the interaction of multiple reviewers, we further design a cross-review match mechanism to capture both consistency and divergence among different reviews.

4.1.1 Encoding Abstract and Review Sentences

We first pretrain the word embeddings using the word2vec model (Mikolov et al., 2013) using all the scientific corpus. To effectively encode the abstract and review sentences, we adopt the convolution-based method in (Kim, 2014) to model the sentences, sequentially consisting of a lookup layer, a convolution layer of 100 filters, and a max pooling layer. We denote the learned sentence representations of the abstract text as $\{\boldsymbol{s}_j^A\}_{j=1}^{n_d}$ and the k-th review text is denoted as $\{\boldsymbol{s}_{k,j}^R\}_{j=1}^{n_k}$, where each $\boldsymbol{s}_j^A$ or $\boldsymbol{s}_{k,j}^R$ is a h_S-dimensional vector for the j-th sentence in the abstract or the k-th review, and n_d and n_k is the number of sentences in abstract of paper d and its k-th review.

4.1.2 Improving the Review Representations with Abstract-Review Match

Review text reflects the subject assessment on a paper by the reviewers. A review is likely to cover the detailed comments from multiple aspects. It may contain irrelevant information for the prediction task, such as requesting source code release or pointing out minor spelling errors. It is key to identify relevant information focusing on the core contributions of a paper.

Intuitively, we can utilize the abstract information to purify the original review sentence representations, since it provides a good summary for the main contributions of a paper. Inspired by the recent progress on machine reading comprehension, we adopt the gated attention-based recurrent networks (Wang et al., 2017) for refining the review representations regarding to the abstract text. In our task, the abstract is considered as a question, and a review is considered as a passage. Similar to machine reading comprehension, we aim to learn a "question"-relevant review sentence representation that focuses on the core content from the abstract. For simplicity, we only consider the interaction between the abstract and an individual review, and omit the review index from the notations. Formally, we update the representation of the t-th sentence in a review as $\boldsymbol{u}_t^R \in \mathbb{R}^{h_H}$:

$$\boldsymbol{u}_t^R = \text{BiGRU}(\boldsymbol{u}_{t-1}^R, [\boldsymbol{s}_t^R, \boldsymbol{p}_t]^*), \tag{2}$$

where $\boldsymbol{p}_t \in \mathbb{R}^{h_S}$ is an attentional vector of a review computed based on the interaction between review and abstract sentence representations:

$$\begin{aligned} \boldsymbol{p}_t &= \sum_{i=1}^{n_d} \alpha_i^t \cdot \boldsymbol{s}_i^A, \\ \alpha_i^t &= \exp(\boldsymbol{h}_i^t) / \sum_{j=1}^{n_d} \exp(\boldsymbol{h}_j^t), \\ \boldsymbol{h}_j^t &= \boldsymbol{u}^\top \tanh(\boldsymbol{W}_s^A \boldsymbol{s}_j^A + \boldsymbol{W}_s^R \boldsymbol{s}_t^R + \boldsymbol{W}_u^R \boldsymbol{u}_{t-1}^R), \end{aligned} \tag{3}$$

where $\boldsymbol{W}$s $\in \mathbb{R}^{h_H \times h_S}$are parameter matrices to learn, $\boldsymbol{s}_j^A$ and $\boldsymbol{s}_t^R$ are the learned sentence representations for abstract and review text respectively in Sec. 4.1.1, αs are the attention coefficients, and $[\boldsymbol{s}_t^R, \boldsymbol{p}_t]^*$ is a gated update of the concatenation vector $[\boldsymbol{s}_t^R, \boldsymbol{p}_t]$:

$$[\boldsymbol{s}_t^R, \boldsymbol{p}_t]^* = \boldsymbol{g}_t \odot [\boldsymbol{s}_t^R, \boldsymbol{p}_t], \tag{4}$$

$$\boldsymbol{g}_t = \text{sigmoid}(\boldsymbol{W}_g [\boldsymbol{s}_t^R, \boldsymbol{p}_t]), \tag{5}$$

where " $\odot$ " is an element-wise product operation for vectors.

In this way, for a review, we can obtain the abstract-aware review sentence representations $\{\boldsymbol{u}_j^R\}_{j=1}^{n_d}$, which encode more relevant information emphasized by the abstract. To learn the overall representation for the k-th review, we concatenate the sentence embeddings of the first and last sentences in it:

$$\boldsymbol{v}_k^R = [\boldsymbol{u}_1^R, \boldsymbol{u}_{n_k}^R], \tag{6}$$

where $\boldsymbol{u}_1^R$ and $\boldsymbol{u}_{n_k}^R$ are learned sentence embeddings using bidirectional Gated Recurrent Unit (BiGRU) in Eq. 2.

4.1.3 Improving Review Representations with Cross-Review Match

Previously, we have considered the interaction between the abstract and an individual review. The evaluation process of a paper typically requires multiple reviewers to make the final decision. According to (Hirschauer, 2010), coverage and divergence should be considered for the acceptance decision of a paper. Therefore, we propose to utilize cross-review match to learn a comprehensive semantic representation from different reviewers.

Given a review, we take the rest of the reviews as a reference source. We aim to learn the common semantics that are also discussed by other reviews (maybe with different attitudes), and identify unmentioned semantics by other reviews. To implement this idea, we adopt the orthogonal decomposition strategy proposed in (Wang et al., 2016). We decompose the original review representation into a *parallel* representation and an *orthogonal* representation. Formally, the representation of the k-th review $\boldsymbol{v}_k^R \in \mathbb{R}^{h_H}$ (Eq. 6) is decomposed to:

$$\boldsymbol{v}_{k,\parallel}^R = \frac{\boldsymbol{v}_k^{R\top} \cdot \boldsymbol{v}_{\neg k}^R}{\boldsymbol{v}_{\neg k}^{R\top} \cdot \boldsymbol{v}_{\neg k}^R} \cdot \boldsymbol{v}_{\neg k}^R, \quad (7)$$

$$\boldsymbol{v}_{k,\perp}^R = \boldsymbol{v}_k^R - \boldsymbol{v}_{k,\parallel}^R, \quad (8)$$

$$\boldsymbol{v}_{\neg k}^R = \text{avg-pooling}(\{\boldsymbol{v}_j^R\}_{j \neq k}). \quad (9)$$

where the parallel representation $\boldsymbol{v}_{k,\parallel}^R \in \mathbb{R}^{h_H}$ encodes common semantics also discussed by other reviews, and the orthogonal representation $\boldsymbol{v}_{k,\perp}^R \in \mathbb{R}^{h_H}$ encodes unmentioned semantics in other reviews. Such a decomposition is useful to extract more comprehensive semantics from multiple reviews. We use average pooling to construct the reference vector of other reviews.

We perform the above decomposition for each review associated with a paper. The parallel representation reflects the common semantics shared by other reviews. Since different reviewers may have divergent comments (or attitudes) towards the same content, we further introduce a corresponding attentional representation for enriching the semantics of the original representation:

$$\widetilde{\boldsymbol{v}}_{k,\parallel}^R = \sum_{j=1}^{K} \alpha_{kj} \cdot \boldsymbol{v}_{j,\parallel}^R, \quad (10)$$

$$\alpha_{k,j} = \exp(s_{k,j}) / \sum_{j'=1}^{K} \exp(s_{i,j'}),$$

$$s_{k,j} = \begin{cases} 0, & \text{if } k = j \\ (\boldsymbol{v}_{k,\parallel}^R)^\top \cdot \boldsymbol{v}_{j,\parallel}^R, & \text{otherwise.} \end{cases}$$

Then we combine the three representations and adopt a fully connected layer to obtain the refined representation for the k-th review $\hat{v}_k^R \in \mathbb{R}^{h_H}$:

$$\hat{v}_k^R = \boldsymbol{W}[\boldsymbol{v}_{k,\perp}^R, \boldsymbol{v}_{k,\parallel}^R, \widetilde{\boldsymbol{v}}_{k,\parallel}^R]. \quad (11)$$

It is able to capture the coverage and divergence in semantics for peer review text to some extent. Finally we use an average pooling operation over all review representations of paper d as its final representation $\boldsymbol{z}_d \in \mathbb{R}^{h_H}$:

$$\boldsymbol{z}_d = \text{avg-pooling}(\{\hat{v}_k^R\}_{k=1}^K). \quad (12)$$

4.2 The Wide Component

Besides review-based features, we consider directly integrating other important features for the prediction task, called *wide features*. Here, we use a vectorized representation $\boldsymbol{x}_d$ to represent all the wide features. We construct the vector by using the features proposed in previous studies (Yan et al., 2011; Bhat et al., 2015):

- Topic distribution: We utilize the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to learn the probability distribution over topics as the topic features.
- Diversity: We calculate the entropy of the paper's topic distribution to measure the topical breadth of a paper.
- Recency: We use the year of publication as the temporal feature to predict the citation count.
- Author influence: We use the number of authors and the average h-index as author features.

4.3 The Joint Deep and Wide Model

Finally, we integrate the two components into a unified model. We take as input the deep and wide features respectively discussed in Section 4.1 and Section 4.2, and combine them as the prediction function (Eq. 1) :

$$\hat{c}_d = \tanh(\boldsymbol{w}_{deep}^\top \cdot \boldsymbol{z}_d + \boldsymbol{w}_{wide}^\top \cdot \boldsymbol{x}_d + b), \quad (13)$$

where $\boldsymbol{z}_d$ and $\boldsymbol{x}_d$ are the derived feature representations from the deep and wide components respectively, and $\boldsymbol{w}_{deep}$ and $\boldsymbol{w}_{wide}$ are the corresponding parameter vectors. Furthermore, we define the citation count prediction error over the training set with the Mean Squared Error (MSE):

$$L(\theta) = \frac{1}{|\mathcal{D}|} \sum_{d \in \mathcal{D}} (\hat{c}_d - c_d)^2. \quad (14)$$

where c_d is the normalized real citation count of each scholarly paper. We learn our model parameters via optimizing the $L(\theta)$ loss. The parameters in GRU and CNN are initialized by a normal distribution with zero mean and 0.01 variance, and the biases are initialized as zeros. To optimize our model, we adopt the Stochastic Gradient Descent (SGD) optimizer to learn the

model parameters. More implementation details can be found in Section 5.1.

5 Experiments

In this section, we first set up the experiments, and then present the results and analysis.

5.1 Experimental Setup

Datasets. Peer review data is not available for the majority of mainstream journals and conferences. Fortunately, ICLR and NIPS have provided the review text on their website. NIPS does not provide rating scores from the reviewers, and we only consider utilizing text data in this paper. For most of the published papers, it is difficult to accumulate a considerable number of citations in a short period. Hence, we only use the data ICLR 2013-2017 and NIPS 2013-2016 for evaluation, which has a two-year span to now for long-term impact prediction. The data of NIPS 2013-2016 and ICLR 2017 have been shared by Kang et al. (2018). The data of ICLR 2013-2016 was crawled from the OpenView website[3], including abstract text, review text and author data. Note that we only consider the accepted papers for citation prediction. We further crawl author data (*e.g.,* h-index) and paper citation from Google Scholar[4]. When encountering any ambiguity on author names or paper titles, a senior graduate student will manually collect the corresponding data. All the Google Scholar data has been accessed on March 31, 2019 to guarantee the recency of citation data. We remove the papers with only one reviewer. We perform basic text preprocessing using NLTK[5], including tokenization, lowercase, and stopword removal, and only retain the words that occur three times or more. In order to simulate the real situation, for both datasets, we take the data from the last year as test data, and the previous data as training set. The detailed statistics of the two datasets are summarized in Table 2. Since both datasets have a limited number of papers, we only hold out 5% training data as validation set. Our dataset and code are available at https://github.com/RUCAIBox/Citation-Count-Prediction.

Implementation Details. We pre-trained 300-dimensional word vectors as initial word embeddings using all the data in our dataset. The word vectors were fixed during the training process. The number of CNN filters h_S and GRU hidden size h_H are set to 128. For the wide component, we utilize the LDA to train a 100-topic model. All of the features in the wide component and the citation count are normalized within the interval $(0, 1)$. The dropout rate is set to 0.5 to prevent overfitting. For the hyper-parameters of SGD optimizer, we set the learning rate as 0.001.

Baseline Models. We compare our model against a number of baseline models:

• Linear Regression (LR), K-NearestNeighbor (KNN), Support Vector Regression (SVR) and Gradient Boost Regression Tree (GBRT): The four methods are commonly used regression models for citation prediction (Yan et al., 2011; Bhat et al., 2015). We adopt the same wide features from (Yan et al., 2011) as our wide component.

• Wide & Deep (Cheng et al., 2016): We borrow the Wide & Deep leaning framework from recommender systems to predict the citation count. We modify the deep component by implementing it as a feed-forward neural network on top of a bi-directional RNN component over review text.

• MILAM (Wang and Wan, 2018): It is a multiple instance learning network with a novel abstract-based memory mechanism to predict the overall decision (accept, reject, or borderline) based on review text. We modify the loss of this model as the MSE loss for citation regression. For a fair comparison, we also integrate the wide features in a similar way as our wide component.

Evaluation Metrics. To evaluate the performance of different methods on citation count prediction, following previous studies (Bhat et al., 2015; Yuan et al., 2018), we adopt five evaluation metrics, including MAE, RMSE, OR@30, OR@50, and Spearman's rank correlation coefficient. MAE and RMSE measure the difference between the real value and the predicted value for a regression task.

	MILAM	0.2093	0.2510	0.47	0.72	0.2510
	Our model	**0.1866**	**0.2279**	**0.50**	**0.76**	**0.3026**

Table 3: Performance comparisons of different methods for citation count prediction using two datasets. "↑" ("↓") indicates that a larger (smaller) value corresponds to a better performance.

Spearman's Rank measures the overall correlation between the predicted list and the ground-truth list sorted by the citation number descendingly. OR@k measures the overlapping ratio between top k predicted results and the real ordered list.

5.2 Results and Analysis

In this subsection, we construct a series of experiments on the effectiveness of the proposed model for the citation count prediction task.

Main Results. Table 3 presents the performance of different methods on citation count prediction. We can make the following observations. First, the four traditional baselines (LR, KNN, SVR and GBRT) perform worse than the two deep learning baselines (W&D, MILAM). These four baselines only utilize the wide features with traditional machine learning models. Second, MILAM performs consistently better than W&D, since it has designed a more elaborate architecture to model the review text. Finally, our model outperforms all the baselines with a substantial margin, especially for the ICLR dataset. Our model is able to integrate the wide features and learn the comprehensive representation for peer review text, which is the key of the performance improvement over baselines. Overall, the two datasets show the similar findings. In what follows, we will report the results on ICLR dataset due to space limit.

Ablation Analysis. The major novelty of our model is that it utilizes abstract-review match and cross-review match to learn a comprehensive abstract-aware representation for peer review text.

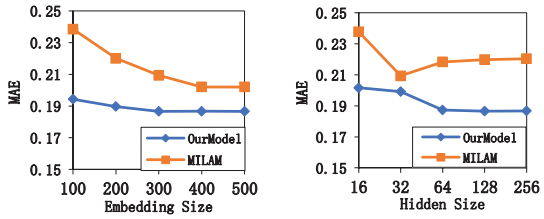
Models	MAE	SR
Our full model	**0.1866**	**0.3026**
w/o abstract-review match	0.1983	0.2861
w/o cross-review match	0.2025	0.2735
w/o wide component	0.2065	0.2697

Table 4: Ablation analysis on ICLR dataset (SR = Spearman's Rank).

Models	MAE		SR	
	original	+review	original	+review
LR	0.2395	0.2289	0.1475	0.1700
KNN	0.2293	0.2176	0.1874	0.2155
SVR	0.2226	0.2174	0.1328	0.1768
GBRT	0.2223	0.2157	0.1469	0.2239
Our Model	**0.1866**		**0.3026**	

Table 5: Analysis of the usefulness of peer review text on ICLR dataset (SR = Spearman's Rank).

Moreover, we integrate the wide features for the prediction task. To examine the contribution of the three parts, we examine the performance of the model variants by removing each module from the complete model. We present the MAE results of our model and its three variants in Table 4. As we can see, all components are useful to improve the final performance.



Usefulness of Peer Review Text. A major motivation of this paper is that peer review text is useful to the citation prediction task, which has been seldom studied in previous studies. Hence, we examine whether peer review text is also

Abstract								
· · · we present a general end-to-end approach to sequence learning that makes minimal assumptions on the sequence structure. Our method uses a multilayered Long Short-Term Memory (LSTM) to map the input sequence to a vector of a fixed dimensionality, and then another deep LSTM to decode the target sequence from the vector. Our main result is that on an English to French translation task · · · Additionally, the LSTM did not have difficulty on long sentences. The LSTM also learned sensible phrase and sentence representations that are sensitive to word order and are relatively invariant to the active and the passive voice. Finally, we found that reversing the order of the words in all source sentences (but not target sentences) improved the LSTM's performance markedly.

useful to improve traditional prediction models (LR, KNN, SVR and KNN). Note that our focus is to verify the general usefulness of peer review text instead of the most suitable text features for the baselines. Here, we adopt the simple yet classic doc2vec model (Le and Mikolov, 2014) to encode peer text into a vectorized representation. Then, we integrate these text features into the four baseline methods. As shown in Table 5, the performance of all the four methods have been improved with the text features. The results have shown that the peer text is indeed generally useful for the citation prediction.

Cross-venue Evaluation. To examine the robustness of our model, we further perform a cross-venue evaluation. For ICLR (NIPS) test set, we apply the models trained on the full NIPS (ICLR) dataset. We only select the best baseline MILAM as a comparison. As shown in Table 6, we are able to see that the performance decreases compared with the results in Table 3, since we use a training set from a different venue. But the decline is not obvious. In the future we will consider how to improve the performance. Our model is still better than the baseline MILAM for both datasets.

Parameter Sensitivity. Next, we investigate the performance with respect to two major parameters in our model, *e.g.,* the word embedding size and the GRU hidden size. As shown in Figure 2(a) and Figure 2(b), our model is consistently better than the best baseline MILAM with all the parameter values. An embedding size of 300 and a hidden size of 128 yield the best results for our model.

5.3 Qualitative Analysis

Previously, we have shown that both the review-abstract match and cross-review match are useful in the prediction performance. In Table 7, we perform the qualitative analysis on a sample paper with three reviews for understanding how the two mechanisms work.

We first compute the similarity weight between the abstract representation and a review sentence, and sort the review sentences according to such weights. As we can see, the comments on model design have been overall ranked in a higher position than those on experiments. With the abstract-review match, our model indeed identifies

more relevant content regarding to the abstract text.

Then, we analyze the corresponding semantic explanation of the cross-review match, in which we decompose an overall review representation into a parallel representation $\boldsymbol{v}_{\parallel}$ and an orthogonal representation $\boldsymbol{v}_{\perp}$. It is difficult to directly understand the two vectors. Instead, we compute the similarity between a comment sentence and the review parallel (or orthogonal) representation. Then we normalize the two similarity values into a distribution over two representations (parallel or orthogonal). It can be seen that the comments focusing on the common aspect have a larger weight on $\boldsymbol{v}_{\parallel}$. For example, for the comments from the first row, reviewer #2 and reviewer #3 have similar general comments about the model architecture, and both comments have very large weights on the parallel representation. While, reviewer #1 raises a different comment on other model detail, corresponding to a large weight on the orthogonal representation. Interestingly, the fourth row corresponds to the comments on the experiments. The three comment sentences are more related to the parallel representation (*i.e.,* the common issue), while they have conveyed different attitudes. This phenomenon can be partially captured by the representation $\widetilde{\boldsymbol{v}}^{R}_{k,\parallel}$ (Eq. 10) by attending to the parallel representations of other reviews.

6 Conclusion

In this paper, we studied how to utilize the peer review text to improve the citation prediction task. We developed a joint deep and wide model that was able to integrate both deep and wide features into a unified predictive function. The deep features were learned from peer review text by applying the abstract-review and cross-review match mechanisms. We constructed two evaluation datasets with peer review text. Extensive results have demonstrated the effectiveness of our proposed model. Currently, we only consider the semantic-level representations from peer review. As future work, we will consider how to extend our work by modeling sentiments of review text.

Acknowledgments

Abstract

Document-level relation extraction is a complex human process that requires logical inference to extract relationships between named entities in text. Existing approaches use graph-based neural models with words as nodes and edges as relations between them, to encode relations across sentences. These models are node-based, i.e., they form pair representations based solely on the two target node representations. However, entity relations can be better expressed through unique edge representations formed as paths between nodes. We thus propose an edge-oriented graph neural model for document-level relation extraction. The model utilises different types of nodes and edges to create a document-level graph. An inference mechanism on the graph edges enables to learn intra- and inter-sentence relations using multi-instance learning internally. Experiments on two document-level biomedical datasets for chemical-disease and gene-disease associations show the usefulness of the proposed edge-oriented approach.[1]

1 Introduction

The extraction of relations between named entities in text, known as Relation Extraction (RE), is an important task of Natural Language Processing (NLP). Lately, RE has attracted a lot of attention from the field, in an effort to improve the inference capability of current methods (Zeng et al., 2017; Christopoulou et al., 2018; Luan et al., 2019).

In real-world scenarios, a large amount of relations are expressed across sentences. The task of identifying these relations is named inter-sentence RE. Typically, inter-sentence relations occur in textual snippets with several sentences, such as documents. In these snippets, each entity is usually repeated with the same phrases or aliases, the occurrences of which are often named entity mentions and regarded as instances of the entity. The multiple mentions of the target entities in different sentences can be useful for the identification of inter-sentential relations, as these relations may depend on the interactions of their mentions with other entities in the same document.

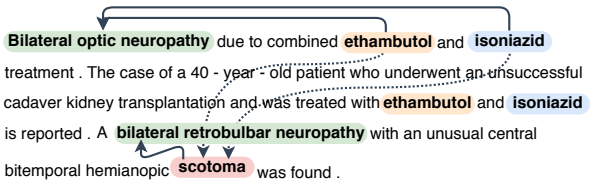

Figure 1: Example of document-level, inter-sentence relations adapted from the CDR dataset (Li et al., 2016a). The solid and dotted lines represent intra- and inter-sentence relations, respectively.

As shown in the example of Figure 1, the entities *bilateral optic neuropathy*, *ethambutol* and *isoniazid* have two mentions each, while the entity *scotoma* has one mention. The relation between the chemical *ethambutol* and the disease *scotoma* is clearly inter-sentential. Their association can only be determined if we consider the interactions between the mentions of these entities in different sentences. A mention of *bilateral optic neuropathy* interacts with a mention of *ethambutol* in the first sentence. Another mention of the former interacts with the mention of *scotoma* in the third sentence. This chain of interactions can help us infer that the entity *ethambutol* has a relation with the entity *scotoma*.

The most common technique that is currently

used to deal with multiple mentions of named entities is Multi-Instance Learning (MIL). Initially, MIL was introduced by Riedel et al. (2010) in order to reduce noise in distantly supervised corpora (Mintz et al., 2009). In DS, training instances are created from large, raw corpora using Knowledge Base (KB) entity linking and automatic annotation with heuristic rules. MIL in this setting considers multiple sentences (bags) that contain a pair of entities serving as the multiple instances of this pair. Verga et al. (2018) introduced another MIL setting for relation extraction between named entities in a document. In this setting, entities mapped to the same KB ID are considered as mentions of an entity concept and pairs of mentions correspond to the pair's multiple instances. However, document-level RE is not common in the general domain, as the entity types of interest can often be found in the same sentence (Banko et al., 2007). On the contrary, in the biomedical domain, document-level relations are particularly important given the numerous aliases that biomedical entities can have (Quirk and Poon, 2017).

To deal with document-level RE, recent approaches assume that only two mentions of the target entities reside in the document (Nguyen and Verspoor, 2018; Verga et al., 2018) or utilise different models for intra- and inter-sentence RE (Gu et al., 2016; Li et al., 2016b; Gu et al., 2017). In contrast with approaches that employ sequential models (Nguyen and Verspoor, 2018; Gu et al., 2017; Zhou et al., 2016), graph-based neural approaches have proven useful in encoding long-distance, inter-sentential information (Peng et al., 2017; Quirk and Poon, 2017; Gupta et al., 2019). These models interpret words as nodes and connections between them as edges. They typically perform on the nodes by updating the representations during training. However, a relation between two entities depends on different contexts. It could thus be better expressed with an edge connection that is unique for the pair. A straightforward way to address this is to create graph-based models that rely on edge representations rather focusing on node representations, which are shared between multiple entity pairs.

In this work, we tackle document-level, intra- and inter-sentence RE using MIL with a graph-based neural model. Our objective is to infer the relation between two entities by exploiting other interactions in the document. We construct a document graph with heterogeneous types of nodes and edges to better capture different dependencies between nodes. In the proposed graph, a node corresponds to either entities, mentions, or sentences, instead of words. We connect distinct nodes based on simple heuristic rules and generate different edge representations for the connected nodes. To achieve our objective, we design the model to be edge-oriented in a sense that it learns edge representations (between the graph nodes) rather than node representations. An iterative algorithm over the graph edges is used to model dependencies between the nodes in the form of edge representations. The intra- and inter-sentence entity relations are predicted by employing these edges. Our contributions can be summarised as follows:

- We propose a novel edge-oriented graph neural model for document-level relation extraction. The model deviates from existing graph models as it focuses on constructing unique nodes and edges, encoding information into edge representations rather than node representations.
- The proposed model is independent of syntactic dependency tools and can achieve state-of-the-art performance on a manually annotated, document-level chemical-disease interaction dataset.
- Analysis of the model components indicates that the document-level graph can effectively encode document-level dependencies. Additionally, we show that inter-sentence associations can be beneficial for the detection of intra-sentence relations.

2 Proposed Model

We build our model as a significant extension of our previously proposed sentence-level model (Christopoulou et al., 2018) for document-level RE. The most critical difference between the two models is the introduction and construction of a partially-connected document graph, instead of a fully-connected sentence-level graph. Additionally, the document graph consists of heterogeneous types of nodes and edges in comparison with the sentence-level graph that contains only entity-nodes and single edge types among them. Furthermore, the proposed approach utilises multi-instance learning when mention-level annotations are available.

As illustrated in Figure 2, the proposed model consists of four layers: sentence encoding, graph

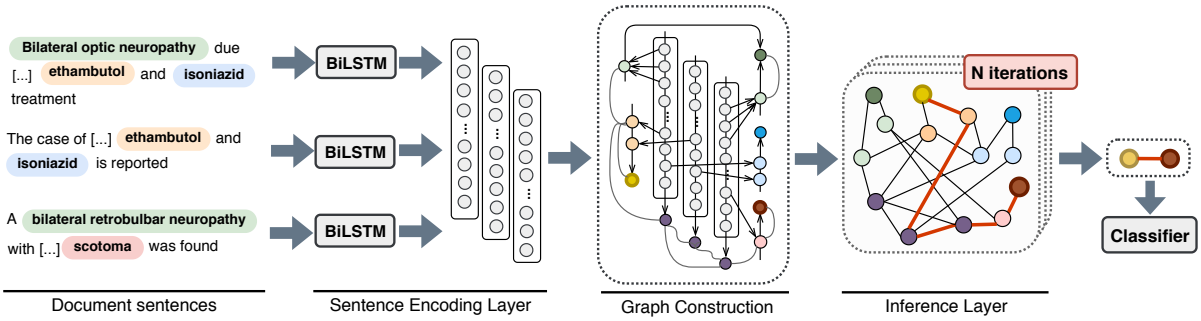

Figure 2: Abstract architecture of the proposed approach. The model receives a document and encodes each sentence separately. A document-level graph is constructed and fed into an iterative algorithm to generate edge representations between the target entity nodes. Some node connections are not shown for brevity.

construction, inference and classification layers. The model receives as input a document with identified concept-level entities and their textual mentions. Next, a document-level graph with multiple types of nodes and edges is constructed. An inference algorithm is applied on the graph edges to generate concept-level pair representations. In the final layer, the edge representations between the target concept-entity nodes are classified into relation categories.

For the remainder of this section, we first briefly introduce the document-level RE task setting and then explain the four layers of the proposed model.

2.1 Task Setting

In concept, document-level RE the input is considered an annotated document. The annotations include concept-level entities (with assigned KB IDs), as well as multiple occurrences of each entity under the same phrase of alias, i.e., entity mentions. We consider the associations of mentions to concept entities given (also known as entity linking (Shen et al., 2014)). The objective of the task is given an annotated document, to identify all the related concept-level pairs in that document. In this work, we refer to concept-level annotations as *entities* and mention-level annotations as *mentions*.

2.2 Sentence Encoding Layer

First, each word in the sentences of the input document is transformed into a dense vector representation, i.e., a word embedding. The vectorised words of each sentence are then fed into a Bi-directional LSTM network (BiLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997), named the encoder. The output of the encoder results in contextualised representations for each word of the input sentence.

2.3 Graph Layer

The contextualised word representations from the encoder are used to construct a document-level graph structure. The graph layer comprises of two sub-layers, a node construction layer and an edge construction layer. We compose the representations of the graph nodes in the first sub-layer and the representations of the edges in the second.

2.3.1 Node construction

We form three distinct types of nodes in the graph: mention nodes (M) n_m, entity nodes (E) n_e, and sentence nodes (S) n_s. Each node representation is computed as the average of the embeddings of different elements. Firstly, mention nodes correspond to different mentions of entities in the input document. The representation of a mention node is formed as the average of the words (w) that the mention contains. Secondly, entity nodes represent unique entity concepts. The representation of an entity node is computed as the average of the mention (m) representations associated with the entity. Finally, sentence nodes correspond to sentences. A sentence node is represented as the average of the word representations in the sentence. In order to distinguish different node types in the graph, we concatenate a node type (t) embedding to each node representation. The final node representations are then estimated as $\mathbf{n}_m = [\text{avg}_{w_i \in m}(\mathbf{w}_i); \mathbf{t}_m]$, $\mathbf{n}_e = [\text{avg}_{m_i \in e}(\mathbf{m}_i); \mathbf{t}_e]$, $\mathbf{n}_s = [\text{avg}_{w_i \in s}(\mathbf{w}_i); \mathbf{t}_s]$.

2.3.2 Edge construction

We initially construct non-directed edges between the graph nodes using heuristic rules that stem from the natural associations between the elements of a document, i.e., mentions, entities and sentences. As we cannot know in advance if two

entities are related, we do not directly connect entity nodes. Connections between nodes are based on pre-defined document-level interactions. The model objective is to generate entity-to-entity (EE) edge representations using other existing edges in the graph and consequently infer entity-to-entity relations. The different pre-defined edge types are described below.

Mention-Mention (MM): Co-occurrence of mentions in a sentence might be a weak indication of an interaction. For this reason, we create mention-to-mention edges only if the corresponding mentions reside in the same sentence. The edge representation between each mention pair m_i and m_j is generated by concatenating the representations of the nodes, the contexts c_{m_i,m_j} and a distance embedding associated with the distance between the two mentions d_{m_i,m_j}, in terms of intermediate words: $\mathbf{x}_{\text{MM}} = [\mathbf{n}_{m_i}; \mathbf{n}_{m_j}; \mathbf{c}_{m_i,m_j}; \mathbf{d}_{m_i,m_j}]$. Here, we generate the context representation for these pairs in order to encode local, pair-centric information. We use an argument-based attention mechanism (Wang et al., 2016), to measure the importance of other words in the sentence towards the mention, denoting $k \in \{1, 2\}$ as the mention arguments.

$$\begin{aligned} \alpha_{k,i} &= \mathbf{n}_{m_k}^{\intercal} \mathbf{w}_i, \\ \mathrm{a}_{k,i} &= \frac{\exp(\alpha_{k,i})}{\sum_{j \in [1,n], j \notin m_k} \exp(\alpha_{k,j})}, \\ \mathrm{a}_i &= (\mathrm{a}_{1,i} + \mathrm{a}_{2,i})/2, \\ \mathbf{c}_{m_1,m_2} &= \mathbf{H}^{\intercal}\, \mathbf{a}, \end{aligned} \tag{1}$$

where $\mathbf{n}_{m_k}$ is a mention node representation, $\mathbf{w}_i$ is a sentence word representation, a_i is the attention weight of word i for mention pair m_1, m_2, $\mathbf{H} \in \mathbb{R}^{w \times d}$ is a sentence word representations matrix, $\mathbf{a} \in \mathbb{R}^w$ is the attention weights vector for the pair and $\mathbf{c}_{m_1,m_2}$ is the final context representation for the mention pair.

Mention-Sentence (MS): Mention-to-sentence nodes are connected only if the mention resides in the sentence. Their initial edge representation is constructed as a concatenation of the mention and sentence nodes, $\mathbf{x}_{\text{MS}} = [\mathbf{n}_m; \mathbf{n}_s]$.

Mention-Entity (ME): We connect a mention node to an entity node if the mention is associated with the entity, $\mathbf{x}_{\text{ME}} = [\mathbf{n}_m; \mathbf{n}_e]$.

Sentence-Sentence (SS): Motivated by Quirk and Poon (2017), we connect sentence nodes to encode non-local information. The main differences with prior work is that our edges are unlabelled, non-directed and span multiple sentences. To encode the distance between sentences, we concatenate to the sentence node representations their distance in the form of an embedding: $\mathbf{x}_{\text{SS}} = [\mathbf{n}_{s_i}; \mathbf{n}_{s_j}; \mathbf{d}_{s_i,s_j}]$. We connect all sentence nodes in the graph. We consider $\textbf{SS}_{\textbf{direct}}$ as direct, ordered edges (distance equal to 1) and $\textbf{SS}_{\textbf{indirect}}$ as indirect, non-ordered edges (distance > 1) between S nodes, respectively. In our setting, **SS** denotes the combination of $\text{SS}_{\text{direct}}$ and $\text{SS}_{\text{indirect}}$.

Entity-Sentence (ES): To directly model entity-to-sentence associations, we connect an entity node to a sentence node if at least one mention of the entity resides in this sentence, $\mathbf{x}_{\text{ES}} = [\mathbf{n}_e; \mathbf{n}_s]$.

In order to result in edge representations of equal dimensionality, we use different linear reduction layers for different edge representations,

$$\mathbf{e}_z^{(1)} = \mathbf{W}_z\, \mathbf{x}_z, \tag{2}$$

where $\mathbf{e}_z^{(1)}$ is an edge representation of length 1, $\mathbf{W}_z \in \mathbb{R}^{d_z \times d}$ corresponds to a learned matrix and $z \in [\text{MM}, \text{MS}, \text{ME}, \text{SS}, \text{ES}]$.

2.4 Inference Layer

We utilise an iterative algorithm to generate edges between different nodes in the graph, as well as to update existing edges. We initialise the graph only with the edges described in Section 2.3.2, meaning that direct entity-to-entity (EE) edges are absent. We can only generate EE edge representations by representing a path between their nodes. This implies that entities can be associated through an edge path of minimum length equal to 3[2].

For this purpose, we adapt our two-step inference mechanism, proposed in Christopoulou et al. (2018), to encode interactions between nodes and edges in the graph and hence model EE associations.

At the first step, we aim to generate a path between two nodes i and j using intermediate nodes k. We thus combine the representations of two consecutive edges e_{ik} and e_{kj}, using a modified bilinear transformation. This action generates an edge representation of double length. We combine all existing paths between i and j through k. The i, j, and k nodes can be any of the three node types E, M, or S. Intermediate nodes without adjacent

[2]Length 2 for an intra-sentence pair (E-S-E) or length 3 for an inter-sentence pair (E-S-S-E)

edges to the target nodes are ignored.

$$f\left(\mathbf{e}_{ik}^{(l)}, \mathbf{e}_{kj}^{(l)}\right) = \sigma\left(\mathbf{e}_{ik}^{(l)} \odot \left(\mathbf{W}\ \mathbf{e}_{kj}^{(l)}\right)\right), \quad (3)$$

where σ is the sigmoid non-linear function, $\mathbf{W} \in \mathbb{R}^{d_z \times d_z}$ is a learned parameter matrix, $\odot$ refers to element-wise multiplication, l is the length of the edge and $\mathbf{e}_{ik}$ corresponds to the representation of the edge between nodes i and k.

During the second step, we aggregate the original (short) edge representation and the new (longer) edge representation resulted from Equation (3) with linear interpolation as follows:

$$\mathbf{e}_{ij}^{(2l)} = \beta\ \mathbf{e}_{ij}^{(l)} + (1-\beta) \sum_{k \neq i,j} f\left(\mathbf{e}_{ik}^{(l)}, \mathbf{e}_{kj}^{(l)}\right), \quad (4)$$

where $\beta \in [0, 1]$ is a scalar that controls the contribution of the shorter edge presentation. In general β is larger for shorter edges as we expect that the relation between two nodes is better expressed through the shortest path between them (Xu et al., 2015; Borgwardt and Kriegel, 2005).

The two steps are repeated a finite number of times N. The number of iterations is correlated with the final length of the edge representations. With initial edge length l equal to 1, the first iteration results in edges of length up-to 2. The second iteration results in edges of length up-to 4. Similarly, after N iterations, the length of edges will be up-to 2^N.

2.5 Classification Layer

To classify the concept-level entity pairs of interest, we incorporate a softmax classifier, using the entity-to-entity edges (EE) of the document graph that correspond to the concept-level entity pairs.

$$\mathbf{y} = \text{softmax}\left(\mathbf{W}_c\ \mathbf{e}_{\text{EE}} + \mathbf{b}_c\right), \quad (5)$$

where $\mathbf{W}_c \in \mathbb{R}^{r \times d_z}$ and $\mathbf{b}_c \in \mathbb{R}^r$ are learned parameters of the classification layer and r is the number of relation categories.

3 Experimental Settings

The model was developed using PyTorch (Paszke et al., 2017). We incorporated early stopping to identify the best training epoch and used Adam (Kingma and Ba, 2015) as the model optimiser.

3.1 Data and Task Settings

We evaluated the proposed model on two datasets:
CDR (BioCreative V): The Chemical-Disease Reactions dataset was created by Li et al. (2016a) for document-level RE. It consists of 1,500 PubMed abstracts, which are split into three equally sized sets for training, development and testing. The dataset was manually annotated with binary interactions between Chemical and Disease concepts. For this dataset, we utilised PubMed pre-trained word embeddings (Chiu et al., 2016).
GDA (DisGeNet): The Gene-Disease Associations dataset was introduced by Wu et al. (2019), containing 30,192 MEDLINE abstracts, split into 29,192 articles for training and 1,000 for testing. The dataset was annotated with binary interactions between Gene and Disease concepts at the document-level, using distant supervision. Associations between concepts were generated by aligning the DisGeNet (Piñero et al., 2016) platform with PubMed[3] abstracts. We further split the training set into a 80/20 percentage split as training and development sets. For the GDA dataset, we used randomly initialized word embeddings.

3.2 Model Settings

We explore multiple settings of the proposed graph using different edges (MM, ME, MS, ES, SS) and enhancements (node type embeddings, mention-pairs context embeddings, distance embeddings). We name our model EoG, an abbreviation of Edge-oriented Graph. We briefly describe the model settings in this section.
EoG refers to our main model with edges {MM, ME, MS, ES, SS }. The EoG (`Full`) setting refers to a model with a *fully connected* graph, where the graph nodes are all connected to each other, including E nodes. For this purpose, we introduce an additional linear layer for the EE edges as in Equation (2). The EoG (`NoInf`) setting refers to a *no inference* model, where the iterative inference algorithm (Section 2.4) is ignored. The concatenation of the entity node embeddings is used to represent the target pair. In this case, we also make use of an additional EE linear layer for EE edges. Finally, the EoG (`Sent`) setting refers to a model that was trained on *sentences* instead of documents. For each entity-level pair we merge the predictions of the mention-level pairs in different sentences using a maximum assumption: if at

Table 1: Overall, intra- and inter-sentence pairs performance comparison with the state-of-the-art on the CDR test set. The methods below the double line take advantage of additional training data and/or incorporate external tools.

least one mention-level prediction indicates a relation then we predict the entity pair as related, similarly to Gu et al. (2017). All of the settings incorporate node type embeddings, contextual embeddings for MM edges and distance embeddings for MM and SS edges, unless otherwise stated.

4 Results

Table 1 depicts the performance of our proposed model on the CDR test set, in comparison with the state-of-the-art. We directly compare our model with models that do not incorporate external knowledge. Verga et al. (2018) and Nguyen and Verspoor (2018) consider a single pair per document, while Gu et al. (2017) develops separate models for intra- and inter-sentence pairs. As it can be observed, the proposed model outperforms the state-of-the-art in CDR dataset by 1.3 percentage points of overall performance. We also show the methods that take advantage of syntactic dependency tools. Li et al. (2016b) uses co-training with additional unlabeled training data. Our model performs significantly better on intra- and inter-sentential pairs, even compared to most of the models with external knowledge, except for Li et al. (2016b).

In addition, we report the performance of three baseline models. The EoG model outperforms all baselines for all pair types. In particular, for the inter-sentence pairs, performance significantly drops with a fully connected graph (`Full`) or without inference (`NoInf`). The former might indicate the existence of certain reasoning paths that should be followed in order to relate entities residing in different sentences. It is also important to note that the intra-sentence pairs substantially benefit from the document-level information, as EoG surpasses the performance of training on single sentences (`Sent`) by 3%. Finally, the performance drop in intra-sentence pairs, as a result of the inference algorithm removal (`NoInf`), suggests that multiple entity associations exist in sentences (Christopoulou et al., 2018). Their interactions can be beneficial in cases of lack of word context information.

EoG (`Sent`)	73.8	73.8	78.1	78.8	-	-

Table 2: Performance comparison on the GDA development and test sets.

We also apply our model on the distantly supervised GDA dataset. As shown in Table 2 results for intra-sentence pairs are consistent with the findings of the CDR dataset for both development and test sets. This indicates that document-level information is helpful. However, performance differs for inter-sentence pairs and in particular for the fully connected graph (`Full`) baseline. We partially attribute this behavior to the small number of inter-sentence pairs in the GDA dataset (only 13% compared to 30% in the CDR dataset) that results in inadequate learning patters for EoG. We leave further investigation as part of future work.

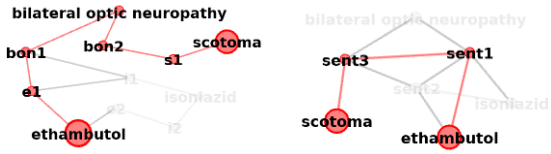
5 Analysis & Discussion

We first analyse the performance of our main model (EoG) using different pre-trained word embeddings. Table 3 shows the performance difference between domain-specific (PubMed) (Chiu et al., 2016), general-domain (GloVe) (Pennington et al., 2014) and randomly initialized (random) word embeddings. As observed, our proposed model performs consistently with both in-domain and out-of-domain pre-trained word embeddings. The low performance of random embeddings is due to the small size of the dataset, which results in lower quality embeddings.

For further analysis, we choose the CDR dataset as it is manually annotated. To better analyse the behaviour of our model, we conduct analysis on the effect of direct and indirect sentence-to-sentence edges as a function of the inference steps. Figures 3a, 3b and 3c illustrate the performance of both graphs for overall, intra- and inter-sentence pairs respectively.

The first observation is that usage of direct edges only, reduces the overall performance almost by 4%, for inference step $l = 8$. This drop mostly affects inter-sentence pairs, where a 18% point drop is observed. In fact, ordered edges (SS_{direct}) need longer inference to perform better, in comparison with additional indirect edges (SS) for which less steps are required. The superiority of SS edges, for all inference steps, compared to SS_{direct} edges on inter-sentence pairs detection, indicates that in a narrative, some intermediate information is not important. The observation that indirect edges perform slightly better than direct for intra-sentence pairs ($l \leq 16$) agrees with the results of Table 1 where we showed that inter-sentence information can act as complementary evidence for intra-sentence pairs.



Edge Types	F1 (%)		
	Overall	Intra	Inter

Table 4: Ablation analysis for different edge and node types on the CDR development set.

We additionally conduct ablation analysis on the graph edges and nodes, as shown in Table 4. Usage of EE edges only results in poor performance across pairs. Removal of MM and ME edges does not significantly affect the performance as ES edges can replace their impact. Complete removal of connections to M nodes results in low inter-sentence performance. This behaviour pinpoints the importance of some local dependencies in identifying cross-sentence relations.

Removal of ES edges reduces the performance of all pairs, as encoding of EE edges becomes more difficult[4]. We further observe very poor identification of inter-sentence pairs without sentence-to-sentence connections. This is complementary with the inability of the model to identify any inter-sentence pairs without connections to S nodes. In this scenario, we enable identification of pairs across sentences only through MM and ME edges, as shown in Figure 4a. In the CDR dataset,

Table 5: Ablation analysis of edge enhancements on the CDR development set.

78% of inter-sentential pairs have at least one argument that is mentioned only once in the document. The identification of these pairs, without S nodes, requires very long inference paths[5]. As shown in Figure 4b, the introduction of S nodes results in a path with half the length, which we expect to better represent the relation. Longer inference representations are much weaker than shorter ones. This suggests that the inference mechanism has limited capability in identifying very complex associations.

We then investigate the additional enhancements of the graph edges in Table 5. In general, intra-sentence pairs are not affected by these settings. However, for inter-sentence pairs, removal of node type embeddings and distance embeddings results in a 2% and 5% drop in terms of F1-score. These results indicate that the interactions between different elements in a document, along with the distance between sentences and mentions, play an important role in inter-sentence pair inference. Removing all of these settings does not perform worse than removing one of them, which might indicate model overfitting. We plan to further investigate this as part of future work.

We examine the performance of different models on inter-sentence pairs, based on their sentence-level distances. Figure 5 illustrates that for long-distanced pairs, EoG has lower performance, indicating the difficulty in predicting them and a possible requirement for other, latent document-level information (EoG (Full)).

Table 6: Inter-sentence pairs from the CDR development set that EoG fails to detect.

As final analysis, we investigate some of the cases where the graph models are unable to identify inter-sentence related pairs. For this purpose, we randomly check some of the common false negative errors among the EoG models. We identify three frequent cases of errors, as shown in Table 6. In the first case, when multiple entities reside in the same sentence and are connected with conjunctions (e.g., 'and') or commas, the model often failed to find associations with all of them. The second error derives from missing coreference connections. For instance, *pyeloureteritis cystica* is referred to as *disease*. Although our model cannot directly create these edges, S nodes potentially simulate such links, by encoding the co-referring entities into the sentence representation. Finally, incomplete entity linking results into additional model errors. For instance, in the third example, *hemorrhage* and *intracranial bleeding* are synonymous terms. However, they are assigned different KB IDs, hence treated as different entities. The model can find the intra-sentential relation but not the inter-sentential one.

6 Related Work

Traditional approaches focus on intra-sentence supervised RE, utilising CNN or RNN, ignoring multiple entities in a sentence (Zeng et al., 2014; Nguyen and Grishman, 2015) as well as incorporating external syntactic tools (Miwa and Bansal,

2016; Zhang et al., 2018). Christopoulou et al. (2018) considered intra-sentence entity interactions without domain dependencies by modelling long dependencies between the entities of a sentence.

Other approaches deal with distantly-supervised datasets but are also limited to intra-sentential relations. They utilise Piecewise Convolutional Neural Networks (PCNN) (Zeng et al., 2015), attention mechanisms (Lin et al., 2016; Zhou et al., 2018), entity descriptors (Jiang et al., 2016) and graph CNNs (Vashishth et al., 2018) to perform MIL on bags-of-sentences that contain multiple mentions of an entity pair. Recently, Zeng et al. (2017) proposed a method for extracting paths between entities using the target entities' mentions in several different sentences (in possibly different documents) as intermediate connectors. They allow mention-mention edges only if these mentions belong to the same entity and consider that a single mention pair exists in a sentence. On the contrary, we not only allow interactions between all mentions in the same sentence, but also consider multiple edges between mentions, entities and sentences in a document.

Current approaches that try to deal with document-level RE are mostly graph-based. Quirk and Poon (2017) introduced the notion of a document graph, where nodes are words and edges represent intra- and inter-sentential relations between the words. They connected words with different dependency edges and trained a binary logistic regression classifier. They evaluated their model on distantly supervised full-text articles from PubMed for Gene-Drug associations, restricting pairs within a window of consecutive sentences. Following this work, other approaches incorporated graphical models for document-level RE such as graph LSTM (Peng et al., 2017), graph CNN (Song et al., 2018) or RNNs on dependency tree structures (Gupta et al., 2019). Recently, Jia et al. (2019) improved n-ary RE using information from multiple sentences and paragraphs in a document. Similar to our approach, they choose to directly classify concept-level pairs rather than multiple mention-level pairs. Although they consider sub-relations to model related tuples, they ignore interactions with other entities outside of the target tuple in the discourse units.

Non-graph-based approaches utilise different intra- and inter-sentence models and merge the resulted predictions (Gu et al., 2016, 2017). Other approaches extract document-level representations for each candidate entity pair (Zheng et al., 2018; Li et al., 2018; Wu et al., 2019), or use syntactic dependency structures (Zhou et al., 2016; Peng et al., 2016). Verga et al. (2018) proposed a Transformer-based model for document-level relation extraction with multi-instance learning, merging multiple mention pairs. Nguyen and Verspoor (2018) used a CNN with additional character-level embeddings. Singh and Bhatia (2019) also utilised Transformer and connected two target entities by combining them directly and via a contextual token. However, they consider a single target entity pair per document.

7 Conclusion

We presented a novel edge-oriented graph neural model for document-level relation extraction using multi-instance learning. The proposed model constructs a document-level graph with heterogeneous types of nodes and edges, modelling intra- and inter-sentence pairs simultaneously with an iterative algorithm over the graph edges. To the best of our knowledge, this is the first approach to utilise an edge-oriented model for document-level RE.

Analysis on intra- and inter-sentence pairs indicated that the proposed, partially-connected, document graph structure can effectively encode dependencies between document elements. Additionally, we deduce that document-level information can contribute to the identification of intra-sentence pairs leading to higher precision and F1-score.

As future work, we plan to improve the inference mechanism and potentially incorporate additional information in the document-graph structure. We hope that this study will inspire the community to further investigate the usage of edge-oriented models on RE and other related tasks.

A Datasets

In Tables 7-8 we summarise the statistics for the CDR and GDA datasets, respectively. For all datasets, we used the GENIA Sentence Splitter[6] and GENIA Tagger[7] for sentence splitting and word tokenisation respectively. We additionally removed mentions in the given abstracts that were not grounded to a Knowledge Base ID (ID equal to -1).

Due to the small size of the CDR dataset, some approaches create a new split from the union of train and development sets (Verga et al., 2018; Zhou et al., 2018). We select to merge the train and development sets and re-train our model on their entire union for evaluation on the test set following Lin et al. (2016) and Zhou et al. (2016). To compare with related work, we followed Verga et al. (2018) and Gu et al. (2016) and ignored non-related pairs that correspond to general concepts (MeSH vocabulary hypernym filtering).

B Hyper-parameter Setting

We used the development set to identify the stopping training epoch and tune the number of inference iterations. Except from these parameters, all experiments used the same hyperparameters, with a fixed initialisation seed. For the CDR dataset EoG, (`Full`) and (`Sent`) models performed best with $l = 8, 2, 4$ inference steps, respectively. The chosen batchsize was equal to 2. For the GDA dataset, EoG and EoG (`Full`) performed best with $l = 16$ and EoG (`Sent`) with $l = 8$ inference steps. The chosen batchsize was equal to 3. For all experiments performance was measured in terms of micro precision (P), recall (R) and F1-score (F1). We list the hyper-parameters used to train the proposed model in Table 9.

Abstract

Text style transfer task requires the model to transfer a sentence of one style to another style while retaining its original content meaning, which is a challenging problem that has long suffered from the shortage of parallel data. In this paper, we first propose a semi-supervised text style transfer model that combines the small-scale parallel data with the large-scale nonparallel data. With these two types of training data, we introduce a projection function between the latent space of different styles and design two constraints to train it. We also introduce two other simple but effective semi-supervised methods to compare with. To evaluate the performance of the proposed methods, we build and release a novel style transfer dataset that alters sentences between the style of ancient Chinese poem and the modern Chinese.

1 Introduction

Recently, the natural language generation (NLG) tasks have been attracting the growing attention of researchers, including response generation (Vinyals and Le, 2015), machine translation (Bahdanau et al., 2014), automatic summarization (Chopra et al., 2016), question generation (Gao et al., 2019), etc. Among these generation tasks, one interesting but challenging problem is text style transfer (Shen et al., 2017; Fu et al., 2018; Logeswaran et al., 2018). Given a sentence from one style domain, a style transfer system is required to convert it to another style domain as well as keeping its content meaning unchanged. As a fundamental attribute of text, style can have a broad and ambiguous scope, such as ancient poetry style v.s. modern language style and positive sentiment v.s. negative sentiment.

Building such a style transfer model has long suffered from the shortage of parallel training data, since constructing the parallel corpus that could align the content meaning of different styles is costly and laborious, which makes it difficult to train in a supervised way. Even some parallel corpora are built, they are still in a deficient scale for neural network based models. To tackle this issue, previous works utilize nonparallel data to train the model in an unsupervised way. One commonly used method is disentangling the style and content from the source sentence (John et al., 2018; Shen et al., 2017; Hu et al., 2017). For the input, they learn the representations of styles and style-independent content, expecting the later only keeps the content information. Then the content-only representation is coupled with the representation of a style that differs from the input to produce a style-transferred sentence. The crucial part of such methods is that the encoder should accurately disentangle the style and content information. However, Lample et al. (2019) illustrated that disentanglement is not a facile thing and the existing methods are not adequate to learn the style-independent representations.

Considering the above-discussed issues, in this paper, instead of disentangling the input, we propose a differentiable encoder-decoder based model that contains a projection layer to build a bridge between the latent spaces of different styles. Concretely, for texts in different styles, the encoder converts them into latent representations in different latent spaces. We introduce a projection function between two latent spaces that projects the representation in the latent space of one style to another style. Then the decoder generates an output using the projected representation.

In the majority of cases, nonparallel corpora of different styles are accessible. Based on these datasets, it is feasible to build small-scale paral-

*This work was done when Mingyue Shang was an intern at Tencent AI Lab.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4937–4946, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

lel datasets. Therefore, we design two kinds of objective functions for our model so that it could be trained under both supervised settings and unsupervised settings. With the parallel data, the model learns the projection relationship and the standard representation of the target latent space from ground-truth. Without the parallel data, we train the model by back-projection between the source and target latent space so that it could learn from itself. During training, we incorporate these two kinds of signals to train the model in a semi-supervised way.

We conduct experiments on an English formality transfer task that alters the sentence between formal and informal styles, and a Chinese literal style transfer task that alters between the ancient Chinese poem sentences and modern Chinese sentences. We evaluate the performance of models from the degree of content preservation, the accuracy of the transferred styles, and the fluency of sentences using both automatic metrics and human annotations. Experimental results show that our proposed semi-supervised method can generate more preferred output.

In summary, our contributions are manifolds:

- We designed a semi-supervised model that crossly projects the latent spaces of two styles to each other. In addition, this model is flexible in alternating the training mode between supervised and unsupervised.
- We introduce another two semi-supervised methods that are simple but effective to leverage both the nonparallel and parallel data.
- We build a small-scale parallel dataset that contains ancient Chinese poem style and modern Chinese style sentences. We also collect two large nonparallel datasets of these styles.[1]

2 Related Works

Recently, text style transfer has stimulated great interests of researchers from the area of neural language processing and some encouraging results are obtained (Shen et al., 2017; Rao and Tetreault, 2018; Prabhumoye et al., 2018; Hu et al., 2017; Jin et al., 2019). In the primary stage, due to the lacking of parallel corpus, most of the methods employ unsupervised learning paradigm to conduct the semantic modeling and transfer.

[1]Download link: https://tinyurl.com/yyc8zkqg

Unsupervised Learning Methods. Mueller et al. (2017) modify the latent variables of sentences in a certain direction guided by a classifier to generate the sentence with classifier favored style. Hu et al. (2017) employ variational autoencoders (Kingma and Welling, 2013) to conduct the style latent variable learning and design a strategy to disentangle the variables for content and style. Shen et al. (2017) first map the text corpora belonging to different styles to their own space respectively, and leverages the alignment of latent representations from different styles to perform style transfer. Chen et al. (2019) propose to extract and control the style of the image caption through domain layer normalization. Prabhumoye et al. (2018) and Zhang et al. (2018b) employ the back-translation mechanism to ensure that the input from the source style can be reconstructed from the transferred result in the target style. Liao et al. (2018) associate the style latent variable with a numeric discrete or continues numeric value and can generate sentences controlled by this value. Among them, many use the adversarial training mechanism (Goodfellow et al., 2014) to improve the performance of the basic models (Shen et al., 2017; Zhao et al., 2018).

To sum up, most of the existing unsupervised frameworks on the text style transfer focus on getting the disentangled representations of style and content. However, Lample et al. (2019) illustrated that the disentanglement not adequate to learn the style-independent representations, thus the quality of the transferred text is not guaranteed.

Supervised Learning Methods. Fortunately, Rao and Tetreault (2018) release a high-quality parallel dataset - GYAFC, which consists of two domains for Formality style transfer: Entertainment & Music and Family & Relationships. The quantity of the dataset is sufficient to train an attention-based sequence-to-sequence framework.

Nevertheless, building parallel corpus that could align the content meaning of different styles is costly and laborious, and it is impossible to build the parallel corpus for all the domains.

3 Task Formulation

We assume two nonparallel datasets A and B that are sentences in two different styles, denoted as style s^a and style s^b, and a parallel dataset P that contains the pairs of sentences with two styles. The size of the three

datasets are denoted as $|A|$, $|B|$ and $|P|$, respectively. As the nonparallel data is abundant but the parallel data is limited, size $|A|$, $|B| \gg |P|$. Formally, two nonparallel datasets are denoted as $A = \{a_1, a_2, \cdots, a_{|A|}\}$ and $B = \{b_1, b_2, \cdots, b_{|B|}\}$, where a_i and b_i refer to the i-th sentences of s^a style and s^b style, respectively. It should be clear that as A and B are nonparallel datasets, the sentences in the two datasets are not aligned with each other, which means that a_i and b_i are not required to have the same or similar content meaning though they have the same subscript. The parallel dataset is denoted as $P = \{(a_1^p, b_1^p), (a_2^p, b_2^p), \cdots, (a_{|P|}^p, b_{|P|}^p)\}$, where (a_i^p, b_i^p) is the i-th pair of sentences that have the same content meaning but expressed in style s^a and s^b separately.

Due to the situation that the limited parallel data is deficient for neural network based model to train, our goal is to train a model in a semi-supervised way that could leverage the large volumes of nonparallel data to improve the performance. Given a sentence of the source style as input, the model learns to generate a target style output which preserves the meaning of the input to the greatest extent. In this paper, the style transfer process could be exerted in two directions, from s^a to s^b as well as from s^b to s^a.

4 Basic Model Architecture

The text style transfer task could be interpreted as transforming a sequence of source style words to a sequence of target style words, which makes the sequence-to-sequence framework a suitable architecture. In this section, we describe the formulation of sequence-to-sequence (S2S) (Sutskever et al., 2014) model, which contains an encoder and a decoder, and our proposed models are built based on such an architecture.

Given an input, the encoder first converts it into an intermediate vector, then the decoder takes the intermediate representation as input to generate a target output. In this paper, we implement the encoder by a bi-directional Long Short-Term Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) and the decoder by a one layer LSTM.

Formally, with an input sentence $x = \{w_1^x, \cdots, w_T^x\}$ of length T, and a target sentence $y = \{w_1^y, \cdots, w_{T'}^y\}$ of length T', where w_i is the embedding of the i-th word, the probability of generating the target sentence y given x is defined as:

$$p(y|x) = \prod_{i=1}^{T'} p\left(w_i^y | x, w_1^y, \ldots, w_{i-1}^y\right) \quad (1)$$

In the training process, the encoder first encodes x into an intermediate representation c_x. More specifically, at each time step t, the encoder produces a hidden state vector $h_t = [\overrightarrow{h}_t; \overleftarrow{h}_t]$, where the $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ represents the forward and backward hidden state, respectively, and $[;]$ means concatenation. The intermediate vector is formed by the concatenation of the forward and backward last hidden states, denoted as $c_x = Enc(x) = [\overrightarrow{h}_T; \overleftarrow{h}_1]$. Then this vector is fed to the decoder to generate a target sentence step by step as formulated in Equation 1.

Such neural network based models always have a large amount of parameters which empower the model with the ability to fit complex datasets. However, when trained with limited data, the model may get so closely fitted to the training data that loses the power of generalization, and thus performances poorly on new data.

5 Cross Projection in Latent Space

In this paper, we propose a semi-supervised style transfer method named cross projection in latent space (CPLS) to leverage the large volumes of nonparallel data as well as the limited parallel data. Based on the S2S architecture, we consider the representations in the latent space, and propose to establish projection relations between different latent spaces. To be specific, in the S2S architecture, the encoder converting the input into an intermediate vector is a process of extracting the semantic information of the input, including the style and the content information. Thus the intermediate vectors could be seen as the compressed representations in the latent space of the inputs. Since texts in different styles are in different latent spaces, we introduce a projection function to project the intermediate vector from one latent space to another. To combine the nonparallel data and parallel data in training, we design two kinds of constraints for the projection functions.

Concretely, we first train an auto-encoder for each style to learn the standard latent spaces of the style. After that, we train the projection functions which are exerted on latent vectors to establish projection relations between different latent spaces. We design a cross projection strategy and

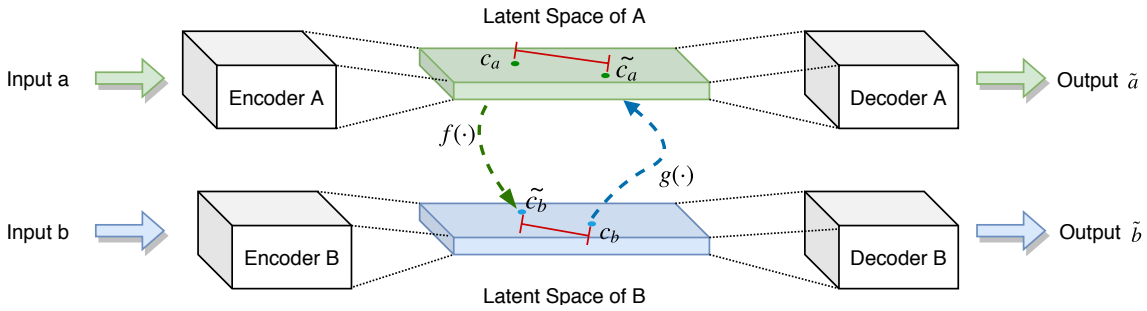

Figure 1: The process of training the sequence-to-sequence model. Take a sentence pair (a, b) for example. After a is encoded into c_a by the encoder A, the projection function $f(\cdot)$ (shown by the dotted green line) projects it to the latent space of B, which is then fed to the decoder B to generate the output $\tilde{a}$. The encoder B gives the latent representation of b. One of the constraints is computed from the distance of $\tilde{c}_b$ and c_b (shown by the red lines) and another is the NLL-loss of $\tilde{b}$ and b. The dotted blue line refers to the projection function from the space of B to A.

a cycle projection strategy to utilize the parallel data and nonparallel data. These two strategies are exerted iteratively in the training process, thus our model is compatible with the two types of training data. The following subsections give the details of the modules and the strategies of model training.

5.1 Denoising Auto-Encoder

To learn the latent space representations of styles, we train an auto-encoder for each style of text through reconstructing the input, which is composed of an encoder and a decoder. The encoder takes a sentence as input and maps the sentence to a latent vector representation, and the decoder reconstructs the sentence based on the vector. But a common pitfall is that the decoder may simply copy every token from the input, making the encoder lose the ability to extract the features. To alleviate this issue, we adopt the denoising auto-encoder (DAE) following the previous work (Lample et al., 2019) that tries to reconstruct the corrupted input. Specifically, we randomly shuffle a small portion of words in the original sentence to the corrupted input which are then fed to the denoising auto-encoder. For example, the original input is "Listen to your heart and your mind.", then the corrupted version could be "Listen your to and heart your mind.". The decoder is required to reconstruct the original sentence.

The training of a DAE model relies on the corpus of one style only, thus we train each DAE model using the nonparallel corpus of each style. Formally, the encoder and decoder of style s^a and s^b are referred as $\text{Enc}^{(a)}$ - $\text{Dec}^{(a)}$ and $\text{Enc}^{(b)}$ - $\text{Dec}^{(b)}$. Given sentences a and b from two styles, the corresponding encoder takes the sentence as input and converts it to the latent vector c_a and c_b, respectively, by which each encoder therefore constructs the latent space for the corresponding style.

5.2 Cross Projection

To perform the style transfer task, we establish a projection relationship between latent spaces and cross link the encoder and the decoder from different styles. Take the transfer from style s^a to s^b for example. Given a sentence a that is required to transferred to b, we cross link the $\text{Enc}^{(a)}$ as the encoder and $\text{Dec}^{(b)}$ as the decoder to form the style transfer model. However, considering the DAE models for different styles are trained respectively, therefor the latent vector spaces are usually different. The latent vector produced by $\text{Enc}^{(a)}$ is the representation on the latent space of style s^a while the $\text{Dec}^{(b)}$ relies on the information and features from the latent space of style s^b. Therefore, we introduce a projection function to project the latent vector from the latent space of s^a to s^b.

Concretely, after we get the c_a from $\text{Enc}^{(a)}$, a projection function $f(\cdot)$ is employed to project c_a from the latent space of style s^a to the latent space of s^b, denoted as $\tilde{c}_b = f(c_a)$. Then the decoder $\text{Dec}^{(b)}$ takes the the projected vector $\tilde{c}_b$ as input and generates a sentence $\tilde{b}$ of style s^b base on the prediction probability, denoted as $p_b(\tilde{b}|\tilde{c}_b)$.

It is worth noting that we have only exploited the nonparallel corpus for the style transfer up to now. Recall that our framework can employ both the parallel corpus and nonparallel corpus for the model training. With parallel corpus, we design the cross projection strategy. When the input a is accompanied with a ground-truth b, we can get the standard latent representation of b by the $\text{Enc}^{(b)}$, denoted as c_b. In order to align the latent vectors from different spaces, we design the constraints to

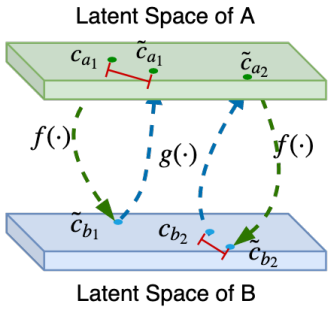

Figure 2: The cycle projection process between the latent space of A and B when training the denoising auto-encoders. The encoders and decoders are the same as illustrated in Figure 1 and are omitted in this figure.

train the $f(\cdot)$ from two aspects: the distance between $\tilde{c}_b$ and c_b in the latent space should be close; the generated sentence $\tilde{b}$ should be similar with b. Then we define two losses as follows:

$$\tilde{c}_b = f(\text{Enc}^{(a)}(a)) \quad (2)$$
$$l_{s_1} = \|\tilde{c}_b - c_b\| \quad (3)$$
$$l_{s_2} = -\log p(b|\tilde{c}_b) \quad (4)$$
$$l_s = \alpha * l_{s_1} + \beta * l_{s_2} \quad (5)$$

where l_{s_1} measures the Euclidean distance between $\tilde{c}_b$ and c_b and l_{s_2} is the negative log-likelihood (NLL) loss given a as input and b as the ground-truth. α and β is the hyper-parameters that control the weight of l_{s_1} and l_{s_2}.

Figure 1 shows the training process of the cross projection. Similarly, to transfer the style of text from s^b to s^a, we cross link $\text{Enc}^{(b)}$ and $\text{Dec}^{(a)}$, and the projection function to project c_b to the latent space of s^a is denoted as $g(\cdot)$.

5.3 Cycle Projection Enhancement

Inspired by the concept of back-translation in machine translation (Sennrich et al., 2015; Lample et al., 2018; He et al., 2016), we design a cycle projection strategy to train the model on the nonparallel data. Given the input without the ground-truth, we train the projection function $f(\cdot)$ and $g(\cdot)$ by projecting back and forth to reconstruct the input. The cycle projection process is shown in Figure 2.

Formally, for a sentence a in style s^a, after getting its latent representation c_a in its own latent space by the $\text{Enc}^{(a)}$, we first project it to the latent space of s^b by $f(\cdot)$ and get $\tilde{c}_b = f(c_a)$. Then we exert $g(\cdot)$ to project $\tilde{c}_b$ back to the latent space of style s^a, denoted as $\tilde{c}_a = g(\tilde{c}_b)$. Finally $\tilde{c}_a$ is fed to $\text{Dec}^{(a)}$ to produce an output $\tilde{a}$. Though the latent vector $\tilde{c}_b$ has no reference to train, the latent vector $\tilde{c}_a$ and the output $\tilde{a}$ could be trained by treating c_a and a as the references. The loss functions are formulated as:

$$\tilde{c}_a = g(f(\text{Enc}^{(a)}(a))) \quad (6)$$
$$l_{c_1} = \|\tilde{c}_a - c_a\| \quad (7)$$
$$l_{c_2} = -\log p(a|\tilde{c}_a) \quad (8)$$
$$l_c = \alpha * l_{c_1} + \beta * l_{c_2} \quad (9)$$

5.4 Training Procedure

In the training stage, we first pretrain DAE models for each style separately on the nonparallel data to get the latent spaces of styles. Then we alternately apply the cross projection strategy and cycle projection enhancement on parallel data and nonparallel data with loss l_s and l_c.

6 Straightforward Semi-supervised Methods

We also introduce another two semi-supervised methods as the baselines to provide a more comprehensive comparison with the proposed CPLS model. The two semi-supervised methods are built from different perspectives.

6.1 Data Augmentation via Retrieval

One semi-supervised baseline is from the perspective of data augmentation. In order to alleviate the over-fitting issue caused by the small-scale parallel data, we propose a simple but efficient method that augments the parallel dataset by retrieving pseudo-references for the nonparallel datasets, denoted as DAR model.

Pseudo-parallel Corpus Construction. We employ Lucene[2] to build indexes for the nonparallel corpus of each style. Then the pseudo-references are retrieved based on the TF-IDF scores. To build the pseudo-parallel corpus of style s^a and s^b, we first samples 80,000 sentences in style s^a as queries. Specifically, each query searches a pseudo-reference from the nonparallel corpus of style s^b according to the TF-IDF based cosine similarity. The sampled query is therefore coupled with the pseudo-reference to form a training pair. We also conduct the same operation that uses sampled queries from style s^b to search pseudo-references from sentences of style s^a. After searching pseudo-references from two sides,

[2] http://lucene.apache.org/

Dataset	Parallel			Nonparallel
	Train	Valid	Test	
Anc.p	3,362	400	998	269k
M.zh				77k
F.en	5,000	2,247	1,019	2,483k
Inf.en		2,788	1,332	4,891k

Table 1: Statistics of two style transfer datasets.

we construct a pseudo-parallel corpus in the size of 150,000 pairs[3]. With the pseudo-parallel corpus, the model is exposed to more information and thus the problem of over-fitting can be mitigated to some extent. Though the relevance of the content between the input sentence and the pseudo-reference is not guaranteed, the encoder could better learn to extract the language features and the decoder could also benefit from the weak contextual correlation information.

Training Procedure. In the training stage, we first train the S2S model on the pseudo-parallel dataset and save a checkpoint every 2,000 steps. We then calculate the BLEU score of checkpoints on the validation set and select the one with the highest BLEU score as the final pretrained model. Then based on this pretrained model, we fine-tune the parameters using the true parallel data.

6.2 Shared Latent Space Model

The second semi-supervised baseline is similar to CPLS that first trains a DAE model on the corpus of each style. Instead of building a bridge between the latent spaces of two styles through projection functions, in this method, we simply share the latent representations by cross linking the encoder and decoder, denoted as SLS model. Given a pair of sentence (a^p, b^p), the encoder $\text{Enc}^{(a)}$ encodes it into context c_a, then the decoder $\text{Dec}^{(b)}$ directly takes c_a to produce $\tilde{b}$.

Training Procedure. For this method, we first pre-train two DAE models. Then we train the DAE models and the cross-linked S2S models from two transfer directions alternately. Considering the size imbalance between the nonparallel corpora and parallel corpus, to avoid the S2S falling into over-fitting too fast, We alternate the training in the form of training 20-step DAE models and then training one step S2S model.

[3]Some quires did not have corresponding retrieved result, therefore the total size is less than the number of queries.

7 Experiment

We conduct experiments on two bilateral style transfer tasks that each of them has a small-scale parallel corpus and two large-scale nonparallel corpora in two styles. DAR model and SLS model are treated as two baselines of CPLS model. In addition, we also train a S2S model with attention mechanism on the parallel data as the vanilla baseline. The following subsections elaborate the construction of the datasets and the detailed experimental settings.

7.1 Datasets

We construct a Chinese literal style dataset with ancient poetry style and modern Chinese style, and an English formality style dataset with formal style and informal style. The texts of ancient Chinese poem, modern Chinese, formal English and informal English are referred as Anc.P, M.zh, F.en and Inf.en for short. The overall statistics are shown in Table 1.

Chinese Literal Style Dataset. We consider the texts of ancient Chinese poem style and modern Chinese style which differ greatly in expression. As the ancient poems from different dynasties vary in style and form, in this paper, we focus on the poem from Tang dynasty.

To build the parallel dataset, we crawl from the website named Gushiwen[4] that provides ancient Chinese poems and some are coupled with modern Chinese interpretation in paragraphs. We split the collected paragraphs into independent sentences using punctuation based rules, and manually align the poem sentence with the interpretation sentence to form the parallel pair.

For the nonparallel corpus of ancient Chinese poem style, we collect all the poems from Quan Tangshi[5] and split them into sentences. To build the nonparallel dataset in modern Chinese style, we collect data from the Chinese ballad and took the lyrics. The reason we choose the Chinese ballad is that the content domain of the two styles should be close. Considering that most of the poems are about the natural scenery and the sentiments, the most suitable literary form is the lyrics of ballad. [6]

[4]https://www.gushiwen.org/

[5]The largest collection of Tang poems commissioned by the Qing dynasty Kangxi Emperor.

[6] We count the overlap of the topic words involved in the top 20 topics between the poem translation and ballad, and compare the overlap ratio with other modern Chinese corpora

	CPLS	It is wrong that they can't go out with her.

Table 2: Case study: the sentences in the brackets are the translation of the corresponding sentence.

Formality Dataset. The formality dataset used in this paper is built based on the parallel dataset released by Rao and Tetreault (2018) which contains texts of formal and informal style.

With the released data, we randomly sample 5,000 sentence pairs from it as the parallel corpus with limited data volume. We then use the Yahoo Answers L6 corpus[7] as the source which is in the same content domain as the parallel data to construct the large-scale nonparallel data. To divide nonparallel dataset into two styles, we train a CNN-based classifier (Kim, 2014) on the parallel data with annotation of styles and use it to classify the nonparallel data.

7.2 Experimental Settings

We perform different data preprocessing on different datasets. The Chinese literary datasets are segmented by characters instead of word to alleviate the issue of unknown words. Our statistics show that the average length of ancient poems is 9 while 17 for modern Chinese sentences. Therefore, we set the minimum length of the ancient poem as 3, and the maximum length of the modern Chinese sentence as 30. For the formality datasets, we use NLTK (Loper and Bird, 2002) to tokenize the texts and set the minimum length as 5 and the maximum length as 30 for both formal and informal styles.

We adopt GloVE (Pennington et al., 2014) to pretrain the embeddings, and the dimensions of the embeddings are set to 300 for all the datasets. The hidden states are set to 500 for both encoders and decoders. We adopt SGD optimizer with the learning rate as 1 for DAE models and 0.1 for S2S models. The dropout rate is 0.4. In the inference stage, the beam size is set to 5.

8 Comparison Models and Evaluations

8.1 Baselines

We train a S2S model with attention mechanism on the parallel data as the supervised learning baseline. Since the existing works on text style transfer seldom explore the semi-supervised methods, we propose DAR and SLS model as two semi-supervised baselines.

8.2 Automatic Evaluation Metrics

Following previous works (Prabhumoye et al., 2018; Zhang et al., 2018a), we employ BLEU score (Papineni et al., 2002) and style accuracy

(news, open-domain conversations).

as the automatic evaluation metrics to measure the content preservation degree and the style changing degree. BLEU calculates the N-gram overlap between the generated sentence and the references, thus can be used to measure the preservation of text content. Considering that text style transfer is a monolingual text generation task, we also use GLEU, a generalized BLEU proposed by (Napoles et al., 2015). To evaluate the extent to which the sentences are transferred to the target style, we follow Shen et al. (2017); Hu et al. (2017) that build a CNN-based style classifier and use it to measure the style accuracy.

8.3 Human Evaluation

We also adopt human evaluations to judge the quality of the transferred sentences from three aspects, namely content, style and fluency. These aspects evaluate how well the transferred text preserve the content of the input, the style strength and the fluency of the transferred text. Take the content relevance for example, the criterion is as follows: **+2:** The transferred sentence has the same meaning with the input sentence. **+1:** The transferred sentence preserves part of the content meaning of the input sentence. **0:** The transferred sentence and the input sentence are irrelevant in content. The criteria for style strength and fluency are similar to the content relevance criterion.

To get the evaluation results, we first randomly sample 50 test cases from each dataset. As the style transfer is bilateral in this paper, there are 400 test cases in all. We invited four well-educated volunteers to score the results from the supervised baseline and the three semi-supervised models.

9 Results and Analysis

Evaluation Results. Table 3 presents the evaluation results of automatic metrics on the models. It can be seen that the BLEU scores and GLEU scores of the semi-supervised models on almost all the datasets are better than the baseline S2S model. This result indicates that the model benefits from the nonparallel data in terms of content preservation. One interesting thing is that the overall BLEU scores on the ancient poems and modern Chinese datasets are lower than other datasets. This result may be explained by the fact that the edit distance between formal and informal texts are smaller than between ancient poems and modern Chinese texts. Therefore, it is more challenging for model to preserve the content meaning when transferring between ancient poems and modern Chinese text. Among three semi-supervised models, CPLS model achieves the greatest improvement, verifying the effectiveness of the projection functions. However, the gain of CPLS model in the aspect of style accuracy is not that significant. A possible explanation may be the bias of the style classifier. Take the transfer task from ancient poems to modern Chinese text for example. We observe that the classifier tends to classify short sentences into ancient poems as length is an obvious feature. We analyse the sentences generated by S2S model and by the CPLS model, and the statistics show that the average length of the text generated by S2S model is shorter, which may lead to the bias of the style classifier. Therefore, we also adopt human evaluation to alleviate this issue.

Table 4 compares the human evaluation results of S2S model and CPLS model on all the datasets, which are calculated by the average score of the human annotations. As shown in the Table 4, the CPLS model outperforms the S2S model in

the aspects of the content preservation and style strength, and is on par in terms of fluency.

Case Study. We select the generated results of the S2S baseline and three semi-supervised models on two style transfer tasks due to the limited space as shown in Table 2. Compared with the Chinese literacy style datasets, the formality datasets are less challenging as discussed before. Thus it can be seen from the table that the generated sentences on the formality datasets are more fluent. For the task that transferring from the modern Chinese text to the ancient poem, the S2S generates a shorter sentence while the CPLS model generates the sentence that preserve the most content information.

10 Conclusion

In this paper, we design a differentiable semi-supervised model that introduces a projection function between the latent spaces of different styles. The model is flexible in alternating the training mode between supervised and unsupervised learning. We also introduce another two semi-supervised methods that are simple but effective to use the nonparallel and parallel data. We evaluate our models on two datasets that have small-scale parallel data and large-scale nonparallel data, and verify the effectiveness of the model on both automatic metrics and human evaluation.

Abstract

Privacy policies are long and complex documents that are difficult for users to read and understand, and yet, they have legal effects on how user data is collected, managed and used. Ideally, we would like to empower users to inform themselves about issues that matter to them, and enable them to selective explore those issues. We present PRIVACYQA, a corpus consisting of 1750 questions about the privacy policies of mobile applications, and over 3500 expert annotations of relevant answers. We observe that a strong neural baseline underperforms human performance by almost 0.3 F1 on PRIVACYQA, suggesting considerable room for improvement for future systems. Further, we use this dataset to shed light on challenges to *question answerability*, with domain-general implications for any question answering system. The PRIVACYQA corpus offers a challenging corpus for question answering, with genuine real-world utility.

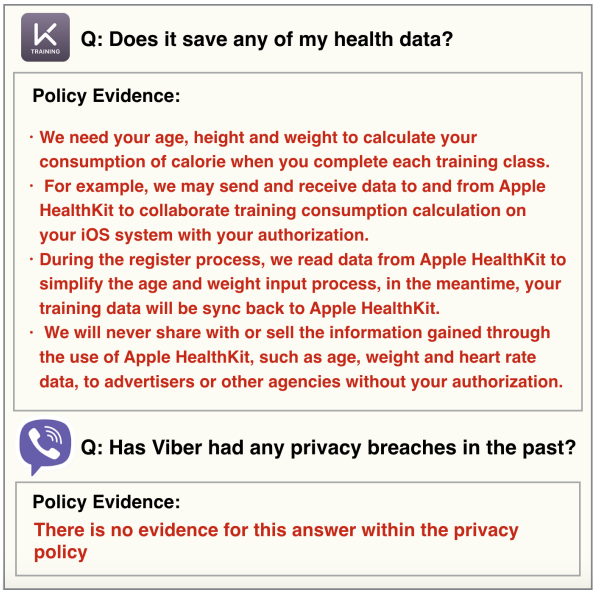

Figure 1: Examples of privacy-related questions users ask, drawn from two mobile applications: Keep[1] and Viber.[2] Policy evidence represents sentences in the privacy policy that are relevant for determining the answer to the user's question.[3]

1 Introduction

Privacy policies are the documents which disclose the ways in which a company gathers, uses, shares and manages a user's data. As legal documents, they function using the principle of *notice and choice* (Federal Trade Commission, 1998), where companies post their policies, and theoretically, users read the policies and decide to use a company's products or services only if they find the conditions outlined in its privacy policy acceptable. Many legal jurisdictions around the world accept this framework, including the United States and the European Union (Patrick, 1980; OECD, 2004). However, the legitimacy of this framework depends upon users actually reading and understanding privacy policies to determine whether company practices are acceptable to them (Reidenberg et al., 2015). In practice this is seldom the case (Cate, 2010; Cranor, 2012; Schaub et al., 2015; Gluck et al., 2016; Jain et al., 2016; US Federal Trade Commission et al., 2012; McDonald and Cranor, 2008). This is further complicated by the highly individual and nuanced compromises that users are willing to make with their data (Leon et al., 2015), discouraging a 'one-size-fits-all' approach to notice of data practices in privacy documents.

With devices constantly monitoring our environment, including our personal space and our bodies, lack of awareness of how our data is being used easily leads to problematic situations where users are outraged by information misuse, but companies insist that users have consented. The discovery of increasingly egregious uses of data by companies, such as the scandals involv-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4947–4958, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing Facebook and Cambridge Analytica (Cadwalladr and Graham-Harrison, 2018), have further brought public attention to the privacy concerns of the internet and ubiquitous computing. This makes privacy a well-motivated application domain for NLP researchers, where advances in enabling users to quickly identify the privacy issues most salient to them can potentially have large real-world impact.

Motivated by this need, we contribute PRIVACYQA, a corpus consisting of 1750 questions about the contents of privacy policies[4], paired with over 3500 expert annotations. The goal of this effort is to kickstart the development of question-answering methods for this domain, to address the (unrealistic) expectation that a large population should be reading many policies per day. In doing so, we identify several understudied challenges to our ability to answer these questions, with broad implications for systems seeking to serve users' information-seeking intent. By releasing this resource, we hope to provide an impetus to develop systems capable of language understanding in this increasingly important domain.[5]

2 Related Work

Prior work has aimed to make privacy policies easier to understand. Prescriptive approaches towards communicating privacy information (Kelley et al., 2009; Micheti et al., 2010; Cranor, 2003) have not been widely adopted by industry. Recently, there have been significant research effort devoted to understanding privacy policies by leveraging NLP techniques (**?**Liu et al., 2016; Oltramari et al., 2017; Mysore Sathyendra et al., 2017; Wilson et al., 2017), especially by identifying specific data practices within a privacy policy. We adopt a personalized approach to understanding privacy policies, that allows users to query a document and selectively explore content salient to them. Most similar is the PolisisQA corpus (Harkous et al., 2018), which examines questions users ask corporations on Twitter. Our approach differs in several ways: 1) The PRIVACYQA dataset is larger, containing 10x as many questions and answers. 2) Answers are formulated by domain experts with legal training. [6] 3) PRIVACYQA includes diverse question types, including unanswerable and subjective questions.

Our work is also related to reading comprehension in the open domain, which is frequently based upon Wikipedia passages (Rajpurkar et al., 2016, 2018; Joshi et al., 2017; Choi et al., 2018) and news articles (Trischler et al., 2017; Hermann et al., 2015; Onishi et al., 2016). Table.1 presents the desirable attributes our dataset shares with past approaches. This work is also tied into research in applying NLP approaches to legal documents (Monroy et al., 2009; Quaresma and Rodrigues, 2005; Do et al., 2017; Kim et al., 2015; Liu et al., 2015; Mollá and Vicedo, 2007; Frank et al., 2007). While privacy policies have legal implications, their intended audience consists of the general public rather than individuals with legal expertise. This arrangement is problematic because the entities that write privacy policies often have different goals than the audience. Feng et al. (2015); Tan et al. (2016) examine question answering in the insurance domain, another specialized domain similar to privacy, where the intended audience is the general public.

3 Data Collection

We describe the data collection methodology used to construct PRIVACYQA. With the goal of achieving broad coverage across application types, we collect privacy policies from 35 mobile applications representing a number of different categories in the Google Play Store.[7][8] One of our goals is to include both policies from well-known applications, which are likely to have carefully-constructed privacy policies, and lesser-known applications with smaller install bases, whose policies might be considerably less sophisticated. Thus, setting 5 million installs as a threshold, we ensure each category includes applications with installs on both sides

[1] https://play.google.com/store/apps/details?id=com.gotokeep.keep.intl

[2] https://play.google.com/store/apps/details?id=com.viber.voip

[3] A question might not have any supporting evidence for an answer within the privacy policy.

[4] All privacy policies in this corpus are in English.

[5] PRIVACYQA is freely available at https://github.com/AbhilashaRavichander/PrivacyQA_EMNLP.

[6] This choice was made as privacy policies are legal documents, and require careful expert understanding in order to be interpreted correctly.

[7] We choose categories that occupy atleast a 2% share of all application categories on the Play Store (Story et al., 2018)

[8] As of April 1, 2018

Table 1: Comparison of the PRIVACYQA dataset to other question answering datasets. Expert annotator indicates domain expertise of the answer provider. Simple evaluation indicates the presence of an automatically calculable evaluation metric. Unanswerable questions indicates if the respective corpus includes unanswerable questions. 'Asker Cannot See Evidence' indicates that the asker of the question was not shown evidence from the document at the time of formulating questions.

Figure 2: User interface for question elicitation.

of this threshold.[9] All policies included in the corpus are in English, and were collected before April 1, 2018, predating many companies' GDPR-focused (Voigt and Von dem Bussche, 2017) updates. We leave it to future studies (Gallé et al., 2019) to look at the impact of the GDPR (e.g., to what extent GDPR requirements contribute to making it possible to provide users with more informative answers, and to what extent their disclosures continue to omit issues that matter to users).

3.1 Crowdsourced Question Elicitation

The intended audience for privacy policies consists of the general public. This informs the decision to elicit questions from crowdworkers on the contents of privacy policies. We choose not to show the contents of privacy policies to crowdworkers, a procedure motivated by a desire to avoid inadvertent biases (Weissenborn et al., 2017; Kaushik and Lipton, 2018; Poliak et al., 2018; Gururangan et al., 2018; Naik et al., 2018), and encourage crowdworkers to ask a variety of questions beyond only asking questions based on practices described in the document.

Instead, crowdworkers are presented with public information about a mobile application available on the Google Play Store including its name, description and navigable screenshots. Figure 2 shows an example of our user interface.[10] Crowdworkers are asked to imagine they have access to a trusted third-party privacy assistant, to whom they can ask any privacy question about a given mobile application. We use the Amazon Mechanical Turk platform[11] and recruit crowdworkers who have been conferred "master" status and are located within the United States of America. Turkers are asked to provide five questions per mobile application, and are paid $2 per assignment, taking ~eight minutes to complete the task.

[9] The final application categories represented in the corpus consist of books, business, education, entertainment, lifestyle, music, health, news, personalization, photography, productivity, tools, travel and game applications.

[10] Color blindness affects approximately 4.5% of the worlds population (Deeb, 2005) We design all our crowdworker user interfaces to accommodate red-green color blindness.

Word	(%)	Example Question From PRIVACYQA
Will	13.03	will my data be sold or available to be used by third party entities?
Do	2.70	do you sell any of my information
What	1.84	what is the worst case scenario of giving my information to this game?
Are	1.60	are there any safety concerns i should know about using this app?
Can/ could	1.47	can i control who sees my data?
How	1.40	how secure is my stored data?
Where	1.14	where is my account info and online activity stored?
Has	0.69	has there ever been a security breach?
If	0.61	if i delete the app will you keep my data?
Does	0.46	does the app save the addresses that i enter?

Table 2: Ten most frequent first words in questions in the PRIVACYQA dataset. We observe high lexical diversity in prefixes with 35 unique first word types and 131 unique combinations of first and second words.

3.2 Answer Selection

To identify legally sound answers, we recruit seven experts with legal training to construct answers to Turker questions. Experts identify relevant evidence within the privacy policy, as well as provide meta-annotation on the question's relevance, subjectivity, OPP-115 category (Wilson et al., 2016), and how likely any privacy policy is to contain the answer to the question asked.

3.3 Analysis

Table.4 presents aggregate statistics of the PRIVACYQA dataset. 1750 questions are posed to our imaginary privacy assistant over 35 mobile applications and their associated privacy documents. As an initial step, we formulate the problem of answering user questions as an extractive sentence selection task, ignoring for now background knowledge, statistical data and legal expertise that could otherwise be brought to bear. The dataset is partitioned into a training set featuring 27 mobile applications and 1350 questions, and a test set consisting of 400 questions over 8 policy documents. This ensures that documents in training and test splits are mutually exclusive. Every question is answered by at least one expert. In addition, in order to estimate annotation reliability and provide for better evaluation, every question in the test set is answered by at least two additional experts.

Table 2 describes the distribution over first words of questions posed by crowdworkers. We also observe low redundancy in the questions posed by crowdworkers over each policy, with each policy receiving ~49.94 unique questions despite crowdworkers independently posing questions. Questions are on average 8.4 words long. As declining to answer a question can be a legally sound response but is seldom practically useful, answers to questions where a minority of experts abstain to answer are filtered from the dataset. Privacy policies are ~3000 words long on average. The answers to the question asked by the users typically have ~100 words of evidence in the privacy policy document.

3.3.1 Categories of Questions

Questions are organized under nine categories from the OPP-115 Corpus annotation scheme (Wilson et al., 2016):

1. First Party Collection/Use: What, why and how information is collected by the service provider
2. Third Party Sharing/Collection: What, why and how information shared with or collected by third parties
3. Data Security: Protection measures for user information
4. Data Retention: How long user information will be stored
5. User Choice/Control: Control options available to users
6. User Access, Edit and Deletion: If/how users can access, edit or delete information
7. Policy Change: Informing users if policy information has been changed
8. International and Specific Audiences: Practices pertaining to a specific group of users
9. Other: General text, contact information or practices not covered by other categories.

For each question, domain experts indicate one or more[12] relevant OPP-115 categories. We mark a category as relevant to a question if it is identified as such by at least two annotators. If no such category exists, the category is marked

[12]For example, some questions such as *'What information of mine is collected by this app and who is it shared with?'* can be identified as falling under both first party data/collection and third party collection/sharing categories.

Privacy Practice	Proportion	Example Question From PRIVACYQA
First Party Collection/Use	41.9 %	what data does this game collect?
Third Party Sharing/Collection	24.5 %	will my data be sold to advertisers?
Data Security	10.5 %	how is my info protected from hackers?
Data Retention	4.1 %	how long do you save my information?
User Access, Edit and Deletion	2.0 %	can i delete my information permanently?
User Choice/Control	6.5 %	is there a way to opt out of data sharing
Other	4.8 %	does the app connect to the internet at any point?
Policy Change	0.2 %	where is the privacy statement
International and Specific Audiences	0.2 %	what are your GDPR policies?
No Agreement	5.4 %	how are features personalized?

Table 3: OPP-115 categories most relevant to the questions collected from users.

Dataset	Train	Test	All
# Questions	1350	400	1750
# Policies	27	8	35
# Sentences	3704	1243	4947
Avg Q. Length	8.42	8.56	8.46
Avg Doc. Length	3121.3	3629.13	3237.37
Avg Ans. Length	123.73	153.44	139.62

Table 4: Statistics of the PRIVACYQA Dataset, where # denotes number of questions, policies and sentences, and average length of questions, policies and answers in words, for training and test partitions.

as 'Other' if atleast one annotator has identified the 'Other' category to be relevant. If neither of these conditions is satisfied, we label the question as having no agreement. The distribution of questions in the corpus across OPP-115 categories is as shown in Table.3. First party and third party related questions are the largest categories, forming nearly 66.4% of all questions asked to the privacy assistant.

3.3.2 Answer Validation

When do experts disagree? We would like to analyze the reasons for potential disagreement on the annotation task, to ensure disagreements arise due to valid differences in opinion rather than lack of adequate specification in annotation guidelines. It is important to note that the annotators are experts rather than crowdworkers. Accordingly, their judgements can be considered valid, legally-informed opinions even when their perspectives differ. For the sake of this question we randomly sample 100 instances in the test data and analyze them for likely reasons for disagreements. We consider a disagreement to have occurred when more than one expert does not agree with the majority consensus. By disagreement we mean there is no overlap between the text identified as relevant by one expert and another.

We find that the annotators agree on the answer for 74% of the questions, even if the supporting evidence they identify is not identical i.e full overlap. They disagree on the remaining 26%. Sources of apparent disagreement correspond to situations when different experts: have differing interpretations of question intent (11%) (for example, when a user asks *'who can contact me through the app'*, the questions admits multiple interpretations, including seeking information about the features of the app, asking about first party collection/use of data or asking about third party collection/use of data), identify different sources of evidence for questions that ask if a practice is performed or not (4%), have differing interpretations of policy content (3%), identify a partial answer to a question in the privacy policy (2%) (for example, when the user asks *'who is allowed to use the app'* a majority of our annotators decline to answer, but the remaining annotators highlight partial evidence in the privacy policy which states that children under the age of 13 are *not* allowed to use the app), and other legitimate sources of disagreement (6%) which include personal subjective views of the annotators (for example, when the user asks 'is my DNA information used in any way *other than what is specified*', some experts consider the boilerplate text of the privacy policy which states that it abides to practices described in the policy document as sufficient evidence to answer this question, whereas others do not).

	Acc.	P	R	F1
Majority	24.75	24.75	100	39.6
SVM-BOW	75.75	50.8	58.5	54.4
+ LEN	76.75	52.7	57.5	55.0
+ LEN + POS	77.0	53.2	58.5	55.7
CNN	80.0	61.1	52.5	56.5
BERT	81.15	62.6	62.6	62.6

Table 5: Classifier Performance (%) for answerability of questions. The Majority Class baseline always predicts that questions are unanswerable.

Model	Precision	Recall	F1
No Answer (NA)	28.0%	28.0%	28.0%
Word Count -2	24.0%	16.4%	19.4%
Word Count -3	21.8%	17.8%	19.6%
Word Count -5	18.1%	20.3%	19.2%
BERT	44.2%	34.8%	39.0%
BERT + Unans.	44.3%	36.1%	**39.8**%
Human	68.8%	69.0%	68.9%

Table 6: Performance of baselines on PRIVACYQA dataset.

4 Experimental Setup

We evaluate the ability of machine learning methods to identify relevant evidence for questions in the privacy domain.[13] We establish baselines for the subtask of deciding on the answerability (§4.1) of a question, as well as the overall task of identifying evidence for questions from policies (§4.2). We describe aspects of the question that can render it unanswerable within the privacy domain (§5.2).

4.1 Answerability Identification Baselines

We define answerability identification as a binary classification task, evaluating model ability to predict if a question can be answered, given a question in isolation. This can serve as a prior for downstream question-answering. We describe three baselines on the answerability task, and find they considerably improve performance over a majority-class baseline.

SVM: We define 3 sets of features to characterize each question. The first is a simple bag-of-words set of features over the question (SVM-BOW), the second is bag-of-words features of the question as well as length of the question in words (SVM-BOW + LEN), and lastly we extract bag-of-words features, length of the question in words as well as part-of-speech tags for the question (SVM-BOW + LEN + POS). This results in vectors of 200, 201 and 228 dimensions respectively, which are provided to an SVM with a linear kernel.

CNN: We utilize a CNN neural encoder for answerability prediction. We use GloVe word embeddings (Pennington et al., 2014), and a filter size of 5 with 64 filters to encode questions.

BERT: BERT (Devlin et al., 2019) is a bidirectional transformer-based language-model (Vaswani et al., 2017).[14] We fine-tune BERT-base on our binary answerability identification task with a learning rate of 2e-5 for 3 epochs, with a maximum sequence length of 128.

[13]The task of evidence identification can serve as a first step for future question answering systems, that can further learn to form abstractive summaries when required based on identifying relevant evidence.

Privacy Practice	NA	BERT-U	Human
First Party	0.22	0.36	0.67
Third Party	0.10	0.26	0.61
Data Security	0.24	0.42	0.74
Data Retention	0.02	0.33	0.67
User Access	0.07	0.32	0.66
User Choice	0.35	0.41	0.65
Other	0.44	0.45	0.72

Table 7: Stratification of classifier performance by OPP-115 category of questions.

	BERT
# Answerability Mistakes	137
% Answerable ->Unanswerable	124
% Unanswerable ->Answerable	13
Out-of-scope	2
Subjective	46
Policy Silent	19
Unexpected	6

Table 8: Analysis of BERT performance at identifying answerability. The majority of mistakes made by BERT are answerable Questions identified as unanswerable. These answerable questions are further analyzed along the factors of scope, subjectivity, presence of answer and whether the question could be anticipated.

[14]We utilize the HuggingFace implementtation available at https://github.com/huggingface/pytorch-transformers

4.2 Privacy Question Answering

Our goal is to identify evidence within a privacy policy for questions asked by a user. This is framed as an answer sentence selection task, where models identify a set of evidence sentences from all candidate sentences in each policy.

4.2.1 Evaluation Metric

Our evaluation metric for answer-sentence selection is sentence-level F1, implemented similar to (Choi et al., 2018; Rajpurkar et al., 2016). Precision and recall are implemented by measuring the overlap between predicted sentences and sets of gold-reference sentences. We report the average of the maximum F1 from each n−1 subset, in relation to the heldout reference.

4.2.2 Baselines

We describe baselines on this task, including a human performance baseline.

No-Answer Baseline (NA) : Most of the questions we receive are difficult to answer in a legally-sound way on the basis of information present in the privacy policy. We establish a simple baseline to quantify the effect of identifying every question as unanswerable.

Word Count Baseline : To quantify the effect of using simple lexical matching to answer the questions, we retrieve the top candidate policy sentences for each question using a word count baseline (Yang et al., 2015), which counts the number of question words that also appear in a sentence. We include the top 2, 3 and 5 candidates as baselines.

BERT: We implement two BERT-based baselines (Devlin et al., 2019) for evidence identification. First, we train BERT on each query-policy sentence pair as a binary classification task to identify if the sentence is evidence for the question or not (BERT). We also experiment with a two-stage classifier, where we separately train the model on questions only to predict answerability. At inference time, if the answerable classifier predicts the question is answerable, the evidence identification classifier produces a set of candidate sentences (BERT + UNANSWERABLE).

Human Performance: We pick each reference answer provided by an annotator, and compute the F1 with respect to the remaining references, as described in section 4.2.1. Each reference answer is treated as the prediction, and the remaining n-1 answers are treated as the gold reference. The average of the maximum F1 across all reference answers is computed as the human baseline.

5 Results and Discussion

The results of the answerability baselines are presented in Table 5, and on answer sentence selection in Table 6. We observe that BERT exhibits the best performance on a binary answerability identification task. However, most baselines considerably exceed the performance of a majority-class baseline. This suggests considerable information in the question, indicating it's possible answerability within this domain.

Table.6 describes the performance of our baselines on the answer sentence selection task. The No-answer (NA) baseline performs at 28 F1, providing a lower bound on performance at this task. We observe that our best-performing baseline, BERT + UNANSWERABLE achieves an F1 of 39.8. This suggest that BERT is capable of making some progress towards answering questions in this difficult domain, while still leaving considerable headroom for improvement to reach human performance. BERT + UNANSWERABLE performance suggests that incorporating information about answerability can help in this difficult domain. We examine this challenging phenomena of unanswerability further in Section **??**.

5.1 Error Analysis

Disagreements are analyzed based on the OPP-115 categories of each question (Table.7). We compare our best performing BERT variant against the NA model and human performance. We observe significant room for improvement across all categories of questions but especially for first party, third party and data retention categories.

We analyze the performance of our strongest BERT variant, to identify classes of errors and directions for future improvement (Table.8). We observe that a majority of answerability mistakes made by the BERT model are questions which are in fact answerable, but are identified as unanswerable by BERT. We observe that BERT makes 124 such mistakes on the test set. We collect expert judgments on relevance, subjectivity , silence and information about how likely the question is to be answered from the privacy pol-

icy from our experts. We find that most of these mistakes are relevant questions. However many of them were identified as subjective by the annotators, and at least one annotator marked 19 of these questions as having no answer within the privacy policy. However, only 6 of these questions were unexpected or do not usually have an answer in privacy policies. These findings suggest that a more nuanced understanding of answerability might help improve model performance in his challenging domain.

5.2 What makes Questions Unanswerable?

We further ask legal experts to identify potential causes of unanswerability of questions. This analysis has considerable implications. While past work (Rajpurkar et al., 2018) has treated unanswerable questions as homogeneous, a question answering system might wish to have different treatments for different categories of 'unanswerable' questions. The following factors were identified to play a role in unanswerability:

- **Incomprehensibility**: If a question is incomprehensible to the extent that its meaning is not intelligible.
- **Relevance**: Is this question in the scope of what could be answered by reading the privacy policy.
- **Ill-formedness**: Is this question ambiguous or vague. An ambiguous statement will typically contain expressions that can refer to multiple potential explanations, whereas a vague statement carries a concept with an unclear or soft definition.
- **Silence**: Other policies answer this type of question but this one does not.
- **Atypicality**: The question is of a nature such that it is unlikely for any policy policy to have an answer to the question.

Our experts attempt to identify the different 'unanswerable' factors for all 573 such questions in the corpus. 4.18% of the questions were identified as being incomprehensible (for example, 'any difficulties to occupy the privacy assistant'). Amongst the comprehendable questions, 50% were identified as likely to have an answer within the privacy policy, 33.1% were identified as being privacy-related questions but not within the scope of a privacy policy (e.g., *'has Viber had any privacy breaches in the past?'*) and 16.9% of questions were identified as completely out-of-scope (e.g., *"will the app consume much space?'*). In the questions identified as relevant, 32% were ill-formed questions that were phrased by the user in a manner considered vague or ambiguous. Of the questions that were both relevant as well as 'well-formed', 95.7% of the questions were not answered by the policy in question but it was reasonable to expect that a privacy policy would contain an answer. The remaining 4.3% were described as reasonable questions, but of a nature generally not discussed in privacy policies. This suggests that the answerability of questions over privacy policies is a complex issue, and future systems should consider each of these factors when serving user's information seeking intent.

We examine a large-scale dataset of "natural" unanswerable questions (Kwiatkowski et al., 2019) based on real user search engine queries to identify if similar unanswerability factors exist. It is important to note that these questions have previously been filtered, according to a criteria for bad questions defined as "(questions that are) ambiguous, incomprehensible, dependent on clear false presuppositions, opinion-seeking, or not clearly a request for factual information." Annotators made the decision based on the content of the question without viewing the equivalent Wikipedia page. We randomly sample 100 questions from the development set which were identified as unanswerable, and find that 20% of the questions are not questions (e.g., "all I want for christmas is you mariah carey tour"). 12% of questions are unlikely to ever contain an answer on Wikipedia, corresponding closely to our atypicality category. 3% of questions are unlikely to have an answer anywhere (e.g., 'what guides Santa home after he has delivered presents?'). 7% of questions are incomplete or open-ended (e.g., 'the south west wind blows across nigeria between'). 3% of questions have an unresolvable coreference (e.g., 'how do i get to Warsaw Missouri from here'). 4% of questions are vague, and a further 7% have unknown sources of error. 2% still contain false presuppositions (e.g., 'what is the only fruit that does not have seeds?') and the remaining 42% do not have an answer within the document. This reinforces our belief that though they have been understudied in past

work, any question answering system interacting with real users should expect to receive such unanticipated and unanswerable questions.

6 Conclusion

We present PRIVACYQA, the first significant corpus of privacy policy questions and more than 3500 expert annotations of relevant answers. The goal of this work is to promote question-answering research in the specialized privacy domain, where it can have large real-world impact. Strong neural baselines on PRIVACYQA achieve a performance of only 39.8 F1 on this corpus, indicating considerable room for future research. Further, we shed light on several important considerations that affect the *answerability* of questions. We hope this contribution leads to multidisciplinary efforts to precisely understand user intent and reconcile it with information in policy documents, from both the privacy and NLP communities.

Stick to Facts: Towards Fidelity-oriented Product Description Generation

Abstract

Different from other text generation tasks, in product description generation, it is of vital importance to generate faithful descriptions that stick to the product attribute information. However, little attention has been paid to this problem. To bridge this gap we propose a model named Fidelity-oriented Product Description Generator (FPDG). FPDG takes the entity label of each word into account, since the product attribute information is always conveyed by entity words. Specifically, we first propose a Recurrent Neural Network (RNN) decoder based on the Entity-label-guided Long Short-Term Memory (ELSTM) cell, taking both the embedding and the entity label of each word as input. Second, we establish a keyword memory that stores the entity labels as keys and keywords as values, and FPDG will attend to keywords through attending to their entity labels. Experiments conducted a large-scale real-world product description dataset show that our model achieves the state-of-the-art performance in terms of both traditional generation metrics as well as human evaluations. Specifically, FPDG increases the fidelity of the generated descriptions by 25%.

1 Introduction

The effectiveness of automatic text generation has been proved in various natural language processing applications, such as neural machine translation (Luong et al., 2015; Zhou et al., 2017), dialogue generation (Tao et al., 2018a; Hu et al., 2019), and abstractive text summarization (Chen et al.; Gao et al., 2019). One such task, product description generation has also attracted considerable attention (Lipton et al., 2015; Wang et al., 2017; Zhang et al., 2019a). An accurate and attractive description not only helps customers make an informed decision but also improves the likelihood of purchase. Concretely, the product description generation task takes several keywords describing the attributes of a product as input, and then outputs fluent and attractive sentences that highlight the feature of this product.

Input	high-waist; straight; jeans; blue; ZARA
Bad output	This ~~UNIQLO low-waist~~ jeans are suitable for the curvature of the waistline and will not slip when worn for a long time. The straight version and ~~black~~ color together makes you even slimmer.
Good output	This blue jeans look personalized and chic, making you more distinctive. With a high-waist design, the legs look even more slender, and the whole person looks taller. The straight design hides the fat in the legs and is visually slimmer.

Table 1: Example of product description generation. The text with underline demonstrates faithful description, and text with deleteline demonstrates wrong description.

There is one intrinsic difference between product description generation and other generation tasks, such as story or poem generation (Li et al., 2018; Yao et al., 2019); the generated description has to be faithful to the product attributes. An example case is shown in Table 1, where the good product description matches the input information, while the bad description mistakes the brand and the style of the jeans. Our preliminary study reveals that 48% of the outputs from a state-of-the-art sequence-to-sequence system suffer from this problem. In the real-world e-commerce product description generation system, generating text with unfaithful information is unacceptable. A wrong brand name will damage the interests of advertisers, while a wrong product category might break the law by misleading consumers. Any kind of unfaithful description will bring huge economic

losses to online platforms.

Though of great importance, no attention has been paid to this problem. Existing product description generators include (Chen et al., 2019; Zhang et al., 2019b), where they focus on generating personalized descriptions and pattern-controlled descriptions, respectively.

In this paper, we address the fidelity problem in generation tasks by developing a model named *Fidelity-oriented Product Description Generator* (FPDG), which takes keywords about the product attributes as inputs. Since product attribute information is always conveyed by entity words (up to 89.72% in input keywords), FPDG generates faithful product descriptions by taking into account the entity label of each word. Specifically, first, we propose an Entity-label-guided Long Short-Term Memory (ELSTM) as the cell in the decoder RNN, which takes the entity label of an input word, as well as the word itself as input. Then, we establish a keyword memory storing the input keywords with their entity labels. In each decoding step, the current hidden state of the ELSTM focuses on proper words in this keyword memory in regard to their entity categories. We also collect a large-scale real-world product description dataset from one of the largest e-commerce platforms in China. Extensive experiments conducted on this dataset show that FPDG outperforms the state-of-the-art baselines in terms of traditional generation metrics and human evaluations. Specifically, FPDG greatly improves the fidelity of generated description by 24.61%.

To our best knowledge, we are the first to explore the fidelity problem of product description generation. Besides, to tackle this problem, we propose an ELSTM and a keyword memory to incorporate entity label information, so as to generate more accurate descriptions.

2 Related Work

We detail related work on text generation, entity-related generation, and product description.

Text generation. Recently, sequence-to-sequence (Seq2Seq) neural network models have been widely used in NLG approaches. Their effectiveness has been demonstrated in a variety of text generation tasks, such as neural machine translation (Luong et al., 2015; Bahdanau et al., 2014; Wu et al., 2016), abstractive text summarization (See et al., 2017a; Hsu et al., 2018; Chen and Bansal, 2018), dialogue generation (Tao et al., 2018a; Xing et al., 2017), etc. Along another line, there are also works based on an attention mechanism. Vaswani et al. (2017) proposed a Transformer architecture that utilizes the self-attention mechanism and has achieved state-of-the-art results in neural machine translation. Since then, the attention mechanism has been used in a variety of tasks (Devlin et al., 2018; Fan et al., 2018; Zhou et al., 2018).

Entity-related generation. Named entity recognition (NER) is a fundamental component in language understanding and reasoning (Greenberg et al., 2018; Katiyar and Cardie, 2018). In (Ji et al., 2017), they proved that adding entity related information can improve the performance of language modeling. Building upon this work, in (Clark et al., 2018), they combined entity context with previous-sentence context, and demonstrated the importance of the latter in coherence test. Another line of related work generates recipes using neural networks to track and update entity representations (Bosselut et al., 2018). Different from the above works, we utilize entity labels as supplementary information to assist decoding in the text generation task.

Product descriptions. Quality product descriptions are critical for providing a competitive customer experience in an e-commerce platform. Due to its importance, automatically generating the product description has attracted considerable interests. Initial works include (Wang et al., 2017), which incorporates statistical methods with the template to generate product descriptions. With the development of neural networks, (Chen et al., 2019) explored a new way to generate personalized product descriptions by combining the power of neural networks and a knowledge base. (Zhang et al., 2019b) proposed a pointer-generator neural network to generate product description whose patterns are controlled.

In real-world product description generation application, however, the most important prerequisite is the fidelity of generated text, and to the best of our knowledge, no research has been conducted on this so far.

3 Problem Formulation

FPDG takes a list of keywords $X = \{x_1, ..., x_{T_X}\}$ as inputs, where T_X is the number of keywords. These keywords are all about the important at-

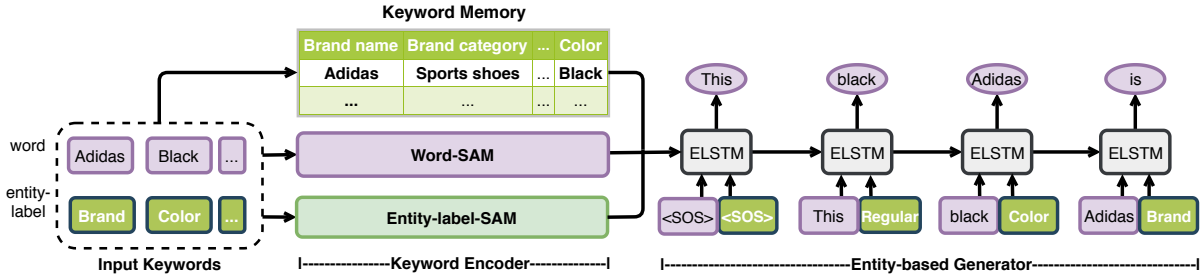

Figure 1: Overview of FPDG. Green denotes an entity label and purple denotes a word. We divide our model into two components: (1) The *Keyword Encoder* stores the word and its entity label in the token memory, and uses Self-Attention Modules (SAMs) to encode words and entity labels; (2) The *Entity-based Generator* generates product description based on the token memory and SAM encoders.

tributes of the product. The goal of FPDG is to generate a product description $\hat{Y} = \{\hat{y}_1, ..., \hat{y}_{T_{\hat{Y}}}\}$ that is not only grammatically correct but also consistent with the input information, such as the brand name and the fashion style. Essentially, FPDG tries to optimize the parameters to maximize the probability $P(Y|X) = \prod_{t=1}^{T_Y} P(y_t|X)$, where $Y = \{y_1, ..., y_{T_Y}\}$ is the ground truth answer.

4 Model

In this section, we introduce our *Fidelity-oriented Product Description Generator* (FPDG) model in detail. An overview of FPDG is shown in Figure 1 and can be split into two modules:

(1) *Keyword Encoder* (See § 4.1): We first use a key-value memory to store the entity-label as key and the corresponding word as value. To better learn the interaction between words, we employ two self-attention modules from Transformer (Vaswani et al., 2017) to model the input keywords and their entity-labels separately.

(2) *Entity-based Generator* (See § 4.2): We propose a recurrent decoder based on Entity-label-guided LSTM (ELSTM) to generate the product description.

4.1 Keyword Encoder

In the product description dataset, most of the input keywords are entity words (up to 89.72%), and the description text should be faithful to these entity words. Hence, we incorporate entity label information to improve the accuracy of the generated text. In this section, we introduce how to embed input keywords with entity label information.

To begin with, we use an embedding matrix e to map a one-hot representation of each word in x_i into a high-dimensional vector space. Since our input keywords have no order information, we use the Self-Attention Module (SAM) from Transformer (Vaswani et al., 2017) to model the temporal interactions between the words, instead of RNN-based encoder. We use three fully-connected layers to project $e(x_i)$ into three spaces, i.e., the query $q_i = F_q(e(x_i))$, the key $k_i = F_k(e(x_i))$ and the value $v_i = F_v(e(x_i))$. The attention module then takes q_i to attend to each $k_\cdot$, and uses these attention distribution results $\alpha_{i,\cdot} \in \mathbb{R}^{T_X}$ as weights to obtain the weighted sum of v_i, as shown in Equation 2. Next, we add the original word representation $e(x_i)$ on β_i as the residential connection layer, as shown in Equation 3:

$$\alpha_{i,j} = \frac{\exp(q_i k_j)}{\sum_{n=1}^{T_X} \exp(q_i k_n)}, \quad (1)$$

$$\beta_i = \sum_{j=1}^{T_X} \alpha_{i,j} v_j, \quad (2)$$

$$\hat{h}_i = e(x_i) + \beta_i, \quad (3)$$

where $\alpha_{i,j}$ denotes the attention weight of the i-th word on the j-th word. Finally, we apply a feed-forward layer on $\hat{h}_i$ to obtain the final word representation h_i:

$$h_i = \max(0, \hat{h}_i \cdot W_1 + b_1) \cdot W_2 + b_2, \quad (4)$$

where W_1, W_2, b_1, b_2 are all trainable parameters. We refer to the above process as:

$$h_i = \text{SAM}\left(F_q(x_i), F_k(x.), F_v(x.)\right). \quad (5)$$

In the meantime, we leverage the e-commerce-adapted AliNER[1] to label each word in the input such as "brand name" and "color". Non-entity words are labeled as "normal word". We denote c_i

[1] https://ai.aliyun.com/nlp/ner

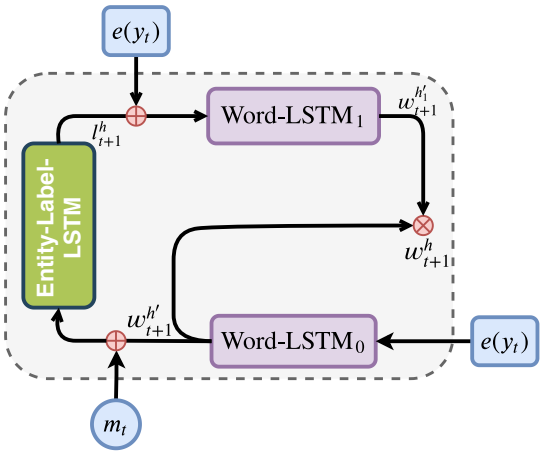

Figure 2: The structure of ELSTM, which is a hybrid of three LSTMs.

as the entity label for the i-th word. To better learn the interaction between these entity labels, we use a second SAM, taking $c.$ as input, and obtain the final representation for c_i as m_i:

$$m_i = \text{SAM}\left(F_q(c_i), F_k(c.), F_v(c.)\right). \quad (6)$$

We also propose a key-value keyword memory that stores the label results as shown in Figure 1. The keys in the keyword memory are T_C representations of different entity-labels, where T_C is the number of entity categories. The values in the memory are self-attention representations of words that belong to each category. We denote the k-th entity-label in the keyword memory as c^k, and the i-th word belonging to this category as $e(x^k_i)$. This keyword memory will be incorporated into the generation process in §4.2.3.

4.2 Entity-based Generator

To incorporate entity label information into generation process, we propose a modified version of LSTM, named Entity-label-guided Long Short-Term Memory (ELSTM). We first introduce ELSTM and then introduce the RNN decoder based on ELSTM.

4.2.1 ELSTM

As shown in Figure 3, ELSTM consists of three LSTMs, two Word-LSTMs and one Entity-label-LSTM. The hidden states of the two Word-LSTMs are integrated together, forming w^h_t, while the hidden state of Entity-Label-LSTM is l^h_t. The word hidden state w^h_t attends to the SAM outputs to predict the next word, while the entity label hidden state l^h_t is used to attend to the keyword memory and predict entity label of next word. In other words, ELSTM is a hybrid of three LSTMs with a deeper interaction between these cells. Overall, ELSTM takes two variables as input, the embedding of an input word $e(y_t)$ and its entity label m_t.

The structure of each LSTM in ELSTM is the same as original LSTM, thus, is omitted here due to space limitations. Next, we introduce the interaction in ELSTM in detail. As shown in Figure 2, Word-LSTM$_0$ takes the $e(y_t)$ as input, and outputs the initial word hidden state $w^{h'}_{t+1}$:

$$w^{h'}_{t+1} = \text{Word-LSTM}_0(w^h_t, e(y_t)). \quad (7)$$

Next we calculate the entity label hidden state by Entity-Label-LSTM, taking both m_t and $w^{h'}_{t+1}$ as input:

$$l^{h'}_{t+1} = \text{Entity-Label-LSTM}(l^h_t, m_t + w^{h'}_{t+1}). \quad (8)$$

To further improve the accuracy of entity label prediction, we also apply another multi-layer projection, incorporating entity label context vector c^m_t (introduced in §16) to obtain polished entity hidden state l^h_{t+1}:

$$l^h_{t+1} = FC([l^{h'}_{t+1}, c^m_t]), \quad (9)$$

where $[,]$ denotes the concatenation operation.

Finally, Word-LSTM$_1$ takes the entity-label hidden state l^h_{t+1} and word embedding $e(y_t)$ as input, and outputs predicted word hidden state that contains entity label information:

$$w^{h'_1}_{t+1} = \text{Word-LSTM}_1(w^h_t, e(y_t) + l^h_{t+1}). \quad (10)$$

Note that it is possible that the predicted entity-label hidden state is not accurate enough. Hence, we apply a gate fusion combining $w^{h'_1}_{t+1}$ with initial word hidden state $w^{h'}_{t+1}$ to ensure the word hidden state quality:

$$\gamma = \sigma(FC([w^{h'_1}_{t+1}, w^{h'}_{t+1}])), \quad (11)$$

$$w^h_{t+1} = \gamma w^{h'_1}_{t+1} + (1-\gamma) w^{h'}_{t+1}. \quad (12)$$

The fusion result is w^h_{t+1}, *i.e.*, the updated word hidden state.

In this way, the entity label information and word information are fully interacted in ELSTM cell, while the hidden states are updated.

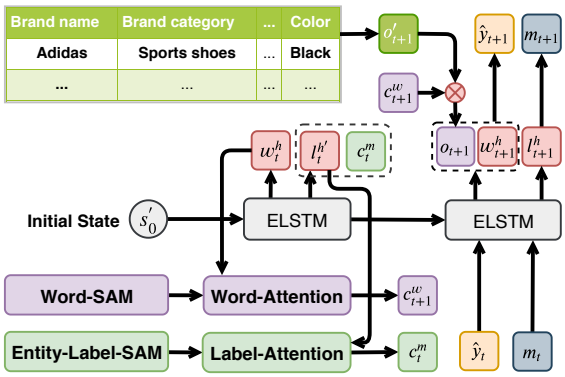

Figure 3: An overview of the description generator.

4.2.2 ELSTM-based Attention Mechanism

Established on ELSTMs, we now have a new RNN decoder to generate descriptions, incorporating the two SAM encoders and the keyword memory. First, we apply an Bi-RNN to encode input keywords, and use its last hidden state as decoder initial hidden states, i.e., w_0^h and l_0^h. The t-th decoding step is calculated as:

$$\begin{bmatrix} w_{t+1}^h \\ l_{t+1}^h \end{bmatrix} = \text{ELSTM}\left(\begin{bmatrix} w_t^h \\ l_t^h \end{bmatrix}, (e(y_t), m_t)\right). \quad (13)$$

Next, similar to the traditional attention mechanism from (Bahdanau et al., 2015), we summarize the input word representation $e(y_.)$ and entity label representation $m_.$ into the *word context vector* c_t^w and *entity label vector* c_t^m, respectively. As for how to obtain c_t^w and c_t^m, we use the two hidden states in ELSTM, i.e., w_t^h and l_t^h to attend to $h_.$ and $m_.$, respectively. Specifically, the entity label context vector c_t^m is calculated as:

$$\hat{\gamma}_{t,i} = W_a \tanh\left(W_b l_t^h + W_h h_i\right), \quad (14)$$

$$\gamma_{t,i} = \exp\left(\hat{\gamma_{t,i}}\right) / \sum_{j=1}^{T_X} \exp\left(\hat{\gamma_{t,j}}\right), \quad (15)$$

$$c_t^m = \sum_{i=1}^{T_X} \gamma_{t,i} m_i. \quad (16)$$

The decoder state l_t^h is used to attend to each entity label representation m_i, resulting in the attention distribution $\gamma_t \in \mathbb{R}^{T_X}$, as shown in Equation 15. Then we use the attention distribution γ_t to obtain a weighted sum of the entity label representations $m_.$ as the word context vector c_t^m, shown in Equation 16. c_t^w is obtained in a similarity by using hidden state w_t^h attending to $e(y_.)$, and we omit the details for brevity. This two context vectors play different parts, and is introduced in §4.2.4.

4.2.3 Incorporating Keyword Memory

So far, we have finished calculating the context vector. Next, we describe how to incorporate the guidance from the keyword memory. We first use the entity label hidden state to attend to the entity label keys in the keyword memory by gumbel softmax (Jang et al., 2016) (Equation 17), and then use the attention weights to obtain the weighted sum of self-attention representation of values in the memory (Equation 19):

$$\pi_t^{k'} = \frac{\exp((l_t^h W_e c^k + p^k)/\tau)}{\sum_{j=1}^{T_c} \exp((w_t^h W_e c^j + p^k)/\tau)}, \quad (17)$$

$$v_i^{k'} = \text{SAM}\left(F_q(e(x_i^k), F_k(e(x_.^k), F_v(e(x_.^k)\right), \quad (18)$$

$$o_{t+1}^{'} = \sum_{k=1}^{T_C}\left(\pi_t^k \sum_{i=1}^{T_{c^k}} (v_i^{k'})\right), \quad (19)$$

where $p^k = -\log(-\log(g^k)), g^k \sim U(0,1), \tau \in [0,1]$ is the softmax temperature. T_{c_k} denotes the number of words in the input keywords that belong to the k-th entity category. We choose gumbel-softmax instead of regular softmax because a generated word can only belong to one entity category. In this way, FPDG first predicts the entity label of the predicted word and then uses $o_{t+1}^{'}$ to store the information of words that belong to this category.

4.2.4 Projection Layers

Next, using a fusion gate g_t, $o_{t+1}^{'}$ is combined with word hidden state c_{t+1}^w in a similar way in Equation 12 to obtain o_{t+1}. Finally, we obtain the final generation distribution P_v over vocabulary:

$$P_{t+1}^v = \text{softmax}\left(W_v[o_{t+1}, w_{t+1}^h] + b_v\right). \quad (20)$$

We concatenate the memory vector o_{t+1}, the word context vector c_{t+1}^w, and the output of the decoder ELSTM w_{t+1}^h as the input of the output projection layer.

Apart from predicting the next word, we also use the entity label hidden state l_t^h to predict the entity label of the next word as an auxiliary task. The distribution P_{t+1}^e over entity categories is calculated as:

$$P_{t+1}^e = \text{softmax}(W_e[l_{t+1}^{h'}, c_{t+1}^m] + b_e) \quad (21)$$

We use negative log-likelihood as loss function:

$$\mathcal{L} = -(\sum_{t=1}^{T_{\hat{Y}}} \log P_v(y_t) + \lambda \cdot \sum_{t=1}^{T_{\hat{Y}}} \log P_e(m_t)), \quad (22)$$

where λ is the weight of entity label prediction loss. The gradient descent method is employed to update all parameters and minimize this loss function.

5 Experimental Setup

5.1 Research Questions

We list four research questions that guide the experiments: **RQ1** (See § 6.1): What is the overall performance of FPDG? Are generated descriptions faithful? **RQ2** (See § 6.2): What is the effect of each module in FPDG? **RQ3** (See § 6.3): How does the keyword memory work in each decoding step? **RQ4** (See § 6.4): Can ELSTM successfully capture entity label information?

5.2 Dataset

We collect a large-scale real-world product description dataset from one of the largest e-commerce platforms in China[2]. The inputs are keywords about the product attributes selected by sellers on the platform, and the product descriptions are written by professional experts that are good at marketing. Overall, there are 404,000 training samples, and 5,000 validation and test samples. On average, there are 10 keywords in the input, and 63 words in the product description. 89.72% inputs are entity words.

5.3 Evaluation Metrics

Following (Fu et al., 2017), we use the evaluation package of (Chen et al., 2015), which includes BLEU-1, BLEU-2, BLEU-3, BLEU-4, METEOR and ROUGE-L. BLEU is a popular machine translation metric that analyzes the co-occurrences of n-grams between the candidate and reference sentences. METEOR is calculated by generating an alignment between the words in the candidate and reference sentences, with an aim of 1:1 correspondence. ROUGE-L is a metric designed to evaluate text summarization algorithms.

(Tao et al., 2018b) notes that only using the BLEU metric to evaluate text quality can be misleading. Therefore, we also evaluate our model by human evaluation. Three highly educated participants are asked to score 100 randomly sampled summaries generated by Pointer-Gen and FPDG. We chose Pointer-Gen since its performance is relatively higher than other baselines. The statistical significance of observed differences between the performance of two runs are tested using a two-tailed paired t-test and is denoted using $^{\blacktriangle}$(or $^{\blacktriangledown}$) for strong significance for $\alpha = 0.01$.

5.4 Comparison Methods

We first conduct an ablation study to prove the effectiveness of each module in FPDG. Model w/o ELSTM is implemented with only keys in the memory because there are no entity representations as values. Then, to evaluate the performance of our proposed dataset and model, we compare it with the following baselines:

(1) **Seq2Seq**: The sequence-to-sequence framework (Sutskever et al., 2014) is one of the initial works proposed for the language generation task.

(2) **Pointer-Gen**: A sequence-to-sequence framework with pointer and coverage mechanism proposed in (See et al., 2017b).

(3) **Conv-Seq2seq**: A model combining the convolutional neural networks and the sequence-to-sequence network (Gehring et al., 2017).

(4) **FTSum**: A faithful summarization model proposed in (Cao et al., 2018), which leverages open information extraction and dependency parse technologies to extract actual fact descriptions from the source text.

(5) **Transformer**: A network architecture that solely based on attention mechanisms, dispensing with recurrence and convolutions entirely (Vaswani et al., 2017).

(6) **PCPG**: A pattern-controlled product description generation model proposed in (Zhang et al., 2019b). We adapt the model for our scenario.

To verify whether the performance improvement is obtained by adding additional entity label inputs, we directly concatenate the word embedding with the entity embedding as input for these baselines, denoted as "with Entity Embedding" in Table 2.

5.5 Implementation Details

We implement our experiments in Pytorch[3] on Tesla V100 GPUs[4]. The word and entity-label embedding dimensions are set to 256. The number of hidden units and the entity-label hidden size are also set to 256. All inputs were padded with zeros to a maximum keyword number of the batch. There are 36 categories of entity labels together.

w/o ELSTM	31.41	14.57	8.430	5.630	14.98	25.25

Table 2: RQ1: Comparison between baselines.

λ is set to 0 in the first 500 steps, and 0.6 in the rest of the training process. We performed mini-batch cross-entropy training with a batch size of 256 documents for 15 training epochs. we set the minimum encoding step to 15 and maximum decoding step size to 70. During decoding, we employ beam search with a beam size of 4 to generate a more fluent sentence. It took around 6 hrs on GPUs for training. After each epoch, we evaluated our model on the validation set and chose the best performing model for the test set. We use the Adam optimizer (Duchi et al., 2010) as our optimizing algorithm and the learning rate is 1e-3.

6 Experimental Results

6.1 Overall Performance

For research question **RQ1**, we examine the performance of our model and baselines in terms of BLEU, as shown in Table 2. Firstly, among all baselines, Pointer-Gen obtains the best performance, outperforming the worst baseline Conv-Seq2Seq by 2.44 in BLEU-1. Secondly, directly concatenating the entity label embedding with the word embedding does not bring much help, only leading to an improvement of 0.26 in BLEU-1 for the Pointer-Gen model. Finally, our model outperforms all baselines for all metrics, outperforming the strongest baseline Pointer-Gen, by 5.22%, 6.86%, 6.79%, and 6.65% in terms of BLEU-1, BLEU-2, BLEU-3, and BLEU-4, respectively.

	Fluency	Informativity	Fidelity
Pointer-Gen	2.23	1.84	1.91
FPDG	**2.46**$^{\blacktriangle}$	**2.19**$^{\blacktriangle}$	**2.38**$^{\blacktriangle}$

Table 3: RQ1: Human evaluation comparison with Pointer-Gen baseline.

As for human evaluation, we ask three highly educated participants to rank generated summaries in terms of fluency, informativity, and fidelity. The rating score ranges from 1 to 3 with 3 being the best. The results are shown in Table 3, where FPDG outperforms Pointer-Gen by 10.31% and 19.02% in terms of fluency and informativity, and, specifically, FPDG greatly improves the fidelity value by 24.61%. We also conduct the paired student t-test between our model and Pointer-Gen, and the result demonstrates the significance of the above results. The kappa statistics are 0.35 and 0.49, respectively, which indicates fair and moderate agreement between annotators[5].

[5](Landis and Koch, 1977) characterize kappa values < 0 as no agreement, 0-0.20 as slight, 0.21-0.40 as fair, 0.41-0.60 as moderate, 0.61-0.80 as substantial, and 0.81-1 as almost

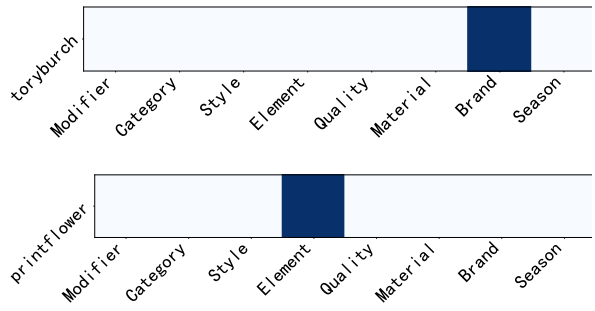

Figure 4: RQ3: Visualizations of entity-label-attention when generating the word on the left.

6.2 Ablation Study

Next, we turn to research question **RQ2**. We conduct ablation tests on the usage of the keyword memory and ELSTM, corresponding to FPDG w/o KW-MEM and ELSTM, respectively. The ROUGE score result is shown at the bottom of Table 2. Performances of all ablation models are worse than that of FPDG in terms of almost all metrics, which demonstrates the necessity of each module in FPDG. Specifically, ELSTM makes the greatest contribution to FPDG, improving the BLEU-1, BLEU-2 scores by 2.71% and 1.51%.

6.3 Analysis of Keyword Memory

We then address **RQ3** by analyzing the entity-label-level attention on the keyword memory. Two representative cases are shown in Figure 4. The figure in the above is the attention map when generating the word "toryburch", and the bottom figure is when generating the word "printflower". The darker the color, the higher the attention. Due to limited space, we omit irrelevant entity categories. When generating "toryburch", which is a brand name, the entity-label-level attention pays most attention to the "Brand" entity label, and when generating "flower", which is a style element, it mostly pays attention to "Element". This example demonstrates the effectiveness of the entity-label-level attention.

6.4 Analysis of ELSTM

We now turn to **RQ4**; whether or not the ELSTM can capture entity label information. We examine this question by verifying whether ELSTM can predict the entity label of the generated word. The accuracy of the predicted entity label is calculated in a teacher-forcing style, i.e., each ELSTM takes the ground truth entity label and word as input, and outputs the entity label of the next word. We employ recall at position k in n candidates ($R_n@k$) as evaluation metrics. Over the whole test dataset, $R_1@36$ is 64.12%, $R_2@36$ is 80.86%, and $R_3@36$ is 94.02%, which means ELSTM can capture the entity label information to a great extent and guide the word generation.

We also show a case study in Table 4. The description generated by Pointer-Gen introduces the Prada bag as a "clamshell bag has a good anti-theft effect", which is contrary to the fact. While our model generates the faithful description: "The opening and closing design of the zipper smoothes the stroke".

Input: 正品; Prada;/;普拉达; 男包; 尼龙; 双肩背包; 男士; 休闲; 旅行包; 电脑包; 登山包(authentic; Prada; man bag; leisure; travel bag; laptop bag; backpack)	
Reference	这款来自prada的拉链双肩包。采用纯色设计，包面上的字母印花图案十分显眼，令人眼前一亮，瞬间脱颖而出。开合双拉链处理，使用顺滑，方便拿取物品。大容量的包包，为物品的放置提供足够的空间。(This zippered shoulder bag from Prada. With a solid color design, the letter print on the surface of the bag is very conspicuous, making it instantly stand out. Open and close double zipper makes it easy to use take items smoothly. Large-capacity bag provides enough space for the placement of items.)
Pointer-Gen	这款来自prada的翻盖双肩包。采用了翻盖的设计，具有很好的防盗效果，让你的出行更加安全可靠。大容量的包型设计，满足日常的生活所需，让你的出行更加方便快捷。(This flipover bag from Prada. The ~~clamshell design has a good anti-theft effect, making your trip safer and more reliable~~. The large-capacity package design meets the needs of everyday life, making your travel more convenient and quick.
FPDG	这款来自prada的纯色双肩包。纯色的设计，给人一种大气又干练的感觉，打造时下流行的简约风格。拉链的开合设计，划拉顺畅，增加物品安全性。大容量的包型，既能容纳生活物品，还让携带更加的便捷。(This solid color backpack from Prada. The solid color design gives people an atmosphere and a sense of exquisiteness, creating a simple style that is popular nowadays. The opening and closing design of the zipper smoothes the stroke and increases the safety of the item. Large-capacity package can accommodate living items and make it easier to carry.

Table 4: Examples of the generated answers by Pointer-Gen and FPDG. The text with underline demonstrates faithful description, and text with deleteline demonstrates wrong description.

7 Conclusion and Future Work

In this paper, we explore the fidelity problem in product description generation. To tackle this

perfect agreement.

challenge, based on the consideration that product attribute information is typically conveyed by entity words, we incorporate the entity label information of each word to enable the model to have a better understanding of the words and better focus on key information. Specifically, we propose an Entity-label-guided Long Short-Term Memory (ELSTM) and a token memory to store and capture the entity label information of each word. Our model outperforms state-of-the-art methods in terms of BLEU and human evaluations by a large margin. In the near future, we aim to fully prevent the generation of unfaithful descriptions and bring FPDG online.

Abstract

This paper addresses the problem of inferring the fine-grained type of an entity from a knowledge base. We convert this problem into the task of graph-based semi-supervised classification, and propose Hierarchical Multi Graph Convolutional Network (**HMGCN**), a novel Deep Learning architecture to tackle this problem. We construct three kinds of connectivity matrices to capture different kinds of semantic correlations between entities. A recursive regularization is proposed to model the *subClassOf* relations between types in given type hierarchy. Extensive experiments with two large-scale public datasets show that our proposed method significantly outperforms four state-of-the-art methods.

1 Introduction

Nowadays, Knowledge Base ($\mathcal{KB}$ for short) attracts increasing research interests in various areas. One of the fundamental components in $\mathcal{KB}$ is the information of entity type, which clusters a group of entities with same properties, and is the glue that holds our mental world together (Murphy, 2004). Traditional entity typing focuses on a small set of types, such as *Person*, *Location* and *Organization* (Ratinov and Roth, 2009; Nadeau and Sekine, 2007), while Fine-Grained Entity Typing assigns more specific types to an entity, which normally forms a *type-path* in the type hierarchy in $\mathcal{KB}$ (Ren et al., 2016). For example, *Messi* is classified as having the path of following types: $FootballPlayer \subset Athlete \subset Person$. Types in $\mathcal{KB}$ are usually organized as a hierarchical structure, namely *type hierarchy*. Unfortunately, most $\mathcal{KB}$s are incomplete and lack of type information. For example, in DBpedia, the average number of types is only 2.9 (5,044,223 entities with 14,760,728 types), while 36.53% entities do not have type information. As Figure 1 shows, for each unlabeled entity, we will fully utilize its textual description, category and property to predict missing types. In this paper, we aim at assigning Fine-grained Entity Typing for entities in $\mathcal{KB}$ (such as Wikipedia and DBpedia).

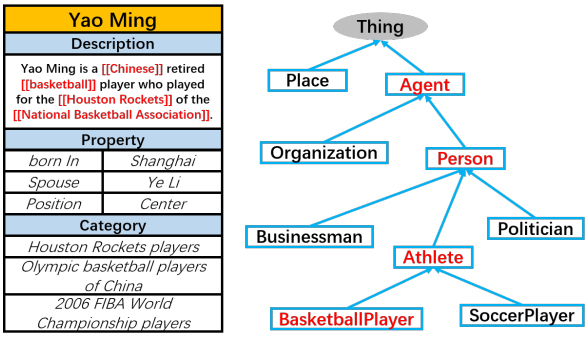

Figure 1: Entity (i.e., Yao Ming) with textual description (with anchor text in red), property (e.g., bornIn Shanghai) and category (e.g., Houston Rockets players). Yao Ming is associated with a type-path: $BasketballPlayer \subset Athlete \subset Person \subset Agent \subset Thing$

Many researches have been carried out in this field. State-of-the-art methods normally learn distributed representation for each entity, and apply a multi-label classification model to make type inference. For example, (Neelakantan and Chang, 2015) and (Xu et al., 2016) exploit various kinds of information to construct the feature representation of an entity, such as entity textual description, property and category. After that, a predict function is learned to infer whether entity e is an instance of type t. (Yaghoobzadeh et al., 2017) focus on the names of entities and the context of entity mentions (in text), and design two scoring models for pairs of entities and types. All these works ignore the internal relations among entities, and assign types for each entity in isolation. (Jin et al., 2018) viewed the internal relations

among entities as the structural information, and constructed an Entity Graph, further proposed a network embedding framework to learn the correlation among entities. It will be profitable to enrich entity features to entity graph structures, as recent studies have suggested to bring both node feature and graph structure information in a convolutional manner (Defferrard et al., 2016; Atwood and Towsley, 2016). Among these works, graph convolutional network (GCN) is the most widely-used model which can directly operate on graphs with arbitrary sizes and shapes (Kipf and Welling, 2016). The inputs of a GCN are feature vectors of nodes and graph structure. The most significant aspect of GCN is information diffusion, with which node's feature vector can be enriched by all the feature vectors of its neighbors.

Here, we convert entities in $\mathcal{KB}$ into three semantic graphs, each encoding a specific kind of correlation among entities, as follows: $\mathbf{A}_{co}$ a graph of the topical co-occurrence relations among entities, $\mathbf{A}_{cat}$ a category-based graph encoding the category-proximity between entities, and $\mathbf{A}_{prop}$ a property-based graph encoding the property-proximity between entities. We propose Hierarchical Multi Graph Convolutional Network (**HMGCN**), a novel deep learning architecture consisting of three Graph Convolutional Networks (GCNs): $\mathbf{GCN}_{co}$ and $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$. Each connectivity matrix is fed to its corresponding GCN model, and the three GCN models are learned by shared parameters and consistency regularization. We adopt a simple and effective recursive regularization to deal with *subClassOf* relations between types. The main contributions of this paper are as follows:

- Graph convolutional network is applied for fine-grained entity typing task, which effectively integrates entity feature and structural information.
- Multi connectivity matrices are constructed to encode different kinds of semantic relatedness between entities. A recursive regularization is proposed to model *subClassOf* relations between types.
- Extensive experiments show that our proposed method significantly outperforms four state-of-the-art methods, with 1.7% and 1.3% improvement in Mi-F1 and Ma-F1 (on FIGER dataset), respectively.

The rest of this paper is organized as follows. Section 2 formally defines the problem of Fine-Grained Entity Typing in knowledge bases. Section 3 describes the proposed approach in detail. Section 4 reports a number of experiments with evaluations. Section 5 outlines some related works. Section 6 concludes our work.

2 Problem Formulation

In this section, we formally define the problem of *Fine-Grained Entity Typing* in $\mathcal{KB}$.

Definition 1 ***Knowledge Base*** *$\mathcal{KB} = (\mathcal{E}, \mathcal{T}, \mathcal{R})$, where $\mathcal{E}$, $\mathcal{T}$ and $\mathcal{R}$ are sets of entities, types and isA relations, respectively. $|\mathcal{E}| = N$ and $|\mathcal{T}| = K$. $\mathcal{R} = \mathcal{R}_i \cup \mathcal{R}_s$ consists of instanceOf and subClassOf triples. $\mathcal{R}_i = \{(e_i, isA, t_j) | e_i \in \mathcal{E}, t_j \in \mathcal{T}\}$ collects all instanceOf triples and $\mathcal{R}_s = \{(t_i, isA, t_j) | t_i, t_j \in \mathcal{T}\}$ collects all subClassOf triples.*

Note that not each entity in a knowledge base $\mathcal{KB}$ is assigned with types. We split the entity set $\mathcal{E}$ into two subsets: $\mathcal{E}^l$ and $\mathcal{E}^u$, $\mathcal{E} = \mathcal{E}^l \cup \mathcal{E}^u$, $\mathcal{E}^l \cap \mathcal{E}^u = \emptyset$. $\mathcal{E}^l$ denotes the entity set whose member is assigned with type information. $\mathcal{E}^u$ denotes the entity set whose member has no type information. $|\mathcal{E}^l| = N^l$, $|\mathcal{E}^u| = N^u$. Types in $\mathcal{T}$ form a tree or a directed acyclic graph (DAG) via *subClassOf* relations, we refer it as type hierarchy $\mathcal{H} = (\mathcal{T}, \mathcal{R}_s)$.

For each entity, we distinguish three kinds of features, namely, *Text Description*, *Category*, and *Property*, which are beneficial to *Fine-Grained Entity Typing* task.

- *Text Description* is a succinct summary of an entity, providing valuable clues to predict entity types. As Figure 1 shows, there are a large number of anchor texts in textual description.
- *Category* refers, in Wikipedia, actually to tags/topics that group entities on similar subjects. For instance, *Yao Ming* in Wikipedia has category *Olympic basketball players of China*, which is the topic of the entity instead of its type. *Category* can be a useful information to infer missing type information.
- *Property* of entities is important cue in type inference. For instance, from *Yao Ming*'s property *playing position*, one may infer that *Yao Ming* is an *Athlete*.

Besides entity features above, there are many kinds of semantic correlations between entities, which organize entities into graph structures. We refer it as **entity graph**. Each kind of semantic correlation corresponds to a kind of connectivity matrix. There are many ways to construct entity graph via different connectivity manner, which will be discussed in Section 3.

Definition 2 ***Entity Graph*** $\mathcal{G} = (\mathbf{A}, \mathbf{X}, \mathbf{Y})$. $\mathbf{A} \in \mathbb{R}^{N \times N}$ *is the connectivity matrix representing a kind of link relation between entities.* $\mathbf{X} \in \mathbb{R}^{N \times M}$ *is the feature matrix representing inherent features for all entities, where M is the number of features. Each row in* $\mathbf{X}$ *refers to an entity's feature vector* $\mathbf{X}_i$. $\mathbf{X}$ *can either be binary or take any real value.* $\mathbf{Y} \in \mathbb{R}^{N^l \times K}$ *is the type matrix collecting type information for entities in* $\mathcal{E}^l$. *Each row in* $\mathbf{Y}$ *refers to the instanceOf relations between an entity and all types.* $\mathbf{Y}_{ij} = 1$ *if* e_i *has been assigned with type* t_j, *otherwise 0.*

The task of Fine-Grained Entity Typing can be formally described as follows: Given a partially-labeled Entity Graph $\mathcal{G} = (\mathbf{A}, \mathbf{X}, \mathbf{Y})$, we aim at learning a type predictor from $\mathbf{Y}$, which comprehensively takes graph structure and entity features into account. Then we utilize the learned type predictor to predict the missing *instanceOf* relations in $\mathcal{E}^u$, i.e., whether $(e_i, instanceOf, t_j)$ is true. In this way, we convert the task of Fine-Grained Entity Typing into a task of graph-based semi-supervised classification.

3 Hierarchical Multi Graph Convolutional Network (HMGCN)

State-of-the-art methods convert entities in $\mathcal{KB}$ into entity graph, then apply graph-based algorithm. The difficulties lie in two facts:

- Firstly, it is hard to effectively integrate entity features and structural information. Although network embedding methods, in terms of attributed network embedding, can take both graph structure and features into consideration (Huang et al., 2017), the node features are usually only served as auxiliary information in structure learning (Yang et al., 2016; Liao et al., 2017).

- Secondly, it is not easy to effectively integrate different connectivity matrix which capture different kinds of structural information (Wang et al., 2018; Zhuang and Ma, 2018).

We propose a Hierarchical Multi GCN model (**HMGCN**) to encode heterogeneous structural information in an ensemble manner, as illustrated in Figure 2. We construct three undirected entity graphs to capture different kinds of semantic correlations between entities, i.e., co-occurrence graph $\mathbf{A}_{co}$, category-based graph $\mathbf{A}_{cat}$, and property-based graph $\mathbf{A}_{prop}$. $\mathbf{A}_{co}$ encodes the topical relevance between entities, and is derived from textual anchor texts. $\mathbf{A}_{cat}$ is constructed through similarity computation based on category information, based on the assumption that entities with similar categories tend to have the same type. In the same way, we construct property-based graph $\mathbf{A}_{prop}$. Each entity graph is fed to corresponding GCN model, namely, $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$. These models use shared parameters and unsupervised consistency regularization, so that they can jointly consider opinions from three semantic perspectives. To achieve this, a simple and effective recursive regularization is adopted to deal with the *subClassOf* relations between types.

3.1 GCN-Based Entity Type Classification

GCN model consists of multiple stacked GCN layers. Given the input feature matrix $\mathbf{X} \in \mathbb{R}^{N \times M}$ and adjacency matrix $\mathbf{A} \in \mathbb{R}^{N \times N}$, the output of the i-th hidden layer of the network $\mathbf{Z}^{(i)}$ is defined as:

$$\mathbf{Z}^{(i)} = \sigma(\tilde{\mathbf{D}}^{-\frac{1}{2}}\tilde{\mathbf{A}}\tilde{\mathbf{D}}^{-\frac{1}{2}}\mathbf{Z}^{(i-1)}\mathbf{W}^{(i)}) \quad (1)$$

$\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{I_n}$ is the adjacency matrix with self-loops, where $\mathbf{I_n} \in \mathbb{R}^{N \times N}$ is the identity matrix. $\tilde{\mathbf{D}}_{ii} = \sum_j \tilde{\mathbf{A}}_{ij}$. Accordingly, $\tilde{\mathbf{D}}^{-\frac{1}{2}}\tilde{\mathbf{A}}\tilde{\mathbf{D}}^{-\frac{1}{2}}$ is the normalized adjacency matrix. $\mathbf{Z}_A^{(i-1)}$ is the output of the $(i-1)$-th layer, and $\mathbf{Z}^{(0)} = \mathbf{X}$. $\mathbf{W}^{(i)}$ are the trainable parameters of the network, and $\sigma(\cdot)$ denotes an activation function (e.g., *ReLU*, *Sigmoid*). A detailed explanation of GCN model is presented in the original work (Kipf and Welling, 2016).

Since Fine-grained Typing is a multi-label classification problem. The final layer further connects to a set of K Sigmoid functions, which correspond to the K types in the type hierarchy. Given the set of labeled entities $\mathcal{E}^l$, our model optimizes

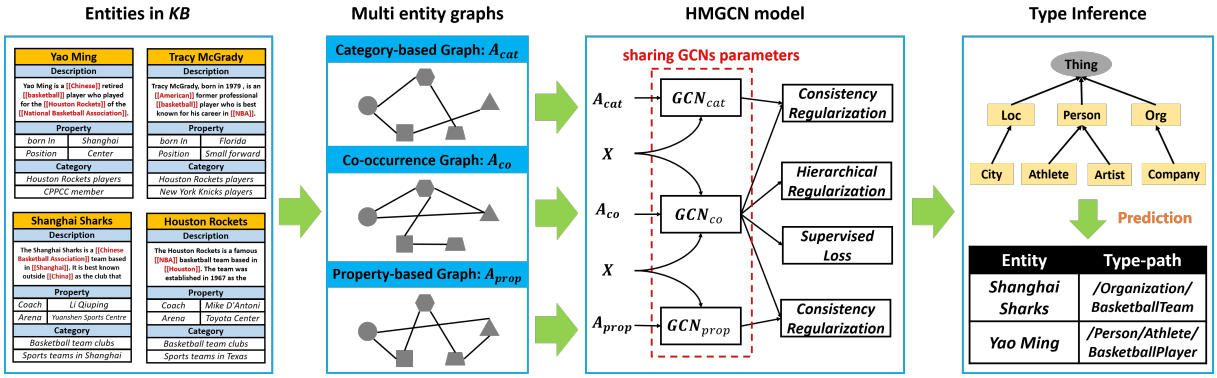

Figure 2: Framework of **HMGCN**. We convert entities in $\mathcal{KB}$ into multi kinds of semantic graphs. The co-occurrence graph $\mathbf{A}_{co}$ is constructed from anchor text in textual description. The category-based graph $\mathbf{A}_{cat}$ is derived from category proximity. The property-based graph $\mathbf{A}_{prop}$ is derived from property proximity. Each graph is fed to corresponding GCN model with same feature matrix $\mathbf{X}$. The three GCN models are learned by sharing parameters and consistency regularization. A hierarchical regularization is used to deal with the subClassOf relations between types.

the cross-entropy between the true type distribution and the predicted distribution.

$$L_s = -\sum_{i=1}^{N_l}\sum_{j=1}^{K} \mathbf{Y}_{i,j} \ln \hat{\mathbf{Z}}_{i,j} + (1-\mathbf{Y}_{i,j}) \ln (1-\hat{\mathbf{Z}}_{i,j}) \tag{2}$$

Where $\mathbf{Y}_{i,j}$ indicates whether entity e_i belongs to type t_j. $\hat{\mathbf{Z}}_{i,j}$ refers to the probability of GCN prediction.

The role of $\tilde{\mathbf{D}}^{-\frac{1}{2}}\tilde{\mathbf{A}}\tilde{\mathbf{D}}^{-\frac{1}{2}}\mathbf{Z}^{(i-1)}\mathbf{W}^{(i)}$ is to exactly conduct a 1-hop diffusion process in each layer. Namely, a node's feature vector is enriched in the way of linearly adding all the feature vectors of its neighbors. With more hidden layers, an entity's feature can diffuse to further entities (2-hop, 3-hop and so on). Research shows that there's no significant increase when the number of layers is higher than 3 (Kipf and Welling, 2016). Here, we assume adjacency matrix $\mathbf{A}$ and feature matrix $\mathbf{X}$ are given. In the next part of this section, we show how to compute $\mathbf{A}$ and $\mathbf{X}$.

3.2 Connectivity Matrix Designing

In Knowledge Graphs, there are large numbers of descriptive anchor texts that are helpful for type inference. For an entity e, $CXT(e)$ is an entity set which contains all entities occur in its textual description. For example in Figure 1, *Houston Rockets* is in $CXT(YaoMing)$. If entity $e_i \in CXT(e_j)$, we can say that e_i occurs in e_j'context or e_j cites e_i in its textual description. These are co-occurrence information among entities, and can be explicitly extracted and represented by the connectivity matrix $\mathbf{A}_{co}$.

$$A_{co}[i,j] = \begin{cases} 1 & e_i \in CXT(e_j) \text{ or } e_j \in CXT(e_i) \\ 0 & otherwise \end{cases} \tag{3}$$

$\mathbf{A}_{co}$ can capture co-occurrence relations, though not precise enough. For example, *Houston Rockets* and *NBA* occur in *Yao Ming*'s context, but they do not belong to same type.

Besides $\mathbf{A}_{co}$, we calculate the correlation between entities via category information. If entity e_i and e_j share common categories, e_i and e_j will be likely belong to a same type. For example in Figure 2, both *Houston Rockets* and *Shanghai Sharks* have category *Basketball team clubs*, they have same type *BasketballTeam*. We construct $\mathbf{A}_{cat}$, and use Jaccard similarity coefficient to calculate each element $\mathbf{A}_{cat}[i,j]$:

$$\mathbf{A}_{cat}[i,j] = \frac{|Cat(e_i) \cap Cat(e_j)|}{|Cat(e_i) \cup Cat(e_j)|} \tag{4}$$

in which, $Cat(e)$ is the category set of entity e. In the same way, we can calculate the correlation between entities via property information, and construct $\mathbf{A}_{prop}$, whose element is calculated as follows.

$$\mathbf{A}_{prop}[i,j] = \frac{|Prop(e_i) \cap Prop(e_j)|}{|Prop(e_i) \cup Prop(e_j)|} \tag{5}$$

in which $Prop(e)$ is the property set of entity e.

Each connectivity matrix is fed to its corresponding GCN model, i.e., $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and

$\mathbf{GCN}_{prop}$, respectively. As mentioned in Section 2, each entity is associated with text description, category and property. We used category and property information to construct connectivity matrix, therefore, words appeared in the text description of an entity can be approximately viewed as features of this entity. We apply fastText method, which treats the average of word/n-grams embeddings as entity feature (Joulin et al., 2016), and construct the feature matrix $\mathbf{X}$. As shown in Figure 2, both $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$ take $\mathbf{X}$ as input feature matrix.

3.3 Parameters Sharing and Consistency Regularization

The success of our model largely relies on the strategy that three GCN models share common parameters (i.e., neural network weights $\mathbf{W}^{(i)}$ in Eqs. 1), as shown in Figure 2. By doing so, our model (which is characterized by the parameters $\mathbf{W}^{(i)}$) can simultaneously consider the knowledge encoded in $\mathbf{A}_{co}$, $\mathbf{A}_{cat}$ and $\mathbf{A}_{prop}$. The prediction of $\mathbf{GCN}_{co}$ and $\mathbf{GCN}_{cat}$ are denoted as $\hat{\mathbf{Z}}^{co}$ and $\hat{\mathbf{Z}}^{cat} \in \mathbb{R}^{N\times K}$, respectively. To jointly consider the opinions from $\mathbf{GCN}_{co}$ and $\mathbf{GCN}_{cat}$, we apply an unsupervised regularizer for the ensemble. We minimize the mean squared difference between $\hat{\mathbf{Z}}^{co}$ and $\hat{\mathbf{Z}}^{cat}$ for all N entities.

$$L_{c1} = \sum_{i=1}^{N} \left\| \hat{\mathbf{Z}}^{cat}_{i,:} - \hat{\mathbf{Z}}^{co}_{i,:} \right\|^2 \tag{6}$$

The prediction of $\mathbf{GCN}_{prop}$ is denoted as $\hat{\mathbf{Z}}^{prop}$. In the same way, we minimize the mean squared differences between $\hat{\mathbf{Z}}^{co}$ and $\hat{\mathbf{Z}}^{prop}$ over all N entities.

$$L_{c2} = \sum_{i=1}^{N} \left\| \hat{\mathbf{Z}}^{prop}_{i,:} - \hat{\mathbf{Z}}^{co}_{i,:} \right\|^2 \tag{7}$$

Our model can jointly consider the opinions of $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$. Although sharing the same parameters $\mathbf{W}^{(i)}$, three GCN models utilize different connectivity matrices as input, which capture different semantic correlations between entities. This difference may cause the predictions of three GCN models to differ. Our model is expected to give a consistent prediction via the proposed unsupervised consistency regularizations, i.e., minimizing Eqs. 6 and 7. As a result, the learned parameter matrix $\mathbf{W}^{(i)}$ considers the judgments from both $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$.

3.4 Recursive Hierarchical Regularization

Leaf nodes (in type hierarchy) may have insufficient training examples. In that case, decisions can be regularized by its parent, if a type hierarchy is available. We introduce dependency relations among types to improve the classification performance. Similar to (Peng et al., 2018; Gopal and Yang, 2013), we use a recursive regularization over the final layer. Two types shall have similar embeddings, if they are close in a graph. In particular, types that are related by *subClassOf* relation shall have similar embeddings. For example, in Figure 1, there is an edge between *Athlete* and *BasketballPlayer*, so the parameters of the two types could be similar to each other. Assuming there are n hidden layers, the last layer parameter matrix $\mathbf{W}^{(n)}$ can be regarded as the type embedding matrix, each row in $\mathbf{W}^{(n)}$ refers to a type representation. Let $C(t)$ refer to the sub-type set of t (t's children in the hierarchy). We use the following recursive regularization term to regularize the parameter of each type:

$$L_{hie} = \sum_{i=1}^{K} \sum_{j\in C(t_i)} \frac{1}{2} \left\| \mathbf{W}^{(n)}_{i,:} - \mathbf{W}^{(n)}_{j,:} \right\|^2 \tag{8}$$

3.5 Model Training

We calculate the supervised loss over all labeled entities for $\mathbf{GCN}_{co}$ (Eqs. 2). Although $\mathbf{Z}^{co}_i$ is regarded as the final type prediction result, our model can consider the opinions from three GCN models via parameters sharing and consistency regularization. The total loss is the sum of supervised loss, two consistency regularizations and recursive regularization.

$$Loss = L_s + \lambda(t)(L_{c1} + L_{c2}) + \lambda' L_{hie} \tag{9}$$

in which $\lambda(t)$ is a dynamic weight function, and λ' is chosen among a fixed set based on performance on the dev set. At the beginning of the training process, $\lambda(t)$ is small, the loss function is mainly dominated by L_s. **HMGCN** is inclined to agree with $\mathbf{GCN}_{co}$ when making decisions, which encodes co-occurrence relation between entities. $\lambda(t)$ increases as time goes on, our model will obtain posterior distribution over the types using $\mathbf{GCN}_{co}$, and $\lambda(t)$ will force our model to consider simultaneously the knowledge encoded in $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$. $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$ play more important role when making decision. We adopt Adam (Kingma and Ba, 2014) to minimize the

above loss functions. For each $e_i \in \mathcal{E}^u$, we use $\mathbf{Z}_i^{co}$ as the type prediction result.

4 Experiments

4.1 Datasets and Metrics

Datasets: There are two public large-scale datasets available for Fine-Grained Entity Typing in $\mathcal{KB}$, *FIGER*[1] and *DBpedia* (Zhang et al., 2015). *FIGER* is a widely used dataset which is proposed by Yaghoobzadeh et al.. The *DBpedia* dataset is constructed by picking 14 non-overlapping types for text classification originally, we expand these 14 types and form a hierarchy. For each dataset, we extract entity feature from *DBpedia*[2]. For *FIGER* and *DBpedia*, we split entities into train (50%), dev (20%) and test (30%) sets. Since *DBpedia* dataset contains 630,000 entities, which is too big for computation, we divide it equally into three parts (i.e., DB-1, -2 and -3). Table 1 shows some statistics about the two datasets. Our source code is available[3] for reference. More detailed information can be found there.

Table 1: Statistics of the datasets.

Dataset	**FIGER**	**DB-1**	**DB-2**	**DB-3**
#Entities	200,000	210,000	210,000	210,000
#Types	102	48	48	48

Metrics: To evaluate the performance of our proposed method, we use Accuracy (**Strict-F1**), Micro-averaged F1 (**Mi-F1**) and Macro-averaged F1 (**Ma-F1**), which have been used in many fine-grained typing systems (Ling and Weld, 2012; Ren et al., 2016; Yaghoobzadeh et al., 2017).

4.2 Methods for Comparison

Baseline: we compare **HMGCN** with four state-of-the-art of methods and three variants of **HMGCN**:

- **CUTE:** (Xu et al., 2016) utilizes three kinds of entity features: category, property and property-value pair, and employs a hierarchical multi-label classification method.
- **MuLR:** (Yaghoobzadeh and Schütze, 2017) applies embeddings of words, entities and types in entity typing task, and uses multi-level representations of entities via character, word, and entity embedding technologies.
- **FIGMENT:** (Yaghoobzadeh et al., 2017) introduces global model and context model to provide complementary information for entity typing.
- **APE:** (Jin et al., 2018) applies an attributed and predictive entity embedding method to learn entity representations. In a way, it takes graph structure and entity features into account.
- **HMGCN's variants:** $\textbf{HMGCN}_{no_cat}$ only use $\textbf{GCN}_{co}$ and $\textbf{GCN}_{prop}$ to make type inference. $\textbf{HMGCN}_{no_prop}$ only use $\textbf{GCN}_{co}$ and $\textbf{GCN}_{cat}$ to make type inference. $\textbf{HMGCN}_{no_co}$ only use $\textbf{GCN}_{cat}$ and $\textbf{GCN}_{prop}$ to make type inference. $\textbf{HMGCN}_{flat}$ ignores the correlation between types, i.e., removes hierarchical recursive regularization.

Parameter Settings: **HMGCN** is implemented based on the original GCN model (Kipf and Welling, 2016). In our implementation, both $\textbf{GCN}_{co}$, $\textbf{GCN}_{cat}$ and $\textbf{GCN}_{prop}$ have two hidden layers. Namely, there are two separate parameter vectors, $\mathbf{W}^{(1)}$ and $\mathbf{W}^{(2)}$, that need training. Table 2 presents detailed information about the implementation of our method for each dataset, including (1) number of hidden units; (2) dropout rate; and (3) learning rate η. λ' is chosen among $\{0.00625, 0.0125, 0.025, 0.05, 0.1, 0.2, 0.4, 0.8\}$, we found $\lambda' = 0.2$ achieves best performance. We set $\lambda(t)$ in several ways, which is discussed in Section 4.4. We train all models for a maximum of 200 epochs (training iterations) using Adam (Kingma and Ba, 2014) and early stopping with a window size of 10 to minimize loss functions.

Table 2: Values of the Hyper-Parameters in **HMGCN** model.

Dataset	$\mathbf{W}^{(1)}$	$\mathbf{W}^{(2)}$	Dropout rate	Learning rate
DBpedia	32	48	30%	0.001
FIGER	64	102	10%	0.002

[3] https://github.com/SIGKDD/HMGCN

4.3 Overall Comparison Results

Table 3 and 4 shows the overall performance on two datasets and we have the following conclusions:

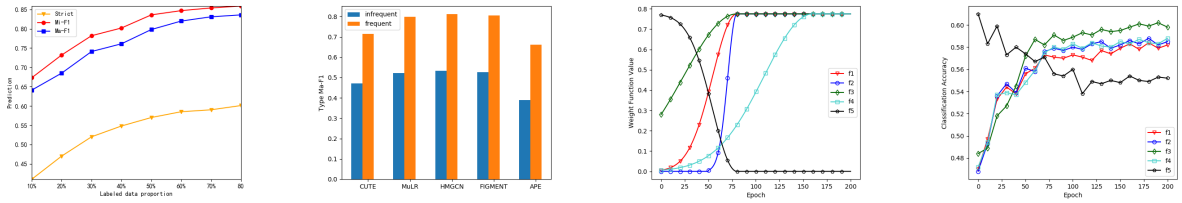
Comparison with Entity Typing methods. Our model significantly outperforms the state-of-the-art entity typing methods over all datasets. **HMGCN** outperforms the best baseline with 1.7% and 1.3% improvement in Mi-F1 and Ma-F1 on *FIGER* dataset, 3.2% and 3.6% improvement in Mi-F1 and Ma-F1 on *DB-1* dataset, 3.9% and 3.5% improvement in Mi-F1 and Ma-F1 on *DB-2* dataset, 3.7% and 3.8% improvement in Mi-F1 and Ma-F1 on *DB-3* dataset, respectively. Compared with other methods, the performance of **CUTE** is relatively poor, as it ignores the rich structure information both in entity graph and type hierarchy. **FIGMENT** and **MuLR** achieve better performance, in part because powerful embedding technologies are applied and the decision is made in global-view and context-view. **APE** considers graph structure and entity features in attributed network embedding manner, while **HMGCN** applies this in a convolutional manner, which can embed the graph knowledge more sufficiently (Kipf and Welling, 2016; Zhuang and Ma, 2018).

Comparison with Variants. **HMGCN** consistently outperforms all four variants, because in **HMGCN** three GCN models provide complementary information. The key of **HMGCN** is parameter-sharing ($\mathbf{W}^{(i)}$ in $\mathbf{GCN}_{co}$, $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$) and unsupervised regularizer for ensemble. The three GCNs encode different kinds of semantic correlations between entities, so that **HMGCN** could have a trade-off in decision-making. As a result, the trained parameters $\mathbf{W}^{(i)}$ have considered opinions from all three GCNs. $\mathbf{HMGCN}_{no_co}$ and $\mathbf{HMGCN}_{no_prop}$ demonstrate better performance than $\mathbf{HMGCN}_{no_cat}$, which suggests that category information should be more import than co-occurrence and property information. $\mathbf{HMGCN}_{flat}$ ignores the correlations between types (i.e., *subClassOf* relations), while **HMGCN** take the structure of type hierarchy as prior knowledge. Infrequent types benefit from the recursive regularization in **HMGCN**. Because when an infrequent type has less training example, the decision can be regularized by its parent (super-type).

4.4 Result Analysis

Effects of Labeled Data. Intuitively, our model can learn better embeddings and achieve better performance, if we have more labeled entities. We investigate the effect of labeled data proportion. The results show that three metrics strikingly increase with more labeled data added, and gradually become stable when the proportion is over 0.5, as illustrated in Figure 3(a). This shows that our model can achieve a satisfactory result, even with not enough labeled data, and this advantage is benefited from the information diffusion of the GCN model, i.e., similar entities should share information between each other.

Results of Frequent/Infrequent Types. We evaluate the performance on *frequent types* ($frequency > 3,000$; 15 types) and *infrequent types* ($frequency < 200$; 36 types). The classification measure is the type macro average F1 (F1 of entities assigned to a type, then averaged over types) (Yosef et al., 2012). Note that it is different from Ma-F1 reported in Table 3. Generally, the performance on infrequent types is worse than frequent ones. Our model consistently outperforms the other methods on infrequent types, which demonstrates its ability on dealing with rare types. The results for infrequent and frequent types in *FIGER* dataset are illustrated in Figure 3(b).



Effect of Regularization Weight $\lambda(\mathbf{t})$. Our model uses a weight function $\lambda(t)$ to balance the trade-off between the supervised loss and unsupervised consistency regularizer. We devised several different weight functions (Zhuang and Ma, 2018), as shown in Figure 3(c). Here, t is defined as the number of epochs. f_i $(1 \leq i \leq 4)$ increases with different increment speed, as the number of epochs increases; while f_5 decreases as the number of epochs increases. f_i $(1 \leq i \leq 4)$ strikingly outperforms f_5, as shown in Figure 3(d). We can see that the knowledge embedded in $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$ is beneficial to entity typing task. At the beginning of training process, supervised loss function plays the leading role. After several epochs, $\lambda(t)$ forces our model to simultaneously consider the knowledge encoded in $\mathbf{GCN}_{cat}$ and $\mathbf{GCN}_{prop}$.

isting methods do type inference by utilizing entity's inherent feature (textual description, property and category) or mention in text (anchor text). (Neelakantan and Chang, 2015) use text description as entity feature representation, then design a global objective function to predict missing entity types in a $\mathcal{KB}$. (Xu et al., 2016) use property and category information, along with a multi-label hierarchical classifier, to assign DBpedia types to Chinese entities. (Yaghoobzadeh and Schütze, 2015)first propose FIGMENT to address this problem. They only used contextual information to assign types for entities in $\mathcal{KB}$. After that, they present FIGMENT-Multi to learn multi-level representations of entities on three complementary levels (character, word and entity) (Yaghoobzadeh and Schütze, 2017). FIGMENT-Multi predicts whether an entity is a member of a type based on the learned embeddings. Finally, they propose an embedding based method which combines a global model with a context model. A global model that scores based on aggregated context information and a context model that aggregates the scores of individual contexts (Yaghoobzadeh et al., 2017). Recent research convert entities in $\mathcal{KB}$ to an entity graph and apply graph-based algorithm on it. (Jin et al., 2018) use links between entities to construct an entity graph, jointly utilize entity feature and graph structure to make type inference. They apply an attributed and predictive network embedding method to encode entity feature and graph structure. After that, a multi-label classifier is employed to carry out type classification.

6 Conclusion

We convert the task of Fine-Grained Entity Typing in $\mathcal{KB}$ to graph-based semi-supervised classification task, and propose a hierarchical multi graph

convolutional network (**HMGCN**) that fully utilizes entity features, entity graph structure, and type hierarchy structure to address this task. Three GCN models are devised to embed multi kinds of semantic correlations between entities. A recursive regularization is proposed to make the model understand, to a certain extent, the structure of type hierarchy. Experiments on two real datasets demonstrate the effectiveness of the proposed model.

Abstract

Recently we proposed the Span Attribute Tagging (SAT) Model (Du et al., 2019) to infer clinical entities (e.g., symptoms) and their properties (e.g., duration). It tackles the challenge of large label space and limited training data using a hierarchical two-stage approach that identifies the span of interest in a tagging step and assigns labels to the span in a classification step.

We extend the SAT model to jointly infer not only entities and their properties but also relations between them. Most relation extraction models restrict inferring relations between tokens within a few neighboring sentences, mainly to avoid high computational complexity. In contrast, our proposed Relation-SAT (R-SAT) model is computationally efficient and can infer relations over the entire conversation, spanning an average duration of 10 minutes.

We evaluate our model on a corpus of clinical conversations. When the entities are given, the R-SAT outperforms baselines in identifying relations between symptoms and their properties by about 32% (0.82 vs 0.62 F-score) and by about 50% (0.60 vs 0.41 F-score) on medications and their properties. On the more difficult task of jointly inferring entities and relations, the R-SAT model achieves a performance of 0.34 and 0.45 for symptoms and medications respectively, which is significantly better than 0.18 and 0.35 for the baseline model. The contributions of different components of the model are quantified using ablation analysis.

1 Introduction

The widespread adoption of Electronic Health Records by clinics across United States has placed a disproportionately heavy burden on clinical providers, causing burnouts among them (Wachter and Goldsmith, 2018; Xu, 2018; Arndt et al., 2017). There has been considerable interest, both in academia and industry, to automate aspects of documentation so that providers can spend more time with their patients. One such approach aims to generate clinical notes directly from the doctor-patient conversations (Patel et al., 2018; Finley et al., 2018a,b). The success of such an approach hinges on extracting relevant information reliably and accurately from clinical conversations.

In this paper, we investigate the tasks of jointly inferring entities, specifically, symptoms (Sx), medications (Rx), their properties and relations between them from clinical conversations. These tasks are defined in Section 2. The key contributions of the work reported here include: (i) a novel model architecture for jointly inferring entities and their relations, whose parameters are learned using the multi-task learning paradigm (Section 4), (ii) comprehensive empirical evaluation of our model on a corpus of clinical conversations (Section 6), and (iii) understanding the model performance using ablation study and human error analysis (Section 6.7). Since clinical conversations include domain specific knowledge, we also investigate the benefit of augmenting the input feature representation with knowledge graph embedding. Finally, we summarize our conclusions and contributions in Section 7.

2 Task Definitions

For the purpose of defining the tasks, consider the snippet of a clinical conversation in Table 1.

2.1 The Symptom Task (Sx)

This task consists of extracting the tuples (*symType, propType, propContent*).

The "pain" in the example in Table 1 is annotated as *symType* (sym/msk/pain), where msk stands for musculo-skeletal system. We have

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4979–4990, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

DR: How often do you have pain in your arms?
PT: It hurts every morning.
DR: Are you taking anything for it?
PT: I've been taking Ibuprofen. Twice a day.

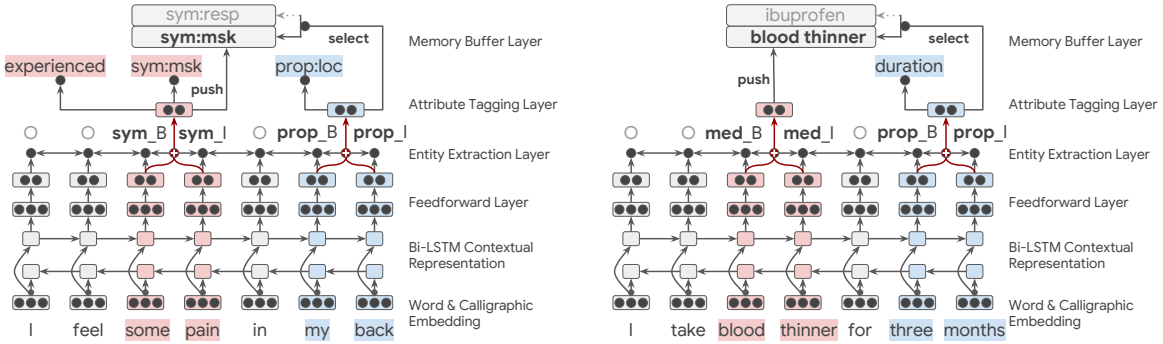
Table 1: An example to illustrate entities, properties and their relations. Entities – (sym/msk/pain: *pain*) & (meds/name: *Ibuprofen*); Properties – (symprop/freq: *every morning*) & (medsprop/freq: *twice a day*); Relations: (sym/msk/pain, symprop/freq, *every morning*), (Ibuprofen, medsprop/freq, *twice a day*).

pre-defined 186 categories for symptom types, curated by a team of practising physicians and scribes, based on how they appear in clinical notes. We deliberately abstained from the more exhaustive symptom labels such as UMLS and ICD codes (Bodenreider, 2004) in favor of this smaller set since our training data is limited.

The properties associated with the symptoms, *propType*, fall into four categories: symprop/severity, symprop/duration, symprop/location, and symprop/frequency. The *propContent* denotes the content associated with the property. In the running example, "every morning" is the content associated with the property type *symprop/frequency*.

Not all the symptoms mentioned in the course of clinical conversations are experienced by the patients. We explicitly infer the status of a symptom as experienced or not. This secondary task extracts the pair: (*symType, symStatus*).

2.2 The Medication Task (Rx)



This task consists of extracting tuples of the form: (*medContent, propType, propContent*).

While symptoms can be categorized into a closed set, the set of medications is very large and continually updated. Moreover, in conversations, we would like to extract indirect references such as "pain medications" as *medContent*. We define three types of properties: medsprop/dosage, medsprop/duration and medsprop/frequency. In the running example,"twice a day" is the *propContent* of the type *medsprop/frequency* associated with the *medContent* "ibuprofen".

3 Previous Work

Relation extraction is a long studied problem in the NLP domain and include tasks such as the ACE (Doddington et al., 2004), the SemEval (Hendrickx et al., 2010), the i2b2/VA Task (Uzuner et al., 2011a), and the BioNLP Shared Task (Kim et al., 2013). Many early algorithms such as DIPRE algorithm by Brin (1998) and SNOWBALL algorithm by Agichtein and Gravano (2000) relied on regular expressions and rules (Fundel et al., 2007; Peng et al., 2014). Subsequent work exploited syntactic dependencies of the input sentences. Features from the dependency parse tree were used in maximum entropy models (Kambhatla, 2004) and neural network models (Snow et al., 2005). Kernels were defined over tree structures (Zelenko et al., 2003; Culotta and Sorensen, 2004; Qian et al., 2008). More efficient methods were investigated including shortest dependency path (Bunescu and Mooney, 2005) and sub-sequence kernels (Mooney and Bunescu, 2006). Recent work on deep learning models investigated convolutional neural networks (Liu et al., 2013), graph convolutional neural networks over pruned trees (Zhang et al., 2018), recursive matrix-vector projections (Socher et al., 2012) and Long Short Term Memory (LSTM) networks (Miwa and Bansal, 2016). Other more recent approaches include two-level reinforcement learning models (Takanobu et al., 2019), two layers of attention-based capsule network models (Zhang et al., 2019), and self-attention with transformers (Verga et al., 2018). In particular, (Miwa and Sasaki, 2014; Katiyar and Cardie, 2016; Zhang et al., 2017; Zheng et al., 2017; Verga et al., 2018; Takanobu et al., 2019) also seek to jointly learn the entities and relations among them together. A large fraction of the past work focused on relations within a single sentences. The dependency tree based approaches have been extended across sentences by linking the root notes of adjacent sentences (Gupta et al., 2019). Coreference resolution is a similar task which requires finding all mentions of the same entity in the text (Martschat and Strube, 2015; Clark and Manning, 2016; Lee et al., 2017).

In the medical domain, the BioNLP shared task deals with gene interactions and is very different from our domain (Kim et al., 2013). The *i2b2/va challenge* is closer to our domain of clinical notes, however, that task is defined on a small corpus of written discharge summaries (Uzuner et al., 2011b). Written domain benefits from cues such as the section headings which are unavailable in clinical conversations. For a wider survey of extracting clinical information from written clinical documents, see (Liu et al., 2012).

(a) Model architecture for the symptoms task.

(b) Model architecture for the medications task.

Figure 1: Variants of the R-SAT model architecture. The entity spans ("some pain", "blood thinner") are identified in a tagging step, which are pushed into a memory buffer along with their latent representation and in a subsequent step the property spans ("my back", "three months") selects the most related entity from the buffer.

4 Model

Our application requires performing multiple inferences simultaneously, that of identifying symptoms, medications, their properties and relations between them. For this purpose, we adopt the well-suited multitask learning framework and develop a model architecture, illustrated in Figure 1, that utilizes our limited annotated corpus efficiently.

4.1 Input Encoder Layer

Let $\mathbf{x}$ be an input sequence. We compute the contextual representation at the k-th step using a bidirectional LSTM, $\mathbf{h}'_\mathbf{k} = [\vec{\mathbf{h}}(\mathbf{x}_{\leq \mathbf{k}}|\vec{\Theta}_{LSTM}), \overleftarrow{\mathbf{h}}(\mathbf{x}_{\geq \mathbf{k}}|\overleftarrow{\Theta}_{LSTM})]$, which is fed into a two-layer fully connected feed-forward network. For simplicity, we drop the index k from the rest. The final features are represented as $\mathbf{h}'' = MLP(\mathbf{h}'|\Theta_{FF})$. In our task, we found that the LSTM-based encoder performs better that the transformer-based encoder (Vaswani et al., 2017; Chen et al., 2018).

Extending a Standard Tagging Model In a typical tagging model, the contextual representation of the encoder $\mathbf{h}''$ is fed into a conditional random field (CRF) layer to predict the BIO-style tags (Collobert et al., 2011; Huang et al., 2015; Ma and Hovy, 2016; Chiu and Nichols, 2016; Lample et al., 2016; Peters et al., 2017; Yang et al., 2017; Changpinyo et al., 2018). Such a model can be extended to predict the relations. For example, in the utterance, "I feel some pain in my back", we could setup the tagger to predict the association between the symptom (*sym/msk*), and its property (*symprop/loc*) using a cross-product space where "my back" is tagged with *sym/msk+symprop/loc* so that the relation prediction problem is reformulated as a standard sequence labeling task. Although this would be a viable option for tasks where the tag set is small (e.g., place, organization, etc.), the cross-product space in our Sx task is unfortunately large (e.g., 186 Sx labels $\times$ 3 Sx property types, and 186 Sx labels $\times$ 3 Sx status types).

4.2 Span Extraction Layer

We propose an alternative formulation that tackles the problem in a hierarchical manner. We first identify the span of interest using ***generic*** tags with BIO notation, namely, (*sym_B*, *sym_I*) for symptoms and (*symprop_B*, *symprop_I*) for their properties, as in Figure 1(a). Likewise, (*med_B*, *med_I*) for medications and (*medsprop_B*, *medsprop_I*) for their properties as shown in Figure 1(b). This corresponds to highlighting, for example, "some pain" and "my back" as spans of interest.

Given the latent representations, $\mathbf{h} = (\boldsymbol{h}''_\mathbf{1}, \cdots, \boldsymbol{h}''_\mathbf{N})$, and the target tag sequence $\mathbf{y}^e = (y_1, \cdots, y_N)$ (e.g., *sym_B, sym_I, O, symprop_B, symprop_I*), we use the negative log-likelihood $-\log P(\mathbf{y}^e|\mathbf{h})$ under CRF as the loss of identifying spans of interest $-S(\mathbf{y}^e, \mathbf{h}) + \log \sum_{\mathbf{y}'} \exp(S(\mathbf{y}', \mathbf{h}))$, where $S(\mathbf{y}, \mathbf{h}) = \sum_{i=0}^{N} \mathbf{A}_{y_i, y_{i+1}} + \sum_{i=0}^{N} P(\mathbf{h}_i, \mathbf{y}_i)$ measures the compatibility between a sequence $\mathbf{y}$ and $\mathbf{h}$. The first component estimates the accumulated cost of transition between two neighboring tags using a learned transition matrix $\mathbf{A}$. $P(\mathbf{h}_i, \mathbf{y}_i)$ is computed via the inner product $\mathbf{h}_i^\top \mathbf{y}_i$ where

y_i belongs to any sequence of tags $\mathbf{y}$ that can be decoded from $\mathbf{h}$. During training, the $\log P(\mathbf{y}^e|\mathbf{h})$ is estimated using forward-backward algorithm and during inference, the most probable sequence is computed using the Viterbi algorithm.

4.3 Attribute Tagging Layer

Using the latent representation of the highlighted span, we can predict one or more ***attributes*** of the span. In Figure 1(a), we can predict two attributes associated with "some pain": *sym/msk* as the symptom label and *symStatus/experienced* as its status. Similarly, in Figure 1(b), the span property span "three months" has the predicted property type *medsprop/duration*. Therefore, by forming semantic abstractions for each highlighted text span, we decompose a single complex tagging task in a large label space into correlated but simpler sub-tasks, which are likely to generalize better when the training data is limited.

Given the spans, either from the inferred or the ground truth sequence $\mathbf{y}^*$, a richer representation of the contexts can be used to predict attributes than otherwise possible. A contextual representation is computed from the starting i and ending j index of each span.

$$\boldsymbol{h}^s_{ij} = \text{Aggregate}(\boldsymbol{h}_k|\boldsymbol{h}_k \in \mathbf{h}, i \leq k < j) \quad (1)$$

where $\text{Aggregate}(\cdot)$ is the pooling function, implemented as mean, sum or attention-weighted sum of the latent states of the input encoder. The kth attributes associated with the span are modeled using $P(y^k_{attr}|\boldsymbol{h}^s_{ij})$. For example, while prediction symptom labels s_x and their associated status s_t, the target attributes are $y^0_{attr} := y^{s_x}$ and $y^1_{attr} := y^{s_t}$. For predicting medication entities r_x and their properties p_r, each span only has one attribute. Since each attribute comes from a pre-defined ontology, the multi-nomial distribution $P(y^k_{attr}|\boldsymbol{h}^s_{ij})$ can be modeled as $\text{Softmax}(\boldsymbol{h}^s_{ij}|\Theta^k)$ for each attribute.

4.4 Memory Buffer Layer

One of the critical components of our model is the memory buffer. Most previous models on joint inference of entities and relations consider all spans of entities and properties. This has the computational complexity of $\mathcal{O}(n^4)$ in the length of the input n, and makes it infeasible for application such as ours where the input could often be 1k words or more. We circumvent this problem using a memory buffer to cache all inferred candidate spans and test their relationship with inferred property spans. Note, unlike methods that cascade two such stages, our model is trained end-to-end jointly with multi-task learning.

The memory buffer saves different entries for symptom and medication tasks, as illustrated in Figure 1. At each occurrence of a symptom (medication) entity span, we push $\boldsymbol{m}^k = \text{Aggregate}(\{\boldsymbol{h}^{\boldsymbol{s}}_{\boldsymbol{ij}}, \boldsymbol{e}^{\boldsymbol{s}}\})$ into the k-th position of the memory buffer. For the symptom task, $\boldsymbol{e}^{\boldsymbol{s}}$ is the learned word embedding of one of the labels in the closed label set. In the medication case, $\boldsymbol{e}^{\boldsymbol{s}}$ is the Aggregate of learned word embedding of the verbatim sub-sequence corresponding to the medication entity.

4.5 Relation Inference Layer

Each span of inferred property in the conversation is compared against each entry in the buffer. A property entity span is represented as $\boldsymbol{y}^p = \text{Aggregate}(\{\boldsymbol{h}^{\boldsymbol{p}}_{\boldsymbol{ij}}, \boldsymbol{e}^p\})$ where $\boldsymbol{e}^p$ is the Aggregate of word embedding corresponding to the span. The multi-nomial likelihood is computed using a bilinear weight matrix $\boldsymbol{W}$. The most likely entry (k) is picked from the memory stack $\boldsymbol{M} = (\boldsymbol{m}^1, ..., \boldsymbol{m}^K)$ by maximizing the likelihood.

$$\begin{aligned} \hat{k} &= \arg\max_k P(k|\boldsymbol{y}^p) \\ &= \arg\max_k \text{Softmax}(\boldsymbol{y}^{p\top}\boldsymbol{W}\boldsymbol{M}) \end{aligned} \quad (2)$$

Remarks The computation cost of inferring relation between a property span and all the entities in the input is proportional to the memory buffer size. On our corpus, for Sx task, the mean and standard deviation per conversation was 22 and 15 respectively, and for Rx task, it was 32 and 23 respectively. Hence, the set of candidate entities considered is substantially smaller than all potential entities $O(n^2)$ in the input sequence.

The small size of the memory buffer also has an impact on rate of learning. In each training step, rather than updating all embedding, we only update a smaller number of embedding, those associated with the entries in the memory buffer. This makes the learning fast and efficient.

4.6 An End-to-end Learning Paradigm

We train the model end-to-end by minimizing the following loss function for each conversation:

$$\begin{aligned}\mathcal{L} = & - \alpha \log P(\mathbf{y}^e|\mathbf{h}) \\ & - \sum_{\{y^k_{attr} \in S\}} \log P(y^i_{attr}|\mathbf{h}) \\ & - \sum_{\{y^j_{pos} \in P\}} \log P(y^j_{pos}|\mathbf{h}) \end{aligned} \quad (3)$$

where $\mathbf{y}^e$ is the target sequence (sym_B, sym_I, $prop_B$, $prop_I$), $\{y^k_{attr}\}$ is the set of attribute labels for each highlighted span, $\{y^j_{pos}\}$ is the list of buffer slot indices and α is a relative weight.

During training, we are simultaneously attempting to detect the location of tags as well as classify the tags. Initially our model for locating the tags is unlikely to be reliable, and so we adopt a curriculum learning paradigm. Specifically, we provide the classification stage the reference location of the tag from the training data with probability p, and the inferred location of the tag with probability $1 - p$. We start the joint multi-task training by setting this probability to 1 and decrease it as training progresses (Bengio et al., 2015).

Since our model consists of span extraction and attribute tagging layers followed by relation extraction, we refer to our model as **Relational Span-Attribute Tagging Model** (R-SAT). One advantage of our model is that the computational complexity of joint inference is $\mathcal{O}(n)$ which is linear in the length of the conversation n. This is substantially cheaper than other previous work on joint relation prediction models where the computational complexity is $\mathcal{O}(N^4)$ (Lee et al., 2017).

5 Knowledge Graph Features

Medical domain knowledge could be helpful in increasing the likelihood of symptoms when related medications is mentioned in a conversation, and vice versa. One such source is a knowledge graph (KG) whose embedding represent a low-dimensional projection that captures structural and semantic information of its nodes. Previous work has demonstrated that KG embedding can improve relation extraction in written domain (Han et al., 2018). We utilize an internally developed KG that contains about 14k medical nodes of 87 different types (e.g., medications, symptoms, treatments, etc.). The nodes are represented by 256 dimension embedding vectors, which were trained

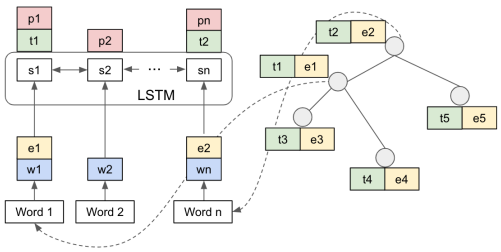


Figure 2: Illustration of how POS (p) features and knowledge graph (KG) are incorporated into our encoder. Dashed lines represent mappings from words (w) to KG nodes, which contain the embedding (e) and the type (t) information.

to minimize word2vec loss function on web documents (Mikolov et al., 2013). A given node may belong to multiple types and this is encoded as a sum of one-hot vectors. The input word sequences were mapped to KG nodes using an internal tool (Brown, 2013). For words that do not map to KG nodes, we use a learnable UNK vector of the same dimension as the KG embedding. In addition, we also represented linguistic information using part-of-speech (POS) tags as one-hot vector. The POS tags were inferred from the input sequence using an internal tool with 47 distinct tags (Andor et al., 2016). In our experiments, we find it most effective to concatenate word embedding with KG entities, and the encoder output with the embedding of POS tags and the KG entity types.

6 Experiments

We describe our corpus, evaluation metrics, the experimental setup, the evaluations of the proposed model and comparison with different baselines on both the symptom and medication tasks.

6.1 Corpus

Given the privacy-sensitive nature of clinical conversations, there aren't any publicly available corpora for this domain. Therefore, we utilize a private corpus consisting of 92K de-identified and manually transcribed audio recordings of clinical conversations, typically about 10 minutes long [IQR: 5-12 minutes] with mostly 2 participants (72.7%). Other participants when present included, for example, nurses and caregivers. The corresponding manual transcripts contained sequences that were on average 208 utterances or 1,459 words in length. We note that due to the casual conversational style of speech, an entity mentioned at the beginning can be related to a property mentioned at the end of the conversation. This

makes the problem of modeling relations much harder than previous work on extracting relations.

A subset of about 2,950 clinical conversations, related to primary care, were annotated by professional medical scribes. The ontology for labeling medication consisted of the type of medications (e.g., medications, supplements) and their properties (e.g., dosage, frequency, duration), and that for symptoms consisted of 186 symptom names and their properties. This resulted in 77K and 99K tags for the medication and symptom tasks, respectively. In all, there were 23k and 16k relationships between medications and symptoms and their properties, respectively. The conversations were divided into training (1,950), development (500) and test (500) sets.

In the case of medications, about 70% of the labels were about medications and the rest about their properties, of which 51% were dosage or quantity, and 40% were frequency. In the case of symptoms, 41% of the labels were about symptom names, another 41% about status, and the rest about properties, of which 39% were about frequency and 37% about body locations.

6.2 Pretraining

Since our labeled data is small, only about 3k, the input encoder of the model was pre-trained over the entire 92k conversations. For pre-training, given a short snippet of conversation, the model was tasked with predicting the next turn, similar to skip-thought (Kiros et al., 2015). Our models were trained using the Adam optimizer (Kingma and Ba, 2015) and the hyperparameters are described in the supplementary material.

6.3 Evaluation Metrics

As described in Section 2, our tasks consist of extracting tuples – (*symType, propType, propContent*) for symptoms task and (*medContent, propType, propContent*) for medications. The precision, recall and F1-scores are computed jointly over all the three elements and the content is treated as a list of tokens for evaluation purposes. To allow for partial content matches, we generalize the calculation of precision and recall such that

$$Precision = \frac{1}{|\mathcal{S}_{\hat{Y}}|} \sum_{i \in \mathcal{S}_{\hat{Y}}} \prod_{j=1}^{3} \mathcal{I}_{\hat{y}_i^j}(\hat{y}_i^j, y_i^j)$$

$$Recall = \frac{1}{|\mathcal{S}_{Y}|} \sum_{i \in \mathcal{S}_{Y}} \prod_{j=1}^{3} \mathcal{I}_{y_i^j}(\hat{y}_i^j, y_i^j)$$

where $\mathcal{S}_{\hat{Y}}$ denotes the set of predictions, $\mathcal{S}_Y$ denotes the set of ground truths, and $\mathcal{I}_{z_i^j}(\hat{x}_i^j, x_i^j) = |\hat{x}_i^j \cap x_i^j| / |z_i^j|$. We note that, as *symType* and *propType* are simply target classes, $\mathcal{I}$ reduces to a simple indicator function. Under the scenario that the content includes single elements, the entire calculation simplifies to the exact matching-based calculation of precision and recall over the set of predictions and ground truths. For the symptom task, we additionally evaluate the performance of predicting *symType* and *symStatus* by performing the exact matching-based calculation.

We illustrate this evaluation metric with an example below: There are two symptoms in the reference and the model extracted one of them. In the extracted symptom, the model correctly identified one out of the two content words. So, we score the precision as $1/1(1 * 1 * (1/1)) = 1$ and recall as $1/2((0 * 0 * 0) + (1 * 1 * (1/2))) = 0.25$.

Prediction: [(sym/sob, prop/severity, [bad])]
Reference: [(sym/unk, prop/location, [arm]),
(sym/sob, prop/severity, [really, bad])]

6.4 Baselines

Symptom Task As a baseline for this task, we train an extension of the standard tagging model, described in Section 4.1. The label space for extracting the relations between symptoms and their properties is *186 symptoms* $\times$ *3 properties*, and for extracting symptoms and their status is *186 symptoms* $\times$ *3 status*. Using the BIO-scheme, that adds up to 2,233 labels in total. The baseline consists of a bidirectional LSTM-encoder followed by two feed-forward layers $[512, 256]$ and then a 2,233 dimension softmax layer. The label space is too large to include a CRF layer. The encoder was pre-trained in the same way as described in Section 6.2, the hyperparameters were selected according to Table 2, and the model parameters were trained using cross-entropy loss.

Medication Task For this task, we adopt a different baseline since the generic medication entity type (e.g., drug name, supplement name) does not provide any useful information unlike the 186 symptom entity labels (e.g., sym/msk/pain). Instead, we adopt the neural co-reference resolution approach which is better suited to this task (Lee et al., 2017). The encoder is the same as the baseline for symptom task and pre-trained in the same manner. Since the BIO labels contain only 9 elements in this case, the encoder output is fed into a CRF layer. Each candidate relation is represented by concatenating the latent states of the head tokens of the medication entity and the property. This representation is augmented with an embedding of the token-distance, which is fed to a softmax layer whose binary output encodes whether they are related or not. Note our R-SAT model does not take the advantage of this distance embedding.

6.5 Parameter Tuning

Table 2 shows the parameters that were selected after evaluating over a range on a development set. In all experiments, the $\mathrm{Aggregate}(\cdot)$ function is implemented as the mean function for its simplicity.

Parameter	Used	Range
Word emb	256	[128 – 512]
LSTM Cell	1024	[256 – 1024]
Enc/dec layers	1	[1 – 3]
Dropout	0.4	[0.0 – 0.5]
L2	1e-4	[1e-5 – 1e-2]
Std of VN	1e-3	[1e-4 – 0.2]
α	0.01	[1e-4 – 0.1]
Learning rate	1e-2	[1e-4 – 1e-1]

Table 2: Hyperparameters of our models for model reproducibility.

6.6 Results & Ablation Analysis

The performance of the proposed R-SAT model was compared with the baseline models, and the results are reported in Table 3.

Symptom Task The model was trained using multi-task learning for both tasks: (*symType, propType, propContent*) as well as (*symType, symStatus*). The performance was evaluated using all the elements of the tuple as described in Section 6.3. The baseline performs better on (*symType, symStatus*) compared to (*symType, propType, propContent*) possibly because there are more instances of the former in the training data than the latter. The R-SAT model performs significantly better than baselines on both tasks.

For understanding the contribution of different components of the model, we performed a series of ablation analysis by removing them one at a time. In extracting relations in *Sx + Property*, the KG embeddings along with POS tags contribute a relative gain of **13%** while the memory buffer brings a relative gain of **8%**. Neither of them impact *Sx + status*, and that is expected for memory buffer since the status is tagged on the same span as the contents of the memory buffer. Multi-task learning brings a relative improvement of **4%** on *Sx + Property*, and this may be because there are fewer instances of this relation in the training data, and jointly learning with *Sx + Status* helps to learn better representations. Note we have not checked other sequences for removing model components (e.g., removing Multi-tasking earlier or KG later).

Medication Task In the Rx case, we only have one task (*Rx + Property*), that is, predicting the relations between medications and their properties, e.g., ([ibuprofen], prop/dosage, [10 mg]). The baseline gives reasonable performance. Ablation analysis reveals that KG and POS features contribute about **4.6%** relative improvement, while the contextual span in memory buffer adds a substantial **43%** relative improvement. Since the medications are from an open set, we cannot run experiments without the buffer. Compared to symptoms task, the model performs better on medication task, and this may be due to lower variability in dosage.

Relation Only Prediction For teasing apart the strength and weakness of the model, we evaluated its performance when the entities and their properties were given, and the model was only required to decide whether a relation exists or not.

As a baseline, we compare our model with a most recently proposed model for document-level joint entity and relation extraction: BRAN, which achieved state-of-art performance for chemical-disease relation (Verga et al., 2018). When this model was originally used to test relations between all pairs of entities and properties in the entire conversation, it performed relatively poorly. Using the implementation released by the authors, the performance of BRAN was then optimized by restricting the distance between the pairs and by fine-tuning the threshold. The best results are re-

Model	Sx + Property	Sx + Status	Rx + Property
Baseline	0.18	0.44	0.35
R-SAT	**0.34**	**0.57**	**0.45**
w/o [KG]	0.30	0.56	0.43
w/o [KG, Context]	0.26	0.55	0.30
w/o [KG, Context, Buffer]	0.24	0.55	n/a
w/o [KG, Context, Buffer, Multi-task]	0.23	n/a	n/a
Human	0.51	0.78	0.52

Table 3: Comparison of the performance of the proposed R-SAT model with baselines and ablation analysis on different components (KG, Context, Buffer, Multi-task) where 'context' is the latent representation of the span $\boldsymbol{h}_{ij}^{s}$ in the memory buffer.

Model	*Sx + Property*	*Rx + Property*
BRAN	0.62	0.41
R-SAT	0.82	0.60

Table 4: Performance of the model when the entities and properties are given and it is only required to predict existence of relations.

ported in Table 4. Our proposed R-SAT model without any such constraints performs better than BRAN on both tasks by an absolute F1-score gain of about 0.20.

Interestingly, the performance of our model on *Sx + Property* jumps from 0.34 in the joint prediction task to 0.82 in the relation only prediction task. This reveals the primary weakness of the Sx model is in tagging the entities and the properties accurately. In contrast, the F1-score for *Rx + Property* is impacted less, and only moves up from 0.45 to 0.6.

The task of inferring whether a relation is present between a medication and its properties is more challenging than in the case of symptoms task. This is not entirely surprising since there is a higher correlation between symptom type and location (e.g., respiratory symptom being associated with nose) and relatively low correlation between dosage and medications (e.g., 400mg could be the dosage for several different medications).

6.7 Analysis

For understanding the inherent difficulty of extracting symptoms and medications and their properties from clinical conversations, we estimated human performance. A set of 500 conversations were annotated by 3 different scribes. We created a "voted" reference and compared the 3 annotations from each of the 3 scribes against them.

The F1-score of scribes were surprisingly low, with 0.51 for *Sx + Property* and 0.78 for *Sx + Status*. The model performance also finds extracting relation in *Sx + Property* to be more difficult than *Sx + Status* task. In summary, the model performance reaches 67% of human performance for *Sx + Property* and 73% for *Sx + Status*. The F1-score of scribes for *Rx + Property* is similar to that of *Sx + Property*. In this case, the model achieves about 85% of human performance. The human errors or inconsistencies in Sx and Rx annotations appear to be largely due to missed labels and not due to inconsistent spans for the same tags, or inconsistent tags for the same span.

While the majority of our relations in the reference annotations occurred within the same sentence, approximately 11.1% of relations occurred across 3 or more sentences. This typically occurred when the symptoms or medications are discussed over multiple dialog turns, as illustrated in Table 1. Among the relations correctly identified by the model, 10.6% were also across 3 or more sentences, which is very similar to the priors on the reference and seem to contain no bias. We notice that in certain cases, the model is able to link a property to an entity that is far away (100+ sentences) when a nearby mention of the same entity was missed by the model. Models that only examine relations in nearby sentences (2-3 sentences) would have missed the relation in such a scenario.

The majority of the errors result from our model missing the property span. Specifically, we see that 35% and 81% of the errors are due to model not detecting medications and symptoms property. For example, when i really have to, every three three months, which are rare mentions in informal language.

Our reference links each property to only one

entity. In certain cases, we notice that the model links the entity to an alternative mention or entity that is equally valid (Advil vs pain killer). So, our performance measure underestimates the actual model performance.

7 Conclusions

We propose a novel model to jointly infer entities and relations. The key components of the model are: a mechanism to highlight the spans of interest, classify them into entities, store the entities of interest in a memory buffer along with the latent representation of the context, and then infer relation between candidate property spans with the entities in the buffer. The components of the model are not tied to any domain. We have demonstrated applications in two different tasks. In the case of symptoms, the entities are categorized into 188 classes, while in the case of medications, the entities are an open set. The model is tailored for tasks where the training data is limited and the label space is large but can be partitioned into subsets. The two stage processing where the candidates are stored in a memory buffer allows us to perform the joint inference at a computational cost of $\mathcal{O}(n)$ in the length of the input n compared to methods that explore all spans of entities and properties at a computational cost of $\mathcal{O}(n^4)$. The model is trained end-to-end. We evaluate the performance on three related tasks, namely, extracting symptoms and their status, relations between symptoms and their properties, and relations between medications and their properties. Our model outperforms the baselines substantially, by about 32-50%. Through ablation analysis, we observe that the memory buffer and the KG features contribute significantly to this performance gain. By comparing human scribes against "voted" reference, we see that the task is inherently difficult, and the models achieve about 67-85% of human performance.

Abstract

Despite great scalability on large data and their ability to understand correlations between topics, spectral topic models have not been widely used due to the absence of reliability in real data and lack of practical implementations. This paper aims to solidify the foundations of spectral topic inference and provide a practical implementation for anchor-based topic modeling. Beginning with vocabulary curation, we scrutinize every single inference step with other viable options. We also evaluate our matrix-based approach against popular alternatives including a tensor-based spectral method as well as probabilistic algorithms. Our quantitative and qualitative experiments demonstrate the power of Rectified Anchor Word algorithm in various real datasets, providing a complete guide to practical correlated topic modeling.

1 Introduction

Increasing access to massive data streams is useful only if it is equipped with proper tools to discover meaningful patterns. Topic models are capable of learning low-dimensional latent structures from groups of discrete observations, while being flexibly applicable to a wide range of modalities without human annotations. Users can assess consumer profiles by collecting purchase habits (Reisenbichler and Reutterer, 2019), shared sentiments or topics among comments in social networks (Nguyen et al., 2015), hidden genres/preferences on movie or music consumption (Lee et al., 2015), and latent communities from network snapshots (Gerlach et al., 2018). For clarity this paper sticks to the standard terms — words, documents, and topics — but the concepts generalize to various applications beyond these examples.

Traditional algorithms for topic modeling lack scalability. To learn quality topics, probabilistic algorithms such as Variational Inference (VI) or Markov Chain Monte Carlo (MCMC) require multiple passes through the input dataset until convergence, and thus struggle to process millions of documents. Online or stochastic algorithms (Hoffman et al., 2010, 2013) achieve some scalability but at the cost of sacrificing the quality of topics. As a result, the basic Latent Dirichlet Allocation (Blei et al., 2003) is still prevalent for practitioners despite various recent advances (Srivastava and Sutton, 2017; Xun et al., 2017; Xu et al., 2018). However, topics are *likely co-occurring terms* in essence. Spectral methods explicitly construct word co-occurrence moments as statistically unbiased estimators, providing alternatives to the probabilistic algorithms via moment-matching. Once the co-occurrence statistics is built with a single trivially parallelizable pass through the corpus, topic inference no longer needs to revisit individual training documents.

The Anchor Word algorithm (Arora et al., 2012, 2013; Lee et al., 2015) and tensor decomposition algorithms (Anandkumar et al., 2012a,b, 2013) factorize the second and third-order co-occurrence between pairs or triples of words, respectively, matching the corresponding posterior moments. In contrast to VI or MCMC, these spectral algorithms do not suffer from spurious local minima or slow mixing problems, learning consistently with provable guarantees under weak assumptions. However, inference is known to be sensitive to statistical noise, and its quality quickly degrades if the input data does not agree well with the underlying models similar to (Kulesza et al., 2014; Marinho, 2015). As a result, these algorithms have not been popular for real applications despite their great scalability.

This paper aims to provide a complete guide to practical correlated topic modeling. We first explain theoretical insights for spectral topic models based on the framework of Joint Stochastic Matrix Factorization (JSMF) (Lee et al., 2015). Then we

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4991–5001, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

introduce scalable implementations of the Rectified Anchor Word (RAW) algorithm and various evaluation metrics, investigating the impact of each inference step from vocabulary curation to topic inference. We also analyze quality of topics learned from annotated non-textual datasets as well as unsupervised textual corpora based on their top contributing words to the individual topics. To the best of our knowledge, this paper is the first comparative study that measures both quantitative and qualitative performance across different spectral topic models and their probabilistic counterparts.

The experimental results show that the rectification step in RAW is crucial for overcoming the *model-data mismatch* (Kulesza et al., 2014) but only needs a few iterations. The learned topics substantially outperform tensor-based methods and online VI, being comparable to expensive MCMC. Running RAW on a non-textual music dataset reveals quality genre topics, whereas the probabilistic correlated model (Blei and Lafferty, 2007) often learns overfitted topics that only maximize the co-occurrence of popular songs. To better support the community, we also provide scalable implementations in MATLAB[1] and Python[2] with full algorithmic details in the supplementary material.

2 Spectral Topic Inference

Topic modeling assumes a document representation that is sufficiently simple to allow tractable inference but also realistic to be useful. Each topic k is defined as a distribution $p_{X|Z}(\cdot|k)$ over words where $p_{X|Z}(i|k)$ is a probability to choose a word i given the topic k. Assuming there are N words in the vocabulary and K prepared topics, all topics can be compactly represented by the column-stochastic matrix $\boldsymbol{B} \in \mathbb{R}^{N\times K}$, where each column vector $\boldsymbol{b}_k \in \Delta^{N-1}$ stands for the topic k. Suppose there are M documents in a corpus which are all written by admixing some of these K topics with respect to a certain prior $\mathfrak{f}$. Then topic models explain that each document m with length n_m is written by: 1) Select a topic composition $\boldsymbol{w}_m \in \Delta^{K-1}$ with respect to $\mathfrak{f}$; 2) Write n_m words by repeatedly selecting a topic z from the composition $\boldsymbol{w}_m$ and a word x from the topic $\boldsymbol{b}_z$.

Different models adopt different priors $\mathfrak{f}$ to better explain proper admixing of topics for the given data. For example, LDA assumes $\mathfrak{f} = \text{Dir}(\boldsymbol{\alpha})$ for $\boldsymbol{\alpha} \in \mathbb{R}^K_+$ (Blei et al., 2003). In correlated topic models, $\mathfrak{f} = \text{Logit-Normal}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ (CTM) or Probit-Normal$(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ for $\boldsymbol{\mu} \in \mathbb{R}^{K-1}$, $\boldsymbol{\Sigma} \in \mathbb{R}^{(K-1)\times(K-1)}$ (Blei and Lafferty, 2007; Yu and Fokoue, 2014). These models differ only in explaining the stochastic generation of topic composition: $\boldsymbol{w}_m \sim \mathfrak{f}$. Note that entries in every column vector $\boldsymbol{b}_k$ of $\boldsymbol{B}$ are parameters to recover in our setting, whereas probabilistic topic models often put another parametric prior $\mathfrak{g}(\boldsymbol{\beta})$ from which each $\boldsymbol{b}_k$ is sampled. The form of $\mathfrak{g}$ is not as crucial in learning quality topics as the form of $\mathfrak{f}$ (Asuncion et al., 2012), and can be similarly incorporated in spectral inference by putting additional regularizers when recovering each $\boldsymbol{b}_k$ (Nguyen et al., 2014).

Let $\boldsymbol{H} \in \mathbb{R}^{N\times M}$ be the word-document matrix where the m-th column vector $\boldsymbol{h}_m$ indicates the observed term-frequencies in document m. Say $\widetilde{\boldsymbol{H}}$ is the column-normalized $\boldsymbol{H}$ where each column is $\boldsymbol{h}_m/n_m$. Topic compositions of individual documents can also be described compactly by another column-stochastic matrix $\boldsymbol{W} \in \mathbb{R}^{K\times M}$ whose m-th column vector is $\boldsymbol{w}_m \in \Delta^{K-1}$. Then the main learning task of topic models is to find the word-topic matrix $\boldsymbol{B}$ and topic-document matrix $\boldsymbol{W}$ that approximates $\widetilde{\boldsymbol{H}} \approx \boldsymbol{B}\boldsymbol{W}$ with the column-stochastic constraints $\boldsymbol{B} \in \mathcal{CS}^{N\times K}$, $\boldsymbol{W} \in \mathcal{CS}^{K\times M}$. While this Non-negative Matrix factorization (NMF) is identifiable under additional sparsity constraints (Huang et al., 2014), directly applying NMF methods (Lee and Seung, 2001) produces incoherent topics despite small approximation errors (Stevens et al., 2012). $\boldsymbol{H}$ is too noisy and sparse to learn quality topics $\boldsymbol{B}$ and plausible compositions $\boldsymbol{W}$.

2.1 Joint Stochastic Matrix Factorization

Instead of directly decomposing $\widetilde{\boldsymbol{H}}$, JSMF decomposes smaller but aggregated statistics for revealing the latent topics and their correlations. Let $\boldsymbol{C} \in \mathbb{R}^{N\times N}$ be the empirical word co-occurrence matrix where $\boldsymbol{C}_{ij}$ is the joint probability $p_{X_1X_2}(i,j)$ to observe a pair of words i and j in the corpus. Define the topic co-occurrence matrix $\boldsymbol{A} \in \mathbb{R}^{K\times K}$ where $\boldsymbol{A}_{kl}$ is the joint probability $p_{Z_1Z_2}(k,l)$ between two latent topics k and l. Then JSMF transforms the topic modeling objective into a second-order NMF: $\boldsymbol{C} \approx \boldsymbol{B}\boldsymbol{A}\boldsymbol{B}^T$, which is algebraically equivalent to $p(X_1, X_2|\boldsymbol{A}; \boldsymbol{B}) = \sum_{z_1}\sum_{z_2} p(X_1|Z_1; \boldsymbol{B})p(Z_1, Z_2|\boldsymbol{A})p(X_2|Z_2; \boldsymbol{B})$. The question is how this formulation provides better hints to learn the latent topics $\boldsymbol{B}$ given $\boldsymbol{C}$.

[1] https://github.com/moontae/jsmf-raw
[2] https://github.com/sc782/pyJSMF-RAW

Define $\boldsymbol{x}_1 \in \mathbb{R}^N$ as a random basis vector where only a single component corresponding to one randomly drawn word from the document m is 1. Let $\boldsymbol{p}_m$ be the vector where its i-th component denotes the probability for word i to occur in the document m. Then $\boldsymbol{p}_m = \boldsymbol{B}\boldsymbol{w}_m \in \mathbb{R}^N$, satisfying

$$\boldsymbol{x}_1 \sim \text{Categorical}(\boldsymbol{p}_m) \Rightarrow \mathbb{E}[\boldsymbol{x}_1|\boldsymbol{w}_m] = \boldsymbol{B}\boldsymbol{w}_m.$$

Denote n_m consecutive random draws of words by $\{\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_{n_m}\}$, and let $\boldsymbol{h}_m = \sum_{t=1}^{n_m} \boldsymbol{x}_t$. Then

$$\boldsymbol{h}_m \sim \text{Mult}(n_m, \boldsymbol{p}_m) \Rightarrow \mathbb{E}[\boldsymbol{h}_m|\boldsymbol{w}_m] = n_m\boldsymbol{B}\boldsymbol{w}_m.$$

As explained earlier, assuming that each observed $\boldsymbol{h}_m$ follows this model does not produce statistically meaningful information toward recovering $\boldsymbol{B}$. Since different words in each document m share the same topic composition $\boldsymbol{w}_m$, however, the *cross moments* can provide useful information about co-occurring words even within a single document: $\mathbb{E}[\boldsymbol{h}_m\boldsymbol{h}_m^T|\boldsymbol{w}_m] = \mathbb{E}[\boldsymbol{h}_m|\boldsymbol{w}_m]\mathbb{E}[\boldsymbol{h}_m|\boldsymbol{w}_m]^T + \text{Cov}(\boldsymbol{h}_m|\boldsymbol{w}_m) = n_m(n_m - 1)\boldsymbol{B}\boldsymbol{w}_m\boldsymbol{w}_m^T\boldsymbol{B}^T + n_m \cdot \text{diag}(\boldsymbol{B}\boldsymbol{w}_m)$. Hence,

$$\frac{\mathbb{E}[\boldsymbol{h}_m\boldsymbol{h}_m^T|\boldsymbol{w}_m] - n_m \cdot \text{diag}(\boldsymbol{B}\boldsymbol{w}_m)}{n_m(n_m-1)} = \boldsymbol{B}\boldsymbol{w}_m\boldsymbol{w}_m^T\boldsymbol{B}^T.$$

Define the co-occurrence $\boldsymbol{C}_m$ for a single document m in terms of the observed $\boldsymbol{h}_m$:

$$\boldsymbol{C}_m = \frac{\boldsymbol{h}_m\boldsymbol{h}_m^T - \text{diag}(\boldsymbol{h}_m)}{n_m(n_m-1)}. \tag{1}$$

If our observation $\boldsymbol{h}_m$ follows the model, then $\mathbb{E}[\boldsymbol{C}_m|\boldsymbol{w}_m] = \boldsymbol{B}\boldsymbol{w}_m\boldsymbol{w}_m\boldsymbol{B}^T$ by linearity of expectation. Then by the Law of Iterated Expectation,

$$\mathbb{E}[\boldsymbol{C}_m] = \mathbb{E}_{\boldsymbol{w}_m}[\mathbb{E}[\boldsymbol{C}_m|\boldsymbol{w}_m]] = \boldsymbol{B}\mathbb{E}_{\boldsymbol{w}_m}[\boldsymbol{w}_m\boldsymbol{w}_m^T]\boldsymbol{B}^T.$$

We can now construct the empirical word co-occurrence by averaging $\boldsymbol{C}_m$ across M documents: $\boldsymbol{C} := \frac{1}{M}\sum_{m=1}^M \boldsymbol{C}_m$. Denoting the posterior topic-topic matrix by $\boldsymbol{A}^* := \frac{1}{M}\boldsymbol{W}\boldsymbol{W}^T \in \mathbb{R}^{K\times K}$, it is proven that $\boldsymbol{A}$ is entry-wisely close to both $\boldsymbol{A}^*$ and the population moments $\mathbb{E}_{\boldsymbol{w}\sim\mathfrak{f}}[\boldsymbol{w}\boldsymbol{w}^T]$ when M is sufficiently large (Arora et al., 2012). Thus

$$\begin{aligned}\boldsymbol{C} \approx \mathbb{E}[\boldsymbol{C}] &= \boldsymbol{B}\big(\frac{1}{M}\sum_{m=1}^M \mathbb{E}_{\boldsymbol{w}_m}[\boldsymbol{w}_m\boldsymbol{w}_m^T]\big)\boldsymbol{B}^T \\ &= \boldsymbol{B}\mathbb{E}_{\boldsymbol{w}\sim\mathfrak{f}}[\boldsymbol{w}\boldsymbol{w}^T]\boldsymbol{B}^T \approx \boldsymbol{B}\boldsymbol{A}^*\boldsymbol{B}^T \approx \boldsymbol{B}\boldsymbol{A}\boldsymbol{B}^T.\end{aligned}$$

Once we construct the empirical moment $\boldsymbol{C}$ from the input data as an unbiased estimator of the underlying generative process, JSMF enables users to recover the correct $\boldsymbol{B}$ and $\boldsymbol{A}$ up to some precision by matching $\boldsymbol{C}$ to its posterior moments $\boldsymbol{B}\boldsymbol{A}^*\boldsymbol{B}^T$. The **separability assumption**: every topic has one specific *anchor word* that occurs only in the context of that topic, allows the model to satisfy non-negative-rank($\boldsymbol{B}$)=rank($\boldsymbol{B}$)=K, guaranteeing the existence of an identifiable factorization.

2.2 Tensor Decomposition

The separability assumption is necessary for JSMF because having only up to the second moments is not sufficient by itself to identify latent topics (Anandkumar et al., 2013). While one can release this assumption by adopting the *sufficiently scattered* condition, it maps the factorization into another NP-hard optimization problem (Huang et al., 2016). Alternatively, one can leverage third-order moments to provide sufficient statistics for identifiable topic inference (Anandkumar et al., 2012a,b). In contrast to JSMF, tensor-based algorithms first specify $\mathfrak{f}$ as a tractable parametric prior like the Dirichlet distribution. For example, if $\mathfrak{f} = \text{Dir}(\boldsymbol{\alpha})$ with $\alpha_0 = \sum_k \alpha_k$, then $\mathbb{E}^{(1st)}_{\boldsymbol{w}\sim\mathfrak{f}(\boldsymbol{\alpha})}[\boldsymbol{w}] = \boldsymbol{\alpha}/\alpha_0$, and

$$\mathbb{E}^{(2nd)}_{\boldsymbol{w}\sim\mathfrak{f}(\boldsymbol{\alpha})}[w_k w_l] = \begin{cases} \frac{\alpha_k(\alpha_k+1)}{\alpha_0(\alpha_0+1)} & (k=l) \\ \frac{\alpha_k\alpha_l}{\alpha_0(\alpha_0+1)} & (k\neq l)\end{cases}. \tag{2}$$

It makes the marginal expectations $\mathbb{E}[\boldsymbol{x}_1]$ and $\mathbb{E}[\boldsymbol{x}_1\boldsymbol{x}_2^T]$ further parametrized by $\boldsymbol{\alpha}$.

$$\begin{aligned}\mathbb{E}[\boldsymbol{x}_1] &= \mathbb{E}_{\boldsymbol{w}_m}[\boldsymbol{x}_1|\boldsymbol{w}_m] = B\mathbb{E}[\boldsymbol{w}_m] = B\boldsymbol{\alpha}/\alpha_0 \\ \mathbb{E}[\boldsymbol{x}_1\boldsymbol{x}_2^T] &= \mathbb{E}_{\boldsymbol{w}_m}[\mathbb{E}[\boldsymbol{x}_1|\boldsymbol{w}_m]\mathbb{E}[\boldsymbol{x}_2|\boldsymbol{w}_m]^T] \\ &= \boldsymbol{B}\mathbb{E}_{\boldsymbol{w}_m}[\boldsymbol{w}_m\boldsymbol{w}_m^T]\boldsymbol{B}^T = \boldsymbol{B}\mathbb{E}^{(2nd)}_{\boldsymbol{w}\sim\mathfrak{f}(\boldsymbol{\alpha})}\boldsymbol{B}^T\end{aligned}$$

Similarly we can represent up to the third moments:

$$\begin{aligned}\mathbb{E}[\boldsymbol{x}_1 \otimes \boldsymbol{x}_2] &= \mathbb{E}^{(2nd)}_{\boldsymbol{w}\sim\mathfrak{f}(\boldsymbol{\alpha})}[\boldsymbol{w}\otimes\boldsymbol{w}](\boldsymbol{B},\boldsymbol{B}), \\ \mathbb{E}[\boldsymbol{x}_1 \otimes \boldsymbol{x}_2 \otimes \boldsymbol{x}_3] &= \mathbb{E}^{(3rd)}_{\boldsymbol{w}\sim\mathfrak{f}(\boldsymbol{\alpha})}[\boldsymbol{w}^{\otimes 3}](\boldsymbol{B},\boldsymbol{B},\boldsymbol{B}).\end{aligned}$$

By assuming $\boldsymbol{w} \sim \text{Dir}(\boldsymbol{\alpha})$, we can fortunately attain closed form expressions of all three population moments only in terms of $\boldsymbol{B}$ and $\boldsymbol{\alpha}$, allowing the non-central second and third moments to be further represented by lower-order moments and α_0 (Anandkumar et al., 2012a). Therefore, once users construct the empirical moments given the training data and choose α_0, tensor decomposition allows us to recover $\boldsymbol{B}$ and $\boldsymbol{\alpha}$ up to some precision by

matching the empirical moments to these population moments.[3] But there are several caveats.

First, finding such closed-form moment combinations is not obvious. Normally all higher-order moments are necessary for learning with the general prior $\mathfrak{f}$ (Arabshahi and Anandkumar, 2017).[4] Second, $\mathbb{E}[\boldsymbol{w}^{\otimes 3}]$ should be a diagonal tensor in order to apply the popular CP-decomposition for learning topics $\boldsymbol{B}$. It means that we need to assume **uncorrelated topics** instead of the separability assumption. Whereas most large topics models are proven indeed separable (Ding et al., 2015), users of CP-decomposition can only capture weak negative correlations via the learned $\boldsymbol{\alpha}$ but depending on the user choices of α_0 and $\mathfrak{f} = \mathrm{Dir}$. Tucker decomposition is another option for learning correlated topics, but it instead requires additional sparsity constraints on $\boldsymbol{B}$, demanding notably more parameters to be estimated (Anandkumar et al., 2013). Overall, correlated topic modeling via tensor decomposition is not as flexible as using JSMF even if we factor out the trivial difference in time and space complexities.

3 The Rectified Anchor Word Algorithm

Whereas probabilistic algorithms have an intrinsic capability to fit their models on the data that does not necessarily follow their generative processes, spectral algorithms are susceptible to model-data mismatch (Kulesza et al., 2014). The Rectified Anchor Word (RAW) algorithm (Lee et al., 2015) is the first working formalism that can learn quality topics and their correlations from real data. The overall algorithm consists of five clearly divided steps: 0) construct the word co-occurrence matrix $\boldsymbol{C}$; 1) rectify $\boldsymbol{C}$; 2) find the set of anchor words $\boldsymbol{S}$; 3) recover the topics $\boldsymbol{B}$; 4) recover the topic correlations $\boldsymbol{A}$. Each step has various algorithmic decisions that have been previously unclear. We carefully explore other viable options, providing details on efficient implementations in the supplementary material.

Step 0: Create $\boldsymbol{C}$. For spectral inference, we first construct the empirical word co-occurrence statistics as an unbiased estimator for the underlying generative process: $\boldsymbol{C} = (1/M)\sum_{m=1}^{M} \boldsymbol{C}_m$ with $\boldsymbol{C}_m$ specified in Equation (1). Due to the efficiency of anchor-based inference, the moment construction often becomes the most expensive step for large corpora, but it is trivially parallelizable as the last averaging step is the only computation that couples individual documents.

Instead of using the entire vocabulary, the standard procedure is to remove stop words and prune off rare words based on either corpus frequencies or tf-idf scores. Excluding words appearing on a majority of documents is also known to improve the quality of topics (Schofield et al., 2017a,b). Measuring the impact of vocabulary curation is not so straightforward in probabilistic topic models due to random draws in their algorithms. In contrast, spectral topic models learn topics consistently without any randomness. We later show how to pick the plausible size of vocabulary in the experiment section.

Step 1: Rectify $\boldsymbol{C}$. Rectifying the co-occurrence estimator is key to successful inference as low-rank spectral learning is highly susceptible to the mismatch between the model and the data (Lee et al., 2015). Though $\boldsymbol{C}$ is shown to be more statistically robust than $\widetilde{\boldsymbol{H}}$ (Arora et al., 2012), its empirical construction from real data hardly exhibits the proper structures of the posterior moments $\boldsymbol{B}\boldsymbol{A}^*\boldsymbol{B}^T$: low-rank ($\mathcal{LR}$), positive semidefinite ($\mathcal{PSD}$), nonnegative ($\mathcal{NN}$), and normalized ($\mathcal{NOR}$).[5] The rectification step transforms the noisy $\boldsymbol{C}$ into a desirable estimator by alternatingly projecting it to individual spaces (Lee et al., 2015). We also discover that cyclic Douglas-Rachford (DR) iterations can properly rectify $\boldsymbol{C}$, but its computational cost is almost twice as expensive as Alternating Projection (AP). Refer to the supplementary material for details.

By running a truncated eigenvalue decomposition, the first step of AP only finds K largest eigenvalues $\boldsymbol{\Lambda}_K$ and the corresponding eigenvectors $\boldsymbol{U}$ at minimal cost. It then projects $\boldsymbol{C}$ to the intersection of $\mathcal{PSD}_N$ and $\mathcal{LR}_K$ by reconstructing $\boldsymbol{U}\boldsymbol{\Lambda}_K^{+}\boldsymbol{U}^T$. The next step orthogonally projects $\boldsymbol{C}$ to $\mathcal{NOR}_N$ by subtracting the mean average entry-wisely from the desired total, 1.0. The negative entries are then zeroed out in the subsequent projection to $\mathcal{NN}_N$. While the order of projec-

[3] JSMF does not ask users to specify α_0, flexibly and transparently modeling arbitrary pairwise correlations between topics by the co-occurrence between pairs of the corresponding anchor words.

[4] They recently discover that having up to third-order moments suffices to perform CP-decomposition when $\mathfrak{f}$ is a class of Normalized Infinitely Divisible (NID) prior.

[5] Due to the diagonal penalty in (1) for the unbiased construction and the variance of the generative process, $\boldsymbol{C}$ is almost always full-rank and indefinite in finite real data.

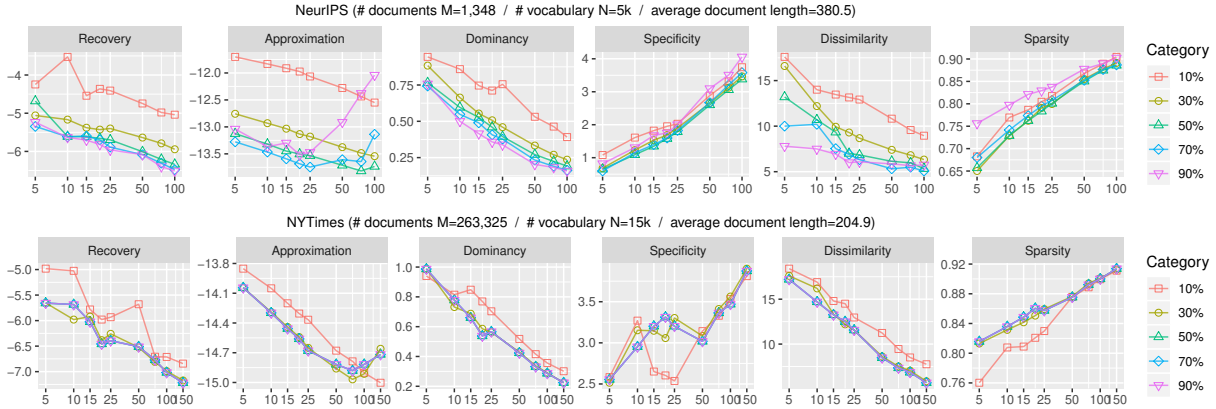

Figure 1: Vocabulary pruning assessed with AP+ADMM. A threshold of 50% implies that all words occurring in more than half of the documents are pruned. X-axis: the number of topics. Columns 1, 2, 3: lower is better / 4, 5, 6: higher is better.

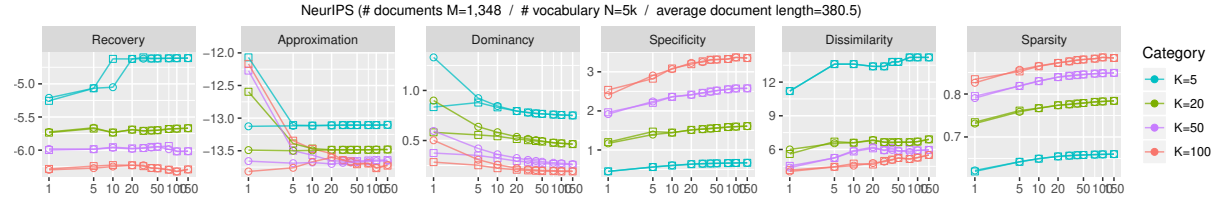

Figure 2: Alternating Projection (AP) vs Douglas-Rachford (DR). X-axis: the number of iterations in rectification. ⊟ AP+ADMM and ⊖ DR+ADMM mostly agree each other and converge within 15-20 iterations. 5 iterations are often enough.

tions in each iteration does not matter, performing a $\mathcal{NOR}_N$-projection after the loop ends helps with feasibility.[6] Note that tensor-based methods have a similar step called *whitening*, which runs a full SVD to transform the third-order moments into an orthogonal tensor for CP-decomposition.

Step 2: Find S. Say $\boldsymbol{C}$ now indicates the rectified co-occurrence. Then the next step is to find the anchor words. Denoting the set of K anchor words by $\boldsymbol{S} = \{s_1, ..., s_K\}$, the separability assumption suggests: $p_{Z_1|X_1}(k'|s_k) = 1$ if $k' = k$ and $p_{Z_1|X_1}(k'|s_k) = 0$ if $k' \neq k$. Let $\overline{\boldsymbol{C}}$ be the row-normalized version of $\boldsymbol{C}$. Then by the conditional independence between a pair of words given one of their topics ($X_1 \perp X_2 | Z_1$ or Z_2) and separability, $\overline{\boldsymbol{C}}_{ij} = p_{X_2|X_1}(j|i) = \sum_{k'} p_{X_2|Z_1}(j|k') p_{Z_1|X_1}(k'|i)$. Thus $\overline{\boldsymbol{C}}_{ij} = \sum_k p_{Z_1|X_1}(k|i) \overline{\boldsymbol{C}}_{s_k,j}$, implying that every row vector of $\overline{\boldsymbol{C}}$ corresponding to a non-anchor word can be represented by a convex combination: $\sum_k p_{Z_1|X_1}(k|i) = 1$ of the rows $\{\overline{\boldsymbol{C}}_{s_k}\}$ corresponding to the anchor words $\{s_k\}$. Therefore, the inference quality depends primarily on the choice of the anchor words S, providing a clear metric for diagnosis. Note that rectification is also crucial for finding better anchors (Lee et al., 2015).

While using the pivoted QR (Arora et al., 2013) substantially expedites the running time against solving a number of LPs (Arora et al., 2012), its explicit projection of each non-anchor row to the current orthogonal complement quickly damages the sparsity of $\overline{\boldsymbol{C}}$. As a result, random projections are suggested for sizable vocabulary (Arora et al., 2013), but such projections do not maintain the joint-stochasticity of the rectified $\boldsymbol{C}$, degrading the topic quality (Lee and Mimno, 2014). Instead, we develop a sparse implicit pivoted QR that requires only $\mathcal{O}(NK)$ space to store the basis rows and performs implicit updates in $\mathcal{O}(nnz(\boldsymbol{C})K)$ time without modifying any entry in the input $\overline{\boldsymbol{C}}$.

Step 3: Recover B. Provided with the set of anchor words S and the convex coefficients $\breve{\boldsymbol{B}}_{ki} = \{p_{Z_1|X_1}(k|i)\}$, one can easily recover $\boldsymbol{B}$ by applying Bayes' rule: $\boldsymbol{B}_{ik} = (\breve{\boldsymbol{B}}_{ki} c_i) / (\sum_{i'=1}^{N} \breve{\boldsymbol{B}}_{ki'} c_{i'})$, where $c_i := p_{X_1}(i)$ is the unigram probability of the word i, which is equal to $\sum_j \boldsymbol{C}_{ij}$. Hence the core of this step is to find the coefficient matrix $\breve{\boldsymbol{B}}$ by solving a Simplex-Constrained Least Squares (SCLS) that satisfy $\overline{\boldsymbol{C}}_{ij} = \sum_k \breve{\boldsymbol{B}}_{ki} \overline{\boldsymbol{C}}_{s_k,j}$ for each i. While the exponentiated gradient algorithm (ExpGrad) used in previous work (Arora et al., 2013; Lee et al., 2015) converges quickly, it is unclear how to tune the learning rate, weakening confidence in the learned topics. We propose another algorithm based on Alternating Direction Method

[6] Avoiding negative entries is useful because RAW is not a purely algebraic algorithm but uses probabilistic conditions.

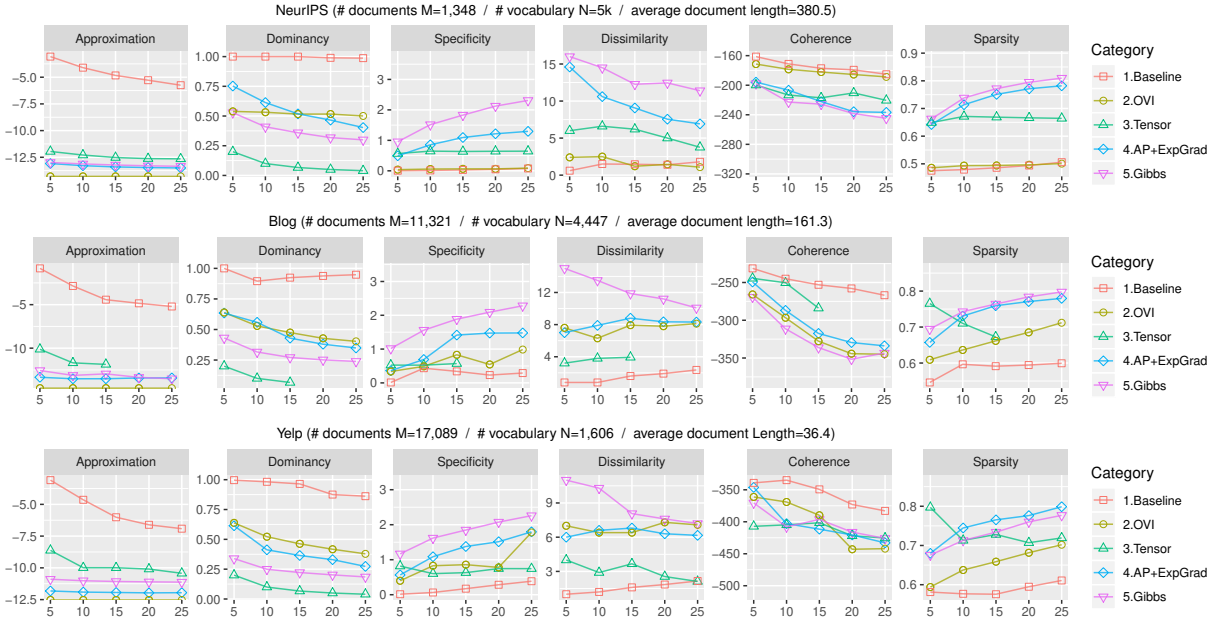

Figure 3: Quantitative results from various methods. Tensor (CP-decomposition (Anandkumar et al., 2012a)) performs better than the Baseline (Anchor Word algorithm with ExpGrad without any rectification (Arora et al., 2013)) and OVI (Online Variational Inference (Hoffman et al., 2010)), but much poorer than the AP+ExpGrad (AP-rectified Anchor Word algorithm (Lee et al., 2015)) and Gibbs (Collapsed Gibbs Sampling (Yao et al., 2009)). Surprisingly the tensor algorithm does not show consistent behavior for increasing number of topics in X-axis. Closer to Gibbs is generally better in Y-axis.

of Multipliers (ADMM), which is not sensitive to different parameter settings. Note that we also provide the Active-Set method that can solve SCLS within machine precision in our implementation, but our practical choice is ADMM due to the much higher cost of running the Active-Set method.

Step 4: Recover $\boldsymbol{A}$. The final step is to recover the topic correlation matrix $\boldsymbol{A}$, which summarizes the latent topic compositions $\boldsymbol{W}$ by $\boldsymbol{A} = (1/M)\boldsymbol{W}\boldsymbol{W}^T$. Instead of learning $\boldsymbol{W}$, Anchor Word algorithms learn the correlations $\boldsymbol{A}$ by again leveraging the separability assumption: $\sum_{l'}\big(\sum_{k'} p_{X_1|Z_1}(s_k|k')p_{Z_1Z_2}(k',l')\big)p_{X_2|Z_2}(s_l|l')$ $= p_{X_1|Z_1}(s_k|k)\big(\sum_{l'} p_{Z_1Z_2}(k,l')p_{X_2|Z_2}(s_l|l')\big)$ $= p_{X_1|Z_1}(s_k|k)p_{Z_1Z_2}(k,l)p_{X_2|Z_2}(s_l|l)$. Thus $p_{Z_1Z_2}(k,l) = p^{-1}_{X_1|Z_1}(s_k|k)p_{X_1X_2}(s_k,s_l)p^{-1}_{X_2|Z_2}(s_l|l)$, which can be simplified to $\boldsymbol{A} = \boldsymbol{B}^{-1}_{S*}\boldsymbol{C}_{SS}\boldsymbol{B}^{-1}_{S*}$. Therefore the co-occurrence of the anchor words s_k and s_l transparently captures the correlation between the pair of topics k and l. Note that the anchor words are generally rare words — in order to be the vertices of an underlying convex hull of the word co-occurrence space — whose co-occurrences are even rarer and noisier. The rectification step in JSMF effectively balances these entries (Lee et al., 2015), thereby realizing robust and transparent correlated topic inference.

4 Experimental Results

We evaluate our models of interest on two standard textual corpora: NeurIPS and NYTimes. Full papers in NeurIPS are generally longer but share a smaller vocabulary (12k), whereas massive news articles in NYTimes have medium length with the largest vocabulary (103k). Due to high complexities of tensor decomposition, we prepare two small textual datasets: Blog and Yelp. They consist of political blogs (Eisenstein et al., 2011) and business reviews (Lee and Mimno, 2014) with the smallest vocabulary (4.4k, 1.6k), respectively. In addition, we adopt two non-textual preference datasets: Movies and Songs. They include 10m movie reviews[7] and music playlists from Yes.com.[8] In contrast to textual datasets, we can retrieve genre information for Movies and Songs.[9] You can find the exact statistics of each dataset in our figures.

Evaluating topic models with held-out likelihoods or perplexities only is often misleading (Passos et al., 2011; Lee and Mimno, 2014). Instead we follow six metrics used on (Lee et al.,

[7]Movies has a vocabulary of 10.7k movies. https://grouplens.org/datasets/movielens/10m/

[8]Songs has a vocabulary of 75.3k songs. http://csinpi.github.io/lme/data_page.html

[9]Genre information are already annotated as tags in these two non-textual datasets. If missing, we scrape the information from IMDB and Discogs.com, respectively.

Our △ AP+ADMM and ◇ AP+ActiveSet algorithms outperform the previous state-of-the-art rectified algorithm ◇ AP+ExpGrad, being more comparable to probabilistic ▽ Gibbs sampling. Columns 1, 2: lower is better / 3, 4, 6: higher is better / 5: closer to Gibbs is better.

2015) for fair and comprehensive evaluations. **Recovery** ($\frac{1}{N}\sum_i \|\overline{\boldsymbol{C}}_i - \sum_k \breve{\boldsymbol{B}}_{ki}\overline{\boldsymbol{C}}_{s_k}\|_2$) evaluates how successfully anchor words reconstruct the word co-occurrence space. **Approximation** ($\|\boldsymbol{C} - \boldsymbol{BAB}^T\|_F$) measures the closeness between the learned factorization and the unbiased co-occurrence statistics. Note that they are measured against *the original* $\boldsymbol{C}$ rather than the rectified one, and are visualized in logarithms of base 1.8 for readability. **Dominancy** ($\frac{1}{K}\sum_k \boldsymbol{A}_{kk}$) is the average self-correlations, indirectly gauging the loss of correlations between different topics. **Specificity** ($\frac{1}{K}\sum_k \mathrm{KL}(\boldsymbol{b}_k||\sum_i \boldsymbol{C}_{*i})$) measures the average KL-distance of each topic from the unigram distribution of the corpus. **Dissimilarity** counts the mean number of top words in each topic that do not belong to the top 20 words of other topics. **Coherence** ($\frac{1}{K}\sum_k \sum_{x_1,x_2\in Top_k}^{x_1\neq x_2} \log\frac{D_2(x_1,x_2)+\epsilon}{D_1(x_2)}$) penalizes any pair of top words in each topic that do not appear together in the training documents.[10] While we report Coherence, the metric could be deceptive if a model learns many duplicated topics whose top words are mostly frequent words (Huang et al., 2016). Thus following the trends of Gibbs generally implies better performance. We newly add **Sparsity** ($\frac{1}{K}\sum_k \frac{\sqrt{N}-(\|\boldsymbol{b}_k\|_1/\|\boldsymbol{b}_k\|_2)}{\sqrt{N}-1}$) (Hoyer, 2004) to gauge the average sparsity of the topics.

[10] $D_2(x_1, x_2)$ means the number of training documents where two words x_1 and x_2 jointly appear. $D_1(x_2)$ counts the number of training documents that include the word x_2.

Vocab pruning: We experiment different document frequency cut-offs. Figure 1 shows that removing all the words that occur more than 10% the documents is too aggressive, thus showing inconsistent behavior as the number of topics grows. In contrast, using 90% cut-off saves too many words. We process vocabulary identically to (Lee et al., 2015) for fair comparison, discarding the words that appear in more than 50% of the documents. The title on top of each figure indicates the size of the pruned vocabulary with the specific statistics.

Quantitative analysis: After constructing $\boldsymbol{C}$ (Step 0), the Baseline method (Arora et al., 2013) skips to finding the anchor words (Step 2) without any rectification. While we use the exponentiated gradient (ExpGrad) method adopted in the previous work (Arora et al., 2013), we do not perform any random projection or pseudo-inverse recovery of $\boldsymbol{A}$ in order to prevent further degradation of learning quality. For methods within the framework of JSMF, we execute 150 iterations of AP or DR rectifications (Step 1) , which is equivalent to (Lee et al., 2015). However, Figure 2 shows that running only 5 iterations of AP or DR sufficiently rectifies $\boldsymbol{C}$, and 15-20 iterations yields almost identical results to 150 iterations.

Whereas our new anchor-finding method (Step 2) only improves the time/space complexity, the method choice for SCLS (Step 3) actually affects

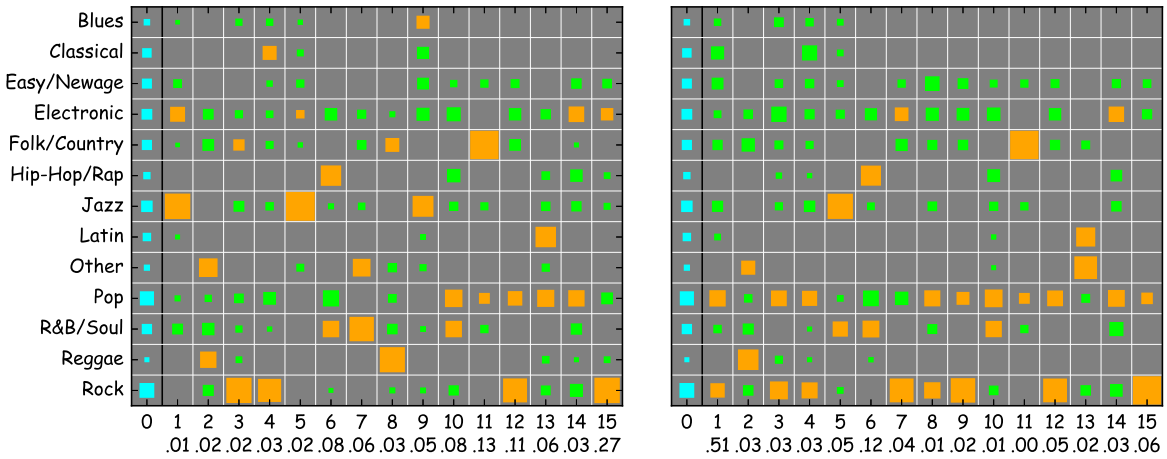

Figure 5: AP+ADMM (left) vs CTM (right). The column 0 shows the genre distribution of the entire corpus. Each column 1-15 stands for k-th topic where two most prominent genres are of orange colors. The size of each box is proportional to the relative intensity. Fractional value below each topic number on the X-axis indicates the marginal probability $p_{z_1}(k)$ of the latent topic k. AP+ADMM learns better topics that capture more coherent information about music genres.

the quality of topics. For ExpGrad, we set the learning rate as 50.0, which is the best-known from (Lee et al., 2015). For our ADMM, we set $\lambda = 1.9$ and $\gamma = 3.0$, but we also find that the algorithm is not at all sensitive to different settings. For probabilistic inference, we adopt a sufficiently mixed collapsed Gibbs Sampling (Gibbs) from the standard Mallet library[11], using 1,000 iterations after discarding the initial 200 burn-in samples. We also run Online Variational Inference (OVI) (Hoffman et al., 2010) in the standard Gensim package. Finally, we run CP-decomposition for the Tensor algorithm.[12]

Figure 3 shows that Tensor decomposition outperforms Baseline and OVI, but evaluation metrics fluctuate as the number of topics increases. We also observe that the topic distribution given a word becomes closer to uniform over growing number of topics. In contrast, AP+ExpGrad exhibits consistent behaviors as expected in spectral inference, being most comparable to Gibbs. Though SCLS (Step 3) is a convex problem, Figure 4 shows that AP+ADMM and AP+ActiveSet improve Specificity and Sparsity over AP+ExpGrad, making the learned topics even more comparable to Gibbs. We choose ADMM as our main optimization method especially because it is not only insensitive to its parameters, but also notably faster than ActiveSet. Users of ExpGrad must search through less intuitive learning rates for optimal performance, which can be different for each dataset.

[11]Gibbs is run on Java Mallet that implements time- and memory-efficient sampling with optimized multicore controls.

[12]https://github.com/FurongHuang/TensorDecomposition4TopicModeling

Qualitative analysis: We first verify the learned topics in the NeurIPS dataset. As given in Figure 6, AP+ADMM and Gibbs learn comparable topics, while the topics learned from OVI and Tensor are not sufficiently separated: OVI repeats 'cell' and 'neuron' in different topics. Similarly, 'neuron' and 'layer' contribute to nearly every topic in Tensor regardless of hidden differences in their themes.

When running Variational CTM (Blei and Lafferty, 2007) with default parameters, the resulting topics do not show distinguishable genre associations. Most topics involve Pop and Rock, emulating the overall genre distribution of the corpus as illustrated in Figure 5. In contrast, our AP+ADMM captures three Jazz topics (T1: Electronic, T5: Pure, T9: Blues style) and four specific Rock topics (T3: Folk Rock, T4: Rock n Roll, T12: Pop style, T15: Alternative Rock). While both models discover Reggae and Latin genres, CTM's associate more with generic Other genres, whereas AP+ADMM's associate more with Folk/Country or Pop.

In addition, CTM puts spuriously high marginal topic probability on T1, which is the topic closest to the corpus genre distribution. While it can highly contribute to maximizing the likelihood of the data, an unseen playlist would most likely be classified as a mixture of Pop and Rock even if it only contains a couple of Pop or Rock songs. This also happens in Movies, explaining why we prefer using various metrics than merely measuring the held-out likelihood or perplexity. Genre association in Movies turns out to be less clear than in Songs. While songs within a playlist are likely to

OVI (Hoffman et al., 2010)	AP+ADMM (This paper)

share a genre-specific theme, people often watch and review recently released movies rather than coherently consume movies within related genres. Thus topics inferred from Movies consist of year-specific topics as well as Fantasy or Sci-Fi.

5 Discussion

Runtime analyses on RAW alongside other methods demonstrate its strong scalability. In our experiment, the tensor algorithm takes 5 hours for learning 5 topics on NeurIPS and 48 days for 25 topics on Yelp. It runs indefinitely for 20-25 topics on Blog, which explains two missing data points in Figure 3. Topic learning with RAW takes less than a minute on these toy datasets and less than an hour on the largest NYTimes when using 15 iterations of AP with ADMM.

Two plots in Figure 6 further verify that RAW with AP+ADMM is approximately 4 times faster than OVI (in addition to learning better topics), and 40 times faster than Gibbs (but showing comparable results across various numbers of topics) on the NYTimes dataset. While OVI runs faster on NeurIPS, the superior quality of topics inferred with RAW far outweighs the additional cost. As running the entire pipeline of RAW takes less than 5 minutes in NeurIPS, OVI is not as competitive as RAW.[13] Lastly, the Variational CTM takes 15 minutes to learn 15 topics on Songs, but 6 hours for 50 topics. In contrast, our RAW method takes less than 10 minutes to find 50 topics on Songs.

[13]Note that slight fluctuations in Figure 6 are due to the load-balancing from the job queue on our high-performance computing cluster. For precision, we draw these two panels by averaging the running times from 10 different trials.

6 Conclusion

By removing the dependency on the training documents, spectral topic modeling provides scalable formalisms for finding compact high-level structures in sparse and discrete data such as text and user-preference. The Rectified Anchor Word (RAW) algorithm enjoys its transparent and consistent behaviors, working seamlessly on various types of textual and non-textual real datasets. In particular, our AP+ADMM algorithm outperforms the previous AP+ExpGrad (Lee et al., 2015), being more comparable to Gibbs sampling and less sensitive to parameters.

Through this paper, we closely investigate each step of inference with various algorithmic decisions. Proper pruning of vocabulary is shown necessary, and rectification is proven crucial for reliable topic inference under the model-data mismatch. Joint Stochastic Matrix Factorization (JSMF) with the rectification better models arbitrary pairwise topic correlations at lower cost than probabilistic correlated topic model and tensor decomposition. We hope that our work, built upon the theoretical insights on spectral inference, provide a complete guide to correlated topic modeling for both researchers and practitioners.

Abstract

Management of collaborative documents can be difficult, given the profusion of edits and comments that multiple authors make during a document's evolution. Reliably modeling the relationship between edits and comments is a crucial step towards helping the user keep track of a document in flux. A number of authoring tasks, such as categorizing and summarizing edits, detecting completed to-dos, and visually rearranging comments could benefit from such a contribution. Thus, in this paper we explore the relationship between comments and edits by defining two novel, related tasks: Comment Ranking and Edit Anchoring. We begin by collecting a dataset with more than half a million comment-edit pairs based on Wikipedia revision histories. We then propose a hierarchical multi-layer deep neural-network to model the relationship between edits and comments. Our architecture tackles both Comment Ranking and Edit Anchoring tasks by encoding specific edit actions such as additions and deletions, while also accounting for document context. In a number of evaluation settings, our experimental results show that our approach outperforms several strong baselines significantly. We are able to achieve a precision@1 of 71.0% and a precision@3 of 94.4% for Comment Ranking, while we achieve 74.4% accuracy on Edit Anchoring.

1 Introduction

Comments are widely used in collaborative document writing as a natural way to suggest and track changes, annotate content and explain the intent of edits. Table 1 shows an example of a comment left by an editor in a Wikipedia revision. The comment explains the intent of adding a missing researcher's name (Sutskever) to a citation.

This example demonstrates that user comments closely relate to the intent of an edit, the actual edit operation, and the content and location in the document that underwent change. However, during collaborative document authoring, the tracking and maintenance of comments becomes increasingly more challenging due to the large number of edits and comments that authors make. For example, structurally refactoring a document can significantly change the order of paragraphs and sentences, stranding comments in confusing and contextually inappropriate locations. Or, comments may have already been addressed but continue to linger in the document without having been marked as completed. These issues, among others, are exacerbated when multiple authors collaborate on a document, often asynchronously. It becomes difficult to know which tasks have been completed and which haven't, especially if authors are not proactive about marking comments as addressed. This situation stands to benefit from an intelligent system capable of marking changes as completed, by understanding the relationship between edits and comments.

Many tasks in document management, such as summarizing and categorizing edits, detecting to-do item completion, prioritizing writing tasks and visually re-arranging document structure to reflect state in multi-author scenarios, require users to understand edit-comment interactions. Consider the scenario where multiple authors make edits to a document using the track-change feature available in popular document authoring apps. The result can be extremely confusing, and it is difficult to disentangle who edited what, over multiple versions. A feature that could summarize these edits, so that the visual burden of tracking changes is not on the UI, would certainly alleviate this problem. Such a system would necessarily first need to learn mappings between edits and natural lan-

[*] The work was done while these authors interned in Microsoft Research.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5002–5011, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

guage comments, before it could learn to generate them. Therefore, automatic solutions to these challenges stand to benefit from an ability to fundamentally model the relationship between edits and comments.

Yet, most existing studies on document revisions focus on modeling the document edits (Bronner and Monz, 2012) or comments (Shaver, 2016) separately; or using comments as a supplementary source of information to study the edits (Yatskar et al., 2010). To the best of our knowledge, no prior work focuses on jointly modeling the relationship between comments and edits.

Thus, in this paper we tackle two novel tasks. **Comment Ranking** considers a document edit operation and seeks to rank a set of candidate comments in order of their relevance to the edit. **Edit Anchoring** seeks to identify the locations in a document that are most likely to have undergone change as the result of a specific comment. Crucially, both tasks require jointly modeling comment-edit relationship.

We start by collecting a dataset of 780K Wikipedia revisions, each with their associated comment and edits. We then build a hierarchical multi-layer deep neural network, a model we call CmntEdit, which is capable of learning the relationship between comments and edits from this data. Our approach addresses both Comment Ranking and Edit Anchoring by sharing many of the model's components and parameters across tasks. Since edits can apply to discontiguous sequences of text, which pose a challenge for sequence modeling approaches, we explore novel ways to represent a document both before and after an edit, while also accounting for contextual information surrounding an edit. To differentiate the context from edit words, we also explore a novel mechanism to encode edit operations such as additions and deletions explicitly in the model. [1]

Finally, we evaluate our model on both tasks and in a number of experimental settings, demonstrating that our solution is significantly better than several strong baselines on jointly capturing the relationship between edits and comments. Our model outperforms the best baseline by 34.6% on NDCG for Comment Ranking and achieves a best score of 0.687 F1 for Edit Anchoring. Additionally, in an ablation study we demonstrate that our various modeling choices, which tackle the inherent challenges of comment-edit understanding, each contribute positively to empirical results.

[1]We are making the code for the CmntEdit model, and generation of our dataset publicly available to the research community at https://github.com/microsoft/WikiCommentEdit.

2 Related Work

Document revisions have been the subject of several studies in recent years (Nunes et al., 2011; Fischer, 2013). Most prior work focuses on modeling document edits only. For instance, Bronner and Monz (2012) build a classifier to distinguish fluency edits from factual edits. Zhu et al. (2017) study the semantic distance between the content in different versions of documents to detect document revisions. Grossman et al. (2013) propose a hierarchical navigation method to display document revision histories.

Some work utilizes comments associated with document edits as supplementary information to study the document revisions. For example, Yatskar et al. (2010) consider both comment and document revision for lexical simplification. However, they use comments as meta-data to identify trusted revisions, rather than directly modeling the relationship between comments and edits. Yang et al. (2017) featurize both comments and revisions to classify edit intent, but without explicitly modeling edit-comment relationship.

Wikipedia revision history data (Nunes et al., 2008) has been used in many NLP tasks (Zesch, 2012; Max and Wisniewski, 2010; Ganter and Strube, 2009). For instance, Yamangil and Nelken (2008) model Wikipedia revision histories for improving sentence compression, Aji et al. (2010) propose a new term weighting model leveraging Wikipedia revision histories, and Zanzotto and Pennacchiotti (2010) expand textual entailment corpora from Wikipedia revision histories using co-training. Again, however, none of these meth-

ods directly consider or model the relationship between comments and edits.

At a basic level, modeling the connection between comments and edits can be seen as a text matching problem, with superficial similarity to other common NLP tasks, such as Question Answering (Seo et al., 2016; Yu et al., 2018), document search (Burges et al., 2005; Nalisnick et al., 2016), and textual entailment (Androutsopoulos and Malakasiotis, 2010), among others. Note however, that edits are a (possibly discontinuous and non-trivial) delta between two versions of a text, making their representation and understanding more challenging than that of a simple string. We demonstrate this in our evaluation in Section 5.2, where we compare against several competing models that were designed for other text matching challenges.

3 Dataset

Our dataset – which we call *WikiCmnt* – is generated from Wikipedia revision histories. In the absence of publicly available document data, Wikipedia is a particularly rich resource: (i) It maintains full revision histories of every Wikipedia page, along with associated editor comments as meta-data. (ii) It is a large-scale instance of multi-author collaboration, with many editors contributing to and maintaining pages.

The specific historical dump we use is from May 1, 2018. It contains approximately 52.7 million pages, and 755.5 million unique revisions made by 300.8 million users. WikiCmnt is a subsample of 786,866 Wikipedia page revisions along with their associated metadata. Revisions are filtered out before sampling, if they violate any one of the following criteria: (i) The length of the comment is longer than 8 words. (ii) The edits made to the Wikipedia page span more than one section[2]. (iii) The Wikipedia page has an edit history containing fewer than 10 unique revisions.

We extract and store a number of data fields from the Wikipedia revision history as summarized in Table 2. For each specific revision of a page, we not only retrieve the text of the comment and edit but also sample 10 non-related comments (*Neg-Cmnts*) and 10 non-related edits (*Neg-Edits*) from the same page's history. Finally we also encode the individual edit operations in both pre-edit and post-edit versions of a text. For example, consider Figure 1, which shows the edit action encoding associated with an change from "chicken wing" to "salmon".

[2] https://en.wikipedia.org/wiki/Help:Section

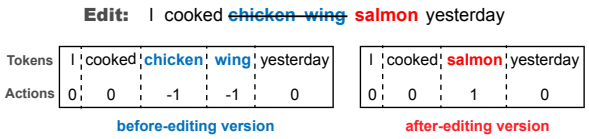

Figure 1: An example of the action encoding associated with changing the phrase "chicken wing" to "salmon". Specifically, the values -1, 1 and 0 are used to represent deletions, additions and unchanged tokens, respectively.

Field	Description
Revision ID	Wiki revision ID
Parent ID	Parent revision ID
Timestamp	Timestamp of revision
Page Title	Title of Wikipedia page
Comment	Revision comment
Neg-Cmnts	Negative sampled comments
Src-Tokens	Tokens of pre-editing document
Src-Actions	Action encoding of pre-editing document
Tgt-Tokens	Tokens of post-editing document
Tgt-Actions	Action encoding of post-editing document
Pos-Edits	Edited sentences in post-editing document
Neg-Edits	Negative sampled sentences in post-editing document

Table 2: Data Fields in *WikiCmnt* Dataset

4 Proposed Model

To model the relationship between edits and comments, we first formulate the problem with respect to the two tasks of Comment Ranking and Edit Anchoring; we then provide details of the neural architecture used to solve these problems; finally we provide some implementation details. We begin with preliminary notation.

Let us define c as a comment consisting of word tokens $\{w_1, ..., w_q\}$. Minimally, let us also define a pre-edit e_s, as the contiguous sequence of words spanning the first to the last edited token (with possibly intervening tokens that are not edited) in a document's *pre-edit version*. The edit e_s may optionally also contain some surrounding context. Formally this can be defined as:

$$\{\underbrace{\mathbf{w}_{i-k}, ...\mathbf{w}_{i-1}}_{\text{context before edit}}, \underbrace{\mathbf{w}_i, ...\mathbf{w}_{i+p}}_{\text{edit words}}, \underbrace{\mathbf{w}_{i+p+1}, ...\mathbf{w}_{i+p+k}}_{\text{context after edit}}\}$$

where i and $i+p$ are the indices of the first and the last edited tokens in a revision, and k is the

context window size. If there is more than one contiguous block of edited tokens, these blocks are concatenated to form the set of edit words with their context words.

We define a document edit as the pair $e = \{e_s, e_t\}$, where e_t is similarly defined over edited tokens and their context words in a document's *post-edit version*.

4.1 Problem Formulation

Comment Ranking is the task of finding the most relevant comment among a list of potential candidates, given a document edit. The inputs of the comment ranking task are some set of user comments $C = \{c_1, c_2, \ldots c_m\}$ pertaining to a document, and an edit $e = \{e_s, e_t\}$ in the same document.The goal of the task is to produce a ranking on C, such that the true comment c_i with respect to the edit $e = \{e_s, e_t\}$ is ranked above all the other comments (i.e. distractors). We use standard ranking metrics to evaluate model performance: Precision@K (P@K), Mean Reciprocal Rank (MRR) and Normalized Discounted Cumulative Gain (NDCG).

Edit Anchoring is the task of finding the sentences in a document that most likely underwent change, given a specific user comment. The inputs to the task are a user comment c and a list of candidate sentences $S = \{s_1, s_2, \ldots s_n\}$ in the post-edit document e_t. Unlike with Comment Ranking, we operate under the assumption that an edit has already been completed, and therefore discard the information from the pre-edit version e_s. In the ground truth, at least one (but possibly more) of the sentences is an edit location for the comment c. The expected output is a list of binary classifications $R = \{r_i\}_{i=1}^{n}$, where $r_i = 1$ indicates that the sentence s_i is a likely edit location, given comment c. We use Accuracy and F1 score to evaluate performance on this task.

4.2 Model Overview

For both tasks, our models are hierarchical deep neural networks with four layers: an input embedding layer, a contextual embedding layer, a comment-edit attention layer, and an output layer. The overall architecture is shown in Figure 2. We describe each of the four layers in what follows. Since both models share many components we will describe the more general case that covers all inputs for Comment Ranking; for Edit Anchoring

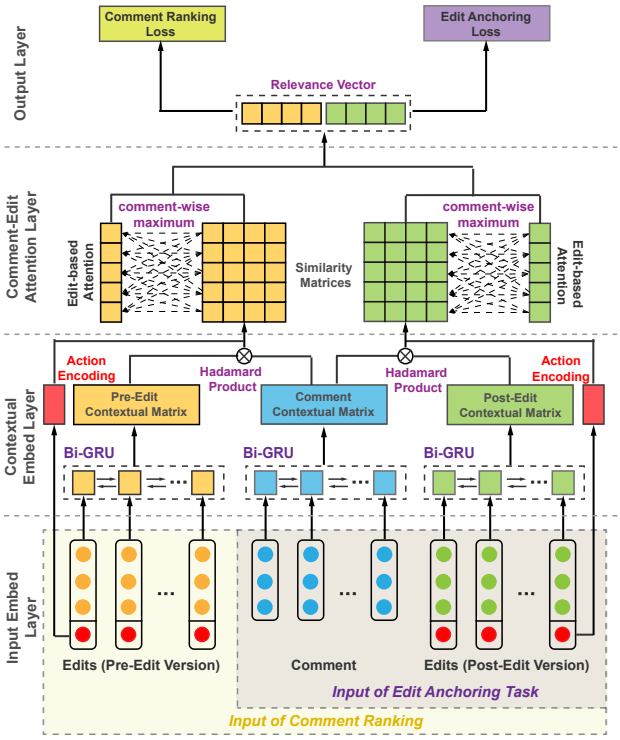

Figure 2: Overall Architecture of Proposed Model

those components that correspond to the pre-edit input are suitably omitted.

Input Embedding Layer. The input embedding layer maps each word in user comments c and edits $e = \{e_s, e_t\}$ to a high-dimensional vector space. The output of the input embedding layer are matrices: $\boldsymbol{U} \in \mathbb{R}^{d \times M}$ representing the pre-edit document, $\boldsymbol{V} \in \mathbb{R}^{d \times M}$ representing the post-edit document, and $\boldsymbol{Q} \in \mathbb{R}^{d \times J}$ representing the comment. Here M is the length of edits and J is the length of the comment, while d is the fixed-length dimension of word vectors.

Contextual Embedding Layer. We use a bi-directional Gated Recurrent Unit (GRU) (Chung et al., 2014) to model the sequential interaction between words. Operating over the output of the previous layer we obtain the contextual embedding matrices $\boldsymbol{U}^c \in \mathbb{R}^{2d \times M}$ and $\boldsymbol{V}^c \in \mathbb{R}^{2d \times M}$ for both pre- and post-edit versions. Also, we obtain $\boldsymbol{Q}^c \in \mathbb{R}^{2d \times J}$ from the comment word vectors. Note that the row dimension of contextual matrices $\boldsymbol{U}^c$, $\boldsymbol{V}^c$ and $\boldsymbol{Q}^c$ are $2d$ because of the concatenation of the GRU's output in both forward and backward directions.

Comment-Edit Attention Layer. Inspired by the attention mechanisms utilized in machine

comprehension (Seo et al., 2016; Yu et al., 2018), the comment-edit attention layer is designed to capture relationships between document edit and comment words. The attention layer maintains and processes both pre- and post-edit documents separately. This is to reduce the information loss that would have occurred if their representations were fused before the attention layer. Additionally, this layer incorporates an action encoding vector, which is designed to reflect the three kinds of edit operations: adding a word, deleting a word, or leaving it unchanged.

The inputs to the layer are the contextual matrices $\boldsymbol{U}^c$ and $\boldsymbol{V}^c$ of the pre- and post-edit documents respectively, the matrix $\boldsymbol{Q}^c$ representing the comment, and the supplemental action encoding vectors $\boldsymbol{a}^\dagger, \boldsymbol{a}^\ddagger \in \mathbb{Z}^M$ which encode the edit operation each token undergoes in the pre- and post-edit documents, respectively. The output is the comment-aware concatenated vector representations of the edit words in both pre- and post-edit documents, $\boldsymbol{h} \in \mathbb{R}^{2J}$.

Internally, we first calculate the shared similarity matrix $\boldsymbol{S}^\dagger \in \mathbb{R}^{M \times J}$ between the comment $\boldsymbol{Q}^c$ and contextual matrix $\boldsymbol{U}^c$ of pre-edit documents, while also accounting for the action encoding vector $\boldsymbol{a}^\dagger$. The elements of this shared similarity matrix are defined as follows:

$$\boldsymbol{S}^\dagger_{ij} = \mathcal{G}(\boldsymbol{U}^c_{:i}, \boldsymbol{Q}^c_{:j}, \boldsymbol{a}^\dagger_i) \tag{1}$$

where $\mathcal{G}$ is a trainable function that generates the similarity between the word-level representations of comments and edits with respect to an edit operation.

Here $\boldsymbol{U}^c_{:i} \in \mathbb{R}^{2d \times 1}$ is the vector representation of the i-th word in the pre-edit document and $\boldsymbol{Q}^c_{:j} \in \mathbb{R}^{2d \times 1}$ is the vector representation of j-th word in the comment. $\boldsymbol{a}^\dagger_i \in \{-1, 0, 1\}$ is the action encoding for the edit operation performed on the i-th word in the pre-edit document. We choose the trainable function $\mathcal{G}(\boldsymbol{u}, \boldsymbol{q}, a) = \boldsymbol{w}^T[\boldsymbol{u} \otimes \boldsymbol{q}; a]$, where $\boldsymbol{w} \in \mathbb{R}^{(2d+1) \times 1}$ is a trainable weight vector, $\otimes$ is the element-wise multiplication operator and $[;]$ represents the vector concatenation across the row dimension. Similarly, we can calculate the shared similarity matrix $\boldsymbol{S}^\ddagger \in \mathbb{R}^{M \times J}$ between the comment and contextual matrix of the post-edit document as $\boldsymbol{S}^\ddagger_{ij} = \mathcal{G}(\boldsymbol{V}^c_{:i}, \boldsymbol{Q}^c_{:j}, \boldsymbol{a}^\ddagger_i)$. Note that the weight vectors in function $\mathcal{G}$ are different for pre- and post-edit versions, and both are trained simultaneously in the model.

After the similarity matrices are computed, we use them to generate the Comment-to-Edit Attention (C2E) weights. C2E is used to represent the relevance of words in the edit to those that appear in the comment. This is critical for modeling the relationship between comments and edits. We obtain the C2E attention weights $\boldsymbol{c}^\dagger \in \mathbb{R}^M$ for edit words in the pre-edit document by taking $\boldsymbol{c}^\dagger = \mathrm{softmax}(\max_{\mathrm{col}}(\boldsymbol{S}^\dagger))$, where the $\max_{\mathrm{col}}(\cdot)$ operator finds the column-wise maximum value from a matrix. Similarly, for the post-edit document, we have $\boldsymbol{c}^\ddagger = \mathrm{softmax}(\max_{\mathrm{col}}(\boldsymbol{S}^\ddagger))$.

Finally we multiply the attention vectors to the previously computed similarity matrices for both pre- and post-edit documents, and concatenate the results to obtain the relevance vector $\boldsymbol{h} \in \mathbb{R}^{2J}$:

$$\boldsymbol{h} = \left[\left(\boldsymbol{c}^\dagger\right)^T \boldsymbol{S}^\dagger \; ; \; \left(\boldsymbol{c}^\ddagger\right)^T \boldsymbol{S}^\ddagger \right]^T \tag{2}$$

The vector $\boldsymbol{h}$ intuitively captures the weighted sum of the relevance of the comment with respect to the edits in both pre- and post-edit documents.

Output Layer and Loss Function. The output layer and loss function of the network is task-specific. Comment Ranking requires ranking the relevance of candidate comments given a document edit. Broadly we obtain a ranked list by computing the relevance score between comments and edits by the output $r = \boldsymbol{\beta}^T \boldsymbol{h}$, where $\boldsymbol{\beta}$ is a trainable weight vector.

A data sample i in Comment Ranking consists of one true comment-edit pair and n_i negative comment-edit distractors. We denote r^+_i as the relevance score of the true pair, and r^-_{ij} as the relevance score of the j-th distractor pair (with $1 \leq j \leq n_i$). The goal of our task is to make $r^+_i > r^-_{ij}$ for all j. We therefore set the loss function to be a pairwise hinge loss between true and distractor relevance scores.

$$\mathcal{L}_c(\Theta) = \sum_{i=1}^{N} \sum_{j=1}^{n_i} \max(0, 1 - r^+_i + r^-_{ij}) \tag{3}$$

where Θ is the set of all trainable weights in the model and N is the number of training samples in the dataset.

For Edit Anchoring, the goal is to predict whether a sentence in the document is likely to be the location of an edit, given a comment. This is a binary classification problem, and we can suitably set the output layer as $p = \mathrm{softmax}(\boldsymbol{\gamma}^T \boldsymbol{h})$ – the

probability of predicting the positive class. Here γ is a trainable weight vector.

Given the binary nature of the classification problem we can use the cross entropy loss:

$$\mathcal{L}_e(\Phi) = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{m_i}\Big[y_{ij}\log p_{ij} + \big(1-y_{ij}\big)\log\big(1-p_{ij}\big)\Big], \tag{4}$$

where Φ is the set of all trainable weights in the model, N is the number of data samples, m_i is the number of sentences in the i-th data sample, p_{ij} is the predicted label of the j-th sentence in the i-th data sample, and y_{ij} is the corresponding ground truth label.

4.3 Implementation Details

The CmntEdit model described in this section is implemented using the Pytorch[3] framework and trained on a single Tesla P100 GPU with 16GB memory. The word vectors are initialized with pre-trained Glove embeddings (Pennington et al., 2014) using the default dimensionality of 100. We set the number of training epochs to 5, the maximum length of a comment to 30 tokens and the maximum length of an edit to 300 tokens. For the Comment Ranking task, we set the batch size to 10 and consider 5 candidate comments in each data sample: one true comment and 4 distractors. We thus have 5 comment-edit pairs for each data sample and 50 pair-wise samples for each training batch. For the Edit Anchoring task, we also set the batch size to 10 and consider 5 candidate sentences, which yields an identical 50 training instances per batch.

It should be noted that while we train our model with only 5 candidate comments or sentences (for Comment Ranking or Edit Anchoring respectively), the models – once trained – can be applied to any number of candidates at test time for either task.

5 Experiment

In this section, we show evaluation results of our model on the previously collected Wikipedia dataset 3. We begin by introducing the experimental settings in Section 5.1. We then compare the performance achieved by the proposed method against several baseline models in Section 5.2. We also conduct an ablation study to evaluate the various components of our model, as well as provide some qualitative results to demonstrate it's effectiveness in practise.

[3] https://pytorch.org/

5.1 Experimental Setup

We begin by introducing the evaluation setting, metrics and baselines we use in our experiments.

5.1.1 Datasets and Labels

We use the *WikiCmnt* dataset described in Section 3 for training and evaluation. The dataset contains 786,886 data samples in total. We reserve 70% of the data for training and split the remainder between 10% for validation and 20% for testing.

For the Comment Ranking task, we always have a single true comment, but in our test we experiment with both 4 and 9 distractors, yielding a total of 5 and 10 candidate comments. Similarly for the Edit Anchoring task, we also test with both 5 and 10 candidate sentences.

5.1.2 Evaluation Metrics

We use common ranking evaluation metrics from the literature to evaluate models on the task of Comment Ranking. These include: (i) **Precision@K**. The proportion of predicted instances where the true comment appears in the ranked top-K result, with $K = 1, 3, 5$. (ii) **Mean Reciprocal Rank (MRR)**. The average multiplicative inverse of the rank of the correct answer, represented mathematically as $\mathrm{MRR} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{\mathrm{rank}_i}$, where N is the number of samples and rank_i is the rank assigned to the true comment by a model. (iii) **Normalized Discounted Cumulative Gain (NDCG)**. the normalized gain of each comment based on its ranking position in the results. We set the relevance score of the true comment to one and those of the distractors to zero.

For the Edit Anchoring task, we use **Accuracy** and **F1 Score** as evaluation metrics. These are computed based on a model's classification of candidate sentences in the post-edit version of the document.

5.1.3 Baseline Methods

For the Comment Ranking task, we compare our approach to the following baselines:
(i) **Cosine-TfIdf** uses the cosine similarity between the TfIdf-weighted vectors of the comment and edit as a measure of relevance. (ii) **Cosine-InferSent** computes the cosine similarity between

	Candidates=5				Candidates=10

Cosine-InferSent	0.228	0.597	0.471	0.600	0.115	0.305	0.497	0.302	0.461
RankNet	0.257	0.658	0.503	0.620	0.034	0.055	0.061	0.139	0.320
LambdaMART	0.310	0.726	0.549	0.661	0.152	0.384	0.593	0.352	0.502
Gated RNN	0.283	0.716	0.531	0.647	0.158	0.411	0.628	0.363	0.511
CmntEdit-MT	0.674	0.930	0.804	0.853	0.529	0.780	0.896	0.680	0.758
CmntEdit-CR	**0.710**	**0.944**	**0.828**	**0.871**	**0.593**	**0.830**	**0.924**	**0.730**	**0.796**

Table 3: Performance on Comment Ranking

comment and edit vectors generated by the state-of-the-art sentence embedding method InferSent (Conneau et al., 2017). (iii) **RankNet** (Burges et al., 2005) minimizes the number of inversions in ranking by optimizing a pair–wise loss function. We use a previous neural network implementation[4] with default settings. (iv) **LambdaMART** (Burges, 2010) leverages gradient boosted decision trees with a cost function derived from LambdaRank (Burges et al., 2007) for solving a ranking task. We use an existing python implementation[5], with a learning rate of 0.02 and 10 max leaf nodes. (v) **Gated Recurrent Neural Network** (Chung et al., 2014) models the sequence of words in comments and edits using pre-trained GloVe vectors as embedding units. Three fully-connected layers compute a final relevance score between comments and edits.

For the Edit Anchoring task, we chose the following popular classifiers as baselines: (i) **Random Forest** (Liaw et al., 2002) (ii) **Adaboost** (Rätsch et al., 2001) (iii) **Passive Aggressive** classifiers (Crammer et al., 2006) (iv) **Gated Recurrent Neural Network**. The features used in these models are based on both TfIdf scores, as well as sentence embedding features generated by InferSent. The Gated RNN model is trained with a task-specific fully connect layer for Edit Anchoring to compute the classification probability.

5.1.4 Model Variants

We train and evaluate several different variants of our neural architecture. They include: (i) **CmntEdit-CR**, a variant of our model only trained with data samples for the Comment Ranking task. (ii) **CmntEdit-EA**, a variant of our model only trained with data samples for the Edit Anchoring task. (iii) **CmntEdit-MT**, a variant of our model jointy trained on data samples of both Comment Ranking and Edit Anchoring tasks. Unless otherwise specified, all models use a standard context window size of 5 tokens[6].

Table 4: Performance on Edit Anchoring

5.2 Experimental Results

We now present and discuss the empirical results of our evaluation on both Comment Ranking and Edit Anchoring.

5.2.1 Comment Ranking

Table 3 summarizes results of the Comment Ranking task. Our models significantly outperform all the baselines in every setting and on all metrics. The results are statistically significant at $p < 0.01$ using the Wilcoxon signed-rank test (Smucker et al., 2007). Since the Comment Ranking task only has one true comment, the other comments being distractors, the P@1 result becomes especially important for practical applications. Our approach achieves 71% precision, which is significantly better than the 31% precision of the best baseline method (LambdaMART) with 5 candidate comments. Our model similarly outperforms the best baseline with 10 candidate comments, ob-

[6] We performed an extensive evaluation of context size with window sizes ranging from 0 to 50. From the result, we found the our model tends to perform best when the context window size is close to 5 tokens.

Comment Ranking	Candidates=5		Candidates=10	
	P@1	MRR	P@1	MRR
w/o Action	0.630	0.778	0.495	0.659
w/o Attention	0.625	0.775	0.488	0.655
w/o Hadamard	0.624	0.774	0.483	0.652
CmntEdit-CR	**0.710**	**0.828**	**0.593**	**0.730**
Edit Anchoring	Candidates=5		Candidates=10	
	Acc	F1	Acc	F1
w/o Action	0.713	0.668	0.684	0.556
w/o Attention	0.723	0.670	0.701	0.562
w/o Hadamard	0.722	0.660	0.706	0.558
CmntEdit-EA	**0.744**	**0.687**	**0.726**	**0.583**

Table 5: Ablation study

taining a P@1 score of 59.3%. Additionally, the higher scores on MRR and NDCG indicate that our approach consistently ranks the true comment higher than the baseline methods.

The performance of CmntEdit-MT is 2% and 5.3% worse than CmntEdit-CR on NDCG and P@1, respectively. Surprisingly, this suggests that training our model in a multi-task fashion leads to slightly lower scores, and a model specifically trained for the individual task of Comment Ranking is to be preferred.

5.2.2 Edit Anchoring

Table 4 shows the results for Edit Anchoring. Our method, CmntEdit-EA, outperforms the best baseline method, Gated-RNN, by 5.5% on F1 and 6.9% on accuracy. The improvements over all the baselines are statistically significant at a p-value of 0.01. The baseline classifiers including Passive-Aggressive, Random Forest and Adaboost have high accuracies, but low F1 scores. This is because of the imbalance between positive and negative samples in our data. Specifically, the number of negative samples is 4 times greater than the number of positive samples when the size of the candidate set is 5 – and even greater when it is 10. Therefore, the baseline classifiers tend to naively predict a negative label, which artificially boosts precision to the detriment of recall. In fact, Adaboost actually outperforms our models on accuracy when the candidate set size is 10, but yields a much lower F1 score.

As with Comment Ranking, the performance of CmntEdit-MT is slightly worse than CmntEdit-EA. Within the scope of our problem space, this reinforces the finding that targeted training seems to work better than joint training.

5.2.3 Ablation Study

To verify the effectiveness of our modeling choices, we evaluate performance in the absence of each of the following model components: 1. **w/o Action**: we remove the action encoding from the trainable function $\mathcal{G}$ and instead simply use $\mathcal{G}(\boldsymbol{u}, \boldsymbol{q}) = \boldsymbol{w}^T[\boldsymbol{u}^T\boldsymbol{q}]$. 2. **w/o Attention**: we remove the edit-based attention from Equation (2). Instead, we generate the relevance vector $\boldsymbol{h}$ as follows: $\boldsymbol{h} = \left[\text{mean}_{\text{col}}(\boldsymbol{S}^{\dagger}); \text{mean}_{\text{col}}(\boldsymbol{S}^{\ddagger})\right]^T$. 3. **w/o Hadamard**: we use the inner product instead of the Hadamard product in the trainable function $\mathcal{G}$ as follows: $\mathcal{G}(\boldsymbol{u}, \boldsymbol{q}, a) = \boldsymbol{w}^T[\boldsymbol{u}^T\boldsymbol{q}; a]$.

Results in Table 5 show that each component improves the overall performance on both Comment Ranking and Edit Anchoring tasks, across our evaluation metrics. This indicates that our modeling choices are particularly suited to tackle the inherent challenges involved in modeling comment-edit relationship.

5.2.4 Qualitative Evaluation

Table 6 provides a few output examples from our model on the Comment Ranking task, demonstrating its ability to learn abstract connections between comments and edits. Due to space constraints, only one illustrative distractor is shown.

The first example shows an edit summarized by the high-level comment "date and capitalization corrections". This comment is correctly assigned the highest relevance score by our model, despite the fact that no words are shared between the comment and edit. Meanwhile, one of the distractors has a lower score even though it shares the lexical item "Walgreens" with the context of the edit.

In the second example an entire sentence is removed by the editor. Again, although no words are shared between the comment and the edit, our model is correctly able to identify the delete operation, possibly by learning the common Wikipedia shorthand for deletions "rm". Meanwhile, one of the distractors contains the phrase "St Helens", which also appears in the edit, but is still assigned a lower score.

6 Conclusion and Future Work

In this paper, we have explored the relationship between comments and edits by defining two novel tasks: Comment Ranking and Editing Anchoring. In order to model the problem we collected a dataset with over 780K comment-edit pairs. Fur-

Case 1: Grammar fixing	
Pre-Edits	In December **of** 2012, **A** judge ordered Walgreens to pay $16.57 million to settle a lawsuit claiming...
Post-Edits	In December 2012, **a** judge ordered Walgreens to pay $16.57 million to settle a lawsuit claiming...
Comment	Date and capitalization corrections [Relevance Score: 4.050]
Distractor	Dane Cook's comments about Walgreens do not belong in "Facts" [Relevance Score: 3.028]
Case 2: Sentence removal	
Pre-Edits	**[http://www.pilkington.co.uk/energikare Pilkington energiKare] - Pilkington product from St Helens helping the environment**...
Post-Edits	(whole sentence removed)
Comment	rm advertising, other link to major employer noted in text seems ok at first glance. [Relevance Score: 5.192]
Distractor	Fixing link to Kevin Brown - You know I never knew he was from St Helens [Relevance Score: 3.479]

Table 6: Example of the edits and comments matched by the proposed model with one more deceptive distractor for each case. The scores for each comment/distractor are presented after the comment/distractor. The addition and removal in edit are highlighted in bold.

ther we proposed a hierarchical multi-layer neural network capable of tackling both our proposed tasks by encoding specific edit actions, such as additions and deletions, as well as document context. In our experiments we show that our approach outperforms several baselines by significant margins on both tasks, yielding a best score of 71% precision@1 for Comment Ranking and 74.4% accuracy for Edit Anchoring.

In future work we plan to explore sequences of revisions through the lifecycle of a document from creation to completion, with the ultimate goal of modeling document evolution. We also hope to apply our modeling approach to practical downstream applications, including: i) detecting completed to-dos based on related edits; ii) localizing the paragraphs that could be edited to address a given comments; iii) summarizing document revisions.

Abstract

Recently, there has been a great interest in the development of small and accurate neural networks that run entirely on devices such as mobile phones, smart watches and IoT. This enables user privacy, consistent user experience and low latency. Although a wide range of applications have been targeted from wake word detection to short text classification, yet there are no on-device networks for long text classification.

We propose a novel projection attention neural network PRADO that combines trainable projections with attention and convolutions. We evaluate our approach on multiple large document text classification tasks. Our results show the effectiveness of the trainable projection model in finding semantically similar phrases and reaching high performance while maintaining compact size. Using this approach, we train tiny neural networks just 200 Kilobytes in size that improve over prior CNN and LSTM models and achieve near state of the art performance on multiple long document classification tasks. We also apply our model for transfer learning, show its robustness and ability to further improve the performance in limited data scenarios.

1 Introduction

One of the fundamental tasks in Natural Language Processing is related to long text classification. Given a document, the goal is to assign one or more categories of interest to the text. This task is of high importance as it has wide applications in spam detection (Jindal and Liu, 2007), product categorization (Kozareva, 2015), sentiment classification (Pang and Lee, 2008) and it also plays an important role for improving document retrieval and ranking (Deerwester et al., 1990).

For a long time, the most successful text classification approaches relied on sparse lexical features such as n-grams, which are later used by linear or kernel models (Joachims, 1998; McCallum and Nigam, 1998; Joulin et al., 2016). However, with the recent advancements in deep learning, various neural network architectures like CNN (Kim, 2014), LSTM (Zhang et al., 2015), hierarchical attention mechanisms (Yang et al., 2016) showed improvement in performance.

Recently, (Ravi and Kozareva, 2018) and (Ravi and Kozareva, 2019) showed the importance of building on-device neural models for short text classification, which preserve user privacy, enable consistent user experience and most importantly perform inference on the device. One of the biggest challenges is how to fit these large and complex neural networks on devices with limited memory and computation capacity while still maintaining high performance. (Ravi and Kozareva, 2018, 2019) developed on-device self-governing neural networks (SGNN) and (SGNN++) based on locality-sensitive projections (Ravi, 2017, 2019). Those methods were evaluated on short text classification tasks such as dialog act and user intent understanding and outperformed prior RNN work (Khanpour et al., 2016; Ortega and Vu, 2017).

In this work, we take one step further by proposing a novel projection attention neural network called PRADO . Unlike SGNN which has static projections, PRADO combines trainable projections with attention and convolutions allowing it to capture long range dependencies and making it a powerful and flexible approach for long text classification. We study the impact of different hyperparameters on accuracy vs model size. We also address the problem of producing compact architectures by develop a quantized version of PRADO . In a series of experimental evaluations on multiple long text classification tasks, we show that our approach PRADO improves over prior baselines and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5012–5021,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

neural networks such as character and word level CNNs and LSTMs. The main contributions of our work are as follows:

- Novel on-device projection attention neural network PRADO which combines transferable projections with attention and convolution for long text classification.
- Exhaustive experimental evaluation on multiple long text classification tasks, outperforming traditional feature engineered linear classifiers and deep learning approaches like CNN and LSTM.
- Quantized PRADO network, which results in tiny 200 Kilobytes in size model that improves over prior CNN and LSTM models.
- Applicability of PRADO for transfer learning, showed its robustness and ability to further improve performance in limited data scenarios.

2 Related Work

Early work on text classification relied on sparse lexical features such as n-grams and linear classifiers (Joachims, 1998; McCallum and Nigam, 1998; Joulin et al., 2016). But with the raise of deep learning, various CNN and LSTM approaches lead to significant improvement in performance and reaching state-of-the-art results. (Kim, 2014) used CNN architecture from computer vision for text classification. (Johnson and Zhang, 2015), used high-dimensional one hot vector and later introduced character-level CNN that achieved even more competitive results. (Tai et al., 2015) used tree structured LSTM for classification, while (Tang et al., 2015) use CNN or LSTM to capture sentence vector followed by bidirectional gated recurrent network which composes the vectors to get a document vector. Recently, (Yang et al., 2016) introduced hierarchical attention neural networks, which captures document representation by incorporating knowledge of the document structure into the model. This approach reaches the best performance on large set of text classification tasks.

The aforementioned prior work mostly focuses on building the best neural network model independent of any model size or memory constrains. However, recent work by (Ravi and Kozareva, 2018, 2019) show the importance of building on-device text classification models that can preserve user privacy, provide consistent user experience and most importantly are compact in size, while yet achieving state-of-art results. Previously, to build lightweight text classification approaches (Ravi, 2013) proposed fast sampling techniques, while (Bui et al., 2018) incorporated deep neural networks with graph learning. While successful, such approaches resulted in large models for response completion (Pang and Ravi, 2012) and Smart Reply (Kannan et al., 2016).

To address the challenge of fitting huge deep neural network on-device, (Ravi and Kozareva, 2018) developed a novel self-governing neural networks (SGNNs) that learns projections on the fly leading to small models. SGNN was applied on short text classification tasks such as dialog act and user intent understanding and showed significant improvement over state-of-the-art RNN (Khanpour et al., 2016) and RNN with attention (Ortega and Vu, 2017) approaches. In this work, we take one step further by developing trainable projection network with attention mechanism that captures long range dependencies making it a powerful and flexible approach for long text classification. In addition, we address the problem of producing compact architectures for text classification when we have limited amount of memory. FastText (Joulin et al., 2016) proposed product quantization to store word embeddings and have carried out evaluation which show models that require two orders of magnitude less memory. We use quantization techniques and show that we achieve 10x to 100x compression rate while still maintaining high performance and improving upon prior CNN and LSTM work. Unlike prior on-device text classification work, we also apply our model in a transfer learning scenario, which demonstrated the robustness of our approach and ability to further improve performance in limited data scenarios. Next, we describe the technical details of our approach, followed by experimental evaluation and results.

3 PRADO: Projection Attention Network

Figure 1 shows the overall architecture of our proposed network PRADO . It consists of a projected embedding layer, a convolutional and attention encoder mechanism and a final classification layer. We describe each component in detail below and contrast them with existing methods.

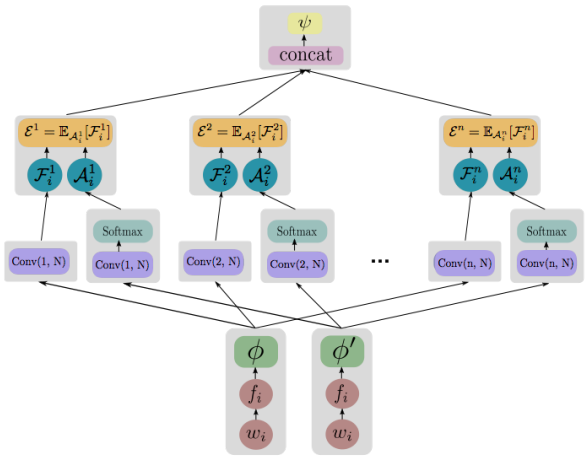

Figure 1: PRADO Model Architecture

3.1 Projected Embedding Layer

Let us assume that the input text has T tokens or words. w_i represents the i-th word, where $i \in \{0, ...T-1\}$. If V is the number of words in the vocabulary, including an out of vocabulary token that represents all missing words, then each word w_i is mapped to $\delta_i \in \mathbb{R}^V$. The first component in most neural networks designed for language tasks uses an embedding layer with trainable parameters $W \in \mathbb{R}^{d \cdot V}$ to map words to fixed length d-dimensional vectors $e_i = W\delta_i$, where $e_i \in \mathbb{R}^d$ are the word vectors that are processed by the rest of the network. A large fraction of the parameters in the network is concentrated in W, since V often has to be large (upto hundreds of thousands or millions of words) to obtain good performance. Furthermore, by choosing V upfront we are assuming that words or phrases relevant for the classification task are known apriori, which may not be true. It should be noted that though we express the operation to obtain the word vector e_i as a matrix multiplication, in reality it is a look-up of the corresponding row in the embedding matrix as δ_i is modeled using the Dirac delta function.

Embeddings via Trainable Projections: Our approach PRADO replaces this embedding with a projection approach to build the word encoder. Instead of mapping w_i to δ_i, we map it to f_i using a projection operator $\mathbb{P}$. Recent work (Ravi, 2017; Ravi and Kozareva, 2018; Ravi, 2019) has shown that projection-based neural approaches can help train compact neural networks that achieve good performance on certain language tasks. These networks learn robust representations (Sankar et al., 2019a) that can be also transferred to other tasks (Sankar et al., 2019b). We follow a similar strategy but unlike the static projections used in these works, we propose a new type of projection that decomposes the operation and makes the projection *trainable*, leading to more powerful encoders capable of capturing contextual information for long-text classification while maintaining a very low memory footprint. Our method does not rely on a fixed vocabulary.

The projection operator we use in this work first fingerprints the words and extracts B bit features from the fingerprint. The word vectors e_i are obtained using a neural network layer $e_i = \phi(f_i)$. This allows us to generate *compact* embeddings, *train the projection encoder* layer better and apply further optimizations like batch normalization (Ioffe and Szegedy, 2015) in this step. First, individual tokens w_i in the input text are fingerprinted using a hashing function to generate $2B$ bits. The projection operator $\mathbb{P}$ then maps every consecutive two-bit sequence to the set $\{-1, 0, 1\}$ resulting in a vector $f_i \in \{-1, 0, 1\}^B$. We chose this specific form since it would enable further optimization such as those described in (Li and Liu, 2016) to reduce the computation in the first layer. We note that there could be alternative modeling choices for the specific form of the projection operator $\mathbb{P}$. Any projection operator that maps bits from the fingerprint to a bounded range is expected to perform equally well. $\phi(.)$ is a trainable function with $B \cdot d$ parameters that maps B-dimensional projection features into d-dimensional word embedding vectors that are computed dynamically during training and inference. In practice, $B \in [128, 512]$ and $d \in [32, 96]$ are tiny compared to V.

3.2 Convolution & Attention over Projections

Next, we introduce an encoder mechanism to map a sequence of projected word embeddings $e_0...e_{T-1}$ to a fixed length vector that represents the entire input text. There are many studies that use 1d convolutions on the word vectors and perform pooling to reduce the sequence to a fixed length vector. But we observe that most words or tokens in a sentence are not relevant for any classification problem, as a result methods like average pooling after convolutions do not effectively reduce the most relevant information needed for the task, especially when the text contains several sen-

tences. Other pooling methods like max or min do not let gradients flow effectively during backpropagation, making it difficult to train the network. To overcome this, we propose a method that uses convolutions and attention mechanism over the word projections and generate a fixed length encoding for the input text.

Projected Attention: In our approach, we use two independent convolutional networks for this step. First one, which we refer to as the *projected feature* network $\mathcal{F}$ captures the features that are useful for the classification task. This is comparable to the convolution networks used in existing studies except we perform convolutions over the sequence of projected word embeddings e_i.

$$\mathcal{F}_i^n = Conv(e_i, n, N) \tag{1}$$

where n is the convolution kernel width, N is the number of output channels in the convolution and $\mathcal{F}_i^n \in \mathbb{R}^N$. The second one, which we refer to as *attention network* $\mathcal{A}$, captures the importance of these features for the task.

$$\mathcal{W}_i^n = Conv(e_i, n, N) \tag{2}$$

We compute softmax over the sequence dimension of the results of $\mathcal{A}$. This provides a distribution over the word sequence that captures the relevance of features at different positions.

$$\mathcal{A}_i^n = \frac{e^{W_i^n}}{\sum_i e^{W_i^n}} \tag{3}$$

We compute an expectation using distribution $\mathcal{A}$ on $\mathcal{F}$ that turns the sequence into a fixed length encoding $\mathcal{E}^n$ for convolution kernel n.

$$\mathcal{E}^n = \sum_i \mathcal{A}_i^n \mathcal{F}_i^n \tag{4}$$

Our pooling scheme reduces to average pooling if the $\mathcal{A}_i^n$ is uniform over the sequence dimension and it becomes max or min pooling if $\mathcal{A}_i^n$ is a Dirac delta in the maximum or minimum value.

3.3 Sequence Convolution Kernels

For the convolution and attention encoder $\mathcal{E}^n$ above, we separately apply n-gram kernels of varying sizes $n = 1, 2, 3, ...$ In addition to n-grams, we used *masked* convolution kernels that simulate the effect of skip-grams. The masking effectively zeros out certain entries in the convolution kernel as shown in Figure 2. Each kernel n generates a corresponding fixed length encoding $\mathcal{E}^n$ of the input sequence.

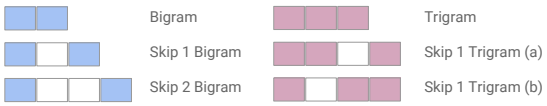

Figure 2: Skip-gram Simulation with Masked Convolution Kernel

3.4 Classification Layer

The convolution kernel width n makes the network react to various word n-grams with a configurable parameter N for each n-gram. We compute various n-gram and skip-gram convolution features and concatenate them to form a fixed length representation for the input document x_k:

$$\text{TextEncoder}(x_k) = \text{concat}(\mathcal{E}^1, \mathcal{E}^2, ...) \tag{5}$$

Finally, we use a feed-forward network with fully-connected layer over the fixed length text encoding for classification.

$$\text{output} = \psi(\text{TextEncoder}(x_k)) \tag{6}$$

We train the network with cross entropy loss and apply softmax over the output layer to obtain predicted probabilities y_k^C for each class C during inference.

4 Experiments & Results

4.1 Data Sets

We evaluate the performance of our approach on large scale document classification tasks, which are widely used in the research community.

- **Yelp** reviews from the Yelp Challenge (Tang et al., 2015) with ratings from 1 to 5.
- **Amazon** reviews from (Zhang et al., 2015) with ratings from 1 to 5.
- **Yahoo Answers** from (Zhang et al., 2015) with documents contain question title, question context and best answer and ten classes such as: Society & Culture; Science & Mathematics; Health; Education & Reference; Computers & Internet; Sports; Business & Finance; Entertainment & Musical; Family & Relationship; Politics & Government;

Table 1 shows the characteristics of each data set. We use the same test sets as (Tang et al., 2015).

Data Sets	#Classes	Training	Test
Yelp	5	650K	50K
Amazon	5	3M	650K
Yahoo Answers	10	1.4M	60K

Table 1: Data Set Characteristics

Parameter	Description
B	Dimension of the projection
d	Dimension of the word embedding computed on the fly
N_1	Number of unigram convolution channels
N_2	Number of bigram convolution channels
N_3	Number of trigram convolution channels
N_4	Number of 4gram convolution channels
N_5	Number of 5gram convolution channels
S_2^1	Number of skip 1 bigram convolution channels
S_2^2	Number of skip 2 bigram convolution channels

Table 2: Hyper Parameters Searched

4.2 Experimental Setting

We setup our experimental evaluation, as follows: given a long text classification task and a data set, we construct a model with the hyper-parameters listed in Table 2 and we use a hyper-parameter search technique to find the optimal model for each data set. In addition to the parameters listed in Table 2, the search method also looks for optimal learning rate schedule and regularization scale. For the purpose of hyper-parameter search, we set aside 8% of the training data and use it as development set. The search method optimizes the *Accuracy* on the development set. Once found, we use the optimal model to evaluate *Accuracy* on the test set.

4.3 Implementation Details

Unlike prior document classification neural networks (Zhang et al., 2015; Tang et al., 2015; Yang et al., 2016) which rely on pre-trained word embeddings, our approach PRADO learns the projection weights on the fly during training (i.e word embeddings (or vocabularies) do not need to be stored). Prior to learning the projections, we did a simple pre-possessing that normalized the text to lowercase, introduced blank space before and after punctuation to make sure they are treated as separate tokens and tokenized the text by space.

We used different regularization scales for the initial fully connected layer and the rest of the network, as the majority of the parameters were in the first layer that computes the word embedding vectors on-the-fly. We used Adam optimizer (Kingma and Ba, 2014) with exponential learning rate schedule. For regularization, we used dropouts after the first layer and also distorted the input text by randomly inserting, deleting and transposing characters in the token with small probability.

4.4 Results and Model Comparisons

It is important to recall that the main goal of our work is to develop fast and efficient on-device neural text classification approach, which can achieve near state-of-the-art performance while satisfying the on-device small size and memory resource constrains. Therefore, it is not fair to directly compare PRADO on-device performance against existing approaches which do inference on cloud without constraints. Yet, we compare our approach against well established baselines and prior non-on-device work taking into consideration these differences. Table 3 shows the obtained results for each data set and method.

Baseline Comparison: We use the same baselines as described in (Zhang et al., 2015; Tang et al., 2015). They are traditional approaches, which rely on hand-crafted features such as bag-of-words with TFIDF and n-grams with TFIDF, and use linear or kernel classifiers. As it can be seen in Table 3, our PRADO approach consistently outperforms all baseline methods with +4.8 to +12.2 for Yelp, +5.9 to +17 for Amazon and +1.3 to +11.8 for Yahoo data sets. This definitely shows the power of the trainable projection on-device neural networks and attention mechanism.

On-device Comparison: We also show comparison against prior on-device neural network approach (Ravi and Kozareva, 2018). Their SGNN approach was targeted towards short text classification tasks and as shown in Table 3, our PRADO model achieves upto +40% improvement over SGNN demonstrating that PRADO is more powerful and suited for long text classification.

Deep Learning Comparison: Similarly, we also compare our PRADO approach against recent neural networks such as LSTM (Zhang et al., 2015), character and word-based CNNs (Zhang et al., 2015; Tang et al., 2015), Convolutional GRNN (Tang et al., 2015) and hierarchical attention (Yang et al., 2016). We compare performance for all data sets against (Tang et al., 2015; Zhang et al., 2015) since their test data sets are exactly the same as ours. However, (Yang et al., 2016) uses different test data sizes for the Yelp and Ya-

Data Set	Yelp	Amazon	Yahoo
PRADO	**64.7**	**61.2**	**72.3**

SVM + Unigrams (Tang et al., 2015)	61.1	-	-
SVM + AverageSG (Tang et al., 2015)	56.8	-	-
SVM + SSWE (Tang et al., 2015)	55.4	-	-
BoW TFIDF (Zhang et al., 2015)	59.9	55.3	71.0
ngrams TFIDF (Zhang et al., 2015)	54.8	52.4	68.5

Table 3: Evaluation Results

hoo Answers evaluation, therefore we do not report their results here. Another interesting aspect is that unlike prior work (Zhang et al., 2015; Tang et al., 2015; Yang et al., 2016) which rely on large word embeddings (with pre-training in many cases), our approach computes dynamically the projection embedding vectors. As shown in Table 3, PRADO significantly outperforms existing neural networks approaches like LSTM, CNN-char and CNN-word with +1.1 up to +6.5% depending on the task and data set, and it achieves comparable results to the hierarchical attention models of (Yang et al., 2016). This is very impressive given that PRADO produces magnitudes smaller and compact neural networks.

4.5 Impact of Hyper-parameters on Performance

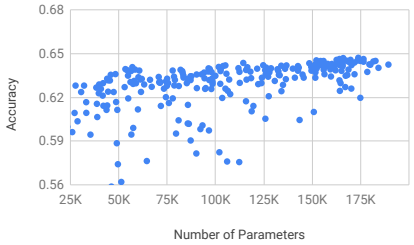

Figure 3 shows *Accuracy* vs Model Size as a result of the different hyper-parameters explored during search. The figure shows results for each data set individually. Overall, PRADO's *Accuracy* improves as the number of parameters increases.

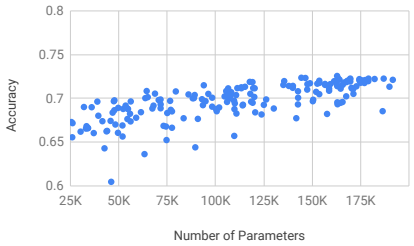
4.6 Model Size: PRADO vs Smaller RNNs



We further compare our PRADO model against smaller-sized variants of widely-used recurrent (LSTM) models. This study helps analyze the effectiveness of PRADO compared to other small neural models and answer the question: *Can popular RNN models be shrunk down to the same size as PRADO and still achieve high performance?* To construct baseline neural models at smaller sizes, we use an LSTM architecture with 64 hidden units as the state size and vary the input vocabulary size (i.e., picking top K words ordered by frequency) and embedding dimensions d. Table 4 compares the performance of PRADO with different small and medium-sized LSTM models (achieved by varying K, d). Our results show that PRADO achieves the best performance with the lowest footprint (just 175K parameters) and high compression ratios (up to 100x smaller) compared to standard LSTM models.

	Compression (PRADO)	#Parameters	Accuracy
LSTM	100x	18.17M	60.4
	43x	7.6M	60.3
	11x	1.9M	60.2
	3x	504.7K	59.9
	1x	179.5K	59.1
PRADO	**1x**	175K	**64.7**

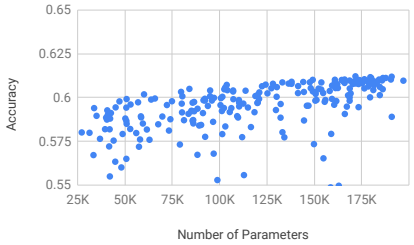


Table 4: Model Size vs. Performance for PRADO and small LSTMs on Yelp. Compression ratio for PRADO is shown wrt corresponding LSTM models.

(b) Yahoo Answers 10

(c) Amazon 5

Figure 3: Model Size (*number of parameters* on x-axis) vs. Performance (*accuracy* on y-axis).

4.7 PRADO Analysis and Discussion

N-gram Attention Focus: To better understand our model, we analyze PRADO's attention distribution. We used a trained PRADO model from a particular data set and computed the attention distribution of the projected n-gram features for all samples in the test set. Then, we pull the word or word sequence index with the maximum attention and order them by frequency of the class. Table 5 shows examples of the bigrams for 5 and 1 star Yelp reviews. Note, that we did not select the vocabulary for the data, the model automatically learned to associate the words with the classes based on the trained projections.

Skipgrams Attention Focus: Similarly, we conduct an analysis for the attention distribution of the skip-1-bigrams channel. Table 5 shows sample of the most frequent entries for the 5 and 1 star Yelp reviews. The model captures and learns basic regular expressions. For instance, the skip gram "*waste * time*" captures " *waste your time*" or "*waste of time*". Similarly "*worst * ever*" captures "*worst food ever*", "*worst service ever*". Our analysis shows that overall our trainable projection with attention and convolution learns embedding representations that are powerful and capture the semantic similarity of words and phrases. This information helps PRADO during classification.

Bigrams	
5 Star	1 Star
highly recommend	*zero stars*
love this	*horrible customer*
hands down	*1 star*
was perfect	*disgusting and*
top notch	*no stars*
amazing service	*better off*
Skip-1-Bigrams	
5 Star	1 Star
*waste * time*	*worst * ever*
*was * reasonable*	*give * stars*
*felt * comfortable*	*a * star*
*is * delicious*	*waste * money*
*you * comfortable*	*horrible * service*
*and * delicious*	*worst * experience*

Table 5: Prado Attention Focus on Yelp Data

5 PRADO Runtime Performance

Our PRADO approach produces compact neural networks with tiny memory footprint. Next, we also show how to further optimize PRADO and help speed up on-device inference during runtime.

5.1 Training with quantization

We train a PRADO model variant with 8-bit quantization as described in (Jacob et al., 2018). This procedure simulates the quantization process during training by nudging the weights and activations towards a grid of discrete levels (2^N levels, where N=8 is the number of bits). We estimate the activation ranges for each training batch and use exponential moving average to smooth the quantization ranges across training steps. (Jacob et al., 2018) noted that by training with quantization, they reached similar accuracy with 8-bit models as floating point ones on several image classification and object detection data sets. For text classification, we observed that training with quantization significantly improves accuracy as shown in Table 3. We believe that this is due to the improved regularization as quantization has the highest impact on Yelp. This dataset has relatively few training samples per class (see Table 1) which causes the model to overfit the training data and regularization provided by the operation that sim-

ulates quantization during training helps it generalize better. Furthermore, the model size of 8-bit quantized PRADO models is equal to the number of parameters. Figure 3 shows that PRADO can reach the performance reported in the Table 3 with model size of less than 200 Kilobytes. PRADO starts getting competitive results on the same data sets with tiny model size as low as 25 Kilobytes.

5.2 Computational Cost for Inference

We evaluate the computational cost of PRADO models for inference wrt *floating point (or integer) operations* and *latency* (in milliseconds). The number of floating point or integer operations in our model is dominated by the below factor

$$Td\left(2B + \sum_{k=1}^{5} kN_k + \sum_{s=1}^{2}(s+2)S_2^s\right) \quad (7)$$

which includes the operations from the first fully connected layer and the convolutional layers. It can be seen that our method scales linearly with the number of time steps T and the dimension of the projected word embedding d. We measured the latency of processing a document with 1000 words using our quantized PRADO model on a Nexus 5x mobile phone to be between 20 to 40 ms.

6 Transfer Learning with PRADO

Recent popularity of several pre-trained word embedding approaches can be primarily attributed to their success and effectiveness at transfer learning for language tasks. Model representations trained on a data-rich domain can be leveraged for tasks and domains in limited-data scenarios. However, as we discussed earlier, these methods require storing and looking up huge pre-trained embedding tables unlike our PRADO approach which results in compact models.

Next, we evaluate the effectiveness of PRADO at learning robust representations and extend it for transfer learning scenarios. To establish a baseline, we took 10% of Yelp training data and trained and evaluated a baseline PRADO model with random initialization of weights. We compared this to initializing the parameters from a PRADO model trained on the larger Amazon data set. We ran two different experiments with this initialization.

- **Experiment A: Full Transfer** We freeze all weights in PRADO except the last fully connected classification layer. With this setup there were around 750 trainable parameters in the model.

- **Experiment B: Projection Transfer** We freeze the weights for only the first (projected embedding) layer and allow the convolution layers and the last classification layer to be trainable.

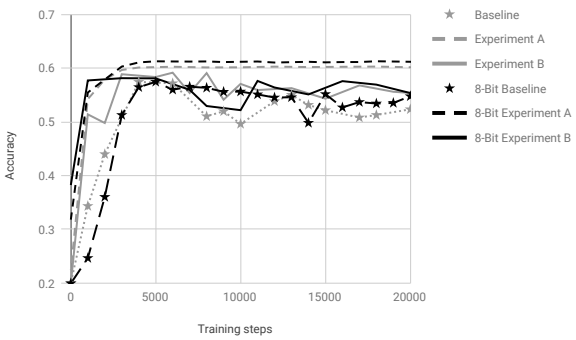

Figure 4: Transfer Learning Results on Yelp Data

We trained the baseline and transfer-learned variants with and without quantization. Figure 4 shows results of the transfer learning runs. We observe that with random initialization, the baseline PRADO model reaches a peak performance of around 57% and starts overfitting on the small Yelp training data set both with and without quantization. When transferring just the *projection layer* and fine-tuning the convolution and classification layers, training converges quickly and it reaches better peak accuracy. This demonstrates that the PRADO projection embeddings trained in one domain, even though tiny in size, captures useful information that can be leveraged to improve classification in another domain with limited training data. This is further improved when transferring the *full* PRADO model and fine-tuning just the last layer. In this case (Experiment A), the model converges to 61% and 60% accuracy with and without quantization respectively. The training also converges quicker than the baseline and it does not overfit anymore. We note that using our approach, a PRADO model transfer-learned on just 10% of training data achieves very competitive performance resulting in less than 10% drop in relative accuracy on Yelp data set (see Table 3).

7 Conclusion

In this paper, we proposed a novel trainable projection on-device neural network with attention,

which is capable of capturing long range dependencies making it flexible for solving long text classification tasks. We introduced trainable projection technique, which via the visualization of the attention mechanism shows that it effectively captures the semantic representation of the document, while still saving on storage and producing compact models. We demonstrated the effectiveness of our approach PRADO by conducting experiments on multiple large scale document classification tasks. The obtained results show that our approach improved upon traditional linear classifiers from 2% to 12%, character and word level CNNs and LSTMs neural approaches with 1% to 6% depending on the data set, task and approach. This is very impressive given the small compact model produced by PRADO . Similarly, the quantized version of our approach had consistent performance. Finally, we applied our model in a transfer learning scenario, which demonstrated the robustness of our approach and ability to further improve performance in limited data scenarios. In the future, we want to extend this approach to more natural language tasks and languages.

Subword Language Model for Query Auto-Completion

Gyuwan Kim
Clova AI, NAVER Corp.
gyuwan.kim@navercorp.com

Abstract

Current neural query auto-completion (QAC) systems rely on character-level language models, but they slow down when queries are long. We present how to utilize subword language models for the fast and accurate generation of query completion candidates. Representing queries with subwords shorten a decoding length significantly. To deal with issues coming from introducing subword language model, we develop a retrace algorithm and a reranking method by approximate marginalization. As a result, our model achieves up to 2.5 times faster while maintaining a similar quality of generated results compared to the character-level baseline. Also, we propose a new evaluation metric, mean recoverable length (MRL), measuring how many upcoming characters the model could complete correctly. It provides more explicit meaning and eliminates the need for prefix length sampling for existing rank-based metrics. Moreover, we performed a comprehensive analysis with ablation study to figure out the importance of each component[1].

1 Introduction

Query auto-completion (QAC) is one of the essential features for search engines. When a user types a query in the search box, QAC systems suggest most likely completion candidates (Cai et al., 2016). It not only saves time for users to enter search terms but also provides new information more than what was initially expected.

Recent neural QAC models in the literature employ character-level language models (Park and Chiba, 2017). It is a natural choice in that QAC systems need to respond whenever a user enters a query as input character-by-character. In addition to the accuracy, speed in terms of latency is also an indispensable prerequisite for practical QAC systems. The generation process is auto-regressive, and the size of the search space is exponential to the sequence length. Long character sequences make prediction slow and inaccurate in the constraints of limited computation. Also, character-level models are prone to errors due to long-range dependency (Sennrich, 2016). Therefore, these limitations arouse to consider alternatives to represent a query in a shorter sequence.

In this paper, we apply a subword language model for query auto-completion. Compared to character language models, subword language models reduce sequence length and the number of decoding steps significantly, thus resulting in much faster decoding. For subword-level modeling, a segmentation algorithm is necessary. Byte pair encoding (BPE) (Sennrich et al., 2015) is widely used, but noise in the data makes segmentation ambiguous and degrades BPE output. To address this issue, as well as BPE, we use subword regularization (SR) algorithm proposed by Kudo (2018) that stochastically samples multiple segmentations by utilizing a unigram language model. To our knowledge, we are the first to apply SR to language modeling.

Interestingly, language models for QAC should take care of the last token that may be incomplete. Like character language models, subword language models can represent incomplete tokens because it can generate any subsequence of sentences, whereas word language models cannot. If we segment prefix as given to encode it using neural networks, the segmentation of prefix may not match with that of ground truth query because the prefix is an incomplete substring of the original desired query. In that case, this enforced segmentation is less likely to appear in training, especially for deterministic segmentation such as BPE. As a result, the model starting from this segmentation

[1]Code is available at https://github.com/clovaai/subword-qac.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5022–5032,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

is unlikely to generate ground truth query. To consider every possible segmentation of target completion, we propose retrace algorithm that is going a few characters back from the end and generating candidates with the restriction that they should match with retraced characters. For the case of SR models, due to the stochasticity of segmentation, we should marginalize over all possible segmentations to calculate the likelihood of a query. For better approximation than just argmax, we perform reranking with approximated marginalization using the output of beam search. Experimental results show that these techniques improve the robustness of the decoding process of the subword language model to achieve close generation quality compared to the character baseline.

We propose a novel metric for query autocompletion evaluation, called mean recoverable length (MRL). This metric remedies shortcomings of common QAC evaluation metrics, mean reciprocal rank (MRR) and partial-matching MRR (PMRR), which require sampling of a prefix length and are favorable to short queries. We conduct comprehensive ablation study and analysis of our models on these three metrics.

2 Related Work

One of the successful traditional QAC approaches is most popular completion (MPC) (Bar-Yossef and Kraus, 2011), which returns the most frequent candidates among all previously observed queries that match the prefix. After extracting candidates, reranking algorithms (e.g., LambdaMART (Burges, 2010)) with additional features are used to align final candidates. These methods cannot generate previously unseen queries by nature. Contrary to traditional approaches based on information retrieval, neural approaches can generalize to unseen prefixes.

Choosing an appropriate granularity level for text segmentation has been long studied over the variety of natural language processing problems. It can be a character, subword, word, phrase, sentence, and even paragraph. A trade-off between them exists, and the best performing granularity often varies depending on tasks and datasets. Character models are widely used to address natural language processing tasks including text classification (Kim, 2014; Zhang et al., 2015; Conneau et al., 2016), language modeling (Hwang and Sung, 2017; Al-Rfou et al., 2018), machine translation (Chung et al., 2016; Lee et al., 2017), etc.

Currently, neural machine translation systems widely use subword segmentation as *de facto*. Mikolov et al. (2012) observed that a subword language model is advantageous in that it achieves better performance compared to character-level models with zero out-of-vocabulary rate and smaller model size. BERT (Devlin et al., 2018) uses a subword as the unit token for their (masked) language models.

Word-level segmentation can easily shorten sequence length compared to character-level. However, word-level models require larger vocabulary size and the number of parameters to learn. Also, it causes data sparsity issue. Because the vocabulary of words is usually fixed before training, it cannot generate out-of-vocabulary words by itself. Search systems are especially in an open vocabulary setting. For word-level models, it is hard to deal with the last incomplete token because it may not be in the vocabulary, unlike character-level naturally handle it. Even if the vocabulary contains this token, the decoding process may be somewhat different from expected.

Word-character hybrid models were proposed to overcome the out-of-vocabulary problem (Luong and Manning, 2016; Wu et al., 2016). A word-level decoder generates a word sequence, and when it generates a special <UNK> token, a character-level decoder generates a character sequence on top of it. These two decoders are connected hierarchically. Word models assume whitespace as the boundary of words. In some languages including Japanese and Chinese, segmentation of sentences into words is unknown in advance and sometimes vague. Moreover, input queries usually include much noise such as typos, grammatical errors and spacing errors. The problems mentioned above hinder word-level processing for QAC.

Park and Chiba (2017) and Fiorini and Lu (2018) incorporate word information by concatenating its embedding with character embedding only at the word boundary and use a special <INC> token embedding for non-boundary positions. This mechanism is inefficient in that the word signal is sparse. Most of the word-character hybrid models focus on input representation rather than generation. Usually, their representations are concatenated, or composition functions are learned (Kim et al., 2016; Miyamoto and Cho,

2016). Even though they use word information to the input, the decoding process of their models is still in the character-level.

We can interpret generating a subword which is a concatenation of characters as parallel decoding of characters (Stern et al., 2018). In this sense, non-autoregressive neural machine translation (Gu et al., 2017; Lee et al., 2018) is related to our work. They also aim to improve decoding speed with minimal performance degradation. Our model and decoding method can be used for non-autoregressive NMT in place of a character-level decoder, and in the opposite direction, we can apply their approaches to QAC vice versa.

3 Subword Language Model

Let Σ be the set of all possible characters and V be the vocabulary of tokens. Each token is a character or a concatenation of characters, and it is a subword in our case. A language model estimates the probability of a token sequence $\mathbf{t}$ where the probability distribution of token t_i at each step i is conditioned on the previous tokens $t_{<i}$:

$$p(\mathbf{t};\theta) = \prod_{i=1}^{|\mathbf{t}|} p(t_i|t_{<i};\theta)$$

where $t_i \in V$ and θ is a set of model parameters. For a token sequence $\mathbf{t}$, we can map it to a query $\mathbf{q} = concat(\mathbf{t})(= t_1 \oplus t_2 \oplus \cdots \oplus t_{|\mathbf{t}|})$ by concatenating itself sequentially. Then, the probability of a given query $\mathbf{q}$ is the sum of the probability over the set of all possible segmentation $\mathbf{t}$, $S(\mathbf{q}) = \{\mathbf{t} : concat(\mathbf{t}) = \mathbf{q}\}$:

$$p(\mathbf{q};\theta) = \sum_{\mathbf{t}\in S(\mathbf{q})} p(\mathbf{t};\theta).$$

Similar to (Chan et al., 2016), segmentation $\mathbf{t}$ can be interpretable as a latent decomposition of the query $\mathbf{q}$.

3.1 Segmentation

In character-level language modeling, token vocabulary V is equal to Σ, and segmentation is performed by merely splitting every character. We exclude word-level language modeling which splits a sentence by whitespace from consideration due to its limitations mentioned in Section 2.

In the case of subword language modeling, we use two widely used segmentation algorithms: (1) byte pair encoding (BPE) and (2) subword regularization (SR). Formally, a segmentation algorithm defines a probability distribution over a token sequence $\mathbf{t}$ conditioned on given query $\mathbf{q}$: $p_{seg}(\mathbf{t}|\mathbf{q})$.

The BPE algorithm is deterministic because it segments greedily from left to right. On the other hand, SR can sample multiple segmentations stochastically. The number of possible segmentations is exponentially large. It is hard to calculate the likelihood of a given sentence using dynamic programming because even with the same prefix, hidden states vary upon different previous tokenization. Marginalization over all possible segmentations of very long sequences is intractable. In sum, we compare character-level and subword-level (BPE, SR) language modeling.

3.2 Training

We can derive an unbiased gradient estimator of the log-likelihood of a query by using Bayes' theorem and the identity of $\nabla_\theta f(x;\theta) = f(x;\theta)\nabla_\theta \log f(x;\theta)$ assuming $f(x;\theta) \neq 0$ for all x (Williams, 1992):

$$\nabla_\theta \log p(\mathbf{q};\theta) = \mathop{\mathbb{E}}_{\mathbf{t}\sim p(\mathbf{t}|\mathbf{q};\theta)} \nabla_\theta \log p(\mathbf{t};\theta).$$

However, since sampling $\mathbf{t}$ from $p(\mathbf{t}|\mathbf{q};\theta)$ is computationally expensive, we heuristically use $p_{seg}(\mathbf{t}|\mathbf{q})$ instead. Regardless of the language model parameters θ, segmentation model p_{seg} is learned before the language model training and can be used to sample $\mathbf{t}$ easily. The better way to approximate the distribution $p(\mathbf{t}|\mathbf{q};\theta)$ will be explored in the future.

Our training objective becomes equivalent to maximizing the average log-likelihood of the segmentation of sentences:

$$\begin{aligned} L(\theta) &= \frac{1}{|Q|}\sum_{\mathbf{q}\in Q} \log p(\mathbf{t};\theta) \\ &= \frac{1}{|Q|}\sum_{\mathbf{q}\in Q}\sum_{i} \log p(t_i|t_{<i};\theta), \end{aligned}$$

where Q is the training set of all queries, and $\mathbf{t}$ is the segmentation of a query $\mathbf{q}$ sampled from $p_{seg}(\mathbf{t}|\mathbf{q})$ which depends on the segmentation algorithm. This objective is equal to the average negative log-likelihood of sentences if and only if the segmentation is deterministic. The gradients of the loss function are computed using the back-propagation through time (BPTT) (Rumelhart et al., 1986).

4 Decoding

Given prefix $\mathbf{p}$, let the set of its completions be $Q_+(\mathbf{p})$ and the set of their tokenizations be $S_+(\mathbf{p}) = \{\mathbf{t} : concat(\mathbf{t}) \in Q_+(\mathbf{p})\}$. We want to find the most likely completion $\hat{\mathbf{q}}$:

$$\begin{aligned}\hat{\mathbf{q}} &= \underset{\mathbf{q}}{\operatorname{argmax}} \log p(\mathbf{q}|\mathbf{p}) \\ &= \underset{\mathbf{q}\in Q_+(\mathbf{p})}{\operatorname{argmax}} \log p(\mathbf{q}) \\ &= \underset{\mathbf{q}\in Q_+(\mathbf{p})}{\operatorname{argmax}} \log \sum_{\mathbf{t}\in S(\mathbf{q})} p(\mathbf{t}) \end{aligned} \quad (1)$$

however, this is obviously intractable to search in the infinitely large token sequence space. We approximate this by decoding for the best token sequence $\hat{\mathbf{t}}$ and then returning its corresponding query $\tilde{\mathbf{q}}$ by concatenating its token sequentially:

$$\begin{aligned}\hat{\mathbf{t}} &= \underset{\mathbf{t}\in S_+(\mathbf{p})}{\operatorname{argmax}} \log p(\mathbf{t}) \\ \tilde{\mathbf{q}} &= concat(\hat{\mathbf{t}})\end{aligned}$$

Basic practice is segmenting $\mathbf{p}$, feeding it into language model to encode $\mathbf{p}$, and using it for the decoding. Since finding $\hat{\mathbf{t}}$ is also intractable, beam search decoding is used but only results in suboptimal predictions. We will improve this incrementally with techniques following.

4.1 Retrace Algorithm

There is no guarantee that the end of given prefix matches the tokenization boundary of the completed query. To address this possibility of the incompleteness at the end of a prefix, we can retrace a few characters and generate from there. For the case (call it R_r) where the last token that overlaps with the prefix finishes r characters before the end of the prefix, first starting from a token sequence of $\mathbf{p}_{1:|\mathbf{p}|-r}$, we can perform beam search decoding on the restriction that the next token should cover the remaining part of the prefix and the next new character. Figure 1 illustrates this algorithm.

This process is unnecessary for a character-level model since every token is a single character. On the other hand, the retrace algorithm is helpful for subword models, especially BPE models which have deterministic segmentation algorithm.

We can limit the maximum step of retrace by L to only consider R_r where $0 \leq r \leq L$ because of the computational issue. We will denote this limitation as R^L. R^0 is the usual case without the retrace algorithm, and R^∞ counts every possible retrace steps.

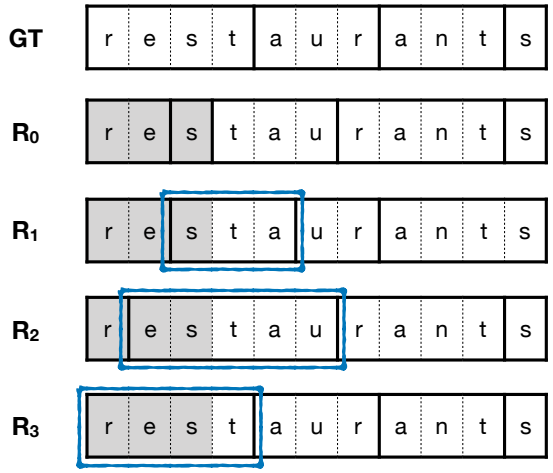

Figure 1: Illustration of retrace algorithm with the example of "restaurants." The gray area means given prefix ("res") of the query. The solid line indicates the boundary of the segmentation. GT is the segmentation of ground truth query. Possible examples of the generated sequence of tokens belonging to the case R_r are visualized. Blue boxes indicate a fixed segmentation with retrace algorithm at the end of the prefix.

4.2 Reranking Method by Approximate Marginalization

QAC system has to suggest N completion candidates sorted in order of likelihood rather than finding only the best completion candidate. We can extract a set of top $B(\geq N)$ candidates using beam search with beam size B, namely $T_B = \{\mathbf{t}^1, \cdots, \mathbf{t}^B\}$ in the descending order of likelihood. In the case of deterministic segmentation, $\mathbf{q}^i = concat(\mathbf{t}^i)$ are mutually different. i.e. $|Q_B| = B$ for $Q_B = \{\mathbf{q}^1, \cdots, \mathbf{q}^B\}$. Then, trivially our prediction would be $(\mathbf{q}^1, \cdots, \mathbf{q}^N)$.

On the other hand, in the case of stochastic segmentation, same query $\mathbf{q}^i, \mathbf{q}^j (i \neq j)$ with different token sequence $\mathbf{t}^i, \mathbf{t}^j$ may exist. The obvious way is merely removing duplicates.

On the assumption that $\log p(\mathbf{t}) \gg \log p(\mathbf{t}')$ for all $\mathbf{t} \in T_B$ and $\mathbf{t}' \notin T_B$, Equation (1) implies that marginalization over the final beam outputs can provide better approximation:

$$\begin{aligned}\hat{\mathbf{q}} &\approx \underset{\mathbf{q}\in Q_+(\mathbf{p})}{\operatorname{argmax}} \log \sum_{\mathbf{t}\in T_B} p(\mathbf{t}) \\ &= \underset{\mathbf{q}\in Q_B}{\operatorname{argmax}} \log \sum_{\mathbf{t}\in T_B} p(\mathbf{t})\end{aligned}$$

In other words, reranking after summing out the probability of duplicates can give better ordered list of candidates.

5 Evaluation Metric

5.1 MRR and PMRR

One of the most standard QAC evaluation metrics is the mean reciprocal rank (MRR). The MRR for the QAC system m is calculated with test dataset Q_{test} as follows:

$$MRR(m) = \frac{1}{|Q_{test}|} \sum_{\mathbf{q} \in Q_{test}} \mathrm{RR}(\mathbf{q}, m(\mathbf{p})),$$

where $\mathbf{p}$ is a prefix of a query $\mathbf{q}$ and $m(\mathbf{p})$ is the ranked list of candidate completions of $\mathbf{p}$ from m. RR is reciprocal rank of $\mathbf{q}$ if $\mathbf{q}$ is in $m(\mathbf{p})$, otherwise 0.

Since it is hard to get a pair of the desired query and its prefix in a real situation, we should synthetically select a prefix by cutting off a given query for the evaluation. Common practice is to uniformly sample from all possible prefixes within minimal length constraint in characters (or words) However, real distribution of the prefix length may differ to the uniform distribution. For example, users tend to engage with QAC at the position close to the boundary of words, and after typing half of query characters (Mitra et al., 2014). Due to the stochastic characteristic of prefix sampling processes or their difference among distinct QAC systems, evaluation results are inconsistent even with the same test dataset. To prevent this problem, a sampling function should be concretely specified.

Park and Chiba (2017) introduced a new metric, partial-matching MRR (PMRR):

$$PMRR(m) = \frac{1}{|Q_{test}|} \sum_{\mathbf{q} \in Q_{test}} \mathrm{PRR}(\mathbf{q}, m(\mathbf{p})),$$

where partial-matching reciprocal rank PRR is the reciprocal of the index of the first candidate such that the original query is the same as it or starts with it plus whitespace. If there is no such candidate, PRR equals to 0.

PMRR also requires sampling of the prefix length. PMRR values are often omitted in the literature because of the similar tendency to MRR. In other words, PMRR does not give much additional information about the quality of the generated results.

5.2 Recoverable Length

To avoid the synthetic sampling process and length dependency, we propose a new evaluation metric for query auto-completion, namely mean recoverable length (MRL). We define recoverable length RL as the number of characters right before the first position where candidates do not have the query. When all characters of a query are known, we can readily suggest itself. If we delete chars from right to left one-by-one, the ground truth query will disappear in the list of candidate completions. For example, if $\mathbf{q} \in m(\mathbf{q}_{1:|\mathbf{q}|-l})$ for $l = 1, 2, 3$ but not 4, recoverable length of this query with respect to the QAC system m is 3. MRL is mean of recoverable length:

$$MRL(m) = \frac{1}{|Q_{test}|} \sum_{\mathbf{q} \in Q_{test}} \mathrm{RL}_m(\mathbf{q})$$

MRL is a useful metric for additive QAC which suggests one word at a time instead of a whole-query completion (Vargas et al., 2016) in that it measures how many characters the system can predict correctly at once. MRL does not care about the order of candidates and check whether they contain the target query or not. Lastly, it eliminates the need to choose a prefix length in the test data.

6 Experiments

6.1 Data

We use the public AOL query log dataset (Pass et al., 2006) for the experiments. We split data based on time. Among three months of the entire span, we use last one week as test data and one week right before the test data as validation data. It is close to a real scenario where future queries are unseen during the training.

We perform Unicode NFKC normalization and remove non-ASCII characters. For simplicity, we change uppercase alphabets to lowercase. After normalization and changing to lowercase, only 43 unique characters including special symbols `<BOS>`, `<EOS>` and `<UNK>` remain. We substituted multiple adjacent spaces to a single one and removed leading or trailing spaces. We merged duplicates which appear adjacently by the same user and the same query. Queries of a length shorter than three characters are filtered out.

In total, the training, validation, test data contain 17,521,031, 1,521,971, and 1,317,632 queries, respectively. Among the test data, 670,810 queries are seen, and 646,822 queries are unseen in the training data. Almost half of the test data are unseen.

Model	MRR			PMRR			MRL			Execution Speed (QPS)		Decode Length
	Seen	Unseen	All	Seen	Unseen	All	Seen	Unseen	All	CPU	GPU

Table 1: Results of completion generation. We group MPC, character language model baseline, and two subword language models separately. +R implies the retrace algorithm. +M implies reranking with approximate marginalization. QPS stands for query per seconds. The higher the QPS, the better. The best results for each column related to accuracy are shown in **bold** for each segmentation algorithm (BPE and SR). SR model shows higher unseen PMRR scores (underlined). Our models are faster than the character baseline.

6.2 Implementation Details

The language model used in the experiments consists of an input layer, a single LSTM layer, a projection layer, and an output layer. For the LSTM layer, following Melis et al. (2017) and Jaech and Ostendorf (2018), we apply layer normalization (Ba et al., 2016) to each gate and couple input and forget gates. We tie input and output embeddings for better generalization (Press and Wolf, 2016; Inan et al., 2016). We set the LSTM hidden size to 600 and the input embedding size to 100.

We train three individual language models: namely Char, BPE, SR. The only difference among models is how to segment a given sentence into tokens. We believe that increasing model size (number of LSTM layers, input size, and hidden size) would improve the performance. Also, the best set of a combination may differ depending on models. However, we use the same model size for the character baseline and our variants for the fairness since our goal is proposing a new method and comparing between baseline and ours rather than achieving the best performance with the restriction of having a similar number of parameters.

We use the off-the-shelf SentencePiece (Kudo and Richardson, 2018) library for vocabulary learning and segmentation of the vocabulary size 256 using BPE, SR algorithms. For the subword regularization, we use sampling parameters $l = \infty$, $\alpha = 0.2$ for the training. We choose this value by the generation accuracy on the validation data. Increase of model size and computation due to larger vocabulary size are not substantial. By setting a manageable amount of vocabulary size, we can balance performance and computational cost.

For the computational efficiency, we truncated queries in the training data to a length of 40. Only less than 3% of queries in the training data are longer than 40 characters. We train models for thirty epochs by the Adam (Kingma and Ba, 2014) optimizer with a learning rate 5e-3 and batch size 1024. Following Smith (2018), we use a large learning rate and batch size. We use recurrent dropout (Semeniuta et al., 2016) with probability of 0.25 for regularization. The best model is chosen using validation data.

Using QAC models, we generate $N = 10$ completion candidates using beam search decoding of a beam width $B = 30$.

For the SR models, the segmentation of $\mathbf{p}$ (or retraced $\mathbf{p}_{1:|\mathbf{p}|-r}$) is not deterministic and generated completions may differ depending on its segmented token sequences with their different encoded representation. By following (Kudo, 2018), we can find the most likely segmentation sequence $\mathbf{t}$ starting from all of the n-best segmentations $\tilde{\mathbf{t}}_1, \cdots, \tilde{\mathbf{t}}_n$ of $S(\mathbf{p})$ rather than from only $\tilde{\mathbf{t}}_1$. However, we observe that this n-best decoding performs worse than one-best decoding. One possi-

ble reason is that segmentations which are not the best have a smaller probability as itself and so less likely to appear in training and less competitive in the process of beam search. For this reason, we set n to 1.

We used a trie (Fredkin, 1960) data structure to implement most popular completion baseline.

All experiments were performed on NAVER Smart Machine Learning (NSML) platform (Sung et al., 2017; Kim et al., 2018).

6.3 Decoding Results

We performed comprehensive experiments to analyze the performance of query auto-completion. Table 1 shows the generation result of MPC, the character baseline, and our model variants. For BPE models, we varied the maximum retrace step to 0 (without retrace algorithm), 1, 2, and ∞ (no limitation on retracing step size). For SR models, we compare decoding results without any techniques, with marginalization only, with retrace algorithm only, and with both.

MPC is a very fast and remarkably strong baseline. It is worse than language models in the overall score (MRR, PMRR, and MRL), but better for previously seen queries. However, it is unable to predict unseen queries. Even with efficient data structures, MPC requires huge memory to keep statistics of all previous queries. As a practical view, combining frequency-based traditional method and neural language model approach can boost the accuracy and meet trade-off between the performance and computational costs.

MRRs and PMRRs of our best methods are close to that of the character model with less than 0.02 point drop. Notably, the SR model has better generalization ability in that their PMRR for unseen queries is higher than that of the character model. In a real scenario, it is more critical because unseen queries come in increasingly as time goes by.

We measure execution time with Tesla P40 GPU and Xeon CPU. Subword-level models are up to 2.5 times faster than the character baseline with minimal loss in performance both in CPU and GPU. Decoding length which is maximum suffix length until beam search ends correlates with the number of floating-point operations. Subword models significantly reduce the decoding length from the character baseline more than two times shorter by generating multiple characters at once.

re		**nat**	
Char	SR	Char	SR
realtor.com	recipes	national city bank	national bank
recipes	rentals	nationalcity.com	national city
real estate	real estate	national city	nationwide
remax	restaurants	national geographic	national parks
realtor	resources	national car rental	national park

Table 2: Examples of top 5 candidates of completions given "re" and "nat" as prefixes generaed by the character baseline and SR model.

Models with additional techniques perform better than without them. Especially, retrace algorithm gives huge improvement for BPE case. Without retrace algorithm, BPE models do not work well. On the other hand, SR models only obtain small improvement. Because retrace algorithm goes back, it increases the decoding length and slows down the speed. Although current retrace algorithm is implemented straightforwardly, it can be improved by merging beams efficiently. Most of the subword lengths are equal or shorter than 3, so retrace of step 2 is quite enough, and R^2 get a close result with R^∞.

The reranking method by approximate marginalization gives a small amount of improvement and is orthogonal to retrace algorithm. Marginalization method increases MRR but decreases PMRR. It is plausible in that it changes the order of candidates by reranking. The effect of marginalization would be better if we use a bigger beam size. Because the reranking process is done after beam search decoding which takes most of the decoding time and only consists of summation and sorting the final beam outputs, it does not take a long time.

We also had experimented by increasing the vocabulary size. The accuracy of BPE models degrades fast as the vocabulary size increases. On the other hand, the performance of SR models is quite stable due to the regularization effect during training. As desired, the larger the dictionary size, the shorter the decoding length. Whereas computations run in parallel in GPU, the number of operations for the output layer in the language model is proportional to the vocabulary size in CPU. Therefore, a larger vocabulary size does not always guarantee speedup for execution in the CPU. More thorough investigation about the correlation between QAC performance and the vocabulary size of subword language models remains for future work.

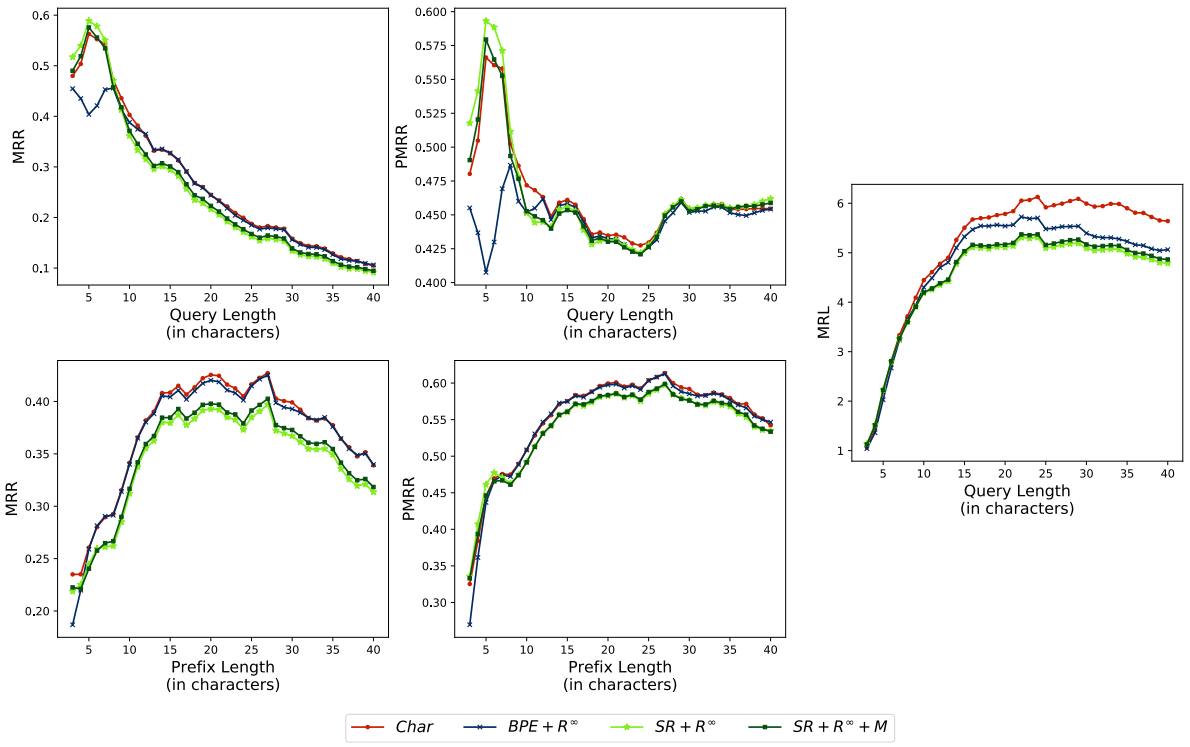

Figure 2: Comparison of the character-level baseline model and our best models by changing query length and prefix length in terms of three evaluation metrics: MRR, PMRR, and MRL. MRL is only varied by query length because it does not require prefix length sampling.

Table 2 shows examples of decoding results. Our model generates more concise and realistic examples.

6.4 Analysis on Evaluation Metrics

As shown in Figure 2, we compared our best models on three evaluation metrics (MRR, PMRR, and MRL) by changing the query length and prefix length. MRR and PMRR are more favorable to shorter queries. They drop very fast as the query becomes longer. For a longer query, the suffix length after sampling prefix has more chance to be longer. The search space increases exponentially with its suffix length. Even though QAC systems could generate realistic candidates, it is quite hard to match a long sequence with the ground truth. As the prefix length becomes longer which means that much information for determining the query has been given, the completion performance improves.

Interestingly, MRR and MRL of BPE are higher than those of SR, although BPE is worse in terms of PMRR than SR. For short queries, SR outperforms the character baseline. On the other hand, BPE is poor when the query length (or prefix length) is short. However, for a longer case, its MRR is almost close to that of the character baseline.

MRR and PMRR are highly dependent on the length distribution of test data. In contrast, MRL keeps the order between different methods as the query length changes. MRL is more reliable in the respect that it could provide consistent order between methods regardless of query length distribution. For long queries lengths, MRL stays in the flat area. Normalizing recoverable length based on the query length might be necessary.

7 Future Work

Approximation in training (Section 3.2) and decoding (Section 4) deteriorate the accuracy of subword language modeling. One possible solution to reduce the accuracy gap between the character language model baseline and the subword language model is knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016; Liu et al., 2018) from character-level language models. A student model can learn to match an estimation of query probability with that of a teacher model.

Another interesting research direction is learning segmentation jointly with language model

(Kawakami et al., 2019; Grave et al., 2019) rather than using fixed pretrained segmentation algorithms. A conditional semi-Markov assumption allows exact marginalization using dynamic programming (Ling et al., 2016; Wang et al., 2017). Nevertheless, beam search decoding on those language models, especially faster decoding, is nontrivial.

Proposed method can be extended to wide range of tasks. Query suggestion (Sordoni et al., 2015; Dehghani et al., 2017) and query reformulation (Nogueira and Cho, 2017) are related to QAC and well-established problems. They both are also possible applications of the subword-level modeling. (Drexler and Glass, 2019) used subword regularization and beam search decoding for end-to-end automatic speech recognition.

Lastly, implementation with more advanced data structure (Hsu and Ottaviano, 2013) and parallel algorithms to speed up and meet memory limitation are necessary for the real deployment (Wang et al., 2018). It would be helpful if the computation is adaptively controllable on-the-fly (Graves, 2016) at the runtime depending on the situation.

8 Conclusion

In this paper, we propose subword language models for query auto-completion with additional techniques, retrace algorithm and reranking with approximate marginalization. We observed subword language models significant speedup compared to the character-level baseline while maintaining the generation quality. Our best models achieve up to 2.5 times faster decoding speed with less than 0.02 point drop of MRR and PMRR.

Using a subword language model, we build an accurate and much faster QAC system compared to the character-level language model baseline. Although there is still much room for improvement on hyperparameter optimization, decoding search, and neural architectures like Transformer (Vaswani et al., 2017; Dai et al., 2019), the goal of this work is to prove that the subword language model is an attractive choice for QAC as an alternative to the character-level language model, especially if latency is considered.

We believe that our newly proposed metric, mean recoverable length (MRL), provides fruitful information for the QAC research in addition to conventional evaluation metric based on ranks.

Abstract

Symptom diagnosis is a challenging yet profound problem in natural language processing. Most previous research focus on investigating the standard electronic medical records for symptom diagnosis, while the dialogues between doctors and patients that contain more rich information are not well studied. In this paper, we first construct a dialogue symptom diagnosis dataset based on an online medical forum with a large amount of dialogues between patients and doctors. Then, we provide some benchmark models on this dataset to boost the research of dialogue symptom diagnosis. In order to further enhance the performance of symptom diagnosis over dialogues, we propose a global attention mechanism to capture more symptom related information, and build a symptom graph to model the associations between symptoms rather than treating each symptom independently. Experimental results show that both the global attention and symptom graph are effective to boost dialogue symptom diagnosis. In particular, our proposed model achieves the state-of-the-art performance on the constructed dataset.

1 Introduction

With the widespread use of electronic health records (EHRs) in medical treatment, symptom diagnosis based on EHRs have received a lot of attention in the natural language processing (NLP) research community (Linder et al., 2007; Shivade et al., 2013). Previous work on EHRs achieved great success in determining the diagnosis of clinical depression (Trinh et al., 2011), identifying community-acquired pneumonia (DeLisle et al., 2013), improving medication reconciliation (Persell et al., 2018) and infection detection (Tou et al., 2018).

Table 1: An example of a doctor-patient dialogue and symptom diagnosis. Underlined phrases are symptom descriptions. *True*, *False*, and *Uncertain* are the inference results for whether the symptom exists in the patient.

However, EHRs usually contained historical information, such as the medical records or health records, which can not well reflect the current symptoms of the patients. In contrast, the dialogues between doctors and patients during the medical consultation process provide many valuable clues for the current symptom diagnosis. Only a few researchers focus on the dialogue between doctors and patients. (Wei et al., 2018) proposed a reinforcement learning based framework for medical dialogue system for automatic diagnosis. As shown in Table 1, a kid has a cough, the doctor asks the patient whether he has a fever. The patient describes his kid's real situation. Some symptoms like coughing appear, but some symptoms like fever don't appear. What's more, some symptoms are uncertain such as cold because doctor can not make a clear judgment at that time. Though the dialogues show great potential in med-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5033–5042,

ical treatment, symptom diagnosis based on dialogues, namely dialogue symptom diagnosis, have rarely been studied. Moreover, there are no public datasets on dialogue symptom diagnosis as far as we know.

In this paper, we focus on the studies of dialogue symptom diagnosis and define it by two subtasks: symptom recognition and symptom inference. The symptom recognition aims to identify the symptom related entities from the dialogues, which is the basic step in finding symptoms or diseases. Symptom recognition is similar with the disease named entity recognition (NER) (Doğan et al., 2014) task that is generally considered as a sequence labeling problem (Chinchor and Robinson, 1997; Sang and De Meulder, 2003). Whereas, symptom recognition in dialogues is more challenging due to the short texts and nonstandard oral description. Regarding to the symptom inference, it focuses on making further decisions whether the symptom is *True*, *False*, or *Uncertain* with the patients, which helps the doctors diagnose the disease better in the next step.

To promote the research of dialogue symptom diagnosis, we collect a large amount of dialogues between patients and doctors from a Chinese online medical forum, and construct a dataset for the above two sub-tasks in dialogue symptom diagnosis. In addition, we provide several classical and advanced baselines on this dataset for further research. Furthermore, we propose an approach, which embeds a global attention and symptom graph to improve the performance of dialogue symptom diagnosis. Specifically, the global attention aims at incorporating more related information from the whole dialogue and corpus for better symptom entity representation, which will be used for symptom recognition and inference. Regarding to the symptom graph, it is built by treating each symptom as a node, and the edges are connected according to the true co-occurrence in the dialogues. We build the symptom graph to model the associations between symptoms rather than treating each symptom independently to improve the inference precision.

The contributions of this work can be summarized as follows:

- We provide a public dataset to promote the research of dialogue symptom diagnosis, which contains the annotation results in dialogues with respect to symptom recognition and symptom inference.
- We present a global attention mechanism, which captures more symptom related information from both dialogues and corpus to boost the performance of dialogue symptom diagnosis.
- We build a symptom graph to model the associations between symptoms, which further helps improve the precision of symptom inference.
- We perform extensive experiments, and the experimental results demonstrate the effectiveness of our proposed approach in the two sub-tasks of dialogue symptom diagnosis.

2 Related Work

Early attempts on biomedical NER task were based on rule-based dictionary matching method and machine learning method. (Lin et al., 2004) used maximum entropy as the underlying machine learning method incorporated with dictionary-based and rule-based methods for post-processing to identify biomedical entities. (Jimeno et al., 2008) used MetaMap which is provided from the National Library of Medicine and a dictionary matching method to identify diseases.

In recent years, researchers had proposed many neural network-based models on this problem. Most models use encoder-decoder architecture. (Collobert et al., 2011) used the convolutional neural network (CNN) as an encoder, and the conditional random field (CRF) (Lafferty et al., 2001) as a decoder. More recent works used LSTM as encoder which performed better in sequential problems, (Huang et al., 2015) used bidirectional LSTM as encoder, and the BiLSTM-CRF model achieved state-of-the-art on many datasets. Therefore, many researchers chose BiLSTM-CRF model as a baseline model when solving sequential problems. Some researchers made attempts to get better word representation. (Ma and Hovy, 2016) used an additional CNN to represent character-level features on the basis of BiLSTM-CRF. With character encoder, it can extract features inside words and get better representations.

In task of symptom NER, some symptom names entities are complex. There were many efforts to exploit features beyond individual sequences. (Yaghoobzadeh and Schütze, 2016) used knowledge base and aggregated corpus-level contextual

information to learn an entity's classes. To address the challenges of identifying rare and complex disease names, (Xu et al., 2019) proposed a method that incorporates both disease dictionary matching and a document-level attention mechanism into BiLSTM-CRF for disease NER. (Xu et al., 2018) used the document-level attention mechanism to capture long-range contextual dependencies and address clinical NER tasks. Symptom recognition is a very important step, but these researchers focus on symptom recognition only and do not further infer the recognized symptoms.

3 Dataset

In this section, we make a description of our dataset. We have constructed a Chinese dataset from the pediatric department of a Chinese online health community[1]. Patients can submit their health problems and then doctors start a conversation to know more about the patient and provide professional suggestions.

Annotation Symptoms reflect the abnormal state of the patient or the presence of the disease. The annotation consists of three parts, namely symptom recognition, symptom normalization and symptom inference. Figure 1 gives an example. We apply BIO (begin-in-out) schema at character level and each symptom is tagged with an extra label (*True*, *False* and *Uncertain*) which indicates whether the patient really has the symptom. Each symptom also links to the most relevant one on SNOMED CT[2] for normalization. In order to ensure the quality of the dataset, we hired three annotators with medical background. Each character is marked by two annotators and the inconsistent part is further judged by the third annotator. The Cohen's kappa coefficient (Fleiss and Cohen, 1973) among the annotators are between 91.80% and 92.71%.

Symptoms	Count	Ratio(%)
upper respiratory infection	480	23.22
functional dyspepsia	485	23.46
infantile diarrhea	546	26.42
bronchitis	556	26.90
Total	2,067	100.00

Table 2: Symptom distributions.

Description of the whole dataset	Avg	Std
# of sentence in each conversation	42.09	13.51
# of SNE in each conversation	15.14	9.53
# of character in each conversation	544.45	276.86
# of character in each sentence	6.47	14.18

Table 3: Statistics of the dataset.

Data Details Our dataset has a total of 2,067 conversations and we focus on four diseases, namely, "upper respiratory infection", "functional dyspepsia", "infantile diarrhea" and "bronchitis". The distribution of the diseases is shown in Table 2. Table 3 presents some statistics of the dataset. SNE stands for symptom named entity. Besides, the proportion of symptom status as *True*, *False* and *Uncertain* is around 63%, 12% and 25%. In order to get a reasonable comparison, we split the dataset by a 3:1:1 ratio to obtain the training set, validation set and test set[3].

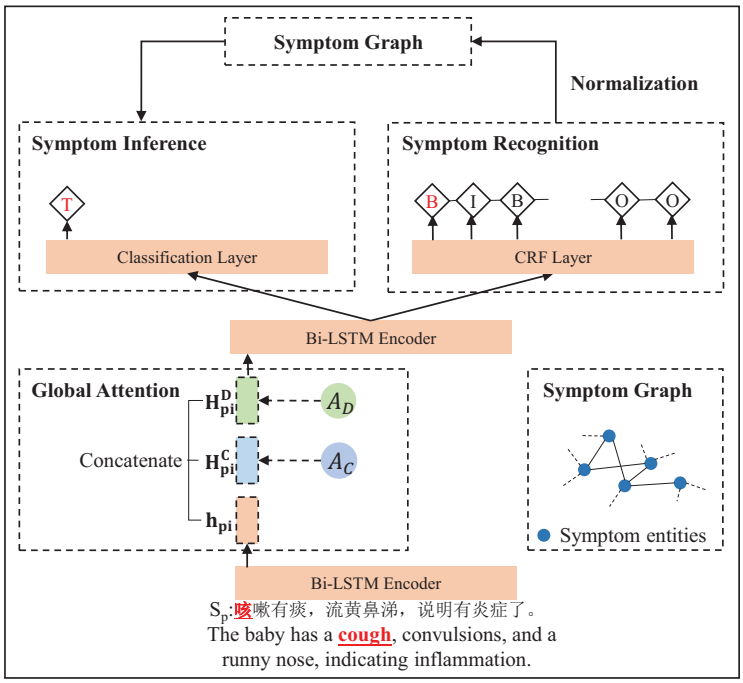

Figure 2: Architecture of our dialogue symptom diagnosis model with global attention and symptom graph. A_D and A_C denote document-level and corpus-level attention respectively.

4 Proposed Model

The framework of our proposed model is presented in Figure 2. Our model consists of three parts, the first part is symptom recognition, the second part is symptom graph, and the third part is symptom inference. We first encode the word sequence by Bi-LSTM. Then we present a global attention mechanism to get the contextual information from document level and corpus level. Next, we re-encode the hidden states obtained above and decode by CRF to recognize the symptoms. To model the associations between disease entities in the dialogue, we construct a symptom graph, which is then incorporated into the classification layer for symptom inference. The detailed description of each step is shown in the following sections.

4.1 Bi-LSTM Encoder

In this work, we use the bidirectional long short-term memory network (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) to encode the input sequences. Bi-LSTM has been widely-used to extract contextual text features. Bi-LSTM encodes the input from left to right and the same sequence in reverse (Huang et al., 2015). Given input sequence $X = (x_1, x_2, ..., x_n)$, we can get the hidden states $H = (h_1, h_2, ..., h_n)$ where h_t =Bi-LSTM(x_t). Formally, the basic units including hidden state h_t and the memory c_t are updated with following equations:

$$\begin{aligned}
\mathbf{f}_t &= \sigma(\mathbf{W}_f[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_f) \\
\mathbf{i}_t &= \sigma(\mathbf{W}_i[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_i) \\
\widetilde{\mathbf{c}}_t &= tanh(\mathbf{W}_c[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \widetilde{\mathbf{c}}_t \\
\mathbf{o}_t &= \sigma(\mathbf{W}_o[\mathbf{h}_{t-1}, \mathbf{x}_t] + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot tanh(\mathbf{c}_t)
\end{aligned} \tag{1}$$

where σ is the sigmoid function and $\odot$ is the element-wise product. $\mathbf{x}_t$ is the input vector at time t. $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$ denote the input, forget and output gate respectively.

4.2 Global Attention

Our global attention mechanism is shown in Figure 3, which consists of two parts, namely document-level attention and corpus-level attention. We will describe the details in the following.

Document-level Attention In a dialogue, the information provided by a single sentence is very limited and the same word may indicate different meanings due to the ambiguity. Therefore, we apply the document-level attention mechanism to make full use of the information in the whole dialogue to alleviate the ambiguity problem.

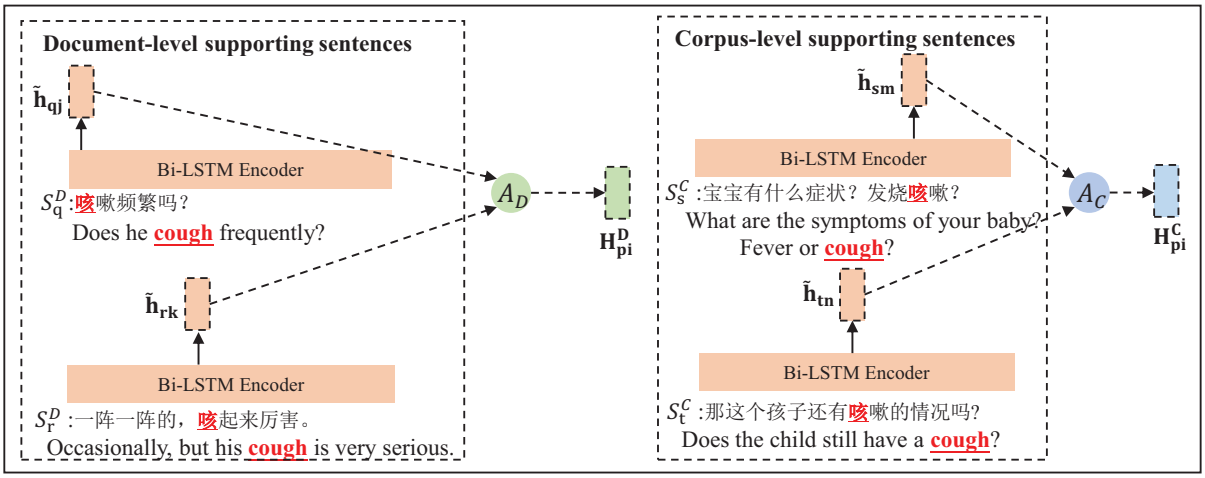

Figure 3: Global attention which consists of the document-level and corpus-level attentions. A_D and A_C denote document-level and corpus-level attention respectively.

We define a document (or dialogue) $D = (S_1, S_2, ...)$ and a sentence $S_p = (w_{p1}, w_{p2}, ...)$. S_p represents the pth sentence of the document and w_{pi} represents the ith word of S_p. $\mathbf{h}_{pi}$ is the hidden state of w_{pi}. We search for the sentence with the same word w_{pi} from the current document, and feed the found sentence into the same Bi-LSTM model. For example, as shown in Figure 3, w_{pi} represents the word "cough". The sentences as S_q^D and S_r^D in the current dialogue also contain "cough" . We add the hidden states of the word in the two sentences into a set $\tilde{\mathbf{h}}_{pi}$=$\{\tilde{\mathbf{h}}_{pi}^1, \tilde{\mathbf{h}}_{pi}^2, ...\}$. In Figure 3, $\tilde{\mathbf{h}}_{qj}$ and $\tilde{\mathbf{h}}_{rk}$ are $\tilde{\mathbf{h}}_{pi}^1$ and $\tilde{\mathbf{h}}_{pi}^2$ respectively. We weight the hidden states by document-level attention and the attentive representation is formulated as follows:

$$\begin{aligned} \mathbf{e}_{pi}^{D,j} &= \mathbf{v}^T \tanh(\mathbf{W}_h \mathbf{h}_{pi} + \mathbf{W}_{\tilde{h}} \tilde{\mathbf{h}}_{pi}^j + \mathbf{b_e}) \\ \boldsymbol{\alpha}_{pi}^D &= \mathbf{Softmax}(\mathbf{e}_{pi}^D) \\ \mathbf{H}_{pi}^D &= \sum_{j=1}^{k} \alpha_{pi}^{D,j} \tilde{\mathbf{h}}_{pi}^j \end{aligned} \tag{2}$$

$\mathbf{v}$, $\mathbf{W}_h$, $\mathbf{W}_{\tilde{h}}$ and $\mathbf{b}_e$ are the parameters to be learned. $\mathbf{H_{pi}^D}$ denotes the contextual information of the word w_{pi} in the dialogue.

Corpus-level Attention Noting that the same word in different dialogues may indicate additional associations, we devise a corpus-level attention mechanism to capture the extra information.

We define the corpus $C = \{D_1, D_2, D_3, ...\}$. Similar to the document-level attention, we find the supporting sentences in the corpus that contain the current word. In Figure 3, the sentences as S_s^C and S_t^C contain the word "cough", and $\tilde{\mathbf{h}}_{sm}$ and $\tilde{\mathbf{h}}_{tn}$ are the corresponding hidden states. We apply corpus-level attention to obtain the attentive representation of the hidden states in the corpus:

$$\mathbf{H}_{pi}^C = \sum_{j=1}^{k} \alpha_{pi}^{C,j} \tilde{\mathbf{h}}_{pi}^j \tag{3}$$

$\mathbf{H}_{pi}^C$ denotes the related information of the word w_{pi} in the corpus, $\alpha_{pi}^{C,j}$ is the attention weight for the corresponding hidden state in the corpus.

Both Document and Corpus-level Attention In order to integrate the information obtained based on document-level attention and corpus-level attention, we concatenate $\mathbf{h}_{pi}$, $\mathbf{H}_{pi}^C$ and $\mathbf{H}_{pi}^D$, and feed it into another Bi-LSTM model. Thus, the final hidden state of each word contains the complementary information from both the dialogue and corpus.

4.3 Symptom Recognition

In this work, we apply the Conditional Random Field (CRF) (Lafferty et al., 2001) as decoder for symptom recognition. CRF can compute the global optimal sequence and efficiently capture the dependencies among tags (e.g. label 'I' can not follow 'O') via jointly decoding the chain of labels. The Viterbi algorithm (Viterbi, 1967) is chosen for inference using dynamic programming. Given the representation of a sequence, we first map it to the tag space by a linear layer. Then, the score of the input along with a prediction y is given by:

$$s(X, y) = \sum_{i=1}^{n} (T_{y_{i-1}, y_i} + P_{i, y_i}) \tag{4}$$

where T is a transition matrix, $T_{i,j}$ represents the score of transition from tag i to tag j; P is a matrix of the output from the last layer, $P_{i,j}$ is the score of the j^{th} tag for the i^{th} word in the sentence. The goal is to predict the best tag path that given by:

$$y = argmax_{\widetilde{y}} s(X, \widetilde{y}) \tag{5}$$

4.4 Symptom Graph

Symptom entities have a certain probability of co-occurrence in a dialogue. For example, "fever" may appear in a conversation with "cold" at the same dialogue, and "cough" may appear in a conversation with "sputum" at the same dialogue. In order to capture the associations between the disease entities, we build a graph $G = (V, E)$, where $V = v_1, v_2, ..., v_m$ is the node set and $E \subset V \times V$ is the edge set. The edges $e_{i,j} = (v_i, v_j)$ in the graph is undirected. The nodes are the normalized symptom entities with status *True* from the training corpus. Edge $e_{i,j} = (v_i, v_j)$ indicates symptom entities v_i and v_j co-occur in a document. The co-occurrence number of two entities is normalized by min-max normalization to obtain the edge weight. Thus, the weight $w_{i,j} \in (0, 1)$.

4.5 Symptom Inference

Intuitively, the associations between symptom entities can help enhance symptom inference. Therefore, we first define a smoothness loss that quantitatively measures the entity associations in the constructed symptom graph:

$$S = \frac{1}{2} \sum_{i,j} w_{i,j} (y_i - y_j)^2 = \mathbf{y}^T L \mathbf{y} \tag{6}$$

where y_i is 0 or 1 that depends whether the entity has been recognized by the symptom recognition module. $L = D - A$ denotes the Laplacian matrix of an undirected subgraph G' with k nodes and m edges corresponding to the current document. $A \in R^{k \times k}$ denotes the weighted adjacency matrix of subgraph G'. D is a degree matrix and $D_{ii} = \sum_j A_{ij}$. $\mathbf{y}^T$ is a k-dimensional vector. Theoretically, if the model fully recognizes the symptoms, the value of S is 0 indicating the symptom graph is smooth. When some symptoms are not recognized, the value of S depends on the weights between the nodes of the incorrect symptoms and the neighbor nodes.

With the smoothness loss defined above, we then incorporate it into the loss function for symptom inference. Symptoms are classified into three categories: *True*, *False*, or *Uncertain*, and we adopt a softmax function in the classification layer to predict the probability of the symptom belonging to each category. The classification layer and the CRF layer share the same hidden states of the upper Bi-LSTM encoder. The objective is defined as minimizing the joint cross-entropy loss in classification and the smoothness loss in the graph:

$$loss = -\sum_{\mathcal{D}} (\sum_i \sum_j \log p^c_{i,j} - \lambda S) \tag{7}$$

where $\mathcal{D}$ is the document set, i is the index of the sentence, j is the index of the symptom, $p^c_{i,j}$ is the predicted probability of the gold-standard polarity class c for the jth symptom in the ith sentence of the document, and λ is a weight parameter to control the importance of the smoothness loss.

5 Experiments and Results

5.1 Experimental Setup

We use 200-dimensional Chinese embeddings trained on Wikipedia and fine tune them during model training by back-propagating the gradients. The parameters of the weight matrix are initialized by the Xavier method (Glorot and Bengio, 2010). The Stochastic gradient descent (SGD) method with a momentum of 0.9 is used for optimization. The initial learning rate $\eta_0 = 0.015$ and the learning rate gradually decreases with the increasing epoch. The specific update formula is $\eta_t = \eta_0/(1 + \rho t)$ where $\rho = 0.05$ and t is the number of trained epoch. Gradient clipping is set to 5 in order to avoid "gradient exploding". Other experimental settings such as the dropout rate is 0.5 and the Bi-LSTM hidden dimension is 200. We build the symptom graph from our training set. There are 1,646 edges and 162 nodes. We initialize the labels as 1 for all nodes.

Look-up Table and Stop Words For the attention mechanism, we select at most three document-level supporting sentences and three corpus-level supporting sentences. We build a look-up table that can quickly get the index of a word in each sentence and the index of a sentence in each document. Therefore, the time complexity of finding supporting sentences and words is O(1). Meanwhile, we use a stop-word list that contains 178 words. In this way, we can further reduce the time cost.

Symptom Normalization We consider the symptom normalization as a text classification

problem. In our dataset, there are 162 normalized symptoms. We apply the convolution neural network (CNN) to classify all symptoms into 162 categories. The accuracy of symptom normalization on the test set is 97.04%. Thus, the symptom normalization doesn't bring too much noise to our model.

5.2 Performance of Symptom Recognition

Symptom recognition is the basis of symptom inference. We report the results of the recent advanced baselines as well as the variants of our proposed method. Specifically, we compare the performance of the following models:

- **Bi-RNNs (Dyer et al., 2015)**: The models use LSTM or GRU for the sentence encoder, and treat symptom entity recognition as a classification problem with the softmax function. From now on, we use RNNs to denote LSTM or GRU for ease of description.
- **Bi-RNNs-CRF (Huang et al., 2015)**: The models use RNNs for the sentence encoder and a CRF layer for decoder, which yields the tagging prediction for each token.
- **CNNs-Bi-RNNs-CRF (Ma and Hovy, 2016)**: Compared with Bi-RNNs-CRF, the CNNs-Bi-RNNs-CRF models additionally incorporate the character level information with CNN for encoder.
- **Corpus-level Attention**: It is a Bi-LSTM-CRF model that incorporates corpus-level features via our corpus-level attention.
- **Document-level Attention**: It is a Bi-LSTM-CRF model that incorporates document-level features via our document-level Attention.
- **Both Corpus and Document-level Attention**: It is a Bi-LSTM-CRF model that incorporates both document-level and corpus-level features via our global attention.

The overall results of symptom recognition are shown in Tabel 4. We observe that the Bi-RNNs models including Bi-GRU and Bi-LSTM have the similar performance, which get about 81% in the F1 score on our dataset. The Bi-RNNs-CRF models perform much better than Bi-RNNs, which indicates the effectiveness of the CRF model for sequence tagging. In addition, the performance can be slightly improved by incorporating the character level information with CNN. Furthermore, by integrating either our corpus-level attention or document-level attention into the existing models, the performance can be significantly boosted. In particular, our model with global attention achieves the best performance in terms of all metrics.

Model	Prec.	Recall	F1
Bi-GRU	76.02%	88.09%	81.61%
Bi-LSTM	76.64%	87.60%	81.62%
Bi-GRU-CRF	86.44%	89.13%	87.77%
Bi-LSTM-CRF	89.93%	89.56%	89.74%
CNNs-Bi-GRU-CRF	87.08%	90.82%	88.91%
CNNs-Bi-LSTM-CRF	90.45%	90.48%	90.47%
Corpus-level attention	90.40%	91.02%	90.71%
Document-level attention	90.53%	91.67%	91.10%
Both Corpus and Document-level attention	91.09%	92.17%	91.62%

Table 4: Performance of various models for symptom recognition.

Method	inference of symptom	F1
Bi-LSTM CRF-inference	True	82.68%
	False	59.22%
	Uncertain	65.02%
Bi-LSTM CRF-inference with graph	True	83.79%
	False	60.04%
	Uncertain	65.80%
Our joint model	True	85.08%
	False	66.09%
	Uncertain	74.13%
Our joint model with graph	True	86.46%
	False	66.88%
	Uncertain	74.25%

Table 5: Performance of various models for symptom inference.

5.3 Performance of Symptom Inference

Table 5 presents the symptom inference results of the classical Bi-LSTM CRF-inference model and our proposed joint model (Figure 2). The results show that our proposed model with global attention significantly outperforms the Bi-LSTM CRF-inference model for symptom inference across all the categories. In particular, we achieve substantial improvements for inferring the *False* and *Uncertain* categories of symptoms, by utilizing the global information in the current dialogue and the whole corpus

To investigate the effect of the symptom graph for symptom inference, we compare the models with and without symptom graphs. The results in Table 5 show that when incorporating the symptom graphs for inference, the performance of each model can be further boosted. These observations have verified the effectiveness of modeling

the associations between symptoms via graphs for symptom inference.

5.4 Qualitative Analysis

Table 6 presents a case of symptom recognition based on the baseline and our model. It is observed that the baseline Bi-LSTM CRF model only identifies the word "allergic" as a symptom. In contrast, our model can recognize the phrase "allergic rhinitis" by utilizing the related information (i.e., "allergies rhinitis" and "allergic caused rhinitis") in the document-level and corpus-level supporting sentences, which is more accurate for the symptom description in this case.

Table 7 shows the results of symptom inference for a case by using the baseline and our joint model. From the patient's answer, we know that the kid has no "allergy". Whereas, the symptom "allergies" in the doctor's question sentence is inferred as *uncertain* by the baseline. By incorporating the global attention mechanism, our joint model can correctly infer the symptom as *false*.

Model	Sentence
Bi-LSTM CRF	医生：相对来说，这个年龄的孩子出现过敏性鼻炎比较少见。 Doctor: Relatively speaking, allergic rhinitis is rare in children of this age.
Our Model	医生：相对来说，这个年龄的孩子出现过敏性鼻炎比较少见。 Doctor: Relatively speaking, allergic rhinitis is rare in children of this age.
Document-level supporting sentence	患者：如果是过敏性的鼻炎，会持续多久? Patient: If it is allergic caused rhinitis , how long will it last?
Corpus-level supporting sentence	医生：那需要考虑过敏性鼻炎的可能。 Doctor: It may be allergic rhinitis.

Table 6: Symptom recognition results of the baseline and our methods. Underlined phrases are symptoms.

Model	Sentence
Bi-LSTM CRF-Inference	医生：孩子小时候湿疹重不重? 平时易过敏吗? Doctor: Is the child eczema serious? Is he susceptible to allergies in daily life? Inference:Uncertain Uncertain 患者：不过敏啊。 Patient: No allergy. Inference:False
Our joint model with graph	医生：孩子小时候湿疹重不重? 平时易过敏吗? Doctor: Is the child eczema serious? Is he susceptible to allergies in daily life? Inference:Uncertain False 患者：不过敏啊。 Patient: No allergy. Inference:False

Table 7: Symptom inference results of the Bi-LSTM CRF-inference model and our joint model with symptom graph. Underlined phrases are symptoms.

To have an insight of why the symptom graph can help boost symptom inference, we select several frequent symptoms in dialogues, namely "Cough", "Sputum", "Fever", "Diarrhea", "Snot", "Cold" and "Indigestion", and visualize the associations between the symptoms in Figure 4. The darker color indicates a larger association weight between the symptoms. We observe that the "cough" and "sputum" are highly associated, which corresponds to our intuition that the patient will probably have a cough and sputum simultaneously. To make it more clear, we show the inference results for each symptom with and without graph in Figure 5. The results show that our model with graph achieves larger improvements than that without graph for inferring the highly associated symptoms such as "cough" and "sputum", which indicates the necessity to incorporate the symptom graph to enhance symptom diagnosis.

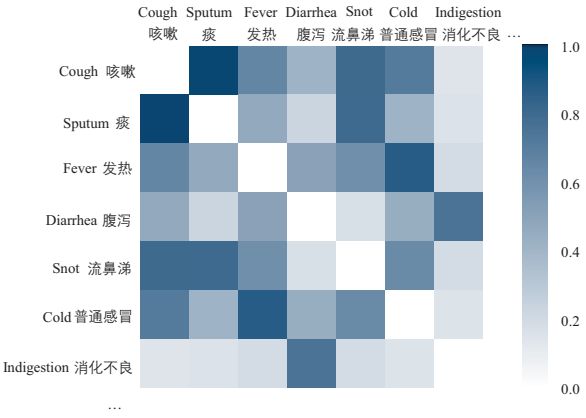

Figure 4: Symptom associations in the symptom graph.

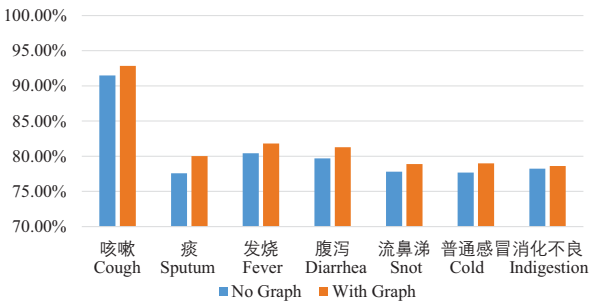

Figure 5: The impact of the symptom graph on F1 scores for symptom inference.

6 Conclusions and Future Works

In this paper, we construct a dataset for dialogue symptom diagnosis, and present a model with global attention and symptom graph for diagnosing symptoms in dialogues. Our global attention mechanism consists of the document-level

and corpus-level attentions, which select supporting sentences from the current dialogue and corpus to overcome the information limitations. Experiments on our dataset show that our global attention can effectively boost the performance of dialogue symptom diagnosis. Furthermore, we build a symptom graph to model the associations between symptoms, which helps improve the performance of symptom inference.

In the future, we will build a larger symptom graph and use external medical information to further improve the performance of symptom diagnosis on dialogues.

Abstract

Counterfactual reasoning requires predicting how alternative events, contrary to what actually happened, might have resulted in different outcomes. Despite being considered a necessary component of AI-complete systems, few resources have been developed for evaluating counterfactual reasoning in narratives.

In this paper, we propose *Counterfactual Story Rewriting*: given an original story and an intervening counterfactual event, the task is to minimally revise the story to make it compatible with the given counterfactual event. Solving this task will require deep understanding of causal narrative chains and counterfactual invariance, and integration of such story reasoning capabilities into conditional language generation models.

We present TIMETRAVEL, a new dataset of 29,849 counterfactual rewritings, each with the original story, a counterfactual event, and human-generated revision of the original story compatible with the counterfactual event. Additionally, we include 81,407 counterfactual "branches" without a rewritten storyline to support future work on semi- or un-supervised approaches to counterfactual story rewriting.

Finally, we evaluate the counterfactual rewriting capacities of several competitive baselines based on pretrained language models, and assess whether common overlap and model-based automatic metrics for text generation correlate well with human scores for counterfactual rewriting.

1 Introduction

A desired property of AI systems is counterfactual reasoning: the ability to predict causal changes in future events given a counterfactual condition applied to the original chain of events (Goodman, 1947; Bottou et al., 2013). For example, given an original story shown in the left chain in Figure 1, where "Pierre loved Halloween. He decided to be a *vampire* this year. He got a *black cape and white face paint*..." and a counterfactual condition, "what if Pierre decided to be a *werewolf* instead of a *vampire*?", an intelligent system should be able to revise the subsequent events in the story appropriately, for example, that a *brown sweater* would be more appropriate than a *black cape*.

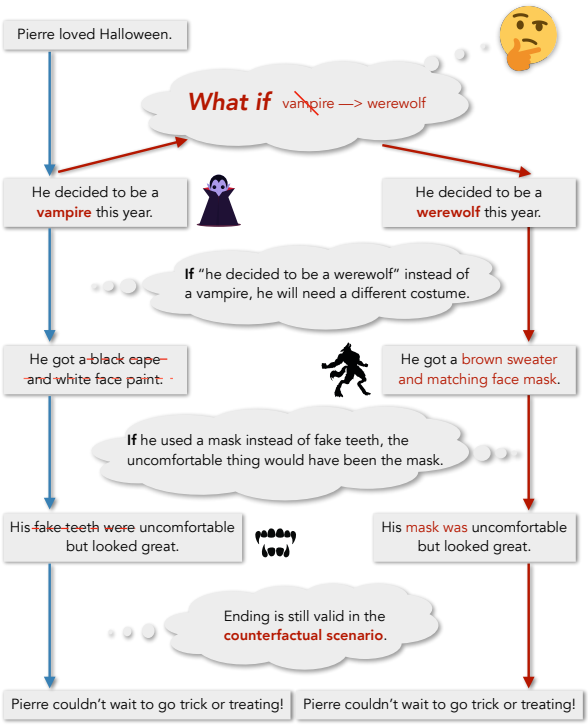

Figure 1: Given a short story (left column) and a *counterfactual context* ("He decided to be a werewolf this year"), the task is to revise the original story with minimal edits to be consistent with both the original premise ("Pierre loved Halloween") and the new counterfactual situation. The modified parts in the new story (right column) are highlighted in red.

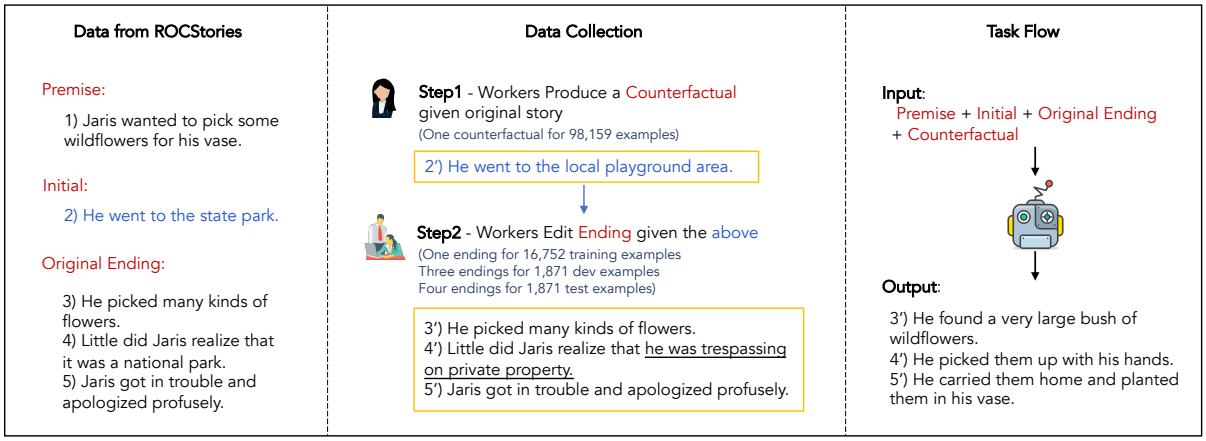

Figure 2: Data annotation process for the TIMETRAVEL dataset. Given a story from the ROCStories corpus, crowdworkers write a counterfactual sentence w.r.t the second sentence of the story. The counterfactual sentence and the original story are then presented to other workers to rewrite the story ending. Models for the task are expected to generate a rewritten ending given the original story and counterfactual sentence.

This notion of counterfactuals has become increasingly relevant in several recent benchmarks such as ROC story cloze (Mostafazadeh et al., 2016), COPA (Roemmele et al., 2011), and HellaSwag (Zellers et al., 2019), where the negative responses in multiple-choice problems implicitly construct counterfactual narratives. However, no existing benchmark to date has been designed to explicitly evaluate counterfactual narrative reasoning and revision as its principal focus, where a system is evaluated on its ability to make modifications to future events based on a counterfactual condition, as illustrated in Figure 1.

In this paper, we introduce *Counterfactual Story Rewriting* as a new challenge to story understanding and generation. Given an original story and a counterfactual condition, the task is to re-write the story to regain narrative consistency through counterfactual reasoning. An important challenge in counterfactual reasoning is *causal invariance*, namely, the aspects of future events that are invariant under the counterfactual conditions. This is necessary to accurately reason about the new consequences with minimal edits to the original sequence of events, instead of being confounded by spurious correlations (Woodward, 2002; Bottou, 2019). Therefore, a key measure of the task besides consistency is that the rewriting must perform *minimal edits* to the original story. This challenges the system to reason about causal invariance, which in turn, challenges the system to reason more carefully about the causal chains of how the story unfolds.

We introduce TIMETRAVEL, a new dataset with 29,849 counterfactual revisions to support research on counterfactual narrative reasoning and revision. In addition, our dataset provides 81,407 counterfactual *branches* without rewritten storylines to support potential future work on semi- or un-supervised approaches. Figure 2 illustrates (1) the structure of the original stories, (2) the counterfactual data construction process, and (3) the final task definition.

We establish baseline performances of state-of-the-art neural language models on this task, such as GPT (Radford et al., 2018) and GPT-2 (Radford et al., 2019), evaluated in zero-shot, unsupervised, and supervised learning settings. Empirical results indicate that while these models are able to capture certain instances of counterfactual reasoning, they generally struggle with rewriting endings with full consistency. Our results suggest that current neural language models operate based primarily on frequent patterns in language without true understanding of the causal chains in narratives, thus requiring more focused future research to integrate reasoning capabilities to neural language models.

2 Background

Counterfactual reasoning is the ability to consider *alternative possibilities* that diverge from current observed narratives. Due to their prevalence in common reasoning situations, counterfactuals have been studied in a wide range of disciplines, including psychology (Epstude and Roese, 2008),

cognitive science (Byrne, 2002), as well as natural language processing (Hobbs, 2005; Lawrence and Riezler, 2018; Son et al., 2017).

Meanwhile, despite the progress made in NLU tasks by adapting pretrained language representations such as BERT (Devlin et al., 2018) or GPT (Radford et al., 2018), models still have trouble discriminating between reasonable and unreasonable counterfactuals, as shown in (Zellers et al., 2019). Moreover, success in tasks linked to discrimination of reasonable alternatives often results in models learning to exploit latent artifacts of the dataset (Niven and Kao, 2019; Zellers et al., 2018), rather than learning to robustly reason about counterfactuals. In response to this, we hypothesize that learning to *generate the result* of counterfactual prompts will encourage models to learn to understand the underlying dynamics of a given situation, whereas discrimination between two alternatives is more likely to take advantage of dataset biases.

This goal shares many similarities with script learning (Pichotta and Mooney, 2014; Chambers, 2013), which attempts to canonicalize stereotypical event sequences for learning causal structure of narratives. However, because it is often difficult to capture the richness of causal dependencies with templatized structures (Sap et al., 2019), we instead study counterfactual reasoning in unstructured text directly and also require the model to *generate* the consequences of the counterfactual reasoning.

The "counterfactual event" in our task can be viewed as a causal intervention (Pearl, 2000) in the latent chain of events of the story. Such interventions demand changes to the written narrative in order to abide by the shared background knowledge that human readers have about how the world works. This neatly embeds the problem of causal reasoning in a space that laymen with no knowledge of formalized causality can understand. It also allows us to evaluate the capabilities and limitations of the recent advances in neural language models in the context of counterfactual reasoning.

Similar issues arise in the area of controllable language generation (e.g., Hu et al., 2017), which involves preserving the content of text while changing it along a single or multiple dimensions, such as theme (Koncel-Kedziorski et al., 2016), style (Lample et al., 2019), and sentiment (Shen et al., 2017). Reasoning in these tasks is limited to discrete axes (e.g., sentiment), which are often categorized with a closed label set ({positive, negative}). Because of controllability motivations, these axes and labels are generally known *a priori*. In contrast, counterfactual rewriting focuses on the causes and effects of a story, dimensions that can require more complex and diverse, yet potentially subtle, changes to accommodate the counterfactual event. Additionally, we put no restrictions on the nature of counterfactual events, yielding no clear set of discrete axes along which the story can change and no closed set of labels for them.

3 Counterfactual Story Rewriting

3.1 Task

We now formally introduce the task and establish the notation used in the paper. Each example consists of a five-sentence story $S = (\boldsymbol{s}_1, \ldots, \boldsymbol{s}_5)$ with a general structure where the first sentence $\boldsymbol{s}_1$ sets up the *premise*, the second sentence $\boldsymbol{s}_2$ provides more information of the *initial context*, and the last three sentences $\boldsymbol{s}_{3:5}$ are the *original ending* of story. We are further given an additional sentence $\boldsymbol{s}'_2$, which is counterfactual to the initial context $\boldsymbol{s}_2$. That is, $\boldsymbol{s}'_2$ states something contrary to that in $\boldsymbol{s}_2$, which in turn can make the original ending $\boldsymbol{s}_{3:5}$ no longer valid. Thus, the goal of the task is to rewrite the ending, such that the *edited ending* $\boldsymbol{s}'_{3:5}$ minimally modifies the original one and regains narrative coherency to the new counterfactual context.

The minimum edit goal differentiates our task from previous story ending studies, which have mostly focused on consistency in a given context. To achieve consistency with minimal edits, a model must understand the key mechanisms that drive the story's narrative so that it can filter out spurious correlations and capture counterfactual invariance. We thus consider the new task as a suitable testbed for studying counterfactual reasoning in combination with language generation.

3.2 Dataset: TIMETRAVEL

Our dataset is built on top of the ROCStories corpus (Mostafazadeh et al., 2016), which contains 98,159 five-sentences stories in the training set, along with 3,742 stories in the evaluation sets. Each story was written by

Premise	Alec's daughter wanted more blocks to play with.
Initial	Alec figured that blocks would develop her scientific mind.
Original Ending	Alec bought blocks with letters on them. Alec's daughter made words with them rather than structures. Alec was happy to see his daughter developing her verbal ability.
Counterfactual	Alec couldn't afford to buy new blocks for his daughter.
Edited Ending	Alec decided to make blocks with letters on them instead. Alec's daughter made words with the blocks. Alec was happy to see his daughter developing her verbal ability.
Premise	Ana had just had a baby girl.
Initial	She wanted her girl to have pierced ears.
Original Ending	She took her baby to the studio and had her ears pierced. Then she fastened tiny diamond studs into the piercings. Ana loved the earrings.
Counterfactual	She didn't like the idea of having her ears pierced.
Edited Ending	She decided not to take her baby to the studio to get her ears pierced. So she took tiny diamond stickers and stuck them to her ear. Ana loved the fake earrings.

Table 1: Examples from TIMETRAVEL

crowdworkers. To collect counterfactual events and new story continuations for TIMETRAVEL, we employ workers from Amazon Mechanical Turk (AMT) for a two-step task, which we describe in detail below.

3.3 Data Collection

Counterfactual Event Collection We present workers with an original five-sentence story $S = (\boldsymbol{s}_1, \boldsymbol{s}_2, \ldots, \boldsymbol{s}_5)$ and ask them to produce a counterfactual event $\boldsymbol{s}'_2$ based on $\boldsymbol{s}_2$. Workers are instructed to produce counterfactual sentences $\boldsymbol{s}'_2$ that are:
(1) Topically related to the original context sentence $\boldsymbol{s}_2$, rather than a completely new sentence.
(2) Relevant to the original premise sentence, $\boldsymbol{s}_1$, allowing for a coherent story continuation.
(3) Influential to the subsequent storyline, such that at least one of the original ending's sentences, $\{\boldsymbol{s}_3, \boldsymbol{s}_4, \boldsymbol{s}_5\}$ is no longer appropriate given $\boldsymbol{s}_1$ and $\boldsymbol{s}'_2$, necessitating a rewritten story ending.

Continuation Rewriting Once a counterfactual sentence $\boldsymbol{s}'_2$ is provided, we present it to a new set of workers with the original story $S = (\boldsymbol{s}_1, \boldsymbol{s}_2, \ldots, \boldsymbol{s}_5)$. Now that $\boldsymbol{s}'_2$ invalidates the original storyline, workers are instructed to make minimal edits to $\boldsymbol{s}_{3:5}$, such that the narrative is coherent again. Before beginning, workers are instructed to validate whether the counterfactual event satisfies the requirements from the previous stage of the pipeline. If not, we ask them to rewrite the counterfactual again, and the continuation rewriting step is reassigned to a new worker.

Summary We summarize the scale of TIMETRAVEL in Table 2. Overall, we collect 16,752 training examples of a counterfactual context and a rewritten ending. We also collect an additional 81,407 counterfactual contexts for the training set with no rewritten ending to support future work in unsupervised learning on this task. For the development and test sets, we gather multiple counterfactual contexts and rewritten endings for *each* example (3 new endings for development and 4 for test). Information regarding quality control and cost are provided in Appendix A.

	Train	Valid	Test
ROCStories data:			
# Stories	98,159	1,871	1,871
TIMETRAVEL*:*			
# Counterfactual Context	98,159	5,613	7,484
# Edited Ending	16,752	5,613	7,484

Table 2: Dataset statistics

4 Learning a Counterfactual Rewriter

Recent work in constructing large-scale generative language models based on transformers (Radford et al., 2018, 2019) has led to considerable improvements in natural language generation tasks. Due to their current prominence, we use them as baselines to study the extent to which the current neural text generation systems can perform and fail counterfactual narrative reasoning and revision. We focus on the family of GPT models, including GPT (Radford et al., 2018) and the latest small- (GPT2-S) and medium-sized (GPT2-M) transformer models from Radford et al. (2019). For each of the three pretrained language models, we fine-tune with multiple objectives, leading to 14 different model variants for the task, which we

describe in more detail below.

4.1 Unsupervised Training

Constructing large-scale counterfactual revision dataset is costly. Therefore, an ideal system must learn to reason without direct supervision. Toward this goal, we examine how unsupervised approaches to counterfactual story rewriting perform on our evaluation task. We devise the following unsupervised settings for models to learn to generate counterfactual story endings.

Zero-shot (ZS) In our simplest setting, we evaluate the counterfactual reasoning abilities already learned by these models due to pretraining on large corpora: the BooksCorpus dataset (Zhu et al., 2015) for GPT and the WebText corpus for GPT-2 (Radford et al., 2019). In this setting, models are not trained on any portion of the training data from TIMETRAVEL and must instead produce counterfactual rewritten stories for the evaluation set using only the representations learned from pretraining. At test time, the model receives the premise and the counterfactual context $(\boldsymbol{s}_1, \boldsymbol{s}'_2)$ as input and generates the tokens that constitute the rewritten counterfactual outcome.

Fine-tuning (FT) Because the domains on which both the GPT and GPT2 models were trained are broad and more complex than the domain of ROCStories, we investigate whether adapting the language model to the data distribution of ROCStories is helpful for learning to reason about counterfactuals. In this setting, the model is further fine-tuned to maximize the log-likelihood of the stories in the ROCStories corpus:

$$\mathcal{L}^{ft}(\boldsymbol{\theta}) = \log p_\theta(S), \tag{1}$$

where p_θ is the language model with parameters $\boldsymbol{\theta}$, and S is the original story as defined in Section 3.1. This fine-tuning step encourages the model to generate text with the same consistent style of the stories. Similar to the zero-shot setting, the premise and the counterfactual sentence $(\boldsymbol{s}_1, \boldsymbol{s}'_2)$ are provided as input to the model.

Fine-tuning + Counterfactual (FT + CF) The above training loss, however, does not make use of the additional 81,407 counterfactual training sentences for fine-tuning. To inform the model with a larger set of possible counterfactual narratives in the training data, we propose an additional loss function that fits the model to the counterfactual sentences given the premise sentence:

$$\mathcal{L}^{cf}(\boldsymbol{\theta}) = \log p_\theta(\boldsymbol{s}'_2|\boldsymbol{s}_1), \tag{2}$$

where $p_\theta(\boldsymbol{s}'_2|\boldsymbol{s}_1)$ denotes that the language model first reads the premise $\boldsymbol{s}_1$ and maximizes the log-likelihood of counterfactual sentence $\boldsymbol{s}'_2$. The model is fine-tuned with both objectives in Eqs (1) and (2):

$$\mathcal{L}^{ft+cf}(\boldsymbol{\theta}) = \mathcal{L}^{ft} + \mathcal{L}^{cf}, \tag{3}$$

and receives inputs in the same format as the zero-shot and fine-tuned models at test time.

Reconstruction + Counterfactual (RC + CF) One issue with the above training procedures is that models are not explicitly trained to retain as much text of the original outcome $\boldsymbol{x}_{3:5}$ as possible (i.e., minimum edits). If these models are to learn to "rewrite" the original story ending given the counterfactual sentence, rather than learning to produce a completely new plot, they must be able to condition on the original ending during generation. Motivated by this requirement and following the goal of developing unsupervised methods for counterfactual rewriting, we design a reconstruction objective for learning a noisy reproduction of the original ending. Specifically, we provide the model with both the original story and a masked context as input $(S, [s], \boldsymbol{s}_1, [mask])$ and train the model to reconstruct the original ending $\boldsymbol{s}_{3:5}$:

$$\mathcal{L}^{rc}(\boldsymbol{\theta}) = \log p_\theta(\boldsymbol{s}_{3:5}|S, [s], \boldsymbol{s}_1, [mask]), \tag{4}$$

where `[s]` denotes a separator token and `[mask]` is a special mask token. In this setting, the model first reads the original story S followed by the separation token `[s]`, and then reads the premise $\boldsymbol{x}_1$ again, followed by the mask token `[mask]`, which serves as a placeholder sentence for the counterfactual sentence. This objective encourages the model to reproduce the original ending $\boldsymbol{s}_{3:5}$ in the general case where the second sentence is not specified, thereby encouraging generations similar to the original ending regardless of the counterfactual provided. At test time, we replace `[mask]` in the input

Premise	Rob loved to play soccer and was on his middle school team.
Initial	They had just started their season and were playing their first game.
Original Ending	Rob accidentally tripped over another player during the game. The other player was mad, but Rob apologized and kept his composure. Rob ended up playing the best game of his life!
Counterfactual	When he graduated from middle school, he started learning to play the guitar.
Model	**Generated Ending**
GPT-M + ZS	He played in bands for about a year, then got into touring with a band called The Muffs. He wrote the music for a few of The Muffs' songs. He was a very talented singer-songwriter and guitarist.
GPT-M + FT + CF	He took classes on the guitar for years to get better. He took a solo lesson and had a great time. Rob now is a famous guitarist.
GPT-M + Supervised	He accidentally tripped over the guitar during the song. The other person was mad, but Rob apologized and kept his composure. Rob ended up playing the best song of his life.
Premise	I called Carly to ask her on a date.
Initial	I got her voicemail.
Original Ending	I texted her that we should talk soon. She texted me back, asking why we should talk soon. I told her I liked her.
Counterfactual	She said that we should just stay friends which made me really sad.
Model	**Generated Ending**
GPT-M + ZS	She said that she went out and did something really stupid and that was all I could think about. I did my best to be nice to Carly by telling her how much I loved her and that I would be her best friend no matter what. There were nights when I felt like crying because I couldn't get out of bed.
GPT-M + FT + CF	I decided to watch a movie instead. After that I decided I should see a movie I had never seen before. I went to the theater and bought a ticket.
GPT-M + Sup	I texted her that we should just stay friends soon. She texted me back, asking why we should just stay friends soon. I told her I liked her.

Table 3: Model Outputs

with the counterfactual sentence s'_2, and the model must generate the continuation of $(S, [s], s_1, s'_2)$. We also use the objective from Eq (2) above to inform the model with counterfactual information during training.

4.2 Supervised Training (Sup)

Our dataset also provides 16,752 training instances that include human annotated rewritten endings for supervised learning. To assess whether being able to train directly on alternative endings is helpful for learning counterfactual narrative understanding, we train models on this portion of data in a supervised manner. More concretely, the input to the model contains the full information $(S, [s], s_1, s'_2)$, and we train the model to maximize the log-likelihood of ground-truth rewritten endings:

$$\mathcal{L}^s(\boldsymbol{\theta}) = \log p_\theta(s'_{3:5}|S, [s], s_1, s'_2). \quad (5)$$

where `[s]` denotes a separator token.

4.3 Hyperparameters

We largely follow the same training and inference setups as in Radford et al. (2018) for the GPT model and Radford et al. (2019) for the GPT2 variants. Experiments are implemented with the text generation toolkit Texar (Hu et al., 2019). We provide more details in Appendix B.

Model	**Pre (1)**	**Plot (2)**	**CF (3)**
GPT + ZS	1.945	1.290	1.555
GPT2-S + ZS	1.945	1.335	1.475
GPT2-M + ZS	2.435	1.615	2.045
GPT + FT	2.485	1.750	2.005
GPT2-S + FT	2.365	1.645	1.895
GPT2-M + FT	2.580	1.790	**2.070**
GPT + FT + CF	2.310	1.595	1.925
GPT2-S + FT + CF	2.310	1.640	1.850
GPT2-M + FT + CF	2.395	1.650	1.945

GPT2-M + RC + CF	**2.780**	2.595	1.660
GPT + Sup	2.630	**2.690**	1.460
GPT2-S + Sup	2.705	2.650	1.625
GPT2-M + Sup	2.750	2.620	1.820
Human	2.830	2.545	2.520

Table 4: Likert scale scores for different models. The top performing model for each question is **bolded**.

5 Human Study of Rewritten Sentences

To assess the quality of rewritten endings, we conduct two sets of human evaluation. To give a sense of the model generation, Table 3 presents example outputs by a subset of representative models on two test cases.

5.1 Rewritten Sentence Scoring

Setup In this setting, workers from Amazon Mechanical Turk were presented 100 outputs from 14 different models. For each example, two workers were presented the original premise sentence, the original ending, the counterfactual sentence, and the rewritten ending, and asked to answer the following three questions on a 3-point Likert scale:
(1) Does the rewritten ending keep in mind details of the original premise sentence?
(2) Is the plot of the rewritten ending relevant to the plot of the original ending?
(3) Does the rewritten ending respect the changes induced by the counterfactual sentence?
In addition to evaluating the 14 models, we also provided gold human annotated counterfactual endings for the same 100 test examples to compute an expected upper bound for how models should perform. We present the results from this study in Table 4 and share key observations below.

Model Size and Pretraining Data We observe that models with more parameters are better at the counterfactual rewriting task than smaller models. The GPT2-M variants consistently outperform the GPT and GPT2-S models, regardless of the objective on which the model was trained. Interestingly, however, the GPT model appears to generally outperform the GPT2-S model on the counterfactual question **(3)**, indicating that the domain on which models are pretrained does affect how adaptable their representations are to the story rewriting task.

Domain Adaptation Another pattern we notice is that fine-tuning on the ROCStories data (FT) is always helpful for increasing performance on counterfactual relevance (**CF (3)** in Table 4), indicating adapting to the ROCStories-style language distribution helps the model learn to produce relevant rewrites for counterfactuals, especially for models with fewer parameters. The **Plot (2)** question in Table 4 indicates why this might be the case, as the zero-shot models tend to produce more creative rewritings that are not at all tied to the original story. Interestingly, however, fine-tuning with the larger set of counterfactuals (CF loss) does not seem to help in rewriting endings that relate to the counterfactuals well.

Supervised vs. Unsupervised Learning A surprising observation is that using the dataset of labeled rewritten endings for training does not seem to help the language models learn to rewrite endings better. While the supervised models are generally able to adhere to the plot better than unsupervised methods, their new endings do not score well on question **(3)**, indicating that they may be copying the original ending or learning to paraphrase the original story ending without acknowledging the counterfactual sentence. This points to the fact that this task cannot be trivially solved by adding more paired data, since adding more data merely simplifies to having more stories in the dataset, without necessarily learning to handle counterfactuals more effectively.

COUNTERFACTUAL - Human Judges Preferred				
Best model		Neutral	Comparator	
M+Sup	20.0	7.0	**29.5**	M+FT+CF
M+Sup	19.0	3.0	**38.5**	M+FT
M+Sup	**23.5**	14.0	4.5	M+Recon+ CF
M+Sup	26.5	5.0	**33.5**	M+ zero-shot
M+Sup	**14.0**	18.5	6.0	S+Sup
M+Sup	**18.5**	20.0	8.0	GPT + Sup

M+Sup	12.5	59.0	**22.5**	Human

Table 5: Pairwise human comparison between the best model (GPT2-M + Sup) and comparison models on all three questions. "Neutral" means both are "equally good". Percentage of "equally bad" are omitted.

5.2 Pairwise Model Preference

Setup We conduct a pairwise comparison between the best model (GPT2-M + Sup) with other models along the same three dimensions as in the first evaluation setting (section 5.1).

Metric	(1) Prem	(2) Plot	(3) CF
BLEU-4	**.2623**	**.6792**	**-.1804**
ROUGE-L	**.3187**	**.7484**	**-.1423**
WMS	**.2713**	**.5809**	-.0343
S+WMS	**.2789**	**.6075**	-.0538
BERT	**.2124**	**.1929**	**.1067**
BERT-FT	**.2408**	**.1847**	**.0995**

Table 6: Pearson correlation between automatic metrics and human scores. **Bolded** numbers are statistically significant at $p < 0.05$.

Specifically, crowdworkers were presented outputs of a pair of systems, and asked to choose which one is better, or "equally good" or "equally bad", in terms of each of the three criteria. As in section 5.1, we evaluate 100 outputs of each model.

Results In Table 5, we present the human preference results, showing that the best model outperforms the comparison baselines in terms of consistency with premise, while being less consistently better with regards to the other two questions. Interestingly, a model that performs better on one of the evaluated dimensions often performs worse for another question, indicating plenty of room for future work in counterfactual reasoning for story rewriting.

6 Challenges for Automatic Metrics

While human scores provide the clearest insight into how models are able to complete the counterfactual rewriting task, their associated cost makes them difficult to scale to larger evaluation sets. To provide further insight into the performance of candidate models, we explore how different automatic metrics evaluate the produced generations.

6.1 Metrics

Overlap Metrics The most common metrics used in evaluating text generation are based on textual overlap between a candidate generated sequence and set of reference sequences provided by the dataset. **BLEU** (Papineni et al., 2002) is perhaps the most widely used metric in text generation, which computes the number of overlapping n-grams between the generated and reference sequences. Another commonly used metric in text generation (though originally designed for extractive summarization) is **ROUGE-L** (Lin, 2004), which measures the length of the longest common subsequence (LCS) between a candidate generation and reference. We report the performance of all models on both of these metrics.

Model-based Metrics Although BLEU and ROUGE are widely used in text generation, they use exact string matching, and thus fail to robustly match paraphrases and capture semantically-critical ordering changes. Recently, there has been a growing body of work in producing model-based metrics (Lowe et al., 2017) that use trained models and embeddings to score a sequence.

Kusner et al. (2015) proposed Word Mover's Distance, which defines the distance between two texts as the minimal cost of transforming one sequence's word embeddings to the other's. The measure finds a matching between the two texts that minimizes the total Euclidean distance between the matched word embeddings. Following Kilickaya et al. (2017), we take the negative exponential of this distance to get **Word Mover's Similarity (WMS)**. More recently, Clark et al. (2019) proposed **Sentence + Word Mover's Similarity (S+WMS)** to extend WMS for longer multi-sentence texts by using sentence representations in the minimum distance calculation in addition to word embeddings.[1]

Other recent methods use contextualized embeddings (Devlin et al., 2018) to compute similarity between sequences. We use **BERTScore** (Zhang et al., 2019), which computes cosine similarity between two sentences using BERT encodings. Zhang et al. show that BERTScore correlates better with human judgments than existing metrics such as BLEU, ROUGE, and other learning-based metrics. To adapt BERTScore to our task, we finetune BERT on ROCStories using the same training framework from Devlin et al. (2018) and compute **BERT-FT** the same way as before.

6.2 Human Correlation with Metrics

Recent work in text generation (Wiseman et al., 2017) and dialogue (Liu et al., 2016) have explored the limitations of automatic metrics for text production tasks. Due to the highly semantic nature of the counterfactual rewriting task and the need to recognize subtle changes in

[1]We follow previous work and use GloVe embeddings (Pennington et al., 2014) to represent words and the averaged word embeddings to represent sentences.

	BLEU-4	ROUGE-L	BERT	BERT-FT	WMS	W+SMS
Training: Pretrained Only				*Input:* $\boldsymbol{s}_1\boldsymbol{s}_2'$

Table 7: Results on automatic metrics for the cross-product of the models and loss functions proposed in Section 4. **Bolded** results are closest to the human score.

event descriptions, we anticipate that automatic metrics would have difficulty assessing rewritten endings. To test the correlation between available evaluation metrics for long-form generation and human opinions of quality of counterfactual generations, we compute the Pearson Correlation between automatic scores and human scores for 800 validation set data points, 300 taken from the gold annotations and 100 generated from each of the 5 GPT2-M variants.[2] For each example, we use the same questions and Likert scale evaluation as in §5 and report the results in Table 6.

As expected, the automatic metrics are decently correlated with human scores for adherence to the premise sentence and plot. However, these same metrics correlate negatively with question **(3)** – adherence to the counterfactual sentence – indicating poor measurement of counterfactual understanding if they were to be reported in their typical manner (i.e., higher score indicating superior performance). Only the BERTScore metrics appear to positively correlate with human scores for counterfactual understanding, making them usable for evaluating generations across properties related to all three questions. However, the correlation is weak, and the results in Table 7 indicate that the BERTScore metrics are difficult to distinguish between models.

[2]We include both human annotations and model-generated outputs in this computation to encourage diversity of source.

7 Conclusion

We introduced a new task of *Counterfactual Story Rewriting* that challenges current language understanding and generation systems with counterfactual reasoning. Our new dataset, TIMETRAVEL, provides nearly 30k counterfactual revisions to simple commonsense stories together with 100k counterfactual sentences. We establish baseline performances of state-of-the-art neural language models with over 14 model variants with zero-shot, unsupervised and supervised settings. The empirical results demonstrate that while neural language models show promises, they generally have difficulties in rewriting the consequences of the counterfactual condition with full consistency, suggesting more focused research on integrating true reasoning capabilities to neural language models.

Abstract

We propose LASERTAGGER—a sequence tagging approach that casts text generation as a text editing task. Target texts are reconstructed from the inputs using three main edit operations: *keeping* a token, *deleting* it, and *adding* a phrase before the token. To predict the edit operations, we propose a novel model, which combines a BERT encoder with an autoregressive Transformer decoder. This approach is evaluated on English text on four tasks: sentence fusion, sentence splitting, abstractive summarization, and grammar correction. LASERTAGGER achieves new state-of-the-art results on three of these tasks, performs comparably to a set of strong seq2seq baselines with a large number of training examples, and outperforms them when the number of examples is limited. Furthermore, we show that at inference time tagging can be more than two orders of magnitude faster than comparable seq2seq models, making it more attractive for running in a live environment.

1 Introduction

Neural sequence-to-sequence (seq2seq) models provide a powerful framework for learning to translate source texts into target texts. Since their first application to machine translation (MT) (Sutskever et al., 2014) they have become the de facto approach for virtually every text generation task, including summarization (Tan et al., 2017), image captioning (Xu et al., 2015), text style transfer (Rao and Tetreault, 2018; Nikolov and Hahnloser, 2018; Jin et al., 2019), and grammatical error correction (Chollampatt and Ng, 2018; Grundkiewicz et al., 2019).

We observe that in some text generation tasks, such as the recently introduced *sentence splitting* and *sentence fusion* tasks, output texts highly overlap with inputs. In this setting, learning a seq2seq model to generate the output text from scratch seems intuitively wasteful. Copy mechanisms (Gu et al., 2016; See et al., 2017) allow for choosing between copying source tokens and generating arbitrary tokens, but although such hybrid models help with out-of-vocabulary words, they still require large training sets as they depend on output vocabularies as large as those used by the standard seq2seq approaches.

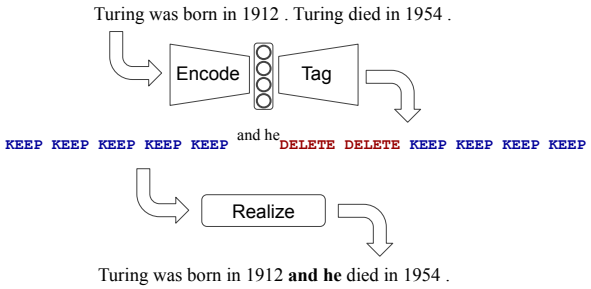

Figure 1: LASERTAGGER applied to sentence fusion.

In contrast, we propose learning a text editing model that applies a set of edit operations on the input sequence to reconstruct the output. We show that it is often enough to use a relatively small set of output tags representing text deletion, rephrasing and word reordering to be able to reproduce a large percentage of the targets in the training data. This results in a learning problem with a much smaller vocabulary size, and the output length fixed to the number of words in the source text. This, in turn, greatly reduces the number training examples required to train accurate models, which is particularly important in applications where only a small number of human-labeled data is available.

Our tagging approach, LASERTAGGER, consists of three steps (Fig. 1): (i) *Encode* builds a representation of the input sequence, (ii) *Tag* assigns edit tags from a pre-computed output vocabulary to the input tokens, and (iii) *Realize* applies a simple set of rules to convert tags into the output text tokens.

An experimental evaluation of LASERTAGGER

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5054–5065,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

on four different text generation tasks shows that it yields comparable results to seq2seq models when we have tens of thousands of training examples and clearly outperforms them when the number of examples is smaller.

Our contributions are the following:

1) We demonstrate that many text generation tasks with overlapping inputs and outputs can be effectively treated as text editing tasks.

2) We propose LASERTAGGER—a sequence tagging-based model for text editing, together with a method for generating the tag vocabulary from the training data.

3) We describe two versions of the tagging model: (i) LASERTAGGER$_{\text{FF}}$—a tagger based on BERT (Devlin et al., 2019) and (ii) LASERTAGGER$_{\text{AR}}$—a novel tagging model combining the BERT encoder with an autoregressive Transformer decoder, which further improves the results over the BERT tagger.

4) We evaluate LASERTAGGER against strong seq2seq baseline models based on the BERT architecture. Our baseline models outperform previously reported state-of-the-art results on two tasks.

5) We demonstrate that a) LASERTAGGER$_{\text{AR}}$ achieves state-of-the-art or comparable results on 3 out of 4 examined tasks, b) LASERTAGGER$_{\text{FF}}$ is up to *100x faster at inference time* with performance comparable to the state-of-the-art seq2seq models. Furthermore, both models: c) require much *less training data* compared to the seq2seq models, d) are more *controllable and interpretable* than seq2seq models due to the small vocabulary of edit operations, e) are *less prone* to typical seq2seq model errors, such as hallucination.

The code will be available at:
`lasertagger.page.link/code`

2 Related Work

Recent work discusses some of the difficulties of learning neural decoders for text generation (Wiseman et al., 2018; Prabhakaran et al., 2018). Conventional seq2seq approaches require large amounts of training data, are hard to control and to constrain to desirable outputs. At the same time, many NLP tasks that appear to be full-fledged text generation tasks are natural testbeds for simpler methods. In this section we briefly review some of these tasks.

Text Simplification is a paraphrasing task that is known to benefit from modeling edit operations. A simple instance of this type are sentence compression systems that apply a drop operation at the token/phrase level (Filippova and Strube, 2008; Filippova et al., 2015), while more intricate systems also apply splitting, reordering, and lexical substitution (Zhu et al., 2010). Simplification has also been attempted with systems developed for phrase-based MT (Xu et al., 2016a), as well as with neural encoder-decoder models (Zhang and Lapata, 2017).

Independent of this work, Dong et al. (2019) recently proposed a text-editing model, similar to ours, for text simplification. The main differences to our work are: (i) They introduce an interpreter module which acts as a language model for the so-far-realized text, and (ii) they generate added tokens one-by-one from a full vocabulary rather than from an optimized set of frequently added phrases. The latter allows their model to generate more diverse output, but it may negatively effect the inference time, precision, and the data efficiency of their model. Another recent model similar to ours is called Levenshtein Transformer Gu et al. (2019), which does text editing by performing a sequence of deletion and insertion actions.

Single-document summarization is a task that requires systems to shorten texts in a meaning-preserving way. It has been approached with deletion-based methods on the token level (Filippova et al., 2015) and the sentence level (Narayan et al., 2018; Liu, 2019). Other papers have used neural encoder-decoder methods (Tan et al., 2017; Rush et al., 2015; Paulus et al., 2017) to do *abstractive* summarization, which allows edits beyond mere deletion. This can be motivated by the work of Jing and McKeown (2000), who identified a small number of fundamental high-level editing operations that are useful for producing summaries (reduction, combination, syntactic transformation, lexical paraphrasing, generalization/specification, and reordering). See et al. (2017) extended a neural encoder-decoder model with a copy mechanism to allow the model to more easily reproduce input tokens during generation.

Out of available summarization datasets (Dernoncourt et al., 2018), we find the one by Toutanova et al. (2016) particularly interesting because (1) it specifically targets abstractive summarization systems, (2) the lengths of texts in this dataset (short paragraphs) seem well-suited for text editing, and (3) an analysis showed that the dataset covers many different summarization operations.

In **Grammatical Error Correction** (Ng et al.,

2013, 2014) a system is presented with input texts written usually by a language learner, and is tasked with detecting and fixing grammatical (and other) mistakes. Approaches to this task often incorporate task-specific knowledge, e.g., by designing classifiers for specific error types (Knight and Chander, 1994; Rozovskaya et al., 2014) that can be trained without manually labeled data, or by adapting statistical machine-translation methods (Junczys-Dowmunt and Grundkiewicz, 2014). Methods for the sub-problem of error *detection* are similar in spirit to sentence compression systems, in that they are implemented as word-based neural sequence labelers (Rei, 2017; Rei et al., 2017). Neural encoder-decoder methods are also commonly applied to the error correction task (Ge et al., 2018; Chollampatt and Ng, 2018; Zhao et al., 2019), but suffer from a lack of training data, which is why task-specific tricks need to be applied (Kasewa et al., 2018; Junczys-Dowmunt et al., 2018).

3 Text Editing as a Tagging Problem

Our approach to text editing is to cast it into a tagging problem. Here we describe its main components: (1) the tagging operations, (2) how to convert plain-text training targets into a tagging format, as well as (3) the realization step to convert tags into the final output text.

3.1 Tagging Operations

Our tagger assigns a tag to each input token. A tag is composed of two parts: a *base tag* and an *added phrase*. The base tag is either `KEEP` or `DELETE`, which indicates whether to retain the token in the output. The added phrase P, which can be empty, enforces that P is added before the corresponding token. P belongs to a vocabulary V that defines a set of words and phrases that can be inserted into the input sequence to transform it into the output.

The combination of the base tag B and the added phrase P is treated as a single tag and denoted by ${}^{P}B$. The total number of unique tags is equal to the number of base tags times the size of the phrase vocabulary, hence there are $\approx 2|V|$ unique tags.

Additional task-specific tags can be employed too. For sentence fusion (Section 5.1), the input consists of two sentences, which sometimes need to be swapped. Therefore, we introduce a custom tag, `SWAP`, which can only be applied to the last period of the first sentence (see Fig. 2). This tag instructs the Realize step to swap the order of the input sentences before realizing the rest of the tags.

For other tasks, different supplementary tags may be useful. E.g., to allow for replacing entity mentions with the appropriate pronouns, we could introduce a `PRONOMINALIZE` tag. Given an access to a knowledge base that includes entity gender information, we could then look up the correct pronoun during the realization step, instead of having to rely on the model predicting the correct tag (${}^{\text{she}}$`DELETE`, ${}^{\text{he}}$`DELETE`, ${}^{\text{they}}$`DELETE`, etc.).

3.2 Optimizing Phrase Vocabulary

The phrase vocabulary consists of phrases that can be added between the source words. On the one hand, we wish to minimize the number of phrases to keep the output tag vocabulary small. On the other hand, we would like to maximize the percentage of target texts that can be reconstructed from the source using the available tagging operations. This leads to the following combinatorial optimization problem.

Problem 1 *Given a collection of phrase sets $A_1, A_2, \ldots A_m$, where $A_i \subseteq P$ and P is the set of all candidate phrases, select a phrase vocabulary $V \subset P$ of at most ℓ phrases (i.e. $|V| \leq \ell$) so that the number of covered phrase sets is maximized. A phrase set A_i is covered if and only if $A_i \subseteq V$.*

This problem is closely related to the minimum k-union problem which is NP-hard (Vinterbo, 2002). The latter problem asks for a set of k phrase sets such that the cardinality of their union is the minimum. If we were able to solve Problem 1 in polynomial time, we could solve also the minimum k-union problem in polynomial time simply by finding the smallest phrase vocabulary size ℓ such that the number of covered phrase sets is at least k. This reduction from the minimum k-union problem gives us the following result:

Theorem 1 *Problem 1 is NP-hard.*

To identify candidate phrases to be included in the vocabulary, we first align each source text s from the training data with its target text t. This is achieved by computing the *longest common subsequence* (LCS) between the two word sequences, which can be done using dynamic programming in time $\mathcal{O}(|s| \times |t|)$. The n-grams in the target text that are not part of the LCS are the phrases that would need to be included in the phrase vocabulary to be able to construct t from s.

Tags:	DELETE	KEEP	KEEP	KEEP	SWAP	KEEP	^{comma}DELETE		KEEP	KEEP	KEEP	^{comma}DELETE	
Realization:	Dylan , an American musician , won Nobel prize .												

Figure 2: An example sentence fusion obtained by tagging using the SWAP tag, which swaps the order of the two source sentences.

In practice, the phrase vocabulary is expected to consist of phrases that are frequently added to the target. Thus we adopt the following simple approach to construct the phrase vocabulary: sort the phrases by the number of phrase sets in which they occur and pick ℓ most frequent phrases. This was found to produce meaningful phrase vocabularies based on manual inspection as shown in Section 5. E.g., the top phrases for sentence fusions include many discourse connectives.

We also considered a greedy approach that constructs the vocabulary one phrase at a time, always selecting the phrase that has the largest incremental coverage. This approach is not, however, ideal for our use case, since some frequent phrases, such as "(" and ")", are strongly coupled. Selecting "(" alone has close to zero incremental coverage, but together with ")", they can cover many examples.

3.3 Converting Training Targets into Tags

Once the phrase vocabulary is determined, we can convert the target texts in our training data into tag sequences. Given the phrase vocabulary, we do not need to compute the LCS, but can leverage a more efficient approach, which iterates over words in the input and greedily attempts to match them (1) against the words in the target, and in case there is no match, (2) against the phrases in the vocabulary V. This can be done in $\mathcal{O}(|s| \times n_p)$ time, where n_p is the length of the longest phrase in V, as shown in Algorithm 1.

The training targets that would require adding a phrase that is not in our vocabulary V, will not get converted into a tag sequence but are filtered out. While making the training dataset smaller, this may effectively also filter out low-quality targets. The percentage of converted examples for different datasets is reported later in Section 5. Note that even when the target cannot be reconstructed from the inputs using our output tag vocabulary, our approach might still produce reasonable outputs with the available phrases. E.g., a target may require the use of the infrequent ";" token, which is not in our vocabulary, but a model could instead choose to predict a more common "," token.

Algorithm 1 Converting a target string to tags.

Input: Source text $s = [s(1), \ldots, s(n_s)]$, target text $t = [t(1), \ldots, t(n_t)]$, phrase vocabulary V, and the maximum added phrase length n_p.
Output: Tag sequence x of length n_s or of length 0 if conversion is not possible.

$x(i) =$ DELETE, $\forall i = 1, \ldots, n_s$ ▷ Initialize tags.
$i_s = 1$ ▷ Current source word index.
$i_t = 1$ ▷ Current target word index.
while $i_t \leq n_t$ **do**
  if $i_s > n_s$ **then**
    return [] ▷ Conversion infeasible.
  if $s(i_s) == t(i_t)$ **then**
    $x(i_s) =$ KEEP
    $i_t = i_t + 1$
  else
    $p = []$ ▷ Added phrase (word sequence).
    match_found $= 0$
    for $j = 1, \ldots, n_p$ **do**
      p.append($t(i_t + j - 1)$)
      if $s(i_s) == t(i_t + j)$ **and** $p \in V$ **then**
        match_found $= 1$
        break
    if match_found **then**
      $x(i_s) = {}^{p}$KEEP
      $i_t = i_t + |p| + 1$
  $i_s = i_s + 1$
return x ▷ Target has been consumed, so return tags.

3.4 Realization

After obtaining a predicted tag sequence, we convert it to text ("realization" step). While classic works on text generation make a distinction between *planning* and *realization*, end-to-end neural approaches typically ignore this distinction, with the exception of few works (Moryossef et al., 2019; Puduppully et al., 2018).

For the basic tagging operations of keeping, deleting, and adding, realization is a straightforward process. Additionally, we adjust capitalization at sentence boundaries. Realization becomes more involved if we introduce special tags, such as PRONOMINALIZE mentioned in Section 3.1. For this tag, we would need to look up the gender of the tagged entity from a knowledge base. Having a separate realization step is beneficial, since we can decide to pronominalize only when confident about the appropriate pronoun and can, otherwise, leave the entity mention untouched.

Another advantage of having a separate realiza-

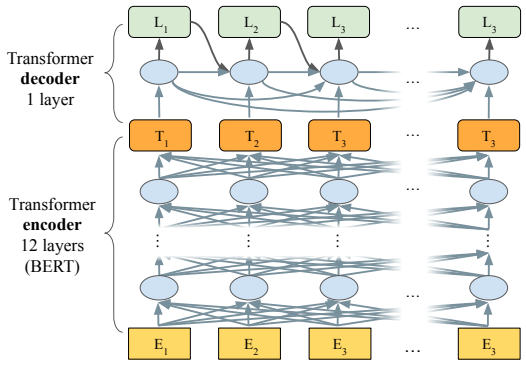

Figure 3: The architecture of LASERTAGGER$_{\text{AR}}$.

tion step is that specific loss patterns can be addressed by adding specialized realization rules. For instance, one could have a rule that when applying tag $^{\text{his}}$DELETE to an entity mention followed by *'s*, the realizer must always DELETE the possessive *'s* regardless of its predicted tag.

4 Tagging Model Architecture

Our tagger is composed of two components: an encoder, which generates activation vectors for each element in the input sequence, and a decoder, which converts encoder activations into tag labels.

Encoder. We choose the BERT Transformer model (Devlin et al., 2019) as our encoder, as it demonstrated state-of-the-art results on a number of sentence encoding tasks. We use the BERT-base architecture, which consists of 12 self-attention layers. We refer the reader to (Devlin et al., 2019) for a detailed description of the model architecture and its input representation. We initialize the encoder with a publicly available checkpoint of the pretrained case-sensitive BERT-base model.[1]

Decoder. In the original BERT paper a simple decoding mechanism is used for sequence tagging: the output tags are generated in a single feed-forward pass by applying an argmax over the encoder logits. In this way, each output tag is predicted independently, without modelling the dependencies between the tags in the sequence. Such a simple decoder demonstrated state-of-the-art results on the Named Entity Recognition task, when applied on top of the BERT encoder.

To better model the dependencies between the output tag labels, we propose a more powerful autoregressive decoder. Specifically, we run a single-layer Transformer decoder on top of the BERT encoder (see Fig. 3). At each step, the decoder is consuming the embedding of the previously predicted label and the activations from the encoder.

There are several ways in which the decoder can communicate with the encoder: (i) through a full attention over the sequence of encoder activations (similar to conventional seq2seq architectures); and (ii) by directly consuming the encoder activation at the current step. In our preliminary experiments, we found the latter option to perform better and converge faster, as it does not require learning additional encoder-decoder attention weights.

We experiment with both decoder variants (*feedforward* and *autoregressive*) and find that the autoregressive decoder outperforms the previously used *feedforward* decoder. In the rest of this paper, the tagging model with an *autoregressive* decoder is referred to as LASERTAGGER$_{\text{AR}}$ and the model with *feedforward* decoder as LASERTAGGER$_{\text{FF}}$.

5 Experiments

We evaluate our method by conducting experiments on four different text editing tasks: Sentence Fusion, Split and Rephrase, Abstractive Summarization, and Grammatical Error Correction.

Baselines. In addition to reporting previously published results for each task, we also train a set of strong baselines based on Transformer where both the encoder and decoder replicate the BERT-base architecture (Devlin et al., 2019). To have a fair comparison, similar to how we initialize a tagger encoder with a pretrained BERT checkpoint, we use the same initialization for the Transformer encoder. This produces a very strong seq2seq baseline (SEQ2SEQ$_{\text{BERT}}$), which already results in new state-of-the-art metrics on two out of four tasks.

5.1 Sentence Fusion

Sentence Fusion is the problem of fusing sentences into a single coherent sentence.

Data. We use the "balanced Wikipedia" portion of Geva et al. (2019)'s DiscoFuse dataset for our experiments (henceforth DfWiki). Out of the 4.5M fusion examples in the dataset, 10.5% require reordering of the input. To cope with this, we introduce the SWAP tag, which enables the model to flip the order of two input sentences. We construct the phrase vocabulary as described in Sec. 3.2 using the validation set of 46K examples. The top 15 phrases are shown in the first column of Table 1.

Evaluation metrics. Following Geva et al. (2019), we use two evaluation metrics: *Exact score*,

[1] github.com/google-research/bert

DfWiki	WikiSplit	AS	GEC
,	.␣⟨::::⟩	,	,
and	,	.	.
however␣,	.␣⟨::::⟩␣he	the	the

,␣which	.␣⟨::::⟩␣however	n't	and
she	he	an	that

Table 1: The 15 most frequently added phrases in the datasets studied in this work, in order of decreasing frequency. ⟨::::⟩ marks a sentence boundary. "AS"/"GEC" is short for Abstractive Summarization/Grammatical Error Correction.

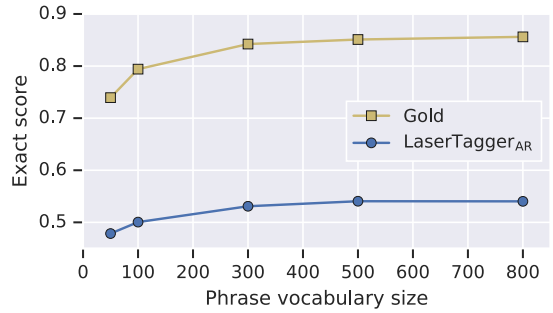

Figure 4: Performance of model LaserTagger$_{AR}$ on the DfWiki dataset, conditioned on the vocabulary size and the gold score, i.e. the percentage of examples that can be reconstructed via text-edit operations.

which is the percentage of exactly correctly predicted fusions, and *SARI* (Xu et al., 2016b), which computes the average F1 scores of the added, kept, and deleted n-grams.[2]

Vocabulary Size. To understand the impact of the number of phrases we include in the vocabulary, we trained models for different vocabulary sizes (only LaserTagger$_{AR}$). The results are shown in Figure 4. After increasing the vocabulary size to 500 phrases, Exact score reaches a plateau, so we set the vocabulary size to 500 in all the remaining experiments of this paper.[3] The Gold curve in Fig. 4 shows that this vocabulary size is sufficient to cover 85% of the training examples, which gives us an upper bound for the Exact score.

Model	Exact	SARI
Transformer (Geva et al., 2019)	51.1	84.5
SEQ2SEQ$_{BERT}$	53.6	85.3
LaserTagger$_{AR}$ (no SWAP)	46.4	80.4
LaserTagger$_{FF}$	52.2	84.1
LaserTagger$_{AR}$	**53.8**	**85.5**

Table 2: Sentence fusion results on DfWiki.

Comparison against Baselines. Table 2 lists the results for the DfWiki dataset. We obtain new SOTA results with LaserTagger$_{AR}$, outperforming the previous SOTA 7-layer Transformer model from Geva et al. (2019) by 2.7% Exact score and 1.0% SARI score. We also find that the pretrained SEQ2SEQ$_{BERT}$ model yields nearly as good performance, demonstrating the effectiveness of unsupervised pretraining for generation tasks. The performance of the tagger is impaired significantly when leaving out the SWAP tag due to the model's inability to reconstruct 10.5% of the training set.

Impact of Dataset Size. We also study the effect of the training data size by creating four increasingly smaller subsets of DfWiki (see Fig. 5a).[4] When data size drops to 450 or 4 500 examples, LaserTagger still performs surprisingly well, clearly outperforming the SEQ2SEQ$_{BERT}$ baseline.

5.2 Split and Rephrase

The reverse task of sentence fusion is the *split-and-rephrase* task, which requires rewriting a long sentence into two or more coherent short sentences.

Data. We use the WikiSplit dataset (Botha et al., 2018), which consists of 1M human-editor created examples of sentence splits, and follow the dataset split suggested by the authors. Using the phrase vocabulary of size 500 yields a 31% coverage of the targets from the training set (top phrases shown in Table 1). The lower coverage compared to DfWiki suggests a higher amount of noise (due to Wikipedia-author edits unrelated to splitting).

Results. Botha et al. (2018) report results using a one-layer, bi-directional LSTM (cell size 512) with attention and a copying mechanism (See

[2]We use the implementation available at git.io/fj8Av, setting $\beta = 1$ for deletion (Geva et al., 2019).

[3]For smaller datasets, a smaller vocabulary size may yield better results, but for simplicity, we do not optimize the size separately for each dataset.

[4]For simplicity, we use the same phrase vocabulary of size 500 computed using the validation set of 46K examples for all experiments. Note that even though some subsampled training sets contain less than 46K examples, using the same vocabulary does not give the taggers an unfair advantage over the baselines, because the tagger will never predict a phrase it has not seen in the training data.

(a) Sentence Fusion on DfWiki.

(b) Split and Rephrase on WikiSplit.

Figure 5: SARI score as a function of the training-data size for three models. Unless we have tens of thousands of training examples, the tagging approach clearly outperforms the seq2seq baseline.

Model	BLEU	Exact	SARI
seq2seq (Botha et al., 2018)	76.0	14.6	60.6
SEQ2SEQ$_{BERT}$	**76.7**	15.1	**62.3**
LASERTAGGER$_{FF}$	76.0	14.4	61.3
LASERTAGGER$_{AR}$	76.3	**15.2**	61.7

Table 3: Results on the WikiSplit dataset.

Model	BLEU-4	Exact	SARI	ROUGE-L
Filippova et al. (2015)	26.7	0.0	36.2	70.3
Clarke and Lapata (2008)	28.5	0.3	41.5	77.5
Cohn and Lapata (2008)	5.1	0.1	27.4	40.7
Rush et al. (2015)	16.2	0.0	35.6	62.5
SEQ2SEQ$_{BERT}$	8.3	0.1	32.1	52.7
LASERTAGGER$_{FF}$	33.7	1.5	44.2	81.9
LASERTAGGER$_{AR}$	**35.6**	**3.8**	**44.8**	**82.8**

Table 4: Results on summarization.

et al., 2017).[5] The results are shown in Table 3. SEQ2SEQ$_{BERT}$ and LASERTAGGER$_{AR}$ yield similar performance with each other, and they both outperform the seq2seq model with a copying mechanism from Botha et al. (2018).

We again studied the impact of training-data size by subsampling the training set, see Figure 5b. Similar to the previous experiment, the LASERTAGGER methods degrade more gracefully when reducing training-data size, and start to outperform the seq2seq baseline once going below circa 10k examples. The smallest training set for LASERTAGGER$_{AR}$ contains merely 29 examples. Remarkably, the model is still able to learn something useful that generalizes to unseen test examples, reaching a SARI score of 53.6% and predicting 5.2% of the targets exactly correctly. The following is an example prediction by the model:

Source: Delhi Public Library is a national depository library in Delhi , India , it has over 35 branches across the state .

Prediction: Delhi Public Library is a national depository library in Delhi , India . ⟨::::⟩ It has over 35 branches across the state .

Here the model has picked the right comma to replace with a period and a sentence separator.

[5]Botha et al. (2018) report only BLEU but they kindly shared with us their model's predictions, allowing us to compute the Exact and SARI score for their method. Similar to their work, we used NLTK v3.2.2 for the BLEU computation.

5.3 Abstractive Summarization

The task of summarization is to reduce the length of a text while preserving its meaning.

Dataset. We use the dataset from Toutanova et al. (2016), which contains 6,168 short input texts (one or two sentences) and one or more human-written summaries. The human experts were not restricted to just deleting words when generating a summary, but were allowed to also insert new words and reorder parts of the sentence, which makes this dataset particularly suited for *abstractive summarization* models.

We set the size of the phrase vocabulary to 500, as for the other tasks, and extract the phrases from the training partition. With a size of 500, we are able to cover 89% of the training data.

Evaluation Metrics. In addition to the metrics from the previous sections, we report ROUGE-L (Lin, 2004), as this is a metric that is commonly used in the summarization literature. ROUGE-L is a recall-oriented measure computed as the longest common sub-sequence between a reference summary and a candidate summary.

Results. Table 4 compares our taggers against seq2seq baselines and systems from the literature.[6] Filippova et al. (2015) and Clarke and Lapata (2008) proposed deletion-based approaches;

[6]Results are extracted from Toutanova et al. (2016).

the former uses a seq2seq network, the latter formulates summarization as an optimization problem that is solved via integer-linear programming. Cohn and Lapata (2008) proposed an early approach to abstractive summarization via a parse-tree transducer. Rush et al. (2015) developed a neural seq2seq model for abstractive summarization.

In line with the results on the subsampled fusion/splitting datasets (Figure 5), the tagger significantly outperforms all baselines. This shows that even though a text-editing approach is not well-suited for extreme summarization examples (a complete paraphrase with zero lexical overlap), in practice, already a limited paraphrasing capability is enough to reach good empirical performance.

Note that the low absolute values for the Exact metric are expected, since there is a very large number of acceptable summaries.

5.4 Grammatical Error Correction (GEC)

GEC requires systems to identify and fix grammatical errors in a given input text.

Data. We use a recent benchmark from a shared task of the 2019 Building Educational Applications workshop, specifically from the Low Resource track[7] (Bryant et al., 2019). The publicly available set has 4,384 ill-formed sentences together with gold error corrections, which we split 9:1 into a training and validation partition. We again create the phrase vocabulary from the 500 most frequently added phrases in the training partition, which gives us a coverage of 40% of the training data.

Evaluation Metrics and Results. We report precision and recall, and the task's main metric $F_{0.5}$, which gives more weight to the precision of the corrections than to their recall.

Table 5 compares our taggers against two baselines. Again, the tagging approach clearly outperforms the BERT-based seq2seq model, here by being more than seven times as accurate in the prediction of corrections. This can be accounted to the seq2seq model's much richer generation capacity, which the model can not properly tune to the task at hand given the small amount of training data. The tagging approach on the other hand is naturally suited to this kind of problem.

We also report the best-performing method by Grundkiewicz et al. (2019) from the shared task for informational purposes. They train a Transformer model using a dataset which is augmented by 100 million synthetic examples and 2 million Wikipedia edits, whereas we only use 4,384 sentences from the provided training dataset.

[7] www.cl.cam.ac.uk/research/nl/bea2019st/

Model	P	R	$F_{0.5}$
Grundkiewicz et al. (2019)	*70.19*	*47.99*	*64.24*
SEQ2SEQ$_{\text{BERT}}$	6.13	14.14	6.91
LASERTAGGER$_{\text{FF}}$	44.17	24.00	37.82
LASERTAGGER$_{\text{AR}}$	**47.46**	**25.58**	**40.52**

Table 5: Results on grammatical-error correction. Note that Grundkiewicz et al. (2019) augment the training dataset of 4,384 examples by 100 million synthetic examples and 2 million Wikipedia edits.

batch size	LASERTAGGER$_{\text{FF}}$	LASERTAGGER$_{\text{AR}}$	SEQ2SEQ$_{\text{BERT}}$
1	13	535	1,773
8	47	668	8,279
32	149	1,273	27,305

Table 6: Inference time (in ms) across various batch sizes on GPU (Nvidia Tesla P100) averaged across 100 runs with random inputs.

5.5 Inference time

Getting state-of-the-art results often requires using larger and more complex models. When running a model in production, one cares not only about the accuracy but also the inference time. Table 6 reports latency numbers for LASERTAGGER models and our most accurate seq2seq baseline. As one can see, the SEQ2SEQ$_{\text{BERT}}$ baseline is impractical to run in production even for the smallest batch size. On the other hand, for a batch size 8, LASERTAGGER$_{\text{AR}}$ is already 10x faster than comparable-in-accuracy SEQ2SEQ$_{\text{BERT}}$ baseline. This difference is due to the former model using a 1-layer decoder (instead of 12 layers) and no encoder-decoder cross attention. We also tried training SEQ2SEQ$_{\text{BERT}}$ with a 1-layer decoder but it performed very poorly in terms of accuracy. Finally, LASERTAGGER$_{\text{FF}}$ is more than 100x faster while being only a few accuracy points below our best reported results.

5.6 Qualitative evaluation

To assess the qualitative difference between the outputs of LASERTAGGER and SEQ2SEQ$_{\text{BERT}}$, we analyzed the texts generated by the models on the test sets of the four tasks. We inspected the respective worst predictions from each model according to BLEU and identified seven main error patterns,

Error type	LaserTagger	Seq2Seq$_{BERT}$	Example
Imaginary words	not affected	affected	In: … Zenica (Cyrillic: "Зеница") is … Out: … Zenica (Cyrillic: "**gratulation**еница") is …
Repeated phrases	not affected	affected	In: I'm your employee, to serve on your company. Out: I'm your **company**, to serve on your **company**.
Premature end-of-sentence	less affected	affected	In: By the way, my favorite football team is Manchester United, they … Out: By the way, my favorite football team is.
Hallucinations	less affected	affected	In: Tobacco smokers may also experience … Out: **anthropology** smokers may also experience …
Coreference issues	affected	affected	In: She is the daughter of Alistair Crane … who secretly built … Out: She is the daughter of Alistair Crane … ⟨::::⟩ **She** secretly built …
Misleading rephrasing	affected	affected	In: … postal service was in no way responsible … Out: … postal service **was responsible** …
Lazy sentence splitting	affected	not affected	In: Home world of the Marglotta located in the Sagittarius Arm. Out: Home world of the Marglotta . ⟨::::⟩ Located in the Sagittarius Arm.

Table 7: Main error patterns observed in the output of the tagging and seq2seq models on their test sets (all tasks).

two of which are specific to the seq2seq model, and one being specific to LaserTagger.

This illustrates that LaserTagger is less prone to errors compared to the standard seq2seq approach, due to the restricted flexibility of its model. Certain types of errors, namely imaginary words and repeated phrases, are virtually impossible for the tagger to make. The likelihood of others, such hallucination and abrupt sentence ending, is at least greatly reduced.

In Table 7, we list the error classes and refer to Appendix A for more details on our observations.

6 Conclusions

We proposed a text-editing approach to text-generation tasks with high overlap between input and output texts. Compared to the seq2seq models typically applied in this setting, our approach results in a simpler sequence-tagging problem with a much smaller output tag vocabulary. We demonstrated that this approach has comparable performance when trained on medium-to-large datasets, and clearly outperforms a strong seq2seq baseline when the number of training examples is limited. Qualitative analysis of the model outputs suggests that our tagging approach is less affected by the common errors of the seq2seq models, such as hallucination and abrupt sentence ending. We further demonstrated that tagging can speed up inference by more than two orders of magnitude, making it more attractive for production applications.

Limitations. Arbitrary word reordering is not feasible with our approach, although limited reordering can be achieved with deletion and insertion operations, as well as custom tags, such as `SWAP` (see Section 3.1). To enable more flexible reordering, it might be possible to apply techniques developed for phrase-based machine translation. Another limitation is that our approach may not be straightforward to apply to languages that are morphologically richer than English, where a more sophisticated realizer might be needed to adjust, e.g., the cases of the words.

In future work, we would like to experiment with more light-weight tagging architectures (Andor et al., 2016) to better understand the trade-off between inference time and model accuracy.

Acknowledgments

We would like to thank Enrique Alfonseca, Idan Szpektor, and Orgad Keller for useful discussions.

Abstract

Generating intriguing question is a key step towards building human-like open-domain chatbots. Although some recent works have focused on this task, compared with questions raised by humans, significant gaps remain in maintaining semantic coherence with the posts, which may result in generating dull or deviated questions. We observe that the answer has strong semantic coherence to its question and post, which can be used to guide question generation. Thus, we devise two methods to further enhance semantic coherence between post and question under the guidance of answer. First, the coherence score between generated question and answer is used as the reward function in a reinforcement learning framework, to encourage the cases that are consistent with the answer in semantic. Second, we incorporate adversarial training to explicitly control question generation in the direction of question-answer coherence. The extensive experiments show that our two methods outperform state-of-the-art baseline algorithms with large margins in raising semantic coherent questions.

1 Introduction

Neural question generation (NQG) has been extensively studied because of its broad application in question answering (QA) systems (Tang et al., 2018; Duan et al., 2017), reading comprehension (Kim et al., 2019; Sun et al., 2018), and visual question answering (Fan et al., 2018). However, the research of open-domain conversational question generation (CQG) (Wang et al., 2018; Hu et al., 2018) is still in its infancy. Different from traditional NQG task, the goal of CQG is to enhance the interactiveness and persistence of chit-chatting. Raising appropriate questions in the conversational system is essential because a mature system should well interact with users by not only responding posts but also asking questions (Li et al., 2016b). Furthermore, asking intriguing questions can proactively probe the users to go deeper and further into the conversational topic (Yu et al., 2016).

The existing CQG methods usually suffer from **dullness** and **deviation** problem, because the semantic coherence is easily disrupted. Wang et al. (2018) first studied the CQG task with PMI model to predict topic words in the inference, which may incorporate noise and generate deviated questions. Hu et al. (2018) proposed an aspect-based question generation model with an encoder-decoder method that did not consider the diversity and might raise dull questions.

Taking Table 1 as a motivating example, the topic of this conversation is about cooking and dishes. For the initial post about enjoying cooking, the appropriate response is a question asking about the special dishes or making appetizers, and the answer tells the exact dish, i.e. "*beef*". If we ignore the answer information, a dull question (e.g. "*What do you mean?*") or a deviated question (e.g. "*How about going singing?*") may be raised.

Table 1 shows that there exists semantic coherence in the post-question-answer conversational thread. The performance limitations of previous CQG literature partially lie in that they only consider the post to generate the question, but the answer that contains rich conversational semantics is ignored. In reading comprehension task, answer information could help to identify appropriate interrogative words (Kim et al., 2019), or copy appropriate phrase by position-aware attention (Sun et al., 2018). Similarly, answer information is leveraged to established the connection between QA and QG (Tang et al., 2018). Although the answer semantics are very effective in traditional NQG tasks, they have never been utilized for generating questions in conversations. Unlike NQG that

● Semantic coherence ● Dullness ● Deviation

Post
I like cooking more and more.
Question candidates
What are your special dishes ? ✓
Are you good at making appetizers ? ✓
What do you mean? ✗
How about going singing? ✗
Answer
Wow, I am only skillful in cooking beef.

Table 1: A motivating example of CQG task, including the post, question, and answer. In question candidate set, we list two intriguing questions and the other two unappropriate questions. The green words indicate the semantic coherence phenomenon. The blue and red words state the dull and deviated responses respectively. Note that the questions asking about the special dishes or making appetizers are all reasonable, and there is no exact match between question and answer.

the question and answer are manually designed according to the context and its goal is to generate an **accurate** and **exact matching** question, the triples are all **casual** and **non-goal-oriented** conversational utterances in CQG as shown in Table 1.

In this paper, we intend to utilize semantics in answer to guide conversational question generation. To the best of our knowledge, there is no prior work incorporating coherence between questions and answers into the CQG task. It is quite challenging to include question-answer semantic coherence into the objective function of supervised CQG models because the coherence also depends on answer information that does not exist in the inference process, i.e. we do not know the answer to the question in advance in a live chatbot. The unavailable answers during inference is the main difference between traditional NQG and CQG task.

To tackle these challenges, we propose two separate learning frameworks based on reinforcement learning (RL) (Sutton et al., 2000) and generative adversarial network (GAN) (Goodfellow et al., 2014) respectively. For the RL framework, we utilize semantic coherence as an estimation of question quality, with inspiration of the fact that the semantic (topic) is coherent in the same question-answer pair. We propose a GRU-MatchPyramid model that incorporates a bi-directional GRU into MatchPyramid model (Pang et al., 2016) to capture higher level's word semantic. Then we employ the pretrained GRU-MatchPyramid to measure the coherence between a question and its corresponding answer. After that, the coherence model is regarded as the environment in an RL framework for optimization, which will guide the learning process to penalize the dull and deviated questions. In addition, the environment is not required during inference.

For the GAN framework, we incorporate adversarial training to explicitly improve coherence between questions and answers. We jointly train a question generator and a discriminator (i.e. GRU-MatchPyramid model) that measures the semantic coherence between generated questions (as well as ground-truth questions) and answers. Only a well-trained generator is needed in inference.

The conditional variational autoencoders (C-VAE) is effective in capturing the diversity of valid responses (Zhao et al., 2017). Based on the advantage of CVAE, we further incorporate prior knowledge of question type to generate questions with reasonable type. Finally, we integrate CVAE into RL framework and GAN frameworks respectively, and propose two novel CQG models, dubbed as RL-CVAE and A-CVAE. Our contributions are summarized in three folds:

- We are the first to incorporate the answer factor into CQG task. The semantic coherence between questions and answers could guide the model to generate more appropriate questions.
- We propose two novel answer-guided semantic coherent CQG models, i.e. RL-CVAE and A-CVAE. The answer information is exploited with reinforcement learning and adversarial learning respectively.
- We conduct comprehensive experiments on our crawled Reddit conversation dataset to confirm the effectiveness of our proposed model. The experimental results demonstrate that our models consistently outperform strong baseline methods.

2 Related Work

The neural network-based methods have been applied successfully in natural language generation problems, such as text summarization (See et al., 2017; Chen et al., 2019), machine translation (Bahdanau et al., 2015; Vaswani et al., 2017) and question generation. Traditional NQG tasks are explored in reading comprehension (Kim et al.,

2019; Sun et al., 2018), QA systems (Tang et al., 2018; Duan et al., 2017). In such tasks, the answer is known and is part of the input to the generated question. The answer information could help to predict reasonable interrogative words (Kim et al., 2019), or perceive appropriate phrase by modelling the relative distance between the context words and the answer (Sun et al., 2018), or bridge the relevance between QA and QG tasks (Tang et al., 2018).

Furthermore, NQG can also be deployed as chatbot components, such as visual question answering (Fan et al., 2018), task-oriented dialogues (Li et al., 2016b), and open-domain dialogue generation (Wang et al., 2018; Hu et al., 2018). Li et al. (2016b) devised several handcrafted templates, which is not applicable to open-domain conversational systems. Wang et al. (2018) first studied on open-domain CQG, and they devised soft and hard typed decoders by capturing different roles of different word types, and used PMI model to predict topic words. Hu et al. (2018) proposed an aspect-based question generation problem, and used an encoder-decoder model to generate aspect-specific questions.

The RL has been widely applied to conversational generation (Zhou and Wang, 2018; Li et al., 2016c; Heeman et al., 2012; Lemon et al., 2014), and the GAN has been successfully applied to text generation (Li et al., 2018; Yu et al., 2017). However, these methods did not explore the answer information. Inspired by the important role of answer information in traditional NQG tasks, we intend to use RL and GAN to solve the open-domain CQG problem. To the best of our knowledge, we are the first to incorporate answer and conversational content into the both RL and GAN frameworks for this task.

3 Proposed Models

3.1 Problem Formalization

Following the conversation question generation paradigm (Wang et al., 2018), our method has a similar task setting where a question is generated based on a post utterance. For the particularity of our task, we further leverage the question type to control and interpret the generated question, and take advantage of the semantic coherence guided by answer information to improve the quality of generated questions.

The conversational content (U, q, l, a), consists of post utterance U, response utterance (i.e. question) q with its question type l, and answer utterance a to question q. In training, we aim to estimate the probability $p(q, l|U)$ utilizing C-VAE, and use reinforcement learning and adversarial learning to explore the answer information a with GRU-MatchPyramid measuring the coherence. In inference, given a new post utterance U, we can generate an appropriate question q' and question type l' according to the generation probability. Note that the answer utterance a is only used in training process, and is unknown in inference process.

3.2 Conditional Variational Autoencoder

The conditional variational autoencoder (C-VAE) (Sohn et al., 2015) is an extention of sequence-to-sequence model, and proves to be very effective in promoting the diversity in conversation generation (Serban et al., 2017). Besides, prior linguistic features (e.g. dialogue acts (Zhao et al., 2017) or sentiment (Shen et al., 2017)) have been incorporated into CVAE for controlling and interpreting dialogue generation. Inspired by previous works, we apply CVAE model to generate diverse and meaningful questions for CQG task. Furthermore, question type can provide semantic hints that enhance the semantic relevance for generating controllable questions. So we incorporate question type into CVAE for controlling question generation with reasonable type.

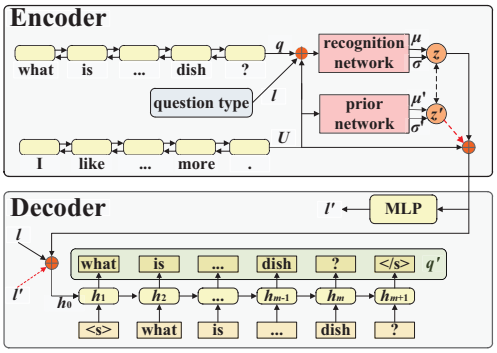

Figure 1: The CVAE model incorporated with question type embedding. $\bigoplus$ denotes the vector concatenation operation. In training process, approximated poster latent variable z obtained from recognition network, together with true question type l and post utterance U are concatenated for decoder process. At the same time, red dashed arrows refer to inference process, where we replace z with prior latent variable z' obtained from prior network, and replace l with predicted question type l' in decoder process.

The CVAE model introduces a latent variable z to capture the distribution over responses, so the generation probability is defined as $p(q, z, l|U) = p(q|z, U, l)p(l|z, U)p(z|U)$. As shown in Figure 1, the encoder neural network is formulated as the bi-directional GRU model, which is used to encode post U and question q. The question type l is represented by a real-valued, low dimensional vector which is learnt through training. Note that the reason why we use the actual question type l during training is to generate appropriate question consistent with the ground-truth in content and question type simultaneously. By assuming z follows multivariate Gaussian distribution, the prior network parameterized by θ_P is introduced to approximate $p_P(z'|U) \sim \mathcal{N}(\mu', \sigma'^2\mathbf{I})$. The recognition network parameterized by θ_R is introduced to approximate $p_R(z|U, q, l) \sim \mathcal{N}(\mu, \sigma^2\mathbf{I})$. The latent variables are sampled by reparameterization trick. The question type prediction network parameterized by θ_L is introduced to approximate $p_L(l|U, z)$. The decoder neural network parameterized by θ_D is formulated as a 1-layer GRU model, which is used to approximate $p_D(q|z, U, l)$. During training, z obtained by recognition network, together with l and U are used to approximate $p_D(q|z, U, l)$. The response decoder then gets sematic representation h_1,...,h_{m+1} with predicting the words of response. During inference, z' obtained by prior network, together with predicted question type l' and U are regarded as input of decoder process, which corresponds to red dashed arrows in Figure 1.

Finally, the CVAE model incorporated with question type is trained by maximizing both the variational lower bound and question type prediction accuracy:

$$\begin{aligned}\mathcal{L}_{CVAE} = &-KL(p_R(z|U, q, l)||p_P(z|U)) \\ &+E_{p_R(z|U,q,l)}logp_D(q|z, U, l) \\ &+E_{p_R(z|U,q,l)}logp_L(l|z, U)\end{aligned} \quad (1)$$

We use KL annealing (Bowman et al., 2016) and bag-of-word loss (Zhao et al., 2017) to avoid the vanishing latent variable problem.

3.3 GRU-MatchPyramid Model

In this paper, we formulate measuring the semantic coherence between questions and answers as a text matching task.

The MatchPyramid (Pang et al., 2016) considers both semantic representation and semantic interactions in text matching. However, for large-scale conversational text, it is more essential to capture the word's higher level semantic rather than superficial meaning, as quite a part of sentence pairs in conversation do not have the same keywords but only contain semantic-related words (e.g. "*dish*" in ground truth question and "*cooking*", "*beaf*" in answer of Table 1). So we introduce bi-directional GRU into MatchPyramid model's word level to capture higher level's word semantic, and propose a new GRU-MatchPyramid model.

For question q's i-th word w_i with embedding e_{w_i}, and answer a's j-th word v_j with embedding e_{v_j}, the matching matrix M is defined as:

$$M_{ij} = BiGRU(e_{w_i}) \otimes BiGRU(e_{v_j}) \quad (2)$$

where M_{ij} is semantic coherence degree between word w_i and word v_j, $BiGRU(e_{w_i})$ and $BiGRU(e_{v_j})$ are words' high-level semantic representation via bi-directional GRU, and $\otimes$ is dot product operation. Then a one-layer convolutional neural network is used to extract the matching pattern based on M, and the features matrix is obtained. Afterwards, a max-over-time pooling operation (Collobert et al., 2011) over the features matrix obtained by convolutional operation is used to capture the most important information M'. We flatten M' and use a MLP model to generate the semantic coherence feature f. The semantic feature M', coherence feature f and coherence score s are defined as:

$$M' = CNN(M) \quad (3)$$

$$f = \varphi(W_f \cdot flatten(M') + b_f) \quad (4)$$

$$s = \varphi(W_s f + b_s) \quad (5)$$

where φ is the rectified linear units activation function, i.e. ReLU, W_f, b_f, W_s, b_s are trainable parameters.

3.4 RL-CVAE

Inspired by reinforcement learning in controlling characteristics of generated responses (e.g. grammatical coherence (Li et al., 2016c), or sentiment expression (Zhou and Wang, 2018)), we conjecture that promoting the question-answer semantic coherence via reinforcement learning can help generate appropriate questions. The supervised learning cannot be applied to calculate question-answer semantic coherence, as it suffers from the non-differentiable problem caused by the sampling-based output decoding procedure.

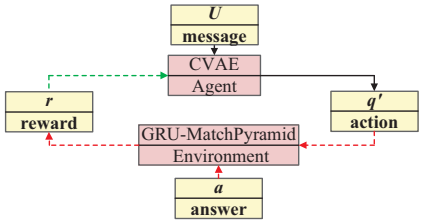

Figure 2: The CVAE with reinforcement learning (RL-CVAE). We formulate the CVAE model as an agent and pretrained GRU-MatchPyramid model as an environment in an RL framework. Solid arrows present the process of generating action q' (i.e. generated question) on the condition of state U (i.e. post). Red dashed arrows refer to agent's interaction process with the environment, where reward r is obtained by using action q' and answer a. Green dashed arrow refer to policy gradient optimization process with reward r.

To explicitly promote the semantic coherence between questions and answers, we propose a RL-CVAE model, as shown in Figure 2. Specifically, RL-CVAE is initialized by the pretrained CVAE model that acts as an agent in reinforcement learning. The action q' is the generated question, and the state is denoted by the post U and will affect the action. The policy of agent takes the form of CVAE, and it will output a probability distribution over actions conditioned on given states U. The pretrained GRU-MatchPyramid model acts as an environment, which considers answer a and question q' as input, and calculates the reward function to output reward value r. The reward value r (i.e. semantic coherence score) can be interpreted as quality estimation of q' so that it can guide the learning process to reward the cases that have strong coherence to the answer, and to penalize the cases that have little coherence to the answer (i.e. the dull and deviated cases).

We utilize pretrained GRU-MatchPyramid model as the measuring method to evaluate semantic coherence between q' and a. When training GRU-MatchPyramid model, we use negative sampling method to construct the training data, which has been successfully applied in retrieval-based chatbot (Zhou et al., 2018; Zhang et al., 2018) and text matching task (Liu et al., 2016). Specifically, for each question (ground-truth) and answer pair (q, a) in the conversation generation training data, we randomly sample five negative questions q^-, chosen from other posts' ground-truth responses. The training objective is that the score of (q, a) should be larger than (q^-, a) with at least $\triangle$ threshold. The loss function is defined as:

$$\mathcal{L}_{coh} = max(\triangle - s(q, a) + s(q^-, a), 0) \quad (6)$$

where s is semantic coherence score between question and answer as defined in Equation 5.

After obtaining a generated question q', we get coherence score ${r_0}^+ = s(q', a)$ between generated question and answer. However, ${r_0}^+$ has a wide range of value that it could not be used as reward value in reinforcement learning directly. Similar with GRU-MatchPyramid's training process, we create a coherence score set R^- with negative examples, and use min-max scaling to normalize the coherence score ${r_0}^+$. Specifically, we randomly select n negative questions ${q_1}^-, {q_2}^-, ... {q_n}^-$ from other posts's ground-truth responses, and then calculate their coherence scores with a via Equation 5, i.e. $R^- = ({r_1}^-, {r_2}^-, ..., {r_n}^-)$. The final coherence score $r(q', a)$ is then defined as follows:

$$r = \frac{{r_0}^+ - min(R^-, {r_0}^+)}{max(R^-, {r_0}^+) - min(R^-, {r_0}^+)} \quad (7)$$

where $min(R^-, {r_0}^+)$ and $max(R^-, {r_0}^+)$ are the minimum value and maximum value of set $(R^-, {r_0}^+)$. We use the policy gradient methods (Sutton et al., 2000) for optimization with the expected reward defined as:

$$J(\theta) = \mathbb{E}_{p(q,z,l|U)}[r(q, a)] \quad (8)$$

The gradient is estimated as:

$$\nabla J(\theta) = r(q, a) \nabla log p(q, z, l|U) \quad (9)$$

3.5 A-CVAE

The GAN (Goodfellow et al., 2014) is effective in controlling attributes of generated text (e.g. sentiment (Logeswaran et al., 2018) or thematic (Li et al., 2018)). Based on our assumption that C-QG task can benefit from question-answer semantic coherence, we propose an A-CVAE model with a question generator and a question-answer coherence discriminator to further improve the quality of generated questions.

In Figure 3, the generator (i.e. CVAE model) is used to generate questions q', and the discriminator (i.e. GRU-MatchPyramid model) is incorporated to learn the matching score between generated question q' (as well as ground-truth question q)

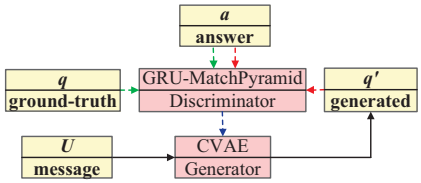

Figure 3: The CVAE with adversarial learning (A-CVAE). We formulate the CVAE as a generator and GRU-MatchPyramid as a discriminator using GAN. Solid arrows present the generation process of question q' conditions on post utterance U. Red dashed arrows refer to the adversarial learning process of negative instance (i.e. q' and answer a), and green dashed arrows refer to the positive instance (i.e. ground-truth question q and a). Blue dashed arrow refer to the back-propagation of the discriminator to the generator.

and answer a. In the discriminator, we treat q' as the negative sample incoherent to answer a, and treat q as the positive sample, which on the contrary is coherent to a. Then the loss from this discriminator is back-propagated to the decoder process of the generator to improve the coherence.

Inspired by (Li et al., 2018), to better perform gradient calculation in adversarial process, the decoder's state sequence $(h_1, h_2, ..., h_m)$ shown in Figure 1 is used to represent generated question q'. To align dimension between q' and a, we conduct nonlinear transformation on state h_i:

$$h'_i = \varphi(W_d h_i + b_d) \tag{10}$$

After transformation, the q' is then denoted as $q' = (h'_1, h'_2, ..., h'_m)$. According to Equation 5, we get the semantic coherence score s_g between q' and a (i.e. $s_g = s(q', a)$), and score s_t between the ground-truth question q and a (i.e. $s_t = s(q, a)$).

Following the routine of improved wasserstein generative adversarial networks, i.e. WGAN-PG (Gulrajani et al., 2017), the discriminator is trained to measure the semantic coherence degree between generated (as well as ground truth) questions and answers, according to the semantic coherence scores s_g and s_t, with minimizing the objective function:

$$\mathcal{L}_D = s_g - s_t \tag{11}$$

Note that the discriminator which utilizes the answer is only applied during the training process, because the answer information is unavailable during inference.

The overall objective of generator is to minimize

$$\mathcal{L}_G = -\mathcal{L}_{CVAE} - \lambda s_g \tag{12}$$

with respect to parameters of the CVAE, where $\mathcal{L}_{CVAE}$ is defined in Equation 1. λ is a balancing parameter. Intuitively, during training the generator is trying to generate answer-coherent questions that would confuse the discriminator as to these questions' origin (i.e. ground-truth or generated) by maximizing $\mathcal{L}_D$, so that the discriminator is forced to become a strong semantic coherence evaluator to distinguish these questions' origin by minimizing $\mathcal{L}_D$, until both the generator and discriminator can not improve any more. In this way, the adversarial learning can push generator to generate questions indistinguishable from ground-truth.

4 Experiment

4.1 Experiment Setup

We extract our experiment corpus on Reddit[1], and the comment utterances are crawled for our experiment evaluation[2]. Inspired by (Fan et al., 2018), we categorize questions into 9 types, i.e. "what", "when", "where","who","why" "how","can (could)","do (did, does)","is (am, are, was, were)" according to interrogative words that are the most significant features to distinguish question types. We filter out the crawled data whose questions are not included in these 9 types, because these data occupy a small proportion in the crawled conversation dataset, and it is difficult to learn satisfying question type representation. Ultimately, we collected 1,164,345 pieces of data, and each of which has a post, a question, and an answer. We randomly selected 30,000 triples for validation and another 30,000 triples for testing. The average number of words in post/response/answer is 18.84/19.03/19.30 respectively. We choose top 40,000 frequent words as the vocabulary.

We use the 200d Glove embedding (Pennington et al., 2014) pretrained on Wikipedia 2014 dataset as word embedding. In CVAE, the size of encoder state is set to 300, and the size of decoder state is set to 400. We set the size of latent Gaussian variable to 200, the size of question type to 100, and the size of mini-batch to 30. The prior network and question type prediction network have a hidden layer whose dimension is 400. All weights are initialized by the xavier method (Glorot and

[1]http://www.reddit.com

[2]The dataset is available at https://drive.google.com /drive/folders/1wNG30YPHiMc_ZNyE3BH5wa1uVtR8l1pG

Bengio, 2010). The dataset is tokenized using the NLTK tokenizer. We optimize our model using Adam (Kingma and Ba, 2014) with learning state of 0.001 and gradient clipping at 5. We use KL-annealing strategy with the temperature varying from 0 to 1 and increased by 1/60k after each iteration of batch update.

For the GRU-MatchPyramid model, the bi-directional GRU model for encoding question and answer has a hidden state of 300 in size. In the convolutional operation, the kernel size is set to (3,3), with the stride size to 2.

In RL-CVAE, we set threshold $\triangle$ to 1 in GRU-MatchPyramid's training, and set number n to 100 in min-max scaling. The pretrained CVAE model is obtained by bag-of-words loss along with KL annealing to 0.5 after training 30k batches. Then we use policy loss to obtain the final model with KL weight kept at 0.5. In A-CVAE, we set balancing parameter λ in generator's loss to 0.1, and train the discriminator one time for every five times training of generator.

4.2 Baselines

Seq2Seq: A simple sequence-to-sequence model with attention mechanism.
CVAE: Conditional variational autoencoders with an auxiliary bag-of-words loss is used to generate diverse responses (Zhao et al., 2017).
STD&HTD: The STD uses soft typed decoder by estimating words' distribution over word types, and HTD uses hard typed decoder by specifying the type of each word explicitly (Wang et al., 2018). Because these two methods depend on PMI, we collected about 100,000 post-response pairs from Reddit to estimate the probabilities in PMI. The HTD is the state-of-the-art model for C-QG task.

4.3 Question Generation Evaluation

Perplexity: The perplexity (PPL) (Vinyals and Le, 2015) could evaluate whether generated responses satisfy the grammatical rules, and lower value reflects better fluency.
RUBER: RUBER (Referenced metric and Unreferenced metric Blended Evaluation Routine) (Tao et al., 2018) has shown a high correlation with human annotation in open-domain conversation response evaluation. RUBER measures the similarity between generated responses and ground-truth responses as referenced metric, and measures the relatedness as unreferenced metric. The similarity is calculated via cosine similarity, and the relatedness is obtained by a neural network pretrained via a utterance matching method. Then the geometric averaging (RubG) and arithmetic averaging (RubA) are obtained via these two metrics, and higher value reflects better semantic coherence.
Distinct2 (Li et al., 2016a): We count numbers of distinct bigrams in the generated responses. The ratio (Dist2) is obtained by dividing the counted number by the total number of generated bigrams, and higher value reflects better diversity.

Question Generation Evaluation				
Models	RubA	RubG	Dist2	PPL
Seq2Seq	0.614	0.574	0.008	63.02
CVAE	0.682	0.649	0.112	20.39
STD	0.658	0.613	0.010	28.75
HTD	0.689	0.654	0.114	26.02
CVAE (qt)	0.688	0.652	0.114	20.03
A-CVAE	0.715	0.661	0.123	19.51
RL-CVAE	**0.720**	**0.668**	**0.185**	**16.93**

Table 2: Evaluation result of question generation.

As shown in Table 2, CVAE(qt) incorporates question type information, and slightly improves the performance compared with CVAE, because it could help generate questions with reasonable type. Furthermore, answer information could further improve the overall performance. First, RL-CVAE and A-CVAE perform fairly well with lower perplexities, because they could generate fluent questions. Second, they can obtain higher RubG and RubA scores, showing that taking advantage of coherence between question and answer could further enhance semantic coherence between post and question. Third, they obtain higher distinct values, because answer information provides extra clues to guide question generation.

Our RL-CVAE performs better than A-CVAE. This is because the decoder's hidden states are utilized to represent generated question word tokens in A-CVAE, which is asymmetric to the ground-truth question in adversarial process. Instead, the question sentence is observed in RL-CVAE after the model arrives at the end of a sequence, and it is then used to calculate coherence degree directly.

4.4 Effect of GRU-MatchPyramid

We use mean average precision (MAP) to evaluate the performance of GRU-MatchPyramid model. MAP is the metric to measure the accuracy of tex-

Post	Generated Question	Answer
that's definitely a third party seller at amazon and not amazon .	Seq2Seq: is it a good thing? CVAE: and how is this an official app? STD: how do you like amazon? HTD: are you heavily subscribed to amazon? CVAE(qt): can you get the link? i'm just using the amazon box. **RL-CVAE: what's the difference between a third party seller and amazon ?** **A-CVAE: does the third party seller ship amazon fulfillment?**	it's still third seller so amazon usually ships the item as it was shipped to them but in a box. i would buy directly from amazon.
i don't know why so many people don't realize the duke o death is only free for returning players.	Seq2Seq: what's your point? CVAE: are you just about having fun? STD: what's the difference? HTD: are you returning player? CVAE(qt): are there any members in your opinion? **RL-CVAE: how much is it for normal players?** **A-CVAE: how to realize that? i'm on the list of returning players.**	it's 660k for normal players. and in the newswire they said all the returning player stuff would be free for returning players.

Table 4: Two cases comparison among different models.

Models	MP	GRU-MatchPyramid
MAP	0.793	**0.826**

Table 3: Evaluation result of GRU-MatchPyramid.

t matching, and it is the average of the maximum precisions at different recall values. As shown in Table 3, GRU-MatchPyramid model performs better than MatchPyramid (dubbed as MP) model in large scale conversational data, because of capturing higher level semantic of word. In this way, we get a better reward function in RL-CVAE, and a better discriminator in A-CVAE.

4.5 Question Answer Coherence Evaluation

To evaluate the degree of semantic coherence between generated questions and answers, we apply two evaluation methods: (1) cosine similarity: inspired by sentence-level similarity evaluation (Li et al., 2018), we use embedding-based metrics to calculate cosine similarity, and higher similarity implies better topic similarity. (2) matching score: we use pretrained GRU-MatchPyramid model to calculate the semantic coherence, and higher scores imply better semantic coherence.

As shown in Table 5, our proposed models could generate questions coherent to answers in inference process. The coherence of question and answer improved overall performance shown in Table 2 by a large margin.

4.6 Human Evaluation

We randomly sampled 500 cases and recruited three graduate students as human annotators. To

Models	cosine	matching score
Seq2Seq	0.494	5.304
CVAE	0.591	8.050
STD	0.540	6.882
HTD	0.593	8.063
CVAE (qt)	0.594	8.053
A-CVAE	0.612	8.420
RL-CVAE	**0.617**	**8.512**

Table 5: Evaluation result of question-answer semantic coherence.

Models	A	S	W	Sum
seq2seq	0.486	0.208	0.196	0.890
CVAE	0.458	0.484	0.408	1.350
STD	0.504	0.322	0.272	1.098
HTD	0.528	0.486	0.406	1.420
CVAE(qt)	0.462	0.508	0.468	1.438
A-CVAE	0.540	0.578	0.514	1.632
RL-CVAE	**0.542**	**0.602**	**0.526**	**1.670**

Table 6: Results of human evalution based on criteria of appropriateness (A), semantic coherence (S) and willingness to answer (W).

each annotator, we showed the same post utterance of a test example with all seven questions generated by different models. The seven questions were presented in random order, and the annotators were asked to evaluate whether each question satisfies criteria defined as: (1) **Appropriateness**: measures whether a question is reasonable in logic and grammar. (2) **Semantic coherence**: measures whether the question are coherent to the

given post. Incoherent questions include dull and deviated cases. (3) **Willingness to answer**: measures whether a user is willing to answer the question. This criterion is to justify how likely the generated questions can elicit further interactions.

We calculate the ratio of each criterion satisfied, and regard the sum as the evaluation result. The results are calculated by averaging the annotations from the three judges. We calculated the Fleiss' kappa (Fleiss, 1971) to measure inter-annotator agreement. Fleiss' kappa for **Appropriateness**, **Semantic coherence** and **Willingness to answer** is 0.486, 0.421 and 0.506 respectively, indicating "Moderate agreement" for all three criteria. As shown in Table 6, RL-CVAE and A-CVAE are consistently in line with the human perspective, especially in semantic coherence and willing to answer criteria. It indicates that with utilizing question-answer semantic coherence, the generated questions are more coherent to posts, and our models could help to drive the conversation to go further proactively. Compared with the state-of-the-art model HTD, our proposed models could effectively alleviate the dullness and deviation issues.

4.7 Case Study

As shown in Table 4, we list two cases from test corpus to compare different methods. The topics about post and answer in the two cases are about "*third-party seller of amazon*" and "*returning players*" respectively. The A-CVAE and RL-CVAE model could generate appropriate questions coherent to both posts and answers semantically, showing that answer information of training process helps to control and guide the question generation obviously. However, without exploring answer information, the baseline models may only generate dull questions (e.g. Seq2Seq), or deviated questions (e.g. CVAE, STD, and HTD). Furthermore, based on the given post and generated questions, we are more willing to answer the questions generated by our methods.

5 Conclusion

In this paper, we propose two novel models A-CVAE and RL-CVAE, which can generate semantic coherent questions under the guidance of answers in open-domain conversational system. For A-CVAE model, we use adversarial training to explicitly control question generation in the direction of question-answer coherence. For RL-CVAE, the coherence between questions and answers is leveraged as the reward function in an RL framework. Furthermore, our work of utilizing RL and GAN with answer information is general, and it can be easily extended to existing work.

Abstract

Automatic news comment generation is a new testbed for techniques of natural language generation. In this paper, we propose a "read-attend-comment" procedure for news comment generation and formalize the procedure with a reading network and a generation network. The reading network comprehends a news article and distills some important points from it, then the generation network creates a comment by attending to the extracted discrete points and the news title. We optimize the model in an end-to-end manner by maximizing a variational lower bound of the true objective using the back-propagation algorithm. Experimental results on two datasets indicate that our model can significantly outperform existing methods in terms of both automatic evaluation and human judgment.

1 Introduction

In this work, we study the problem of automatic news comment generation, which is a less explored task in the literature of natural language generation (Gatt and Krahmer, 2018). We are aware that numerous uses of these techniques can pose ethical issues and that best practices will be necessary for guiding applications. In particular, we note that people expect comments on news to be made by people. Thus, there is a risk that people and organizations could use these techniques at scale to feign comments coming from people for purposes of political manipulation or persuasion. In our intended target use, we explicitly disclose the generated comments on news as being formulated automatically by an entertaining and engaging chatbot (Shum et al., 2018). Also, we understand that the behaviors of deployed systems may need to be monitored and guided with methods, including post-processing techniques (van Aken et al., 2018). While there are risks with this kind of AI research, we believe that developing and demonstrating such techniques is important for understanding valuable and potentially troubling applications of the technology.

Title: FIFA rankings: France number one, Croatia and England soar, Germany and Argentina plummet
Body (truncated): World Cup glory has propelled France to the top of FIFA's latest world rankings, with the impact of Russia 2018 felt for better or worse among a number of football's heavyweight nations. These are the first set of rankings released under FIFA's new formula that "relies on adding/subtracting points won or lost for a game to/from the previous point totals rather than averaging game points over a given time period". FIFA world rankings: 1.France 2.Belgium 3. Brazil 4. Croatia 5. Uruguay 6. England 7. Portugal 8. Switzerland 9. Spain 10. Denmark
Comment A: If it's heavily based on the 2018 WC, hence England leaping up the rankings, how are Brazil at 3? **Comment B:** England above Spain, Portugal and Germany. Interesting.

Table 1: A news example from Yahoo!

Existing work on news comment generation includes preliminary studies, where a comment is generated either from the title of a news article only (Zheng et al., 2018; Qin et al., 2018) or by feeding the entire article (title plus body) to a basic sequence-to-sequence (s2s) model with an attention mechanism (Qin et al., 2018). News titles are short and succinct, and thus only using news titles may lose quite a lot of useful information in comment generation. On the other hand, a news article and a comment is not a pair of parallel text. The news article is much longer than the comment and contains much information that is irrelevant to the comment. Thus, directly applying the s2s model, which has proven effective in machine translation (Bahdanau et al., 2015), to the task of news comment generation is unsuitable, and may bring a lot of noise to generation. Both approaches

oversimplify the problem of news comment generation and are far from how people behave on news websites. In practice, people read a news article, draw attention to some points in the article, and then present their comments along with the points they are interested in. Table 1 illustrates news commenting with an example from Yahoo! News.[1] The article is about the new FIFA ranking, and we pick two comments among the many to explain how people behave in the comment section. First, both commenters have gone through the entire article, as their comments are built upon the details in the body. Second, the article gives many details about the new ranking, but both commenters only comment on a few points. Third, the two commenters pay their attention to different places of the article: the first one notices that the ranking is based on the result of the new world cup, and feels curious about the position of Brazil; while the second one just feels excited about the new position of England. The example indicates a "read-attend-comment" behavior of humans and sheds light on how to construct a model.

We propose a reading network and a generation network that generate a comment from the entire news article. The reading network simulates how people digest a news article, and acts as an encoder of the article. The generation network then simulates how people comment the article after reading it, and acts as a decoder of the comment. Specifically, from the bottom to the top, the reading network consists of a representation layer, a fusion layer, and a prediction layer. The first layer represents the title of the news with a recurrent neural network with gated recurrent units (RNN-GRUs) (Cho et al., 2014) and represents the body of the news through self-attention which can model long-term dependency among words. The second layer forms a representation of the entire news article by fusing the information of the title into the representation of the body with an attention mechanism and a gate mechanism. The attention mechanism selects useful information in the title, and the gate mechanism further controls how much such information flows into the representation of the article. Finally, the third layer is built on top of the previous two layers and employs a multi-label classifier and a pointer network (Vinyals et al., 2015) to predict a bunch of salient spans (e.g., words, phrases, and sentences, etc.) from the article. With the reading network, our model comprehends the news article and boils it down to some key points (i.e., the salient spans). The generation network is an RNN language model that generates a comment word by word through an attention mechanism (Bahdanau et al., 2015) on the selected spans and the news title. In training, since salient spans are not explicitly available, we treat them as a latent variable, and jointly learn the two networks from article-comment pairs by optimizing a lower bound of the true objective through a Monte Carlo sampling method. Thus, training errors in comment prediction can be back-propagated to span selection and used to supervise news reading comprehension.

We conduct experiments on two large scale datasets. One is a Chinese dataset published recently in (Qin et al., 2018), and the other one is an English dataset built by crawling news articles and comments from Yahoo! News. Evaluation results on the two datasets indicate that our model can significantly outperform existing methods on both automatic metrics and human judgment.

Our contributions are three-folds: (1) proposal of "read-attend-comment" procedure for news comment generation with a reading network and a generation network; (2) joint optimization of the two networks with an end-to-end learning approach; and (3) empirical verification of the effectiveness of the proposed model on two datasets.

2 Related Work

News comment generation is a sub-task of natural language generation (NLG). Among various NLG tasks, the task studied in this paper is most related to summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017) and product review generation (Tang et al., 2016; Dong et al., 2017). However, there is stark difference between news comment generation and the other two tasks: the input of our task is an unstructured document, while the input of product review generation is structured attributes of a product; and the output of our task is a comment which often extends the content of the input with additional information, while the output of summarization is a condensed version of the input that contains the main information from the original. Very recently, there emerge some studies on news comment generation. For example, Zheng et al. (2018) propose

[1] https://www.yahoo.com/news/fifa-rankings-france-number-one-112047790.html

a gated attention neural network model to generate news comments from news titles. The model is further improved by a generative adversarial net. Qin et al. (2018) publish a dataset with results of some basic models. Different from all the existing methods, we attempt to comprehend the entire news articles before generation and perform end-to-end learning that can jointly optimize the comprehension model and the generation model.

Our model is partially inspired by the recent success of machine reading comprehension (MRC), whose prosperity can be attributed to an increase of publicly available large scale annotated datasets, such as SQuAD (Rajpurkar et al., 2016, 2018) and MS Marco (Nguyen et al., 2016) etc. A great number of models have been proposed to tackle the MRC challenges, including BiDAF (Seo et al., 2016), r-net (Wang et al., 2017), DCN (Xiong et al., 2016), Document Reader (Chen and Bordes, 2017), QANet (Yu et al., 2018), and s-net (Tan et al., 2018) etc. Our work can be viewed as an application of MRC to a new NLG task. The task aims to generate a comment for a news article, which is different from existing MRC tasks whose goal is to answer a question. Our learning method is also different from those in the MRC works.

3 Approach

3.1 Problem Formalization

Suppose we have a dataset $\mathcal{D} = \{(T_i, B_i, C_i)\}_{i=1}^{N}$, where the i-th triple (T_i, B_i, C_i) consists of a news title T_i, a news body B_i, and a comment C_i. Our goal is to estimate a probability distribution $P(C|T, B)$ from $\mathcal{D}$, and thus, given a new article (T, B) with T the news title and B the news body, we can generate a comment C following $P(C|T, B)$.

3.2 Model Overview

Figure 1 illustrates the architecture of our model. In a nutshell, the model consists of a reading network and a generation network. The reading network first represents a news title and a news body separately in a representation layer, then forms a representation of the entire article by fusing the title into the body through a fusion layer, and finally distills some salient spans from the article by a prediction layer. The salient spans and the news title are then fed to the generation network to synthesize a comment. With the two networks, we can factorize the generation probability $P(C|T, B)$ as $P(S|T, B) \cdot P(C|S, T)$, where $S = (s_1, \ldots, s_w)$ refers to a set of spans in B, $P(S|T, B)$ represents the reading network, and $P(C|S, T)$ refers to the generation network.

3.3 Reading Network

In the representation layer, let $T = (t_1, \ldots, t_n)$ be a news title with t_j the j-th word, and $B = (b_1, \ldots, b_m)$ be the associated news body with b_k the k-th word, we first look up an embedding table and represent t_j and b_k as $e_{T,j} \in \mathbb{R}^{d_1}$ and $e_{B,k} \in \mathbb{R}^{d_1}$ respectively, where $e_{T,j}$ and $e_{B,k}$ are randomly initialized, and jointly learned with other parameters. Different from the title, the body is long and consists of multiple sentences. Hence, to emphasize positional information of words in the body, we further expand $e_{B,k}$ with $o_{B,k}$ and $s_{B,k}$, where $o_{B,k}, s_{B,k} \in \mathbb{R}^{d_2}$ are positional embeddings with the former indexing the position of b_k in its sentence and the latter indicating the position of the sentence in the entire body. The representation of b_k is then given by $\hat{e}_{B,k} = \text{MLP}([e_{B,k}; o_{B,k}; s_{B,k}])$, where $\hat{e}_{B,k} \in \mathbb{R}^{d_1}$, $\text{MLP}(\cdot)$ refers to a multi-layer perceptron with two layers, and $[\cdot;\cdot;\cdot]$ means the concatenation of the three arguments.

Starting from $\mathcal{E}_T = (e_{T,1}, \ldots, e_{T,n})$ and $\mathcal{E}_B = (\hat{e}_{B,1}, \ldots, \hat{e}_{B,m})$ as initial representations of T and B respectively, the reading network then transforms T into a sequence of hidden vectors $\mathcal{H}_T = (h_{T,1}, \ldots, h_{T,n})$ with a recurrent neural network with gated recurrent units (RNN-GRUs) (Cho et al., 2014). In the meanwhile, B is transformed to $\mathcal{H}_B = (h_{B,1}, \ldots, h_{B,m})$ with the k-th entry $h_{B,k} \in \mathbb{R}^{d_1}$ defined as $\text{MLP}([\hat{e}_{B,k}; c_{B,k}])$ (two layers) and $c_{B,k}$ is an attention-pooling vector calculated by a scaled dot-product attention (Vaswani et al., 2017) denoted as *dot-att*$(\mathcal{E}_B, \hat{e}_{B,k})$:

$$
\begin{aligned}
c_{B,k} &= \textstyle\sum_{j=1}^{m} \alpha_{k,j} \hat{e}_{B,j}, \\
\alpha_{k,j} &= \exp(s_{k,j}) / \textstyle\sum_{l=1}^{m} \exp(s_{k,l}), \\
s_{k,j} &= (\hat{e}_{B,k}^{\top} \hat{e}_{B,j}) / \sqrt{d_1}.
\end{aligned} \tag{1}
$$

In Equation (1), a word is represented via all words in the body weighted by their similarity. By this means, we try to capture the dependency among words in long distance.

The fusion layer takes $\mathcal{H}_T$ and $\mathcal{H}_B$ as inputs, and produces $\mathcal{V} = (v_1, \ldots, v_m)$ as new representation of the entire news article by fusing $\mathcal{H}_T$ into $\mathcal{H}_B$. Specifically, $\forall h_{B,k} \in \mathcal{H}_B$, we first let $h_{B,k}$

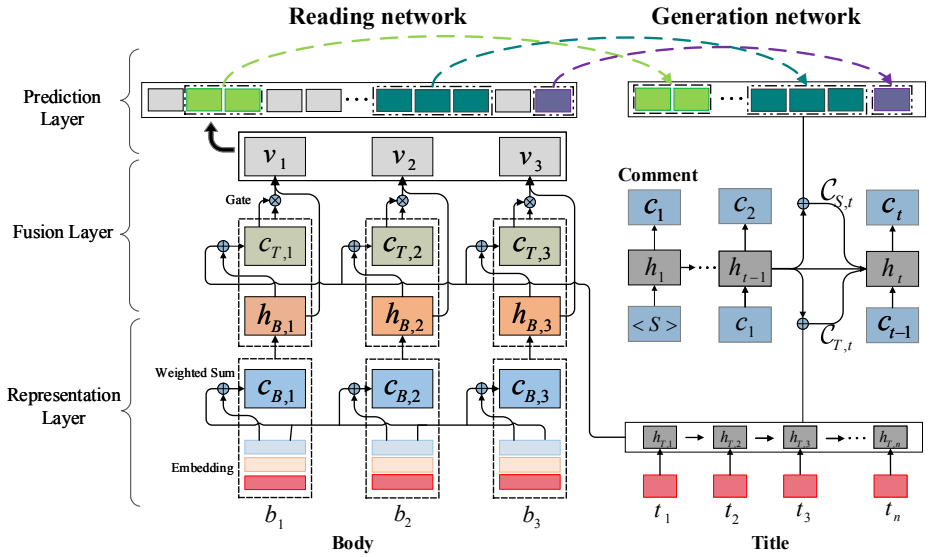

Figure 1: Architecture of our model. The black solid arrows represent differentiable operations and the dashed arrows are non-differentiable operations which represent distilling points from news body.

attend to $\mathcal{H}_T$ and form a representation $c_{T,k} = \textit{dot-att}(\mathcal{H}_T, h_{B,k})$, where $\textit{dot-att}(\mathcal{H}_T, h_{B,k})$ is parameterized as Equation (1). With this step, we aim to recognize useful information in the title. Then we combine $c_{T,k}$ and $h_{B,k}$ as $v_k \in \mathbb{R}^{d_1}$ with a gate g_k which balances the impact of $c_{T,k}$ and $h_{B,k}$ and filters noise from $c_{T,k}$. v_k is defined by:

$$\begin{aligned} v_k &= h_{B,k} + g_k \odot c_{T,k}, \\ g_k &= \sigma(W_g[h_{B,k}; c_{T,k}]), \end{aligned} \tag{2}$$

The top layer of the reading network extracts a bunch of salient spans based on $\mathcal{V}$. Let $S = ((a_1, e_1), \ldots, (a_w, e_w))$ denote the salient spans, where a_i and e_i refer to the start position and the end position of the i-th span respectively, we propose detecting the spans with a multi-label classifier and a pointer network. Specifically, we formalize the recognition of $(a_1, \ldots, a_w)$ as a multi-label classification problem with $\mathcal{V}$ as an input and $L = (l_1, \ldots, l_m)$ as an output, where $\forall k \in \{1, \ldots, m\}$, $l_k = 1$ means that the k-th word is a start position of a span, otherwise $l_k = 0$. Here, we assume that $(a_1, \ldots, a_w)$ are independent with each other, then the multi-label classifier can be defined as m binary classifiers with the k-th classifier given by

$$\hat{y}_k = \text{softmax}(\text{MLP}_k(v_k)), \tag{3}$$

where $\text{MLP}_k(\cdot)$ refers to a two-layer MLP, and $\hat{y}_k \in \mathbb{R}^2$ is a probability distribution with the first entry as $P(l_k = 0)$ and the second entry as $P(l_k = 1)$. The advantage of the approach is that it allows us to efficiently and flexibly detect a variable number of spans from a variable-length news article, as there is no dependency among the m classifiers, and they can be calculated in parallel.

Given a_k, the end position e_k is recognized via a probability distribution $(\alpha_{a_k,1}, \ldots, \alpha_{a_k,m})$ which is defined by a pointer network:

$$\begin{aligned} \alpha_{a_k,j} &= \exp(s_{a_k,j}) / \textstyle\sum_{l=1}^{m} \exp(s_{a_k,l}), \\ s_{a_k,j} &= V^\top \tanh(W_v v_j + W_h h_{a_k,1}), \\ h_{a_k,1} &= \text{GRU}(h_0, [c_0; v_{a_k}]), \end{aligned} \tag{4}$$

where $h_0 = att(\mathcal{V}, r)$ is an attention-pooling vector based on parameter r:

$$\begin{aligned} h_0 &= \textstyle\sum_{j=1}^{m} \beta_j \cdot v_j, \\ \beta_j &= \exp(\beta'_j) / \textstyle\sum_{l=1}^{m} \exp(\beta'_l), \\ \beta'_j &= V_1^\top \tanh(W_{v,1} v_j + W_{h,1} r), \end{aligned} \tag{5}$$

$c_0 = att(\mathcal{V}, h_0)$ is defined in a similar way with r replaced by h_0.

Let us denote $(a_1, \ldots, a_w)$ as $start$ and $P(l_i = 1)$ as p_i, then $P(S|T, B)$ can be formulated as

$$P(S|T,B) = \prod_{k=1}^{w} [p_{a_k} \cdot \alpha_{a_k,e_k}] \prod_{i \notin start, 1 \le i \le m} [1 - p_i]. \tag{6}$$

In practice, we recognize the i-th word as a start position if $p_i > 1 - p_i$, and determine the associated end position by $\arg\max_{1 \le k \le m} \alpha_{i,k}$. Note that we do not adopt a pointer network to detect the start positions, because in this case, either we have to set a threshold on the probability distribution, which is sensitive to the length of the news

article and thus hard to tune, or we can only pick a fixed number of spans for any articles by ranking the probabilities. Neither of them is favorable.

3.4 Generation Network

With $S = ((a_1, e_1), \ldots, (a_w, e_w))$ the salient spans, $\mathcal{V} = (v_1, \ldots, v_m)$ the representation of the news article, and $\mathcal{H}_T$ the representation of the news title given by the three layers of the reading network respectively, we define a representation of S as $\mathcal{H}_S = (v_{a_1}, v_{a_1+1}, \ldots, v_{e_1}, \ldots, v_{a_w}, v_{a_w+1}, \ldots, v_{e_w})$. The generation network takes $\mathcal{H}_T$ and $\mathcal{H}_S$ as inputs and decodes a comment word by word via attending to both $\mathcal{H}_T$ and $\mathcal{H}_S$. At step t, the hidden state is $h_t = \text{GRU}(h_{t-1}, [e_{C,t-1}; \mathcal{C}_{T,t-1}; \mathcal{C}_{S,t-1}])$, $h_t \in \mathbb{R}^{d_1}$. $e_{C,t-1}$ is the embedding of the word generated at step t-1, $\mathcal{C}_{T,t-1} = att(\mathcal{H}_T, h_{t-1})$ and $\mathcal{C}_{S,t-1} = att(\mathcal{H}_S, h_{t-1})$ are context vectors that represent attention on the title and the spans respectively. $att(\cdot, \cdot)$ is defined as Equation (5).

With h_t, we calculate $\mathcal{C}_{T,t}$ and $\mathcal{C}_{S,t}$ via $att(\mathcal{H}_T, h_t)$ and $att(\mathcal{H}_S, h_t)$ respectively and obtain a probability distribution over vocabulary by $\mathcal{P}_t = \text{softmax}(V[h_t; \mathcal{C}_{T,t}; \mathcal{C}_{S,t}] + b)$. Let $C = (c_1, \ldots, c_o)$ be a comment where $\forall k \in \{1, \ldots, o\}$, c_k is the index of the k-th word of C in vocabulary, then $P(C|S, T)$ is defined as

$$\begin{aligned} P(C|S,T) &= P(c_1|S,T) \prod_{t=2}^{o} P(c_t|c_1, \ldots, c_{t-1}, S, T) \\ &= \mathcal{P}_1(c_1) \prod_{t=2}^{o} \mathcal{P}_t(c_t), \end{aligned}$$

where $\mathcal{P}_t(c_t)$ refers to the c_t-th entry of $\mathcal{P}_t$. In decoding, we define the initial state h_0 as an attention-pooling vector over the concatenation of $\mathcal{H}_T$ and $\mathcal{H}_S$ given by $att([\mathcal{H}_T; \mathcal{H}_S], q)$. q is a parameter learned from training data.

3.5 Learning Method

We aim to learn $P(S|T, B)$ and $P(C|S, T)$ from $\mathcal{D} = \{(T_i, B_i, C_i)\}_{i=1}^{N}$, but S is not explicitly available, which is a common case in practice. To address the problem, we treat S as a latent variable, and consider the following objective:

$$\begin{aligned} \mathcal{J} &= \sum_{i=1}^{N} \log P(C_i|T_i, B_i) \\ &= \sum_{i=1}^{N} \log \Big(\sum_{S_i \in \mathcal{S}} P(S_i|T_i, B_i) P(C_i|S_i, T_i) \Big), \end{aligned} \tag{7}$$

where $\mathcal{S}$ refers to the space of sets of spans, and S_i is a set of salient spans for (T_i, B_i). Objective $\mathcal{J}$ is difficult to optimize, as logarithm is outside the summation. Hence, we turn to maximizing a lower bound of Objective $\mathcal{J}$ which is defined as:

$$\mathcal{L} = \sum_{i=1}^{N} \sum_{S_i \in \mathcal{S}} P(S_i|T_i, B_i) \log P(C_i|S_i, T_i) < \mathcal{J} \tag{8}$$

Let Θ denote all parameters of our model and $\frac{\partial \mathcal{L}_i}{\partial \Theta}$ denote the gradient of $\mathcal{L}$ on an example (T_i, B_i, C_i), then $\frac{\partial \mathcal{L}_i}{\partial \Theta}$ is given by

$$\begin{aligned} \sum_{S_i \in \mathcal{S}} P(S_i|T_i, B_i) \Big[&\frac{\partial \log P(C_i|S_i, T_i)}{\partial \Theta} + \\ &\log P(C_i|S_i, T_i) \frac{\partial \log P(S_i|T_i, B_i)}{\partial \Theta} \Big]. \end{aligned} \tag{9}$$

To calculate the gradient, we have to enumerate all possible S_is for (T_i, B_i), which is intractable. Thus, we employ a Monte Carlo sampling method to approximate $\frac{\partial \mathcal{L}_i}{\partial \Theta}$. Suppose that there are J samples, then the approximation of $\frac{\partial \mathcal{L}_i}{\partial \Theta}$ is given by

$$\begin{aligned} \frac{1}{J} \sum_{n=1}^{J} \Big[&\frac{\partial \log P(C_i|S_{i,n}, T_i)}{\partial \Theta} + \\ &\log P(C_i|S_{i,n}, T_i) \frac{\partial \log P(S_{i,n}|T_i, B_i)}{\partial \Theta} \Big], \end{aligned} \tag{10}$$

where $\forall n$, $S_{i,n}$ is sampled by first drawing a group of start positions according to Equation (3), and then picking the corresponding end positions by Equations (4)-(5). Although the Monte Carlo estimator is unbiased, it typically suffers from high variance. To reduce variance, we subtract baselines from $\log P(C_i|S_{i,n}, T_i)$. Inspired by (Mnih and Gregor, 2014), we introduce an observation-dependent baseline $\mathcal{B}_\psi(T_i, C_i)$ to capture the systematic difference in news-comment pairs during training. Besides, we also exploit a global baseline $\mathcal{B}$ to further control the variance of the estimator. The approximation of $\frac{\partial \mathcal{L}_i}{\partial \Theta}$ is then re-written as

$$\begin{aligned} \frac{1}{J} \sum_{n=1}^{J} \Big[&\frac{\partial \log P(C_i|S_{i,n}, T_i)}{\partial \Theta} + \Big(\log P(C_i|S_{i,n}, T_i) \\ &- \mathcal{B}_\psi(T_i, C_i) - \mathcal{B} \Big) \frac{\partial \log P(S_{i,n}|T_i, B_i)}{\partial \Theta} \Big]. \end{aligned} \tag{11}$$

To calculate $\mathcal{B}_\psi(T_i, C_i)$, we first encode the word sequences of T_i and C_i with GRUs respectively, and then feed the last hidden states of the GRUs to a three-layer MLP. $\mathcal{B}$ is calculated as an average of $P(C_i|S_{i,n}, T_i) - \mathcal{B}_\psi(T_i, C_i)$ over the current mini-batch. The parameters

of the GRUs and the MLP are estimated via $\min_{(T_i,B_i)\in\text{mini-batch},1\le n\le J}[\log P(C_i|S_{i,n},T_i) - \mathcal{B}_\psi(T_i,C_i) - \mathcal{B}]^2$.

The learning algorithm is summarized in Algorithm 1. To speed up convergence, we initialize our model through pre-training the reading network and the generation network. Specifically, $\forall(T_i,B_i,C_i)\in\mathcal{D}$, we construct an artificial span set $\tilde{S}_i$, and learn the parameters of the two networks by maximizing the following objective:

$$\sum_{i=1}^{N}\log P(\tilde{S}_i|T_i,B_i)+\log P(C_i|T_i,\tilde{S}_i) \quad (12)$$

$\tilde{S}_i$ is established in two steps: first, we collect all associated comments for (T_i,B_i), extract n-grams $(1\le \text{n}\le 6)$ from the comments, and recognize an n-gram in B_i as a salient span if it exactly matches with one of the n-grams of the comments. Second, we break B_i as sentences and calculate a matching score for a sentence and an associated comment. Each sentence corresponds to a group of matching scores, and if any one of them exceeds 0.4, we recognize the sentence as a salient span. The matching model is pre-trained with $\{T_i,C_i\}_{i=1}^N$ with C_i as a positive example and a randomly sampled comment from other news as a negative example. In the model, T_i and C_i are first processed by GRUs separately, and then the last hidden states of the GRUs are fed to a three-layer MLP to calculate a score.

Algorithm 1: Optimization Algorithm

Input: training data $\mathcal{D}$, initial learning rate lr, MaxStep, sample number n.
Init: Θ
Construct $\{\tilde{S}_i\}_{i=1}^N$ and pre-train the model by maximizing Objective (12).
while *step* $<$ *MaxStep* **do**
  Randomly sample a mini-batch k from $\mathcal{D}$.
  Compute distributions of start positions.
  for $n < J$ **do**
    Sample start positions.
    Compute distributions of end positions.
    Sample end positions.
    Compute the terms related to $S_{i,n}$ in Eq. (11).
  Compute $\mathcal{B}_\psi(C_i,T_i)$ and $\mathcal{B}$ and finish Eq. (11).
  Update the parameters of the model and $\mathcal{B}_\psi(C_i,T_i)$ with SGD.
Output: Θ

4 Experiments

We test our model on two large-scale news commenting datasets.

		Train	Dev	Test
Tencent	# News	191,502	5,000	1,610
	Avg. # Cmts per News	27	27	27
Yahoo	# News	152,355	5,000	3,160
	Avg. # Cmts per News	20.6	20.5	20.5

Table 2: Statistics of the two datasets.

4.1 Experimental Setup

The first dataset is a Chinese dataset built from Tencent News (news.qq.com) and published recently in (Qin et al., 2018). Each data point contains a news article which is made up of a title and a body, a group of comments, and some side information including upvotes and categories. Each test comment is labeled by two annotators according to a 5-scale labeling criteria presented in Table 3. All text in the data is tokenized by a Chinese word segmenter Jieba (https://github.com/fxsjy/jieba). The average lengths of news titles, news bodies, and comments are 15 words, 554 words and 17 words respectively. In addition to the Chinese data, we also build another dataset by crawling news articles and the associated comments from Yahoo! News. Besides upvotes and categories, side information in Yahoo data also includes paragraph marks, WIKI-entities, downvotes, abusevotes, and sentiment tagged by Yahoo!. Text in the data is tokenized by Stanford CoreNLP pipline (Manning et al., 2014). As pre-processing, we filter out news articles shorter than 30 words in the body and comments shorter than 10 words or longer than 100 words. Then, we remove news articles with less than 5 comments. If the number of comments of an article exceeds 30, we only keep top 30 comments with the most upvotes. On average, news titles, news bodies, and comments contain 12 words, 578 words and 32 words respectively. More information about Yahoo data can be found in Appendix A. After the pre-processing, we randomly sample a training set, a validation set, and a test set from the remaining data, and make sure that there is no overlap among the three sets. Table 2 summarizes the statistics of the two datasets. Note that we only utilize news titles, news bodies and comments to learn a generation model in this work, but both datasets allow modeling news comment generation with side information, which could be our future work.

Following (Qin et al., 2018), we evaluate the

Score	Criteria
5	Rich in content; attractive; deep insights; new yet relevant viewpoints
4	Highly relevant with meaningful ideas
3	Less relevant; applied to other articles
2	Fluent/grammatical; irrelevant
1	Hard to read; Broken language; Only emoji

Table 3: Human judgment criteria

performance of different models with both automatic metrics and human judgment. In terms of automatic evaluation, we employ BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin, 2004), and CIDEr (Vedantam et al., 2015) as metrics on both data. Besides these metrics, Qin et al. (2018) propose human score weighted metrics including W-BLEU, W-METEOR, W-ROUGE and W-CIDEr. These metrics, however, requires human judgment on each comment in the test set. Thus, we only involve results w.r.t. these metrics in Tencent data. As Qin et al. (2018) do not publish their code for metric calculation, we employ a popular NLG evaluation project available at `https://github.com/Maluuba/nlg-eval`, and modify the scripts with the scores provided in the data according to the formulas in (Qin et al., 2018) to calculate all the metrics. In human evaluation, for each dataset, we randomly sample 500 articles from the test data and recruit three native speakers to judge the quality of the comments given by different models. For every article, comments from all models are pooled, randomly shuffled, and presented to the annotators. Each comment is judged by the three annotators under the criteria in Table 3.

4.2 Baselines

The following models are selected as baselines:

Basic models: the retrieval models and the generation models used in (Qin et al., 2018) including (1) IR-T and IR-TC: both models retrieve a set of candidate articles with associated comments by cosine of TF-IDF vectors. Then the comments are ranked by a convolutional neural network (CNN) and the top position is returned. The difference is that IR-T only utilizes titles, while IR-TC leverages both titles and news bodies; (2) Seq2seq: the basic sequence-to-sequence model (Sutskever et al., 2014) that generates a comment from a title; and (3) Att and Att-TC: sequence-to-sequence with attention (Bahdanau et al., 2015) in which the input is either a title (Att) or a concatenation of a title and a body (Att-TC). In Seq2seq, Att, and Att-TC, top 1 comment from beam search (beam size=5) is returned.

GANN: the gated attention neural network proposed in (Zheng et al., 2018). The model is further improved by a generative adversarial net.

We denote our model as "DeepCom" standing for "deep commenter", as it is featured by a deep reading-commenting architecture. All baselines are implemented according to the details in the related papers and tuned on the validation sets.

4.3 Implementation Details

For each dataset, we form a vocabulary with the top 30k frequent words in the entire data. We pad or truncate news titles, news bodies, and comments to make them in lengths of 30, 600, and 50 respectively. The dimension of word embedding and the size of hidden states of GRU in all models are set as 256. In our model, we set d_1 as 256 and d_2 (i.e., dimension of the position embedding in the reading network) as 128. The size of hidden layers in all MLPs is 512. The number of samples in Monte Carlo sampling is 1. In pre-training, we initialize our model with a Gaussian distribution $\mathcal{N}(0, 0.01)$ and optimize Objective (12) using AdaGrad (Duchi et al., 2011) with an initial learning rate 0.15 and an initial accumulator value 0.1. Then, we optimize $\mathcal{L}$ using stochastic gradient descent with a learning rate 0.01. In decoding, top 1 comment from beam search with a size of 5 is selected for evaluation. In IR-T and IR-TC, we use three types of filters with window sizes 1, 3, and 5 in the CNN based matching model. The number of each type of filters is 128.

4.4 Evaluation Results

Table 4 reports evaluation results in terms of both automatic metrics and human annotations. On most automatic metrics, DeepCom outperforms baseline methods, and the improvement is statistically significant (t-test with p-value < 0.01). The improvement on BLEU-1 and W-BLEU-1 is much bigger than that on other metrics. This is because BLEU-1 only measures the proportion of matched unigrams out of the total number of unigrams in the generated comments. In human evaluation, although the absolute numbers are different from those reported in (Qin et al., 2018) due to the difference between human judgements, the overall trend is consistent. In human evaluation, the values of Fleiss' kappa over all models are more

Dataset	Models	METEOR	W-METEOR	Rouge_L	W-Rouge_L	CIDEr	W-CIDEr	BLEU-1	W-BLEU-1	Human	Kappa

	BLEU-1	0.490	0.531	0.609	0.665

Table 5: Model ablation results

than 0.6, indicating substantial agreement among the annotators. Although built in a complicated structure, GANN does not bring much improvement over other baseline methods, which demonstrates that only using news titles is not enough in comment generation. IR-TC and Att-TC represent the best retrieval model and the best generation model among the baselines on both datasets, implying that news bodies, even used in a simple way, can provide useful information to comment generation.

4.5 Discussions

Ablation study: We compare the full model of DeepCom with the following variants: (1) No Reading: the entire reading network is replaced by a TF-IDF based keyword extractor, and top 40 keywords (tuned on validation sets) are fed to the generation network; (2) No Prediction: the prediction layer of the reading network is removed, and thus the entire $\mathcal{V}$ is used in the generation network; and (3) No Sampling: we directly use the model pre-trained by maximizing Objective (12). Table 5 reports the results on automatic metrics. We can see that all variants suffer from performance drop and No Reading is the worst among the three variants. Thus, we can conclude that (1) span prediction cannot be simply replaced by TF-IDF based keyword extraction, as the former is based on a deep comprehension of news articles and calibrated in the end-to-end learning process; (2) even with sophisticated representations, one cannot directly feed the entire article to the generation network, as comment generation is vulnerable to the noise in the article; and (3) pre-training is useful, but optimizing the lower bound of the true objective is still beneficial.

To further understand why DeepCom is superior to its variants, we calculate BLEU-1 (denoted as $\text{BLEU}_{\text{span}}$) with the predicted spans and the ground truth comments in the test sets of the two data, and compare it with a baseline BLEU-1 (denoted as $\text{BLEU}_{\text{base}}$) which is calculated with the entire news articles and the ground truth comments. On Tencent data, $\text{BLEU}_{\text{span}}$ and $\text{BLEU}_{\text{base}}$ are 0.31 and 0.17 respectively, and the two numbers on Yahoo data are 0.29 and 0.16 respectively. This means that by extracting salient spans from news articles, we can filter out redundant information while keeping the points that people like to comment on, which explains why DeepCom is better than No Prediction. When comparing DeepCome with No Sampling, we find that spans in DeepCom are longer than those in No Sampling. In the test set of Tencent data, the average lengths of salient spans with and without sampling are 11.6 and 2.6 respectively, and the two numbers in Yahoo data are 14.7 and 2.3 respectively. Thus, DeepCom can leverage discourse-level informa-

		1	2	3	4	5
Tencent	IR-TC	0.3%	55.2%	33.3%	9.50%	1.7%
	Att-TC	19.3%	49.5%	18.5%	11.7%	1.0%
	DeepCom	1.5%	3.3%	32.0%	61.9%	1.3%
Yahoo	IR-TC	1.3%	53.0%	14.7%	20.3%	10.7%
	Att-TC	20.3%	22.3%	22.6%	32.1%	2.7%
	DeepCom	1.7%	17.6%	33.3%	39.4%	8.0%

Table 6: Human score distributions

tion rather than a few single words or bi-grams in comment generation, which demonstrates the advantage of our learning method.

Analysis of human annotations: We check the distributions of human labels for DeepCom, Att-TC, and IR-TC to get insights on the problems these models suffer from. Table 6 shows the results. Most of the bad comments from IR-TC are labeled as "2", meaning that although IR-TC can give attractive comments with rich and deep content, its comments are easy to diverge from the news articles and thus be judged as "irrelevant". In terms of Att-TC, there are much more comments judged as "1" than the other two models, indicating that Att-TC often generates ill-formed sentences. This is because a news article and a comment are highly asymmetric in terms of both syntax and semantics, and thus the generation process cannot be simply modeled with an encoder-decoder structure. Bad cases from DeepCom concentrate on "3", reminding us that we need to further enrich the content of comments and improve their relevance in the future.

Case Study: Finally, to further understand our model, we visualize the predicted salient spans and the generated comment using a test example from Tencent dataset in Table 7. Due to space limitation, we truncate the body and only show three of the selected spans in the truncated body. The full article with the full set of spans and another test example from Yahoo! News dataset are shown in Appendix B. In spite of this, we can see that the model finds some interesting points after "reading" the article and synthesizes a comment along one of the spans (i.e. "Chinese Paladin 3"). More interestingly, the model extends the content of the article in the comment with "Luo Jin", who is Tiffany Tang's partner but is not talked about in the article. On the other hand, comments given by the baseline methods are either too general (Att-TC, the best generation baseline), or totally irrelevant with the article (IR-TC, the best retrieval baseline). The example demonstrates that our model can generate relevant and informative comments through analyzing and understanding news articles.

Title: 唐嫣为什么不演清宫剧? (Why Tiffany Tang never plays a role in a drama set in Qing dynasty?)
Body (truncated): 众多的戏剧影视作品让唐嫣获得不少人气，众多活动的多变造型树立其在大众心中百变小天后的形象。... 如果说唐嫣最美的造型是《仙剑奇侠传三》中的紫萱，那最丑的造型应该就是这个了吧！... (... The numerous television series and movies Tiffany Tang acted in have made her very popular, and her varied modelling in many activities has set her an image of "the queen of reinvention" in the hearts of the public. ... If her most beautiful role is Zi Xuan in "Chinese Paladin 3", then the most ugly one should be this! ...)
DeepCom: 唐嫣罗晋的演技真的很好，特别喜欢她演《仙剑奇侠传》。我觉得这部剧挺好看。(Tiffany Tang and Luo Jin are really good actors. I especially like her role in "Chinese Paladin 3". I think the TV drama is worth watching.) **Att-TC:** 我也是醉了(I have nothing to comment.) **IR-TC:** 星爷和谁开撕过嘛，都是别人去撕星爷！(Stephen Chow never fights with others. It is others that fight with Stephen Chow!)

Table 7: A Case from Tencent News dataset. The contents in the red box represent salient spans predicted by the reading network. The content in the blue box is a generated entity which is included in the salient spans.

5 Conclusions

We propose automatic news comment generation with a reading network and a generation network. Experimental results on two datasets indicate that the proposed model can significantly outperform baseline methods in terms of both automatic evaluation and human evaluation. On applications, we are motivated to extend the capabilities of a popular chatbot. We are aware of potential ethical issues with application of these methods to generate news commentary that is taken as human. We hope to stimulate discussion about best practices and controls on these methods around responsible uses of the technology.

B Case Study

We demonstrate the advantage of DeepCom over IR-TC and Att-TC with examples from the test sets of the two datasets. Table 9 and Table 10 show the comments given by the three models. The content in the red box represents salient spans predicted by the reading network and that in the blue box is generated entities included in the salient spans. We can see that compared to the two baseline methods, comments from DeepCom are more relevant to the content of the news articles. Comments from IR-TC are rich with content, but are irrelevant to the news articles, while Att-TC is prone to generate generic comments.

Title: 唐嫣为什么不演清宫剧？(Why Tiffany Tang never plays a role in a drama set in Qing dynasty?)

Body: 众多的戏剧影视作品让唐嫣博获得不少人气，众多活动的多变造型树立其在大众心中“百变小天后”的形象。商业活动高贵优雅、媒体活动清新脱俗，唐嫣每走到一处总能获得交口称赞和镁光灯的钟爱。唐嫣身材高挑、笑容甜美，精致的脸庞，时尚的装扮，有着“九头身美女”之称。如果说唐嫣最美的造型是《仙剑奇侠传三》中的紫萱，那最丑的造型应该就是这个了吧！无论是发型还是脸都无法直视啊！《仙剑奇侠传三》时候应该算是唐嫣的颜值巅峰期了吧！而穿上宫廷服装的唐嫣，真的不好看，宛如一个智障少女……这一段清宫戏，是唐嫣在电视剧《乱世佳人》的造型，但这部戏简直是唐嫣不堪回首的过去啊！这个民国时期的造型也不好看！终于明白为什么唐嫣从来不演清宫剧了！如果不用假刘海，就算脸在小，她的额头还是很大！对此，大家怎么看？
(The numerous television series and movies Tiffany Tang acted in have made her very popular, and her varied modelling in many activities has set her an image of ”the queen of reinvention” in the hearts of the public. Her elegant and unique nature showed in commercial events and media events brings her a lot of praise and spotlight. Tiffany Tang is tall, slim, has sweet smile and a beautiful face, and is always dressed in fashion. Thus, she is called “9-heads tall” girl by her fans. If her most beautiful role is Zi Xuan in “Chinese Paladin 3”, then the most ugly one should be this! Both hair-style and makeup look terrible. She is most alluring at the time of “Chinese Paladin 3”. When she dressed up with a costume in Qing Dynasty, however, she looks really bad, like an idiot. This is how Tiffany Tang looks like in a TV series “A Beauty in Troubled Times”, but this might be her forgettable moment. Her costume in Republic of China looks terrible too. I finally know why Tiffany Tang never plays a role in a drama set in Qing dynasty. If she does not use fake bangs, even her face is small, her forehead looks too big! What do you think?)

DeepCom: 唐嫣罗晋的演技真的很好，特别喜欢她演《仙剑奇侠传》。我觉得这部剧挺好看。(Tiffany Tang and Luo Jin are really good actors. I especially like her role in Chinese Paladin 3. I think the TV drama is worth watching.)
Att-TC: 我也是醉了(I have nothing to comment.)
IR-TC: 星爷和谁开撕过嘛, 都是别人去撕星爷！（Stephen Chow never fights with others. It is others that fight with Stephen Chow!）

Table 9: A case from Tencent News dataset.

Title: NBA notebook : Rockets targeting Anthony after losing Mbah a Moute

Body: The Houston Rockets are now determined to sign forward Carmelo Anthony after forward Luc Mbah a Moute joined the Los Angeles Clippers on a one-year, $4.3 million deal on Monday, according to an ESPN report. Anthony is currently a member of the Oklahoma City Thunder, but the two sides are reportedly working on parting ways, whether through a trade, a buyout or waiving via the stretch provision. Anthony is likely to become a free agent even if he is traded, as his new team would likely waive him. Multiple reports on Sunday said rockets guard Chris Paul wants Anthony, a good friend of his, to join the rockets, while Anthony is also believed to have interest in joining Lebron James with the Los Angeles Lakers. The Miami Heat are also reportedly interested in adding Anthony. Mbah a Moute spent the 2015-16 and 2016-17 seasons with the Clippers before joining the Rockets last season. The 31-year-old averaged 7.5 points , 3.0 rebounds and 1.2 steals in 25.6 minutes per game across 61 games (15 starts) in Houston. – The Cleveland cavaliers are looking to deal 37-year-old guard Kyle Korver and transition to a younger lineup, according to Terry Pluto of the Cleveland Plain Dealer. . . . Korver’s contract has $ 15.1 million remaining over the next two seasons, although only $ 3.4 million of his 2019-20 salary is guaranteed. He could prove to be a good option for a team looking for better perimeter shooting to compete for a league title. . . . – It ’s unclear whether Joakim Noah will remain with the New York Knicks moving forward, but the center said he hopes to say in the big apple, in a video published by TMZ. “I love New York,” Noah said, “I don’t know what’s going to happen , but Coach Fiz is cool, man.” . . .

DeepCom: the rockets are going to have a lot of fun in this series .
Att-TC: i think he is going to be a contender
IR-TC: the kings have a great future if cousins is n’t the team ’s leader . but if continues to be propped up as the guy , then the kings will only have a good future along with the bottom half of the west . cousins just is n’t enough of a leadership guy who will go through 3 more coaches before he finds a decent match not just for himself , but the team .

Abstract

Text generation is among the most fundamental tasks in natural language processing. In this paper, we propose a text generation model that learns semantics and structural features simultaneously. This model captures structural features by a sequential variational autoencoder component and leverages a topic modeling component based on a Gaussian distribution to enhance the recognition of text semantics. To make the reconstructed text more coherent to the topics, the model further adapts the encoder of the topic modeling component for a discriminator. The results of experiments over several datasets demonstrate that our model outperforms several states of the art models in terms of text perplexity and topic coherence. Moreover, the latent representations learned by our model is superior to others in a text classification task. Finally, given the input texts, our model can generate meaningful texts which hold similar structures but under different topics.

1 Introduction

Text generation is a fundamental task in natural language processing (NLP). Existing methods for text generation are mostly limited in supervised setting and designed for specific applications (e.g., machine translation (Bahdanau et al., 2015), text summarization (Rush et al., 2015)). Several research work (Yu et al., 2017; Zhang et al., 2016) attempts generic text generation based on deep generative models (e.g., GAN, VAE). However, models based on GAN(Generative Adversarial Network) are not able to generate explicit latent codes with salient features of texts. Different from GAN-based models, the VAE (Variational Autoencoder) and its variants can get latent codes of texts with reconstructing texts by its decoder, where it is assumed that the generation process is controlled by codes in a continuous latent space. A natural way to implement the VAEs is to adopt autoregressive networks (e.g., RNNs) as the decoder and encoder. This kind of implementation of VAEs considers sequential information of texts, and is able to model the linguistic structure of texts. But it is not good at modeling semantics (Dieng et al., 2017) and may cause the latent variable collapse problem (Bowman et al., 2016) which leads that the decoder ignores information from the inferred latent codes.

In general, texts inherently contain semantic features and structural features. Only when the latent codes of texts contain structural and semantic information can high-quality texts be generated from the codes. As far as the standard VAE is concerned, it assumes that the latent code is Gaussian distributed so that we cannot distinguish which part of code controls the structure and which part controls the semantics. In other words, it is difficult to generate effective texts by controlling text features directly.

To generate high-quality texts (i.e., with semantic and structural information), we propose a model named TATGM which adopts a sequential VAE to learn structural features of texts and builds a topic modeling component which extracts semantic features of texts. The main contributions of this paper are summarized as follows:

- TATGM can capture the semantics of texts by introducing the topic modeling component. The topic modeling component generates words of texts based on a Gaussian distribution which enables us to take full advantage of information shared by the word embeddings. Moreover, the encoder of the topic modeling component is served as a discriminator to force the decoder of the sequence modeling component to generate texts having the semantics as close to the original texts as

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5090–5099,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

possible. Specifically, no extra training supervised by labeled data is needed for this discriminator.

- The latent code learned by TATGM is a concatenation of the latent variables of the topic modeling component and the sequence modeling component. By two separate parts of the code, TATGM can control structural and semantic information independently. Thus, we can get texts with the changed semantics or structure by changing one part of the code. One interesting practice is that we can get question-answering pairs with the same structure in different semantic spaces.

- The modeling ability of TATGM is evaluated by extensive experiments in terms of perplexity and the coherence of topics. Furthermore, to verify whether TATGM can learn salient features, a classification task using the latent codes is conducted. Experimental results show that TATGM achieves the best performance while compared with many existing models. Finally, several texts generated by TATGM are demonstrated, which indicates that TATGM can generate different expressions of texts of the same structure in different topics.

The rest of the paper is organized as follows. Section 2 introduces the related work. Section 3 describes the model TATGM in detail. Section 4 gives an experimental evaluation. Finally, the paper is concluded in Section 5.

2 Related Work

VAEs (Kingma and Welling, 2014) are a type of deep generative models, which learns explicit latent codes of input data in a continuous latent space and generates data with decoders. VAEs can extract the features of input texts by posterior inference with neural networks and reparameterization tricks. VAE-based models have been widely applied in image generation (Gregor et al., 2015), machine translation (Zhang et al., 2016), and knowledge graph reasoning (Zhang et al., 2018). VAE-based models can also be applied in different tasks of text processing, where the input document is treated as its bag of words (Miao et al., 2016; Srivastava and Sutton, 2017; Miao et al., 2017) or a sequential text (Bowman et al., 2016). The former type of models is always related to topics. For example, Miao et al. (2016) builds the connection by letting weights of the softmax decoder to indicate topic interpretability. Although these models overlook sequential information in texts, they can learn effective latent codes with global semantics. On the other hands, VAE-based models with the input of sequences usually adopt RNNs as encoders or decoders. However, latent variable collapse (i.e., the latent variable collapses to obey the distribution of the prior) makes the sequential VAE to generate texts without information of latent code so that the latent code cannot have enough information of text features.

To avoid the latent variable collapse problem, two types of methods are adopted. The first type tackles this problem by weakening the context modeling ability of decoders mostly in the model architecture level. For example, Bowman et al. (2016) adopts word dropout when feeding the decoder and Yang et al. (2017); Semeniuta et al. (2017) employ non-autoregressive networks (e.g., convolutional neural networks) in the decoder. The second type is to modify the original objective. For example, Bowman et al. (2016) adopts *KL* annealing which can be seen as gradually adding annealing weight into the objective function. Zhao et al. (2018) introduces an additional mutual information term to compensate for the objective function. Xiao et al. (2018) and Zhao et al. (2017) introduce the bag-of-words loss as an auxiliary loss, which measures how well predictions of words can be made from the latent codes. The ideas behind all these methods are same, i.e., to force the models to generate texts from the latent codes so as to make latent codes have more information on text features.

Improving the sequential model by incorporating topics have been explored (Lau et al., 2017; Wang et al., 2018; Dieng et al., 2017; Mikolov and Zweig, 2012). But these models do not have a code for the text structure. Taking TGVAE (Wang et al., 2018) as an example, it guides the generation of the VAE latent code by topic distribution. However, it does not separate the semantic and structure latent codes explicitly. In addition, the models mentioned above use a multinominal LDA which cuts off the possibility of leveraging the semantics in embeddings. As a remedy, Das et al. (2015) and Hu et al. (2012)

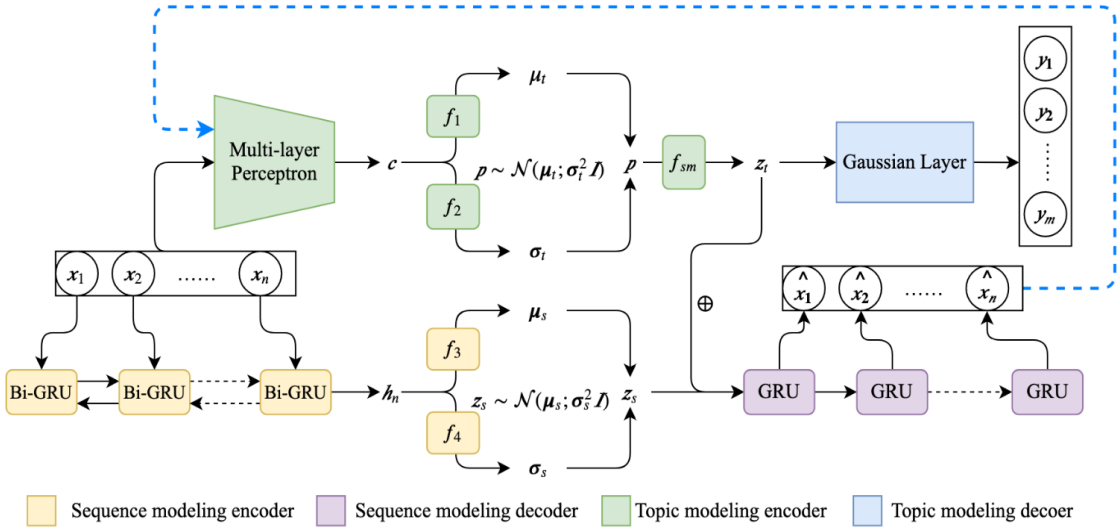

Figure 1: The holistic structure of TATGM. The dotted arrow denotes that the texts which are generated by the sequence modeling decoder are fed into the topic modeling encoder as the input of the discriminator.

propose to adopt a Gaussian-based topic model which assumes each word is generated by a Gaussian distribution. However, their learning algorithms are based on sampling and variational inference, which cannot be assembled in an end-to-end mode.

Hu et al. (2017) proposes a text generation model based on VAE, which aims at generating sentences with controllable styles by learning disentangled latent representations. It feeds generated texts into a discriminator to preserve that these texts have the given style and optimizes the generator with the signals backpropagated from the discriminator. Tian et al. (2018) uses a classifier which is trained with small datasets as the discriminator. Yang et al. (2018) adopts a language model as the discriminator to control the style transfer of generated texts.

Different from existing work, our model combines a sequence modeling component and a topic modeling component so that the final latent code of our model contains both topic semantics and sequential structure of texts. In particular, our model can learn these two features simultaneously, since AutoEncoding Variation Bayes (AEVB) are employed to train these two components. Moreover, our models generate bags-of-words text representations from the latent codes, which avoids the latent variable collapse problem.

3 Model

TATGM is essentially a hybrid autoencoder which comprises a topic modeling component capturing topic information and a sequence modeling capturing structural features. The topic modeling component captures topic information through a Gaussian-based topic model while the sequence modeling component integrates the topic information and generates text. As shown in Fig. 1, the input texts are fed into the two components simultaneously. Each component contains an encoder and decoder, which are labeled by its own color.

3.1 Neural Topic Modeling Component

Similar to existing topic modeling methods, we treat bag-of-words representations of texts as input. However, since the encoder in the topic modeling component is expected to be as a discriminator and guarantee that texts generated by the sequence modeling decoder have specific topic information, the encoder cannot be with the discrete representations (e.g., one-hot representation) of texts as input. It is because such discrete representations of texts cannot be compatible with backward gradients from the discriminator. Therefore, we employ the embeddings of words as input, considering that the word embedding space is continuous and the similarity between every two words can be calculated by the Euclidean distance. Further, we assume that there are K topics in the corpus and each topic is represented as a multivariable Gaussian distribution with a mean and a variance (e.g., $\mathcal{N}(\boldsymbol{\mu}_k, \boldsymbol{\sigma}_k^2 \boldsymbol{I})$ for a given topic k).

In our neural topic modeling component, a document with n words is represented as $\boldsymbol{x} = \{\boldsymbol{x}_i\}_{i=1}^{n}$ where $\boldsymbol{x}_i \in \mathbb{R}^e$ denotes the embedding

of i-th word of the document. The generative process of the document is as follows.

1. For each document, draw the document-topic distribution $\boldsymbol{z}_t \sim Dir(\alpha)$.
2. For i-th word in the document.
   (a) Draw topic assignment $t_i \sim Cat(\boldsymbol{z}_t)$
   (b) Draw the word $\boldsymbol{x}_i \sim \mathcal{N}(\boldsymbol{\mu}_{t_i}, \boldsymbol{\sigma}_{t_i}^2 \boldsymbol{I})$

According to the generative process above and the marginalization of t_i, the likelihood $p(\boldsymbol{x})$ of the document $\boldsymbol{x}$ can be derived as

$$\begin{aligned} &\int_{\boldsymbol{z}_t} p(\boldsymbol{z}_t|\alpha) \left(\prod_{i=1}^{n} \sum_{t_i} p(\boldsymbol{x}_i|\boldsymbol{\mu}_{t_i}, \boldsymbol{\sigma}_{t_i}^2 \boldsymbol{I}) p(t_i|\boldsymbol{z}_t) \right) d\boldsymbol{z}_t \\ &= \int_{\boldsymbol{z}_t} p(\boldsymbol{z}_t|\alpha) \left(\prod_{i=1}^{n} p(\boldsymbol{x}_i|\boldsymbol{\mu}, \boldsymbol{\sigma}^2 \boldsymbol{I}, \boldsymbol{z}_t) \right) d\boldsymbol{z}_t \end{aligned} \tag{1}$$

where $\boldsymbol{\mu} = \{\boldsymbol{\mu}\}_{k=1}^{K}$, $\boldsymbol{\sigma} = \{\boldsymbol{\sigma}\}_{k=1}^{K}$. Further, we adopt AEVB and the reparameterization trick to achieve posterior inference and parameter learning. Specifically, similar to (Srivastava and Sutton, 2017), we first draw a Gaussian random vector by a reparameterization trick and then pass it through a softmax function to parameterize the multinomial document topic distributions. Therefore, we can replace α with the parameters of Gaussian prior $\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0^2$.

Thus, we can get the ELBO of our topic modeling component.

$$\begin{aligned} \mathcal{L}_T =& \mathbb{E}_{q(\boldsymbol{z}_t|\boldsymbol{x})}[\log p(\boldsymbol{x}|\boldsymbol{z}_t)] \\ &- KL(q(\boldsymbol{z}_t|\boldsymbol{x})||p(\boldsymbol{z}_t|\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0^2 \boldsymbol{I})) \end{aligned} \tag{2}$$

In Eq. 2, $\boldsymbol{z}_t$ is inferred by the neural network in the encoder. The inference process is detailed as follows. Document $\boldsymbol{x}$ is fed into a two-layer perceptron with *ReLU* as the activation function. The transformation results of the MLP are then processed by max-pooling, getting fixed-length representation $\boldsymbol{c}$ of the document. Parameters of the posterior $\boldsymbol{\mu}_t$ and $\boldsymbol{\sigma}_t^2$ are obtained from two feedforward neural networks. Next, a Gaussian variable is sampled by the reparameterization trick. Finally, $\boldsymbol{z}_t$ is obtained by passing $\boldsymbol{p}$ to the softmax function. Our choices are specified as follows.

$$\begin{aligned} &\boldsymbol{c} = Pooling(MLP(\boldsymbol{x})) \\ &\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t = f_1(\boldsymbol{c}), f_2(\boldsymbol{c}) \\ &\boldsymbol{p} \sim \mathcal{N}(\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t^2 \boldsymbol{I}) \in \mathbb{R}^K \\ &\boldsymbol{z}_t = f_{sm}(\boldsymbol{W}_t \boldsymbol{p}) \end{aligned}$$

where f_1, f_2 denote two feedforward neural networks, $\boldsymbol{W}_t$ is a trainable parameter, f_{sm} denotes softmax function.

Besides, $KL(q(\boldsymbol{z}_t|\boldsymbol{x})||p(\boldsymbol{z}_t|\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0^2 \boldsymbol{I}))$ in Eq. 2 is obtained by calculating the *KL* divergence between $\mathcal{N}(\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t^2 \boldsymbol{I})$ and $\mathcal{N}(\boldsymbol{\mu}_0, \boldsymbol{\sigma}_0^2 \boldsymbol{I})$.

In general, during the training of topic models, a smaller vocabulary is built after eliminating some specific words (e.g., stop words, frequent words, and rare words) in the corpus. This is a denoising preprocessing step that makes the model more reliable. However, to make the execution of the discriminator applicable, our model takes all of the words in the document as input while outputting the words in a smaller vocabulary as a topic model does. Besides the reason above, this setting can also be regarded as a regulation of the model which strengthen the ability of modeling documents.

Supposing we have a smaller vocabulary, the document represented by this vocabulary is $\boldsymbol{y} = \{\boldsymbol{y}_i\}_{i=1}^{m}$, where $m < n$ is the number of words and $\boldsymbol{y}_i \in \mathbb{R}^e$ is the word embedding of the word at position i.

The topic modeling decoder reconstructs the document from $\boldsymbol{z}_t$. We assume that the distribution of every topic is a Gaussian with identity variance matrix. Therefore, $p(\boldsymbol{x}|\boldsymbol{z}_t)$ of Eq. 2 is indeed $p(\boldsymbol{y}|\boldsymbol{z}_t)$ and can be expanded as:

$$\begin{aligned} p(\boldsymbol{y}|\boldsymbol{z}_t) &= \prod_{i=1}^{m} p(\boldsymbol{y}_i|\boldsymbol{\mu}_{t_i}, \boldsymbol{\sigma}_{t_i}^2 \boldsymbol{I}, \boldsymbol{z}_t) \\ &\propto \prod_{i=1}^{m} \boldsymbol{z}_t^T \exp{(\boldsymbol{y}_i - \boldsymbol{\mu})^T (\boldsymbol{y}_i - \boldsymbol{\mu})} \end{aligned} \tag{3}$$

To stabilize the training process, when calculate the likelihood, we first normalize each $\boldsymbol{y}_i$ and $\boldsymbol{\mu}_k$.

3.2 Sequence Modeling Component

Since the structural features are closely related to the word sequence information, we construct a sequential VAE. By the sequential VAE, the encoder infers the structural latent variable and the decoder reconstructs texts via integrating the topic latent variable and the structural latent variable. This process is depicted by the bottom half of Fig. 1. Since the semantic information is given by the topic modeling component, the reconstruction loss function makes the encoder of sequential VAE focusing on encoding the structural features. Let $\boldsymbol{z}_s$ denote the structural latent variable, the ELBO of this component is in the following form:

$$\begin{aligned}\mathcal{L}_S =& \mathbb{E}_{q(\boldsymbol{z}_t|\boldsymbol{x})q(\boldsymbol{z}_s|\boldsymbol{x})}\left[\log p(\boldsymbol{x}|\boldsymbol{z}_t, \boldsymbol{z}_s)\right] \\ & - KL(q(\boldsymbol{z}_s|\boldsymbol{x})||p(\boldsymbol{z}_s))\end{aligned} \tag{4}$$

We adopt a bi-directional GRU as the encoder. The last hidden state of the encoder is used to infer the parameters $\boldsymbol{\mu}_s, \boldsymbol{\sigma}_s$ of the Gaussian distribution. Then, we get $\boldsymbol{z}_s$ by the reparameterization trick.

$$\begin{aligned}\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_n &= BiGRU(\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n) \\ \boldsymbol{\mu}_s, \boldsymbol{\sigma}_s &= f_3(\boldsymbol{h}_n), f_4(\boldsymbol{h}_n) \\ \boldsymbol{z}_s &\sim \mathcal{N}(\boldsymbol{\mu}_s, \boldsymbol{\sigma}_s^2 \boldsymbol{I})\end{aligned}$$

where f_3 and f_4 are the feedforward neural networks. Further, we obtain the holistic latent code $\boldsymbol{z}$ by concatenating $\boldsymbol{z}_t$ and $\boldsymbol{z}_s$, i.e., $\boldsymbol{z} = [\boldsymbol{z}_t; \boldsymbol{z}_s]$.

We adopt a GRU as the decoder to reconstruct document $\boldsymbol{x} = \{\boldsymbol{x}_i\}_{i=1}^n$ and latent code $\boldsymbol{z}$ as its initial state. So, the likelihood of the reconstructed document can be derived by Eq. 5.

$$\begin{aligned}p(\boldsymbol{x}|\boldsymbol{z}_t, \boldsymbol{z}_s) &= p(\boldsymbol{x}_1|\boldsymbol{z}) \prod_{i=1}^{n} p(\boldsymbol{x}_i|\boldsymbol{x}_{1:i-1}) \\ &= p(\boldsymbol{x}_1|\boldsymbol{z}) \prod_{i=1}^{n} p(\boldsymbol{x}_i|h_i)\end{aligned} \tag{5}$$

where $\boldsymbol{h}_i$ denotes the i-th hidden state of the GRU decoder.

3.3 Topic Encoder as a Discriminator

Although the holistic latent code contains semantics and structure features, the decoder may not fully leverage the semantic part of code. Besides the reconstruction loss which drives the generator to produce realistic sentences, we introduce a discriminator which enforces the generator to produce texts in a coherent topic with $\boldsymbol{z}_t$. Specifically, we let the encoder in our topic modeling component act as the discriminator. It is expected that topic distributions inferred from the generated texts are similar to the topic distributions of the original texts. However, if the outputs of the sequence decoder are discrete, it is impossible to propagate gradients from the discriminator through the discrete samples. We thus resort to a *Gumbel-Softmax* distribution as an approximation of the discrete samples.

In detail, in each step of the generative process of texts, we get the distribution of one word $p(\boldsymbol{x}_i|\boldsymbol{z}_s, \boldsymbol{z}_t) = [\pi_1, \pi_2, ..., \pi_{|V|}]$, and approximate the samples from $p(\boldsymbol{x}_i|\boldsymbol{z}_s, \boldsymbol{z}_t)$ by

$$u_i = \frac{\exp\left(\log(\pi_i) + g_i\right)/\tau}{\sum_{j=1}^{|V|} \exp\left(\log(\pi_j) + g_j\right)/\tau} \tag{6}$$

where g_i and g_j are samples from $Gumbel - Softmax(0, 1)$. As training proceeds, τ gets close to 0, yielding the increasingly peaked distribution that finally emulate the discrete cases. Thus, the i-th word generated by the decoder is

$$\widehat{\boldsymbol{x}}_i = \boldsymbol{u}^T \boldsymbol{W}_v \tag{7}$$

where $\boldsymbol{W}_v \in \mathbb{R}^{|V| \times e}$ denotes word embedding.

We feed the above generative texts into the topic modeling encoder and expect to get the maximum likelihood of the original topic distribution $\boldsymbol{z}_t$. So the loss function of the discriminator is specified as follows.

$$\mathcal{L}_D = \mathbb{E}_{p(\boldsymbol{z}_s)p(\boldsymbol{z}_t)} \log q(\boldsymbol{z}_t|\widehat{\boldsymbol{x}}) \tag{8}$$

Combining three parts of loss functions, we can get the loss function of the model as Eq. 9, where λ_D=0.1.

$$\begin{aligned}\mathcal{L} &= \mathcal{L}_T + \mathcal{L}_S + \lambda_D \mathcal{L}_D \\ &= \mathbb{E}_{q(\boldsymbol{z}_t|\boldsymbol{x})}\left[\log p(\boldsymbol{x}|\boldsymbol{z}_t) + \mathbb{E}_{q(\boldsymbol{z}_s|\boldsymbol{x})}(\log p(\boldsymbol{x}|\boldsymbol{z_s}, \boldsymbol{z_t}))\right] \\ &- \lambda_t KL(q(\boldsymbol{z}_t|\boldsymbol{x})||p(\boldsymbol{z}_t)) - \lambda_s KL(q(\boldsymbol{z}_s|\boldsymbol{x})||p(\boldsymbol{z}_s)) \\ &+ \lambda_D \mathbb{E}_{p(\boldsymbol{z}_s)p(\boldsymbol{z}_t)} \log q(\boldsymbol{z}_t|\widehat{\boldsymbol{x}})\end{aligned} \tag{9}$$

We learn parameters of topic modeling and sequence modeling components alternatively in the multitask learning setting. To avoid the latent variable collapse problem, we add weights λ_t, λ_s to *KL* related terms in the loss function and make the weights increase slowly to 1 in training.

4 Experiments and Result Analyses

To evaluate the text generation ability, we do experiments from four perspectives. First, we evaluate the language modeling ability of the sequence modeling component and the topic coherence of the topic modeling component. Next, to evaluate the effectiveness of the learned latent codes of texts, we perform a semi-supervised classification task. Finally, we transfer the question-answering pairs on Yahoo dataset to different topics and demonstrate generated texts.

4.1 Dataset Description & Experiment Setup

We conduct experiments on five benchmark text datasets: APNEWS[1], IMDB (Maas et al., 2011),

[1]https://www.ap.org/en-gb/

Data	#SM Voc	#TM Voc	#Training Docs	#Development Docs	#Test Docs	#Avg Len
APNEWS	33k	6k	700k	27.4k	26.3k	21.4
IMDB	34k	8k	900k	200k	200k	22.5
BNC	40k	9k	800k	44k	52k	22.6
Yahoo	20k	8k	100k	10k	10k	75.3
Yelp15	20k	7k	100k	10k	10k	97.8

Table 1: Summary statistics for datasets. SM Voc and TM Voc stand for vocabularies of corpus in the sequence modeling component and the topic modeling component, respectively.

BNC (BNC Consortium, 2007), Yahoo Answer (Yahoo) and Yelp15. We randomly sample 100k as training data and 10k as validation and testing data, respectively. For all datasets, we first tokenize the texts using Stanford CoreNLP (Manning et al., 2014). Then we lowercase all word tokens, and filter words that occur less than 10 times. For Yahoo and Yelp15, we truncate the vocabulary to 20k words for fast training. For the bag-of-words input in the topic modeling component, we further remove stop words, and exclude the top 0.1% most frequent words and also words that appear in less than 100 documents. Table 1 shows summary statistics of all datasets.

We fix the max sequence length to 50 for the texts in APNEWS, IMDB, BNC and 150 for Yahoo and Yelp15. The 300-dimentional embeddings of words are shared by two components in our model. For the topic modeling component, we adopt a 2-layer MLP with 200 hidden units and *ReLU* as its activation function. We set the size of $\boldsymbol{z}_t$ to 50. For the sequence modeling component, we adopt a bidirectional single layer GRU with 600 hidden units (300 in each direction) as the encoder and a unidirectional GRU with 300 hidden units as the decoder. The size of $\boldsymbol{z}_s$ is set to 20. We use a batch size of 32 and train the model up to 40 epochs. Linear scheduling is used in the *KL* annealing and the weight grows from 0 at the beginning to 1 at 40k steps.

4.2 Sequence Modeling Evaluation

By the experiments on five datasets, we evaluate the language modeling ability in terms of perplexity (*PPL*). We compare several baselines including models based on language model (i.e., LSTM LM, LSTM+LDA, Topic-RNN, TDLM) and models based on VAE (i.e., LSTM VAE, VAE+HF, TGVAE, DCNNVAE, DVAE). LSTM LM is a plain language model implemented in LSTM. LSTM+LDA concatenates the hidden states with the topic distribution learned by a pre-trained LDA. Different from ours, LDA in LSTM+LDA is trained separately. Topic-RNN (Dieng et al., 2017) learns an LDA with a language model jointly and incorporates the topic distribution by a gate mechanism. TDLM (Lau et al., 2017) incorporates a convolutional topic model and also leverages the topic distribution in the same way that LSTM+LDA does. LSTM VAE is a standard VAE whose encoder and decoder are implemented by two LSTMs, respectively. VAE+HF (Wang et al., 2019) is a VAE with a mixture-of-Gaussians prior with Householder Flow. TGVAE (Wang et al., 2019) is a VAE guided by a Gaussian mixture distribution as prior with a jointly-trained LDA. DCNN-VAE (Yang et al., 2017) is a VAE using dilated CNN as its decoder. DVAE (Xiao et al., 2018) uses a Dirichlet latent variable to improve VAE. Besides the model we propose, we also evaluate our model without the discriminator (i.e., Ours w/o Dis).

The perplexity of VAE-based models is estimated in ELBO approximately which is comprised of a reconstruction term and a *KL* term. Besides the perplexity, we report the *KL* term in the VAE based models. For our model, we report the *KL* values of the sequence modeling component and the topic modeling component in the first and second rows, respectively.

For a fair comparison, the compared results are picked from the models with 50 topics. The results are shown in Table 2. We find that our model and our model without a discriminator occupy the top-2 positions. We attribute the improvements to the decoupling of semantic and structural features. From the results, we also verify that the discriminator in our model can help in decreasing the perplexity. In addition, the *KL* values in the topic modeling component is much larger than the sequential one. One possible reason is that the topic information reveals much of the diversity of texts.

4.3 Topic Coherence Evaluation

Topic models are traditionally evaluated using perplexity. However, (Chang et al., 2009) show that

	APNEWS		IMDB		BNC		Yahoo		Yelp15	
	PPL	*KL*	*PPL*	*KL*	*PPL*	*KL*	*PPL*	*KL*	*PPL*	*KL*
LSTM LM	64.13	-	72.14	-	102.89	-	66.2	-	42.6	-

Ours	**61.47**	**64.75**	**46.03**

* are from the original papers.

Table 4: Test split accuracy of classifiers trained with learned representations.

perplexity does not correlate with the coherence of the generated topic. We adopt normalized PMI (NPMI) to evaluate the topic coherence following (Lau et al., 2017). Given the top-n words of a topic, coherence is computed based on the sum of pairwise NPMI scores between topic words. We average topic coherence over the top 5/10/15/20 topic words. To aggregate topic coherence scores, we calculate the mean coherence over topics. In the experiments, the number of topics remains 50 among all baselines. From Table 3, we find that the discriminator gives little improvement. It is because that the role of the discriminator is to take the topic distributions as the supervised signals to improve the generation so that the sequence decoder can generate more topic relevant texts. That is, the discriminator does not improve the topic modeling component itself.

Besides topic coherence values, to understand the topics concretely, we also provide top five topic words from eight randomly chosen topics on each dataset in the supplementary material.

4.4 Semi-supervised Classification

To evaluate whether latent codes incorporate text features, we perform a semi-supervised classification task and compare our model with the other models. To make a comprehensive comparison, we use Yahoo, Yelp15 as well as 20NEWS for text classification. Here, 20NEWS is a collection of forum-like messages from 20 news-groups categories.

For any model to be evaluated, we first train it by the training documents of the dataset, and then executing the well-trained model to obtain latent codes of all documents in the dataset. Next, we sample 2,000 documents from the training data and train a 2-layer softmax classifier using these documents and their category labels. The accuracy on the testing set of documents is shown in Table 4. Since in our TATGM the latent code comprises two latent variables, we explore the accuracy on the two latent variables solely and collectively.

As shown in Table 4, our model which combines the two latent variables achieves the highest accuracy. For 20NEWS and Yahoo, the model only using the topic latent variable is better than that only using the structural latent variable. Since these two datasets are labeled by the topics, the combination improves little. For Yelp15 dataset, the performances of our two latent variables are similar whereas the combination improves up to

Topic	Question	Answer
Society&Culture	what is the average age of the homeless population?	i think they are younger then they look. i 'd guess 30 years old.
Science&Mathematics	what is the meaning of life in the world?	i know that i can find out about it.
Health	what is the average weight to lose of a week?	i think it varies to lose weight.
Education&Reference	what is the formula for energy?	i have about 10 points for asking questions.
Sports	which team has the most winning world cup?	i think brazil will win the world cup finals. i think they will win.
computers	what is the problem with the yahoo messenger?	i think yahoo messenger is not working on yahoo messenger.
Business&Finance	what is the minimum wage for a tax income?	i do n't know if they are illegal to pay taxes.
Entertainment&Music	what is the way of listen songs?	i think listen a song on internet.
Family&Relationships	what is the average age of have sex?	i am 14 years old and i 'm not sure what age is it?
Politics&Government	what states is the president of the united states?	i do n't know if it is illegal to be illegal.

Table 5: A topic transfer example of one question-answering pair on Yahoo dataset.

15%. The reason may be the fact that the Yelp15 dataset is labeled by the sentiment which is determined by not only single terms but also n-grams. For example, *good* and *not good* represents opposite sentiments. Our sequence modeling component can capture such kind of features more accurately.

4.5 Topic Transfer between Question-answering Pairs

In our model, each dimension of the latent variables in the topic modeling component corresponds to a topic, therefore we can manipulate the variables manually to verify whether the generation can express a given topic while remaining the same structure. Specifically, given a document and its latent code, we change the topic part of the code and keep the structural part of the code unchanged. Then we can check the text the decoder generated from the whole latent code.

We conduct the experiments on the Yahoo dataset where each item contains one question-answering pair and one label corresponds to its topic. At first, we treat each question as a single sentence to check whether the generated texts satisfy our assumption. From the second column of Table 5, we find that the generation can express a different topic while maintaining the original question structure.

We further try to transfer the question-answering pair from its original topic to target topics. We find that the model not only transfers topic of two sentences but also produces reasonable question-answering pairs, i.e., the new answer is meaningful to the new question.This is helpful for the automatic question-answering scenarios. Table 5 shows an example of topic transfer. The first row lists the original question-answering pair which are in the topic of *Society&Culture*. The rest rows show the generated question-answering pairs when we change the original topic to a target topic while keeping the structure latent variable unmodified. Specifically, we modify the original topic distribution to a new distribution whose dimension of the target topic is 1 and others are 0s. From the results, we can observe that while we change the topic to another, the generated questions remain almost the same structure as the original ones. Moreover, the generated answers are also transferred to the target topic and they together with the generated questions compose reasonable question-answering pairs. More examples are shown in the supplementary material.

5 Conclusion

In the paper, we present the text generation model TATGM. The model can learn semantics and structural features simultaneously. Moreover, the model employs a discriminator to ensure that the generated text is more coherent with the given topic information. Experimental results show that our model has a better text modeling ability than several state-of-the-art methods and learns disentangled latent representations for texts which shows the superiority in a classification task. Specifically, our model can generate meaningful question-answering pairs, which provides an alternative transfer learning way and helps to broaden

the knowledge in other fields.

LXMERT: Learning Cross-Modality Encoder Representations from Transformers

Hao Tan **Mohit Bansal**
UNC Chapel Hill
{haotan, mbansal}@cs.unc.edu

Abstract

Vision-and-language reasoning requires an understanding of visual concepts, language semantics, and, most importantly, the alignment and relationships between these two modalities. We thus propose the LXMERT (Learning Cross-Modality Encoder Representations from Transformers) framework to learn these vision-and-language connections. In LXMERT, we build a large-scale Transformer model that consists of three encoders: an object relationship encoder, a language encoder, and a cross-modality encoder. Next, to endow our model with the capability of connecting vision and language semantics, we pre-train the model with large amounts of image-and-sentence pairs, via five diverse representative pre-training tasks: masked language modeling, masked object prediction (feature regression and label classification), cross-modality matching, and image question answering. These tasks help in learning both intra-modality and cross-modality relationships. After fine-tuning from our pre-trained parameters, our model achieves the state-of-the-art results on two visual question answering datasets (i.e., VQA and GQA). We also show the generalizability of our pre-trained cross-modality model by adapting it to a challenging visual-reasoning task, NLVR^2, and improve the previous best result by 22% absolute (54% to 76%). Lastly, we demonstrate detailed ablation studies to prove that both our novel model components and pre-training strategies significantly contribute to our strong results.[1]

1 Introduction

Vision-and-language reasoning requires the understanding of visual contents, language semantics, and cross-modal alignments and relationships. There has been substantial past works in separately developing backbone models with better representations for the single modalities of vision and of language. For visual-content understanding, people have developed several backbone models (Simonyan and Zisserman, 2014; Szegedy et al., 2015; He et al., 2016) and shown their effectiveness on large vision datasets (Deng et al., 2009; Lin et al., 2014; Krishna et al., 2017). Pioneering works (Girshick et al., 2014; Xu et al., 2015) also show the generalizability of these pre-trained (especially on ImageNet) backbone models by fine-tuning them on different tasks. In terms of language understanding, last year, we witnessed strong progress towards building a universal backbone model with large-scale contextualized language model pre-training (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019), which has improved performances on various tasks (Rajpurkar et al., 2016; Wang et al., 2018) to significant levels. Despite these influential single-modality works, large-scale pretraining and fine-tuning studies for the modality-pair of vision and language are still under-developed.

Therefore, we present one of the first works in building a pre-trained vision-and-language cross-modality framework and show its strong performance on several datasets. We name this framework "LXMERT: Learning Cross-Modality Encoder Representations from Transformers" (pronounced: 'leksmert'). This framework is modeled after recent BERT-style innovations while further adapted to useful cross-modality scenarios. Our new cross-modality model focuses on learning vision-and-language interactions, especially for representations of a single image and its descriptive sentence. It consists of three Transformer (Vaswani et al., 2017) encoders: an object relationship encoder, a language encoder, and a cross-modality encoder. In order to better learn

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5100–5111,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the cross-modal alignments between vision and language, we next pre-train our model with five diverse representative tasks: (1) masked cross-modality language modeling, (2) masked object prediction via RoI-feature regression, (3) masked object prediction via detected-label classification, (4) cross-modality matching, and (5) image question answering. Different from single-modality pre-training (e.g., masked LM in BERT), this multi-modality pre-training allows our model to infer masked features either from the visible elements in the same modality, or from aligned components in the other modality. In this way, it helps build both intra-modality and cross-modality relationships.

Empirically, we first evaluate LXMERT on two popular visual question-answering datasets, VQA (Antol et al., 2015) and GQA (Hudson and Manning, 2019). Our model outperforms previous works in all question categories (e.g., Binary, Number, Open) and achieves state-of-the-art results in terms of overall accuracy. Further, to show the generalizability of our pre-trained model, we fine-tune LXMERT on a challenging visual reasoning task, Natural Language for Visual Reasoning for Real (NLVR^2) (Suhr et al., 2019), where we do not use the natural images in their dataset for our pre-training, but fine-tune and evaluate on these challenging, real-world images. In this setup, we achieve a large improvement of 22% absolute in accuracy (54% to 76%, i.e., 48% relative error reduction) and 30% absolute in consistency (12% to 42%, i.e., 34% relative error reduction). Lastly, we conduct several analysis and ablation studies to prove the effectiveness of our model components and diverse pre-training tasks by removing them or comparing them with their alternative options. Especially, we use several ways to take the existing BERT model and its variants, and show their ineffectiveness in vision-and-language tasks, which overall proves the need of our new cross-modality pre-training framework.

2 Model Architecture

We build our cross-modality model with self-attention and cross-attention layers following the recent progress in designing natural language processing models (e.g., transformers (Vaswani et al., 2017)). As shown in Fig. 1, our model takes two inputs: an image and its related sentence (e.g., a caption or a question). Each image is represented as a sequence of objects, and each sentence is represented as a sequence of words. Via careful design and combination of these self-attention and cross-attention layers, our model is able to generate language representations, image representations, and cross-modality representations from the inputs. Next, we describe the components of this model in detail.

2.1 Input Embeddings

The input embedding layers in LXMERT convert the inputs (i.e., an image and a sentence) into two sequences of features: word-level sentence embeddings and object-level image embeddings. These embedding features will be further processed by the latter encoding layers.

Word-Level Sentence Embeddings A sentence is first split into words $\{w_1, \ldots, w_n\}$ with length of n by the same WordPiece tokenizer (Wu et al., 2016) in Devlin et al. (2019). Next, as shown in Fig. 1, the word w_i and its index i (w_i's absolute position in the sentence) are projected to vectors by embedding sub-layers, and then added to the index-aware word embeddings:

$$\begin{aligned}\hat{w}_i &= \text{WordEmbed}\left(w_i\right)\\ \hat{u}_i &= \text{IdxEmbed}\left(i\right)\\ h_i &= \text{LayerNorm}\left(\hat{w}_i + \hat{u}_i\right)\end{aligned}$$

Object-Level Image Embeddings Instead of using the feature map output by a convolutional neural network, we follow Anderson et al. (2018) in taking the features of detected objects as the embeddings of images. Specifically, the object detector detects m objects $\{o_1, \ldots, o_m\}$ from the image (denoted by bounding boxes on the image in Fig. 1). Each object o_j is represented by its position feature (i.e., bounding box coordinates) p_j and its 2048-dimensional region-of-interest (RoI) feature f_j. Instead of directly using the RoI feature f_j without considering its position p_j in Anderson et al. (2018), we learn a position-aware embedding v_j by adding outputs of 2 fully-connected layers:

$$\begin{aligned}\hat{f}_j &= \text{LayerNorm}\left(W_{\text{F}} f_j + b_{\text{F}}\right)\\ \hat{p}_j &= \text{LayerNorm}\left(W_{\text{P}} p_j + b_{\text{P}}\right)\\ v_j &= \left(\hat{f}_j + \hat{p}_j\right)/2\end{aligned} \quad (1)$$

In addition to providing spatial information in visual reasoning, the inclusion of positional information is necessary for our masked object prediction pre-training task (described in Sec. 3.1.2).

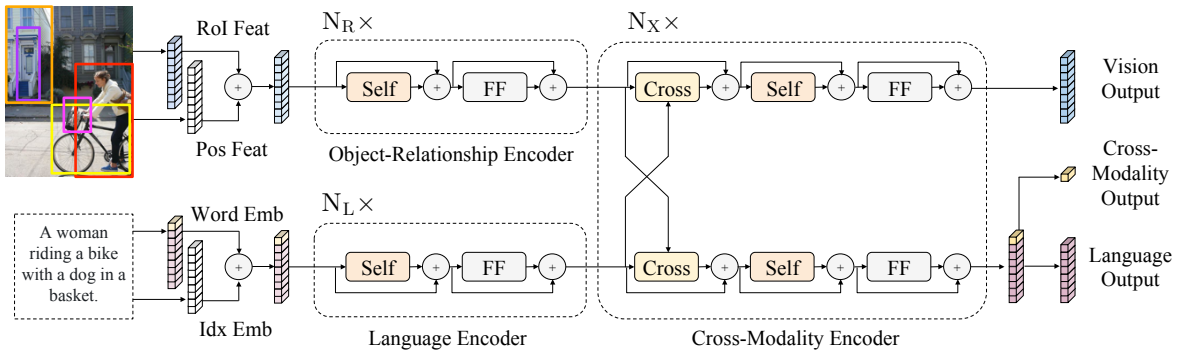

Figure 1: The LXMERT model for learning vision-and-language cross-modality representations. 'Self' and 'Cross' are abbreviations for self-attention sub-layers and cross-attention sub-layers, respectively. 'FF' denotes a feed-forward sub-layer.

Since the image embedding layer and the following attention layers are agnostic to the absolute indices of their inputs, the order of the object is not specified. Lastly, in Equation 1, the layer normalization is applied to the projected features before summation so as to balance the energy of the two different types of features.

2.2 Encoders

We build our encoders, i.e., the language encoder, the object-relationship encoder, and the cross-modality encoder, mostly on the basis of two kinds of attention layers: self-attention layers and cross-attention layers. We first review the definition and notations of attention layers and then discuss how they form our encoders.

Background: Attention Layers Attention layers (Bahdanau et al., 2014; Xu et al., 2015) aim to retrieve information from a set of *context* vectors $\{y_j\}$ related to a *query* vector x. An attention layer first calculates the matching score a_j between the *query* vector x and each *context* vector y_j. Scores are then normalized by softmax:

$$a_j = \text{score}(x, y_j)$$
$$\alpha_j = \exp(a_j) / \sum_k \exp(a_k)$$

The output of an attention layer is the weighted sum of the *context* vectors w.r.t. the softmax-normalized score: $\text{Att}_{\text{X}\to\text{Y}}(x, \{y_j\}) = \sum_j \alpha_j y_j$. An attention layer is called *self-attention* when the *query* vector x is in the set of *context* vectors $\{y_j\}$. Specifically, we use the multi-head attention following Transformer (Vaswani et al., 2017).

Single-Modality Encoders After the embedding layers, we first apply two transformer encoders (Vaswani et al., 2017), i.e., a **language encoder** and an **object-relationship encoder**, and each of them only focuses on a single modality (i.e., language or vision). Different from BERT (Devlin et al., 2019), which applies the transformer encoder only to language inputs, we apply it to vision inputs as well (and to cross-modality inputs as described later below). Each layer (left dashed blocks in Fig. 1) in a single-modality encoder contains a self-attention ('Self') sub-layer and a feed-forward ('FF') sub-layer, where the feed-forward sub-layer is further composed of two fully-connected sub-layers. We take $\mathbf{N_L}$ and $\mathbf{N_R}$ layers in the language encoder and the object-relationship encoder, respectively. We add a residual connection and layer normalization (annotated by the '+' sign in Fig. 1) after each sub-layer as in Vaswani et al. (2017).

Cross-Modality Encoder Each cross-modality layer (the right dashed block in Fig. 1) in the cross-modality encoder consists of two self-attention sub-layers, one bi-directional cross-attention sub-layer, and two feed-forward sub-layers. We stack (i.e., using the output of k-th layer as the input of $(k{+}1)$-th layer) $\mathbf{N_X}$ these cross-modality layers in our encoder implementation. Inside the k-th layer, the bi-directional cross-attention sub-layer ('Cross') is first applied, which contains two uni-directional cross-attention sub-layers: one from language to vision and one from vision to language. The query and context vectors are the outputs of the $(k{-}1)$-th layer (i.e., language features $\{h_i^{k-1}\}$ and vision features $\{v_j^{k-1}\}$):

$$\hat{h}_i^k = \text{CrossAtt}_{\text{L}\to\text{R}}\left(h_i^{k-1}, \{v_1^{k-1}, \ldots, v_m^{k-1}\}\right)$$
$$\hat{v}_j^k = \text{CrossAtt}_{\text{R}\to\text{L}}\left(v_j^{k-1}, \{h_1^{k-1}, \ldots, h_n^{k-1}\}\right)$$

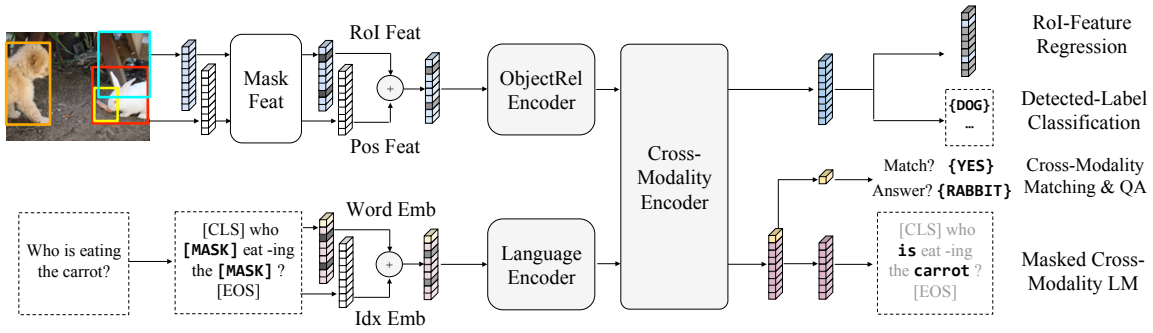

Figure 2: Pre-training in LXMERT. The object RoI features and word tokens are masked. Our five pre-training tasks learn the feature representations based on these masked inputs. Special tokens are in brackets and classification labels are in braces.

The cross-attention sub-layer is used to exchange the information and align the entities between the two modalities in order to learn joint cross-modality representations. For further building internal connections, the self-attention sub-layers ('Self') are then applied to the output of the cross-attention sub-layer:

$$\tilde{h}_i^k = \text{SelfAtt}_{\text{L}\to\text{L}}\left(\hat{h}_i^k, \{\hat{h}_1^k, \ldots, \hat{h}_n^k\}\right)$$
$$\tilde{v}_j^k = \text{SelfAtt}_{\text{R}\to\text{R}}\left(\hat{v}_j^k, \{\hat{v}_1^k, \ldots, \hat{v}_m^k\}\right)$$

Lastly, the k-th layer output $\{h_i^k\}$ and $\{v_j^k\}$ are produced by feed-forward sub-layers ('FF') on top of $\{\hat{h}_i^k\}$ and $\{\hat{v}_j^k\}$. We also add a residual connection and layer normalization after each sub-layer, similar to the single-modality encoders.

2.3 Output Representations

As shown in the right-most part of Fig. 1, our LXMERT cross-modality model has three outputs for language, vision, and cross-modality, respectively. The language and vision outputs are the feature sequences generated by the cross-modality encoder. For the cross-modality output, following the practice in Devlin et al. (2019), we append a special token [CLS] (denoted as the top yellow block in the bottom branch of Fig. 1) before the sentence words, and the corresponding feature vector of this special token in language feature sequences is used as the cross-modality output.

3 Pre-Training Strategies

In order to learn a better initialization which understands connections between vision and language, we pre-train our model with different modality pre-training tasks on a large aggregated dataset.

3.1 Pre-Training Tasks

3.1.1 Language Task: Masked Cross-Modality LM

On the language side, we take the masked cross-modality language model (LM) task. As shown in the bottom branch of Fig. 2, the task setup is almost same to BERT (Devlin et al., 2019): words are randomly masked with a probability of 0.15 and the model is asked to predict these masked words. In addition to BERT where masked words are predicted from the non-masked words in the language modality, LXMERT, with its cross-modality model architecture, could predict masked words from the vision modality as well, so as to resolve ambiguity. For example, as shown in Fig. 2, it is hard to determine the masked word 'carrot' from its language context but the word choice is clear if the visual information is considered. Hence, it helps building connections from the vision modality to the language modality, and we refer to this task as masked *cross-modality* LM to emphasize this difference. We also show that loading BERT parameters into LXMERT will do harm to the pre-training procedure in Sec. 5.1 since BERT can perform relatively well in the language modality without learning these cross-modality connections.

3.1.2 Vision Task: Masked Object Prediction

As shown in the top branch of Fig. 2, we pre-train the vision side by randomly masking objects (i.e., masking RoI features with zeros) with a probability of 0.15 and asking the model to predict proprieties of these masked objects. Similar to the language task (i.e., masked cross-modality LM), the model can infer the masked objects either from visible objects or from the language modality. Inferring the objects from the vision

Image Split	Images	Sentences (or Questions)					
		COCO-Cap	VG-Cap	VQA	GQA	VG-QA	All
MS COCO - VG	72K	361K	-	387K	-	-	0.75M
MS COCO ∩ VG	51K	256K	2.54M	271K	515K	724K	4.30M
VG - MS COCO	57K	-	2.85M	-	556K	718K	4.13M
All	180K	617K	5.39M	658K	1.07M	1.44M	9.18M

Table 1: Amount of data for pre-training. Each image has multiple sentences/questions. 'Cap' is caption. 'VG' is Visual Genome. Since MS COCO and VG share 51K images, we list it separately to ensure disjoint image splits.

side helps learn the object relationships, and inferring from the language side helps learn the cross-modality alignments. Therefore, we perform two sub-tasks: **RoI-Feature Regression** regresses the object RoI feature f_j with L2 loss, and **Detected-Label Classification** learns the labels of masked objects with cross-entropy loss. In the 'Detected-Label Classification' sub-task, although most of our pre-training images have object-level annotations, the ground truth labels of the annotated objects are inconsistent in different datasets (e.g., different number of label classes). For these reasons, we take detected labels output by Faster R-CNN (Ren et al., 2015). Although detected labels are noisy, experimental results show that these labels contribute to pre-training in Sec. 5.3.

3.1.3 Cross-Modality Tasks

As shown in the middle-rightmost part of Fig. 2, to learn a strong cross-modality representation, we pre-train the LXMERT model with 2 tasks that explicitly need both language and vision modalities.

Cross-Modality Matching For each sentence, with a probability of 0.5, we replace it with a mismatched[2] sentence. Then, we train a classifier to predict whether an image and a sentence match each other. This task is similar to 'Next Sentence Prediction' in BERT (Devlin et al., 2019).

Image Question Answering (QA) In order to enlarge the pre-training dataset (see details in Sec. 3.2), around $1/3$ sentences in the pre-training data are questions about the images. We ask the model to predict the answer to these image-related questions when the image and the question are matched (i.e., not randomly replaced in the cross-modality matching task). We show that pre-training with this image QA leads to a better cross-modality representation in Sec. 5.2.

[2] We take a sentence from another image as the mismatched sentence. Although the sentence and the image still have chance to match each other, this probability is very low.

3.2 Pre-Training Data

As shown in Table. 1, we aggregate pre-training data from five vision-and-language datasets whose images come from MS COCO (Lin et al., 2014) or Visual Genome (Krishna et al., 2017). Besides the two original captioning datasets, we also aggregate three large image question answering (image QA) datasets: VQA v2.0 (Antol et al., 2015), GQA balanced version (Hudson and Manning, 2019), and VG-QA (Zhu et al., 2016). We only collect **train and dev** splits in each dataset to avoid seeing any test data in pre-training. We conduct minimal pre-processing on the five datasets to create aligned image-and-sentence pairs. For each image question answering dataset, we take questions as sentences from the image-and-sentence data pairs and take answers as labels in the image QA pre-training task (described in Sec. 3.1.3). This provides us with a large aligned vision-and-language dataset of 9.18M image-and-sentence pairs on 180K distinct images. In terms of tokens, the pre-training data contain around 100M words and 6.5M image objects.

3.3 Pre-Training Procedure

We pre-train our LXMERT model on the large aggregated dataset (discussed in Sec. 3.2) via the pre-training tasks (Sec. 3.1). The details about the data splits are in the Appendix. The input sentences are split by the WordPiece tokenizer (Wu et al., 2016) provided in BERT (Devlin et al., 2019). The objects are detected by Faster R-CNN (Ren et al., 2015) which is pre-trained on Visual Genome (provided by Anderson et al. (2018)). We do not fine-tune the Faster R-CNN detector and freeze it as a feature extractor. Different from detecting variable numbers of objects in Anderson et al. (2018), we consistently keep 36 objects for each

Method	VQA				GQA			NLVR^2	
	Binary	Number	Other	**Accu**	Binary	Open	**Accu**	Cons	**Accu**
Human	-	-	-	-	91.2	87.4	89.3	-	96.3
Image Only	-	-	-	-	36.1	1.74	17.8	7.40	51.9
Language Only	66.8	31.8	27.6	44.3	61.9	22.7	41.1	4.20	51.1

LXMERT	**88.2**	**54.2**	**63.1**	**72.5**	**77.8**	**45.0**	**60.3**	**42.1**	**76.2**

Table 2: Test-set results. VQA/GQA results are reported on the 'test-standard' splits and NLVR^2 results are reported on the unreleased test set ('Test-U'). The highest method results are in bold. Our LXMERT framework outperforms previous (comparable) state-of-the-art methods on all three datasets w.r.t. all metrics.

image to maximize the pre-training compute utilization by avoiding padding. For the model architecture, we set the numbers of layers $\mathbf{N_L}$, $\mathbf{N_X}$, and $\mathbf{N_R}$ to 9, 5, and 5 respectively.[3] More layers are used in the language encoder to balance the visual features extracted from 101-layer Faster R-CNN. The hidden size 768 is the same as $\text{BERT}_{\text{BASE}}$. We pre-train all parameters in encoders and embedding layers from scratch (i.e., model parameters are randomly initialized or set to zero). We also show results of loading pre-trained BERT parameters in Sec. 5.1. LXMERT is pre-trained with multiple pre-training tasks and hence multiple losses are involved. We add these losses with equal weights. For the image QA pre-training tasks, we create a joint answer table with 9500 answer candidates which roughly cover 90% questions in all three image QA datasets.

We take Adam (Kingma and Ba, 2014) as the optimizer with a linear-decayed learning-rate schedule (Devlin et al., 2019) and a peak learning rate at $1e-4$. We train the model for 20 epochs (i.e., roughly 670K[4] optimization steps) with a batch size of 256. We only pre-train with image QA task (see Sec. 3.1.3) for the last 10 epochs, because this task converges faster and empirically needs a smaller learning rate. The whole pre-training process takes 10 days on 4 Titan Xp.

Fine-tuning Fine-tuning is fast and robust. We only perform necessary modification to our model with respect to different tasks (details in Sec. 4.2). We use a learning rate of $1e-5$ or $5e-5$, a batch size of 32, and fine-tune the model from our pre-trained parameters for 4 epochs.

[3]If we count a single modality layer as one half cross-modality layer, the equivalent number of cross-modality layers is $(9+5)/2+5=12$, which is same as the number of layers in $\text{BERT}_{\text{BASE}}$.

[4]For comparison, ResNet on ImageNet classification takes 600K steps and BERT takes 1000K steps.

4 Experimental Setup and Results

In this section, we first introduce the datasets that are used to evaluate our LXMERT framework and empirically compare our single-model results with previous best results.

4.1 Evaluated Datasets

We use three datasets for evaluating our LXMERT framework: VQA v2.0 dataset (Goyal et al., 2017), GQA (Hudson and Manning, 2019), and NLVR^2. See details in Appendix.

4.2 Implementation Details

On VQA and GQA, we fine-tune our model from the pre-trained snapshot without data augmentation (analysis in Sec. 5.2). When training GQA, we only take raw questions and raw images as inputs and do not use other supervisions (e.g., functional programs and scene graphs). Since each datum in NLVR^2 has two natural images img_0, img_1 and one language statement s, we use LXMERT to encode the two image-statement pairs (img_0, s) and (img_1, s), then train a classifier based on the concatenation of the two cross-modality outputs. More details in Appendix.

4.3 Empirical Comparison Results

We compare our single-model results with previous best published results on VQA/GQA test-standard sets and NLVR^2 public test set. Besides previous state-of-the-art (SotA) methods, we also show the human performance and image-only/language-only results when available.

VQA The SotA result is BAN+Counter in Kim et al. (2018), which achieves the best accuracy among other recent works: MFH (Yu et al.,

2018), Pythia (Jiang et al., 2018), DFAF (Gao et al., 2019a), and Cycle-Consistency (Shah et al., 2019).[5] LXMERT improves the SotA overall *accuracy* ('Accu' in Table 2) by 2.1% and has 2.4% improvement on the 'Binary'/'Other' question sub-categories. Although LXMERT does not explicitly take a counting module as in BAN+Counter, our result on the counting-related questions ('Number') is still equal or better.[6]

GQA The GQA (Hudson and Manning, 2019) SotA result is taken from BAN (Kim et al., 2018) on the public leaderbaord. Our 3.2% *accuracy* gain over the SotA GQA method is higher than VQA, possibly because GQA requires more visual reasoning. Thus our framework, with novel encoders and cross-modality pre-training, is suitable and achieves a 4.6% improvement on open-domain questions ('Open' in Table 2).[7]

NLVR^2 NLVR^2 (Suhr et al., 2019) is a challenging visual reasoning dataset where some existing approaches (Hu et al., 2017; Perez et al., 2018) fail, and the SotA method is 'MaxEnt' in Suhr et al. (2019). The failure of existing methods (and our model w/o pre-training in Sec. 5.1) indicates that the connection between vision and language may not be end-to-end learned in a complex vision-and-language task without large-scale pre-training. However, with our novel pre-training strategies in building the cross-modality connections, we significantly improve the *accuracy* ('Accu' of 76.2% on unreleased test set 'Test-U', in Table 2) by 22%. Another evaluation metric *consistency* measures the proportion of unique sentences for which all related image pairs[8] are correctly predicted. Our LXMERT model improves *consistency* ('Cons') to 42.1% (i.e., by 3.5 times).[9]

[5] These are state-of-the-art methods at the time of our EMNLP May 21, 2019 submission deadline. Since then, there have been some recently updated papers such as MCAN (Yu et al., 2019b), MUAN (Yu et al., 2019a), and MLI (Gao et al., 2019b). MCAN (VQA challenge version) uses stronger mixture of detection features and achieves 72.8% on VQA 2.0 test-standard. MUAN achieves 71.1% (compared to our 72.5%).

[6] Our result on VQA v2.0 'test-dev' is 72.4%.

[7] Our result on GQA 'test-dev' is 60.0%.

[8] Each statement in NLVR^2 is related to multiple image pairs in order to balance the dataset answer distribution.

[9] These are the unreleased test set ('Test-U') results. On the public test set ('Test-P'), LXMERT achieves 74.5% Accu and 39.7% Cons.

Method	VQA	GQA	NLVR^2
LSTM + BUTD	63.1	50.0	52.6
BERT + BUTD	62.8	52.1	51.9
BERT + 1 CrossAtt	64.6	55.5	52.4
BERT + 2 CrossAtt	65.8	56.1	50.9
BERT + 3 CrossAtt	66.4	56.6	50.9
BERT + 4 CrossAtt	66.4	56.0	50.9
BERT + 5 CrossAtt	66.5	56.3	50.9
Train + BERT	65.5	56.2	50.9

Pre-train + scratch	**69.9**	**60.0**	**74.9**

Table 3: Dev-set accuracy of using BERT.

5 Analysis

In this section, we analyze our LXMERT framework by comparing it with some alternative choices or by excluding certain model components/pre-training strategies.

5.1 BERT versus LXMERT

BERT (Devlin et al., 2019) is a pre-trained language encoder which improves several language tasks. As shown in Table 3, we discuss several ways to incorporate a $\text{BERT}_{\text{BASE}}$ pre-trained model for vision-language tasks and empirically compare it with our LXMERT approach. Although our full model achieves accuracy of 74.9% on NLVR^2, all results without LXMERT pre-training is around 22% absolute lower.

BERT+BUTD Bottom-Up and Top-Down (BUTD) attention (Anderson et al., 2018) method encodes questions with GRU (Chung et al., 2015), then attends to object RoI features $\{f_j\}$ to predict the answer. We apply BERT to BUTD by replacing its GRU language encoder with BERT. As shown in the first block of Table. 3, results of BERT encoder is comparable to LSTM encoder.

BERT+CrossAtt Since BUTD only takes the raw RoI features $\{f_j\}$ without considering the object positions $\{p_j\}$ and object relationships, we enhance BERT+BUTD with our novel position-aware object embedding (in Sec. 2.1) and cross-modality layers (in Sec. 2.2). As shown in the second block of Table 3, the result of 1 cross-modality layer is better than BUTD, while stacking more cross-modality layers further improves it. However, without our cross-modality pre-

Method	VQA	GQA	NLVR^2

2. P20 + FT	68.9	58.2	72.4
3. P10+QA10 + DA	69.1	59.2	-
4. P10+QA10 + FT	**69.9**	**60.0**	**74.9**

Table 4: Dev-set accuracy showing the importance of the image-QA pre-training task. P10 means pre-training without the image-QA loss for 10 epochs while QA10 means pre-training with the image-QA loss. DA and FT mean fine-tuning with and without Data Augmentation, resp.

Method	VQA	GQA	NLVR^2
1. No Vision Tasks	66.3	57.1	50.9
2. Feat	69.2	59.5	72.9
3. Label	69.5	59.3	73.5
4. Feat + Label	**69.9**	**60.0**	**74.9**

Table 5: Dev-set accuracy of different vision pre-training tasks. 'Feat' is RoI-feature regression; 'Label' is detected-label classification.

training (BERT is language-only pre-trained), results become stationary after adding 3 cross-attention layers and have a 3.4% gap to our full LXMERT framework (the last bold row in Table 3).

BERT+LXMERT We also try loading BERT parameters[10] into LXMERT, and use it in model training (i.e., without LXMERT pre-training) or in pre-training. We show results in the last block of Table. 3. Compared to the 'from scratch' (i.e., model parameters are randomly initialized) approach, BERT improves the fine-tuning results but it shows weaker results than our full model. Empirically, pre-training LXMERT initialized with BERT parameters has lower (i.e., better) pre-training loss for the first 3 pre-training epochs but was then caught up by our 'from scratch' approach. A possible reason is that BERT is already pre-trained with single-modality masked language model, and thus could do well based only on the language modality without considering the connection to the vision modality (as discussed in Sec. 3.1.1).

5.2 Effect of the Image QA Pre-training Task

We show the importance of image QA pre-training task (introduced in Sec. 3.1.3) by excluding it or comparing it with its alternative: data augmentation.

Pre-training w/ or w/o Image QA To fairly compare with our original pre-training procedure (10 epochs w/o QA + 10 epochs w/ QA, details in Sec. 3.3) , we pre-train LXMERT model without image QA task for 20 epochs. As shown in Table 4 rows 2 and 4, pre-training with QA loss improves the result on all three datasets. The 2.1% improvement on NLVR^2 shows the stronger representations learned with image-QA pre-training, since all data (images and statements) in NLVR^2 are not used in pre-training.

Pre-training versus Data Augmentation Data augmentation (DA) is a technique which is used in several VQA implementations (Anderson et al., 2018; Kim et al., 2018; Jiang et al., 2018). It increases the amount of training data by adding questions from other image QA datasets. Our LXMERT framework instead uses multiple QA datasets in pre-training and is fine-tuned only on one specific dataset. Since the overall amounts of data used in pre-training and DA are similar, we thus can fairly compare these two strategies, and results show that our QA pre-training approach outperforms DA. We first exclude the QA task in our pre-training and show the results of DA fine-tuning. As shown in Table. 4 row 1, DA fine-tuning decreases the results compared to non-DA fine-tuning in row 2. Next, we use DA after QA-pre-training (row 3) and DA also drops the results.

5.3 Effect of Vision Pre-training tasks

We analyze the effect of different vision pre-training tasks in Table 5. Without any vision tasks in pre-training (i.e., only using the language and cross-modality pre-training tasks), the results (row 1 of Table 5) are similar to BERT+3 CrossAtt in Table 3. The two visual pre-training tasks (i.e., RoI-feature regression and detected-label classification) could get reasonable results (row 2 and row 3) on their own, and jointly pre-training with these two tasks achieves the highest results (row 4).

6 Related Work

Model Architecture: Our model is closely related to three ideas: bi-directional attention, Transformer, and BUTD. Lu et al. (2016) applies bi-

[10] Since our language encoder is same as BERT$_{\text{BASE}}$, except the number of layers (i.e., LXMERT has 9 layers and BERT has 12 layers), we load the top 9 BERT-layer parameters into the LXMERT language encoder.

directional attention to the vision-and-language tasks while its concurrent work BiDAF (Seo et al., 2017) adds modeling layers in solving reading comprehension. Transformer (Vaswani et al., 2017) is first used in machine translation, we utilize it as our single-modality encoders and design our cross-modality encoder based on it. BUTD (Anderson et al., 2018) embeds images with the object RoI features, we extend it with object positional embeddings and object relationship encoders.

Pre-training: After ELMo (Peters et al., 2018), GPT (Radford et al., 2018), and BERT (Devlin et al., 2019) show improvements in language understanding tasks with large-scale pre-trained language model, progress has been made towards the cross-modality pre-training. XLM (Lample and Conneau, 2019) learns the joint cross-lingual representations by leveraging the monolingual data and parallel data. VideoBert (Sun et al., 2019) takes masked LM on the concatenation of language words and visual tokens, where the visual tokens are converted from video frames by vector quantization. However, these methods are still based on a single transformer encoder and BERT-stype token-based pre-training, thus we develop a new model architecture and novel pre-training tasks to satisfy the need of cross-modality tasks.

Recent works since our EMNLP submission: This version of our paper (and all current results) was submitted to EMNLP[11] and was used to participate in the VQA and GQA challenges in May 2019. Since our EMNLP submission, a few other useful preprints have recently been released (in August) on similar cross-modality pre-training directions: ViLBERT (Lu et al., 2019) and VisualBERT (Li et al., 2019). Our LXMERT methods differs from them in multiple ways: we use a more detailed, multi-component design for the cross-modality model (i.e., with an object-relationship encoder and cross-modality layers) and we employ additional, useful pre-training tasks (i.e., RoI-feature regression and image question answering). These differences result in the current best performance (on overlapping reported tasks): a margin of 1.5% accuracy on VQA 2.0 and a margin of 9% accuracy on NLVR^2 (and 15% in consistency). LXMERT is also the only method which ranks in the top-3 on both the VQA and GQA challenges among more than 90 teams. We provide a detailed analysis to show how these additional pre-training tasks contribute to the fine-tuning performance in Sec. 5.2 and Sec. 5.3.

[11] EMNLP deadline was on May 21, 2019, and the standard ACL/EMNLP arxiv ban rule was in place till the notification date of August 12, 2019.

7 Conclusion

We presented a cross-modality framework, LXMERT, for learning the connections between vision and language. We build the model based on Transfermer encoders and our novel cross-modality encoder. This model is then pre-trained with diverse pre-training tasks on a large-scale dataset of image-and-sentence pairs. Empirically, we show state-of-the-art results on two image QA datasets (i.e., VQA and GQA) and show the model generalizability with a 22% improvement on the challenging visual reasoning dataset of NLVR^2. We also show the effectiveness of several model components and training methods via detailed analysis and ablation studies.

Appendix

A Evaluated Datasets Description

We use three datasets for evaluating our LXMERT framework.

VQA The goal of visual question answering (VQA) (Antol et al., 2015) is to answer a natural language question related to an image. We take VQA v2.0 dataset (Goyal et al., 2017) which reduces the answer bias compared to VQA v1.0. The dataset contains an average of 5.4 questions per image and the total amount of questions is 1.1M.

GQA The task of GQA (Hudson and Manning, 2019) is same as VQA (i.e., answer single-image related questions), but GQA requires more reasoning skills (e.g., spatial understanding and multi-step inference). 22M questions in the dataset are generated from ground truth image scene graph to explicitly control the question quality.

NLVR^2 Since the previous two datasets are used in pre-training for increasing the amount of pre-training data to a certain scale, we evaluate our LXMERT framework on another challenging visual reasoning dataset NLVR^2 where all the sentences and images are not covered in pre-training. Each datum in NLVR^2 contains two related natural images and one natural language statement. The task is to predict whether the statement correctly describes these two images or not. NLVR^2 has 86K, 7K, 7K data in training, development, and test sets, respectively.

B Details of NLVR^2 Fine-tuning

Each datum in NLVR^2 consists of a two-image pair (img_0, img_1), one statement s, and a ground truth label y^* indicating whether the statement correctly describe the two images. The task is to predict the label y given the images and the statement.

To use our LXMERT model on NLVR^2, we concatenate the cross-modality representations of the two images and then build the classifier with GeLU activation(Hendrycks and Gimpel, 2016). Suppose that $\text{LXMERT}(img, sent)$ is the single-vector cross-modality representation, the predicted probability is:

$$\begin{aligned} x_0 &= \text{LXMERT}(img_0, s) \\ x_1 &= \text{LXMERT}(img_1, s) \\ z^0 &= W_0[x_0; x_1] + b_0 \\ z^1 &= \text{LayerNorm}\left(\text{GeLU}(z^0)\right) \\ prob &= \sigma(W_1 z^1 + b_1) \end{aligned}$$

where σ is sigmoid function. The model is optimized by maximizing the log-likelihood, which is equivalent to minimize the binary cross entropy loss:

$$\mathcal{L} = \text{-}y^* \log prob - (1 - y^*) \log(1 - prob)$$

C Training, Validation, and Testing Splits

We carefully split each dataset to ensure that all testing images are not involved in any pre-training or fine-tuning steps. Our data splits for each dataset and reproducible code are available at https://github.com/airsplay/lxmert.

LXMERT Pre-Traininig Since MS COCO has a relative large validation set, we sample a set of 5k images from the MS COCO validation set as the mini-validation (minival) set. The rest of the images in training and validation sets (i.e., COCO training images, COCO validation images besides minival, and all the other images in Visual Genome) are used in pre-training. Although the captions and questions of the MS COCO test sets are available, we exclude all of them to make sure that testing images are not seen in pre-training.

Fine-tuning For training and validating VQA v2.0, we take the same split convention as in our LXMERT pre-training. The data related to images in LXMERT mini-validation set is used to validate model performance and the rest of the data in train+val are used in fine-tuning. We test our model on the VQA v2.0 'test-dev' and 'test-standard' splits. For GQA fine-tuning, we follow the suggestions in official GQA guidelines[12] to take *testdev* as our validation set and fine-tune our model on the joint train + validation sets. We test our GQA model on GQA 'test-standard' split. The images in NLVR^2 are not from either MS COCO or Visual Genome, we thus keep using the original split: fine-tune on train split, validate the model choice on val split, and test on the public ('Test-P') and unreleased ('Test-U') test splits.

D Training Details of 'BERT versus LXMERT'

When training with BERT only, we train each experiments for 20 epochs with a batch size 64/128 since it was not pre-trained on these cross-modality datasets. The learning rate is set to $1e-4$ instead of $5e-5$.

Phrase Grounding by Soft-Label Chain Conditional Random Field

Jiacheng Liu **Julia Hockenmaier**
University of Illinois at Urbana-Champaign, Urbana, IL, USA 61801

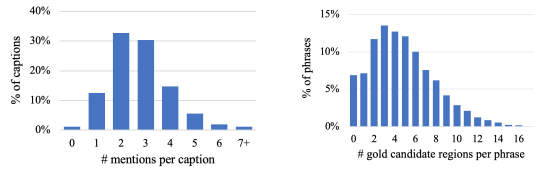
Abstract

The phrase grounding task aims to ground each entity mention in a given caption of an image to a corresponding region in that image. Although there are clear dependencies between how different mentions of the same caption should be grounded, previous structured prediction methods that aim to capture such dependencies need to resort to approximate inference or non-differentiable losses. In this paper, we formulate phrase grounding as a sequence labeling task where we treat candidate regions as potential labels, and use neural chain Conditional Random Fields (CRFs) to model dependencies among regions for adjacent mentions. In contrast to standard sequence labeling tasks, the phrase grounding task is defined such that there may be multiple correct candidate regions. To address this multiplicity of gold labels, we define so-called Soft-Label Chain CRFs, and present an algorithm that enables convenient end-to-end training. Our method establishes a new state-of-the-art on phrase grounding on the Flickr30k Entities dataset. Analysis shows that our model benefits both from the entity dependencies captured by the CRF and from the soft-label training regime. Our code is available at github.com/liujch1998/SoftLabelCCRF

1 Introduction

Given an image and a corresponding caption, the phrase grounding task aims to ground each entity mentioned by a noun phrase in the caption to a region in the image. Phrase grounding has attracted much research interest due to its application in downstream tasks including image captioning (Karpathy et al., 2014; Fang et al., 2015; Donahue et al., 2017; Xu et al., 2015), image retrieval (Chen et al., 2017a; Radenovic et al., 2016), and visual question answering (Agrawal et al., 2017; Yu et al., 2017, 2018a).

(a) Dependency between entities. The visual relationship between grounding regions for "cheerleaders" and "a girl" should agree with context "toss ... high up into the air".



(b) Gold label multiplicity. The green box is the annotated gold grounding region for entity phrase "Old man", while the orange dash boxes are region proposals with IoU ≥ 0.5 with gold.

Figure 1: Example image-caption pairs from Flickr30k Entities, illustrating entity dependencies and gold label multiplicity.

Phrase grounding systems typically work by ranking a set of candidate regions (Chen et al., 2017b; Yu et al., 2018b). Region proposals are generated from the image by a vision backbone model, without conditioning on the caption. Features of the phrase to be grounded are extracted, and subsequently interact with features of candidate regions, to determine phrase-region compatibility. Candidate regions are then ranked based on this compatibility metric, and the highest-scored candidate region is selected as the predicted grounding of the phrase.

In Flickr30k Entities (Plummer et al., 2017b), each caption contains an average of 2.76 entity phrases to ground (Figure 2a; phrases with no corresponding gold regions are not counted). It therefore stands to reason that phrases in the same caption should not be grounded independently (to op-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5112–5122, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(a) Distribution of number of entity phrases per caption.

(b) Distribution of number of gold labels per entity phrase.

Figure 2: Validation set statistics for Flickr30k Entities.

timize each individual phrase-region assignment), but jointly (to optimize the global phrase-region assignment for the entire caption). Figure 1a illustrates this phenomenon. The caption contains a sequence of two entity phrases, "cheerleaders" and "a girl", and the task is to label each phrase with a candidate region that best grounds it. Since there are several women present in the image, "a girl" has ambiguous grounding by itself, but it can be disambiguated by encouraging the visual relationship between "a girl" and "cheerleaders" to conform with context provided in the caption.

Some works are aware that dependencies between entities in the same caption play an important role in building more accurate phrase grounding systems (Wang et al., 2016; Plummer et al., 2017a; Chen et al., 2017b). The success of these structured prediction methods shows the advantage of considering entity dependencies in learning and prediction. However, these approaches capture certain relations in an *ad hoc* manner, and resort to approximate inference (Wang et al., 2016; Plummer et al., 2017a) or non-differentiable losses (Chen et al., 2017b).

To obtain models and inference algorithms that facilitate more globally consistent phrase grounding predictions, we propose to formulate phrase grounding as a sequence labeling task where we treat candidate regions as potential labels for the phrases in the input sequence. This allows us to build phrase grounding models based on Conditional Random Fields (CRFs) (Lafferty et al., 2001) that capture entity dependencies in a universal and differentiable manner. Our results indicate that systems that capture dependencies between phrases in the same caption in a principled manner outperform systems that ignore these dependencies.

A second problem lies in the use of region proposals, which distinguishes phrase grounding from other sequence labeling tasks where CRFs are directly applicable. Following the metrics of object detection, in phrase grounding the correctness of a predicted region is judged by its overlap by Intersection-over-Union (IoU) with the gold region (Plummer et al., 2017b). To cover potential regions with high enough IoU, it is common to generate a myriad of region proposals and for these candidate regions to contain or substantially overlap with each other. As a result, there could be more than one candidate region with high IoU with the gold region, and they should all be considered as correct grounding for the phrase. This phenomenon of gold label multiplicity is illustrated in Figure 1b. We hypothesize that it is important to consider gold label multiplicity and identify all correct region proposals during training, since the model would receive contradictory training signals if some correct proposals were marked as incorrect. With region proposals generated by a Bottom-Up Attention (Anderson et al., 2018) visual backbone, in Flickr30k Entities each phrase has an average of 4.75 gold labels, and detailed statistics are presented in Figure 2b. To address this problem, we adopt the soft-label target distribution proposed by Yu et al. (2018b), and our experiments show that models trained with this regime significantly outperform those trained with one-hot target regime.

To combine the benefits brought by structured prediction from CRFs and by soft-label training regime, we define Soft-Label Chain CRFs, a variation of standard chain CRFs that allows us to work with gold label multiplicity. We adapt learning and inference algorithms from chain CRFs and develop an end-to-end training algorithm for our proposed model.

We evaluate the effectiveness of Soft-Label Chain CRF on phrase grounding by conducting experiments on the Flickr30k Entities dataset (Plummer et al., 2017b) and comparing grounding accuracy with strong baseline models, as well as with existing structured prediction methods and current state-of-the-art models. Experimental results show that our Soft-Label Chain CRF model outperforms its hard-label CRF counterpart by 2.43%, a vanilla non-CRF soft-label model by 0.40%, and the previous best results by about 1.4%, demonstrating that both of our contributions, modeling phrase grounding as a sequence labeling task, and training with soft label targets, matter for this task.

2 Related Work

Phrase Grounding. The phrase grounding task was first postulated by Karpathy and Fei-Fei (2017) and Plummer et al. (2017b), both of which moved from the holistic image captioning to the finer-grained task of matching regions with phrases in the caption. Datasets for this task include Flickr30k Entities (Plummer et al., 2017b), RefCOCO (Yu et al., 2016), and Visual Genome (Krishna et al., 2017). The general framework of proposal-generation-ranking has become adopted by most approaches to phrase grounding, and research in this area has focused on improving specific components of this framework. Our work can be viewed as an improvement to the training and prediction aspects.

Structured Prediction in Phrase Grounding. We summarize some works that consider entity dependencies by structured prediction. Structured Matching (Wang et al., 2016) formulates phrase grounding as a bipartite matching process between phrases and candidate regions, and encourages the spatial relationship between two grounding regions to conform to an extracted *partial coreference* relation between their corresponding phrases. The resulting discrete optimization problem is then relaxed into a linear program to enable end-to-end training. Phrase-Region CCA (Plummer et al., 2017a) mines *frequent patterns* of semantically related paired phrases and trains a separate model for each pattern. The addition of this pairwise score makes the optimization a quadratic programming problem that requires approximate inference. QRC Net (Chen et al., 2017b) assumes that phrases in a caption refer to distinct entities, and thus predicted grounding regions are penalized for *spatial overlapping*. However, overlapping regions can be penalized only after prediction, so this loss is not differentiable, and one has to resort to reinforcement learning. In these works, partial coreference extraction, frequent patterns mining and spatial overlap penalties are *ad hoc* entity dependency capturing, while we aim to universally encompass the spectrum of such dependencies.

Soft-Label Training Regime. Conventionally, region proposal ranking is done by predicting a probability distribution over all candidate regions for grounding a given entity phrase, which is learned to match a target distribution. Chen et al. (2017b) and Rohrbach et al. (2016) define the target distribution as a one-hot vector which only gives credit to the candidate region with highest IoU with the gold region, and cross-entropy loss is used as training objective. Under this hard-label training regime, the model is trained to pick only the best candidate region while rejecting all the inferior-than-best candidate regions, which is intuitively not a good behavior. Yu et al. (2018b) proposes a soft-label target distribution which gives weighted credit to all good candidate regions (i.e. those with above-threshold IoU with the gold region), and uses Kullback-Leibler (KL) divergence loss as training objective.

Conditional Random Fields. CRFs (Lafferty et al., 2001) are discriminative probabilistic models that have been found useful in sequence labeling tasks by capturing label dependencies (Ma and Hovy, 2016; Lample et al., 2016). We summarize some works relevant to CRFs learned in soft-label or multi-label settings. Multi-CRFs (Dredze et al., 2009) learn CRFs with noisy annotated data, where annotators may disagree on the label for input tokens. The assumption is that there is always only one gold label for each token, so the model favors single label while conforming to the prior distribution of labels set by annotators. To work with soft-label targets, it employs a mode-seeking, exclusive KL divergence definition, which does not imply moment-matching, a desired property of CRFs (and in general, exponential family models) that we show in Section 3.1 and 3.2 for the mean-seeking, inclusive KL divergence definition in our model. Rodrigues et al. (2014) models the latent reliability of individual annotators, and use this information to guide the selection of trustworthy annotation sources and estimation of real gold labels. Note that both works always assume one gold label per input token, where the ambiguity comes from unreliability of annotations, while our work focuses on cases where there may be multiple gold labels per input token by the nature of the task.

3 Soft-Label Chain CRF

CRFs model the probability of a label sequence $\boldsymbol{y} = y^{1:T}$ conditioned on an input sequence $\boldsymbol{x} = x^{1:T}$ in terms of a score function $s(\boldsymbol{x}, \boldsymbol{y})$:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \frac{\exp s(\boldsymbol{y}, \boldsymbol{x})}{\sum_{\boldsymbol{y}'} \exp s(\boldsymbol{y}', \boldsymbol{x})}$$

For a given training example $\{(\boldsymbol{x}, \boldsymbol{y})\}$, the negative log-likelihood loss (i.e. cross-entropy loss

w.r.t. a one-hot target distribution that gives credit to the gold label only) is

$$L = -\log p(\boldsymbol{y}|\boldsymbol{x}) = -s(\boldsymbol{y}, \boldsymbol{x}) + \log Z(\boldsymbol{x})$$

where $Z(\boldsymbol{x}) = \sum_{\boldsymbol{y}'} \exp s(\boldsymbol{y}', \boldsymbol{x})$. The gradient of this loss w.r.t. score function is

$$\frac{\partial L}{\partial s(\boldsymbol{y}', \boldsymbol{x})} = -\mathbb{I}(\boldsymbol{y}' = \boldsymbol{y}) + p(\boldsymbol{y}'|\boldsymbol{x})$$

which is known as moment-matching. This allows us to train CRFs with gradient methods and conveniently connect to backpropagation when the score function is modeled by a neural architecture.

3.1 Soft-Label CRF

In the standard CRF above, each input x^t corresponds to a single gold label y^t. To account for gold label multiplicity in training stage, we replace the sequence of gold labels $\boldsymbol{y}$ with a sequence of distributions $\boldsymbol{q} = q^{1:T}$ where $q^t \in \mathbb{R}^K$ is the gold label distribution over all K possible labels for input x^t. Note that this distribution should not be interpreted as the confidence of each label being correct; rather, it should be understood as a probabilistic gold label model: if we randomly choose a gold label, how likely is each label to be selected. With independence assumption, the gold probability of an arbitrary label sequence $\boldsymbol{y}$ is

$$q(\boldsymbol{y}|\boldsymbol{x}) = \prod_t q(y^t|\boldsymbol{x}) = \prod_t q(y^t|x^t) = \prod_t q^t_{y^t}$$

It is easy to see that $q(\boldsymbol{y}|\boldsymbol{x})$ is a distribution:

$$\sum_{\boldsymbol{y}} q(\boldsymbol{y}|\boldsymbol{x}) = \sum_{\boldsymbol{y}} \prod_t q^t_{y^t} = \prod_t \sum_{y^t} q^t_{y^t} = 1$$

And our goal is to learn this target distribution.

Since this target distribution is no longer degenerate, we use Kullback-Leibler (KL) divergence to measure the discrepancy between the model and the target distribution. Our training objective is the KL divergence loss (in mean-seeking, inclusive form):

$$L = \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) \log \frac{q(\boldsymbol{y}|\boldsymbol{x})}{p(\boldsymbol{y}|\boldsymbol{x})} \Big\}$$

which also gives gradients that demonstrate moment-matching:

$$\frac{\partial L}{\partial s(\boldsymbol{y}', \boldsymbol{x})} = -q(\boldsymbol{y}'|\boldsymbol{x}) + p(\boldsymbol{y}'|\boldsymbol{x})$$

Note that if we had defined the KL divergence loss in its mode-seeking, exclusive form $\sum_{\boldsymbol{y}} p(\boldsymbol{y}|\boldsymbol{x}) \log \frac{p(\boldsymbol{y}|\boldsymbol{x})}{q(\boldsymbol{y}|\boldsymbol{x})}$, we would have lost this desired moment-matching property.

3.2 Factorization of Soft-Label Chain CRF

Learning CRFs of general graphs requires inference in unit of cliques, which is usually computationally intractable. By restricting to local, pairwise potentials, we reduce the model to a first-order linear chain CRF, whose scoring function factorizes as

$$\begin{aligned} s(\boldsymbol{y}, \boldsymbol{x}) &= \sum_t s(y^t, y^{t-1}, \boldsymbol{x}) \\ &= \sum_t \Big\{ \tau(y^t, y^{t-1}, \boldsymbol{x}) + \varepsilon(y^t, \boldsymbol{x}) \Big\} \end{aligned}$$

where $\tau(\cdot, \cdot, \cdot)$ is the transition score between labels at $t-1$ and t that captures the dependency between labels for adjacent input tokens, and $\varepsilon(\cdot, \cdot)$ is the emission score between label and input at t.

Combining this factorization with soft-label targets gives the formal definition of Soft-Label Chain CRF. The loss can be written as

$$\begin{aligned} L &= \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) \log \frac{q(\boldsymbol{y}|\boldsymbol{x})}{p(\boldsymbol{y}|\boldsymbol{x})} \Big\} \\ &= \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) \big[\log q(\boldsymbol{y}|\boldsymbol{x}) - s(\boldsymbol{y},\boldsymbol{x}) + \log Z(\boldsymbol{x}) \big] \Big\} \\ &\qquad \text{(Expand } p(\boldsymbol{y}|\boldsymbol{x}) \text{ by CRF modeling)} \\ &= \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) \big[\log q(\boldsymbol{y}|\boldsymbol{x}) - s(\boldsymbol{y},\boldsymbol{x}) \big] \Big\} + \log Z(\boldsymbol{x}) \\ &\qquad \text{(Marginalize } q(\boldsymbol{y}|\boldsymbol{x})\text{)} \\ &= \sum_t \sum_{y^t} \Big\{ q(y^t|\boldsymbol{x}) \log q(y^t|\boldsymbol{x}) \Big\} \\ &\quad - \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) s(\boldsymbol{y},\boldsymbol{x}) \Big\} + \log Z(\boldsymbol{x}) \\ &\qquad \text{(Independence of } q(y^t|\boldsymbol{x}) \text{ across } t\text{)} \\ &= \sum_t \sum_{y^t} \Big\{ q(y^t|\boldsymbol{x}) \log q(y^t|\boldsymbol{x}) \Big\} \\ &\quad - \sum_{\boldsymbol{y}} \Big\{ q(\boldsymbol{y}|\boldsymbol{x}) \sum_t s(y^t,y^{t-1},\boldsymbol{x}) \Big\} + \log Z(\boldsymbol{x}) \\ &\qquad \text{(Factorization of } s(\boldsymbol{y},\boldsymbol{x})\text{)} \\ &= \sum_t \sum_{y^t} \Big\{ q(y^t|\boldsymbol{x}) \log q(y^t|\boldsymbol{x}) \Big\} \\ &\quad - \sum_t \sum_{y^t y^{t-1}} \Big\{ s(y^t,y^{t-1},\boldsymbol{x}) \sum_{\boldsymbol{y}|y^t y^{t-1}} q(\boldsymbol{y}|\boldsymbol{x}) \Big\} \\ &\quad + \log Z(\boldsymbol{x}) \\ &\qquad \text{(Reorganize sums by } s(y^t,y^{t-1},\boldsymbol{x})\text{)} \\ &= \sum_t \sum_{y^t} \Big\{ q(y^t|\boldsymbol{x}) \log q(y^t|\boldsymbol{x}) \Big\} \end{aligned}$$

Algorithm 1 Modified forward algorithm to compute the KL divergence loss for Soft-Label Chain CRFs

procedure SOFTLABELCHAINCRFLOSS($\boldsymbol{q}, \varepsilon(y^t, \boldsymbol{x}), \tau(y^t, y^{t-1}, \boldsymbol{x})$)
  for all label y^0 **do**
    $\alpha^0_{y^0} \leftarrow 0$
    $g^0_{y^0} \leftarrow 0$
  for $t = 1 \dots T$ **do**
    for all label y^t **do**
      $\alpha^t_{y^t} \leftarrow \sum_{y^{t-1}} \left\{ \alpha^{t-1}_{y^{t-1}} \exp\left[\tau(y^t, y^{t-1}, \boldsymbol{x}) + \varepsilon(y^t, \boldsymbol{x})\right] \right\}$
      $g^t_{y^t} \leftarrow \sum_{y^{t-1}} \left\{ \left[g^{t-1}_{y^{t-1}} + \tau(y^t, y^{t-1}, \boldsymbol{x})\right] q^{t-1}_{y^{t-1}} + \left[\varepsilon(y^t, \boldsymbol{x}) - \log q^t_{y^t}\right] \right\}$
  $Z \leftarrow \sum_{y^T} \alpha^T_{y^T}$
  $G \leftarrow \sum_{y^T} g^T_{y^T} q^T_{y^T}$
  $L \leftarrow -G + \log Z$
  return L

$$-\sum_t \sum_{y^t y^{t-1}} \left\{ q(y^t, y^{t-1}|\boldsymbol{x}) s(y^t, y^{t-1}, \boldsymbol{x}) \right\} + \log Z(\boldsymbol{x})$$

which gives moment-matching gradients

$$\frac{\partial L}{\partial s(y^t, y^{t-1}, \boldsymbol{x})} = -q(y^t, y^{t-1}|\boldsymbol{x}) + p(y^t, y^{t-1}|\boldsymbol{x})$$
$$\frac{\partial L}{\partial \tau(y^t, y^{t-1}, \boldsymbol{x})} = -q(y^t, y^{t-1}|\boldsymbol{x}) + p(y^t, y^{t-1}|\boldsymbol{x})$$
$$\frac{\partial L}{\partial \varepsilon(y^t, \boldsymbol{x})} = -q(y^t|\boldsymbol{x}) + p(y^t|\boldsymbol{x})$$

where

$$q(y^t|\boldsymbol{x}) = q^t_{y_t}$$
$$q(y^t, y^{t-1}|\boldsymbol{x}) = q^t_{y^t} q^{t-1}_{y^{t-1}}$$

are the probability of local label(s) marginalized over all possible non-local labels. Smoothing inference $p(y^t|\boldsymbol{x})$ and $p(y^t, y^{t-1}|\boldsymbol{x})$ can be computed with forward-backward algorithm.

3.3 As an Extension of Soft-Label Model

Note that if we omit all transition terms in Soft-Label Chain CRF, the loss reduces to

$$L' = \sum_t \sum_{y^t} \left\{ q(y^t|\boldsymbol{x}) \left[-\varepsilon(y^t, \boldsymbol{x}) + \log q(y^t|\boldsymbol{x})\right] \right\} + \log Z(\boldsymbol{x})$$
$$= \sum_t \sum_{y^t} \left\{ q(y^t|\boldsymbol{x}) \log \frac{q(y^t|\boldsymbol{x})}{p(y^t|\boldsymbol{x})} \right\}$$

which is a total factorization over time. This is as if each label is predicted independently using a soft-label training regime, which is exactly the KL divergence loss proposed by Yu et al. (2018b). Therefore, our Soft-Label Chain CRF can be viewed as an extension of this soft-label discriminative model.

3.4 Modified Forward Algorithm

For chain CRFs, computing the loss only requires forward algorithm, while computing the gradients requires a full forward-backward algorithm. It can be proved that backpropagation on the loss gives the same result as running forward-backward. This is a commonly used trick in modern deep learning frameworks to eliminate the need of implementing the backward pass. Algorithm 1 presents a modified forward algorithm that computes the loss for Soft-Label Chain CRF. In Section 1 and 2 of the Supplementary Materials, we prove the correctness of this algorithm, and that its backpropagation is also equivalent to forward-backward.

4 Phrase Grounding as Sequence Labeling

4.1 Task Formulation

We formulate phrase grounding as a sequence labeling task. Given an image I, a caption sentence $[c^1 \dots c^L]$ where c^l is a word token, and a set of non-overlapping noun phrase spans $[p^1 \dots p^T]$ where $p^t = (s^t, e^t)$ denotes that the t'th phrase covers tokens c^{s^t} to c^{e^t} (inclusive), we generate a set of region proposals $\{r_1 \dots r_K\}$, label each phrase with a candidate region, and refine the region by performing a bounding box regression.

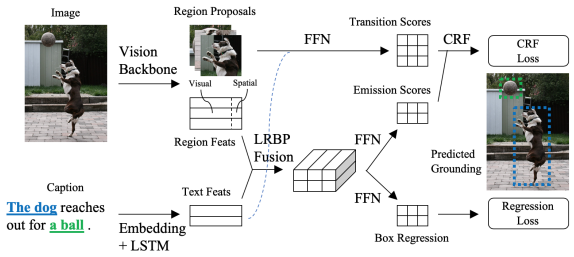


Figure 3: Our model for phrase grounding as a sequence labeling task. The $K \times K$ transition score matrix is derived from the features of K region proposals. The $T \times K$ emission score matrix is derived from a joint representation of phrase-region pairs, which is fused from features of region proposals and T entity phrases. Bounding box regression is applied to the sequence of regions predicted by the CRF. Cyan dashed line: contextualized transition score prediction (Section 4.2).

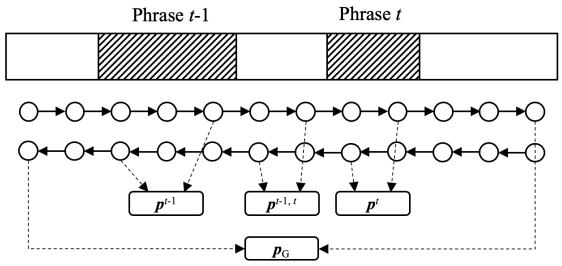

Figure 4: Text feature extraction for phrases in a caption. Shaded regions are entity phrase spans; circles represent LSTM cells. For phrase t hidden states at its span boundaries are concatenated to form its text features $\boldsymbol{p}^t$, which is used in fusion with region features. For the contextualized transition score between phrases $t-1$ and t, hidden states at the boundaries of the context between them are concatenated into a context feature vector $\boldsymbol{p}^{t-1,t}$, which can be further extended by phrase features $\boldsymbol{p}^{t-1}$ and $\boldsymbol{p}^t$ as well as global text features $\boldsymbol{p}_G$.

4.2 Model Specification

Figure 3 outlines our phrase grounding model. K region proposals and their visual and spatial features are extracted from an object detection vision backbone. We feed the token embeddings of the caption into a bi-directional LSTM (Hochreiter and Schmidhuber, 1997), and then concatenate the forward hidden state at the ending boundary of the phrase with the backward hidden state at the starting boundary of the phrase (see Figure 4). This phrase representation captures context both preceding and following the phrase in the caption.

$$(\overrightarrow{\boldsymbol{h}^{1:L}}, \overleftarrow{\boldsymbol{h}^{1:L}}) = \text{BiLSTM}(\text{Embed}([c^1 \dots c^L]))$$
$$\boldsymbol{p}^t = [\overrightarrow{\boldsymbol{h}^{e^t}} || \overleftarrow{\boldsymbol{h}^{s^t}}]$$

We use low-rank bilinear pooling (LRBP) (Kim et al., 2017) to fuse text and region features. Compared to simple concatenation, LRBP supports pairwise interaction between bimodal feature channels while keeping a reasonable computation overhead. Given a text feature vector $\boldsymbol{p}^t \in \mathbb{R}^{d_{\text{text}}}$ and a region feature vector $\boldsymbol{r}_k \in \mathbb{R}^{d_{\text{vis}}}$, LRBP fuses them into a joint representation $\boldsymbol{f}_k^t \in \mathbb{R}^{d_{\text{joint}}}$:

$$\boldsymbol{f}_k^t = \boldsymbol{P}^\top (\boldsymbol{U}^\top \boldsymbol{p}^t \circ \boldsymbol{V}^\top \boldsymbol{r}_k) + \boldsymbol{b}$$

where $\boldsymbol{U} \in \mathbb{R}^{d_{\text{text}} \times r}$, $\boldsymbol{V} \in \mathbb{R}^{d_{\text{vis}} \times r}$, pooling matrix $\boldsymbol{P} \in \mathbb{R}^{r \times d_{\text{joint}}}$, bias $\boldsymbol{b} \in \mathbb{R}^{d_{\text{joint}}}$, and $\circ$ is the Hadamard (i.e. element-wise) product.

As discussed in Section 3.2, the CRF score function consists of emission score and transition score. The emission score $\varepsilon(r_k, p^t)$ models the compatibility between each phrase and each candidate region. We feed the joint representation to a single-layer feed-forward neural network:

$$\varepsilon(r_k, p^t) = \text{FFN}(\boldsymbol{f}_k^t)$$

The transition score $\tau(r_k, r_{k'}, p^{1:T})$ is modeled by a two-layer feed-forward neural network with ReLU activation for the hidden layer:

$$\tau(r_k, r_{k'}, p^{1:T}) = \text{FFN}(\sigma(\text{FFN}([\boldsymbol{r}_k || \boldsymbol{r}_{k'}])))$$

To condition the transition scores on local and global context from the caption, we can extend the input $[\boldsymbol{r}_k || \boldsymbol{r}_{k'}]$ with the following text features: context in between the two phrases (feature vector $\boldsymbol{p}^{t-1,t}$), context from phrase features $\boldsymbol{p}^{t-1}$ and $\boldsymbol{p}^t$, and global context $\boldsymbol{p}_G$.

One important difference between the standard use of CRFs for sequence labeling and our task is that our "labels" do not correspond to a fixed set of classes that can be predicted for any input, but are as specific to the particular input example as the sequences to be labeled themselves. Hence, our transition and emission scores do not depend on the (arbitrary) indices of regions to be ground, but on their visual and spatial features (as well as on their corresponding linguistic contexts). Finally, although our approach could in principle be extended to higher-order CRFs, we restrict our attention here to first-order CRFs for computational efficiency. As a consequence, our models can only capture dependencies between string-adjacent phrases.

4.3 Training Objectives

For each image-caption instance, the loss is a linear combination of the labeling and bounding box regression loss:

$$L = L_{\text{label}} + \gamma L_{\text{reg}}$$

L_{label} is the CRF loss defined in Section 3.2. L_{reg} (Ren et al., 2017) is defined as

$$L_{\text{reg}} = (\beta, \hat{\beta}) \quad = \sum_{i \in \{x,y,w,h\}} \text{SmoothL1}(\hat{\beta}_i - \beta_i)$$

with the ground truth regression parameterization

$$\beta = [\frac{x - x_a}{w_a}, \frac{y - y_a}{h_a}, \log \frac{w}{w_a}, \log \frac{h}{h_a}]$$

and

$$\text{SmoothL1}(x) = \begin{cases} 0.5x^2 & \text{if } |x| < 1 \\ |x| - 0.5 & \text{otherwise} \end{cases}$$

5 Experiments

5.1 Experiment Setup

Dataset. We train and evaluate our models on the Flickr30k Entities dataset (Plummer et al., 2017b), which contains $31,783$ images, each accompanied by 5 captions. In keeping with previous work on this dataset, we assume that entity phrase boundaries are given, so inferring which phrases to ground is not part of our task. Following Plummer et al. (2017b), we merge all regions that are ground to the same phrase into one larger bounding box, and split the dataset into $29,783$ training images, $1k$ validation images and $1k$ test images.

We do not apply our method to RefCOCO (Yu et al., 2016) or Visual Genome (Krishna et al., 2017) because they consist of independently grounded entity phrases without any entity dependencies that CRFs could leverage.

Implementation details. For text feature extraction, we use the 1024-d contextualized word embeddings from the last layer of ELMo (Peters et al., 2018), followed by a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) encoder with hidden dimension $d_{\text{hidden}} = 512$ for each direction, so that the text feature vector has dimension $d_{\text{text}} = 1024$. We use the Bottom-Up Attention model (Anderson et al., 2018) to generate region proposals and extract visual features, as in the state-of-the-art BAN (Kim et al., 2018) and DDPN (Yu et al., 2018b) models. $K = 100$ region proposals are generated for each image. Each candidate region with coordinates $(x_{\text{min}}, y_{\text{min}})$, $(x_{\text{max}}, y_{\text{max}})$ is represented by a $d_{\text{vis}} = 2053$ feature vector that consists of 2048-d visual features concatenated with 5-d spatial features $[x_{\text{min}}/W, y_{\text{min}}/H, x_{\text{max}}/W, y_{\text{max}}/H, wh/WH]$. The low-rank bilinear pooling (LRBP) layer used for text-region bimodal feature fusion has rank $r = 1024$ and output dimension $d_{\text{joint}} = 1024$. We train with a mini-batch size of 16 image-caption instances. Each instance contains all entity phrases to be grounded in the caption. Weights are initialized with Xavier (Glorot and Bengio, 2010). We apply a dropout rate of $p = 0.2$ after the word embedding layer, LSTM layer, and LRBP fusion layer. The loss weighting parameter γ is 10.0. All gradients are clipped by ∞-norm of 10.0 to prevent gradient explosion. We do not fine-tune ELMo or the Bottom-Up Attention model. All models are trained for $50k$ iterations using Adam (Kingma and Ba, 2015) with learning rate $5e-5$ and $\beta_1 = 0.9, \beta_2 = 0.98$. Model snapshots are taken every $5k$ iterations and the model with the highest validation set accuracy is selected.

Metrics. We predict one grounded region for each entity phrase. Following Plummer et al. (2017b), a prediction is deemed accurate if it has at least 0.5 IoU overlap with the gold region. We report the percentage of accurately grounded phrases.

5.2 Quantitative Results

We compare our Soft-Label Chain CRF model against three baselines: a Hard-Label non-CRF model, a Hard-Label CRF, and a Soft-Label non-CRF model. The non-CRF models ground each phrase independently with a loglinear model. The Hard-Label models are trained with a standard one-hot training regime. The Soft-Label models use the soft-label training regime described above. The Soft-Label non-CRF model corresponds to the reduced form of the Soft-Label Chain CRF in Section 3.3.

Table 1 shows the performance of previous structured prediction models, current state-of-the-art models, our baseline models and the Soft-Label Chain CRF model. For a fair comparison with BAN (Kim et al., 2018), we also report result of the hard-label baseline with GloVe (Pennington et al., 2014) embeddings, while we obtain 0.33% higher result with ELMo. Training a non-CRF model on soft-label target distributions

Method	Vision Backbone	Grounding Accuracy (%)

Smoothing	**72.30**	**74.73**

Table 3: Decoding algorithms' impact on performance.

improves accuracy by a further 2.08%. On top of that, Soft-Label Chain CRF improves accuracy by another 0.40%, which shows the effectiveness of treating phrase grounding as a sequence labeling task and using CRFs to capture entity dependencies. We also observe that the Hard-Label Chain CRF outperforms the hard-label baseline by a mere margin of 0.05%, so our conjecture is that using chain CRFs works well only with a suitable choice of training regime. Soft-Label Chain CRF gives an overall improvement of 2.48% over the hard-label baseline; it significantly outperforms previous structured prediction models including Structured Matching (Wang et al., 2016), Phrase-Region CCA (Plummer et al., 2017a) and QRC Net (Chen et al., 2017b), and surpasses the state-of-the-art BAN (Kim et al., 2018) and DDPN (Yu et al., 2018b) models by a margin of 5.00% and about 1.4%, respectively.

We conduct an ablation study to find the most appropriate combination of context features for the transition scores in the SL-CCRF model. Table 2 shows that we obtain the best results by including the context in between the two phrases, which gives an improvement of 0.41%. We did not see any benefit from adding further text features from the left and right side of the phrases, or from the entire caption.

Besides the Viterbi decoding algorithm used in prediction in CRFs, we also experiment with a smoothing decoding algorithm. While Viterbi finds the MAP label sequence conditioned on the input sequence $\arg\max_{\boldsymbol{y}} p(\boldsymbol{y}|\boldsymbol{x})$, smoothing decoding finds the best label for each input x^t: $\arg\max_{y^t} p(y^t|\boldsymbol{x})$. This makes sense in some scenarios where we want to refine the predicted grounding of one entity by referring to the context instead of attempting to ground all entities mentioned in the description. Table 3 shows that in both Hard-Label Chain CRF and Soft-Label Chain CRF, smoothing decoding gives a prediction accuracy 0.04% higher than Viterbi decoding.

Without bounding box regression, the Soft-Label Chain CRF model has an accuracy of 69.85%, a 4.84% reduction compared to the setting with bounding box regression.

5.3 Qualitative Results

We visualize some phrase grounding results in the validation set of Flickr30k Entities in Figure 5. In (a), our CRF model avoids the error in grounding "a lounge chair" by constraining its relative posi-

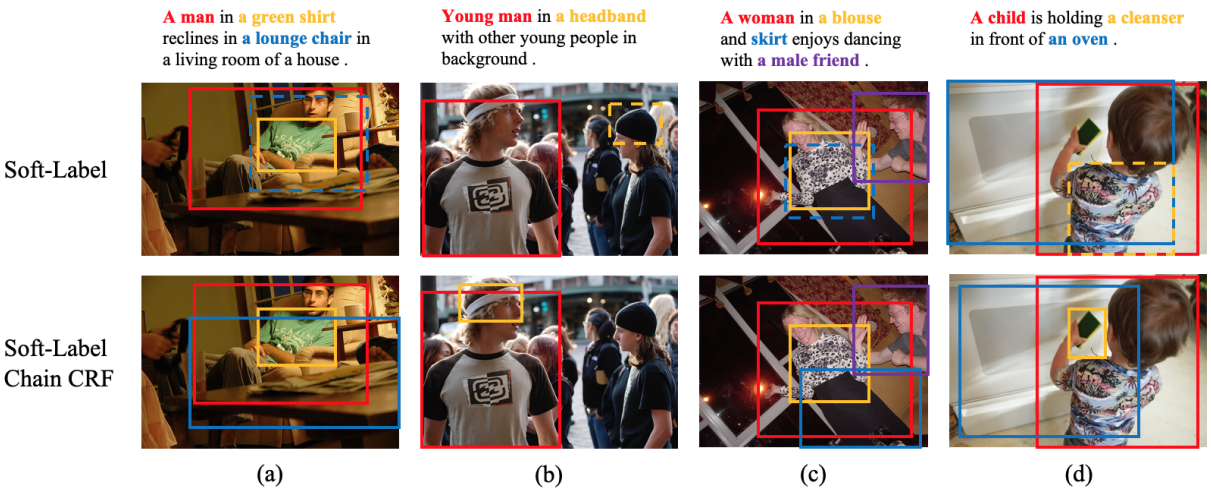

Figure 5: Selected visualization of phrase grounding results in the validation set of Flickr30k Entities. Solid boxes are correct predicted groundings, while dashed boxes are incorrect predicted groundings. Gold regions are not shown. Each entity phrase and its predicted grounding are marked with same color. Best viewed in color.

tion to "a man". In (b), although it may not have learned to distinguish "headband" and "hat", the CRF constrains the spatial position of "headband" to agree with the ownership dependency provided in context. In (c), it avoids the error in grounding "skirt" by spatially discriminating it from "a blouse". In (d), it avoids the error in grounding "a cleanser" by constraining its relative size w.r.t. "a child". These examples indicate that the CRF model may avoid grounding errors made by non-CRF models by leveraging entity dependencies, including relative position, spatial overlapping, and relative size.

6 Conclusion

In this paper, we formulate phrase grounding as a sequence labeling task and propose the Soft-Label Chain CRF model that successfully combines the benefits brought by global structured prediction and soft-label training regime that addresses the gold label multiplicity problem. Experimental results show that we achieve an overall improvement of 2.48% on grounding accuracy compared to a strong baseline, and that our model outperforms previous methods on phrase grounding.

Abstract

Grounding a pronoun to a visual object it refers to requires complex reasoning from various information sources, especially in conversational scenarios. For example, when people in a conversation talk about something all speakers can see, they often directly use pronouns (e.g., it) to refer to it without previous introduction. This fact brings a huge challenge for modern natural language understanding systems, particularly conventional context-based pronoun coreference models. To tackle this challenge, in this paper, we formally define the task of visual-aware pronoun coreference resolution (PCR) and introduce VisPro, a large-scale dialogue PCR dataset, to investigate whether and how the visual information can help resolve pronouns in dialogues. We then propose a novel visual-aware PCR model, VisCoref, for this task and conduct comprehensive experiments and case studies on our dataset. Results demonstrate the importance of the visual information in this PCR case and show the effectiveness of the proposed model.

1 Introduction

The question of how human beings resolve pronouns has long been an attractive research topic in both linguistics and natural language processing (NLP) communities, for the reason that pronoun itself has weak semantic meaning (Ehrlich, 1981) and the correct resolution of pronouns requires complex reasoning over various information. As a core task of natural language understanding, pronoun coreference resolution (PCR) (Hobbs, 1978) is the task of identifying the noun (phrase) that pronouns refer to. Compared with the general coreference resolution task, the string-matching methods are no longer effective for pronouns (Stoyanov et al., 2009), which makes PCR more challenging than the general coreference resolution task.

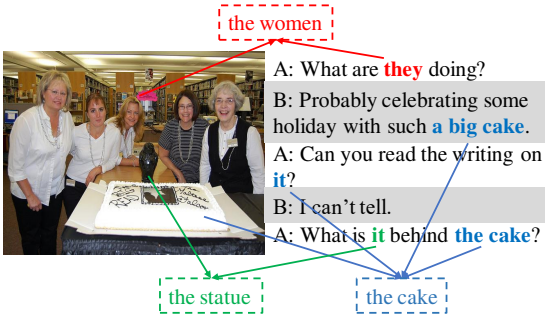

Figure 1: An example of a visual-related dialogue. Two people are discussing the view they can both see. Pronouns and noun phrases referring to the same entity are marked in same color. The first "it" in the dialogue labeled with blue color refers to the object "the big cake" and the second "it" labeled with green color refers to the statue in the image.

Recently, great efforts have been devoted into the coreference resolution task (Raghunathan et al., 2010; Clark and Manning, 2015, 2016; Lee et al., 2018) and good performance has been achieved on formal written text such as newspapers (Pradhan et al., 2012; Zhang et al., 2019a) and diagnose records (Zhang et al., 2019b). However, when it comes to dialogues, where more abundant information is needed, the performance of existing models becomes less satisfying. The reason behind is that, different from formal written language, correct understanding of spoken language often requires the support of other information sources. For example, when people chat with each other, if they intend to refer to some object that all speakers can see, they may directly use pronouns such as "it" instead of describing or mentioning it in the first place. Sometimes, the object (name or text description) that pronouns refer to may

[*] Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5123–5132,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

not even appear in a conversation, and thus one needs to ground the pronouns into something outside the text, which is extremely challenging for conventional approaches purely based on human-designed rules (Raghunathan et al., 2010) or contextual features (Lee et al., 2018).

A visual-related dialogue is shown in Figure 1. Both A and B are talking about a picture, in which several people are celebrating something. In the dialogue, the first "it" refers to the "the big cake," which is relatively easy for conventional models, because the correct mention just appears before the targeting pronoun. However, the second "it" refers to the statue in the image, which does not appear in the dialogue at all. Without the support of the visual information, it is almost impossible to identify the coreference relation between "it" and "the statue."

In this work, we focus on investigating how visual information can help better resolve pronouns in dialogues. To achieve this goal, we first create VisPro, a large-scale visual-supported PCR dataset. Different from existing datasets such as ACE (NIST, 2003) and CoNLL-shared task (Pradhan et al., 2012), VisPro is annotated based on dialogues discussing given images. In total, VisPro contains annotations for 29,722 pronouns extracted from 5,000 dialogues. Once the dataset is created, we formally define a new task, visual pronoun coreference resolution (Visual PCR), and design a novel visual-aware PCR model VisCoref, which can effectively extract information from images and leverage them to help better resolve pronouns in dialogues. Particularly, we align mentions in the dialogue with objects in the image and then jointly use the contextual and visual information for the final prediction.

The contribution of this paper is three-folded: (1) we formally define the task of visual PCR; (2) we present VisPro, the first dataset that focuses on PCR in visual-supported dialogues; (3) we propose VisCoref, a visual-aware PCR model. Comprehensive experiments and case studies are conducted to demonstrate the quality of VisPro and the effectiveness of VisCoref. The dataset, code, and models are available at: https://github.com/HKUST-KnowComp/Visual_PCR.

2 The VisPro Dataset

To generate a high-quality and large-scale visual-aware PCR dataset, we select VisDial (Das et al., 2017) as the base dataset and invite annotators to annotate. In VisDial, each image is accompanied by a dialogue record discussing that image. One example is shown in Figure 1. In addition, VisDial also provides a caption for each image, which brings more information for us to create VisPro[1]. In this section, we introduce the details about the dataset creation in terms of pre-processing, survey design, annotation, and post-processing.

2.1 Pre-processing

To make the annotation task clear to annotators and help them provide accurate annotation, we first extract all the noun phrases and pronouns with Stanford Parser (Klein and Manning, 2003) and then provide the extracted noun phrases as candidate mentions to annotate on. To avoid the overlap of candidate noun phrases, we choose noun phrases with a height of two in parse trees. One example is shown in Figure 2. In the syntactic tree for the sentence "A man with a dog is walking on the grass," we choose "A man," "a dog" and "the grass" as candidates. If the height of noun phrases is not limited, then the noun phrase "A man with a dog" will cover "A man" and "a dog," leading to confusion in the options.

Following (Strube and Müller, 2003; Ng, 2005), we only select third-person personal (it, he, she, they, him, her, them) and possessive pronouns (its, his, her, their) as the targeting pronouns. In total, the VisPro dataset contains 29,722 pronouns of 5,000 dialogues selected from 133,351 dialogues in VisDial v1.0 (Das et al., 2017). We choose dialogues in which the number of pronouns ranges from four to ten for the following reasons. For one thing, dialogues with few pronouns are of lit-

[1]The information contained in the caption only helps provide noun phrase candidates for workers to annotate and will not be treated as part of the dialogue.

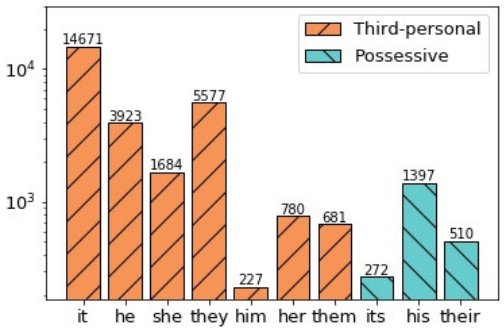

Figure 3: Distribution of pronouns in VisPro.

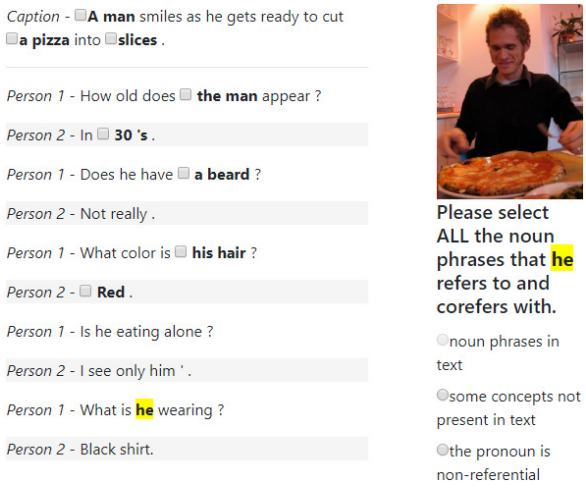

Figure 4: Annotation interface on MTurk. Workers are asked to select the anaphoricity type of the highlighted pronoun in the right panel and all the antecedents of an anaphoric pronoun on the left panel.

tle use to the task. For another, dialogues with too many pronouns often contain repeating pronouns referring to the same object, which makes the task too easy. The dialogues selected contain 5.94 pronouns on average. Figure 3 presents the distribution of different pronouns. From the figure we can see that "it" and "they" are used most frequently in the dialogues.

2.2 Survey Design

We divide 29,722 pronouns from 5,000 dialogues into 3,304 surveys. In each survey, besides the normal questions, we also include one checkpoint question to control the annotation quality[2]. In total, each survey contains ten questions (nine normal questions and one checkpoint question). Each question is about one pronoun.

The survey consists of three parts. We begin by explaining the task to the annotators, including how to deal with particular cases such as multi-word expressions. Then, we present examples to help the annotators better understand the task. Finally, we invite them to provide annotations for the pronouns in the dialogues.

One example of the annotation interface is shown in Figure 4. The text and the image of the dialogue are displayed on the left and right panel, respectively. For each of the targeting pronoun, the workers are asked to select all the mentions that it refers to. If any of the noun phrases is selected, the reference type of the pronoun on the right panel will be set to "noun phrases in text" automatically, and vice versa. If the concept that the pronoun refers to is not available in the options, or the pronoun is not referring to anything in particular, workers are asked to choose "some concepts not present in text" or "the pronoun is non-referential" on the right panel accordingly. The nine normal questions in each survey are consecutive so that pronouns in the same dialogue are displayed sequentially.

[2]We design the checkpoint dialogue straightforward and unambiguous such that any responsive worker can easily provide the correct annotation.

2.3 Annotation

We employ the Amazon Mechanical Turk platform (MTurk) for our annotations.

We require that our annotators have more than 1,000 approved tasks and a task approval rate more than 90%. They are also asked to pass a simple test of pronoun resolution to prove that they understand the instruction of the task. Based on these criteria, we identify 186 valid annotators. For each dialogue, we invite at least four different workers to annotate. In total, we collect 122,443 annotations at a total cost of USD 3,270.80. We support the multiple participation of annotators by ensuring that subsequent surveys are generated with their previously-unlabelled dialogues.

2.4 Post-processing

Before processing the annotation result, we first exclude the annotation of workers who fail to answer the checkpoint questions correctly. As a result, 116,300 annotations are kept, which is 95% of the overall annotation results. We then decide the gold mentions that pronouns refer to using the following procedure:

- Step one: We look into the annotations of each

worker to find out the coreference clusters he annotates for each dialogue. To achieve this goal, we merge the intersecting sets of noun phrase antecedents for pronouns in the same dialogue. We observe that annotators often make the right decision for noun phrases near the anaphor pronoun, but neglect antecedents far away. It also happens in the annotation of other coreference datasets (Chen et al., 2018). Therefore, we generate clusters from different pronouns in the same dialogue rather than merging antecedents for each pronoun separately. If an entity is mentioned and referred to by pronouns for multiple times in the dialogue, combining the antecedents for all pronouns could create a more accurate coreference cluster for the entity.

- Step two: We adjudicate the coreference clusters for the dialogue by majority voting within all workers.

- Step three: We then decide the anaphoric type of all pronouns by voting. If a pronoun is considered to refer to somef noun phrases in the text, we find out the coreference cluster it belongs to and choose the noun phrases in the cluster that precede it as its antecedents.

- Step four: We randomly split the collected data into train/val/test sets of 4,000/500/500 dialogues, respectively.

After collecting the data, we found out that 73.43% of pronouns act as an anaphor to some noun phrases, 5.67% of pronouns do not have a suitable antecedent, and the rest 20.90% are not referential. Among all the pronouns that have noun phrases as antecedents, 13.45% of them do not have an antecedent in the dialogue context.[3] For anaphoric pronouns, each has 2.06 antecedents on average. In the end, we calculate the inner-annotator agreement (IAA) to demonstrate the quality of the resulting dataset. Following conventional approaches (Pradhan et al., 2012), we use the average MUC score between individual workers and the adjudication result as the evaluation metric. The final IAA score is 72.4, which indicates that the workers can clearly understand our task and provide reliable annotation.

[3]The antecedent labeled by the worker is provided by the caption.

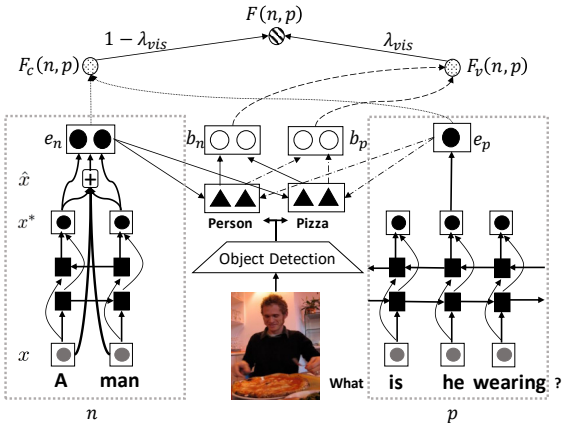

Figure 5: Overall structure of the VisCoref model. Text embedding e is acquired via LSTM and inner-span attention mechanism. Object labels are detected from the image and the possibility b of each text span referring to them is calculated. The contextual and visual score $F_c(n,p)$ and $F_v(n,p)$ are calculated upon the features, and the final score $F(n,p)$ is their weighted sum.

3 The Task

In this work, we focus on jointly leveraging the contextual and visual information to resolve pronouns. Thus, we formally define the visual-aware pronoun coreference resolution as follows:

Given an image I, a dialogue record D which discusses the content in I, and an external mention set $\mathcal{M}$, for any pronoun p that appears in D, the goal is to optimize the following objective:

$$\mathcal{J} = \frac{\sum_{c \in \mathcal{C}} e^{F(c,p,I,D)}}{\sum_{s \in \mathcal{S}} e^{F(s,p,I,D)}}, \quad (1)$$

where $F(\cdot)$ is the overall scoring function of p refers to c given I and D. c and s denote the correct mention and the candidate mention, and $\mathcal{C}$ and $\mathcal{S}$ denote the correct mention set and the candidate mention set, respectively. Note that in the case where no golden mentions are annotated, the union of all possible spans in D and $\mathcal{M}$ are used to form $\mathcal{S}$.

4 The Model

The overall framework of the proposed model VisCoref is presented in Figure 5. In VisCoref, we want to leverage both the contextual and visual information to resolve pronouns. Thus we split the scoring function into two parts as follows:

$$F(n,p) = (1-\lambda_{vis}) \cdot F_c(n,p) + \lambda_{vis} \cdot F_v(n,p), \quad (2)$$

where $F_c(\cdot)$ and $F_v(\cdot)$ are the scoring functions based on contextual and visual information respectively. λ_{vis} is the hyper-parameter to control the importance of visual information in the model. The details of the two scoring functions are described in the following subsections.

4.1 Contextual Scoring

Before computing F_c, we first need to encode the contextual information into all the candidates and targeting pronouns through a mention representation module, which is shown as the dotted box in Figure 5.

Following (Lee et al., 2018), a standard bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) is used to encode each span with attentions (Bahdanau et al., 2015). Assume initial embeddings of words in a span s_i are denoted as $\mathbf{x}_1, ..., \mathbf{x}_T$, and their encoded representation after BiLSTM as $\mathbf{x}_1^*, ..., \mathbf{x}_T^*$, the weighted embeddings of each span $\hat{\mathbf{x}}_i$ are obtained by

$$\hat{\mathbf{x}}_i = \sum_{t=1}^{T} a_t \cdot \mathbf{x}_t, \tag{3}$$

where a_t is the inner-span attention computed by

$$a_t = \frac{e^{\alpha_t}}{\sum_{k=1}^{T} e^{\alpha_k}}, \tag{4}$$

in which α_t is obtained by a standard feed-forward neural network[4] $\alpha_t = NN_\alpha(\mathbf{x}_t^*)$.

After that, we concatenate the embeddings of the starting word ($\mathbf{x}_{start}^*$) and the ending word ($\mathbf{x}_{end}^*$) of each span, as well as its weighted embedding ($\hat{\mathbf{x}}_i$) and the length feature ($\phi(i)$) to form its final representation $\mathbf{e}$:

$$\mathbf{e}_i = [\mathbf{x}_{start}^*, \mathbf{x}_{end}^*, \hat{\mathbf{x}}_i, \phi(i)]. \tag{5}$$

On top of the extracted mention representation, we then compute the contextual score as follows:

$$F_c(n, p) = NN_c([\mathbf{e}_p, \mathbf{e}_n, \mathbf{e}_p \odot \mathbf{e}_n]), \tag{6}$$

where [ ] represents the concatenation, $\mathbf{e}_p$ and $\mathbf{e}_n$ are the mention representation of the targeting pronoun and current candidate mention, and $\odot$ indicates the element-wise multiplication.

[4]We use NN to represent feed-forward neural networks.

4.2 Visual Scoring

In order to align mentions in the text with objects in the image, the first step of leveraging the visual information is to recognize the objects from the picture. We use a object detection module to identify object labels from each image I, such as "person," "car," or "dog." After that, we convert the identified labels into vector representations following the same encoding process in 4.1. For each image, we add a label "null," indicating that the pronoun is referring to none of the detected objects in I. We denote the resulting embeddings as $\mathbf{e}_{c_1}, \mathbf{e}_{c_2}, ..., \mathbf{e}_{c_K}$, in which c_i denotes the detected labels, and K is the total number of unique labels in the corresponding image.

After extracting objects from the image, we would like to know whether the mentions are referring to them. To achieve this goal, we calculate the possibility of a mention n_i corresponding to each detected object c_k:

$$\beta_{n_i,c_k} = \mathrm{NN}_\beta\left(\mathrm{NN}_o(\boldsymbol{e}_{n_i}) \odot \mathrm{NN}_o(\boldsymbol{e}_{c_k})\right). \tag{7}$$

Then we take the softmax of β_{n_i,c_k} as the final possibility of n_i aligned with the object label c_k:

$$b_{n_i,c_k} = \frac{e^{\beta_{n_i,c_k}}}{\sum_{l=1}^{K} e^{\beta_{n_i,c_l}}}. \tag{8}$$

If n_i corresponds to a certain object in I, the score of that label should be large. Otherwise, the possibility of "null" should be the largest. Therefore, we use the maximum of possibility scores among all K classes except "null"

$$m_i = \max_{k=1,...,K} b_{n_i,c_k} \tag{9}$$

as the probability of n_i related to some object in I.

Similarly, given two mentions n_i and n_j, if they refer to the same detected object c_k, then both b_{n_i,c_k} and b_{n_j,c_k} should be large. Thus, we can use the maximum of their product among all K classes except "null"

$$m_{i,j} = \max_{k=1,...,K} b_{n_i,c_k} \cdot b_{n_j,c_k} \tag{10}$$

as the probability of n_i and n_j related to the same object in I.

In the end, we define the visual scoring function as follows:

$$F_v(n, p) = NN_v([m_p, m_n, m_p \cdot m_n, m_{p,n}]). \tag{11}$$

5 The Experiment

In this section, we introduce the implementation details, experiment setting, and baseline models.

5.1 Experiment Setting

As introduced in Section 2.4, we randomly split the data into training, validation, and test sets of 4,000, 500, and 500 dialogues, respectively. For each dialogue, a mention pool of size 30 is provided for models to detect plausible mentions outside the dialogue. The pool contains both mentions extracted from the corresponding caption and randomly selected negative mention samples from other captions. All models are evaluated based on the precision (P), recall (R), and F1 score. Last but not least, we split the test dataset by whether the correct antecedents of the pronoun appear in the dialogue or not. We denote these two groups as "Discussed" and "Not Discussed."

5.2 Implementation Details

Following previous work (Lee et al., 2018), we use the concatenation of the 300d GloVe embedding (Pennington et al., 2014) and the ELMo (Peters et al., 2018) embedding as the initial word representations. Out-of-vocabulary words are initialized with zero vectors. We adopt the "ssd_resnet_50_fpn_coco" model from Tensorflow detection model zoo[5] as the object detection module. The size of hidden states in the LSTM module is set to 200, and the size of the projected embedding for computing similarity between text spans and object labels is 512. The feed-forward networks for contextual scoring and visual scoring have two 150-dimension hidden layers and one 100-dimension hidden layer, respectively.

For model training, we use cross-entropy as the loss function and Adam (Kingma and Ba, 2015) as the optimizer. All the parameters are initialized randomly. Each mention selects the text span of the highest overall score among all previous text spans in the dialogue or the mention pool as its antecedent, so that all mentions in one dialogue are clustered into several coreference chains. The noun phrases in the same coreference cluster as a pronoun are deemed as the predicted antecedents of that pronoun. The models are trained with up to 50,000 steps, and the best one is selected based on its performance on the validation set.

5.3 Baseline Methods

Since we are the first to proposed a visual-aware model for pronoun coreference resolution, we compare our results with existing models of general coreference resolution.

- Deterministic model (Raghunathan et al., 2010) is a rule-based system that aggregates multiple functions for determining whether two mentions are coreferent based on hand-craft features.
- Statistical model (Clark and Manning, 2015) learns upon human-designed entity-level features between clusters of mentions to produce accurate coreference chains.
- Deep-RL model (Clark and Manning, 2016) applies reinforcement learning to mention-ranking models to form coreference clusters.
- End-to-end model (Lee et al., 2018) is the state-of-the-art method of coreference resolution. It predicts coreference clusters via an end-to-end neural network that leverages pretrained word embeddings and contextual information.

Last but not least, to demonstrate the effectiveness of the proposed model, we also present a variation of the End-to-end model, which can also use the visual information, as an extra baseline:

- End-to-end+Visual first extracts features from images with ResNet-152 (He et al., 2016). Then it concatenates the image feature with the contextual feature in the original End-to-end model together to make the final prediction.

As the Deterministic, Statistical, and Deep-RL model are included in the Stanford CoreNLP toolkit[6], we use their released model as baselines. For the End-to-end model, we also use their released code[7].

6 The Result

The experimental results are shown in Table 1. Our proposed model VisCoref outperforms all the baseline models significantly, which indicates that the visual information is crucial for resolving pronouns in dialogues. Besides that, we also have the following interesting findings:

[6] https://stanfordnlp.github.io/CoreNLP/coref.html

[7] https://github.com/kentonl/e2e-coref

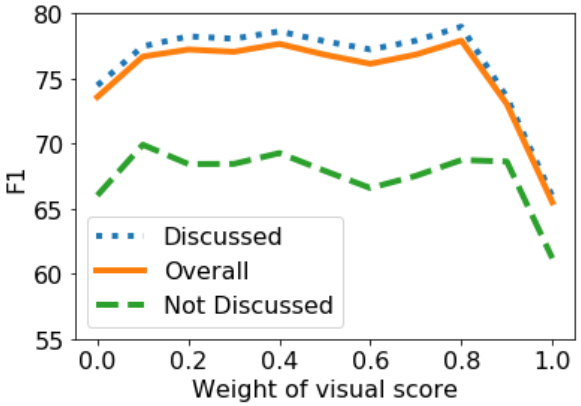
Model	Discussed			Not Discussed			Overall		
	P	R	F1	P	R	F1	P	R	F1
Deterministic	61.16	25.54	36.03	17.39	8.26	11.20	56.65	24.01	33.73
Statistical	79.37	26.65	39.90	6.10	1.03	1.77	76.18	24.23	36.76
Deep-RL	72.69	26.97	39.35	32.86	14.46	20.09	68.51	25.93	37.62
End-to-end	89.65	63.69	74.47	67.33	64.76	66.02	86.94	63.79	73.59
End-to-end+Visual	89.78	66.31	76.28	65.17	62.38	63.75	86.91	65.95	74.99
Viscoref	85.95	72.45	**78.63**	67.04	71.67	**69.28**	83.78	72.38	**77.66**
Human	95.03	81.82	87.93	86.18	93.57	89.73	94.02	82.91	88.12

Table 1: Experimental results on VisPro. Precision (P), recall (R) and F1 scores are presented. The best performed F1 scores are indicated with bold font.

1. For all the conventional models, the "Not Discussed" pronouns whose antecedents are absent in dialogues are more challenging than "Discussed" pronouns whose antecedents appear in the dialogue context. The reason behind is that if the correct mentions appear in the near context of pronouns, the information about the correct mention can be aggregated to the targeting pronoun through either human-designed rules or deep neural networks (Bi-LSTM). However, when the correct mention is not available in the near context, it is quite challenging for conventional models to understand the dialogue and correctly ground the pronoun to the object both speakers can see, as they do not have the support of visual information.

2. As is shown in the result of the "End-to-end+Visual" model, simply concatenating the visual feature to the contextual feature can help resolve "Discussed" pronouns but may hurt the performance of the model on "Not Discussed" pronouns. Different from them, the proposed Viscoref can improve the resolution of both the "Discussed" and "Not Discussed" pronouns. There are mainly two reasons behind: (1) The visual information in our model is first converted into textual labels and then transformed into vector representation in the same way as the dialogue context. Thus the vector space of contextual and visual information is perfectly aligned. (2) We introduce a hyper-parameter λ_{vis} to balance the influence of different knowledge resources.

3. Even though our model outperforms all the baseline methods, we still can observe a huge gap between our model and human being. It indicates that current models still cannot fully understand the dialogue even with the support of visual information and further proves the value and necessity of proposing VisPro.



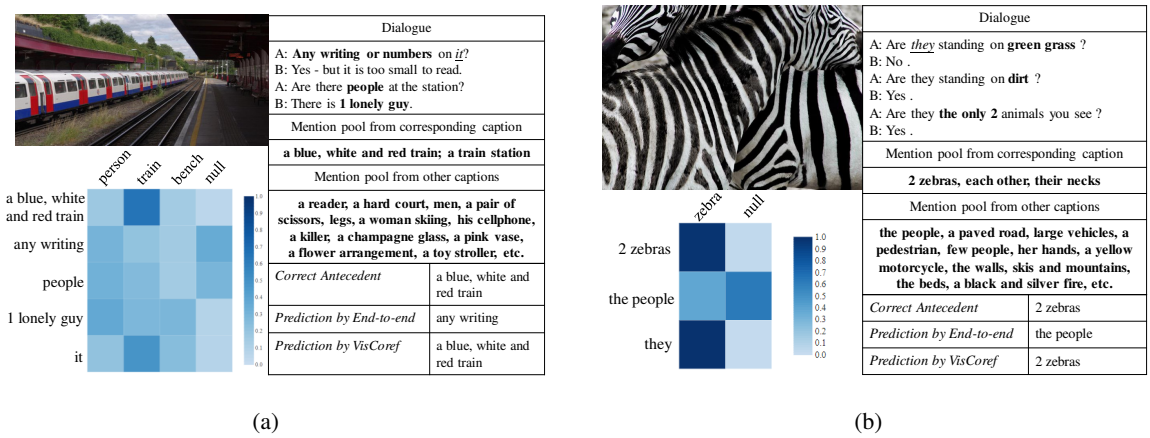


Figure 6: Effect of λ_{vis}. F1 scores of all categories are reported.

6.1 Hyper-parameter Analysis

We traverse different weights of visual and contextual information from 0 to 1, and the result is shown in Figure 6. Along with the increase of λ_{vis}, our model puts more weight on the visual information. As a result, our model can perform better. However, when our model focuses too much on the visual information (when λ_{vis} equals to 0.9 or 1), the model overfits to the visual information and thus performs poorly on the task. To achieve the balance between the visual and contextual information, we set λ_{vis} to be 0.4.

Dialogue	
A: **Any writing or numbers** on *it*? B: Yes - but it is too small to read. A: Are there **people** at the station? B: There is **1 lonely guy**.	
Mention pool from corresponding caption	
a blue, white and red train; a train station	
Mention pool from other captions	
a reader, a hard court, men, a pair of scissors, legs, a woman skiing, his cellphone, a killer, a champagne glass, a pink vase, a flower arrangement, a toy stroller, etc.	
Correct Antecedent	a blue, white and red train
Prediction by End-to-end	any writing
Prediction by VisCoref	a blue, white and red train

(a)

Dialogue	
A: Are *they* standing on **green grass** ? B: No . A: Are they standing on **dirt** ? B: Yes . A: Are they **the only 2** animals you see ? B: Yes .	
Mention pool from corresponding caption	
2 zebras, each other, their necks	
Mention pool from other captions	
the people, a paved road, large vehicles, a pedestrian, few people, her hands, a yellow motorcycle, the walls, skis and mountains, the beds, a black and silver fire, etc.	
Correct Antecedent	2 zebras
Prediction by End-to-end	the people
Prediction by VisCoref	2 zebras

(b)

Figure 7: Randomly selected examples from VisPro. The image, dialogue record, prediction result, and heatmap of the mention-object similarity are provided. We indicate the target pronoun with the *underlined italics* font and the candidate mentions with **bold** font. Only relevant parts of dialogues are presented. The row of the heatmap represents mentions in the context, and the column means detected object labels from the image.

6.2 Case Study

To further investigate how visual information can help solve PCR, we randomly select two examples and show the prediction results of VisCoref and End-to-end model in Figure 7.

In the first example in Figure 7(a), given the pronoun "it," the End-to-end model picks "any writing" from the dialogue, while the VisCoref model chooses "a blue, white and red train" from the candidate mention sets. Without looking at the picture, we cannot distinguish between these two candidates. However, when the picture is taken into consideration, we observe that there is a train in the image and thus "a blue, white and red train" is a more suitable choice, which proves the importance of visual information. A similar situation happens in Figure 7(b), where the End-to-end model connects "they" to "the people" but there is no human being in the image at all. On the contrary, as VisPro can effectively leverage the visual information and make the decision that "they" should refer to "2 zebras."

7 Related Work

In this section, we introduce the related work about pronoun coreference resolution and visual-aware natural language processing problems.

7.1 Pronoun Coreference Resolution

As one core task of natural language understanding, pronoun coreference resolution, the task of identifying mentions in text that the targeting pronoun refers to, plays a vital role in many downstream applications in natural language processing, such as machine translation (Guillou, 2012), summarization (Steinberger et al., 2007) and information extraction (Edens et al., 2003). Traditional studies focus on resolving pronouns in expert-annotated formal textual dataset such as ACE (NIST, 2003) or OntoNotes (Pradhan et al., 2012). However, models that perform well on these datasets might not perform as well in other scenarios such as dialogues due to the informal language and the lack of essential information (e.g., the shared view of two speakers). In this work, we thus focus on the PCR in dialogues and show that the information contained in the shared view can be crucial for understanding the dialogues and correctly resolving the pronouns.

7.2 Visual-aware NLP

As the intersection of computer vision (CV) and natural language processing (NLP), visual-aware NLP research topics have been popular in both communities. For instance, image captioning (Xu et al., 2015) focuses on generating captions for images, visual question answering (VQA) (Antol et al., 2015) on answering questions about a image, and visual dialogue (Das et al., 2017) on generating a suitable response based on images. As one vital step of all the aforementioned visual-aware natural language processing tasks (Kottur et al., 2018), the visual-aware PCR is still unexplored. To fill this gap, in this paper, we create VisPro, which is a large-scale visual-aware PCR

dataset, and introduce VisCoref to demonstrate how to leverage information hidden in the shared view to resolve pronouns in dialogues better and thus understand the dialogues better.

Another related work is the comprehension of referring expressions (Mao et al., 2016), which is inferring the object in an image that an expression describes. However, the task is formulated on isolated noun phrases specially designed for discriminative descriptions without putting them into a meaningful context. Instead, our task focuses on resolving pronouns in dialogues based on images as the shared view, which enhances the understanding of dialogues based on the comprehension of expressions and images.

8 Conclusion

In this work, we formally define the task of visual pronoun coreference resolution (PCR) and present VisPro, the first large-scale visual-supported pronoun coreference resolution dataset. Different from conventional pronoun datasets, VisPro focuses on resolving pronouns in dialogues which discusses a view that both speakers can see.

Moreover, we also propose VisCoref, the first visual-aware PCR model that aligns contextual information with visual information and jointly uses them to find the correct objects that the targeting pronouns refer to. Extensive experiments demonstrate the effectiveness of the proposed model. Further case studies also demonstrate that jointly using visual information and contextual information is an essential path for fully understanding human language, especially dialogues.

{wy.wang, 2015202012, cszhe1, qjin}@ruc.edu.cn

Abstract

Multimodal semantic comprehension has attracted increasing research interests in recent years, such as visual question answering and caption generation. However, due to the data limitation, fine-grained semantic comprehension which requires to capture semantic details of multimodal contents has not been well investigated. In this work, we introduce "YouMakeup", a large-scale multimodal instructional video dataset to support fine-grained semantic comprehension research in specific domain. YouMakeup contains 2,800 videos from YouTube, spanning more than 420 hours in total. Each video is annotated with a sequence of natural language descriptions for instructional steps, grounded in temporal video range and spatial facial areas. The annotated steps in a video involve subtle difference in actions, products and regions, which require fine-grained understanding and reasoning both temporally and spatially. In order to evaluate models' ability for fined-grained comprehension, we further propose two groups of tasks including generation tasks and visual question answering tasks from different aspects. We also establish a baseline of step caption generation for future comparison. The dataset will be publicly available at https://github.com/AIM3-RUC/YouMakeup to support research investigation in fine-grained semantic comprehension.

1 Introduction

Videos which naturally contain rich multimodal semantic information have been one of the main sources for knowledge acquisition. In recent years, video semantic comprehension has attracted much research attention, with a number of datasets and tasks being proposed such as activity recognition (Xu et al., 2017), dense video captioning (Krishna et al., 2017a), visual question answering (Lei et al., 2018, 2019) etc. However, most works are limited to only capturing coarse semantic information such as action recognition in broad categories. Fine-grained comprehension instead has not been fully explored, especially for discriminating actions with subtle difference or understanding temporal relations of actions in a certain activity.

Instructional videos, which contain series of steps to accomplish certain tasks, are suitable sources to investigate fine-grained semantic comprehension and reasoning. As shown in Table 1, different instructional video datasets have been released. However, current datasets suffer from small data scales or coarse annotations to support fine-grained analysis. For example, datasets collected in (Alayrac et al., 2016; Rohrbach et al., 2012; Stein and McKenna, 2013; Kuehne et al., 2014; Das et al., 2013) only contain hundreds or fewer videos and actions. Although COIN dataset (Tang et al., 2019) is in large scale, it aims to cover wide range of action categories instead of distinguishing actions with subtle difference, and also lacks fine-grained step annotations. The YouCook2 dataset (Zhou et al., 2018) contains fairly large number of videos and temporal grounded sentences in the cooking domain. However, since different cooking steps contain apparent visual variation in actions, food and kitchen utilities, it might not require fine-grained reasoning over temporal and spatial dimensions to identify different steps.

In order to overcome previous limitations, we collect a new instructional video dataset named "YouMakeup" in specific makeup domain for fine-grained multimodal semantic comprehension. The advantages of opting for the makeup domain are threefolds. Firstly, makeup instructional videos are more fine-grained in nature because different steps share the same facial background but con-

Table 1: Comparison of different instructional video datasets. Ctg. = pre-defined categories; Sent. = sentence; T.G = temporal grounding; S.G = spatial grounding; 'recorded' means videos are self-recorded by collectors. The YouMakeup dataset is unique in large-scale data size and fine-grained annotations.

tain at least one subtle but critical difference in action, tool or facial area. Therefore, it requires fine-grained discrimination within temporal and spatial context. Secondly, there are abundant makeup instructional videos on the Internet with manual commentary or scripts, which makes it easy to collect and annotate. Last but not least, makeup video analysis is of great value which can facilitate both editing and searching process for cosmetic companies and users. The collected YouMakeup dataset consists of 2,800 makeup videos crawled from YouTube, which spans more than 420 hours. As shown in Figure 1, we manually annotate a sequence of natural language sentences to describe different instructional steps for each video and each step is grounded both in temporal video segment and spatial face areas in fine-grained details. There are totally 30,626 steps with 10.9 steps on average for each video, indicating the complexity of makeup activities.

For the purpose of comprehensively evaluating fine-grained analysis, we propose two groups of potential semantic comprehension tasks on YouMakeup: Generation and Question Answering (QA) tasks. The Generation tasks include temporal step segmentation, step caption generation and spatial area grounding, which reflects an overall semantic comprehension performance. In order to further measure video semantic reasoning ability, we design four QA tasks for detailed evaluations from four aspects as illustrated in Figure 8. The Facial Image Ordering task aims to track subtle changes on facial appearance after each step, which requires to reason influences of actions on object states. The Step Ordering task is to sort step descriptions according to their temporal order in the video, requiring temporal action reasoning and visual semantic matching. The Time Range Selection task requires the precise temporal localization of specific step in the video, forcing models to distinguish fine-grained difference between makeup steps. The Theme Inference task aims to select a best theme for the video, which demands high-level summarization of video content.

The main contributions of this work are threefolds: 1) We introduce a large-scale fine-grained instructional video dataset "YouMakeup" in makeup domain to support research on fine-grained multimodal semantic comprehension. To the best of our knowledge, it is the largest instructional video dataset in specific domain with fine-grained temporal and spatial grounded annotation. 2) We propose two groups of tasks to evaluate fine-grained video comprehension abilities, including generation tasks and four QA tasks, which require fine-grained semantic understanding and reasoning in different aspects and levels. 3) We propose a baseline framework for the step caption generation task to demonstrate that the fine-grained analysis and long temporal dependencies are essential for multimodal semantic comprehension.

2 Related Work

2.1 Instructional Video Datasets

Existing instructional video datasets can be divided into two groups according to the domain diversity as summarized in Table 1. The first group aims to involve diverse activities from different domains. (Alayrac et al., 2016) contains 5 tasks such as "Making a coffee" and "Changing car tire". COIN (Tang et al., 2019) is a large scale dataset which contains videos of 180 different tasks in 12 domains related to our daily life. These datasets are constructed to improve model's generalization ability rather than support the fine-grained semantic comprehension. The

Step	Temporal range	Spatial Face Area	Step Description
Step 1	00:02:10~00:02:39	eyelid	Apply eyeshadow over eyelid with brush
Step 2	00:02:40~00:02:54	brow	Draw eyebrow using the brow shadow with brush
Step 3	00:02:56~00:03:10	lashline	Draw winged eyelinear with eyelinear pen
Step 4	00:03:11~00:03:24	lip	Apply red lipgloss on lips
Step 5	00:03:25~00:03:28	cheek, hailine	Apply bronzer on the cheeks and hairline with brush
Step 6	00:03:29~00:03:34	cheekbone, forehead, nose	Apply highlighter on the cheekbones, forehead and nose with brush
Step 7	00:03:35~00:03:47	lash	Curl the lashes and apply mascara on the lashes
Step 8	00:03:54~00:04:15	lash	Apply false lashes on the lashes

Figure 1: An example video in YouMakeup dataset. We annotate a sequence of step descriptions grounded in temporal video range and spatial face areas for each video. Best viewed in color.

other group focuses on specific domain, such as furniture assembling and cooking. (Rohrbach et al., 2012; Stein and McKenna, 2013; Kuehne et al., 2014) contain videos about simple cooking activities. YouCook (Das et al., 2013) consists of 88 videos with long text summarization. These datasets are limited in both number of videos and actions. YouCook2 (Zhou et al., 2018) is relatively large with 2000 videos, spanning 176 hours. Though cooking events are of rich semantics containing various foods, kitchen utilities and actions (Nishimura et al., 2019; Hahn et al., 2018), such variety makes it hard to measure fine-grained comprehension ability of models. For example, objects in "Sprinkle salt and pepper to the taste" and "Place the bacon at the top" are very different so that it might not be necessary to understand the whole details of actions to distinguish the two steps.

The strengths of our YouMakeup dataset compared with previous works are in two aspects: (1) it is large in scale with 420 hours in total. To the best of our knowledge, it is the largest instructional dataset in specific domain with rich fine-grained annotations. (2) Facial makeup is suitable for fine-grained comprehension in nature for all activities occur on the local facial area with subtle differences.

2.2 Video Comprehension Tasks

A wide range of tasks have been proposed for semantic comprehension on videos, such as action detection, dense video captioning and video question answering etc. The general video captioning task requires to generate a single sentence for the whole video, which cannot describe video content in details especially for long videos. So in the dense video captioning task, the model needs to detect meaningful events in the video and generate sentence to describe each one. Comparing to the dense captioning tasks which focus on activities with very different actions such as ActivityNet challenge (Krishna et al., 2017a), makeup instructional videos are more fine-grained which contain actions with subtle difference, providing more challenges for semantic comprehension.

Question answering is another way to effectively evaluate semantic understanding. Apart from image based QA datasets such as (Malinowski and Fritz, 2014; Antol et al., 2015; Ren et al., 2015a; Johnson et al., 2017), several video based datasets have been released to explore spatial and temporal inference of the video content. However, they mainly focus on comprehension within short video clips which contain simple activities and interactions, such as (Jang et al., 2017; Kim et al., 2016; Tapaswi et al., 2016; Maharaj et al., 2017), etc. The TVQA dataset (Lei et al., 2018, 2019) is constructed from complex TV shows, but each question is associated with a short clip up to 90 seconds and more focused on joint understanding of visual and speech content. In comparison, our proposed four QA tasks on YouMakeup dataset are used to evaluate video semantic reasoning abilities from different aspects, such as spatial and temporal understanding for long videos, causality reasoning of actions and

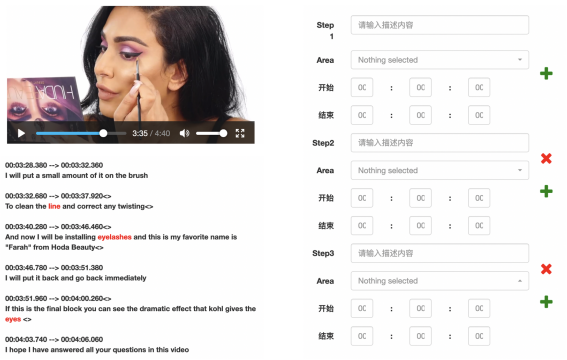

Figure 2: Annotation website

global semantic summarization.

3 YouMakeup Dataset

3.1 Data Collection

Our goal is to build a large-scale multimodal instructional video dataset in the makeup domain to support the fine-grained semantic comprehension research. We start from collecting a list of famous cosmetic brands, such as Chanel, Mac, etc., and beauty bloggers with more than tens of thousands followers. These companies and bloggers are authoritative and professional in the makeup domain with many people learning makeup skills from them. Videos in their official channels are of high quality. Based on the list, we search their official channels on the YouTube and crawl makeup instructional videos together with available meta data such as video id, duration, title, tags and English subtitles generated by YouTube automatically. We process the subtitles into complete sentences aligned with video time stamps.

Since specific names of cosmetic brands are not important to understand makeup procedures, we filter out them in raw titles and subtitles of videos. We first create an initial list of cosmetic brands and then refine it gradually by checking words frequency and finding similar words via word embedding model (Tomas Mikolov, 2013). Finally, we utilize the refined list to remove cosmetic brands in raw texts. We also create lists for facial areas and cosmetic products through the similar process.

3.1.1 Step Annotation

We build an annotation system for step annotation. Figure 2 shows the interface of our annotation system. We provide video and English subtitles in the annotation page to assist the annotation. The products and facial areas in the subtitle are emphasized in red color to help annotators focus on related information. Annotators are asked to segment the video into a series of steps, which includes labeling the start and end time of each step, selecting the related facial areas in the given facial area list and creating the caption to describe the step according to the video and subtitles. We recruit female college students with more than two years of makeup experience as annotators. Before starting the annotation, each annotator is asked to annotate a test video to verify their capability for annotation. During annotation, each video is annotated by one person and reviewed by another to ensure the annotation quality.

3.1.2 Facial Image Annotation

We extract two groups of facial images from the video. The first group is used to understand the effect of makeup activities on facial appearance, which supports our proposed QA task described in Section 4.2. We extract images at the beginning and the end of each step to capture the facial appearance before and after each step. In order to select images containing faces, we extract images in 40 frames around each time stamp and filter them with a pretrained Multi-Task CNN (MTCNN) (Zhang et al., 2016) for face detection. We then manually filter out unsuitable images such as side face images and pure product images.

The second group is to localize all facial areas referred in each step for spatial grounding. We extract key frames within the annotated segment of each step via comparing similarity of different frames followed by manual filtering of redundant frames. Then we automatically detect facial landmarks in the facial image and align the image region to corresponding facial areas of each step annotated in Section 3.1.1. Finally, we ask annotators to adjust the bounding box of these facial areas on the images and obtain the final grounded facial areas for each step.

3.1.3 Theme Annotation

Inferring the theme of a video is a basic ability to understand the video content. Therefore, we annotate the theme for each makeup video. The original title of the video usually summarizes the content or highlights specific features in the video, which can be treated as the theme of the video. As mentioned above, the specific cosmetic brand names are removed in the title for generalization.

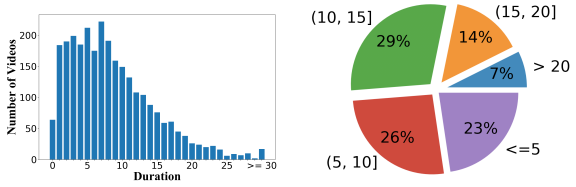

Figure 3: Different categories of the makeup instructional video

We further ask annotators to refine the title with the help of related meta information to make the theme more accurate.

3.2 Dataset Statistics

The final YouMakeup dataset contains 2800 videos, spanning 420 hours 50 minutes, and rich annotations. Videos can be mainly divided into three categories as shown in Figure 3: 1) Makeup for special occasions, such as school days or wedding days; 2) Makeup tips for specific facial area or cosmetic products, such as eye makeup or wearing red lipstick; 3) Makeup transformation, such as celebrities transformation. The first and third types usually create full looks, while the second focuses on specific step or facial area. We split the dataset into training, testing and validation set by 70%: 20%:10% and set up all the tasks on this division.

(a) Video duration. (b) Step number.

Figure 4: Statistics of video duration and step number.

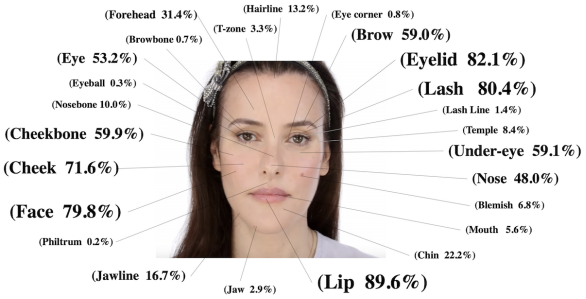
3.2.1 Video Length

Different from previous datasets containing videos with similar duration (Lei et al., 2018; Tang et al., 2019), videos in YouMakeup dataset are of various lengths, which reflects the complex situation in the realistic world. As shown in Figure 4(a), the length of videos varies from 15s to 1h with 9min on average. The large diversity of length results from the diverse video categories and styles. For example, tutorials from companies are usually short and come straight to the point, while those from beauty bloggers are more complex for they may show makeup skills or share their opinions about products in details.

3.2.2 Makeup Steps

There are 30,626 annotated steps in total with average 10.9 steps per video in YouMakeup. Figure 4(b) shows the distribution of step number. Compared with instructional video datasets in general domains, YouMakeup is more complex with more steps on average and therefore bringing more challenge for semantic understanding.

Each step associates with at least one and up to seven facial areas. The frequency of grounded facial areas are presented in Figure 5. All these areas are close to each other on the face and might contain overlaps for some of them. For example, brow and brow bone are closely adjacent to each other and the under-eye area overlaps with cheeks. Therefore, fine-grained understanding is required to distinguish these areas.



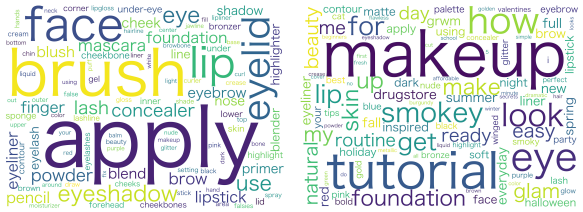


Figure 5: Frequency of grounded facial areas in YouMakeup dataset.

There are more than 1500 unique words occurred in the step captions. Figure 6(a) shows the Wordcloud for most frequent 100 words excluding stopwords. The most frequent words include actions, products, facial areas and tools as summarized in Table 2. These four categories of words can be combined in various ways, generating large number of different fine-grained makeup activities. For example, Figure 7 illustrates the fine-grained activities for the action "apply". The graph shows that the number of activities is large. Though the activities are similar, they are distinct in actions, products, facial areas or other aspects. Therefore, fine-grained comprehension is required for telling such subtle differences.

(a) Step caption. (b) Theme.

Figure 6: Wordcloud for different text annotations.

Type	Terms
Actions	apply, use, blend, highlight, draw, curler, fix, clean, pat, shape, emphasize, press, sweep, correct, bake, tap, contour
Products	eyeshadow, concealer, powder, pencil, foundation, lipstick, eyeliner, blush, primer, shadow, highlighter, contour, bronzer, gel, cream, lipgloss, false lashes, blam, spray
Areas	face, lips, eyelid, eye, lashes, brow, cheek, nose, under-eye, cheekbone, lash line, forehead, chin, mouth, blemish, temple, jaw, hairline, jawline, t-zone, nosebone, browbone, eye corner, lash line, philtrum, eyeball
Tools	brush, blender, sponge, finger, puff, tweezer

Table 2: Top words of four categories in step captions.

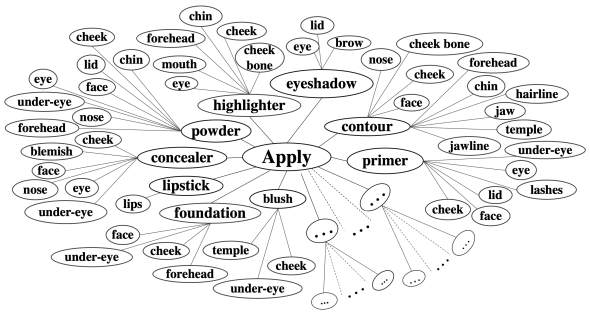

Figure 7: Fine-grained activity graph stemmed from action 'Apply'.

4 Semantic Comprehension Tasks

For the purpose of exploring fine-grained semantic comprehension in different aspects and levels, we propose two groups of tasks namely generation and question answering, which contain 5 detailed tasks according to the instructional and multimodal characteristics of YouMakeup.

4.1 Task I: Step Generation

The step generation task includes identifying the temporal boundaries for steps, grounding the facial areas and generating natural language step description for each step as shown in Figure 1. It is a classical task in instructional video analysis for evaluating model's ability to capture the temporal flow of steps and grasp the procedural knowledge. Due to the similarity between makeup activities such as the similar motion, appearance of products and the adjacent location of facial areas, this task calls for a fine-grained comprehension of video content. The task is closely related to dense video captioning (Krishna et al., 2017a), however, it needs to integrate makeup procedural knowledge to generate fine-grained step segmentation and step description instead of independent event descriptions.

4.2 Task II: Facial Image Ordering

The facial image ordering task is to sort a series of shuffled facial images into the right order according to the ordered step captions, as shown in Figure 8(a). Instructional videos present steps for accomplishing a certain task. Tracking the changes of object is crucial for procedure comprehension. The effect of makeup is the fine-grained changes of facial appearances. Some steps bring apparent changes, for example, "Apply red lipsticks on the lips" turns the lip color from nude to bold red. However, some changes can be subtle and difficult to identify, such as "Apply foundation on the face with brush", which may result in subtle changes of the skin tone. Under most circumstances, the result brought by each step is very complex, which not only depends on the current step but also relies on the prior state of the facial appearance. Tracking changes on the face is an effective way to evaluate models' fine-grained comprehension ability.

We choose five facial images of different steps from a video randomly to form a question. Then we set their original order as the ground truth and the other three random sorts as the candidate answers. We finally generate 12,000 questions, including 8,400 for training, 1,200 for validation, and 2,400 for testing.

4.3 Task III: Step Ordering

The step ordering task evaluates the capability of sorting a series of step captions into the right order according to the video. For human beings, comprehension is the prerequisite of ordering. The step ordering task aims at developing model's comprehension ability in a multimodal scenario, which calls for a joint understanding across different modalities. Models need to align natural language step captions with video content to solve the problem as shown in Figure 8(b), fine-grained understanding in both text and video content for temporal action reasoning and visual semantic matching is required.

We select videos with more than four steps to generate questions. For each question, we provide five captions of different steps from the video and four different order choices as the candidate

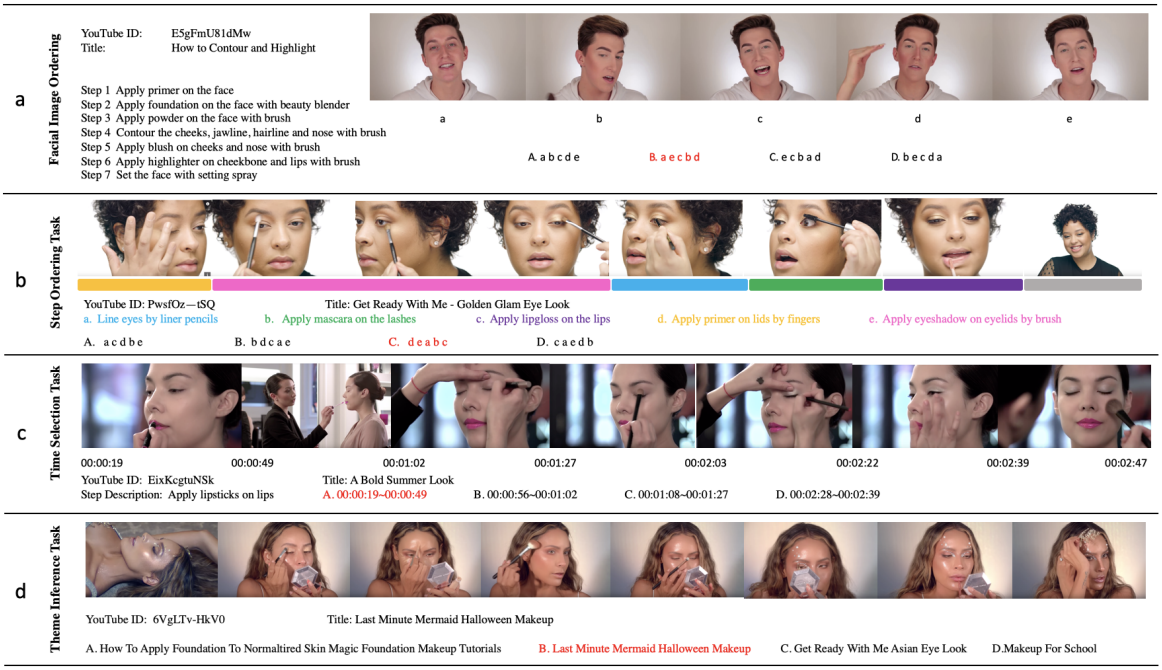

Figure 8: Four VQA tasks on YouMakeup Dataset. Best viewed in color.

answers, including the original one as the ground truth. We finally collect 12,000 questions for this task, including 8,400 for training, 1,200 for validation, and 2,400 for testing.

4.4 Task IV: Time Range Selection

In the time range selection task, models are required to localize a specific step in the video accurately. We set the task in QA form where both the video, the step caption and four candidate answers are provided. As the case shown in Figure 8(c), given the caption, the model needs to select the most accurate time range from four candidate answers after reviewing the whole video. To accomplish this task, models need to jointly understand the step caption and the video, distinguish the fine-grained difference of the makeup activities in each video clips to find the best answer.

To form the question, we first select one step from the video, provide its step caption as question and set its time range as ground truth. Then we choose the other three steps which have some overlap in facial area with the question step from the same video, and set their time range as the candidate answers. We finally collect 12,000 questions for this task, including 8,400 for training, 1,200 for validation and 2,400 for testing.

4.5 Task V: Theme Inference

The theme inference task requires to inference the theme of a video. People can compress complicated content and extract key information. Several tasks have been set up to help the model develop such ability, such as the video summarization task which summarizes the video in several sentences. Theme inference is another way to evaluate this kind of ability. Since a video can be summarized with focus on multiple aspects, it is difficult to treat theme inference as generation task. We set it in QA form based on the annotation in Section 3.1.3.

As shown in Figure 8(d), we provide four candidate answers including the ground-truth. To generate candidate answers, we set up the candidate answer set with titles and tags of all videos. Then we utilize the FastText (Bojanowski et al., 2016), Doc2Vec (Le and Mikolov, 2014) and Word2Vec (Tomas Mikolov, 2013) together for theme feature representation to search the top 10 nearest themes for each video. These themes are then selected by the annotator to form the candidate answers. Given the makeup videos, the model needs to select the most suitable theme from four choices.

Different from the video classification task which divides videos into fixed pre-defined categories, the candidate answers in the theme inference task are natural language sentences different from each other. As shown in Figure 6(b), the

themes involve diverse aspects, such as "smokey" and "natural" for makeup style, "night" and "halloween" for occasions, and "pink" and "red" for color tone. Thus, the theme inference task requires a fine-grained comprehensive understanding of the video content in various aspects.

5 Experiment

We build a step caption generation system to provide a baseline for our YouMakeup dataset and demonstrate the necessity of fine-grained spatial and temporal understanding to solve the task. The system utilizes the groundtruth step segmentation in order to evaluate the captioning ability alone, and is evaluated by the standard captioning metrics including BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), ROUGE (Flick, 2004), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016).

Implementation Details Our step caption generation model is based on the encoder-decoder captioning framework, which is widely used in video caption generation (Vinyals et al., 2015; Chen et al., 2019). The encoder converts the video clip into a fixed-dimensional vector and then the decoder generates word sequences conditioning on the encoded vector. Since both spatial and temporal reasoning are important for the task, we propose two types of encoder as follows: 1) spatial encoder: faster RCNN (Ren et al., 2015b) pretrained on the VisualGenome dataset (Krishna et al., 2017b) is used to extract object features in a single frame. We select one frame for each video clip and detect at most 36 objects in the frame. Mean pooling is applied on the extracted object features to generate the video-level representation. 2) temporal encoder: Resnet152 (He et al., 2016) pretrained on the ImageNet dataset (Deng et al., 2009) is used to extract features for each frame. We extract global frame-level features for every 16 frames and apply mean pooling on the temporal dimension to generate the global video-level representation. We employ the LSTM as our decoder, which contains 1 hidden layer with 512 hidden units. Adam optimizer is used to train our model with batch size of 128 and learning rate of 0.0001. We train at most 100 epochs and select the best model according to captioning performance on the validation set.

Results. Table 3 presents the step captioning performance with ground truth step segmentation on the testing set of YouMakeup. We can see that the combination of spatial and temporal features achieves the best performance, demonstrating spatial and temporal information is complementary to generate step captions. The captioning model based on the spatial feature alone is inferior to that based on the temporal feature because our framework does not utilize all clip information. The overall performance on Cider of the baseline step caption generation model is relatively higher than baselines on other video captioning datasets (Krishna et al., 2017a) due to the fine-grained characteristics of the proposed dataset. In the YouMakeup dataset, the styles of step captions are similar which can make it easy for the caption generation system to achieve high scores since evaluation metrics are not aware of the aspect importance in the caption such as detailed tools, actions etc.

Table 3: Step captioning performance with groundtruth step segmentation on the YouMakeup dataset.

	B@4	Meteor	Rouge	Cider	Spice
spatial	13.1	19.7	46.3	94.6	27.1
temporal	16.9	21.9	48.8	130.8	34.3
spatial+temporal	**17.9**	**22.4**	**50.3**	**134.7**	**34.5**

Although the generation system achieves high evaluation scores, we find it fails to capture the fine-grained details in the makeup instructional videos. Figure 9 shows the caption generation results of the baseline system using both temporal and spatial features on a specific video for the first 6 steps. According to the captions of step 1 and 3, the system traces out the procedure roughly, lacking of details such as makeup tools and related facial area. The other three step captions indicate the system's weak ability on fine-grained video comprehension and confirm the fine-grained characteristics of YouMakeup. In step 2, the system mistakes color correction palette for eyeshadow due to their similar appearance. However, the eyeshadow is applied around eyes while color correction palette is used on the face for color correcting. From step 4 to 6, system shows confusion about the procedure of applying foundation and concealer because they are similar in both appearance and usage. System needs to associate products with their usage methods and facial areas they are applied in order to grasp the subtle difference between different makeup activities for generating accurate step description.

Step	Generated Caption	Ground Truth
Step 1	apply primer on face	apply the primer on face with fingers
Step 2	apply eyeshadow on eyelid with brush	apply the color correction palette on face with fingers
Step 3	apply concealer on face with sponge	apply the concealer with sponge on one side of the face
Step 4	apply foundation on face with sponge	blend the concealer with brush on another side of the face
Step 5	apply foundation on face	apply the foundation on skin with brush
Step 6	apply concealer on face with sponge	apply the foundation on face with beauty sponge

Figure 9: Comparison of generated captions and ground-truth captions for different steps. Best viewed in color.

6 Conclusion

In this paper, we introduce a new large-scale instructional video dataset named YouMakeup for fine-grained semantic comprehension. The YouMakeup dataset contains 2,800 makeup instructional videos spanning more than 420 hours in total. Based on the characteristics of makeup instructional videos and the rich annotations of temporal boundaries, grounded facial areas and natural language descriptions of steps, our collected dataset is more suitable to support the fine-grained video comprehension research than previous datasets. We further design a generation task and four question answering tasks to thoroughly evaluate the fine-grained semantic comprehension ability from different aspects and levels. A baseline system for step caption generation also demonstrates the necessity of fine-grained spatial and temporal information. In the future work, we plan to make thorough exploration on these proposed tasks. We will make the dataset publicly accessible in order to support the research investigation in fine-grained semantic comprehension.

Abstract

In this paper, we focus on natural language video localization: localizing (*i.e.*, grounding) a natural language description in a long and untrimmed video sequence. All currently published models for addressing this problem can be categorized into two types: (i) top-down approach: it does classification and regression for a set of pre-cut video segment candidates; (ii) bottom-up approach: it directly predicts probabilities for each video frame as the temporal boundaries (*i.e.*, start and end time point). However, both two approaches suffer several limitations: the former is computation-intensive for densely placed candidates, while the latter has trailed the performance of the top-down counterpart thus far. To this end, we propose a novel *dense bottom-up* framework: DEnse Bottom-Up Grounding (DEBUG). DEBUG regards all frames falling in the ground truth segment as foreground, and each foreground frame regresses the unique distances from its location to bi-directional ground truth boundaries. Extensive experiments on three challenging benchmarks (TACoS, Charades-STA, and ActivityNet Captions) show that DEBUG is able to match the speed of bottom-up models while surpassing the performance of the state-of-the-art top-down models.

1 Introduction

Vision-and-language understanding, *e.g.*, what the vision and text are, and how they relate with each other, is one of the core tasks in both computer vision and natural language processing. To test the machine comprehension of complex video scene and natural language simultaneously, a challenging task was proposed (Gao et al., 2017; Hendricks et al., 2017, 2018), called **Natural Language Video Localization** (NLVL). As shown in Figure 1, given a natural language description query and an untrimmed video sequence, NLVL needs to localize a segment in the video (*i.e.*, identify the start and end time point of the segment) which semantically corresponds to the reference sentence. Moreover, NLVL is an indispensable technique for many important applications, *e.g.*, text-oriented video highlight detection or retrieval.

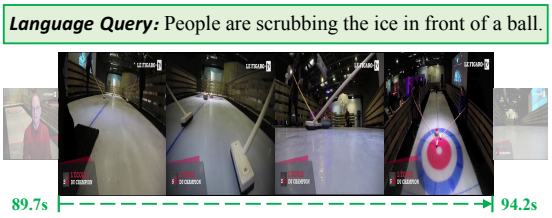

Figure 1: Natural language video localization is to localize a segment with the start point (89.7s) and end point (94.2s) in the video given a language description.

Currently, the overwhelming majority of NLVL models are ***top-down*** approaches: they first cut a video into a set of segment candidates, then they do classification and regression for each candidate. Specifically, they can be further grouped into two sub-types: 1) *sliding-window-based* (Gao et al., 2017; Hendricks et al., 2017; Liu et al., 2018b,a; Ge et al., 2019; Chen and Jiang, 2019; Xu et al., 2019; Zhang et al., 2019b): the video is explicitly segmented by multiple predefined temporal sliding-window scales. After extracting features for the query and all candidates, NLVL degrades into a multimodal matching problem. 2) *anchor-based* (Chen et al., 2018; Zhang et al., 2019a): it assigns each frame[1] with multi-scale temporal anchors, which follows the same spirit of anchor box in object detection (Ren et al., 2015).

Although top-down approaches have dominated NLVL for years, it is worth noting that they suffer

[*] Chujie Lu and Long Chen are co-first authors with equal contributions.

[†] Jun Xiao is the corresponding author.

[1]The frame is a general description for a frame in a video sequence or an element in a video frame feature sequence.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5144–5153, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

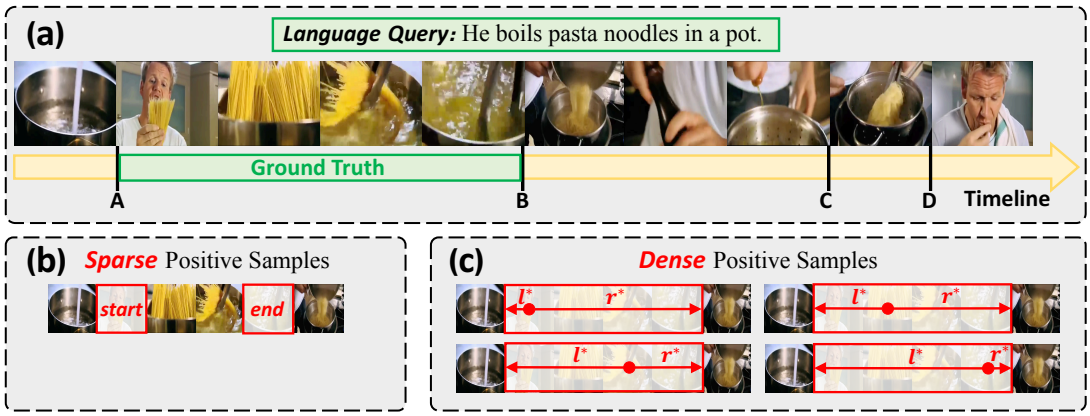

Figure 2: (a): A NLVL sample with ground truth segment (A→B). (b): Sparse positive samples in existing sparse bottom-up models (*i.e.*, two frames). (c): Dense positive samples in DEBUG (*i.e.*, all frames in range (A→B)).

several notorious limitations: 1) The performance is sensitive to the heuristic rules (*e.g.*, the temporal scales or the number of candidates). 2) In order to achieve a high recall, they are required to densely place candidates, which significantly increase the amount of computation and localization time.

To eliminate these inherent drawbacks in top-down framework, some recent NLVL works (Chen et al., 2019a; Yuan et al., 2019) start to borrow idea from reading comprehension (Xiong et al., 2017, 2018; Yu et al., 2018), which directly predicts the start and end boundaries. Although this ***sparse bottom-up*** approach is highly computation-efficient, the localization accuracy, especially for long videos (*e.g.*, TACoS) is behind its top-down counterpart. We argue that the main reasons come from three-fold: 1) Two boundary predictions are independent, *i.e.*, the model ignores the content consistency between two predictions. As an example shown in Figure 2 (a), two frames in B and D have a similar visual appearance. Thus, the model is prone to predict the result as (A→D), without considering the distinct content change in range (B→C). 2) The positive and negative training samples are extremely imbalanced. Since the number of video frames is large (*e.g.*, each video in TACoS has average 9,000 frames), but the positive training samples are *sparse*, *i.e.*, only two frames (Figure 2 (b)). 3) Detecting temporal action boundary from frames, *i.e.*, predicting a frame is query-related and at temporal boundary simultaneously by a single network, is still a challenging task, even without query constraint (Shou et al., 2018).

In this paper, we propose a ***dense bottom-up*** framework for NLVL: DEnse Bottom-Up Grounding (DEBUG), to mitigate the problems in existing NLVL frameworks. Specifically, we regard all frames falling in the ground truth segment as positive samples (*i.e.*, foreground). For each positive frame, DEBUG has a classification subnet to predict its relatedness with the query, and a boundary regression subnet to regress the unique distances from its location to bi-directional ground truth boundaries. This design helps to disentangle the temporal boundary detection from query-related prediction, relieving the burden of the single classification network in existing sparse bottom-up models. Meanwhile, we can utilize as many positive samples as possible to alleviate the imbalance problem between positive and negative samples (Figure 2 (c)). Since each pair of boundary predictions are based on the same frame feature, *i.e.*, two predictions act as a whole, which helps to avoid falling into the local optimum caused by independent predictions. In addition, we propose a temporal pooling to relieve unstable performance caused by single prediction. Moreover, DEBUG is agnostic to the upstream multimodal interaction network, *i.e.*, it can be seamlessly incorporated into any stronger backbone to boost performance.

We demonstrate the effectiveness of DEBUG on three challenging benchmarks: TACoS (Regneri et al., 2013), Charades-STA (Gao et al., 2017), and ActivityNet Captions (Krishna et al., 2017). Without bells and whistles, DEBUG surpasses the performance of the state-of-the-art models over various benchmarks and metrics at the highest speed.

2 Related Work

2.1 Natural Language Video Localization

NLVL is a very difficult task, which needs to understand both complex video scene and natu-

ral language simultaneously. Because most of NLVL models are under the top-down framework, they focus on designing more effective multi-modal interaction networks, *e.g.*, query-based attention on video frames (Liu et al., 2018a), visual-based attention on language words (Liu et al., 2018b), or co-attention between each frame-and-word pairs (Chen et al., 2018, 2019a; Yuan et al., 2019). It is worth noting that the improvement in multimodal interaction network is orthogonal to the DEBUG, *i.e.*, DEBUG can be seamlessly incorporated into any stronger interaction network.

To the best of our knowledge, there are only two exceptions among all NLVL models: RWM (He et al., 2019) and SM-RL (Wang et al., 2019), which are not under either top-down or bottom-up frameworks. They both formulate NLVL as a sequential decision making problem, solved by reinforcement learning, *e.g.*, actor critic (Chen et al., 2019b). The action space for each step is a set of handcraft-designed temporal box transformations.

2.2 Top-Down vs. Bottom-Up

Top-down and bottom-up approaches, which are widely co-exist in many CV and NLP tasks, are two different philosophical viewpoints for solving problems. The most related top-down and bottom-up concepts as the one in NLVL frameworks are:

Object Detection. Most of the object detectors after Faster-RCNN (Ren et al., 2015) are top-down models, *i.e.*, it predicts classification scores and regression offsets for multiple predefined anchors in each position. These models suffer the same drawbacks as above mentioned in the top-down approach for NLVL. However, with the advent of the first performance comparable bottom-up object detector: CornerNet (Law and Deng, 2018), the bottom-up approaches begin to gain unprecedented attention (Zhou et al., 2019b,a; Duan et al., 2019; Tian et al., 2019), which inspires us to explore a decent bottom-up framework for NLVL.

Attention Mechanism. Top-down attention has dominated many vision-and-language tasks, *e.g.*, visual captioning (Xu et al., 2015; Chen et al., 2017), visual QA (Xu and Saenko, 2016; Ye et al., 2017). Recently, a model combining both top-down and bottom-up attention reaches the winner of multiple challenges (Anderson et al., 2018). Thus, how to combine the top-down and bottom-up attentions effectively is still an unexplored problem in the vision-and-language tasks.

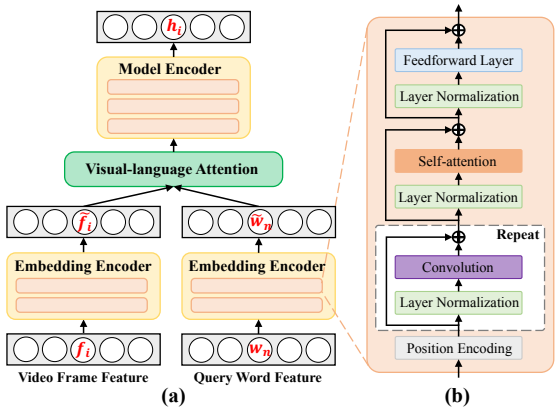

Figure 3: (a): The overview of QANet backbone. (b): The encoder block throughout the QANet.

3 Approach

The NLVL task considered in this paper, is defined as follows. Given a long and untrimmed video sequence V, and a natural language query Q which describes a segment in V from start time point t_s to end time point t_e, NLVL needs to predict these two time points (t_s, t_e) given V and Q.

In this section, we first introduce the multi-modal interaction backbone of DEBUG, which is built upon the recently proposed QANet (Yu et al., 2018) for reading comprehension (Section 3.1). Then, we demonstrate the details about the proposed dense bottom-up grounding (Section 3.2). Finally, we describe the training and test stage of the whole DEBUG (Section 3.3).

3.1 Backbone: QANet

We adopt the QANet to model the interaction between two different modalities (*i.e.*, video and language), which serves as the backbone of DEBUG. The details of the QANet are shown in Figure 3 (a), which consists of three main components:

Embedding Encoder Layer. The input for this layer in two different branches are extracted video frame features $\boldsymbol{F} = \{\boldsymbol{f}_i\}_{i=1}^{T}$ and query word features $\boldsymbol{W} = \{\boldsymbol{w}_n\}_{n=1}^{N}$, respectively (see details in Section 4.2). T and N are the numbers of frames and words. The embedding encoder layer is a stack of encoder blocks as shown in Figure 3 (b), which contains multiple components, including convolutional layer, layer-normalization layer, self-attention layer, and feedforward layer. The output of this layer is new frame features $\tilde{\boldsymbol{F}} = \{\tilde{\boldsymbol{f}}_i\}_{i=1}^{T}$ or word features $\tilde{\boldsymbol{W}} = \{\tilde{\boldsymbol{w}}_n\}_{n=1}^{N}$, which encode the context in its respective modality.

Visual-language Attention Layer. It calculates

two different attention weights between the two modal features. Specifically, it first computes a similarity matrix $\boldsymbol{S} \in \mathbb{R}^{T\times N}$, where $\boldsymbol{S}_{ij}$ denotes the similarity between frame feature $\tilde{\boldsymbol{f}}_i$ and word feature $\tilde{\boldsymbol{w}}_j$. Then the two attention weights are:

$$\boldsymbol{A} = \bar{\boldsymbol{S}} \cdot \tilde{\boldsymbol{W}}, \quad \boldsymbol{B} = \bar{\boldsymbol{S}} \cdot \bar{\bar{\boldsymbol{S}}}^T \cdot \tilde{\boldsymbol{F}}, \tag{1}$$

where $\bar{\boldsymbol{S}}$ and $\bar{\bar{\boldsymbol{S}}}$ are the row-wise and column-wise normalized matrix of S, respectively.

Model Encoder Layer. Given the two attention weights $\boldsymbol{A}$ and $\boldsymbol{B}$, the model encoder layer begins to encode the interaction between the two modal features. This layer is also a stack of encoder blocks (Figure 3 (b)), and these encoder blocks share parameters. The input in i-th position is $[\boldsymbol{f}_i, \boldsymbol{a}_i, \boldsymbol{f}_i \odot \boldsymbol{a}_i, \boldsymbol{f}_i \odot \boldsymbol{b}_i]$, where $\boldsymbol{a}_i$ and $\boldsymbol{b}_i$ are i-th row of $\boldsymbol{A}$ and $\boldsymbol{B}$, $\odot$ is the element-wise multiplication, and $[\cdot]$ is a vector concatenate operation. The output is $\boldsymbol{H} = \{\boldsymbol{h}_i\}_{i=1}^T, \boldsymbol{H} \in \mathbb{R}^{T\times D}$, where $\boldsymbol{h}_i \in \mathbb{R}^D$ is a frame feature encoded with multimodal context. Then $\boldsymbol{H}$ is fed into the following head network (*i.e.*, dense bottom-up grounding) for boundaries prediction. We refer readers to QANet (Yu et al., 2018) paper for more details.

3.2 Dense Bottom-Up Grounding

Since the nature of the bottom-up approach, DEBUG regards each frame as a training sample. Different from the existing sparse bottom-up models which only use the exact start and end boundary frames as foreground, DEBUG utilizes all frames falling in the ground truth segment as positive samples. For each sample, there are three branch subnets, which aim to predict its classification score, boundary distances, and confidence score respectively. Specifically, the whole architecture of DEBUG is shown in Figure 4, and the details about the three branch subnets are:

Classification Subnet. The classification subnet predicts the relatedness between each video frame and the language query, *i.e.*, whether the frame is a foreground frame. Taking the multimodal feature $\boldsymbol{H} \in \mathbb{R}^{T\times D}$ from the backbone, this subnet applies four 1×3 conv layers, each with D filters and each followed by ReLU activations, followed by a 1×3 conv layer with 1 filter. Finally, sigmoid activations are attached to output the foreground prediction score per location. For a positive sample (*i.e.*, foreground), its ground truth classification label is $c_i^* = 1$, otherwise $c_i^* = 0$.

Boundary Regression Subnet. The boundary regression subnet predicts the unique distances from

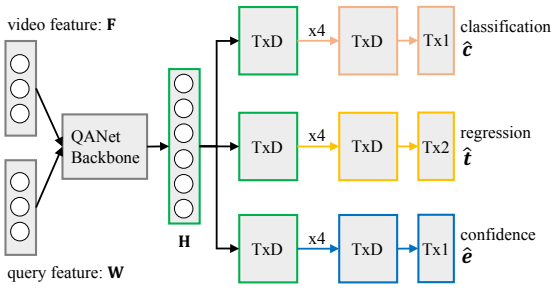

Figure 4: The whole architecture of the DEBUG. It consists of a QANet backbone and a head network with three branch subnets. $T \times *$ denotes the shape of corresponding matrix.

the location of each frame to the bi-directional ground truth boundaries. The design of the boundary regression subnet is identical to the classification subnet except it terminates in 2 outputs for both left and right distances. We only assign boundary regression targets for positive frames. Specifically, for a positive frame at i-th position, if the ground truth segment range is (t_s, t_e) (*i.e.*, $t_s \le i \le t_e$), the regression target is $\boldsymbol{t}_i^* = (l_i^*, r_i^*)$:

$$l_i^* = i - t_s, \quad r_i^* = t_e - i, \tag{2}$$

where l_i^* and r_i^* represents the distance from i-th frame to the left and right boundaries, respectively.

Confidence Subnet. The design of the confidence subnet is identical to the classification subnet, but it predicts the confidence of the boundary regression results for each frame. The motivation of this subnet design comes from that the prediction confidences from different frames should be different, *e.g.*, it is more difficult for a frame near the start point to detect the end point than a frame near the end point. Therefore, we set the ground truth confidence of each frame based on its "centerness" in the segment. Given the regression target l_i^* and r_i^*, the ground truth confidence score is defined as:

$$e_i^* = \frac{\min(l_i^*, r_i^*)}{\max(l_i^*, r_i^*)}. \tag{3}$$

The confidence score ranges from 1 to 0 with the frame position from segment center to boundary.

3.3 Training and Inference

Loss. Given all frames predictions $\{(\hat{c}_i, \hat{\boldsymbol{t}}_i, \hat{e}_i)\}$ and the corresponding ground truth $\{(c_i^*, \boldsymbol{t}_i^*, e_i^*)\}$, the total training loss function for DEBUG is:

$$L = \frac{1}{N}\sum_i L_{cls}(\hat{c}_i, c_i^*) + \frac{\alpha}{N_p}\mathbb{1}_{\{c_i^*=1\}} L_{reg}(\hat{\boldsymbol{t}}_i, \boldsymbol{t}_i^*) + \frac{\beta}{N_p}\mathbb{1}_{\{c_i^*=1\}} L_{conf}(\hat{e}_i, e_i^*) \tag{4}$$

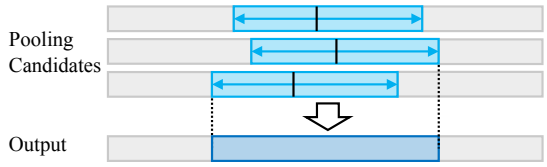

Figure 5: Illustration of temporal pooling.

where L_{cls} and L_{conf} both are binary cross entropy (BCE) loss for classification subnet and confidence subnet. L_{reg} is the IOU loss for boundary regression subnet (*i.e.*, $-\ln \frac{\min(r_i^*,\hat{r}_i)-\max(l_i^*,\hat{l}_i)}{\max(r_i^*,\hat{r}_i)-\min(l_i^*,\hat{l}_i)}$). N and N_p denotes the number of total samples and positive samples, respectively. α and β are loss weights to balance different losses, we set both α and β to 1 in all experiments. $\mathbb{1}_{\{c_i^*=1\}}$ is an indicator function, being 1 if $c_i^* = 1$ and 0 otherwise.

Inference. Given a video and a language query, we forward them through the network and obtain $\hat{c}_i$, $\hat{\boldsymbol{t}}_i$, $\hat{e}_i$ for each frame from three subnets. Then, we rank all segment predictions by the score $\hat{s}$: $\hat{s}_i = \hat{c}_i \times \hat{e}_i$. A straightforward solution is selecting the segment with the highest score as the final prediction. However, segment prediction from a single frame is usually with high variance. To relieve this situation, we propose a simple yet effective strategy: **Temporal Pooling**, to fuse multiple frame predictions. As shown in Figure 5, temporal pooling directly uses the leftmost and rightmost boundaries among all pooling candidates as its output. As for the pooling candidates, they need to meet with two conditions simultaneously: 1) the predicted segment is overlapped with the one with the highest score; 2) the score is large than the highest score multiple a threshold δ[2].

4 Experiments

4.1 Datasets and Metrics

Datasets. We evaluated the DEBUG on three challenging NLVL benchmarks: **TACoS** (Regneri et al., 2013). It consists of 127 videos and 17,344 text-to-clip pairs. In our experiments, we used the standard split same as (Gao et al., 2017), *i.e.*, 50% for training, 25% for validation and 25% for test. The average length of each video is 5 minutes. **Charades-STA** (Gao et al., 2017). It consists of 12,408 text-to-clip pairs for training, and 3,720 pairs for test. The average length of each video is 30 seconds. **ActivityNet Captions** (Krishna et al., 2017). It is not only the largest NLVL dataset (19,209 videos) but also with much more diverse context than the others. We followed (Yuan et al., 2019) and utilized the public train set (*i.e.*, 37,421 text-to-clip pairs) for training, and the validation set (*i.e.*, 17,505 text-to-clip pairs) for test. The average length of each video is 2 minutes.

Evaluation Metrics. Following the conventions in previous works, we evaluated NLVL on two prevailing evaluation metrics: 1) **R@N, IoU@θ**: The percentage of testing samples which have at least one of the top-N results with IoU larger than θ. Since the nature of the bottom-up framework, we only use N=1 in all our experiments; 2) **mIoU**: The average IoU over all testing samples.

4.2 Implementation Details

Given an untrimmed video V, we first downsampled frames and utilized the C3D (D.Tran et al., 2015) feature pretrained on Sports-1M (A.Karpathy et al., 2014) as the initial frame features. Then, we reduced the dimension of these features to 500 using PCA, which are the video frame features $\boldsymbol{F}$ (Section 3.1). For query Q, it was truncated or padded to a maximum length of 15 words. Each word was initialized with the 300-d Glove vector (J.Pennington et al., 2014), and all word embeddings were fixed. Then we learned a transformation matrix to map these embeddings to 500-d, which are the sentence word features $\boldsymbol{W}$ (Section 3.1). The dimension of all intermediate layers in the backbone and three subnets was set to 128. We trained the whole network for 100 epochs from scratch, and the loss was optimized by Adam algorithm (D.P.Kingma and J.Ba, 2015). The learning rate started from 0.0001 and was divided by 10 when the loss plateaus. The batch size was set to 16, and the dropout rate was 0.5.

4.3 Comparisons with State-of-the-Arts

Settings. We compared the DEBUG with all recently published state-of-the-art NLVL models. From the viewpoint of top-down and bottom-up framework, we group them into: 1) Sliding-window-based models: **VSA-RNN**, **VSA-STV**, **CTRL** (Gao et al., 2017), **ROLE** (Liu et al., 2018b), **ACRN** (Liu et al., 2018a), **MCF** (Wu and Han, 2018), **ACL** (Ge et al., 2019), **SAP** (Chen and Jiang, 2019), **QSPN** (Xu et al., 2019). 2) Anchor-based models: **TGN** (Chen et al., 2018). 3) Sparse bottom-up models: **L-Net** (Chen et al., 2019a), **ABLR-af**, **ABLR-aw** (Yuan et al., 2019)

[2]In experiments, we tested $\delta \in \{0.1, 0.2, ..., 0.9\}$ and selected the one with the highest performance for each dataset.

4) Others (*i.e.*, RL-based models): **RWM** (He et al., 2019), **SM-RL** (Wang et al., 2019).

Results. The results are reported in Table 1. From Table 1, we can observe that the DEBUG achieves a new state-of-the-art performance under all evaluation metrics and benchmarks. It is worth noting that DEBUG can especially improve the performance significantly in some more strict metrics (*e.g.*, 2.62% and 2.52% absolute improvement in mIoU on dataset TACoS and ActivityNet Captions, and 2.12% absolute improvement in IoU@0.7 on Charades-STA[3]), which demonstrates the effectiveness of the DEBUG.

4.4 Ablative Studies

In this section, we did extensive ablative experiments to thoroughly investigate the DEBUG.

4.4.1 Sparse vs. Dense Bottom-Up

Setting. To eliminate the influence of backbones and equally investigate the performance gain between DEBUG and the existing sparse bottom-up framework, we designed a strong baseline dubbed as **QANet-SE**. Its backbone is identical to DEBUG (Figure 3), but its head network follows the sparse bottom-up framework, *i.e.*, it predicts the start and end time points directly.

Results. The results are reported in Table 2. We can observe that DEBUG surpasses QANet-SE over all metrics and benchmarks. Especially, the performance gains are much more obvious in TACoS (*e.g.*, over 20%∼40% relative improvements in all metrics). This is because the average length of each video in TACoS is largest among all benchmarks, and the QANet-SE style (*i.e.*, sparse bottom-up) method suffers severe positive and negative samples imbalance in long videos. Instead, DEBUG can relieve this problem by utilizing much more positive training samples.

4.4.2 Importance of Each Component

We ran a number of experiments to analyze the importance of each component in DEBUG. Results are shown in Table 3 and discussed in detail next.

Classification vs. Confidence Subnet. From Table 3, we can observe that models with only a single classification or confidence subnet can get comparable performance. More precisely, the latter one is slightly better than the former. This is

[3]Since all published works had not reported their mIoU scores on Charades-STA, we only compare with them on the metric IoU@θ.

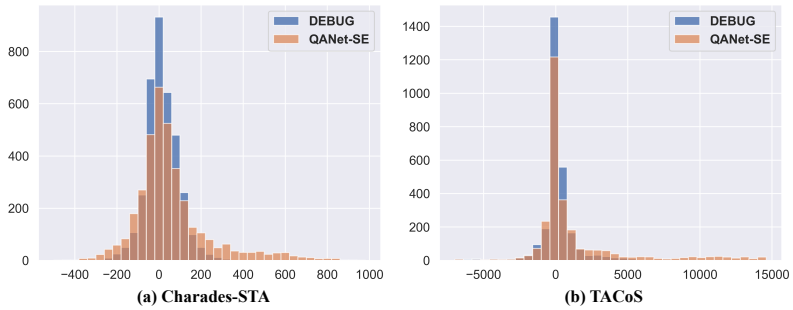

Figure 6: The number of samples across the length error (#frames difference) between predicted segment and ground truth segment on Charades-STA and TACoS.

because the confidence subnet considers the importance of each frame, instead, the classification subnet regards all foreground equally. Meanwhile, the performance of both models can be further boosted by utilizing two subnets simultaneously, which demonstrates that this multi-task design helps each subnet to focus on their own goal and both subnets benefit from sharing features (*i.e.*, one for foreground prediction, and another for "centerness" prediction).

With vs. Without Temporal Pooling. From Table 3, we can observe that the temporal pooling trick improves the performance in most of the situations, and the performance gains in TACoS are largest over all benchmarks. The main reason is that the visual appearance of each frame in TACoS is quite similar, *i.e.*, the performance based on single frame prediction is very unstable since multiple frames have similar predictions. Instead, the model with temporal pooling helps to avoid this by fusing multiple frame predictions.

4.4.3 Efficiency Analysis.

We evaluated the efficiency of DEBUG, by comparing the average run time to localize one sentence in the video. As shown in Table 4, the DEBUG significantly reduce the localization time compared to all top-down models (MCN, VSA-RNN, VSA-STV, CTRL, ACRN), and the gap is much wider in long video datasets (*e.g.*, TACoS). This meets with the notorious drawback of the top-down framework, *i.e.*, it is computation-intensive for dense sliding windows or anchors. Meanwhile, DEBUG is even slightly faster than the sparse bottom-up model (ABLR), this is because the QANet backbone only uses conv and self-attention layer instead of the time-consuming RNN in ABLR backbone. All experiments are conducted on the same hardware (an NVIDIA GTX 1080Ti).

To analyze the bottleneck of DEBUG and the existing sparse bottom-up framework, and help pave

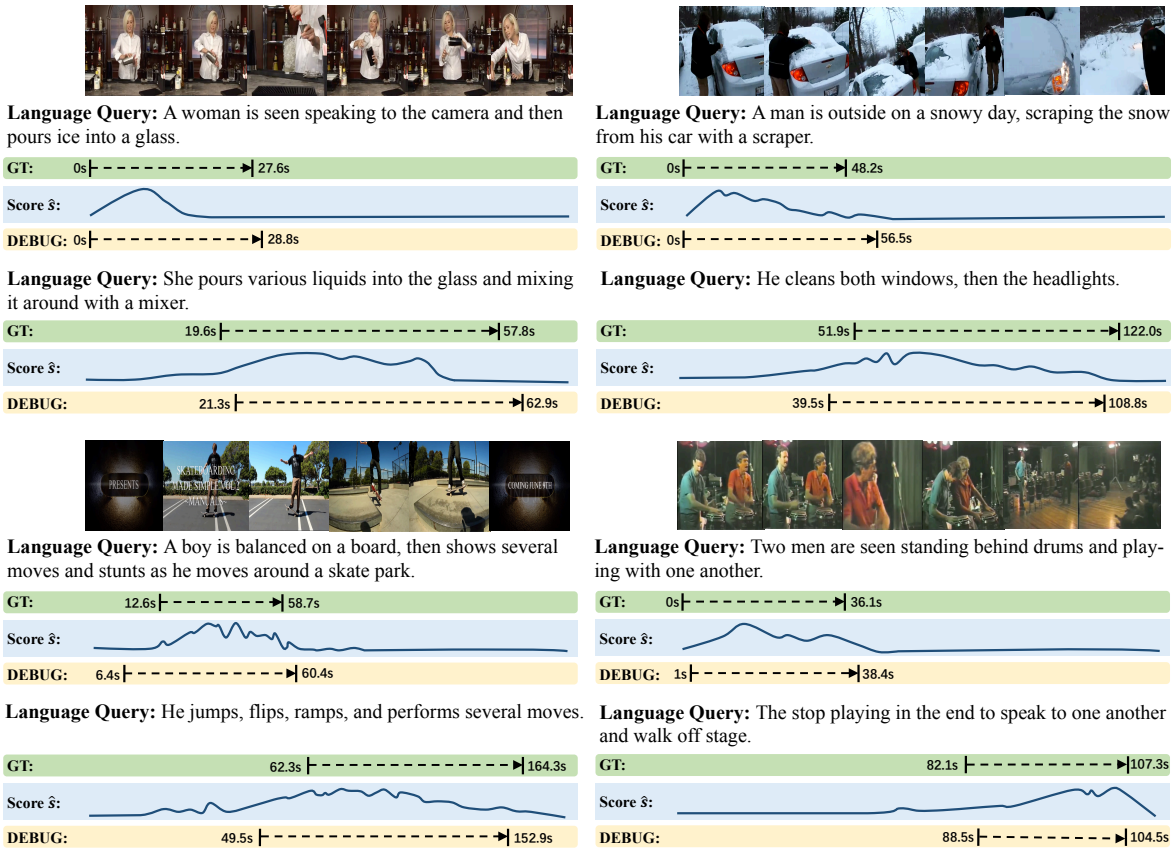

Figure 7: The qualitative results of DEBUG on the ActivityNet Captions dataset.

the way for future research on bottom-up approach for NLVL, We conducted several statistical analysis about the results of DEBUG and its sparse bottom-up counterpart QANet-SE (Section 4.4.1):

Segment Length. We compared the length error of the segments predicted by DEBUG and QANet-SE, the results are illustrated in Figure 6. We observe that QANet-SE is prone to predicting overlong segment range (*e.g.*, the samples with length error larger than 300 frames in Chardes-STA or 5,000 frames in TACoS take a large proportion.)

Keypoint Accuracy. We compared the accuracy of three keypoints of the ground truth segment: the left, right, and middle point. We regard a keypoint prediction as right if the absolute frame difference between the prediction and ground truth is smaller than a threshold. We used three thresholds (100, 200, 300) and the results are reported in Table 5. We have two observations: 1) For middle point, DEBUG always gets higher accuracy. 2) For boundary points, DEBUG only drops behind QANet-SE in TACoS at threshold 100.

Analysis. The sparse bottom-up approach (*e.g.*, QANet-SE) can get good boundary predictions even for long video datasets (*e.g.*, TACoS), which meets with the design of training a boundary classifier. But the bottleneck of this approach is that the predictions of start and end point are independent, which is prone to result in an overlong segment prediction. However, DEBUG predicts boundary from the same frame feature, which can avoid predicting overlong segments. Meanwhile, DEBUG has a confidence subnet to predict "centerness" of each frame, which helps to predict the middle point. But the bottleneck of DEBUG is the accuracy of boundary point in long video dataset.

4.4.5 Qualitative Results.

The qualitative results of DEBUG on ActivityNet Captions is illustrated in Figure 7. We can observe that DEBUG is sensitive to language query, *i.e.*, the predicted scores $\hat{s}$ are totally different when given different language queries even for the same video. Meanwhile, the score $\hat{s}$ is always a unimodal curve with its peak near the midpoint of ground truth segment, which meets with the design of DEBUG which uses "centerness" as the confidence target.

5 Conclusion

We proposed a novel dense bottom-up framework DEBUG for NLVL. It is the first bottom-up model, which surpasses all top-down models with the highest speed. Compared to the existing bottom-up models, DEBUG improve performance significantly by: 1) making full use of positive samples to alleviate the severe imbalance problem; 2) disentangling boundary detection from query-related prediction to relieve the burden of a single network; 3) predicting boundaries from same frame to avoid local optimum caused by independent predictions. Moving forward, we are going to narrow the gap between top-down and bottom-up models, and design a hybrid framework exploring both choices.

Abstract

Everyone makes mistakes. So do human annotators when curating labels for named entity recognition (NER). Such label mistakes might hurt model training and interfere model comparison. In this study, we dive deep into one of the widely-adopted NER benchmark datasets, CoNLL03 NER. We are able to identify label mistakes in about 5.38% test sentences, which is a significant ratio considering that the state-of-the-art test F_1 score is already around 93%. Therefore, we manually correct these label mistakes and form a cleaner test set. Our re-evaluation of popular models on this corrected test set leads to more accurate assessments, compared to those on the original test set. More importantly, we propose a simple yet effective framework, CrossWeigh, to handle label mistakes during NER model training. Specifically, it partitions the training data into several folds and train independent NER models to identify potential mistakes in each fold. Then it adjusts the weights of training data accordingly to train the final NER model. Extensive experiments demonstrate significant improvements of plugging various NER models into our proposed framework on three datasets. All implementations and corrected test set are available at our Github repo [1].

1 Introduction

Named entity recognition (NER), identifying both spans and types of named entities in text, is a fundamental task in the natural language processing pipeline. On one of the widely-adopted NER benchmarks, the CoNLL03 NER dataset (Sang and Meulder, 2003), the state-of-the-art NER performance has been pushed to a F_1 score around 93% (Akbik et al., 2019), through building end-to-end neural models (Lample et al., 2016; Ma and Hovy, 2016) and introducing language models for contextualized representations (Peters et al., 2017, 2018; Akbik et al., 2018; Liu et al., 2018a). Such high performance makes the label mistakes in manually curated "gold standard" data non-negligible. For example, given a sentence "*Chicago won game 1 with Derrick Rose scoring 25 points.*", this "*Chicago*", representing the NBA team Chicago Bulls, should be annotated as an organization. However, when annotators are not careful or lack background knowledge, this "*Chicago*" might be annotated as a location, thus being a label mistake.

These label mistakes bring up two challenges to NER: (1) mistakes in the test set can interfere the evaluation results and even lead to an inaccurate assessment of model performance; and (2) mistakes in the training set can hurt NER model training. Therefore, in this paper, we conduct empirical studies to understand these mistakes, correct the mistakes in the test set to form a cleaner benchmark, and develop a novel framework to handle the mistakes in the training set.

We dive deep into the CoNLL03 NER dataset, and find label mistakes in about 5.38% test sentences. Considering that the state-of-the-art F_1 score on this test set is already around 93%, these 5.38% mistakes should be considered as significant. So we hire human experts to correct these label mistakes in the test set. We then re-evaluate recent state-of-the-art NER models on this new, cleaner test set. Compared to the results on the original test set, the re-evaluation results are more accurate and stable. Therefore, we believe this new test set can better reflect the performance of NER models.

We further propose a novel, general framework, CrossWeigh, to handle the label mistakes during the NER model training stage. Figure 1 presents an overview of our proposed framework. It contains two modules: (1) mistake estimation: it iden-

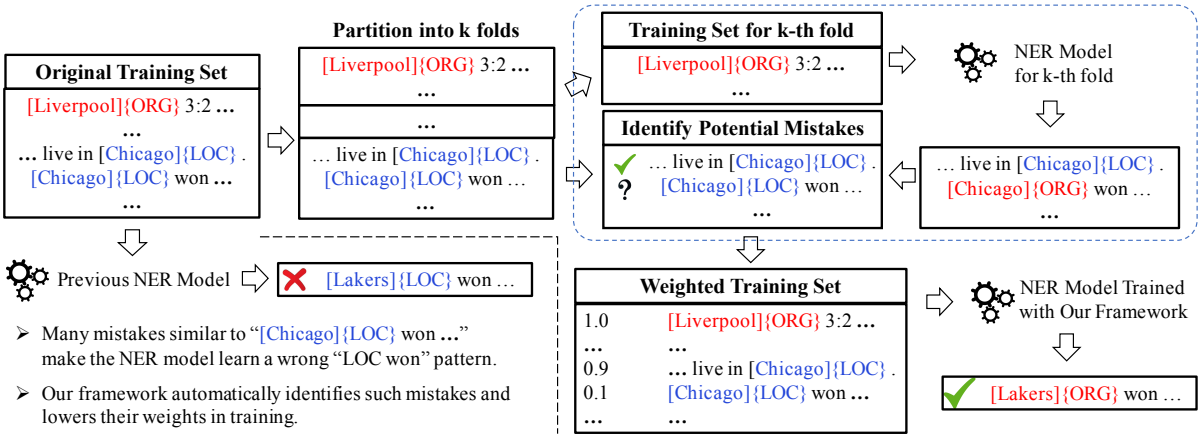

Figure 1: An overview of our proposed CrossWeigh framework. It can better handle label mistakes, identify low quality annotations and conduct learning from a weighted training set.

tifies the potential label mistakes in training data through a cross checking process and (2) mistake re-weighing: it lowers the weights of these instances during the training of the final NER model. The cross checking process is inspired by the k-fold cross validation; differently, in each fold's training data, it removes the data containing any of entities that appeared in this fold. In this way, each sentence will be scored by a NER model trained on a subset of training data not containing any entity in this sentence. Once we know where the potential mistakes are, we lower the weights of these sentences and train the final NER model based on this weighted training set. The final NER model is trained in a mistake-aware way, thus being more accurate. Note that, our proposed framework is general and fits most of, if not all, NER models that accept weighted training data.

To the best of our knowledge, we are the first to handle the label mistake issues systematically in the NER problem. We conduct extensive experiments on both the original CoNLL03 NER dataset and our corrected dataset. CrossWeigh is able to consistently improve performance when plugging with different NER models. In addition, we verify the effectiveness of CrossWeigh on emerging-entity and low-resource NER datasets. In summary, our major contributions are the following:

- We correct label mistakes in the test set of the CoNLL03 NER dataset and re-evaluate popular NER models. This establishes a more accurate NER benchmark.
- We propose a novel framework CrossWeigh to accommodate the mistakes during the model training stage. The proposed framework fits most of, if not all, NER models.
- Extensive experiments demonstrate the significant, robust test F_1 score improvements of plugging NER models into our proposed framework on three datasets, not only CoNLL03 but also emerging-entity and low-resource datasets.

Reproducibility. We release both the corrected test set and the implementation of CrossWeigh framework[2].

2 CoNLL03 NER Re-Examination

The CoNLL03 NER dataset is one of the widely-adopted NER benchmark datasets. Its annotation guideline is based on MUC Conventions[3] (Sang and Meulder, 2003). Following this guideline, the annotators are asked to mark entities of person (PER), location (LOC), and organization (ORG), while using an extra miscellaneous (MISC) type to deal with entities that do not fall in these categories. This dataset has been split into training, development, and test sets, with 14041, 3250, and 3453 sentences, respectively.

2.1 Test Set Correction

In order to understand and correct the label mistakes, we have hired 5 human experts as annotators. Before looking at the data, we first train the annotators by carefully going through the aforementioned guideline. During the correction process, we strongly encourage the annotators to use search engines for suspicious token spans. This helps them

[2] https://github.com/ZihanWangKi/CrossWeigh

[3] https://www-nlpir.nist.gov/related_projects/muc/proceedings/ne_task.html

Sentence	Original labels	Corrected labels
Sporting Gijon 15 4 4 7 15 22 16	[Sporting]{ORG}	[Sporting Gijon]{ORG}
SOCCER - JAPAN GET LUCKY WIN , CHINA IN SURPRISE DEFEAT .	[JAPAN]{LOC}, [China]{PER}	[JAPAN]{LOC}, [China]{LOC}
NZ 's Bolger says Nats to meet NZ First on Sunday .	[NZ]{LOC}, [Bolger]{PER}, [Nats]{PER}, [NZ]{LOC}	[NZ]{LOC}, [Bolger]{PER}, [Nats]{ORG}, [NZ First]{ORG}
Seagramd ace 20/11/96 5,000 Japan	[Seagramd] {MISC}, [Japan]{LOC}	[Seagramd ace]{MISC}, [Japan] {LOC}

Table 1: Typical Examples of Our Corrections on the CoNLL03 NER dataset.

have more background knowledge. We also allow annotators to look at the original paragraph containing the sentence. This helps them have a better understanding of the context.

For the whole test set, we randomly split the test sentences between each pair combination of 5 annotators. In this way, each sentence in the test set is checked by exactly two annotators. The inter-annotator agreement is 95.66%. This is a reasonable score, given that the inter-annotator agreement in POS tagging annotations is about 97% (Manning, 2011). After we collected all annotations, we run a final round of verification on each sentence, where the original annotation and the two annotators' are not all the same. In the end, we have corrected label mistakes in 186 sentences, which is about 5.38% of the test set.

Table 1 presents some typical examples of our corrections. In the first sentence, as a sport team, "Sporting Gijon" was not annotated completely. In the second sentence, while "JAPAN" is correctly marked as LOC, "China" is wrongly identified as PER instead of LOC. One may notice that they both represent sport teams. However, according to the aforementioned guideline, country names should be marked as LOC even when they are sports teams. More details about this type of labels are discussed in Section 5. In the third sentence, "NZ" is the abbreviation of New Zealand. However, "Nat" and "NZ First" in fact refer to political parties (i.e., New Zealand Young Nationals and New Zealand First). So they should be labelled as ORG. In the forth sentence, looking at its paragraph, our annotators figure out that this is a table about ships and vessels loading items at different locations. Through comparing with other sentences in the context, such as "Algoa Day 21/11/96 6,000 Africa", our annotators identified "Seagramd ace" as a vessel, thus marking it as MISC. We have verified that there is indeed a vessel called "Seagrand Ace" ("Seagramd ace" might be a typo).

2.2 CoNLL03 Re-Evaluation

NER Algorithms. We re-evaluate following popular NER algorithms:

Method	Original	Corrected
LSTM-CRF	90.64 (±0.23)	91.47 (±0.15)
LSTM-CNNs-CRF	90.65 (±0.57)	91.87 (±0.50)
VanillaNER	91.44 (±0.16)	92.32 (±0.16)
Elmo	92.28 (±0.19)	93.42 (±0.15)
Flair	92.87 (±0.08)	93.89 (±0.06)
Pooled Flair	93.14 (±0.14)	94.13 (±0.11)

Table 2: CoNLL03 Re-Evaluation: Test F_1 scores and standard deviations on both original and corrected datasets. The results are based on 5 different runs.

- **LSTM-CRF** (Lample et al., 2016) incorporates long short term memory (LSTM) neural network with conditional random field (CRF). It also uses a word-wise character LSTM.
- **LSTM-CNNs-CRF** (Ma and Hovy, 2016) has a similar structure as LSTM-CRF, but captures character-level information through a convolutional neural network (CNN) over the character embedding.
- **VanillaNER** (Liu et al., 2018a) also extends LSTM-CRF and LSTM-CNNs-CRF by using a sentence-wise character LSTM.
- **ELMo** (Peters et al., 2018) extends LSTM-CRF and leverages pre-trained word-level language models for better contextualized representations.
- **Flair** (Akbik et al., 2018) also aims for contextualized representations, utilizing pretrained character level language models.
- **Pooled-Flair** (Akbik et al., 2018) extends Flair and maintains an embedding pool for each word to bring in dataset-level word embedding.

We use the implementation released by the authors for each algorithm and report the performance on original test set and corrected test set averaging 5 runs.

Results & Discussions. We re-evaluate the performance of the NER algorithms on the corrected test set. Their performance on the original test set is also listed for the reference. From the results in Table 2, one can observe that all models have higher F_1 scores as well as smaller standard deviations on the corrected test set, compared to those on the orig-

inal test set. Moreover, LSTM-CRF has a similar performance as LSTM-CNNs-CRF on the original test set, but on average lower performance on the corrected test set. This indicates that the corrected test set may be more discriminative. Therefore, we believe this corrected test set can better reflect the accuracy of NER algorithms in a stable way.

3 Our Framework: CrossWeigh

In this section, we introduce our framework. It is worth mentioning that our framework is designed to be general and fits most of, if not all, NER models. The only requirement is the capability to consume weighted training set.

3.1 Overview

As we have seen in the Section 2, human curated NER datasets are by no means perfect. Label mistakes in the training set can directly hurt the model's performance. As shown in Figure 1, if there are many similar mistakes like wrongly annotating "Chicago" in "Chicago won ..." as `LOC` instead of `ORG`, the NER model will likely capture the wrong pattern "`LOC` won" and make wrong predictions in future.

Our proposed CrossWeigh framework automates this process. Figure 1 presents an overview. It contains two modules: (1) mistake estimation: it identifies the potential label mistakes in training data through a cross checking process and (2) mistake re-weighing: it lowers the weights of these instances for the NER model training. The workflow is summarized in Algorithm 1.

3.2 Preliminary

We denote the training sentences as $\{x_1, x_2, \ldots, x_n\}$ where n is the number of sentences. Each sentence x_i is formed up of a sequence of words. Correspondingly, the label sequence for each sentence is denoted as $\{y_1, y_2, \ldots, y_n\}$. We use $\mathbf{D}$ to denote the training set, including both sentences and their labels. We use w_i to represent the weight of the i-th sentence. In most NER papers, the weights are uniform, i.e., $w_i = 1$.

We use $f(\mathbf{D}, w)$ to describe the training process of an NER model using the training set $\mathbf{D}$ weighted by w. This training process will return an NER model $M = f(\mathbf{D}, w)$. During this training, the weighted loss function is as below.

$$\mathcal{J} = \sum_{i=1}^{n} w_i \cdot l(M(x_i), y_i) \tag{1}$$

where $l(M(x_i), y_i)$ is the loss function of prediction $M(x_i)$ against its label sequence y_i. Typically, it is the negative log-likelihood of the model's prediction $M(x_i)$ compared to labeling sequence y_i.

Algorithm 1: Our CrossWeigh Framework

Input: A NER model f, the training set $\mathbf{D} = \langle\{x_1, \ldots, x_n\}, \{y_1, \ldots, y_n\}\rangle$, and hyper-parameters k, t, and ϵ.
Output: A final NER model
for *i = 1 ... n* **do**
  $c_i \leftarrow 0, w_i \leftarrow 1$
for *iter* = $1 \ldots t$ **do**
  Randomly partition $\mathbf{D}$ into k folds.
  for *Each fold* D_i **do**
    Obtain test_entities$_i$. (Eq. 2)
    Build train_set$_i$. (Eq. 3).
    Train a NER model $M_i = f(\text{train_set}_i, w)$.
    for *Each* $x_j \in D_i$ **do**
      $\hat{y}_j \leftarrow M_i$'s prediction on x_j.
      if $y_j \neq \hat{y}_j$ **then**
        $c_i \leftarrow c_i + 1$
for $i = 1 \ldots n$ **do**
  Compute w_i (Eq. 4).
Return $f(\mathbf{D}, w)$.

3.3 Mistake Estimation

Our mistake estimation module is designed to let an NER model itself decide which sentences contain mistake and which do not. We would like to find sentences with label mistakes as many as possible (i.e. high recall), while keeping away from wrongly identified non-mistake sentences (i.e. high precision).

The basic idea of our mistake estimation module is similar to k-fold cross validation, however, in each fold's training data, it further removes the data containing any of entities appearing in this fold. The details are presented as follows.

We first randomly partition the training data into k folds: $D_1, D_2, \ldots, D_k$.

We then train k NER models separately based on these k folds. The i-th ($1 \leq i \leq k$) NER model M_i will be evaluated on the sentences in the hold-out fold D_i.

During its training, we avoid any sentence that may lead to "easy prediction" on this hold-out set.

	Original CoNLL03		Corrected CoNLL03	
	w/o CrossWeigh	w/ CrossWeigh	w/o CrossWeigh	w/ CrossWeigh
VanillaNER	91.44 (±0.16)	**91.78 (±0.06)**	92.32 (±0.16)	**92.64 (±0.08)**
Flair	92.87 (±**0.08**)	**93.19** (±0.09)	93.89 (±**0.06**)	**94.18 (±0.06)**
Pooled-Flair	93.14 (±0.14)	**93.43 (±0.06)**	94.13 (±0.11)	**94.28 (±0.05)**

Table 3: Test F_1 scores and its standard deviations of models trained without or with CrossWeigh.

Therefore, we inspect every sentence in D_i and get the set of entities as follows.

$$\text{test_entities}_i = \bigcup_{x_j \in D_i} e_j \tag{2}$$

where e_j is the set of named entities in sentence x_j. We only consider the surface name in this entity set. That is, no matter "Chicago" is `LOC` or `ORG`, it only counts as its surface name "Chicago".

All training sentences that have entities included in test_entities_i will be excluded in training process of the model M_i. Specifically,

$$\text{train_set}_i = \{x_j | e_j \cap \text{test_entities}_i = \emptyset, 1 \leq j \leq n\} \tag{3}$$

We call this step as *entity disjoint filtering*. The intuition behind this step is that we want the model to make prediction of an entity without prior information of the entity itself from training. This will be helpful to detect sentences that are inconsistent.

We train k models M_i by feeding each train_set_i into $f(\cdot, \cdot)$ with default uniform weight, and we use each M_i to make predictions for D_i and check for each sentence, whether the original label is the same as the model output. In this way, if the trained model M_i makes correct predictions on some sentences in D_i, they are more likely mistake-free. For those sentences that have labels disagreeing with the model output, we mark them as *potentially mistake*.

We run this mistake estimation module multiple iterations (i.e. t iterations) using different random partitions. Then, for each sentence in the training set, we get t estimations for it. We denote c_i ($0 \leq c_i \leq t$) as the confidence that sentence x_i contains label mistakes. c_i is defined as the the number of *potentially mistake* indications among all t estimations.

The number of folds k plays the role of a trade-off between the efficiency of the mistake estimation process and the number of training examples that can be used in each M_i. When k becomes larger, each fold D_i will be smaller, thus leading to a smaller size of test_entities_i; correspondingly, a larger train_set_i will be picked. The model can therefore be trained with more examples. However, it also slows down the whole mistake estimation process. On the CoNLL03 NER dataset, we observe that $k = 10$ leads to effective results, while having a reasonable running time.

3.4 Mistake Reweighing

In the mistake reweighing module, we adjust weight w_i for each sentence x_i that is marked as *potentially mistake* in the mistake estimation step. Here, we assign a weight w_i to all sentences marked, while the weights of other sentences remain 1. Specifically, we set $\forall i (1 \leq i \leq n)$,

$$w_i = \epsilon^{c_i} \tag{4}$$

where ϵ is a parameter. In practice, it can be chosen according to the quality of mistake estimation module. Particularly, we first estimate the precision of the detected mistakes of a single iteration. Let p be the ratio of the number of true detected label mistakes over the number of detected label mistakes. p can be roughly estimated through a manual check of a random sample from the detected label mistakes. Then, we choose $\epsilon = 1 - p$, because $1 - p$ represents the fraction of these detected label mistakes that might be still useful during the model training. Therefore, for the sentences that are marked as *potentially mistake* in that iteration, ϵ of them are actually correct. With more iterations, the confidence of being correct lowers like a binomial distribution, which is the reason that we chose an exponential decaying weight function in Equation 4.

4 Experiments

In this section, we conduct several experiments to show effectiveness of our CrossWeigh framework. We first evaluate the overall performance of CrossWeigh on benchmark NER datasets, by plugging it into three base NER models. Since we have two modules in CrossWeigh, we then dive into each module and explore different variants and ablations. In addition, we further verify the effectiveness of CrossWeigh on two more datasets:

an emerging-entity NER dataset from WNUT'17 and a low-resource language NER dataset of the Sinhalese language.

4.1 Experimental Settings

Dataset. We use both the original and corrected CoNLL03 datasets. We follow the standard train/dev/test splits and use both the train set and dev set for training (Peters et al., 2017; Akbik et al., 2018). Entity-wise F_1 score on the test set is the evaluation metric.

Base NER Algorithm. We mainly choose Flair as our base NER algorithm. Flair is a strong NER algorithm using external resources (large corpus to train a language model). While Pooled-Flair has even better performance, its computational cost refrains us from doing extensive experiments.

Default Parameters in CrossWeigh. For all NER algorithms we experiment with, their default parameters are used. For CrossWeigh parameters, by default, we set $k = 10$, $t = 3$, and $\epsilon = 0.7$. We decide $\epsilon = 0.7$ because among 100 randomly sampled sentences with *potentially mistake*, we find that 27 of them really contain label mistakes (i.e., the probability of one annotation to be correct is roughly 70%). We use both train and development set to train the models, and report average F_1 and its standard deviation on both original test set and our corrected test set across 5 different runs (Peters et al., 2017).

4.2 Overall Performance

We pair CrossWeigh with our base algorithm (i.e. Flair) and two best-performing NER algorithms with or without language models in Table 2 (i.e. Pooled-Flair and VanillaNER), and evaluate their performance. As shown in Table 3, compared with the three algorithms, applying CrossWeigh always leads to a higher F_1 score and a comparable, sometimes even smaller, standard deviation. Therefore, it is clear that CrossWeigh can improve the performance of NER models. The smaller standard deviations also imply that the models trained with CrossWeigh are more stable. All these results illustrate the superiority of training with CrossWeigh.

4.3 Ablations and Variants

We pick Flair as the base algorithm to conduct ablation study.

Entity Disjoint Filtering. There is an entity disjoint filtering step, when we are collecting training data train_set$_i$ for the NER model M_i during the mistake estimation step. To study its importance, we have done a few ablation experiments.

Method	Original	Corrected
w/o CrossWeigh	92.87 (±0.08)	93.89 (±0.06)
w/ CrossWeigh	93.19 (±0.09)	94.18 (±0.06)
− Entity Disjoint	92.88 (±0.11)	93.84 (±0.08)
+ Random Discard	93.01 (±0.10)	93.94 (±0.10)

Table 4: Importance of Entity Disjoint Filtering.

We have evaluated the following variants:

- Flair w/ CrossWeigh **– Entity Disjoint**: Skip the entity disjoint filtering step.
- Flair w/ CrossWeigh **+ Random Discard**: Instead of entity disjoint filtering, randomly discard the same number of sentences from each train_set$_i$ as it would do.

The results are listed in Table 4. One can easily observe that without the entity disjoint filtering, the F_1 scores are very close to the raw Flair model. This demonstrates that the entity disjoint filtering is critical to reduce the over-fitting risk in the mistake estimation step. Also, our proposed entity disjoint filtering strategy works more effective than random discard. This further confirms the effectiveness of entity disjoint filtering.

Variants in Computing c_i. There is definitely more than one way to determine c_i. Let δ be the number of "potentially mistake"s among the t estimations, we can apply any of the following heuristics:

- **Ratio**: c_i is the number of "potentially mistake" (i.e. $c_i = \delta$). This is the method mentioned in Section 3, and used by default.
- **At Least One**: c_i is the indicator of at least one estimation being "potentially mistake" (i.e. $c_i = t \iff \delta >= 1$).
- **Majority**: c_i is the indicator of at least $\lfloor t/2 \rfloor + 1$ estimations being "potentially mistake" (i.e. $c_i = t \iff \delta >= \lfloor t/2 \rfloor + 1$).
- **All**: c_i is the indicator of all t estimations being "potentially mistake" (i.e. $c_i = t \iff \delta = t$).

We evaluate the performance of these heuristics when used in CrossWeigh, as shown in Table 5. There is not much difference across these heuristics, while our default choice "Ratio" is the most stable.

4.4 Label Mistake Identification Results

Another usage of CrossWeigh is to identify potential label mistakes during label annotation process, thus improving the annotation quality. This could

Heuristic	Original	Corrected
At Least One	93.10 (±0.10)	94.16 (±0.07)
Majority	93.20 (±0.09)	94.12 (±0.07)
All	93.16 (±0.09)	94.11 (±0.09)
Ratio	93.19 (±0.09)	94.18 (±0.06)

ϵ	Original	Corrected
0.3	92.79 (±0.14)	93.68 (±0.15)
0.5	93.21 (±0.09)	94.18 (±0.07)
0.9	93.01 (±0.10)	93.96 (±0.09)
0.7	93.19 (±0.09)	94.18 (±0.06)

Table 8: Different Weight Adjustments ϵ.

be also helpful to active learning.

Specifically in this experiment, we apply our noise estimation module to the concatenation of training and testing data. As we have manually corrected the label mistakes in the testing set, we are able to report the number of true mistakes among the potential mistakes discovered in the test set.

The results are presented in Table 9. The potential mistakes are the total number of mistakes identified by CrossWeigh, and actual mistakes is the true positives among all identifications. From the results, we can see that when the base model is Flair, CrossWeigh is able to spot more than 75% of label mistakes, while maintaining a precision about 25%. It is worth noting that 25% is a reasonably high precision, given that the label mistake ratio is only 5.38%. The 75% recall indicates that CrossWeigh is able to identify most of the label mistakes, which are extremely valuable to improve the annotation quality.

4.5 Parameter Study

We study how CrossWeigh performs with different hyper-parameters, i.e., t (the number of iterations that we run mistake estimation), k (the number of folds in mistake estimation), and ϵ (the weight scaling factor of identified potential mistakes).

In principle, a larger t usually gives us a more stable mistake estimation. However, a larger t also requires more computation resources. In our experiments (see Table 6), we find that $t = 3$ provides a good enough result.

Specifically, during mistake estimation, we have to choose the number of folds to partition the data. The more partitions made, the smaller each D_i is and the fewer sentences will be filtered, leading to more training data train_set$_i$ and better trained M_i. On the other hand, this is at the cost of higher computational expense. As shown in Table 7, we observe that $k = 5, k = 10$ are significantly better than $k = 2$. In fact, when $k = 2$, each train_set$_i$ has only around 5000 sentences and 1500 entities inside. These numbers become 7000 and 4000 when $k = 5$, and 9000 and 7000 when $k = 10$.

As we mentioned before, the value ϵ can be chosen by estimating the quality of mistake estimation. Table 8 presents some results when other values are used. $\epsilon = 0.3$ leads to the worst performance. Since our estimation does not have high precision, assigning ϵ to a low value like 0.3 may not be a good choice. Interestingly $\epsilon = 0.5$ performs on par with $\epsilon = 0.7$, and even slightly better in the original test set. We hypothesize that this is because there are some ambiguous sentences that we did not count during estimating the quality of mistake estimation, see Section 5, and the actual precision could be higher.

4.6 Other Datasets

To show the generalizability of our method across domains and languages, we further evaluate CrossWeigh on an emerging-entity NER dataset from WNUT'17 and a Sinhalese NER dataset from LORELEI[4]. Sinhalese is a low-resource, morphology-rich language. For WNUT'17, we use the Flair as our base NER algorithm. For Sinhalese, we use BERT (Devlin et al., 2018) followed by a BiLSTM-CRF as our base NER algorithm. We use the same parameters as used in the previous CoNLL03 experiments, namely $k = 10, t = 3, \epsilon = 0.7$.

The results averaged across 5 runs are reported in Table 10. One can observe quite similar results as those in the previous CoNLL03 experiments.

[4]LDC2018E57

Algorithm	Potential Mistakes	Actual Mistakes	Precision	Recall	F1
Flair	573.0	144.0	0.2513	0.7742	0.3794
VanillaNER	821.67	146.33	0.1781	0.7867	0.2904

Table 9: Quality of noise estimation. The number of true mistakes, based on our manual correction, is 186. The potential mistakes are counted based on average of 3 runs.

Dataset	**w/o CrossWeigh**	**w/ CrossWeigh**
WNUT'17	48.96 (±0.97)	50.03 (±0.40)
Sinhalese	66.34 (±0.34)	67.68 (±0.21)

Table 10: Applying CrossWeigh on other datasets

Training with CrossWeigh leads to a significantly higher F1 and a smaller standard deviation. This suggests that CrossWeigh works well in other datasets and languages.

5 Case Studies

Test Set Correction. Despite the label mistakes that we have corrected, we also find some ambiguous but consistent cases. For instances, (1) All NBA/NHL divisions such as "CENTRAL DIVISION", "WESTERN DIVISION" were annotated as `MISC`, while all European leagues, such as "SPANISH FIRST DIVISION" and "ENGLISH PREMIER LEAGUE", are not marked as `MISC` correctly — only "SPANISH" and "ENGLISH" are labelled as `MISC`. And (2) "Team A at Team B" is a way to say "Team A" as an away team playing with Team B as a home team. However, in almost all cases (only 1 exception out of more than 100), "Team A" was labelled as `ORG` while "Team B" was labelled as `LOC`. For example, in "MINNESOTA AT MILWAUKEE", "NEW YORK AT CALIFORNIA", and "ORLANDO AT LA LAKERS", the second sports team "MILWAUKEE", "CALIFORNIA" and "LA LAKERS" were always labelled as `LOC`. Because these parts behave consistently and generally follow the annotation guideline, we didn't touch them during the test set correction.

CrossWeigh Framework. The mistakes in the training set can harm the generalizability of the trained model. For example, in Table 11, the original training sentence "Hapoel Haifa 3 Maccabi Tel Aviv 1" contains a label mistake, because "Maccabi Tel Aviv" is a sports team but was not annotated completely. Interestingly, there is a similar sentence in the test set – "Hapoel Jerusalem 0 Maccabi Tel Aviv 4". In all 5 different runs of the original Flair model, they failed to predict correctly that "Maccabi Tel Aviv" in the test sentence as `ORG` because of the label mistake in the training sentence, even though "`ORG` number `ORG` number" is an obvious pattern in the training set. In CrossWeigh, this label mistake in the training set was detected in all $t = 3$ iterations and therefore assigned a very low weight during training. After that, in all 5 different runs of Flair w/ CrossWeigh, they successfully predict that "Maccabi Tel Aviv" is `ORG` as a whole.

6 Related Work

In this section, we review related works from three aspects, mistake identification, cross validation & boosting, and NER algorithms.

6.1 Mistake Identification

Researchers have noticed the label mistakes in sophisticated natural language processing tasks for a while. For example, it is reported that the inter-annotator agreement is about 97% on the Penn Treebank POS tagging dataset (Manning, 2011; Subramanya et al., 2010).

There are a few attempts towards detecting label mistakes automatically. For example, Nakagawa and Matsumoto (2002) designed a support vector machine-based model to assign weights to examples that were hard to classify in the POS tagging task. Helgadóttir et al. (2014) further applied previous detection models and manually corrected Icelandic Frequency Dictionary (Pind et al., 1991) POS tagging dataset. However, these two methods are specifically developed for POS tagging and cannot be directly applied to NER.

Recently, Rehbein and Ruppenhofer (2017) extends variational inference with active learning to detect label mistakes in "silver standard" data generated by machines. In this paper, we focus on detecting label mistakes in "gold standard" data, which is a different scenario.

6.2 Cross Validation & Boosting

Our mistake estimation module shares some similarity with cross validation. Applying cross valida-

	Training Set	Test Set
Text	Hapoel Haifa 3 Maccabi Tel Aviv 1	Hapoel Jerusalem 0 Maccabi Tel Aviv 4
Original Annotations	[Hapoel Haifa]{ORG}, **[Tel Aviv]{ORG}**	[Hapoel Jerusalem]{ORD}, [Maccabi Tel Aviv]{ORG}
Correct Annotations	[Hapoel Haifa]{ORG}, [Maccabi Tel Aviv]{ORG}	[Hapoel Jerusalem]{ORD}, [Maccabi Tel Aviv]{ORG}
	Action	**Result**
Flair	Assumes this sentence is equally reliable as others.	[Hapoel Jerusalem]{ORD}, **[Tel Aviv]{ORG}**
Flair w/ CrossWeight	Lowers the weight of this sentence as mistakes.	[Hapoel Jerusalem]{ORD}, [Maccabi Tel Aviv]{ORG}

Table 11: Case Study on the CoNLL03 dataset. Errors are marked with red

tion to the training set is the same as our mistake estimation module, except that we have an *entity disjoint filtering* step. Experiments in Table 4 show that this step is crucial to our performance gain. The choice of ten folds also stems from cross validation (Kohavi, 1995).

Another similar thread of work is boosting, such as Adaboost (Freund et al., 1999; Schapire and Singer, 1999). For example, Abney et al. (1999) has applied Adaboost on the Penn Treebank POS tagging dataset and gained encouraging results on model performance. In boosting algorithms, the training data is assumed to be perfect. Therefore, it trains models using the full training set and then increases the weights of training instances that fails the current model in the next round of learning. In contrast, we decrease the weights of sentences that differ from the model built upon the entity disjoint training set. More importantly, our framework is a better fit for neural models, because they can likely overfit the training data and thus being bad choices as weak classifiers in boosting.

6.3 NER Algorithms

Neural models have been widely used for Named Entity Recognition, and the state-of-the-art models integrate LSTMs, conditional random field and language models (Lample et al., 2016; Ma and Hovy, 2016; Liu et al., 2018b; Peters et al., 2018; Akbik et al., 2018). In this paper, we focus on improving the annotation quality for NER, and our method has a big potential to help other methods, especially for noisy datasets (Shang et al., 2018).

7 Conclusion & Future work

In this paper, we explore and correct the label mistakes in the CoNLL03 NER dataset. Based on the corrected test set, we re-evaluate most of recent NER models. We further propose a novel framework, CrossWeigh, that is able to detect label mistakes in the training set and then train a more robust NER model accordingly. Extensive experiments demonstrate the effectiveness of CrossWeigh on three datasets and also indicate the potentials of using CrossWeigh to improve the annotation quality during the label curation process.

In future, we plan to extend our framework into an iterative setting, similar to those boosting algorithms. The bottleneck of doing this lies in the efficiency problems of training multiple deep neural models hundreds of times. One solution to overcome it is to apply meta learning. We can first train a meta model and only fine-tune on different training data on each fold. In this way, we can identify label mistakes more accurately and obtain a series of weighted models at the end.

Abstract

Most state-of-the-art models for named entity recognition (NER) rely on the availability of large amounts of labeled data, making them challenging to extend to new, lower-resourced languages. However, there are now several proposed approaches involving either cross-lingual transfer learning, which learns from other highly resourced languages, or active learning, which efficiently selects effective training data based on model predictions. This paper poses the question: given this recent progress, and limited human annotation, what is the most effective method for efficiently creating high-quality entity recognizers in under-resourced languages? Based on extensive experimentation using both simulated and real human annotation, we find a dual-strategy approach best, starting with a cross-lingual transferred model, then performing targeted annotation of only uncertain entity spans in the target language, minimizing annotator effort. Results demonstrate that cross-lingual transfer is a powerful tool when very little data can be annotated, but an entity-targeted annotation strategy can achieve competitive accuracy quickly, with just one-tenth of training data. The code is publicly available here.[1]

1 Introduction

Named entity recognition (NER) is the task of detecting and classifying named entities in text into a fixed set of pre-defined categories (person, location, etc.) with several downstream applications including machine reading (Chen et al., 2017), entity and event co-reference (Yang and Mitchell, 2016), and text mining (Han and Sun, 2012). Recent advances in deep learning have yielded state-of-the-art performance on many sequence labeling tasks, including NER (Collobert et al., 2011; Ma and Hovy, 2016; Lample et al., 2016; Peters et al., 2018). However, the performance of these models is highly dependent on the availability of large amounts of annotated data, and as a result their accuracy is significantly lower on languages that have fewer resources than English. In this work, we ask the question "how can we efficiently bootstrap a high-quality named entity recognizer for a low-resource language with only a small amount of human effort?" Specifically, we leverage recent advances in data-efficient learning for low-resource languages, proposing the following "recipe" for bootstrapping low-resource entity recognizers: First, we use *cross-lingual transfer learning* (Yarowsky et al., 2001; Ammar et al., 2016), which applies a model trained on another language to low-resource languages, to provide a good preliminary model to start the bootstrapping process. Specifically, we use the model of Xie et al. (2018), which reports strong results on a number of language pairs. Next, on top of this transferred model we further employ *active learning* (Settles and Craven, 2008; Marcheggiani and Artieres, 2014), which helps improve annotation efficiency by using model predictions to select informative, rather than random, data for human annotators. Finally, the model is *fine-tuned* on data obtained using active learning to improve accuracy in the target language.

Within this recipe, the choice of specific method for choosing and annotating data within active learning is highly important to minimize human effort. One relatively standard method used in previous work on NER is to select full sequences based on a criterion for the uncertainty of the entities recognized therein (Culotta and McCallum, 2005). However, as it is often the case that only a single entity within the sentence may be of interest, it can still be tedious and wasteful to annotate full sequences when only a small portion of the

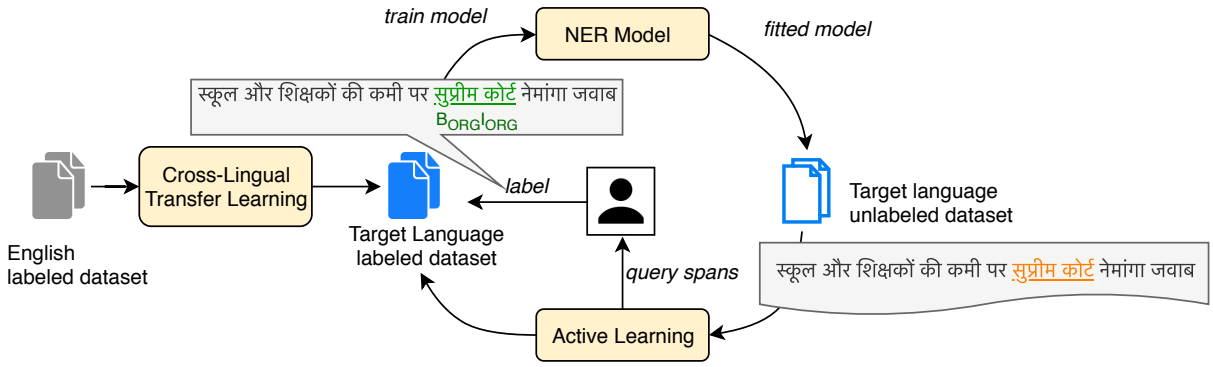

Figure 1: Our proposed recipe: cross-lingual transfer is used for projecting annotations from an English labeled dataset to the target language. Entity-targeted active learning is then used to select informative sub-spans which are likely entities for humans to annotate. Finally, the NER model is fine-tuned on this partially-labeled dataset.

sentence is of interest (Neubig et al., 2011; Sperber et al., 2014). Inspired by this finding and considering the fact that named entities are both important and sparse, we propose an entity-targeted strategy to save annotator effort. Specifically, we select uncertain subspans of tokens within a sequence that are most likely named entities. This way, the annotators only need to assign types to the chosen subspans without having to read and annotate the full sequence. To cope with the resulting partial annotation of sequences, we apply a constrained version of conditional random fields (CRFs), partial CRFs, during training that only learn from the annotated subspans (Tsuboi et al., 2008; Wanvarie et al., 2011).

To evaluate our proposed methods, we conducted simulated active learning experiments on 5 languages: Spanish, Dutch, German, Hindi and Indonesian. Additionally, to study our method in a more practical setting, we conduct human annotation experiments on two low-resource languages, Indonesian and Hindi, and one simulated low-resource language, Spanish. In sum, this paper makes the following contributions:

1. We present a bootstrapping recipe for improving low-resource NER. With just one-tenth of tokens annotated, our proposed entity-targeted active learning method provides the best results among all active learning baselines, with an average improvement of 9.9 F1.

2. Through simulated experiments, we show that cross-lingual transfer is a powerful tool, outperforming the un-transferred systems by an average of 8.6 F1 with only one-tenth of tokens annotated.

3. Human annotation experiments show that annotators are more accurate in annotating entities when using the entity-targeted strategy as opposed to full sequence annotation. Moreover, this strategy minimizes annotator effort by requiring them to label fewer tokens than the full-sequence annotation.

2 Approach

As noted in the introduction, our bootstrapping recipe consists of three components (1) cross-lingual transfer learning, (2) active learning to select relevant parts of the data to annotate, and (3) fine-tuning of the model on these annotated segments. Steps (2) and (3) are continued until the model has achieved an acceptable level of accuracy, or until we have exhausted our annotation budget. The system overview can be seen in Figure 1. In the following sections, we describe each of these three steps in detail.

2.1 Cross-lingual Transfer Learning

The goal of cross-lingual learning is to take a recognizer trained in a source language, and transfer it to a target language. Our approach to doing so for NER follows that of Xie et al. (2018), and we provide a brief review in this section.

To begin with, we assume access to two sets of pre-trained monolingual word embeddings in the source and target languages, X and Y, one small bilingual lexicon, either provided or obtained in an unsupervised manner (Artetxe et al., 2017; Conneau et al., 2017a), and labeled training data in the source language. Using these resources, we train bilingual word embeddings (BWE) to create a word-to-word translation dictionary, and finally

use this dictionary to translate the source training data into the target language, which we use to train an NER model.

To learn BWE, we first obtain a linear mapping W by solving the following objective:

$$W^* = \arg\min_W \|WX_D - Y_D\|_F \text{ s.t. } WW^\top = I,$$

where X_D and Y_D correspond to the aligned word embeddings from the bilingual lexicon. F denotes the Frobenius norm. We can first compute the singular value decomposition $Y_D^T X_D = U\sum V^\top$, and solve the objective by taking $W^* = UV^\top$. We obtain BWE by linearly transforming the source and target monolingual word embeddings with U and V, namely XU and YV.

After obtaining the BWE, we find the nearest neighbor target word for every source word in the BWE space using the cross-domain similarity local scaling (CSLS) metric (Conneau et al., 2017b), which produces a word-to-word translation dictionary. We use this dictionary to translate the source training data into the target language, and simply copy the label for each word, which yields transferred training data in the target language. We train an NER model on this transferred data as our preliminary model. Going forward, we refer to the use of cross-lingual transferred data as CT.

2.2 Entity-Targeted Active Learning

After training a model using cross-lingual transfer learning, we start the active learning process based on this model's outputs. We begin by training a NER model Θ using the above model's outputs as training data. Using this trained model, our proposed entity-targeted active learning strategy, referred as ETAL, then selects the most informative spans from a corpus D of unlabeled sequences. Given an unlabeled sequence s, ETAL first selects a span of tokens $s_i^j = s_i \cdots s_j$ such that s_i^j is a likely named entity, where $i, j \in [0, |s|]$. Then, in order to obtain highly informative spans across D, ETAL computes the entropy H for each occurrence of the span s_i^j in D and then aggregates them over the entire corpus D, given by:

$$H_{aggregate}(s_i^j) = \sum_{x_i^j \in D} H(x_i^j)\mathbb{1}(x_i^j = s_i^j)$$

where x is an unlabeled sequence in D. Finally, the spans s_i^j with the highest aggregate uncertainty $H_{aggregate}$ are selected for manual annotation.

We now describe the procedure for calculating $H(x_i^j)$, which is the entropy of a span x_i^j being a likely entity. Given an unlabeled sequence x, the trained NER model Θ is used for computing the marginal probabilities $p_\theta(y_i|\mathbf{x})$ for each token x_i across all possible labels $y_i \in Y$ using the forward-backward algorithm (Rabiner, 1989), where Y is the set of all labels. Using these marginals we calculate the entropy of a given span x_i^j being an entity as shown in Algorithm 1.

Algorithm 1 Entity-Targeted Active Learning

B ← *label-set denoting beginning of an entity*
I ← *label-set denoting inside of an entity*
O ← *outside of an entity span*
$p_\theta(y_i|\mathbf{x})$ ← *marginal probability of label* y_i *for token* x_i

for $i \leftarrow 1...len(x), j = 1$ **do**
  $p_{span}^{ij} = \sum_{y \in B} p_\theta(y_i|\mathbf{x})$
  for $j \leftarrow i+1...len(x)$ **do**
    $p_{entity} = p_{span}^{ij} * p_\theta(O_j|\mathbf{x})$
    $H =$ *entropy* (p_{entity})
    if $H > H_{threshold}$ **then**
      $H_{aggregate}(x_i^j) += H$
    $p_{span}^{ij} = p_{span}^{ij} * \sum_{y \in I} p_\theta(y_j|\mathbf{x})$

Let B denote the set of labels indicating beginning of an entity, I the set of labels indicating inside of an entity and O denoting outside of an entity. First, we compute the probability of a span x_i^j being an entity, starting with the token i, by marginalizing $p_\theta(y_i|\mathbf{x})$ over all labels in B, denoted as p_{span}^{ij}. Since an entity can span multiple tokens, for each subsequent token j being part of that entity, we marginalize $p_\theta(y_j|\mathbf{x})$ over all labels in I and combine it with p_{span}^{ij}. Finally, we compute $p_{entity} = p_{span}^{ij} * p_\theta(O_j|\mathbf{x})$, which denotes end of a likely entity. Since we use the marginal probability for computing p_{entity}, it already factors in the transition probability between tags. Thus, any invalid sequences such as $B_{PER}I_{ORG}$ have low scores. Since contiguous spans have overlapping tokens, using dynamic programming (DP) to compute p_{span}^{ij} avoids an exponential computation when considering all possible spans in a sequence. Using p_{entity}, we compute the entropy H and only consider the spans having H higher than a pre-defined threshold $H_{threshold}$. The reason for this thresholding is purely for computational purposes as it allows us to discard all spans

that have a very low probability of being an entity, keeping the number of spans actually stored in memory low. As mentioned above, we aggregate the entropy of spans $H_{aggregate}$ over the entire unlabeled set, thus combining uncertainty sampling with a bias towards high frequency entities.

Using this strategy, we select subspans in each sequence for annotation. The annotator only needs to assign named entity types to the chosen subspans, adjust the span boundary if needed, and ignore the rest of the sequence, saving much effort.

2.3 Training the NER model

With the newly obtained training data from active learning, we attempt to improve the original transferred model. In this section, we first describe our model architecture, and try to address: 1) how to train the NER model effectively with partially annotated sequences? 2) what training scheme is best suited to improve the transferred model?

2.3.1 Model Architecture

Our NER model is a BiLSTM-CNN-CRF model based on Ma and Hovy (2016) consisting of: a character-level CNN, that allows the model to capture subword information; a word-level BiLSTM, that consumes word embeddings and produces context sensitive hidden representations; and a linear-chain CRF layer that models the dependency between labels for inference. We use the above model for training the initial NER model on the transferred data as well as for re-training the model on the data acquired from active learning.

2.3.2 PARTIAL-CRF

Active learning with span-based strategies such as ETAL, produces a training dataset of partially labeled sequences. To train the NER model on these partially labeled sequences, we take inspiration from Bellare and McCallum (2007); Tsuboi et al. (2008) and use a constrained CRF decoder. Normally, CRF computes the likelihood of a label sequence $\mathbf{y}$ given a sequence $\mathbf{x}$ as follows:

$$p_\theta(\mathbf{y}|\mathbf{x}) = \frac{\prod_{t=1}^{T} \psi_i(y_{t-1}, y_t, \mathbf{x}, t)}{Z(\mathbf{x})}$$

$$Z(\mathbf{x}) = \sum_{\mathbf{y} \in \mathbf{Y}(T)} \prod_{t=1}^{T} \psi_i(y_{t-1}, y_t, \mathbf{x}, t)$$

where T is the length of the sequence, $\mathbf{Y}(T)$ denotes the set of all possible label sequences with length T, and $\psi_i(y_{t-1}, y_t, \mathbf{x}) = \exp(\mathbf{W}^T_{y_{t-1},y_t}\mathbf{x}_i + \mathbf{b}_{y_{t-1},y_t})$ is the energy function. To compute the likelihood of a sequence where some labels are unknown, we use a constrained CRF which marginalizes out the un-annotated tokens. Specifically, let $\mathbf{Y_L}$ denote the set of all possible sequences that include the partial annotations (for un-annotated tokens, all labels are possible), and we compute the likelihood as: $p_\theta(\mathbf{Y_L}|\mathbf{x}) = \sum_{\mathbf{y} \in \mathbf{Y_L}} p_\theta(\mathbf{y}|\mathbf{x})$, referred as PARTIAL-CRF.

2.3.3 Training Scheme

To improve our model with the newly labeled data, we directly fine-tune the initial model, trained on the transferred data, on the data acquired through active learning, referred as FINETUNE. Each active learning run produces more labeled data, for which this training procedure is repeated again. We also compare the NER performance using two other training schemes: CORPUSAUG, where we train the model on the concatenated corpus of transferred data and the newly acquired data, and CORPUSAUG+FINETUNE, where we additionally fine-tune the model trained using CORPUSAUG on just the newly acquired data.

3 Experiments

In this section, we evaluate the effectiveness of our proposed strategy in both simulated (§3.2) and human-annotation experiments (§3.3).

3.1 Experimental Settings

Datasets: The first evaluation set includes the benchmark CoNLL 2002 and 2003 NER datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) for Spanish (from the Romance family), Dutch and German (like English, from the Germanic family). We use the standard corpus splits for train/dev/test. The second evaluation set is for the low-resource setting where we use the Indonesian (from the Austronesian family), Hindi (from the Indo-Aryan family) and Spanish datasets released by the Linguistic Data Consortium (LDC).[2] We generate the train/dev/test split by random sampling. Details of the corpus statistics are in the Appendix.

English-transferred Data: We use the same experimental settings and resources as described in Xie et al. (2018) to get the translations of the English training data for each target language.

[2]LDC2017E62,LDC2016E97,LDC2017E66

Active Learning Setup: As described in Section §2.2, a DP-based algorithm is employed to select the uncertain entity spans which runs for all n-grams having length $<= 5$. This length was approximated by computing the 90th percentile on the length of entities in the English training data. $H_{threshold}$ is a hyper-parameter set to 1e-8. The details of the NER model hyper-parameters can be found in the Appendix.

3.2 Simulation Experiments

Setup: We use cross-lingual transfer (§2.1) to train our initial NER model and test on the target language. This is the same setting as Xie et al. (2018) and serves as our baseline. Then we use several active learning strategies to select data for manual annotation using this trained NER model. We compare our proposed ETAL strategy with the following baseline strategies:

SAL: Select whole sequences for which the model has least confidence in the most likely labeling (Culotta and McCallum, 2005).

CFEAL: Select least confident spans within a sequence using the confidence field estimation method (Culotta and McCallum, 2004).

RAND: Select spans randomly from the unlabeled set for annotation.

In this experimental setting, we simulate manual annotation by using gold labels for the data selected by active learning. At each subsequent run, we annotate 200 tokens and fine-tune the NER model on all the data acquired so far, which is then used to select data for the next run of annotation.

3.2.1 Results

Figure 2 summarizes the results for all datasets across the different experimental settings. Each data-point on the x-axis corresponds to the NER performance after annotating 200 additional tokens. CT denotes using cross-lingual transferred data to train the initial NER model for both kick-starting the active learning process and also for fine-tuning the NER model on the newly-acquired data. PARTIAL-CRF/FULL-CRF denote the type of CRF decoder used in the NER model. Throughout this paper, we report results averaged across all active learning runs unless otherwise noted. Individual scores are reported in the Appendix.

As can be seen in the figure, our proposed recipe ETAL+PARTIAL-CRF+CT outperforms the previous active learning baselines for all the datasets. Holding the other two components of CT and PARTIAL-CRF constant, we conduct experiments to compare the different active learning strategies, which are denoted by the solid lines in Figure 2. We see that ETAL outperforms the other strategies by a significant margin for both the CoNLL datasets: German (+6.1 F1), Spanish (+5.3 F1), Dutch (+6.3 F1) and the LDC datasets: Hindi (+9.3 F1), Indonesian (+9.0 F1), Spanish (+7.5 F1), at the end of all runs. Furthermore, even with just one-tenth annotated tokens, the proposed recipe is only (avg.) -5.2 F1 behind the model trained using all labeled data, denoted by SUPERVISED ALL. Although CFEAL also selects informative spans, ETAL outperforms it because ETAL is optimized to select likely entities, causing more entities to be annotated for Hindi (+43), Indonesian (+207), Spanish-CoNLL (+1579), German (+906), Dutch (+836), except for Spanish-LDC (-184). Despite fully labeled data being adding in SAL, ETAL outperforms it because SAL selects longer sentences with fewer entities: Hindi (-934), Indonesian (-1290), Spanish-LDC (-527), Spanish-CoNLL (-2395), German (-2086), Dutch (-2213).

Dataset	Tokens	ETAL	SAL	RAND	CFEAL
Hindi LDC	200	54.8 ± 2.6	49.6 ± 2.8	50.2 ± 0.4	50.4 ± 2.8
	600	64.7 ± 2.6	51.5 ± 2.9	56.1 ± 2.6	54.3 ± 2.5
	1200	69.9 ± 2.5	56.6 ± 2.7	56.8 ± 2.6	64.4 ± 2.7
Indonesian LDC	200	**47.4± 2.6**	**47.9 ± 2.4**	**46.8 ± 2.3**	**48.5 ± 2.3**
	600	54.5 ± 2.4	44.5 ± 2.2	47.2 ± 2.2	46.0 ± 2.3
	1200	60.5 ± 2.3	44.7 ± 2.3	51.9 ± 2.3	49.5 ± 2.3
Spanish LDC	200	66.3 ± 3.8	62.0 ± 3.6	61.2 ± 1.2	62.5 ± 3.7
	600	65.8 ± 4.1	62.5 ± 3.7	61.9 ± 2.0	63.8 ± 3.7
	1200	78.9 ± 3.5	62.3 ± 3.6	64.6 ± 4.0	68.6 ± 3.9

Table 1: Variance analysis for significance testing of different active learning systems using paired bootstrap resampling. ± denotes the 95% confidence intervals. Systems which are not statistically significant than the best system ETAL are in bold. The CoNLL datasets reflect the same observation, as can be seen in Appendix.

From Figure 2 we see that ETAL performs better than the baselines across multiple runs. To verify that this is not an artifact of randomness in the test data, we use a paired bootstrap resampling method, as illustrated in Koehn (2004), to compare SAL, CFEAL, RAND with ETAL. For each system, we compute the F1 score on randomly sampled 50% of the data and perform 10k bootstrapping steps at three active learning runs. From Table 1 we see that the baselines are significantly worse than ETAL at 600 and 1200 annotated tokens.

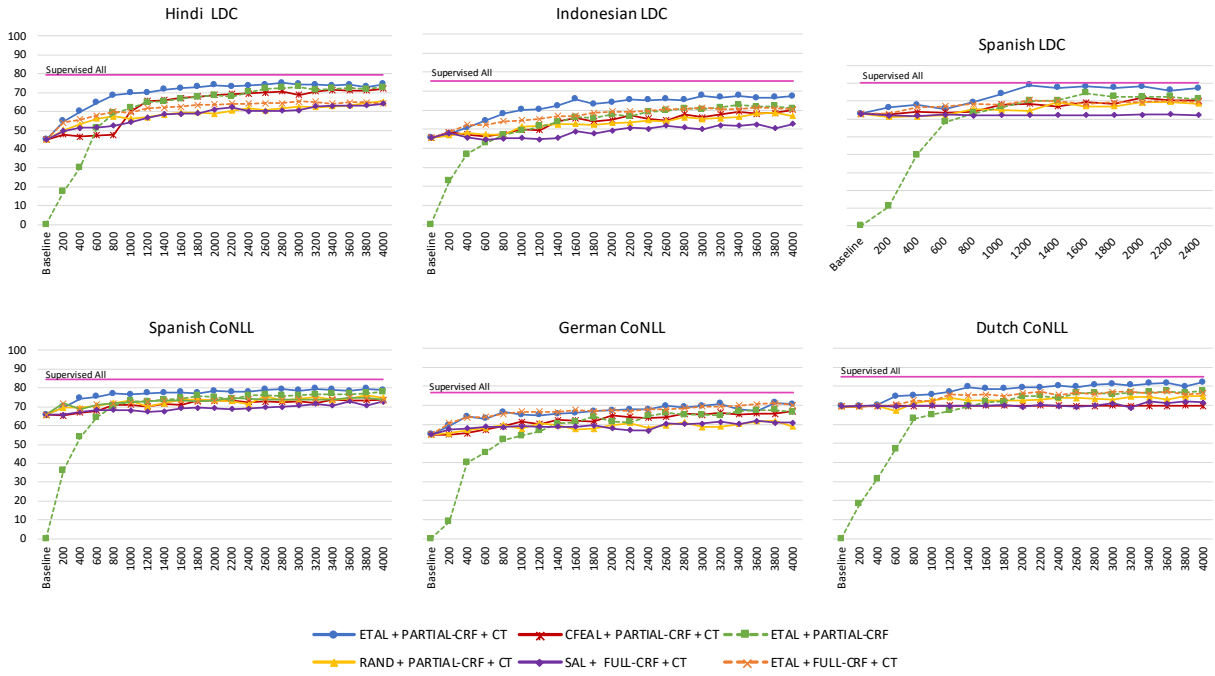

Figure 2: Comparison of the NER performance trained with the FineTune scheme, across six datasets. Solid lines compare the different active learning strategies. Dashed lines show the ablation experiments. The x-axis denotes the total number of tokens annotated and the y-axis denotes the F1 score.

3.2.2 Ablation Study

In order to study the contribution of CT and PARTIAL-CRF in improving the NER performance, we conduct the following ablation, denoted by dashed lines in Figure 2.

CT: We observe that the transferred data from English provides a good start to the NER model: 69.4 (Dutch), 63.0 (Spanish-LDC), 65.7 (Spanish-CoNLL), 54.7 (German), 45.4 (Indonesian), 45.0 (Hindi) F1. As expected, cross-lingual transfer helps more for the languages closely related to English which are Dutch, German, Spanish. For this ablation, we train a ETAL+PARTIAL-CRF where no transferred data is used. Therefore, to create the seed data, we randomly annotate 200 tokens in the target language and thereafter use ETAL. We observe that as more in-domain data is acquired, the un-transferred setting soon approaches the transferred setting ETAL+PARTIAL-CRF+CT suggesting that an efficient annotation strategy can help close the gap between these two systems with as few as ∼1000 tokens (avg.).

PARTIAL-CRF: We study the effect of using the original CRF (FULL-CRF) instead of the PARTIAL-CRF for training with partially labeled data. Since the former requires fully labeled sequences, the un-annotated tokens in a sequence are labeled with the model predictions. We see from Figure 2 that the ETAL+FULL-CRF+CT performs worse (avg. -4.1 F1) than ETAL+PARTIAL-CRF+CT. This is because the FULL-CRF significantly hurts the recall, as much as by an average of -11.0 points for Hindi, -1.4 for Indonesian, -7.4 for Spanish-LDC, -3.3 for German, -3.7 for Dutch, -4.8 for Spanish CoNLL.

3.2.3 Comparison of Training Schemes

We experiment with different NER training regimes (described in §2.3.3) for ETAL. We observe that generally fine-tuning not only speeds up the training but also gives better performance than CORPUSAUG. For brevity of space, we compare results for two languages in Figure 3:[3] Dutch, a relative of English, and Hindi, a distant language. We see that FINETUNE performs better for Hindi whereas CORPUSAUG+FINETUNE performs better for Dutch. This is because Dutch is closely related to English and benefits the most from the transferred data being explicitly augmented. Whereas for Hindi, which is typologically distant from English, the transferred data is noisy and thus the model doesn't gain much from the transferred data. Xie et al. (2018) make a similar observation in their

[3]The results for other datasets can be found in Appendix.

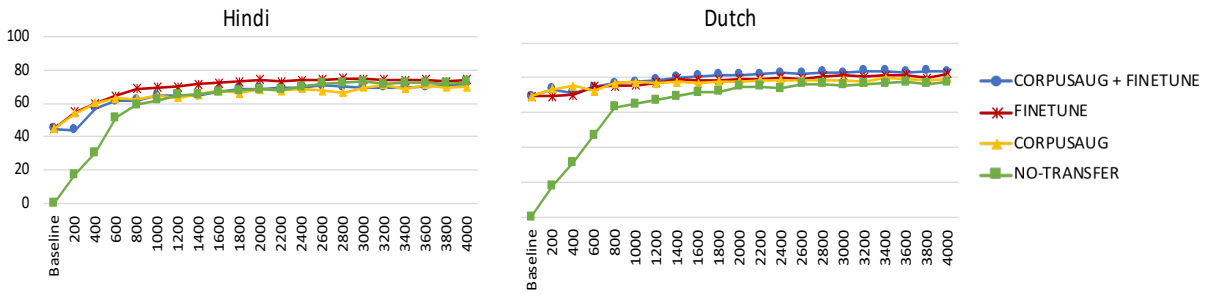

Figure 3: Comparison of the NER performance trained with different schemes for the ETAL strategy. The x-axis denotes the total number of tokens annotated and the y-axis denotes the F1 score.

experiments with German.

3.3 Human Annotation Experiments

Setup: We conduct human annotation experiments for Hindi, Indonesian and Spanish to understand whether ETAL helps reduce the annotation effort and improve annotation quality in practical settings. We compare ETAL with the full sequence strategy (SAL). We use six native speakers, two for each language, with different levels of familiarity with the NER task. Each annotator was provided with practice sessions to gain familiarity with the annotation guidelines and the user interface. The annotators annotated for 20 mins time for each strategy. For ETAL, the annotator was required to annotate single spans i.e each sequence contained one span of tokens. This involved assigning the correct label and adjusting the span boundary if required. For SAL, the annotator was required to annotate all possible entities in the sequence. We randomized the order in which the annotators had to annotate using ETAL and SAL strategy. Figure 5 illustrates the human annotation process for the ETAL strategy in the annotation interface. [4]

3.3.1 Results

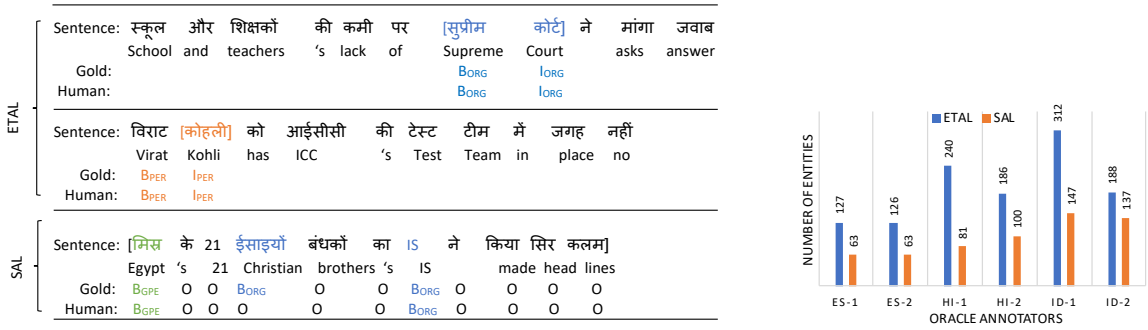

Table 2 records the results of the human annotation experiments. We first compare each annotator's annotation quality with respect to the oracle under both ETAL and SAL, denoted by *Annotator Performance*. We see that both Hindi and Spanish annotators have higher annotation quality using ETAL. This is because by selecting possible entity spans, ETAL not only saves effort on searching the entities in a sequence but also allows the annotators to read less overall and concentrate more on the things that they do read, as seen in Figure 4(a). However, for SAL we see that the annotator missed a likely entity because they focused on the other more salient entities in the sequence. For Indonesian, we see an opposite trend due to several inconsistencies in the gold labels. The most common inconsistency being when a common noun is part of an entity. For instance, the gold standard annotates the span *Kabupaten Bogor* as an entity where *Kabupaten* means "district". Whereas for ~~*Kabupaten*~~ *Aceh tengah*, the gold standard does not include *Kabupaten*. Similarly, the same span *gunung krakatau* is annotated inconsistently across different mentions where sometimes they exclude the *gunung* (mountain) token.Since the annotators referred to these examples during their practice session, their annotations had similar inconsistencies. This issue affects ETAL more than SAL because ETAL selects more entities for annotation.

	Annotator Performance		**Test Performance (# annotated tokens)**		
	ETAL	SAL	ETAL	SAL	SAL-Full
HI-1	**78.8**	63.7	**50.4** (326)	44.2 (326)	53.3 (1894)
HI-2	**82.7**	72.2	**49.1** (234)	45.9 (234)	55.6 (2242)
ID-1	66.1	**77.8**	**50.4** (425)	45.8 (425)	51.3 (3232)
ID-2	73.0	**79.5**	**51.2** (251)	46.5 (251)	54.0 (2874)
ES-1	**79.7**	75.0	**63.7** (204)	62.2 (204)	64.6 (2134)
ES-2	**83.1**	70.4	**63.8** (199)	62.2 (199)	62.6 (2134)

Table 2: Annotator performance measures F1 of each annotator with respect to the oracle. Test Performance measures the NER F1 scores using the annotations as training data. The number in the brackets denote the number of annotated tokens used for training the NER model. ES:Spanish, HI:Hindi, ID: Indonesian.

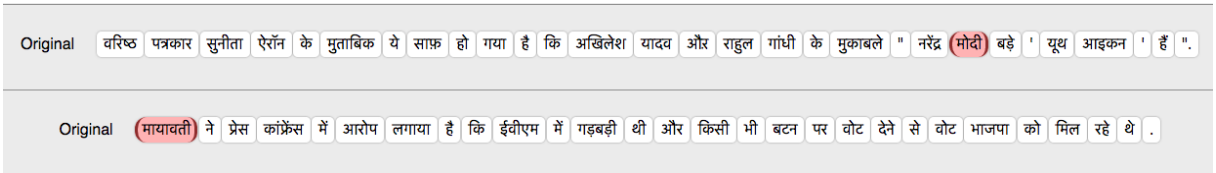
The *Test Performance* compares the performance of the NER models trained with these annotations. The number in the brackets denotes the total number of annotated tokens used for train-

[4]The code for the annotation interface can be found at https://gitlab.com/cmu_ariel/ariel-annotation-interface.

(a) (b)

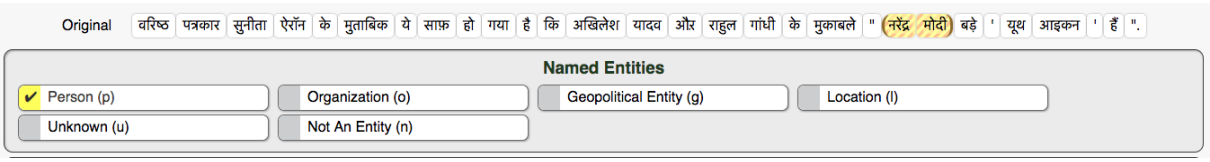
Figure 4: (a) Examples from Hindi human annotation experiments for both ETAL and SAL. Square brackets denote the spans (for ETAL) or the entire sequence (for SAL) selected by the respective active learning strategy. (b) Comparing the number of entities in the data selected by ETAL and SAL, as annotated by oracle.

ing the NER model. We observe that SAL has a larger number of annotated tokens than ETAL. This is because most sequences selected by SAL did not have any entities. Since "not-an-entity" is the default label in the annotation interface, no operation is required for annotating these, allowing for more tokens to be annotated per unit times. When we count the number of entities present in the data selected by the two strategies, we see in Figure 4(b) that data selected by ETAL has a significantly larger number of entities than SAL, across all the 6 annotation experiments. Therefore, we first compare the NER performance on the same number of annotated tokens. From Table 2 we see that under this setting ETAL outperforms SAL, similar to the simulation results. We note that when we consider all the annotated tokens, SAL (denoted by SAL-FULL) has slightly better results. However, despite having 6 times fewer annotated tokens, the difference between ETAL and SAL-FULL is (avg.) 2.1 F1. This suggests that ETAL can achieve competitive performance with fewer annotations.



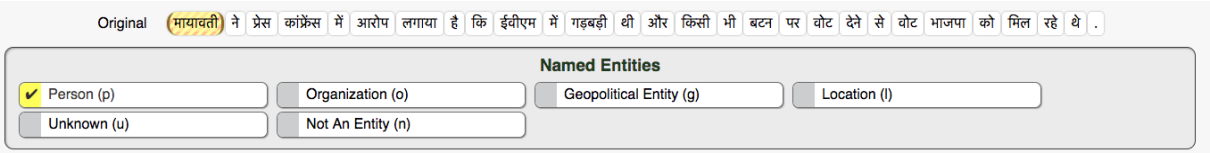
From both the simulation and human experiments, we can conclude that a targeted annotation strategy such as ETAL achieves competitive performance with less manual effort while maintaining high annotation quality. Given that ETAL can help find twice as many entities as SAL, a potential application of ETAL can also be for creating a high-quality entity gazetteer under a short time budget. Since a naive strategy of SAL allows for more labelled data to be acquired in the same amount of time, in the future we plan to explore mixed-mode annotation where we choose either full sequences or spans for annotation.

4 Related Work

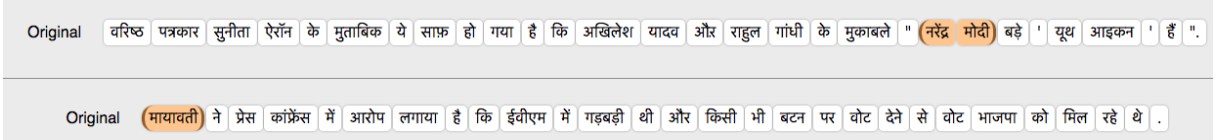


Cross-Lingual Transfer: Transferring knowledge from high-resource languages has been extensively used for improving low-resource NER. More common approaches rely on annotation projection methods where annotations in source language are projected to the target language using parallel corpora (Zitouni and Florian, 2008; Ehrmann et al., 2011) or bilingual dictionaries (Xie et al., 2018; Mayhew et al., 2017). Cross-lingual word embeddings (Bharadwaj et al., 2016; Chaudhary et al., 2018) also provide a way to leverage annotations from related languages.

Active Learning (AL): AL has been widely explored for many NLP tasks- NER: Shen et al. (2017) explore token-level annotation strategies, Chen et al. (2015) present a study on AL for clinical NER; Baldridge and Palmer (2009) evaluate how well AL works with annotator expertise and label suggestions, Garrette and Baldridge (2013) study type and token based strategies for low-resource languages. Settles and Craven (2008) present a nice survey on the different AL strategies for sequence labeling tasks, whereas Marcheggiani and Artieres (2014) discuss the strategies for acquiring partially labeled data. Wanvarie et al. (2011); Neubig et al. (2011); Sperber et al. (2014) show the advantages of training a model on this partially labeled data. All above methods focus on either token or full sequence annotation.



The most similar work to ours perhaps is that of



(a) Selected spans using ETAL strategy are highlighted for the human annotator to annotate.

(b) Human annotator correcting the span boundary and assigning the correct entity type.

(c) Human annotator assigning the correct entity type only since selected span boundary is correct.

(d) Partially-annotated sequences after being annotated by the human annotator.

Figure 5: Example of the human annotation process for Hindi.

Fang and Cohn (2017), which selects informative word types for low-resource POS tagging. However, their method requires the annotator to annotate single tokens, which is not trivially applicable for multi-word entities in practical settings.

5 Conclusion

In this paper, we presented a study on how to efficiently bootstrap NER systems for low-resource languages using a combination of cross-lingual transfer learning and active learning. We conducted both simulated and human annotation experiments across different languages and found that: 1) cross-lingual transfer is a powerful tool, constantly beating systems without using transfer; 2) our proposed recipe works the best among known active learning baselines; 3) our proposed active learning strategy saves annotator much effort while ensuring high quality. In future, to account for different levels of annotator expertise, we plan to combine proactive learning (Li et al., 2017) with our proposed method.

Abstract

This paper studies keyphrase extraction in real-world scenarios where documents are from diverse domains and have variant content quality. We curate and release OpenKP, a large scale open domain keyphrase extraction dataset with near one hundred thousand web documents and expert keyphrase annotations. To handle the variations of domain and content quality, we develop BLING-KPE, a neural keyphrase extraction model that goes beyond language understanding using visual presentations of documents and weak supervision from search queries. Experimental results on OpenKP confirm the effectiveness of BLING-KPE and the contributions of its neural architecture, visual features, and search log weak supervision. Zero-shot evaluations on DUC-2001 demonstrate the improved generalization ability of learning from the open domain data compared to a specific domain.

1 Introduction

Automatically extracting keyphrases that are salient to the document meanings is an essential step to semantic document understanding. An effective keyphrase extraction (KPE) system can benefit a wide range of natural language processing and information retrieval tasks (Turney, 2001; Hasan and Ng, 2014). Recent neural methods formulate the task as a document-to-keyphrase sequence-to-sequence task. These neural KPE models have shown promising results compared to previous systems (Chen et al., 2018; Meng et al., 2017; Ye and Wang, 2018).

Noticeably, the recent progress in neural KPE is mostly observed in documents originating from the scientific domain (Meng et al., 2017; Augenstein et al., 2017). Perhaps because the scientific domain has sufficient training data for these neural methods: Authors are in the practice of assigning keyphrases to their publications. In real-world scenarios, most potential applications of KPE deal with diverse documents originating from sparse sources that are rather different from scientific papers. They often include a much diverse document structure and reside in various domains whose contents target much wider audiences than scientists. It is unclear how well the neural methods trained in the scientific domain generalize to other domains and in real-world scenarios.

This paper focuses on the task of open domain web keyphrase extraction, which targets KPE for web documents without any restriction of the domain, quality, nor content of the documents. We curate and release a large scale open domain KPE dataset, OpenKP, which includes about one hundred thousand web documents with expert keyphrase annotations.[1] The web documents are randomly sampled from the English fraction of a large web corpus and reflect the characteristics of typical web pages, with large variation in their domains and content qualities. To the best of our knowledge, this will be the first publicly available open domain manually annotated keyphrase extraction dataset at this scale.

This paper develops BLING-KPE, **B**eyond **L**anguage Understand**ING** **K**ey**P**hrase **E**xtraction, that tackles the challenges of KPE in documents from variant domains and content qualities. BLING-KPE uses a convolutional transformer architecture to model the language properties in the document, while also goes beyond by introducing the visual representation of the document and weak supervision from search user clicks.

The *visual presentations* of the document, including the location, size, font, and HTML structure of each text piece in the document, are integrated as visual features to the word embeddings

[1] The dataset, resources, and future updates are available at aka.ms/BLING.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5175–5184,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

in BLING-KPE. BLING-KPE learns to model the visual representations together with the document language in its network.

The *weak supervision from search clicks* is formulated as a pre-training task: Query Prediction. It trains the model to predict which phrase in the document has been used as a "click query", a query that a user issued to search and click on the document. The click queries on a document reflect the user's perceptions of the relatedness and importance when searching the document and can be considered as pseudo keyphrases. Pre-training on this weak supervision brings in training signals available at scale in commercial search systems.

Our experiments on OpenKP demonstrate the effectiveness of BLING-KPE. It outperforms standard KPE baselines, recent neural approaches and a highly optimized commercial KPE system by large margins. Ablation studies show the contributions of the neural architecture, visual features, and search weak supervision to BLING-KPE; removing any of them significantly reduces its accuracy.

Another advantage of learning from real-world open domain documents is improved generalization ability. We conduct zero-shot evaluations on the DUC-2001 news KPE datasets (Wan and Xiao, 2008b), where neural KPE systems are evaluated without seeing any labels from their news articles. BLING-KPE trained on OpenKP is the only neural method that outperforms traditional non-neural KPE methods, while neural KPE systems trained on the scientific documents do not generalize well to the news domain due to the domain differences.

2 Related Work

The classic keyphrase extraction systems typically include two components: *candidate keyphrase extraction* and *keyphrase importance estimation* (Hasan and Ng, 2014). The candidate keyphrases are often extracted by heuristic rules, for example, finding phrases following certain POS tag sequences (Wan and Xiao, 2008b; Liu et al., 2009a; Mihalcea and Tarau, 2004), predefined lexical patterns (Nguyen and Phan, 2009; Medelyan et al., 2009), or using entities as candidate phrases (Grineva et al., 2009).

The importance of the candidate keyphrases can be estimated by unsupervised or supervised methods. The unsupervised methods leverage the graph structures between phrases in the document (Mihalcea and Tarau, 2004; Wan and Xiao, 2008a,b), and topic information from topic modeling (Grineva et al., 2009; Liu et al., 2009b, 2010). The supervised keyphrase selection methods formulate a classification or ranking task and combine features from phrase frequencies (Witten et al., 2005), document structures (Chen et al., 2005; Yih et al., 2006), and external resources such as Wikipedia (Medelyan et al., 2009) and query log (Yih et al., 2006).

Recently, neural techniques have been applied to keyphrase tasks. Meng et al. formulate a seq2seq learning task that learns to extract and generate the keyphrase sequence from the document sequence; they incorporate a copy mechanism to the seq2seq RNN to extract phrases in the generation process (CopyRNN) (Meng et al., 2017). Improving this seq2seq setup has been the focus of recent research, for example, adding diverse constraints to reduce the duplication of produced keyphrases (Yuan et al., 2018; Chen et al., 2018), bringing auxiliary tasks to reduce the needs of training data (Ye and Wang, 2018), and adding title information to improve model accuracy (Chen et al., 2019).

The recent neural KPE methods have shown strong performances on the scientific domain, where large scale training data is available from the author assigned keyphrases on papers (Meng et al., 2017). Such specific domain training data limits the model generalization ability. Chen et al. show the seq2seq keyphrase generation models trained on scientific papers do not generalize well to another domain (Chen et al., 2018).

In general, previous research finds automatic keyphrase extraction a challenging task: its state-of-the-art accuracy is much lower than other language processing tasks, while supervised methods do not necessarily outperform simple unsupervised ones. Hasan and Ng (2014) pointed out potential ways to improve automatic keyphrase extraction, including better incorporation of *background knowledge*, better handling *long documents*, and better *evaluation* schemes. BLING-KPE aims to address these challenges by incorporating pre-training as a form of *background knowledge*, visual information to improve *long document* modeling, and OpenKP as a large scale open domain *evaluation* benchmark.

3 Open Domain Keyphrase Benchmark

This section describes the curation of OpenKP and its notable characteristics.

3.1 Data Curation

Documents in OpenKP include about seventy thousand web pages sampled from the index of Bing search engine.[2] The sampling is conducted on the pool of pages seen by United State users between Nov 2018 and Feb 2019.

There is no restriction on the domain or type of documents. They can be content-oriented pages like news articles, multi-media pages from video sites, or indexing pages with many hyperlinks. OpenKP is designed to reflect the diverse properties of web documents in the internet.

Keyphrase Labels are generated by our expert annotators. For each document, they examine the rendered web page and manually label 1-3 keyphrases following these definitions:

- *Salience:* A keyphrase captures the essential meaning of the page with no ambiguity.
- *Extraction:* The keyphrase has to appear in the document.
- *Fine-Grained:* The keyphrase cannot be general topics, such as "Sports" and "Politics".
- *Correct & Succinct:* The keyphrase has to form a correct English noun phrase, while also cannot be clauses or sentences.

We use the extraction setting to ensure labeling consistency and to increase annotation speed, which is around 42 pages per hour.

Expert Agreements. Our annotation experts are trained employees dedicated to providing high-quality annotations on web documents. We follow standard practice in generating annotations for production systems, which included regular touch-points to understand the confusion, as well as updates on the judgment guidelines to resolve ambiguities.

To study the task difficulty, we had five judges each annotate the same 50 random URLs. We measure the pairwise agreements between experts at different depths by Exact Match on the whole keyphrase, as well as the overlap between select keyphrases' unigrams. The agreement between judges is listed in Table 1.

[2] A new OpenKP version with 150K documents is available at msmarco.org.

Table 1: The agreements between pairs of expert judges at different annotation depth. Exact and Unigram show the percentage of judge agreement on exact keyphrases and overlapped unigrams.

Judge Depth	Exact Match	Unigram Match
Keyphrase@1	64.74%	64.74%
Keyphrase@2	48.30%	63.12%
Keyphrase@3	43.51%	57.66%

The results confirm that open domain keyphrase extraction is not an easy task. When measuring agreement for the top 3 keyphrases, our expert judges completely agree on about 43% of keyphrase pairs. Compared to the previous small scale annotations, for example, on DUC-2001's news articles (Wan and Xiao, 2008b), annotating web pages with diverse contents and domains are harder.

We manually examined these annotations and found two sources of disagreement: Chunking Variances and KP Choices.

Chunking Variances we define as two judges pick different boundaries of the same concept. For example, one judge may select "Protein Synthesis" as the keyphrase, and others may select "Protein" and "Synthesis" as two separate keyphrases. We found Chunking Variances consist of about 20% of disagreements. As shown in Table 1, the judge agreements is substantially higher on Unigram overlaps than on Exact matches, indicating that they may select chunks that overlap with each other but not exactly the same.

KP Choices we define as two judges pick different keyphrases. The judges agree mostly (64%) on the first entered keyphrase, as shown in Table 1. The variations on the second and third keyphrases are larger. However, we found the variations are more about which keyphrases they choose to enter, *not about whether a phrase is a keyphrase or not*. The variations on judge labels mostly reflect the missing positives in OpenKP; most of the keyphrases annotated by judges are correct. We can reduce the missing positives by a deeper annotation, i.e. ten keyphrases per document, or by labeling all candidate phrases with classification labels (Liu et al., 2018). However, that will significantly reduce the number of total documents in OpenKP, as each document costs much more to annotate. We chose the current design choice of OpenKP to favor a larger amount of training labels, which, in our experience, is more effective in

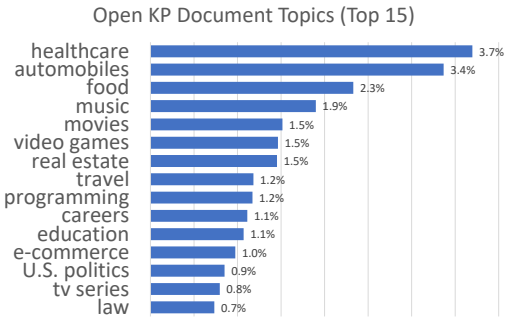

Figure 1: The most popular topics in OpenKP .

Table 2: Statistics of OpenKP used in our experiments. The new version on MSMARCO include 150K documents.

Statistics	Mean	STD
Doc Length	900.4	1494.4
# of KPs per Doc	1.8	0.8
Keyphrase Length	2.0	0.96
Doc Vocabulary Size	1.5M	n.a.
KP Vocabulary Size	62K	n.a.
# of Documents	68K	n.a.
# of Unique KPs	99.6K	n.a.

training deep neural models.

3.2 Data Characteristics

Table 2 lists the statistics of OpenKP. The document length is the length of the text parsed from the HTML of the web page, using a production HTML parser. The parsed texts will be released with the dataset. These statistics reflect the large variations in the document contents; their length varies a lot and share little common keyphrases, as shown by a large number of unique keyphrases.

We also leverage a production classifier to classify OpenKP documents into 5K predefined domains. The top 15 most popular classes and their distributions are shown in Figure 1. As expected, these documents have a large variation in their topic domains. The most popular domain, "healthcare", only covers 3.7% documents; the tenth most popular topic only covers 1% of documents. Moreover, the top 15 classes make up less than 25% of the entire dataset which showcases what a domain diverse dataset OpenKP is.

4 Keyphrase Extraction Model

This section describes the architecture, visual features, and weak supervision of BLING-KPE.

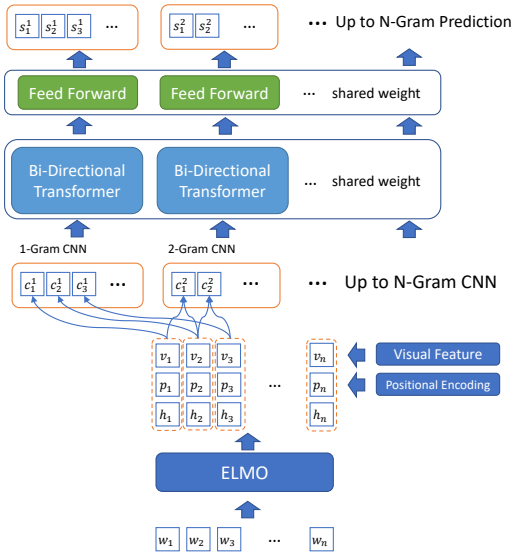

Figure 2: The BLING-KPE model architecture

4.1 Network Architecture

As shown in Figure 2, BLING-KPE is a keyphrase *extraction* model. It takes the word sequence of the document, $d = \{w_1, ...w_i, ...w_n\}$, and assigns keyphrase scores to its n-gram: $f(w_{i:i+k}, d)$. This process includes two main components: Hybrid Word Embedding and Convolutional Transformer.

Hybrid Word Embedding. BLING-KPE represents each word by its ELMo embedding, position embedding, and visual features.

The ELMo embedding brings the local contextual information:

$$\vec{h}_i = \text{ELMo}(w_i). \quad (1)$$

The standard pre-trained ELMo is used (Peters et al., 2018).

The position embedding models the location the word in the document content. It uses the standard sinusoidal position embedding (Vaswani et al., 2017):

$$\vec{\text{pos}}_i(2p) = sin(i/10000^{2p/P}), \quad (2)$$

$$\vec{\text{pos}}_i(2p+1) = cos(i/10000^{2p/P}). \quad (3)$$

The p-th dimension of the position embedding is a function of its position (i) and dimension (p).

The visual features represent the visual presentation of each word. We denote the visual feature as $\vec{v}_i$ and will describe its details in §4.2.

The hybrid word embedding is the concatenation of the three:

$$\vec{w}_i = \vec{h}_i \frown \vec{\text{pos}}_i \frown \vec{v}_i. \quad (4)$$

Convolutional Transformer. BLING-KPE uses a convolutional transformer architecture to model n-grams and their interactions.

It first composes the hybrid word embeddings to n-gram embeddings using CNNs. The embedding of i-th k-gram is calculated as

$$\vec{g}_i^k = \text{CNN}^k(\vec{w}_{i:i+k}), \tag{5}$$

where k is the length of the n-gram, $1 \leq k \leq K$. K is the maximum length of allowed candidate n-grams. Each k-gram has its own set of convolution filters CNN^k with window size k and stride 1.

It then models the interactions between k-grams using Transformer (Vaswani et al., 2017).

$$\vec{t}_i^k = \text{Transformer}_i(\vec{G}^k), \tag{6}$$

$$\vec{G}^k = \vec{g}_1^k \frown ... \frown \vec{g}_i^k ... \frown \vec{g}_{n-k+1}^k. \tag{7}$$

The sequence $\vec{G}^k$ is the concatenations of all k-gram embeddings. The Transformer models the self-attentions between k-grams and fuses them to global contextualized embeddings.

The Transformer is convolutional on all length k of n-grams; the same parameters are used model the interactions between n-grams at each length, to reduce the parameter size. The intuition is that the interactions between bi-grams and that between tri-grams are not significantly different.

The final score of an n-gram is calculated by a feedforward layer upon the Transformer. Like the Transformer, the same feedforward layer is applied (convolutional) on all n-grams.

$$f(w_{i:i+k}, d) = \text{softmax}_{i,k}(s_i^k), \tag{8}$$

$$s_i^k = \text{Feedforward}(\vec{t}_i^k). \tag{9}$$

The softmax is taken over all possible n-grams at each position i and each length k. The model decides the span location and length jointly.

Learning. The whole model is trained as a classification problem using cross-entropy loss:

$$l = \text{Cross-Entropy}(y_i^k, f(w_{i:i+k}, d)), \tag{10}$$

where y_i^k is the label of whether the phrase $w_{i:i+k}$ is a keyphrase of the document.

4.2 Visual Features

We extract four groups of visual features for each word in the document.

- **Size** features include the height and width of the text block a word appears in.
- **Location** features include the 2-d location of the word in the rendered web page.
- **Font** feature includes the font size and whether the word is in Bold.
- **DOM** features include whether the word appears in "inline" or "block" HTML tags, also whether it is in a leaf node of the DOM tree.

Table 3: Visual Features. All features are extracted at per word level and the parent block level (the parent node of the word in the HTML DOM tree).

Name	Dimension
Font Size	1×2
Text Block Size	2×2
Location in Rendered Page	2×2
Is Bold Font	1×2
Appear In Inline	1×2
Appear In Block	1×2
Appear In DOM Tree Leaf	1×2

The full feature set is listed in Table 3. We double the features by including the same features from the word's parent block in the DOM tree. The visual features are included in the OpenKP releases.

4.3 Weak Supervisions from Search

An application of keyphrases is information retrieval. The extracted keyphrases are expected to capture the main topic of the document, thus can provide high quality document indexing terms (Gutwin et al., 1999) or new semantic ranking features (Xiong et al., 2018). Reversely, user clicks bring the user's perception of the document during the search and provide a large number of feedback signals for document understanding (Croft et al., 2010).

BLING-KPE leverages the user feedback signals as weak supervision, in the task of Query Prediction. Given the document d, BLING-KPE learns to predict its click queries $Q = \{q_1, ..., q_m\}$.

This pre-training step uses the same cross entropy loss:

$$l_{pre} = \text{Cross-Entropy}(y_i', f(q_i, d)), \tag{11}$$

where y_i' indicates whether the query q_i is a click query and also appears as an n-gram in the document d. The Query Prediction labels exist at scale in commercial search logs and provide a large number of pre-training signals.

Table 4: Statistics of Query Prediction Dataset. The data is from a sample of Bing search log in on week.

Statistics	Mean	STD
Doc Length	1211.8	1872.6
# of Query per Doc	1.32	0.76
Query Length	2.4	1.07
Doc Vocabulary Size	15M	n.a
Query Vocabulary Size	383K	n.a
# of Documents	1.6M	n.a.
# of Unique Queries	1.5M	n.a.

5 Experimental Methodology

Datasets used in our experiments include OpenKP, as described in §3, Query Prediction, and DUC-2001 (Wan and Xiao, 2008b).

The Query Prediction data is sampled from the Bing search log with navigational and offensive queries filtered out. We keep only the click queries that are included as an n-gram in the document to be consistent with OpenKP's extractive setting. The statistics of the sample is listed in Table 4.

DUC-2001 is the KPE extraction dataset on DUC news articles (Wan and Xiao, 2008b). It includes 309 news articles and on average 8 keyphrase per article.

We use random 80%-20% train-test splits on OpenKP and Query Prediction. On OpenKP, BLING-KPE is first pre-trained on Query Prediction and then further trained on its manual labels. There is no overlap between the documents in Query Prediction and OpenKP.

DUC-2001 uses the zero-shot evaluation setting from prior research (Meng et al., 2017; Chen et al., 2018); no labels in DUC-2001 are used to train nor validate the neural models. It tests neural models' generalization ability from the training domain to a different testing domain.

Evaluation Metrics. OpenKP and Query Prediction use **P**recision and **R**ecall@{1, 3, 5}. DUC-2001 uses F1@10, the same as prior research (Meng et al., 2017; Chen et al., 2018).

Statistically, significant improvements are evaluated by permutation test with $p<0.05$ on OpenKP and Query Prediction. The baselines on DUC-2001 reuse scores from previous results; the statistical significant test is not applicable as per document results are not shared.

Baselines. OpenKP and Query Prediction experiments compare `BLING-KPE` with: traditional KPE methods, production systems, and a neural baseline.

Table 5: Parameters to learn in BLING-KPE.

Component	Dimensions
ELMo	pre-trained and frozen
Position Embedding	256
Visual Feature	18
N-gram CNN	512 filter, 1-5 window size (ngram)
Transformer	8 head, 512 hidden dimension
Feedforward	512-relu-512-relu-1

Traditional KPE baselines include the follows.

- TFIDF is the unsupervised frequency based KPE system. The IDF scores are calculated on the corresponding corpus.
- TextRank is the popular graph-based unsupervised KPE model (Mihalcea and Tarau, 2004). Our in-house implementation is used.
- LeToR is the feature-based KPE model. It use LambdaMart (Burges, 2010) and standard KPE features, i.e. those in KEA (Witten et al., 2005).

The production baselines include two versions.

- PROD is our current feature-based production KPE system. It uses many carefully engineered features and LambdaMart.
- PROD (Body) is the same system but only uses the body text, i.e. the title is not used.

All these unsupervised and feature-based methods use the same keyphrase candidate selection system with PROD.

The neural baseline is CopyRNN (Meng et al., 2017). We use their open-source implementation and focus on the OpenKP dataset which is publicly available.

Implementation Details. Table 5 lists BLING-KPE parameters. The training uses Adam optimizer, learning rate 0.3 with logarithmic decreasing to 0.001, batch size 16, and 0.2 dropout probability in n-gram CNN, Transformer and feedforward layers. Learning takes about 2.5 hours (2 epochs) to converge on `OpenKPE` and about 13 hours (3 epochs) on Query Prediction, based on validation loss. In BLING-KPE, the maximum document length is 256 and documents are zero-padded or truncated to this length. Baselines use the original documents, except CopyRNN which works better with 256. The maximum n-gram length is set to five (K=5).

Table 6: Keyphrase Extraction Accuracy. **Bold** marks statistically significant improvements over all baselines.

6 Evaluation Results

Three experiments are conducted to evaluate the accuracy of BLING-KPE, the source of its effectiveness, and its generalization ability.

6.1 Overall Accuracy

The overall extraction accuracy on OpenKP and Query Prediction is shown in Table 6.

TFIDF works well on both tasks. Frequency-based methods are often strong baselines in document representation tasks. LeToR performs better than its frequency feature TFIDF in OpenKP but worse on Query Prediction. Supervised methods are not necessarily stronger than unsupervised ones in KPE (Hasan and Ng, 2014). TextRank does not work well in our dataset; its word graph is likely misguided by the noisy contents.

PROD, our feature-based production system, outperforms all other baselines by large margins on OpenKP. It is expected as it is highly optimized with a lot of engineering efforts. Nonetheless, adapting a complex feature-based system to a new task/domain requires extra engineering work; directly applying it to the Query Prediction task does not work well. The feature-based Production system also needs the title information; PROD (Body) performs much worse than PROD.

CopyRNN performs relatively well on OpenKP, especially on later keyphases. The main challenge for CopyRNN is the low-quality and highly variant contents on the web. Real-world web pages are not cohesive nor well-written articles but include various structures such as lists, media captions, and text fragments. Modeling them as a word sequence is not ideal. The other differences are not as significant: The vocabulary size and training data size on Query Prediction are similar to CopyRNN's KP 40K dataset; CopyRNN performs better on keyphrase extraction than generation in KP20k (Meng et al., 2017).

BLING-KPE outperforms all other methods by large margins. The improvements are robust and significant on both tasks, both metrics, and on all depths. It achieves 0.404 P@1 on OpenKP and recovers 72% of clicked queries at depth 5 on Query Prediction. The sources of this effectiveness is studied in the next experiment.

6.2 Ablation Study

Table 7 shows ablation results on BLING-KPE's variations. Each variation removes a component and keeps all others unchanged.

ELMo Embedding. We first verify the effectiveness of using ELMo embedding by replacing ELMo with the WordPiece token embedding (Wu et al., 2016). The accuracy of this variation is much lower than the accuracy of the full model and others. The result is shown in the first row of Table 7. The context-aware word embedding is a necessary component of `BLING-KPE`.

Network Architecture. The second part of

Table 8: Performance on DUC-2001. Neural models are evaluated directly on DUC-2001 without fine-tuning on DUC labels. Results better than TFIDF are marked **Bold**.

Method	F1@10	Method	F1@10
TFIDF	0.270	TopicRank	0.154
TextRank	0.097	KeyCluster	0.140
SingleRank	0.256	ExpandRank	0.269
Trained by Scientific Papers			
CopyRNN	0.164	CorrRNN	0.173
BLING-KPE (No Visual, No Pretraining)			0.267
Trained by Open Domain Documents			
BLING-KPE (No Visual, No Pretraining)			**0.282**

Table 7 studies the contribution of Transformer and position embedding. Transformer contributes significantly to Query Prediction; with a lot of training data, the self-attention layers capture the global contexts between n-grams. But on OpenKP, its effectiveness is mostly observed on the first position. The position embedding barely helps, since real-world web pages are often not one text sequence.

Beyond Language Understanding. As shown in the second part of Table 7, both visual features and search pretraining contribute significantly to BLING-KPE's effectiveness. Without either of them, the accuracy drops significantly. Visual features even help on Query Prediction, though users issued the click queries and clicked on the documents *before* seeing its full page.

The crucial role of ELMo embeddings confirm the benefits of bringing background knowledge and general language understanding, in the format of pre-trained contextual embedding, in keyphrase extraction. The importance of visual features and search weak supervisions confirms the benefits of going beyond language understanding in modeling real-world web documents.

6.3 Generalization Ability

This experiment studies the generalization ability of BLING-KPE using the zero-shot evaluation on DUC-2001 (Meng et al., 2017; Chen et al., 2018). For fair comparisons, we use KP20K or OpenKP, the two public datasets, to train the No Visual & No Pretraining version of BLING-KPE, and evaluate on DUC-2001 directly. No labels in DUC are used to fine-tune the neural models.

To adjust to DUC's larger number of keyphrases, we apply the trained BLING-KPE on the 256-length chunks of DUC articles

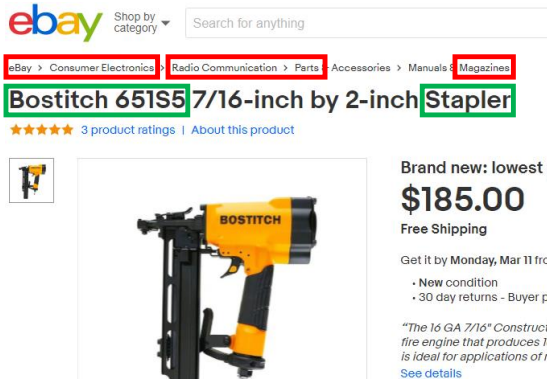

Figure 3: An example of visual feature contributions in BLING-KPE. The big green blocks are the keyphrases extracted with visual features. The small read blocks are those extracted without visual information.

and merge the extracted keyphrases using simple heuristics:

- Weighted Sum: Scores of the same keyphrase from different chunks are summed with weights 0.9^p. P is the index of the chunk.
- Deduplication: A keyphrase is discarded if it is a sub-string of a top 1/4 ranked keyphrase.

The results are shown in Table 8. `BLING-KPE`, when trained with `OpenKP`, is the only neural method that outperforms TFIDF in this zero-shot evaluation. It outperforms previous neural methods by more than 60%, and itself when trained on KP20k, confirming the strong generalization ability of `BLING-KPE` and the training with `OpenKP`.

6.4 Discussion

Our manual case studies found many interesting examples that illustrate the advantage of modeling documents with visual information.

For example, in Figure 3, the page is annotated with "Bostitch 651S5", the product name, and "Stapler", the product type. Their salience is highlighted by larger and bold fonts, which are picked up by BLING-KPE. However, without the visual information, the product ontology names are extracted as keyphrases: they are meaningful concepts, correlated with the page content, and positioned at the beginning of the document—only that they appear less important in the web page by design.

7 Conclusion

This paper curates OpenKP, the first public large scale open domain keyphrase extraction benchmark to facilitate future research keyphrase extraction research in real-world scenarios. It also develops BLING-KPE, which leverages visual representation and search-based weak supervision to model real-world documents with variant contents, appearances, and diverse domains.

Our experiments demonstrate the robust improvements of BLING-KPE compared to previous approaches. Our studies showcase how BLING-KPE's language understanding, visual features and search weak supervision jointly deliver this effective performance, as well as its generalization ability to an unseen domain in zero-shot setting.

In the future, we plan to extend OpenKP with more annotated documents and connect it with downstream applications.

Abstract

Knowledge graphs are structured representations of real world facts. However, they typically contain only a small subset of all possible facts. Link prediction is a task of inferring missing facts based on existing ones. We propose TuckER, a relatively straightforward but powerful linear model based on Tucker decomposition of the binary tensor representation of knowledge graph triples. TuckER outperforms previous state-of-the-art models across standard link prediction datasets, acting as a strong baseline for more elaborate models. We show that TuckER is a fully expressive model, derive sufficient bounds on its embedding dimensionalities and demonstrate that several previously introduced linear models can be viewed as special cases of TuckER.

1 Introduction

Vast amounts of information available in the world can be represented succinctly as *entities* and *relations* between them. *Knowledge graphs* are large, graph-structured databases which store facts in triple form (e_s, r, e_o), with e_s and e_o representing subject and object entities and r a relation. However, far from all available information is currently stored in existing knowledge graphs and manually adding new information is costly, which creates the need for algorithms that are able to automatically infer missing facts.

Knowledge graphs can be represented as a third-order binary tensor, where each element corresponds to a triple, 1 indicating a true fact and 0 indicating the unknown (either a false or a missing fact). The task of *link prediction* is to predict whether two entities are related, based on known facts already present in a knowledge graph, i.e. to infer which of the 0 entries in the tensor are indeed false, and which are missing but actually true.

A large number of approaches to link prediction so far have been linear, based on various methods of factorizing the third-order binary tensor (Nickel et al., 2011; Yang et al., 2015; Trouillon et al., 2016; Kazemi and Poole, 2018). Recently, state-of-the-art results have been achieved using non-linear convolutional models (Dettmers et al., 2018; Balažević et al., 2019). Despite achieving very good performance, the fundamental problem with deep, non-linear models is that they are non-transparent and poorly understood, as opposed to more mathematically principled and widely studied tensor decomposition models.

In this paper, we introduce TuckER (E stands for entities, R for relations), a straightforward linear model for link prediction on knowledge graphs, based on *Tucker decomposition* (Tucker, 1966) of the binary tensor of triples, acting as a strong baseline for more elaborate models. Tucker decomposition, used widely in machine learning (Schein et al., 2016; Ben-Younes et al., 2017; Yang and Hospedales, 2017), factorizes a tensor into a core tensor multiplied by a matrix along each mode. It can be thought of as a form of higher-order SVD in the special case where matrices are orthogonal and the core tensor is "all-orthogonal" (Kroonenberg and De Leeuw, 1980). In our case, rows of the matrices contain entity and relation embeddings, while entries of the core tensor determine the level of interaction between them. Subject and object entity embedding matrices are assumed equivalent, i.e. we make no distinction between the embeddings of an entity depending on whether it appears as a subject or as an object in a particular triple. Due to the low rank of the core tensor, TuckER benefits from *multi-task learning* by parameter sharing across relations.

A link prediction model should have enough expressive power to represent all relation types (e.g. symmetric, asymmetric, transitive). We thus show

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5185–5194, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

that TuckER is *fully expressive*, i.e. given any ground truth over the triples, there exists an assignment of values to the entity and relation embeddings that accurately separates the true triples from false ones. We also derive a dimensionality bound which guarantees full expressiveness.

Finally, we show that several previous state-of-the-art linear models, RESCAL (Nickel et al., 2011), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016) and SimplE (Kazemi and Poole, 2018), are special cases of TuckER.

In summary, key contributions of this paper are:

- proposing TuckER, a new *linear* model for link prediction on knowledge graphs, that is simple, expressive and achieves *state-of-the-art results* across all standard datasets;
- proving that TuckER is *fully expressive* and deriving a bound on the embedding dimensionality for full expressiveness; and
- showing how TuckER subsumes several previously proposed tensor factorization approaches to link prediction.

2 Related Work

Several *linear* models for link prediction have previously been proposed:

RESCAL (Nickel et al., 2011) optimizes a scoring function containing a bilinear product between subject and object entity vectors and a full rank relation matrix. Although a very expressive and powerful model, RESCAL is prone to overfitting due to its large number of parameters, which increases quadratically in the embedding dimension with the number of relations in a knowledge graph.

DistMult (Yang et al., 2015) is a special case of RESCAL with a diagonal matrix per relation, which reduces overfitting. However, the linear transformation performed on entity embedding vectors in DistMult is limited to a stretch. The binary tensor learned by DistMult is symmetric in the subject and object entity mode and thus DistMult cannot model asymmetric relations.

ComplEx (Trouillon et al., 2016) extends DistMult to the complex domain. Subject and object entity embeddings for the same entity are complex conjugates, which introduces asymmetry into the tensor decomposition and thus enables ComplEx to model asymmetric relations.

SimplE (Kazemi and Poole, 2018) is based on Canonical Polyadic (CP) decomposition (Hitchcock, 1927), in which subject and object entity embeddings for the same entity are independent (note that DistMult is a special case of CP). SimplE's scoring function alters CP to make subject and object entity embedding vectors dependent on each other by computing the average of two terms, first of which is a bilinear product of the subject entity head embedding, relation embedding and object entity tail embedding and the second is a bilinear product of the object entity head embedding, inverse relation embedding and subject entity tail embedding.

Recently, state-of-the-art results have been achieved with *non-linear* models:

ConvE (Dettmers et al., 2018) performs a global 2D convolution operation on the subject entity and relation embedding vectors, after they are reshaped to matrices and concatenated. The obtained feature maps are flattened, transformed through a linear layer, and the inner product is taken with all object entity vectors to generate a score for each triple. Whilst results achieved by ConvE are impressive, its reshaping and concatenating of vectors as well as using 2D convolution on word embeddings is unintuitive.

HypER (Balažević et al., 2019) is a simplified convolutional model, that uses a hypernetwork to generate 1D convolutional filters for each relation, extracting relation-specific features from subject entity embeddings. The authors show that convolution is a way of introducing sparsity and parameter tying and that HypER can be understood in terms of tensor factorization up to a non-linearity, thus placing HypER closer to the well established family of factorization models. The drawback of HypER is that it sets most elements of the core weight tensor to 0, which amounts to hard regularization, rather than letting the model learn which parameters to use via soft regularization.

Scoring functions of all models described above and TuckER are summarized in Table 1.

3 Background

Let $\mathcal{E}$ denote the set of all entities and $\mathcal{R}$ the set of all relations present in a knowledge graph. A triple is represented as (e_s, r, e_o), with $e_s, e_o \in \mathcal{E}$ denoting subject and object entities respectively and $r \in \mathcal{R}$ the relation between them.

3.1 Link Prediction

In link prediction, we are given a subset of all true triples and the aim is to learn a *scoring function* ϕ

Model	Scoring Function	Relation Parameters	Space Complexity
RESCAL (Nickel et al., 2011)	$\mathbf{e}_s^\top \mathbf{W}_r \mathbf{e}_o$	$\mathbf{W}_r \in \mathbb{R}^{{d_e}^2}$	$\mathcal{O}(n_e d_e + n_r d_r^2)$
DistMult (Yang et al., 2015)	$\langle \mathbf{e}_s, \mathbf{w}_r, \mathbf{e}_o \rangle$	$\mathbf{w}_r \in \mathbb{R}^{d_e}$	$\mathcal{O}(n_e d_e + n_r d_e)$
ComplEx (Trouillon et al., 2016)	$\text{Re}(\langle \mathbf{e}_s, \mathbf{w}_r, \overline{\mathbf{e}}_o \rangle)$	$\mathbf{w}_r \in \mathbb{C}^{d_e}$	$\mathcal{O}(n_e d_e + n_r d_e)$
ConvE (Dettmers et al., 2018)	$f(\text{vec}(f([\underline{\mathbf{e}}_s; \underline{\mathbf{w}}_r] * w))\mathbf{W})\mathbf{e}_o$	$\mathbf{w}_r \in \mathbb{R}^{d_r}$	$\mathcal{O}(n_e d_e + n_r d_r)$
SimplE (Kazemi and Poole, 2018)	$\frac{1}{2}(\langle \mathbf{h}_{e_s}, \mathbf{w}_r, \mathbf{t}_{e_o} \rangle + \langle \mathbf{h}_{e_o}, \mathbf{w}_{r^{-1}}, \mathbf{t}_{e_s} \rangle)$	$\mathbf{w}_r \in \mathbb{R}^{d_e}$	$\mathcal{O}(n_e d_e + n_r d_e)$
HypER (Balažević et al., 2019)	$f(\text{vec}(\mathbf{e}_s * \text{vec}^{-1}(\mathbf{w}_r \mathbf{H}))\mathbf{W})\mathbf{e}_o$	$\mathbf{w}_r \in \mathbb{R}^{d_r}$	$\mathcal{O}(n_e d_e + n_r d_r)$
TuckER (ours)	$\mathcal{W} \times_1 \mathbf{e}_s \times_2 \mathbf{w}_r \times_3 \mathbf{e}_o$	$\mathbf{w}_r \in \mathbb{R}^{d_r}$	$\mathcal{O}(n_e d_e + n_r d_r)$

Table 1: Scoring functions of state-of-the-art link prediction models, the dimensionality of their relation parameters, and significant terms of their space complexity. d_e and d_r are the dimensionalities of entity and relation embeddings, while n_e and n_r denote the number of entities and relations respectively. $\overline{\mathbf{e}}_o \in \mathbb{C}^{d_e}$ is the complex conjugate of $\mathbf{e}_o$, $\underline{\mathbf{e}}_s, \underline{\mathbf{w}}_r \in \mathbb{R}^{d_w \times d_h}$ denote a 2D reshaping of $\mathbf{e}_s$ and $\mathbf{w}_r$ respectively, $\mathbf{h}_{e_s}, \mathbf{t}_{e_s} \in \mathbb{R}^{d_e}$ are the head and tail entity embedding of entity e_s, and $\mathbf{w}_{r^{-1}} \in \mathbb{R}^{d_r}$ is the embedding of relation r^{-1} (which is the inverse of relation r). $*$ is the convolution operator, $\langle \cdot \rangle$ denotes the dot product and $\times_n$ denotes the tensor product along the n-th mode, f is a non-linear function, and $\mathcal{W} \in \mathbb{R}^{d_e \times d_e \times d_r}$ is the core tensor of a Tucker decomposition.

that assigns a score $s = \phi(e_s, r, e_o) \in \mathbb{R}$ which indicates whether a triple is true, with the ultimate goal of being able to correctly score all missing triples. The scoring function is either a specific form of tensor factorization in the case of linear models or a more complex (deep) neural network architecture for non-linear models. Typically, a positive score for a particular triple indicates a true fact predicted by the model, while a negative score indicates a false one. With most recent models, a non-linearity such as the logistic sigmoid function is typically applied to the score to give a corresponding probability prediction $p = \sigma(s) \in [0, 1]$ as to whether a certain fact is true.

3.2 Tucker Decomposition

Tucker decomposition, named after Ledyard R. Tucker (Tucker, 1964), decomposes a tensor into a set of matrices and a smaller core tensor. In a three-mode case, given the original tensor $\mathcal{X} \in \mathbb{R}^{I \times J \times K}$, Tucker decomposition outputs a tensor $\mathcal{Z} \in \mathbb{R}^{P \times Q \times R}$ and three matrices $\mathbf{A} \in \mathbb{R}^{I \times P}$, $\mathbf{B} \in \mathbb{R}^{J \times Q}$, $\mathbf{C} \in \mathbb{R}^{K \times R}$:

$$\mathcal{X} \approx \mathcal{Z} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}, \tag{1}$$

with $\times_n$ indicating the tensor product along the n-th mode. *Factor matrices* $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$, when orthogonal, can be thought of as the principal components in each mode. Elements of the *core tensor* $\mathcal{Z}$ show the level of interaction between the different components. Typically, P, Q, R are smaller than I, J, K respectively, so $\mathcal{Z}$ can be thought of as a compressed version of $\mathcal{X}$. Tucker decomposition is not unique, i.e. we can transform $\mathcal{Z}$ without affecting the fit if we apply the inverse transformation to $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$ (Kolda and Bader, 2009).

4 Tucker Decomposition for Link Prediction

We propose a model that uses Tucker decomposition for link prediction on the binary tensor representation of a knowledge graph, with entity embedding matrix $\mathbf{E}$ that is equivalent for subject and object entities, i.e. $\mathbf{E} = \mathbf{A} = \mathbf{C} \in \mathbb{R}^{n_e \times d_e}$ and relation embedding matrix $\mathbf{R} = \mathbf{B} \in \mathbb{R}^{n_r \times d_r}$, where n_e and n_r represent the number of entities and relations and d_e and d_r the dimensionality of entity and relation embedding vectors.

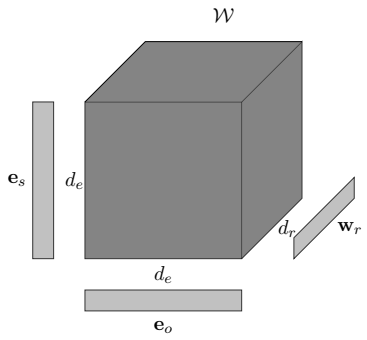

Figure 1: Visualization of the TuckER architecture.

We define the scoring function for TuckER as:

$$\phi(e_s, r, e_o) = \mathcal{W} \times_1 \mathbf{e}_s \times_2 \mathbf{w}_r \times_3 \mathbf{e}_o, \tag{2}$$

where $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^{d_e}$ are the rows of $\mathbf{E}$ representing the subject and object entity embedding vectors, $\mathbf{w}_r \in \mathbb{R}^{d_r}$ the rows of $\mathbf{R}$ representing the relation embedding vector and $\mathcal{W} \in \mathbb{R}^{d_e \times d_r \times d_e}$ is the core tensor. We apply logistic sigmoid to each score $\phi(e_s, r, e_o)$ to obtain the predicted probability p of a triple being true. Visualization of the TuckER architecture can be seen in Figure 1. As proven in Section 5.1, TuckER is *fully expressive*. Further, its number of parameters increases *linearly* with

respect to entity and relation embedding dimensionality d_e and d_r, as the number of entities and relations increases, since the number of parameters of $\mathcal{W}$ depends only on the entity and relation embedding dimensionality and not on the number of entities or relations. By having the core tensor $\mathcal{W}$, unlike simpler models such as DistMult, ComplEx and SimplE, TuckER does not encode all the learned knowledge into the embeddings; some is stored in the core tensor and shared between all entities and relations through *multi-task learning*. Rather than learning distinct relation-specific matrices, the core tensor of TuckER can be viewed as containing a shared pool of "prototype" relation matrices, which are linearly combined according to the parameters in each relation embedding.

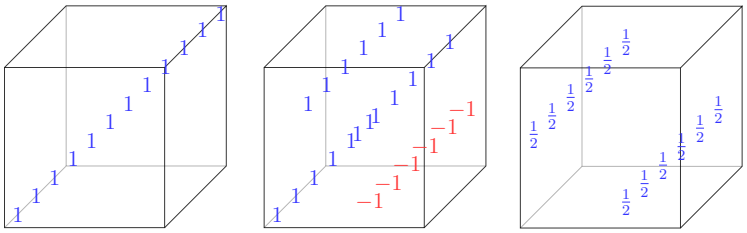
4.1 Training

Since the logistic sigmoid is applied to the scoring function to approximate the true binary tensor, the implicit underlying tensor is comprised of $-\infty$ and ∞. Given this prevents an explicit analytical factorization, we use numerical methods to train TuckER. We use the standard data augmentation technique, first used by Dettmers et al. (2018) and formally described by Lacroix et al. (2018), of adding reciprocal relations for every triple in the dataset, i.e. we add (e_o, r^{-1}, e_s) for every (e_s, r, e_o). Following the training procedure introduced by Dettmers et al. (2018) to speed up training, we use *1-N scoring*, i.e. we simultaneously score entity-relation pairs (e_s, r) and (e_o, r^{-1}) with all entities $e_o \in \mathcal{E}$ and $e_s \in \mathcal{E}$ respectively, in contrast to *1-1 scoring*, where individual triples (e_s, r, e_o) and (e_o, r^{-1}, e_s) are trained one at a time. The model is trained to minimize the Bernoulli negative log-likelihood loss function. A component of the loss for one entity-relation pair with all others entities is defined as:

$$L = -\frac{1}{n_e} \sum_{i=1}^{n_e} (\mathbf{y}^{(i)} \log(\mathbf{p}^{(i)}) + (1 - \mathbf{y}^{(i)}) \log(1 - \mathbf{p}^{(i)})), \tag{3}$$

where $\mathbf{p} \in \mathbb{R}^{n_e}$ is the vector of predicted probabilities and $\mathbf{y} \in \mathbb{R}^{n_e}$ is the binary label vector.

5 Theoretical Analysis



5.1 Full Expressiveness and Embedding Dimensionality

A tensor factorization model is fully expressive if for any ground truth over all entities and relations, there exist entity and relation embeddings that accurately separate true triples from the false. As shown in (Trouillon et al., 2017), ComplEx is fully expressive with the embedding dimensionality bound $d_e = d_r = n_e \cdot n_r$. Similarly to ComplEx, Kazemi and Poole (2018) show that SimplE is fully expressive with entity and relation embeddings of size $d_e = d_r = \textit{min}(n_e \cdot n_r, \gamma + 1)$, where γ represents the number of true facts. They further prove other models are not fully expressive: DistMult, because it cannot model asymmetric relations; and transitive models such as TransE (Bordes et al., 2013) and its variants FTransE (Feng et al., 2016) and STransE (Nguyen et al., 2016), because of certain contradictions that they impose between different relation types. By Theorem 1, we establish the bound on entity and relation embedding dimensionality (i.e. decomposition rank) that guarantees full expressiveness of TuckER.

Theorem 1. *Given any ground truth over a set of entities $\mathcal{E}$ and relations $\mathcal{R}$, there exists a TuckER model with entity embeddings of dimensionality $d_e = n_e$ and relation embeddings of dimensionality $d_r = n_r$, where $n_e = |\mathcal{E}|$ is the number of entities and $n_r = |\mathcal{R}|$ the number of relations, that accurately represents that ground truth.*

Proof. Let $\mathbf{e}_s$ and $\mathbf{e}_o$ be the n_e-dimensional one-hot binary vector representations of subject and object entities e_s and e_o respectively and $\mathbf{w}_r$ the n_r-dimensional one-hot binary vector representation of relation r. For each subject entity $e_s^{(i)}$, relation $r^{(j)}$ and object entity $e_o^{(k)}$, we let the i-th, j-th and k-th element respectively of the corresponding vectors $\mathbf{e}_s$, $\mathbf{w}_r$ and $\mathbf{e}_o$ be 1 and all other elements 0. Further, we set the ijk element of the tensor $\mathcal{W} \in \mathbb{R}^{n_e \times n_r \times n_e}$ to 1 if the fact (e_s, r, e_o) holds and -1 otherwise. Thus the product of the entity embeddings and the relation embedding with the core tensor, after applying the logistic sigmoid, accurately represents the original tensor. □

The purpose of Theorem 1 is to prove that TuckER is capable of potentially capturing all information (and noise) in the data. In practice however, we expect the embedding dimensionalities needed for full reconstruction of the underlying binary tensor to be much smaller than the bound stated above, since the assignment of values to the tensor is not random but follows a certain structure, otherwise nothing unknown could be predicted. Even more so, low decomposition rank is actually a desired property of any bilin-

(a) DistMult (b) ComplEx (c) SimplE

Figure 2: Constraints imposed on the values of core tensor $\mathcal{Z} \in \mathbb{R}^{d_e \times d_e \times d_e}$ for DistMult and $\mathcal{Z} \in \mathbb{R}^{2d_e \times 2d_e \times 2d_e}$ for ComplEx and SimplE. Elements that are set to 0 are represented in white.

ear link prediction model, forcing it to learn that structure and generalize to new data, rather than simply memorizing the input. In general, we expect TuckER to perform better than ComplEx and SimplE with embeddings of lower dimensionality due to parameter sharing in the core tensor (shown empirically in Section 6.4), which could be of importance for efficiency in downstream tasks.

5.2 Relation to Previous Linear Models

Several previous tensor factorization models can be viewed as a special case of TuckER:

RESCAL (Nickel et al., 2011) Following the notation introduced in Section 3.2, the RESCAL scoring function (see Table 1) has the form:

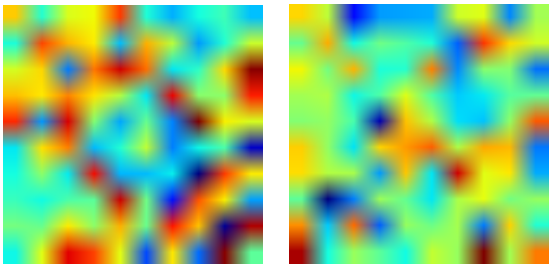
$$\mathcal{X} \approx \mathcal{Z} \times_1 \mathbf{A} \times_3 \mathbf{C}. \tag{4}$$

This corresponds to Equation 1 with $I = K = n_e$, $P = R = d_e$, $Q = J = n_r$ and $\mathbf{B} = \mathbf{I}_J$ the $J \times J$ identity matrix. This is also known as Tucker2 decomposition (Kolda and Bader, 2009). As is the case with TuckER, the entity embedding matrix of RESCAL is shared between subject and object entities, i.e. $\mathbf{E} = \mathbf{A} = \mathbf{C} \in \mathbb{R}^{n_e \times d_e}$ and the relation matrices $\mathbf{W}_r \in \mathbb{R}^{d_e \times d_e}$ are the $d_e \times d_e$ slices of the core tensor $\mathcal{Z}$. As mentioned in Section 2, the drawback of RESCAL compared to TuckER is that its number of parameters grows *quadratically* in the entity embedding dimension d_e as the number of relations increases.

DistMult (Yang et al., 2015) The scoring function of DistMult (see Table 1) can be viewed as equivalent to that of TuckER (see Equation 1) with a core tensor $\mathcal{Z} \in \mathbb{R}^{P \times Q \times R}$, $P = Q = R = d_e$, which is *superdiagonal* with 1s on the superdiagonal, i.e. all elements z_{pqr} with $p = q = r$ are 1 and all the other elements are 0 (as shown in Figure 2a). Rows of $\mathbf{E} = \mathbf{A} = \mathbf{C} \in \mathbb{R}^{n_e \times d_e}$ contain subject and object entity embedding vectors $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^{d_e}$ and rows of $\mathbf{R} = \mathbf{B} \in \mathbb{R}^{n_r \times d_e}$ contain relation embedding vectors $\mathbf{w}_r \in \mathbb{R}^{d_e}$. It is interesting to note that the TuckER interpretation of the DistMult scoring function, given that matrices $\mathbf{A}$ and $\mathbf{C}$ are identical, can alternatively be interpreted as a special case of CP decomposition (Hitchcock, 1927), since Tucker decomposition with a superdiagonal core tensor is equivalent to CP decomposition. Due to enforced symmetry in subject and object entity mode, DistMult cannot learn to represent asymmetric relations.

ComplEx (Trouillon et al., 2016) *Bilinear models* represent subject and object entity embeddings as vectors $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^{d_e}$, relation as a matrix $\mathbf{W}_r \in \mathbb{R}^{d_e \times d_e}$ and the scoring function as a bilinear product $\phi(e_s, r, e_o) = \mathbf{e}_s \mathbf{W}_r \mathbf{e}_o$. It is trivial to show that both RESCAL and DistMult belong to the family of bilinear models. As explained by Kazemi and Poole (2018), ComplEx can be considered a bilinear model with the real and imaginary part of an embedding for each entity concatenated in a single vector, $[\text{Re}(\mathbf{e}_s); \text{Im}(\mathbf{e}_s)] \in \mathbb{R}^{2d_e}$ for subject, $[\text{Re}(\mathbf{e}_o); \text{Im}(\mathbf{e}_o)] \in \mathbb{R}^{2d_e}$ for object, and a relation matrix $\mathbf{W}_r \in \mathbb{R}^{2d_e \times 2d_e}$, constrained so that its leading diagonal contains duplicated elements of $\text{Re}(\mathbf{w}_r)$, its d_e-diagonal elements of $\text{Im}(\mathbf{w}_r)$ and its -d_e-diagonal elements of -$\text{Im}(\mathbf{w}_r)$, with all other elements set to 0, where d_e and -d_e represent offsets from the leading diagonal.

Similarly to DistMult, we can regard the scoring function of ComplEx (see Table 1) as equivalent to the scoring function of TuckER (see Equation 1), with core tensor $\mathcal{Z} \in \mathbb{R}^{P \times Q \times R}$, $P = Q = R = 2d_e$, where $3d_e$ elements on different tensor diagonals are set to 1, d_e elements on one tensor diagonal are set to -1 and all other elements are set to 0 (see Figure 2b). This shows that the scoring function of ComplEx, which computes a bilinear product with *complex* entity and relation embeddings and disregards the imaginary part of the obtained result, is equivalent to a hard regularization of the core tensor of TuckER in the *real* domain.



SimplE (Kazemi and Poole, 2018) The authors show that SimplE belongs to the family of bilinear models by concatenating embeddings for head and tail entities for both subject and object into vectors $[\mathbf{h}_{e_s}; \mathbf{t}_{e_s}] \in \mathbb{R}^{2d_e}$ and $[\mathbf{h}_{e_o}; \mathbf{t}_{e_o}] \in \mathbb{R}^{2d_e}$ and constraining the relation matrix $\mathbf{W}_r \in \mathbb{R}^{2d_e \times 2d_e}$ so that it contains the relation embedding vector $\frac{1}{2}\mathbf{w}_r$ on its d_e-diagonal and the inverse relation embedding vector $\frac{1}{2}\mathbf{w}_{r^{-1}}$ on its -d_e-diagonal and 0s elsewhere. The SimplE scoring function (see Table 1) is therefore equivalent to that of TuckER (see Equation 1), with core tensor $\mathcal{Z} \in \mathbb{R}^{P \times Q \times R}$, $P = Q = R = 2d_e$, where $2d_e$ elements on two tensor diagonals are set to $\frac{1}{2}$ and all other elements are set to 0 (see Figure 2c).

5.3 Representing Asymmetric Relations

Each relation in a knowledge graph can be characterized by a certain set of properties, such as symmetry, reflexivity, transitivity. So far, there have been two possible ways in which linear link prediction models introduce *asymmetry* into factorization of the binary tensor of triples:

- distinct (although possibly related) embeddings for subject and object entities and a diagonal matrix (or equivalently a vector) for each relation, as is the case with models such as ComplEx and SimplE; or
- equivalent subject and object entity embeddings and each relation represented by a full rank matrix, which is the case with RESCAL.

The latter approach appears more intuitive, since asymmetry is a property of the relation, rather than the entities. However, the drawback of the latter approach is quadratic growth of parameter number with the number of relations, which often leads to overfitting, especially for relations with a small number of training triples. TuckER overcomes this by representing relations as vectors $\mathbf{w}_r$, which makes the parameter number grow linearly with the number of relations, while still keeping the desirable property of allowing relations to be asymmetric by having an asymmetric *relation-agnostic* core tensor $\mathcal{W}$, rather than encoding the relation-specific information in the entity embeddings. Multiplying $\mathcal{W} \in \mathbb{R}^{d_e \times d_r \times d_e}$ with $\mathbf{w}_r \in \mathbb{R}^{d_r}$ along the second mode, we obtain a full rank relation-specific matrix $\mathbf{W}_r \in \mathbb{R}^{d_e \times d_e}$, which can perform all possible linear transformations on the entity embeddings, i.e. rotation, reflection or stretch, and is thus also capable of modeling asymmetry. Regardless of what kind of transformation is needed for modeling a particular relation, TuckER can learn it from the data. To demonstrate this, we show sample heatmaps of learned relation matrices $\mathbf{W}_r$ for a WordNet symmetric relation "derivationally_related_form" and an asymmetric relation "hypernym" in Figure 3, where one can see that TuckER learns to model the symmetric relation with the relation matrix that is approximately symmetric about the main diagonal, whereas the matrix belonging to the asymmetric relation exhibits no obvious structure.

(a) $\mathbf{W}_{\text{derivationally_related_form}}$ (b) $\mathbf{W}_{\text{hypernym}}$

Figure 3: Learned relation matrices for a symmetric (derivationally_related_form) and an asymmetric (hypernym) WN18RR relation. $\mathbf{W}_{\text{derivationally_related_form}}$ is approximately symmetric about the leading diagonal.

6 Experiments and Results

6.1 Datasets

We evaluate TuckER using four standard link prediction datasets (see Table 2):

FB15k (Bordes et al., 2013) is a subset of Freebase, a large database of real world facts.

FB15k-237 (Toutanova et al., 2015) was created from FB15k by removing the inverse of many relations that are present in the training set from validation and test sets, making it more difficult for simple models to do well.

WN18 (Bordes et al., 2013) is a subset of WordNet, a hierarchical database containing lexical relations between words.

WN18RR (Dettmers et al., 2018) is a subset of WN18, created by removing the inverse relations from validation and test sets.

6.2 Implementation and Experiments

We implement TuckER in PyTorch (Paszke et al., 2017) and make our code available on GitHub.[1]

We choose all hyper-parameters by random search based on validation set performance. For

[1] https://github.com/ibalazevic/TuckER

FB15k and FB15k-237, we set entity and relation embedding dimensionality to $d_e = d_r = 200$. For WN18 and WN18RR, which both contain a significantly smaller number of relations relative to the number of entities as well as a small number of relations compared to FB15k and FB15k-237, we set $d_e = 200$ and $d_r = 30$. We use batch normalization (Ioffe and Szegedy, 2015) and dropout (Srivastava et al., 2014) to speed up training. We find that lower dropout values $(0.1, 0.2)$ are required for datasets with a higher number of training triples per relation and thus less risk of overfitting (WN18 and WN18RR), whereas higher dropout values $(0.3, 0.4, 0.5)$ are required for FB15k and FB15k-237. We choose the learning rate from $\{0.01, 0.005, 0.003, 0.001, 0.0005\}$ and learning rate decay from $\{1, 0.995, 0.99\}$. We find the following combinations of learning rate and learning rate decay to give the best results: $(0.003, 0.99)$ for FB15k, $(0.0005, 1.0)$ for FB15k-237, $(0.005, 0.995)$ for WN18 and $(0.01, 1.0)$ for WN18RR (see Table 5 in the Appendix A for a complete list of hyper-parameter values on each dataset). We train the model using Adam (Kingma and Ba, 2015) with the batch size 128.

At evaluation time, for each test triple we generate n_e candidate triples by combining the test entity-relation pair with all possible entities $\mathcal{E}$, ranking the scores obtained. We use the *filtered* setting (Bordes et al., 2013), i.e. all known true triples are removed from the candidate set except for the current test triple. We use evaluation metrics standard across the link prediction literature: mean reciprocal rank (MRR) and hits@k, $k \in \{1, 3, 10\}$. Mean reciprocal rank is the average of the inverse of the mean rank assigned to the true triple over all candidate triples. Hits@k measures the percentage of times a true triple is ranked within the top k candidate triples.

Dataset	# Entities (n_e)	# Relations (n_r)
FB15k	14,951	1,345
FB15k-237	14,541	237
WN18	40,943	18
WN18RR	40,943	11

Table 2: Dataset statistics.

6.3 Link Prediction Results

Link prediction results on all datasets are shown in Tables 3 and 4. Overall, TuckER outperforms previous state-of-the-art models on all metrics across all datasets (apart from hits@10 on WN18 where a non-linear model, R-GCN, does better). Results achieved by TuckER are not only better than those of other linear models, such as DistMult, ComplEx and SimplE, but also better than the results of many more complex deep neural network and reinforcement learning architectures, e.g. R-GCN, MINERVA, ConvE and HypER, demonstrating the expressive power of linear models and supporting our claim that simple linear models should serve as a baseline before moving onto more elaborate models.

Even with fewer parameters than ComplEx and SimplE at $d_e = 200$ and $d_r = 30$ on WN18RR ($\sim$9.4 vs $\sim$16.4 million), TuckER consistently obtains better results than any of those models. We believe this is because TuckER exploits knowledge sharing between relations through the core tensor, i.e. multi-task learning. This is supported by the fact that the margin by which TuckER outperforms other linear models is notably increased on datasets with a large number of relations. For example, improvement on FB15k is $+14\%$ over ComplEx and $+8\%$ over SimplE on the toughest hits@1 metric. To our knowledge, ComplEx-N3 (Lacroix et al., 2018) is the only other linear link prediction model that benefits from multi-task learning. There, rank regularization of the embedding matrices is used to encourage a low-rank factorization, thus forcing parameter sharing between relations. We do not include their published results in Tables 3 and 4, since they use the highly non-standard $d_e = d_r = 2000$ and thus a far larger parameter number (18x more parameters than TuckER on WN18RR; 5.5x on FB15k-237), making their results incomparable to those typically reported, including our own. However, running their model with equivalent parameter number to TuckER shows comparable performance, supporting our belief that the two models both attain the benefits of multi-task learning, although by different means.

6.4 Influence of Parameter Sharing

The ability of knowledge sharing through the core tensor suggests that TuckER should need a lower number of parameters for obtaining good results than ComplEx or SimplE. To test this, we re-implement ComplEx and SimplE with reciprocal relations, 1-N scoring, batch normalization and dropout for fair comparison, perform random search to choose best hyper-parameters

Table 4: Link prediction results on WN18 and FB15k.

(see Table 6 in the Appendix A for exact hyperparameter values used) and train all three models on FB15k-237 with embedding sizes $d_e = d_r \in \{20, 50, 100, 200\}$. Figure 4 shows the obtained MRR on the test set for each model. It is important to note that at embedding dimensionalities 20, 50 and 100, TuckER has fewer parameters than ComplEx and SimplE (e.g. ComplEx and SimplE have $\sim$3 million and TuckER has $\sim$2.5 million parameters for embedding dimensionality 100).

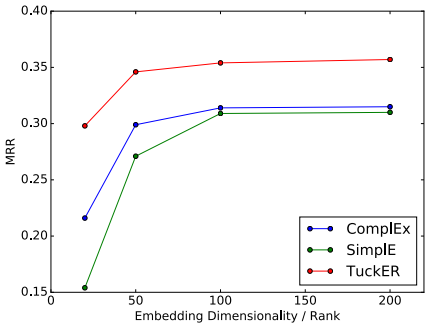

Figure 4: MRR for ComplEx, SimplE and TuckER for different embeddings sizes on FB15k-237.

We can see that the difference between the MRRs of ComplEx, SimplE and TuckER is approximately constant for embedding sizes 100 and 200. However, for lower embedding sizes, the difference between MRRs increases by 0.7% for embedding size 50 and by 4.2% for embedding size 20 for ComplEx and by 3% for embedding size 50 and by 9.9% for embedding size 20 for SimplE. At embedding size 20 ($\sim$300k parameters), the performance of TuckER is almost as good as the performance of ComplEx and SimplE at embedding size 200 ($\sim$6 million parameters), which supports our initial assumption.

7 Conclusion

In this work, we introduce TuckER, a relatively straightforward linear model for link prediction on knowledge graphs, based on the Tucker decomposition of a binary tensor of known facts. TuckER achieves state-of-the-art results on standard link prediction datasets, in part due to its ability to perform multi-task learning across relations. Whilst being fully expressive, TuckER's number of parameters grows linearly with respect to the number of entities or relations in the knowledge graph. We further show that previous linear state-of-the-art models, RESCAL, DistMult, ComplEx and SimplE, can be interpreted as special cases of our model. Future work might include exploring how to incorporate background knowledge on individual relation properties into the existing model.

Abstract

Due to the black-box nature of deep learning models, methods for explaining the models' results are crucial to gain trust from humans and support collaboration between AIs and humans. In this paper, we consider several model-agnostic and model-specific explanation methods for CNNs for text classification and conduct three human-grounded evaluations, focusing on different purposes of explanations: *(1)* revealing model behavior, *(2)* justifying model predictions, and *(3)* helping humans investigate uncertain predictions. The results highlight dissimilar qualities of the various explanation methods we consider and show the degree to which these methods could serve for each purpose.

1 Introduction

Explainable Artificial Intelligence (XAI) is aimed at providing explanations for decisions made by AI systems. The explanations are useful for supporting collaboration between AIs and humans in many cases (Samek et al., 2018). Firstly, if an AI outperforms humans in a certain task (e.g., AlphaGo (Silver et al., 2016)), humans can learn and distill knowledge from the given explanations. Secondly, if an AI's performance is close to human intelligence, the explanations can increase humans' confidence and trust in the AI (Symeonidis et al., 2009). Lastly, if an AI is duller than humans, the explanations help humans verify the decisions made by the AI and also improve the AI (Biran and McKeown, 2017).

One of the challenges in XAI is to explain prediction results given by deep learning models, which sacrifice transparency for high prediction performance. This type of explanations is called *local explanations* as they explain individual predictions (in contrast to *global explanations* which explain the trained model independently of any specific prediction). There have been several methods proposed to produce local explanations. Some of them are model-agnostic, applicable to any machine learning model (Ribeiro et al., 2016; Lundberg and Lee, 2017). Others are applicable to a class of models such as neural networks (Bach et al., 2015a; Dimopoulos et al., 1995) or to a specific model such as Convolutional Neural Networks (CNNs) (Zhou et al., 2016).

With so many explanation methods available, the next challenge is how to evaluate them so as to choose the right methods for different settings. In this paper, we focus on human-grounded evaluations of local explanation methods for text classification. Particularly, we propose three evaluation tasks which target different purposes of explanations for text classification – *(1)* revealing model behavior to human users, *(2)* justifying the predictions, and *(3)* helping humans investigate uncertain predictions. We then use the proposed tasks to evaluate nine explanation methods working on a standard CNN for text classification. These explanation methods are different in several aspects. For example, regarding granularity, four explanation methods select words from the input text as explanations, whereas the other five select n-grams as explanations. In terms of generality, one of the explanation methods is model-agnostic, two are random baselines, another two (newly proposed in this paper) are specific to 1D CNNs for text classification, and the rest are applicable to neural networks in general. Overall, the contributions of our work can be summarized as follows.

- We propose three human-grounded evaluation tasks to assess the quality of explanation methods with respect to different purposes of usage for text classification. (Section 3)
- To increase diversity in the experiments, we develop two new explanation methods for

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5195–5205,

CNNs for text classification. One is based on gradient-based analysis (**Grad-CAM-Text**). The other is based on model extraction using **decision trees**. (Section 4.3.1-4.3.2)

- We evaluate both new methods as well as random baselines and well-known existing methods using the three evaluation tasks proposed. The results highlight dissimilar qualities of the explanation methods and show the degree to which these methods could serve for each purpose. (Section 5)

1.1 Terminology Used

We use the following terms throughout the paper. (1) **Model**: a deep learning classifier we want to explain, e.g., a CNN. (2) **Explanation**: an ordered list of text fragments (words or n-grams) in the input text which are most relevant to a prediction. Explanations for and against the predicted class are called **evidence** and **counter-evidence**, respectively. (3) **(Local) explanation method**: a method producing an explanation for a model and an input text. (4) **Evaluation method**: a process to quantitatively assign to explanations scores which reflect the quality of the explanation method.

2 Background and Related Work

This section discusses recent advances of explanation methods and evaluation for text classification as well as background knowledge about 1D CNNs – the model used in the experiments.

2.1 Local Explanation Methods

Generally, there are several ways to explain a result given by a deep learning model, such as explaining by examples (Kim et al., 2014) and generating textual explanations (Liu et al., 2019). For text classification in particular, most of the existing explanation methods identify parts of the input text which contribute most towards the predicted class (so called *attribution methods* or *relevance methods*) by exploiting various techniques such as input perturbation (Li et al., 2016), gradient analysis (Dimopoulos et al., 1995), and relevance propagation (Arras et al., 2017b). Besides, there are other explanation methods designed for specific deep learning architectures such as attention mechanism (Ghaeini et al., 2018) and extractive rationale generation (Lei et al., 2016).

We select some well-known explanation methods (which are applicable to CNNs for text classification) and evaluate them together with two new explanation methods proposed in this paper.

2.2 Evaluation Methods

Focusing on text classification, early works evaluated explanation methods by *word deletion* – gradually deleting words from the input text in the order of their relevance and checking how the prediction confidence drops (Arras et al., 2016; Nguyen, 2018). Arras et al. (2017a) and Xiong et al. (2018) used relevance scores generated by explanation methods to construct document vectors by weighted-averaging word vectors and checked how well traditional machine learning techniques manage these document vectors. Poerner et al. (2018) proposed two evaluation paradigms – hybrid documents and morphosyntactic agreements. Both check whether an explanation method correctly points to the (known) root cause of the prediction. Note that all of the aforementioned evaluation methods are conducted with no humans involved.

For human-grounded evaluation, Mohseni and Ragan (2018) proposed a benchmark which contains a list of relevant words for the actual class of each input text, identified by human experts. However, comparing human explanations with the explanations given by the tested method may be inappropriate since the mismatches could be due to not only the poor explanation method but also the inaccuracy of the model or the model reasoning differently from humans. Nguyen (2018) asked humans to guess the output of a text classifier, given an input text with the highest relevant words highlighted by the tested explanation method. Informative (and discriminative) explanations will lead to humans' correct guesses. Ribeiro et al. (2016) asked humans to choose a model which can generalize better by considering their local explanations. Also, they let humans remove irrelevant words, existing in the explanations, from the corpus to improve the prediction performance. Compared to previous work, our work is more comprehensive in terms of the various human-grounded evaluation tasks proposed and the number and dimensions of explanation methods being evaluated.

2.3 CNNs for Text Classification

CNNs have been found to achieve promising results in many text classification tasks (Johnson and Zhang, 2015; Gambäck and Sikdar, 2017; Zhang et al., 2019). Figure 1 shows a standard 1D CNN

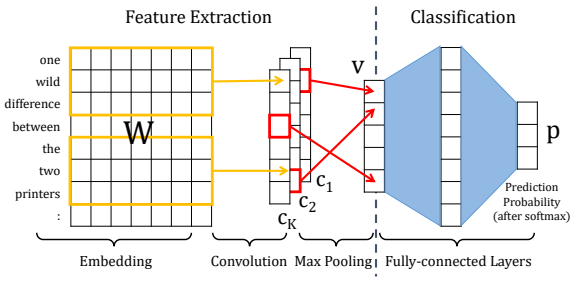

Figure 1: CNN for text classification.

for text classification which consists of four main steps: *(i)* embedding an input text into an embedded matrix $\mathbf{W}$; *(ii)* applying K fixed-size convolution filters to $\mathbf{W}$ to find n-grams that possibly discriminate one class from the others; *(iii)* pooling only the maximum value found by each filter, corresponding to the most relevant n-gram in text, to construct a filter-based feature vector, $\mathbf{v}$, of the input; and *(iv)* using fully-connected layers (FC) to predict the results, and applying a softmax function to the outputs to obtain predicted probability of the classes ($\mathbf{p}$), i.e., $\mathbf{p} = softmax(FC(\mathbf{v}))$. While the original version of this model uses only one linear layer as FC (Kim, 2014), more hidden layers can be added to increase the model capacity for prediction. Also, more than one filter size can be used to detect n-grams with short- and long-span relations (Conneau et al., 2017).

3 Human-grounded Evaluation Methods

We propose three human tasks to evaluate explanation methods for text classification as summarized in Table 1. Figure 2 gives an example question for each task, discussed next.

3.1 Revealing the Model Behavior

Task 1 evaluates whether explanations can expose irrational behavior of a poor model. This property of explanation methods is very useful when we do not have a labelled dataset to evaluate the model quantitatively. To set up the task, firstly, we train two models to make them have different performance on classifying testing examples (i.e., different capability to generalize to unseen data). Then we use these models to classify an input text and apply the explanation method of interest to explain the predictions – highlighting top-m evidence text fragments on the text for each model. Next, we ask humans, based on the highlighted texts from the two models, which model is more reasonable? If the performance of the two models is clearly different, good explanation methods should enable humans to notice the poor model, which is more likely to decide based on non-discriminative words, even though both models predict the same class for an input text.

Additionally, there are some important points to note for this task. First, the chosen input texts must be classified into the same class by both models so the humans make decisions based only on the different explanations. However, it is worth to consider both the cases where both models correctly classify and where they misclassify. Second, we provide the choices for the two models along with confidence levels for the humans to select. If they select the right model with high confidence, the explanation method will get a higher positive score. In contrast, a confident but incorrect answer results in a large negative score. Also, the humans have the option to state no preference, for which the explanation method will get a zero score (See the last row of Table 1).

3.2 Justifying the Predictions

Explanations are sometimes used by humans as the reasons for the predicted class. This task tests whether the evidence texts are truly related to the predicted class and can distinguish it from the other classes, so called *class-discriminative* (Selvaraju et al., 2017). To set up the task, we use a well-trained model and select an input example classified by this model with high confidence ($\max_c \mathbf{p}_c > \tau_h$ where τ_h is a threshold parameter), so as to reduce the cases of unclear explanations due to low model accuracy or text ambiguity. (Note that we will look at low-confidence predictions later in Task 3.) Then we show only the top-m evidence text fragments generated by the method of interest to humans and ask them to guess the class of the document containing the evidence. The explanation method which makes the humans surely guess the class predicted by the model will get a high positive score. As in the previous task, this task considers both the correct and incorrect predictions with high confidence to see how well the explanations justify each of the cases. For incorrect predictions, an explanation method gets a positive score when a human guesses the same incorrect class after seeing the explanation. In real applications, convincing explanations for incorrect classes can help humans understand the

	Task 1 (Section 3.1)	**Task 2** (Section 3.2)	**Task 3** (Section 3.3)
Assumption	Good explanations can reveal model behavior	Good explanations justify the predictions	Good explanations help humans investigate uncertain predictions
Model(s)	Two classifiers with different performance on a test dataset	One well-trained classifier	One well-trained classifier
Input text	A test example for which both classifiers predict the same class	A test example which the classifier predicts with high confidence ($\max_c \mathbf{p}_c > \tau_h$)	A test example which the classifier predicts with low confidence ($\max_c \mathbf{p}_c < \tau_l$)
Information displayed	1. The input text 2. The predicted class 3. (Highlighted) top-m evidence texts of each model	1. Top-m evidence texts	1. The predicted class 2. The predicted probability $\mathbf{p}$ 3. Top-m evidence and top-m counter-evidence texts
Human task	Select the more reasonable model and state if they are confident or not	Select the most likely class of the document which contains the evidence texts and state if they are confident or not	Select the most likely class of the input text and state if they are confident or not
Scores to the explanation method	(-)1.0: (In)correct, confident (-)0.5: (In)correct, unconfident 0.0: No preference	(-)1.0: (In)correct, confident (-)0.5: (In)correct, unconfident 0.0: No preference	(-)1.0: (In)correct, confident (-)0.5: (In)correct, unconfident

Table 1: A summary of the proposed human-grounded evaluation tasks.

model's weakness and create additional fixing examples to retrain and improve the model.

3.3 Investigating Uncertain Predictions

If an AI system makes a prediction with low confidence, it may need to raise the case with humans and let them decide, but with the analyzed results as additional information. This task aims to check if the explanations can help humans comprehend the situation and correctly classify the input text or not. To set up, we use a well-trained model and an input text classified by this model with low confidence ($\max_c \mathbf{p}_c < \tau_l$ where τ_l is a threshold parameter). Then we apply the explanation method of interest to find top-m evidence and top-m counter-evidence texts of the predicted class. We present both types of evidence to humans[1] together with the predicted class and probability $\mathbf{p}$ and ask the humans to use all the information to guess the actual class of the input text, without seeing the input text itself. The scoring criteria of this task are similar to the previous tasks except that we do not provide the "no preference" option as the humans can still rely on the predicted scores when all the explanations are unhelpful.

4 Experimental Setup

4.1 Datasets

We used two English textual datasets for the three tasks.

(1) **Amazon** Review Polarity is a sentiment analysis dataset with positive and negative classes (Zhang et al., 2015). We randomly selected 100K, 50K, and 100K examples for training, validating, and testing the CNN models, respectively.

(2) **ArXiv** Abstract is a text classification dataset we created by collecting abstracts of scientific articles publicly available on ArXiv[2]. Particularly, we collected abstracts from the "Computer Science (CS)", "Mathematics (MA)", and "Physics (PH)" categories, which are the three main categories on ArXiv. We then created a dataset with three disjoint classes removing the abstracts which belong to more than one of the three categories. In the experiments, we randomly selected 6K, 1.5K, and 10K examples for training, validating, and testing the CNN model, respectively.

4.2 Classification Models: 1D CNNs

As for the classifiers, we used 1D CNNs with the same structures for all the tasks and datasets. Specifically, we used 200-dim GloVe vectors as non-trainable weights in the embedding layer (Pennington et al., 2014). The convolution layer had three filter sizes [2, 3, 4] with 50 filters for each size, while the intermediate fully-connected layer had 150 units. The activation functions of the filters and the fully-connected layers are ReLU (except the softmax at the output layer). The models were implemented using Keras and trained with Adam optimizer. The macro-average F1 are 0.90 and 0.94 for the Amazon and the ArXiv datasets, respectively. Overall, the ArXiv appears to be an easier task as it is likely solvable by looking at individual keywords. In contrast, the Ama-

[1] We present counter-evidence as evidence for the other classes to simplify the task questions.

[2] https://arxiv.org

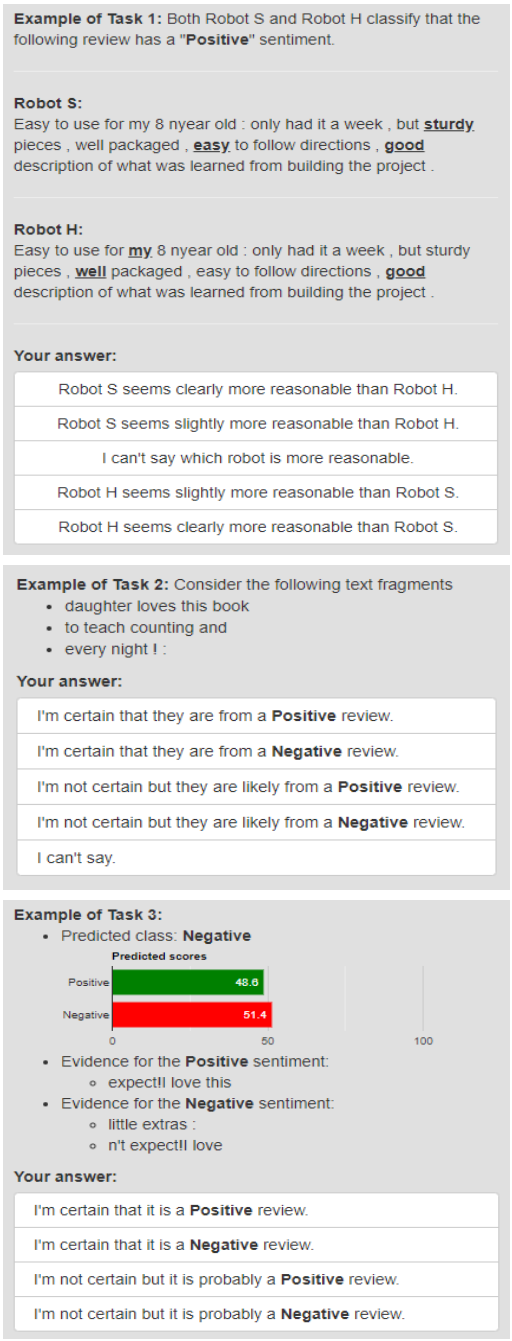

Figure 2: Example questions and user interfaces.

zon sentiment analysis is not quite easy. Many reviews mention both pros and cons of the products, so a classifier needs to analyze several parts of the input to reach a conclusion. However, this is still manageable by the CNN architecture we used.

Also, in task 1, we need another model which performs worse than the well-trained model. In this experiment, we trained the second CNNs (i.e., the worse models) for the two datasets in different ways to examine the capability of explanation methods in two different scenarios. For the Amazon dataset, while the first (well-trained) CNN needed eight epochs until the validation loss converges, we trained the second CNN for only one epoch to make it underfitting. For the ArXiv dataset, we trained the second CNN using the same number of examples as the first model but with more specific topics. To explain, we randomly selected only examples from the subclass 'Computation and Language', 'Dynamical Systems', and 'Quantum Physics' as training and validation examples for the class 'Computer Science', 'Mathematics', and 'Physics', respectively. In other words, the training and testing data of the worse CNN came from different distributions. As a result, the macro-average F1 of the worse CNNs are 0.81 and 0.85 for the Amazon and the ArXiv datasets, respectively.

Method Name	Approach	Granularity
Random (W)	Random Baselines	Words
Random (N)		N-grams
LIME	Perturbation	Words
LRP (W)	Relevance Propagation	Words
LRP (N)		N-grams
DeepLIFT (W)		Words
DeepLIFT (N)		N-grams
Grad-CAM-Text	Gradient	N-grams
Decision Trees (DTs)	Model Extraction	N-grams

Table 2: Nine explanation methods evaluated.

4.3 Explanation Methods

We evaluated nine explanation methods as summarized in Table 2. First, we used Random (W) and Random (N) as two baselines selecting words and non-overlapping n-grams randomly from the input text as evidence and counter-evidence. For the n-gram random baseline (and other n-gram based explanation methods in this paper), n is one of the CNN filter sizes [2, 3, 4].

Second, we selected LIME which is a well-known model-agnostic perturbation-based method (Ribeiro et al., 2016). It trains a linear model using samples (5,000 samples in this paper) around the input text to explain the importance of each word towards the prediction. The importance scores can be either positive (for the predicted class) or negative (against the predicted class).

Third, we selected layer-wise relevance propagation (LRP), specifically ϵ-LRP (Bach et al., 2015b), and DeepLIFT (Shrikumar et al., 2017) which are applicable to neural networks in general and performed very well in several evalua-

tions using proxy tasks (Xiong et al., 2018; Poerner et al., 2018). LRP propagates the output of the target class (before softmax) back through layers to find attributing words, while DeepLIFT does the same but propagates the difference between the output and the predicted output of the reference input (i.e., all-zero embeddings in this paper). These two methods assign relevance scores to every word in the input text. Words with the highest and the lowest scores are selected as evidence for and counter-evidence against the predicted class, respectively. Also, we extended LRP and DeepLIFT to generate explanations at an n-gram level. We considered all possible n-grams in the input text where n is one of the CNN filter sizes. Then the explanations are generated based on the relevance score of each n-gram, i.e., the sum of relevance scores of all words in the n-gram.

Next, we searched for model-specific explanation methods which target 1D CNNs for text classification. We found that Jacovi et al. (2018) proposed one: listing only n-grams corresponding to feature values in $\mathbf{v}$ (see Figure 1) that pass thresholds for their filters. Each of the thresholds is set subject to sufficient purity of the classification results above it. However, their method is applicable to CNNs with only one linear layer as FC, while our CNNs have an additional hidden layer (with ReLU activation). So, we could not compare with their method in this work. To increase diversity in the experiments, we therefore propose two additional model-specific methods applicable to 1D CNNs with multiple layers in FC, presented next.

4.3.1 Grad-CAM-Text

We adapt Grad-CAM (Selvaraju et al., 2017), originally devised for explaining 2D CNNs, to find the most relevant n-grams for text classification. Since each value in the feature vector $\mathbf{v}$ corresponds to an n-gram selected by a filter, we use $E_{j,k}$ to show the effect of an n-gram selected by the k^{th} filter towards the prediction of class j:

$$E_{j,k} = |\max(\frac{\partial FC(\mathbf{v})_j}{\partial \mathbf{v}_k}, 0)| \times \mathbf{v}_k. \quad (1)$$

The partial derivative term shows how much the prediction of class j changes if the value from the k^{th} filter slightly changes. As we are finding the evidence for the target class j, we consider only the positive value of the derivative. Then $E_{j,k}$ combines this term with the strength of $\mathbf{v}_k$ to show the overall effect of the k^{th} filter for the input text. Next, we calculate the effect of each word w_i in the input text by aggregating the effects of all the n-grams containing w_i.

$$E_{j,w_i} = \sum_k (E_{j,k} \times \mathbb{I}[w_i \in N_k])$$

where N_k is an n-gram detected by the k^{th} filter. Lastly, we select, as the evidence, non-overlapping n-grams which are detected by at least one of the filters and have the highest sums of the effects of all the words they contain. For example, to decide whether we will select the n-gram N_k as an evidence text or not, we consider $\sum_{w_i \in N_k} E_{j,w_i}$. Note that we can find counter-evidence by changing, in equation (1), from $\max$ to $\min$.

4.3.2 Decision Trees

This explanation method is based on model extraction (Bastani et al., 2017). We create a decision tree (DT) which mimics the behavior of the classification part (fully-connected layers) of the trained CNN. Given a filter-based feature vector $\mathbf{v}$, the DT needs to predict the same class as predicted by the CNN. Formally, we want

$$DT(\mathbf{v}) = \underset{j}{\text{argmax}}\, \mathbf{p}_j = \underset{j}{\text{argmax}}\, FC(\mathbf{v})_j.$$

For multi-class classification, we construct one DT for each class (one vs. rest classification). We employ CART with Gini index for learning DTs (Leo et al., 1984). All the training examples are generated by the trained CNN using a training dataset, whereas a validation dataset is used to prune the DTs to prevent overfitting.

Also, for each feature v_j in $\mathbf{v}$, we calculate the Pearson's correlation between v_j and the output of each class (before softmax) in $FC(\mathbf{v})$ using the training dataset, so we know which class is usually predicted given a high score of v_j (i.e., correlated most to this feature). We use c_j denoting the most correlated class of the feature v_j.

We can consider the DTs as a global explanation of the model as it explains the CNN in general. To create a local explanation, we use the DT of the predicted class to classify the input. At each decision node, we collect associated n-grams passing the nodes' thresholds to be evidence for (or counter-evidence against) the predicted class (depending on the most correlated class of each splitting feature). For example, an input text X is classified to class a, so we use the DT of class a to predict the input. If a decision node checks whether feature v_j of this input is greater than 0.25 and assume it is true for this input, the n-gram corresponding to v_j will be evidence if the most correlated class of v_j is class a (i.e., $c_j = a$). Otherwise, it will be counter-evidence if $c_j \neq a$.

An example from the Amazon dataset, Actual: Pos, Predicted: Pos, (Predicted scores: Pos 0.514, Neg 0.486):
"*OK but not what I wanted: These would be ok but I didn't realize just how big they are. I wanted something I could actually cook with. They are a full 12" long. The handles didn't fit comfortably in my hand and the silicon tips are hard, not rubbery texture like I'd imagined. The tips open to about 6" between them. Hope this helps someone else know ...*"

Method	Top-3 evidence texts	Top-3 counter-evidence texts
LIME (W)	comfortably / wanted / helps	not / else / someone
LRP (W)	are / not / 6	: / tips / open
LRP (N)	are hard , not / about 6" between / not what I wanted	. The tips open / : These would / in my hand and
Grad-CAM-Text (N)	comfortably in my hand / I wanted : These / . The tips open	not what I wanted / not rubbery texture like / Hope this helps someone
DTs (N)	imagined . The tips	'd imagined . / are . I wanted / would be ok

Table 3: Examples of evidence and counter-evidence texts generated by some of the explanation methods.

4.4 Implementations[3]

We used public libraries of LIME[4], LRP (Alber et al., 2018), and DeepLIFT[5] in our experiments. Besides, the code for computing Grad-CAM-Text was adapted from keras-vis[6], whereas we used scikit-learn (Pedregosa et al., 2011) for decision tree construction. All the DTs achieved over 80% macro-F1 in mimicking the CNNs' predictions.

For the task parameters, we set $m = 3$, $\tau_h = 0.9$, and $\tau_l = 0.7$. For each task and dataset, we used 100 input texts, half of which were classified correctly by the model(s) and the rest were misclassified. So, with nine explanation methods being evaluated, each task had 900 questions per dataset for human participants to answer. Examples of questions for each task are given in Figure 2.

For the Amazon dataset, we posted our tasks on Amazon Mechanical Turk (MTurk). To ensure the quality of crowdsourcing, each question was answered by three workers and the scores were averaged. For the ArXiv dataset which requires background knowledge of the related subjects, we recruited graduates and post-graduate students in Computer Science, Mathematics, Physics, and Engineering to perform the tasks, and each question was answered by one participant. In total, we had 367 and 121 participants for the Amazon and the ArXiv datasets, respectively.

5 Results and Discussion

Examples of the generated explanations are shown in Table 3 and a separate appendix. Table 4 shows the average scores of each explanation method for each task and dataset, while Figure 3 displays the distributions of individual scores for all three tasks. We do not show the distributions of tasks 2 and 3 of the Amazon dataset as they look similar to the associated ones of the ArXiv dataset.

5.1 Task 1

For the Amazon dataset, though Grad-CAM-Text achieved the highest overall score, the performance was not significantly different from other methods including the random baselines. Also, the inter-rater agreement for this task was quite poor. It suggests that existing explanation methods cannot apparently reveal irrational behavior of the underfitting CNN to lay human users. So, the scores of most explanation methods distribute symmetrically around zero, as shown in Figure 3(a).

For the ArXiv dataset, LRP (N) and DeepLIFT (N) got the highest scores when both CNNs predicted correctly. Hence, they can help humans identify the poor model to some extent. However, there was no clear winner when both CNNs predicted wrongly. One plausible reason is that evidence for an incorrect prediction, even by a well-trained CNN, is usually not convincing unless we set a (high) lower bound of the confidence of the predictions (as we did in task 2).

Additionally, we found that psychological factors fairly affect this task. Based on the results, for two explanations with comparable semantic quality, humans prefer the explanation with more evidence texts and select it as more reasonable. This is consistent with the findings by Zemla et al. (2017). Conversely, the DTs method performed in the opposite way. The DT of the better model usually focuses on a few most relevant texts in the input and outputs fewer evidence texts. This possibly causes the low performance of the DTs method in this task. Also, we got feedback from the participants that they sometimes penalized an evidence

Table 4: The average scores of the three evaluation tasks. The score range is [-1,1] in which 1 is better. $\mathcal{A}$, ✔, and ✘are for all, correctly classified, and misclassified input texts, respectively. Boldface numbers are the highest average scores in the columns. A number is underlined when there is no statistically significant difference between the scores of the corresponding method and the best method in the same column (at a significance level of 0.05). The last row reports inter-rater agreement measures (Fleiss' kappa) in the format of α / β where α considers answers with human confidence levels (5 categories for task 1-2 and 4 categories for task 3) and β considers answers regardless of the human confidence levels (3 categories for task 1-2 and 2 categories for task 3).

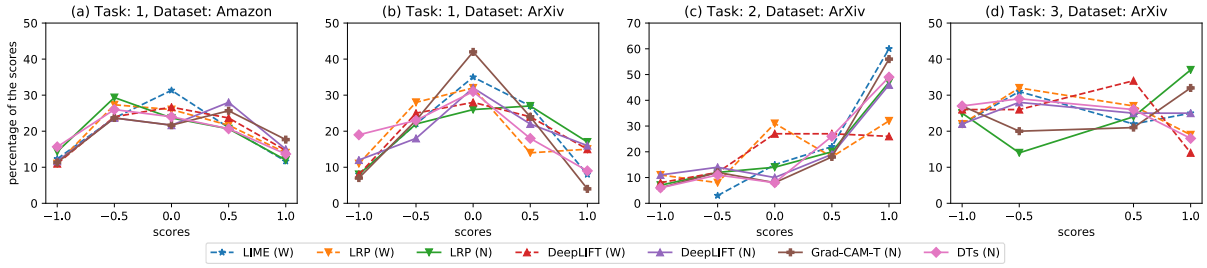

Figure 3: Score distributions from task 1 of the Amazon dataset and from all the tasks of the ArXiv dataset.

text which is highlighted in a strange way, such as "... greedy algorithm. In this paper, we ...". Hence, in real applications, syntax integrity should be taken into account to generate explanations.

5.2 Task 2

LIME clearly achieved the best results in task 2 followed by Grad-CAM-Text and DTs. These methods are class discriminative, being able to find good evidence for the predicted class regardless of whether the prediction is correct.

We believe that LIME performed well because it tests that the missing of evidence words from the input text greatly reduces the probability of the predicted class, so these words are semantically related to the predicted class (given that the model is accurate). Meanwhile, the DTs method selects evidence based on the most correlated class of the splitting features. So, the evidence n-grams are more likely related to the predicted class than the other classes. However, they may be less relevant than LIME's as the evidence is generated from a global explanation of the model (DTs). Besides, Grad-CAM-Text worked relatively well here probably because it preserves the class discriminative property of Grad-CAM (Selvaraju et al., 2017).

By contrast, LRP and DeepLIFT generated acceptable evidence only for the correct predictions. Also, LRP (N) and DeepLIFT (N) performed better than LRP (W) and DeepLIFT (W) in both datasets. This might be because one evidence n-gram contains more information than one evidence word. Nevertheless, even the Random (N) method surpasses the LRP (W) and the DeepLIFT (W) for the ArXiv dataset. Thereby, whenever we use LRP and DeepLIFT, we should present to humans the most relevant words together with their contexts.

5.3 Task 3

The negative scores under the ✘columns of task 3 show that using explanations to rectify the predictions is not easy. Hence, the overall average scores of many explanation methods stay close to zero.

DTs performed well only on the Amazon dataset. The average numbers of n-grams per explanation, generated by the DTs, are 2.00 and 1.77

for the Amazon and ArXiv datasets, respectively. Also, the reported n-grams could be repetitive and overlapping. This reduced the amount of useful information displayed, and it may be insufficient for humans to choose one of the CS, MA, and PH categories, which are more similar to one another than the positive and negative sentiments.

Meanwhile, LRP (N) performed consistently well on both datasets. This is reasonable considering our discussions in task 2. First, LRP (N) generates good evidence for correct predictions, so it can gain high scores in the ✔columns. On the other hand, the evidence for incorrect predictions (✘) is usually not convincing, so the counter-evidence (which is likely to be the evidence of the correct class) can attract humans' attention. Furthermore, the fact that LRP is not class discriminative does not harm it in this task as humans can recognize an evidence text even if it is selected by the LRP (N) as counter-evidence (and vice versa).

For example, in the ArXiv dataset, we found a case in which the predicted class is PH (score = 0.48) but the correct class is CS (score = 0.07). LRP (N) selected 'armed bandit settings with', 'the Wasserstein distance', and 'derive policy gradients' as evidence for the class PH. These n-grams, however, are not truly related to PH. Rather, they revealed the true class of this text and made a human choose the CS option with high confidence despite the low predicted score.

Regarding LIME, the situation is reversed as LIME can find both good evidence and counter-evidence. These make humans be indecisive and, possibly, select a wrong option as the explanation is presented at a word level (without any contexts).

5.4 Model Complexity

Apart from the results of the three tasks, it is worth to discuss the size of the DTs which mimic the four CNNs in our experiments. As shown in Table 5, the size of the DTs can reflect the complexity of the CNNs. Although the well-trained CNN of the Amazon dataset got 0.9 F1 score, the DTs of this CNN needed more than 5,500 nodes to achieve 85% fidelity (compared to only hundreds of nodes required for the ArXiv dataset). This illustrates the high complexity of the Amazon task compared to the ArXiv task even though both tasks were managed effectively by the same CNN architecture.

For the ArXiv dataset, the DTs of the poor CNN are smaller than the ones of the well-trained CNN.

	#Nodes	Depth	#Leaves
Amazon: 1st CNN (well-trained) – $F = 0.85$			
Negative	5535	38	2768
Positive	5537	45	2769
Amazon: 2nd CNN (underfitting) – $F = 0.82$			
Negative	6405	40	3203
Positive	6369	40	3185
ArXiv: 1st CNN (well-trained) – $F = 0.89$			
Computer Science	363	25	182
Mathematics	565	24	283
Physics	325	24	163
ArXiv: 2nd CNN (specific data) – $F = 0.84$			
Computer Science	107	17	54
Mathematics	263	28	132
Physics	237	29	119

Table 5: Metadata of the DTs in the experiments. F refers to fidelity of the DTs (macro-average F1).

This is likely because the poor CNN was trained on a specific dataset (i.e., selected subtopics of the main categories), so it had to deal with fewer discriminative patterns in texts compared to the first CNN trained using texts from all subtopics.

Further studies of this quality of the DTs would be useful for some applications, e.g., measuring model complexity (Bianchini and Scarselli, 2014) and model compression (Cheng et al., 2018).

6 Conclusion

We proposed three human tasks to evaluate local explanation methods for text classification. Using the tasks in this paper, we experimented on 1D CNNs and found that *(i)* LIME is the most class discriminative method, justifying predictions with relevant evidence; *(ii)* LRP (N) works fairly well in helping humans investigate uncertain predictions; *(iii)* using explanations to reveal model behavior is challenging, and none of the methods achieved impressive results; *(iv)* whenever using LRP and DeepLIFT, we should present to humans the most relevant words together with their contexts and *(v)* the size of the DTs can also reflect the model complexity. Lastly, we consider evaluating on other datasets and other advanced architectures beneficial future work as it may reveal further interesting qualities of the explanation methods.

Acknowledgments

We would like to thank all the participants in the experiments as well as Alon Jacovi and anonymous reviewers for helpful comments. Also, the first author would like to thank the support from Anandamahidol Foundation, Thailand.

Abstract

We introduce a new task of *modeling the role and function for on-line resource citations in scientific literature*. By categorizing the on-line resources and analyzing the purpose of resource citations in scientific texts, it can greatly help resource search and recommendation systems to better understand and manage the scientific resources. For this novel task, we are the first to create an annotation scheme, which models the different granularity of information from a hierarchical perspective. And we construct a dataset SciRes, which includes 3,088 manually annotated resource contexts. In this paper, we propose a possible solution by using a multi-task framework to build the scientific resource classifier (SciResCLF) for jointly recognizing the role and function types. Then we use the classification results to help a scientific resource recommendation (SciResREC) task. Experiments show that our model achieves the best results on both the classification task and the recommendation task. The SciRes dataset[1] will be released for future research.

1 Introduction

In this paper, we introduce a new task of *modeling the role and function for on-line resource citations in scientific literature*. With the number of scientific publications growing dramatically, numerous on-line resources are mentioned, released and used within the scientific literature. Tracing and modeling these resources such as software, tools and datasets can greatly help researchers by developing scientific resource searching and recommendation systems or constructing scientific resource knowledge graphs. Google has launched a new search engine[2] in 2018 to help scientists find the datasets they need, whereas the retrieved datasets can only be matched with their official names. Other current academic search engines such as Google Scholar can be only used for detecting the relevant papers where a certain resource is mentioned. However, the limitation actually exists is that the user can not learn more fine-grained information such as what role the resource plays in its paper and why the resource is cited in its contexts. To improve present works, we propose a context-based framework to model both the *resource role* and the *resource function* for on-line resource citations in scientific literature.

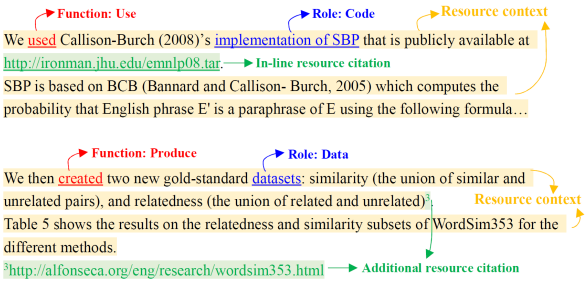

Figure 1: Examples for the two types of resource citations in scientific literature. We note the arguments (which are mostly the key verbs before the citation) for identifying the resource function and the arguments (which are mostly the target nominals before the citation) for identifying the resource role.

As is shown in Figure 1, we give examples for the two types of resource citations considering their appearances in the original publications. Through observing more than three hundred scientific publications from different domains of computer science, we find that most resource citations can be divided into two types according to the locations of their hyperlinks: the **in-line resource citations** in bodytexts and the **additional resource citations** in footnotes. We define a **resource citation** as a hyperlink mentioned in the

scientific paper text, which links to a specific on-line resource. A **resource context** is a word sequence surrounding the resource citation. As Figure 1 shows, we set the context window size to 5 in our work. So that the context includes the sentence where the hyperlink is mentioned, the two sentences to the left and the two to the right. The **resource role** is the class of a resource indicating what role the resource plays in its context (e.g. *Code* and *Data* in Figure 1). The **resource function** is the specific purpose performed by the resource with respect to the current paper's work, indicating why the author has cited this resource here (e.g. *Use* and *Produce* in Figure 1). It's necessary to note that one resource may have different functions in a same paper due to the different contexts.

The information of resource role and function is very important for building applications to assist scientific research. To help develop more powerful resource search systems, identifying the role can enrich the resource repository and identifying the function is crucial for understanding more complicated queries and providing more accurate results. Moreover, to help researchers quickly be acquainted with the scientific resources and easily find applicable resources for their work, the scientific resource recommendation system will have great application prospects in the future. Previous works mostly make the efforts on the task of *citation function classification* (Teufel et al., 2006; Jurgens et al., 2018) and the task of *context-based citation recommendation* (Tang and Zhang, 2009; He et al., 2011; Huang et al., 2015). Different from previous works, our work specially focuses on the on-line resources in scientific text, which are not as well studied as the paper citations. To the best of our knowledge, we are the first to model the on-line resource citations on such a fine-grained level in scientific full text.

In this paper, we first propose a new annotation scheme, which models both the general role types and the fine-grained role types from a two-hierarchy perspective, and models the function types by analyzing the purpose of citing the resources. Based on the scheme, we construct a dataset SciRes by manually annotating more than three thousand resource contexts. To better classify each on-line resource citation and benefit from the associated information between roles and functions, we apply a multi-task framework SciResCLF, which jointly identifies the resource role types and the resource function types based on the word sequences of resource contexts. Experiments show that our model outperforms all the baselines on the classification task. We further address a context-based resource recommendation task and develop a framework SciResREC, which predicts the resource hyperlinks only given the masked resource contexts. Using the classification results, our model achieves good performance by the help of the role and function information in the recommendation task.

In summary, we make the following contributions. We introduce a novel task of modeling fine-grained information, especially the resource role and the resource function of scientific on-line resource citations. For this task, we propose a new annotation scheme and create a dataset for resource classification. We develop a multi-task learning model which can jointly identify the general role types, fine-grained role types and functions for the resource citations. Based on our united classifier we solve a resource recommendation task and analyze the evolution and maturity of the scientific resources.

2 Related Work

Context-based Citation Analysis

Context-based citation analysis addresses a citation's value by interpreting each citation based on its context at both the syntactic and semantic levels. One research focus is the *citation function*, which is defined as the authors reason for citing a given paper. Specific schemes for classifying the function of a citation have been developed (Teufel et al., 2006; Liakata et al., 2012; Jurgens et al., 2018). Jurgens et al. (2018) did their efforts to measure the evolution of a scientific field by framing the citation function. In the past years, many annotation schemes and approaches for identifying arguments in various domains have been developed. Following these previous schemes, we develop our annotation scheme especially for modeling the role and function for scientific resource, which will be detailed in Section 3. Other previous studies focus on the *context-based citation recommendation* (Tang and Zhang, 2009; He et al., 2010, 2011; Huang et al., 2012, 2015), which aims to recommend a short list of papers that need to be cited within the given context. A citation context is defined as a sequence

	#Bodytext	#Footnote	Total	Annotation
ARC	3,718	15,043	18,761	1,026
NeurIPS	686	896	1,582	1,056
PUBMED	31,852	510	32,362	1,006
Total	36,256	16,449	52,705	3,088

Table 1: A description for the collection of 52,705 data sample in the scientific resource corpus.

of words that appear around a particular citation. Based on this definition, we develop the concepts of *resource citation* and *resource context* in this paper.

Resource Discovery for Scientific Text

There are also some relevant research which focus on detecting resources in biomedical literature. Some approaches to this end are reported in (Duck et al., 2012, 2014, 2016; Yamamoto and Takagi, 2007; de la Calle et al., 2009). Yamamoto and Takagi (2007) crawled abstracts from MEDLINE and full text from BioMed to extract the URLs of resources using regular expressions and heuristic rules. The BIRI addressed by de la Calle et al. (2009) utilized handcrafted regular expressions expressed as transition networks for resource naming, functionality detection and resource classification to generate resource inventories. Duck et al. (2012) proposed the BioNERDS, which is a NER system for detecting database and software names in scientific literature using extraction rules generated by examining 30 bioinformatics articles. However, there has been no existing framework for modeling the resource role and function at such a fine-grained level in general domain scientific text.

3 Dataset

There are some current scientific literature datasets (e.g. Semantic Scholar Open Research Corpus[3] and Arxiv Dataset[4]) contain the structured metadata such as title, author and abstract. While as is illustrated in Figure 1, most on-line resource citations are placed in the full texts of the papers. We need to locate the resource citations and extract the resource contexts first to perform further analysis. To the best of our knowledge, due to the difficulties in collecting large scale of scientific full texts from the PDF publications, there is no ready-to-use dataset for our task. Hence we collect a large scientific resource context corpus of 52,705 data samples and construct a manually annotated dataset (called **SciRes**) which includes annotations for the resource role types and the resource function types. SciRes attempts to interpret the role of resource citations from a hierarchical perspective, with both the general role types and more fine-grained role types. And SciRes aims at understanding the author's intention of citing a resource by the function types. We hope the SciRes can facilitate future research for context-based resource analyzing in scientific literature.

3.1 Data Processing

We used the paper full texts from three different sources: the ACL Anthology Reference Corpus (ARC)[5], a corpus of scientific publications about computational linguistics; the NeurIPS Proceedings (NeurIPS)[6], a corpus of conference proceedings about neural information; and the PubMed[7], an archive of biomedical and life sciences journal literature. We collected 21,411 papers of ARC up to 2015, 7,147 papers of NeurIPS from 1988 to 2017, and randomly downloaded 11,043 publications from PubMed. For each paper in the corpus, we downloaded the PDF and used Omnipage[8] to perform OCR in translating the files to characters with coordinates and properties. So that we can detect the footnotes and find their anchors in the bodytext by developing some regular expression filters. Then we applied a conditional random field-based parsing tool, ParsCit[9] to get the structural raw text. To build the SciRes dataset we first extracted all the hyperlinks as resource citations in a scientific paper from both the bodytexts and the footnotes. Three PhD students from the above three fields were asked to read 200 randomly selected resource contexts to investigate the context window size. It was found that 95% samples can be determined the resource role and function types by getting across the 5 sentences around the citations. So we set the window size to 5 and extracted the sentences along with each hyperlink as the resource context. Finally, we construct a collection of 52,705 data samples, with a detailed description shown in Table 1.

3.2 Annotation Scheme

Many annotation schemes for the citation functions have been created over the past years (Teufel et al., 2006; Liakata et al., 2012; Jurgens et al., 2018). Based on these previous works and some recent annotation schemes for ScienceIE (Luan et al., 2017; Augenstein et al., 2017; Zhao et al., 2019), we address our scheme:

3 general (1st-category) Role types: Material, Method, Supplement.

9 fine-grained (2nd-category) Role types: Data, Tool, Code, Algorithm, Document, Website, Paper, License, Media.

6 Function types: Use, Produce, Introduce, Extend, Compare, Other.

The hierarchical relationships between 1st-category role types and 2nd-category role types are shown in Table 2. More detailed definitions and examples for each type can be found in the Appendix. Annotations were performed by a group of 3 PhD students, of which one majors in NLP, one majors in deep learning and another majors in bioinformatics. We randomly selected 1,100 data samples from each scientific literature source. Since too short text might not cover sufficient information for identifying the target role and function types, we filtered out the samples of which the context sequence had less than 10 words. Each resource citation together with its context was assigned at least one label for the general role types, one label for the fine-grained role types and a unique label for the function types. Fleiss's Kappa (κ) is 0.79 for the 1st-category resource role, 0.54 for the 2nd-category resource role and 0.65 for the resource function, indicating a relatively high agreement between annotators considering the number of class and the difficulties of the fine-grained classification task. The decision is made by a majority rule when a conflict occurs. Finally we obtained the manually annotated SciRes dataset of 3,088 data samples. All the function and role types along with their statistics are shown in Table 2 and Table 3.

	#ARC	#NeurIPS	#PUBMED	Total	%
Use	560	578	347	1,485	48.1
Produce	125	308	201	634	20.5
Introduce	254	89	281	624	20.2
Extend	53	30	39	122	4.0
Other	17	1	106	124	4.0
Compare	18	50	30	98	3.2

Table 3: The 6 *resource function* types along with their statistics in **SciRes** from three scientific literature sources.

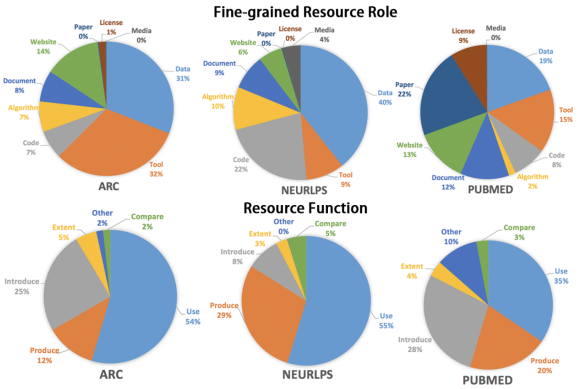

Figure 2: The distributions of resource role and function types in different data sources.

For the more fine-grained role types, the distribution is very skewed. The majority of 2-nd category roles are Data (31.0%) and then come the Tool (19.0%) and the Code (13.0%). The majority of functions are Use (48.1%) while the Compare (3.2%) and Extend (4.0%) are much fewer. The existence of a large imbalance between the types bring challenges for our classification task. There are also some findings when comparing the distributions of roles and functions between different data sources, as shown in Figure 2. For the fine-grained resource roles, the ARC dataset has relatively more Tools reflecting that there are more re-

search about NLP applications in the ARC. While the more theoretical NeurIPS has least Tools but most Algorithm and Data citations. Instead of the packaged software, the papers from NeurIPS prefer the implementations in codebases. Furthermore, due to the difference of article formats and writing styles in different domains, the papers in the field of bioinformatics from the PubMed tend to link papers by in-line hyperlinks in bodytexts while the papers from the ARC and the NeurIPS tend to cite papers in reference lists. For the resource functions, we can see that the papers from the NeurIPS tend to produce or release more new resources while the papers from the ARC and the PubMed tend to introduce more resources as background to support their works. We assume the difference in the resource function is because that the research from the NeurIPS are more theory-based and often put forward new methodologies, whereas the research from the ARC and the PubMed are more comprehensive and contain more application-oriented works which tend to review many related resources.

4 Classification Model

To identify the resource role types and the resource function types for the resource citations, we apply a multi-task learning framework, called **SciResCLF** to jointly classify the 1-st category roles, the 2-nd category roles and the functions by sharing the resource context representations as classification features. Figure 3 shows an overall architecture of our SciResCLF framework.

Based on our SciRes dataset, many challenges make the classification task not easy. First, it is important to parse, encode and model the semantic information in the resource citation contexts, which are relatively short texts having no more than 5 sentences. Second, as the examples shown in Figure 1, by observing the data samples we find in most cases some key nominals or verbs located nearby the citations can imply the role and function types of the resources (e.g. the nearest verb before a resource citation such as "use", "apply" or "adopt" often indicates the function of **Use**). For this reason, the relative positions of the words in the sequence is very significant information to be considered in our task. Furthermore, due to the limited labeled data most neural-based models with a large number of parameters can not be trained well.Therefore, effective methods for solving these particular challenges need to be developed for this new scientific resource classification task.

From the SciRes dataset we can find that there is a strong correlation between the role type and the function type for a resource citation in its context. To better incorporate the associated information, for our classification task we adopt a multi-task setup, which has been proven effective in the ScienceIE problems (Augenstein et al., 2017; Luan et al., 2018). Recently, the pre-trained language models, such as ELMo (Peters et al., 2018), OpenAI GPT (Radford, 2018), and BERT (Devlin et al., 2018), have shown their effectiveness to alleviate the effort of feature engineering. Especially, BERT has achieved excellent results in text classification problems such as sentiment analysis (Sun et al., 2019; Xu et al., 2019) and document classification (Adhikari et al., 2019). Based on previous works, our framework also takes advantage of the pre-trained BERT model to learn contextualized representations for the resource contexts, as shown in Figure 3. To adapt BERT to our classification tasks, following Devlin et al. (2018) we first get the hidden state corresponding to the $[CLS]$ input token. Then the hidden representation h is passed into three separate softmax layers: $\mathbf{L}_{1st_role} = softmax(W_1 h + b_1)$, $\mathbf{L}_{2nd_role} = softmax(W_2 h + b_2)$, $\mathbf{L}_{func} = softmax(W_3 h + b_3)$, where $W_1, W_2, W_3 \in \mathrm{R}^{r_h}$, $h1, h2, h3 \in \mathrm{R}$ and r_h is the size of the hidden dimension. So that given the word sequence input of a resource context, the total loss $\mathbf{L}_{CLF}$ is defined as a weighted sum of the cross entropy loss of the three multinomial classification tasks:

$$\mathbf{L}_{CLF} = \alpha \mathbf{L}_{1st_role} + \beta \mathbf{L}_{2nd_role} + \gamma \mathbf{L}_{func} \quad (1)$$

5 Recommendation Model

To show a practical application scenario of modeling the role and function for scientific resource citations, we further address a new resource recommendation task. The problem takes the scientific text sentences about an indexed resource as a query and aims to predict the hyperlink of a possible on-line resource to fill the citation blank of a resource context. We first give the formalized definition for the resource recommendation task. The input is the word sequence of a resource context $C = \{w_{n-l}, ..., w_{n-1}, w_n, w_{n+1}, ..., w_{n+r}\}$, in which w_n is a placeholder "[URL]" of the resource hyperlink, l is the length of the sequence

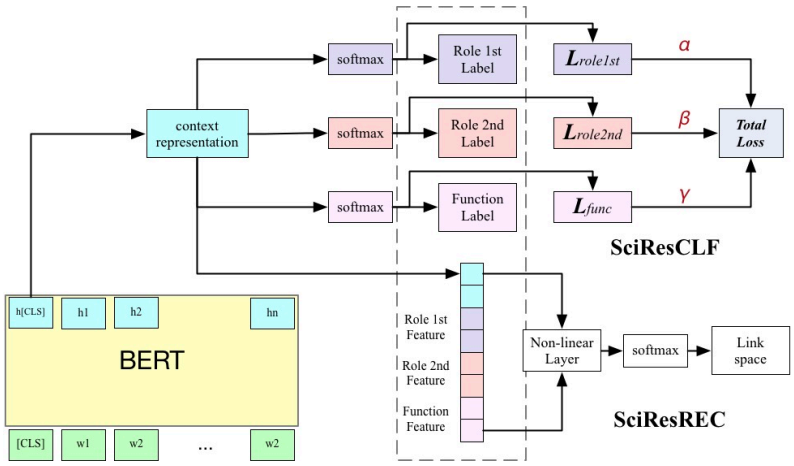

Figure 3: The overall architecture of the SciResCLF and the SciResREC.

left to the hyperlink and r is the length of the sequence right to the hyperlink. To eliminate the information of the original resource citation, we mask the resource names mentioned in the resource context. So that the resource hyperlink can only be determined by the other words related to the target resource from the context query. The output is a ranking list, which contains the top N possible predictions from the resource hyperlink space.

For this task, we develop a framework, called **SciResREC** to predict the resource hyperlinks by learning information of the resource contexts and benefiting from the classification results of the SciResCLF. Figure 3 also shows a high-level overview of the SciResREC framework. For each input resource context sequence, we first apply the SciResCLF to respectively get the output results of the 1-st category role classifier, the 2-nd category role classifier and the function classifier. To incorporate the role and function information, the three classification labels are used as features for predicting the resource hyperlinks. In SciResREC, we use the same pre-trained BERT encoder to learn context representations. Then the hidden output $h_{[CLS]}$ is concatenated with the three label representations, which is passed to a non-linear layer with the ReLU activation function. Hence the recommendation task is transformed into a multi-class classification problem which maps the context feature vectors into the resource hyperlink space.

6 Experiments

6.1 Data and Metrics

To test the performance of SciResCLF, we do experiments on our SciRes dataset, which is split into 3 parts: 80% for training, 10% for testing and 10% for developing. To overcome the class imbalance, we utilize an up-sampling strategy by simply replicating the minority class samples. We respectively deploy the up-sampling strategy for three classification tasks to get the best model for each task. The strategy is only deployed on the training set while not on the testing and developing sets. Finally we get 2,988 data samples for training the 1st-category role classifier, 7,236 for the 2nd-category role classifier and 7,404 for the function classifier. The testing and developing sets are shared by the three tasks, both with 334 samples. The size of the dataset is relatively small to perform most neural-based methods, but we will show that our model can achieve good performance with even limited labeled data. For evaluation, we report the micro-F1 score and the macro-F1 score across the role and function types.

To build the training set for SciResREC, we first collect all the resource contexts and the citation hyperlinks from the ARC dataset (including articles up to December 2015). We select the top 100 most frequent resources and add their hyperlinks into the hyperlink space. For testing, we extract resource contexts from the publications of ACL2016, ACL2017, EMNLP2016 and EMNLP2017 and select the ones of which the hyperlink exists in the space. For each context, either the in-line resource citation or the additional resource citation is replaced by a "[URL]"

Table 4: Comparison results of SciResCLF for the three classification tasks.

placeholder. And the words of resource name are masked with a "[MASK]" token. Finally we get a training set of 2,910 samples and a testing set of 235 samples. To evaluate the predicted ranking list, we report the Precision@Top3 and the MAP metrics.

6.2 Baselines and Setups

For the classification task, we compare the SciResCLF with widely used context classification approaches on the SciRes: **Average Embedding + LR/SVM**, two machine learning algorithms, logistic regression (LR) and SVM, using the average of word embeddings as input; **FastText**, an implementation for FastText of Joulin et al. (2017); **CNN**, an implementation for TextCNN of Kim (2014); **RCNN**, an implementation for a recurrent convolutional neural network of Lai et al. (2015); **LSTM**, a 3-layer structure with input word embeddings, a bidirectional LSTM layer and a softmax output layer; **LSTM+AT**, using the attention mechanism to LSTM; and **LSTM+AT *multi-task***, using LSTM+AT to jointly learn the three tasks.

For the recommendation task, we compare our SciResREC with the **Random Forest (RF) classifier**, which is robust to overfitting even with large numbers of features. For the RF classifier, we use two types of features: **BoW+TFIDF**, the 20,000 most frequent words from the training set are selected and the TFIDF of each word is used as features; **N-grams+TFIDF**, the TFIDF of the most frequent 20,000 N-grams (up to 5-grams).

Our BERT encoder is based on Googles reference implementation[10] (TensorFlow 1.12.0). For training, we begin with the BERT-Base model (uncased, 12-layer, 768-hidden, 12-heads, 110M parameters) and then fine-tune the model on our training sets for the three classification tasks. The maximum word sequence length is 128; the learning rate is set to 5e-5 and all other defaults settings are used. For the recommendation model, the feature embedding dimension of role labels and function labels is 32, which are initialized at random and the hidden size is set to 64. For all the baselines, we use the word embeddings pretrained on our large-scale scientific corpus, which is a full-text collection of 40 thousand research papers. And we stop the training when we found the best result in the developing set.

6.3 Results and Discussions

Classification Results

Our model achieves the best results on all the three classification tasks, as shown in Table 4. And the F1-score for each role or function type is shown in Table 5. From the results we can see that there is still a large gap with other general context-based classification tasks, which provides considerable potential for advancement in the future research. For more in-depth performance

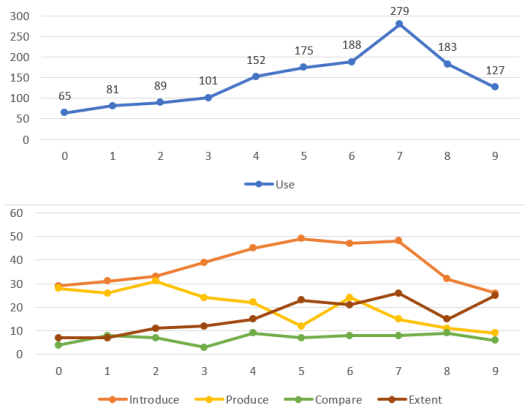

Figure 4: The revolution of resource functions in ten years starting from the first appearance.

analysis, we note that most neural-based models are inferior to the traditional machine learning methods, which is perhaps due to the limited labeled datasets. While our model benefiting from the BERT encoder, which is pre-trained on vast amounts of text and fine-tuned on our task-specific, show an effective solution to the data limitation. We also see that the LSTM performs better when the attention layer introduced. It indicates the attention mechanism, which is sufficient used in the transformer structure of BERT, is significant to learn which words of a sequence are more important for determining the labels in our classification tasks. And the position embeddings in BERT is also effective to learn the relative positions between the resource citation and other words. By comparing the results between different joint models, we can get some interesting findings about the relationships between the resource roles and the resource functions. First, the general role and the fine-grained role can not benefit each other, which is perhaps because the high-level constraints can reduce the inter-class errors but meanwhile introduce more intra-class errors. When introducing the function information, the results for the general role will improve while the fine-grained role will slightly drop off. Moreover, jointly learning the two-level role information can observably enhance the results for function classification. And considering the complex interaction among the three tasks, the multi-task model achieves the best performance.

The resulting function classifier is sufficient to be applied to the entire ARC dataset. Nonetheless, errors remain. Consider the following example:

*To give their network a better initialization, they learn word embeddings ... They **released** their 50-dimensional word embeddings (vocabulary size 130K) under the name SENNA. <CITE>*,

which is notably a review of others' work and the correct function is **Introduce**. While our model mistakes it to **Produce** caused by a higher attention score of the word "released". This case inspires us that the dependency parsing can also be considered in the future research.

Recommendation Results

As Table 6 shows, our SciResREC framework outperforms the two baselines. An ablation test suggests that each feature component of our model contributes to the final performance, which indicates the information of role and function are helpful for understanding the scientific resources. And we can observe that the feature of 2-nd category role label has the largest impact on performance indicating that capturing fine-grained role types is important for recognizing specific resources.

Resource Evolution Analysis

To study what the resource function can tell us about the scientific resource development, we apply our function classifier trained on SciRes to the large ARC dataset. We select the top 100 most frequent resources and filter out the ones which have been existing less than 10 years. Finally we obtain a set of 33 resources and use our trained classifier to identity the function of each resource citation in its context. A statistical result is shown in Figure 4. The horizontal axis represents the number of years after the resource first appeared in the scientific corpus. From the figure we can see that a resource will drive to its maturity stage and be widely used in 4-5 years after it first exists. And in 8-9 years it will gradually be out of date and replaced by other new technologies. Moreover, citing the resources as background and making extensions based on the resources progressively increase along with time, which is consistent with the general expect.

7 Conclusion and Future Work

We introduce a novel task of *modeling the role and function for on-line resource citations in scientific literature*. For this task we first create an annotation scheme, collect a large-scale corpus and construct a manually labeled dataset. And we propose a multi-task model to jointly classify the role and function types based on the resource contexts. By incorporating the associated information, our SciResCLF framework effectively improves the performance across all tasks. Moreover, we propose a resource recommendation task and develop the SciResREC framework using the predicted labels as features. Our frameworks can contribute to build more powerful search and recommendation systems for scientific on-line resources. For future work, we will try using pre-trained BERT for scientific domain such as the SciBERT (Beltagy et al., 2019) and explore using our frameworks to help more tasks such as the evaluation, prediction and knowledge graph construction for scientific resources.

Abstract

In this work, we develop methods to repurpose text classification neural networks for alternate tasks without modifying the network architecture or parameters. We propose a context based vocabulary remapping method that performs a computationally inexpensive input transformation to reprogram a victim classification model for a new set of sequences. We propose algorithms for training such an input transformation in both white box and black box settings where the adversary may or may not have access to the victim model's architecture and parameters. We demonstrate the application of our model and the vulnerability of neural networks by adversarially repurposing various text-classification models including LSTM, bi-directional LSTM and CNN for alternate classification tasks.

1 Introduction

While neural network based machine learning models serve as the backbone of many text and image processing systems, recent studies have shown that they are vulnerable to adversarial examples. Traditionally, an adversarial example is a sample from the classifier's input domain which has been perturbed in such a way that is intended to cause a machine learning model to misclassify it. While the perturbation is usually imperceptible, such an adversarial input results in the neural network model outputting an incorrect class label with higher confidence. Several studies have shown such adversarial attacks to be successful in both the continuous input domain (Szegedy et al., 2014; Papernot et al., 2016a, 2017, 2016b; Brown et al., 2017; Goodfellow et al., 2015) and discrete input spaces (Papernot et al., 2016c; Hu and Tan, 2018; Yang et al., 2018).

Adversarial Reprogramming (Elsayed et al., 2019) is a new class of adversarial attacks where a machine learning model is repurposed to perform a new task chosen by the attacker. The proposed attack is interesting because it allows an adversary to move a step beyond mere mis-classification of a victim network's output onto having the control to repurpose the network fully. The authors demonstrated how an adversary may repurpose a pre-trained ImageNet (Deng et al., 2009) model for an alternate classification task like classification of MNIST digits or CIFAR-10 images without modifying the network parameters. Since machine learning agents can be reprogrammed to perform unwanted actions as desired by the adversary, such an attack can lead to theft of computational resources such as cloud-hosted machine learning models. Besides theft of computational resources, the adversary may perform a task that violates the code of ethics of the system provider.

The adversarial reprogramming approach proposed by (Elsayed et al., 2019) trains an additive contribution θ to the inputs of the neural network to repurpose it for the desired alternate task. This approach assumes a white-box attack scenario where the adversary has full access to the network's parameters. Also, the adversarial program proposed in this work is only applicable to tasks where the input space of the the original and adversarial task is continuous.

In our work, we propose a method to adversarially *repurpose* neural networks which operate on sequences from a *discrete* input space. The task is to learn a simple transformation (adversarial program) from the input space of the adversarial task to the input space of the neural network such that the neural network can be repurposed for the adversarial task. We propose a context-based vocabulary remapping function as an adversarial program for sequence classification networks. We propose training procedures for this adversarial program in both white-box and black-

box scenarios. In the white-box attack scenario, where the adversary has access to the classifier's parameters, a Gumbel-Softmax trick (Jang et al., 2016) is used to train the adversarial program. Assuming a black-box attack scenario, where the adversary may not have access to the classifier's parameters, we present a REINFORCE (Williams, 1992) based optimization algorithm to train the adversarial program.

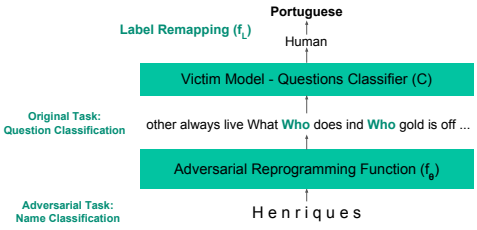

Figure 1: Example of Adversarial Reprogramming for Sequence Classification. We aim to design and train the adversarial reprogramming function f_θ, such that it can be used to repurpose a pre-trained classifier C, for a desired adversarial task.

We apply our proposed methodology on various text classification models including Recurrent Neural Networks such as LSTMs and bidirectional LSTMs, and Convolutional Neural Networks (CNNs). We demonstrate experimentally, how these neural networks trained on a particular (original) text classification task can be repurposed for alternate (adversarial) classification tasks. We experiment with different text classification datasets given in table 1 as candidate original and adversarial tasks and adversarially reprogram the aforementioned text classification models to study the robustness of the attack.

2 Background and Related Work

2.1 Adversarial Examples

Traditionally, adversarial examples are intentionally designed inputs to a machine learning model that cause the model to make a mistake (Goodfellow et al., 2015). These attacks can be broadly classified into *untargeted* and *targeted* attacks. In the untargeted attack scenario, the adversary succeeds as long as the victim model classifies the adversarial input into *any* class other than the correct class, while in the *targeted* attack scenario, the adversary succeeds only if the model classifies the adversarial input into a specific incorrect class. In both these scenarios, the intent of the adversary is usually malicious and the outcome of the victim model is still limited to the original task being performed by the model.

Adversarial attacks of image-classification models often use gradient descent on an image to create a small perturbation that causes the machine learning model to mis-classify it (Szegedy et al., 2014; Biggio et al., 2013). There has been a similar line of adversarial attacks on neural networks with discrete input domains (Papernot et al., 2016c; Yang et al., 2018), where the adversary modifies a few tokens in the input sequence to cause mis-classification by a sequence model. In addition, efforts have been made in designing more general adversarial attacks in which the same modification can be applied to many different inputs to generate adversarial examples (Brown et al., 2017; Goodfellow et al., 2015; Moosavi-Dezfooli et al., 2017). For example, authors (Baluja and Fischer, 2018) trained an Adversarial Transformation Network that can be applied to all inputs to generate adversarial examples targeting a victim model or a set of victim models. In this work, we aim to learn such universal transformations of discrete sequences for a fundamentally different task: *Adversarial Reprogramming* described below.

2.2 Adversarial Reprogramming

Adversarial Reprogramming (Elsayed et al., 2019) introduced a new class of adversarial attacks where the adversary wishes to repurpose an existing neural network for a new task chosen by the attacker, without the attacker needing to compute the specific desired output. The adversary achieves this by first defining a hard-coded one-to-one label remapping function h_g that maps the output labels of the adversarial task to the label space of the classifier f; and learning a corresponding adversarial reprogramming function $h_f(.;\theta)$ that transforms an input $(\tilde{X})$ [1] from the input space of the new task to the input space of the classifier. The authors proposed an adversarial reprogramming function $h_f(.;\theta)$, for repurposing ImageNet models for adversarial classification tasks. An adversarial example X_{adv} for an input image $\tilde{X}$ can be generated using the following adversarial program: [2]

$$X_{adv} = h_f(\tilde{X};\theta) = \tilde{X} + \tanh(\theta)$$

[1] $\tilde{X}$ is an ImageNet size $(n \times n \times 3)$ padded input image

[2] Masking ignored because it is only a visualization convenience

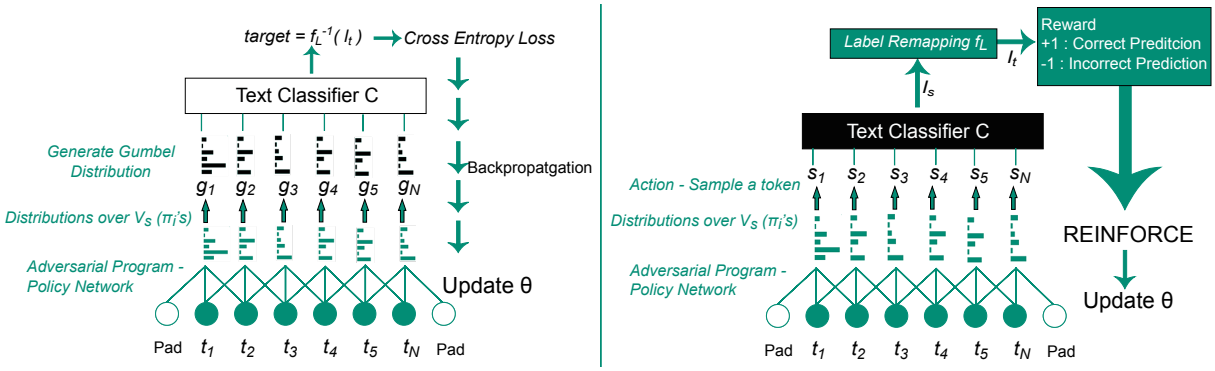

Figure 2: **Adversarial Reprogramming Function and Training Procedures. Left:** *White-box* Adversarial Reprogramming. The adversary generates gumbel distributions g_i at each time-step which are passed as a soft version of one-hot vectors to the classifier C. The cross-entropy loss between the predictions and the mapped class is backpropagated to train the adversarial program θ. **Right:** *Black-box* Adversarial Reprogramming. The adversarial reprogramming function is used as a policy network and the sampled action (sequence s) is passed to the classifier C to get a reward based on prediction correctness. The adversarial program is then trained using REINFORCE.

where $\theta \in \mathbb{R}^{n \times n \times 3}$ is the learnable weight matrix of the adversarial program (where n is the ImageNet image width). Let $P(y|X)$ denote the probability of the victim model predicting label y for an input X. The goal of the adversary is to maximize the probability $P(h_g(y_{adv})|X_{adv})$ where y_{adv} is the label of the adversarial input X_{adv}. The following optimization problem that maximizes the log-likelihood of predictions for the adversarial classification task, can be solved using backpropagation to train the adversarial program parameterized by θ:

$$\hat{\theta} = argmin_\theta \left(-\log P(h_g(y_{adv})|X_{adv}) + \lambda ||\theta||_2^2 \right) \quad (1)$$

where λ is the regularization hyperparameter. Since the adversarial program proposed is a trainable additive contribution θ to the inputs, it's application is limited to neural networks with a continuous input space. Also, since the the above optimization problem is solved by backpropagating through the victim network, it assumes a white-box attack scenario where the adversary has gained access to the victim model's parameters. In this work, we describe how we can learn a simple transformation in the *discrete space* to extend the application of adversarial reprogramming on *sequence classification* problems. We also propose a training algorithm in the black-box setting where the adversary may not have access to the model parameters.

2.3 Transfer Learning

Transfer Learning (Raina et al., 2007) is a study closely related to Adversarial Reprogramming. During training, neural networks learn representations that are generic and can be useful for many related tasks. A pre-trained neural network can be effectively used as a feature extractor and the parameters of just the last few layers are retrained to realign the output layer of the neural network for the new task. Prior works have also applied transfer learning on text classification tasks (Do and Ng, 2006; Semwal et al., 2018). While transfer learning approaches exploit the learnt representations for the new task, they cannot be used to repurpose an exposed neural network for a new task without modifying some intermediate layers and parameters.

Adversarial Reprogramming (2019) studied whether it is possible to keep all the parameters of the neural network unchanged and simply learn an input transformation that can realign the outputs of the neural network for the new task. This makes it possible to repurpose *exposed* neural network models like cloud-based photo services to a new task where transfer learning is not applicable since we do not have access to intermediate layer outputs.

3 Methodology

3.1 Threat Model

Consider a sequence classifier C trained on the original task of mapping a sequence $s \in S$ to a class label $l_S \in L_S$ i.e $C : s \mapsto l_S$. An adversary wishes to repurpose the original classifier C for the adversarial task C' of mapping a sequence $t \in T$ to a class label $l_T \in L_T$ i.e $C' : t \mapsto l_T$. The adversary can achieve this by hard-coding a

one-to-one label remapping function:

$$f_L : l_S \mapsto l_T$$

that maps an original task label to the new task label and learning a corresponding adversarial reprogramming function:

$$f_\theta : t \mapsto s$$

that transforms an input from the input space of the adversarial task to the input space of the original task. The adversary aims to update the parameters θ of the adversarial program f_θ such that the mapping $f_L(C(f_\theta(t)))$ can perform the adversarial classification task $C' : t \mapsto l_T$. Note that the victim model's parameters will be kept frozen while training the reprogramming function f_θ.

3.2 Adversarial Reprogramming Function

The goal of the adversarial reprogramming function $f_\theta : t \mapsto s$ is to map a sequence t to s such that it is labeled correctly by the classifier $f_L(C)$.

The tokens in the sequence s and t belong to some vocabulary lists V_S and V_T respectively. We can represent the sequence s as $s = s_1, s_2, .., s_N$ where s_i is the vocabulary index of the i_{th} token in sequence s in the vocabulary list V_S. Similarly sequence t can be represented as $t = t_1, t_2, .., t_N$ where t_i is the vocabulary index of the i_{th} token of sequence t in the vocabulary list V_T.

In the simplest scenario, the adversary may try to learn a vocabulary mapping from V_T to V_S using which each t_i can be independently mapped to some s_i to generate the adversarial sequence. Such an adversarial program has limited potential since the representational capacity of such a reprogramming function is very limited. We experimentally support this hypothesis by showing how such a transformation has limited potential for the purpose of adversarial reprogramming.

A more sophisticated adversarial program can be a sequence to sequence machine translation model (Sutskever et al., 2014) that learns a translation $t \mapsto s$ for adversarial reprogramming. While theoretically this is a good choice, it defeats the purpose of adversarial reprogramming. This is because the computational complexity of training and using such a machine translation model would be similar if not greater than that of a new sequence classifier for the adversarial task C'.

The adversarial reprogramming function should be computationally inexpensive but powerful enough for adversarial repurposing. To this end, we propose a context-based vocabulary remapping model that produces a distribution over the target vocabulary at each time-step based on the surrounding input tokens. More specifically, we define our adversarial program as a trainable 3-d matrix $\theta_{k \times |V_T| \times |V_S|}$ where k is the context size. Using this, we generate a probability distribution π_i over the vocabulary V_S at each time-step i as follows:

$$h_i = \sum_{j=0}^{k-1} \theta[j, t_{i+\lfloor k/2 \rfloor - j}] \tag{2}$$

$$\pi_i = softmax(h_i) \tag{3}$$

Both h_i and π_i are vectors of length $|V_S|$. To generate the adversarial sequence s we sample each s_i independently from the distribution π_i i.e $s_i \sim \pi_i$

In practice, during training, we implement this adversarial program as a single layer of 1-d convolution over the sequence of one-hot encoded vectors of adversarial tokens t_i with $|V_T|$ input channels and $|V_S|$ output channels with k-length kernels parameterized by $\theta_{k \times |V_T| \times |V_S|}$.

3.3 White-box Attack

In the white-box attack scenario, we assume that the adversary has gained access to the victim network's parameters and architecture. To train the adversarial reprogramming function f_θ, we use an optimization objective similar to equation 1. Let $P(l|s)$ denote the probability of predicting label l for a sequence s by classifier C. We wish to maximize the probability $P(f_L^{-1}(l_t)|f_\theta(t))$ which is the probability of the output label of the classifier being mapped to the correct class l_t for an input t in the domain of the adversarial task. Therefore we need to solve the following log-likelihood maximization problem:

$$\hat{\theta} = argmin_\theta(-\sum_t log(P(f_L^{-1}(l_t)|f_\theta(t)))) \tag{4}$$

Note that that the output of the adversarial program $s = f_\theta(t)$ is a sequence of discrete tokens. This makes the above optimization problem non-differentiable. Prior works (Kusner and Hernández-Lobato, 2016; Gu et al., 2017; Yang et al., 2018) have demonstrated how we can smoothen such an optimization problem using the Gumbel-Softmax (Jang et al., 2016) distribution.

In order to backpropagate the gradient information from the classifier to the adversarial program, we smoothen the generated tokens s_i using Gumbel-Softmax trick as per the following:

For an input sequence t, we generate a sequence of Gumbel distributions $g = g_1, g_2, .., g_N$. The n_{th} component of distribution g_i is generated as follows:

$$g_i^n = \frac{\exp((\log(\pi_i^n) + r_n)/temp)}{\sum_j \exp((\log(\pi_i^j) + r_j)/temp)}$$

where π_i is the softmax distribution at the i_{th} time-step obtained using equation 3, r_n is a random number sampled from the Gumbel distribution (Gumbel, 1954) and $temp$ is the temperature of Gumbel-Softmax.

The sequence then passed to the classifier C is the sequence g which serves as a soft version of the one-hot encoded vectors of s_i's. Since the model is now differentiable, we can solve the following optimization problem using backpropagation:

$$\hat{\theta} = argmin_\theta(-\sum_t log(P(f_L^{-1}(l_t)|g)))$$

During training the temperature parameter is annealed from some high value t_{max} to a very low value t_{min}. The details of this annealing process for our experiments have been included in the appendix.

3.4 Black-box Attack

In the black-box attack scenario, the adversary can only query the victim classifier C for labels (and not the class probabilities). We assume that the adversary has the knowledge of the vocabulary V_S of the victim model. Since the adversarial program needs to produce a discrete output to feed as input to the classifier C, it is not possible to pass the gradient update from the classifier $f_L(C)$ to the adversarial program θ using standard back-propagation. Also, in the black-box attack setting it is not possible to back-propagate the cross entropy loss through the classifier C in the first place.

We formulate the sequence generation problem as a Reinforcement Learning problem (Bachman and Precup, 2015; Bahdanau et al., 2016; Yu et al., 2016) where the adversarial reprogramming function is the policy network. The state of the adversarial program is a sequence $t \in T$ and an action of our policy network is to produce a sequence of tokens $s \in S$. The adversarial program parameterized by θ, models the stochastic policy $\pi_{adv}(s|t;\theta)$ such that a sequence $s \in S$ may be sampled from this policy conditioned on $t \in T$. We use a simple reward function where we assign a reward +1 for a correct prediction and -1 for an incorrect prediction using the classifier $f_L(C)$ where f_L is the label remapping function and C is the classifier. Formally:

$$r(t,s) = \begin{cases} +1, & f_L(C(s)) = l_t \\ -1, & f_L(C(s)) \neq l_t \end{cases}$$

The optimization objective to train the policy network is the following:

$$\max_\theta J(\theta) \quad \text{where,} \quad J(\theta) = \mathbb{E}_{\pi_{adv}}[r(t,s)]$$

Following the REINFORCE algorithm (Williams, 1992) we can write the gradient of the expectation with respect to θ as per the following:

$$\begin{aligned}
\nabla_\theta J &= \nabla_\theta \left[\mathop{\mathbb{E}}_{\pi_{adv}} [r(t,s)] \right] \\
&= \nabla_\theta \left[\sum_s \pi_{adv}(s|t;\theta) r(t,s) \right] \\
&= \sum_s \pi_{adv}(s|t;\theta) \nabla_\theta \log(\pi_{adv}(s|t;\theta)) r(t,s) \\
&= \mathop{\mathbb{E}}_{\pi_{adv}} [r(t,s) \nabla_\theta \log(\pi_{adv}(s|t;\theta))] \\
&= \mathop{\mathbb{E}}_{\pi_{adv}} [r(t,s) \nabla_\theta \log(\pi_{adv}(s_1, .., s_N|t;\theta))] \\
&= \mathop{\mathbb{E}}_{\pi_{adv}} \left[r(t,s) \nabla_\theta \log(\prod_i \pi_{adv}(s_i|t;\theta)) \right] \\
&= \mathop{\mathbb{E}}_{\pi_{adv}} \left[r(t,s) \sum_i \nabla_\theta \log(\pi_{adv}(s_i|t;\theta)) \right]
\end{aligned}$$

Note that $\pi_{adv}(s_i|t;\theta)$ is the same as π_i defined in equation 3 which can be differentiated with respect to θ. The expectations are estimated as sample averages. Having obtained the gradient of expected reward, we can use mini-batch gradient ascent to update θ with a learning rate α as: $\theta \leftarrow \theta + \alpha \nabla_\theta J$.

4 Experiments

4.1 Datasets and Classifiers

We demonstrate the application of the proposed reprogramming techniques on various text-classification tasks. In our experiments, we design adversarial programs to attack both word-level and character-level text classifiers. Additionally, we

aim to adversarially repurpose a character-level text classifier for a word-level classification task and vice-versa. To this end, we choose the following text-classification datasets as candidates for the original and adversarial classification tasks:

1. Surname Classification Dataset **(Names-18, Names-5) (Robertson, 2017)**: The dataset categorizes surnames from 18 languages of origin. We use a subset of this dataset *Names-5* containing Names from 5 classes: *Dutch, Scottish, Polish, Korean* and *Portuguese*, as a candidate for adversarial task in the experiments.

2. Experimental Data for Question Classification **(Questions) (Li and Roth, 2002)**: categorizes around 5500 questions into 6 classes: *Abbreviation, Entity, Description, Human, Location, Numeric*.

3. Sentiment Classification Dataset (Abdulla et al., 2013) **(Arabic)** : contains 2000 binary labeled tweets on diverse topics such as politics and arts.

4. Large Movie Review Dataset **(IMDB) for sentiment classification (Maas et al., 2011)**: contains 50,000 movie reviews categorized into binary class of positive and negative sentiment.

The statistics of the above mentioned datasets have been given in table 1. We train adversarial reprogramming functions to repurpose various text-classifiers based on Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997), bidirectional LSTM network (Graves et al., 2005) and Convolutional neural network (Kim, 2014) models. All the aforementioned models can be trained for both word-level and character-level classification. We use character level classifiers for *Names-18* and *Names-5* datasets and word-level classifiers for *IMDB*, *Questions* and *Arabic* datasets. We use randomly initialized word/character embeddings which are trained along with the classification model parameters. For LSTM, we use the output at last timestep for prediction. For the Bi-LSTM, we combine the outputs of the first and last time step for prediction. For the Convolutional Neural Network we follow the same architecture as (Kim, 2014). Additionally, to understand the effectiveness of adversarial reprogramming, we train a sigle layer CNN with convolutional filter width 5 and discuss the results of this experiment in Section 4.4. The details of these classifiers have been included in table 2 of the supplementary material.

Data Set	# Classes	Train Samples	Test Samples	$\|V\|$	Avg Length
Names-18	18	115,028	28,758	90	7.1
Names-5	5	3632	909	66	6.5
Questions	6	4361	1091	1205	11.2
Arabic	2	1600	400	955	9.7
IMDB	2	25,000	25,000	10000	246.8

IMDB	86.83	89.43	**90.02**	83.32

Table 2: Test accuracy of various classification models. We use character-level models for *Names-5* and *Names-18* and word-level models for all other tasks. 1-CNN is a single layer CNN model with filter width 5.

4.2 Experimental Setup

As described in the methodology section, the label remapping function f_L we use, is a one-to-one mapping between the labels of the original task and the adversarial task. Therefore it is required to apply the constraint that the number of classes of the adversarial task are less than or equal to the number of classes of the original task. We choose *Names-5, Arabic* and *Question Classification* as candidates for the adversarial tasks and repurpose the models allowed under this constraint. We use context size $k = 5$ for all our experiments.

In white-box attacks, we use the Gumbel-Softmax based approach described in the methodology to train the adversarial program. The details of the temperature annealing process are included in table 1 of the supplementary material. For black-box attacks, we use the REINFORCE algorithm described in methodology, on mini-batches of sequences. Since the action space for certain reprogramming problems, (eg. reprogramming of IMDB classifier) is large ($|V_S| = 10000$), we restrict the output of the adversarial program to most frequent 1000 tokens in the vocabulary V_S. We use Adam optimizer (Kingma and Ba, 2015) for all our experiments. Hyperparameter details of all our experiments are included in table 1 of the supplementary material.

Original Task	Adversarial Task	Victim Model	Test Accuracy (%)

Table 3: **Adversarial Reprogramming Experiments:** The accuracies of *white-box* and *black-box* reprogramming experiments on different combinations of original task, adversarial task and model. Figures in bold correspond to our best results on a particular adversarial task in the given attack scenario (black-box and white-box). *White-box on Random Network* column presents results of the white-box attack on an untrained neural network. Context size $k = 5$ is used for all our experiments.

4.3 Results and Discussion

The accuracies of all adversarial reprogramming experiments have been reported in table 3. To interpret the results in context, the accuracies achieved by the LSTM, Bi-LSTM and CNN text classification models on the adversarial tasks can be found in table 1.

We demonstrate how character-level models trained on Names-18 dataset can be repurposed for word-level sequence classification tasks like Question Classification and Arabic Tweet Sentiment Classification. Similarly, word-level classifiers trained on Question Classification Dataset can be repurposed for the character-level Surname classification task. Interestingly, classifiers trained on IMDB Movie Review Dataset can be repurposed for Arabic Tweet Sentiment Classification even though there is a high difference between the vocabulary size (10000 vs 955) and average sequence length(246.8 vs 9.7) of the two tasks. It can be seen that all of the three classification models are susceptible to adversarial reprogramming in both white-box and black-box setting.

White-box based reprogramming outperforms the black-box based approach in all of our experiments. In practice, we find that training the adversarial program in the black-box scenario requires careful hyper-parameter tuning for REINFORCE to work. We believe that improved reinforcement learning techniques for sequence generation tasks (Bahdanau et al., 2016; Bachman and Precup, 2015) can make the training procedure for black-box attack more stable. We propose such improvement as a direction of future research.

To assess the importance of the original task on which the network was trained, we also present results of white-box adversarial reprogramming on untrained random network. Our results are coherent with similar experiments on adversarial reprogramming of untrained ImageNet models (Elsayed et al., 2019) demonstrating that adversarial reprogramming is less effective when it targets untrained networks. The figures in table 3 suggest that the representations learned by training a text classifier on an original task, are important for repurposing it for an alternate task. However another plausible reason as discussed by Elsayed et al. is that the reduced performance on random networks might be because of simpler reasons like poor scaling of network weight initialization making the optimization problem harder.

4.4 Complexity of Reprogramming Function

As motivated earlier in Section 3.2, computational efficiency of the adversarial program is critical for adversarial reprogramming to be of interest to an adversary. If the adversary can achieve the desired results using a computationally inexpensive classifier, it defeats the purpose of adversarial reprogramming. To understand if this is the case, we train a one-layer CNN with the same convolutional filter width as our adversarial program and average the activations across all time-steps to classify a given phrase. The results of such a classifier on various datasets have been reported in Table 2. We can observe that our white-box attack on pretrained networks, outperforms this classifier in all scenarios (refer to Table 3). Our best black-box attacks also outperform a one-layer CNN for all adversarial tasks. This experiment demonstrates that the reprogramming function exploits the learned feature representation of the victim model. Also, the observation that adversarial reprogramming is significantly less effective on randomly initialized

untrained networks further reinforces the importance of utilizing a trained victim model.

Since the reprogramming function is a context based vocabulary remapping function, we can implement it as a look-up table that maps a combination of k tokens from the vocabulary V_t to a token in the source vocabulary V_s. The time complexity for transforming a sentence t to an adversarial sentence is just $O(length(t))$.

4.4.1 Adversarial Sequences

Figure 3 shows some adversarial sequences generated by the adversarial program for Names-5 Classification while attacking a CNN trained on the Question Classification dataset. A sequence t in the first column is transformed into the adversarial sequence s in the second column by the trained adversarial reprogramming function. While these adversarial sequences may not make semantic or grammatical sense, it exploits the learned representation of the classifier to map the inputs to the desired class. For example, sequences that should be mapped to HUMAN class have words like *Who* in the generated adversarial sequence. Similarly, sequences that should be mapped to LOCATION class have words like *world, city* in the adversarial sequence. Other such interpretable transformations are depicted via colored text in the adversarial sequences of Figure 3.

Figure 3: Adversarial sequences generated by our adversarial program for Names-5 Classification (adversarial task), when targeting a CNN trained on the Question Classification dataset (original task). Interpretable transformations are shown as colored words in the second column.

4.4.2 Effect of Context Size

By varying the context size k of the convolutional kernel $\theta_{k\times|V_T|\times|V_S|}$ in our adversarial program we are able to control the representational capacity of the adversarial reprogramming function. Figure 4 shows the percentage accuracy obtained when training the adversarial program with different context sizes k on two different adversarial tasks: Arabic Tweets Classification and Name Classification. Using a context size $k = 1$ reduces the adversarial reprogramming function to simply a vocabulary remapping function from V_S to V_T. It can be observed that the performance of the adversarial reprogramming model at $k = 1$ is significantly worse than that at higher values of k. While higher values of k improve the performance of the adversarial program, they come at a cost of increased computational complexity and memory required for the adversarial reprogramming function. For the adversarial tasks studied in this paper, we observe that $k = 5$ is a reasonable choice for context size of the adversarial program.

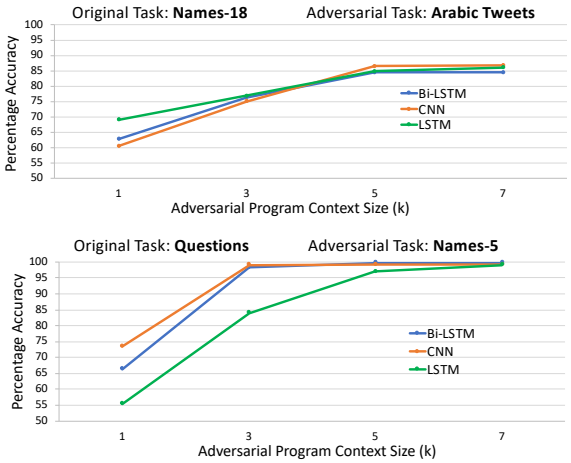

Figure 4: Accuracy vs Context size (k) plots for all 3 classification models on 2 different adversarial reprogramming experiments.

5 Conclusion

In this paper, we extend adversarial reprogramming, a new class of adversarial attacks, to target text classification neural networks. Our results demonstrate the effectiveness of such attacks in the more challenging black-box settings, posing them as a strong threat in real-world attack scenarios. We demonstrate that neural networks can be effectively reprogrammed for alternate tasks, which were not originally intended by a service provider. Our proposed end-to-end approach can be used to further understand the vulnerabilities and blind spots of deep neural network based text classification systems. We recommend future work to study the scope of adversarial reprogramming for other NLP applications such as machine translation, text to speech synthesis and text to im-

age synthesis where the input space is discrete. Furthermore, due to the threat presented by adversarial reprogramming, we recommend future work to study defenses against such attacks.

Abstract

Hashing is promising for large-scale information retrieval tasks thanks to the efficiency of distance evaluation between binary codes. Generative hashing is often used to generate hashing codes in an unsupervised way. However, existing generative hashing methods only considered the use of simple priors, like Gaussian and Bernoulli priors, which limits these methods to further improve their performance. In this paper, two mixture-prior generative models are proposed, under the objective to produce high-quality hashing codes for documents. Specifically, a Gaussian mixture prior is first imposed onto the variational auto-encoder (VAE), followed by a separate step to cast the continuous latent representation of VAE into binary code. To avoid the performance loss caused by the separate casting, a model using a Bernoulli mixture prior is further developed, in which an end-to-end training is admitted by resorting to the straight-through (ST) discrete gradient estimator. Experimental results on several benchmark datasets demonstrate that the proposed methods, especially the one using Bernoulli mixture priors, consistently outperform existing ones by a substantial margin.

1 Introduction

Similarity search aims to find items that look most similar to the query one from a huge amount of data (Wang et al., 2018), and are found in extensive applications like plagiarism analysis (Stein et al., 2007), collaborative filtering (Koren, 2008; Wang et al., 2016), content-based multimedia retrieval (Lew et al., 2006), web services (Dong et al., 2004) etc. Semantic hashing is an effective way to accelerate the searching process by representing every document with a compact binary code. In this way, one only needs to evaluate the hamming distance between binary codes, which is much cheaper than the Euclidean distance calculation in the original feature space.

Existing hashing methods can be roughly divided into data-independent and data-dependent categories. Data-independent methods employ random projections to construct hash functions without any consideration on data characteristics, like the locality sensitive hashing (LSH) algorithm (Datar et al., 2004). On the contrary, data dependent hashing seeks to learn a hash function from the given training data in a supervised or an unsupervised way. In the supervised case, a deterministic function which maps the data to a binary representation is trained by using the provided supervised information (e.g. labels) (Liu et al., 2012; Shen et al., 2015; Liu et al., 2016). However, the supervised information is often very difficult to obtain or is not available at all. Unsupervised hashing seeks to obtain binary representations by leveraging the inherent structure information in data, such as the spectral hashing (Weiss et al., 2009), graph hashing (Liu et al., 2011), iterative quantization (Gong et al., 2013), self-taught hashing (Zhang et al., 2010) etc.

Generative models are often considered as the most natural way for unsupervised representation learning (Miao et al., 2016; Bowman et al., 2015; Yang et al., 2017). Many efforts have been devoted to hashing by using generative models. In (Chaidaroon and Fang, 2017), variational deep semantic hashing (VDSH) is proposed to solve the semantic hashing problem by using the variational autoencoder (VAE) (Kingma and Welling, 2013). However, this model requires a two-stage training since a separate step is needed to cast the continuous representations in VAE into binary codes. Under the two-stage training strategy, the model is more prone to get stuck at poor performance (Xu et al., 2015; Zhang et al., 2010; Wang et al.,

2013). To address the issue, the neural architecture for generative semantic hashing (NASH) in (Shen et al., 2018) proposed to use a Bernoulli prior to replace the Gaussian prior in VDSH, and further use the straight-through (ST) method (Bengio et al., 2013) to estimate the gradients of functions involving binary variables. It is shown that the end-to-end training brings a remarkable performance improvement over the two-stage training method in VDSH. Despite of superior performances, only the simplest priors are used in these models, i.e. Gaussian in VDSH and Bernoulli in NASH. However, it is widely known that priors play an important role on the performance of generative models (Goyal et al., 2017; Chen et al., 2016; Jiang et al., 2016).

Motivated by this observation, in this paper, we propose to produce high-quality hashing codes by imposing appropriate mixture priors on generative models. Specifically, we first propose to model documents by a VAE with a Gaussian mixture prior. However, similar to the VDSH, the proposed method also requires a separate stage to cast the continuous representation into binary form, making it suffer from the same pains of two-stage training. Then we further propose to use a Bernoulli mixture as the prior, in hopes to yield binary representations directly. An end-to-end method is further developed to train the model, by resorting to the straight-through gradient estimator for neural networks involving binary random variables. Extensive experiments are conducted on benchmark datasets, which show substantial gains of the proposed mixture-prior methods over existing ones, especially the method with a Bernoulli mixture prior.

2 Semantic Hashing by Imposing Mixture Priors

In this section, we investigate how to obtain similarity-preserved hashing codes by imposing different mixture priors on variational encoder.

2.1 Preliminaries on Generative Semantic Hashing

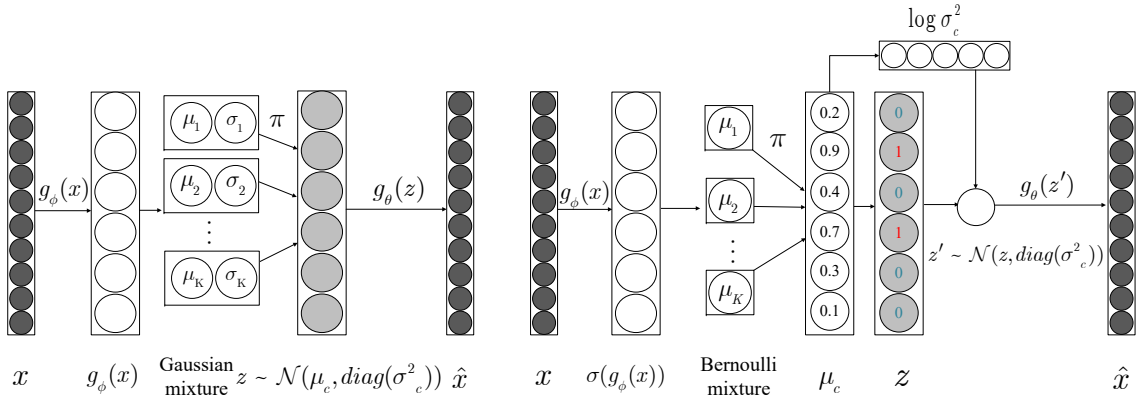
Let $x \in \mathcal{Z}_+^{|V|}$ denote the bag-of-words representation of a document and $x_i \in \{0,1\}^{|V|}$ denote the one-hot vector representation of the i-th word of the document, where $|V|$ denotes the vocabulary size. VDSH in (Chaidaroon and Fang, 2017) proposed to model a document $\mathcal{D}$, which is defined by a sequence of one-hot word representations $\{x_i\}_{i=1}^{|\mathcal{D}|}$, with the joint PDF

$$p(\mathcal{D}, z) = p_\theta(\mathcal{D}|z)p(z), \tag{1}$$

where the prior $p(z)$ is the standard Gaussian distribution $\mathcal{N}(0, I)$; the likelihood has the factorized form $p_\theta(\mathcal{D}|z) = \prod_{i=1}^{|\mathcal{D}|} p_\theta(x_i|z)$, and

$$p_\theta(x_i|z) = \frac{\exp(z^T E x_i + b_i)}{\sum_{j=1}^{|V|} \exp(z^T E x_j + b_j)}; \tag{2}$$

$E \in \mathbb{R}^{m \times |V|}$ is a parameter matrix which connects latent representation z to one-hot representation x_i of the i-th word, with m being the dimension of z; b_i is the bias term and $\theta = \{E, b_1, ..., b_{|V|}\}$. It is known that generative models with better modeling capability often imply that the obtained latent representations are also more informative.



To increase the modeling ability of (1), we may resort to more complex likelihood $p_\theta(\mathcal{D}|z)$, such as using deep neural networks to relate the latent z to the observation x_i, instead of the simple softmax function in (2). However, as indicated in (Shen et al., 2018), employing expressive nonlinear decoders likely destroy the distance-keeping property, which is essential to yield good hashing codes. In this paper, instead of employing a more complex decoder $p_\theta(\mathcal{D}|z)$, more expressive priors are leveraged to address this issue.

2.2 Semantic Hashing by Imposing Gaussian Mixture Priors

To begin with, we first replace the standard Gaussian prior $p(z) = \mathcal{N}(0, I)$ in (1) by the following Gaussian mixture prior

$$p(z) = \sum_{k=1}^{K} \pi_k \cdot \mathcal{N}\left(\mu_k, \text{diag}\left(\sigma_k^2\right)\right), \tag{3}$$

where K is the number of mixture components; π_k is the probability of choosing the k-th component and $\sum_k^K \pi_k = 1$; $\mu_k \in \mathbb{R}^m$ and $\sigma_k^2 \in \mathbb{R}_+^m$ are the mean and variance vectors of the Gaussian distribution of the k-th component; and diag$(\cdot)$ means diagonalizing the vector. For any sample $z \sim p(z)$, it can be equivalently generated by a two-stage procedure: 1) choosing a component $c \in \{1, 2, \cdots, K\}$ according to the categorical distribution Cat(π) with $\pi = [\pi_1, \pi_2, \cdots, \pi_K]$; 2) drawing a sample from the

(a) GMSH (b) BMSH

Figure 1: The architectures of the GMSH and BMSH. The data generative process of GMSH is done as follows: (1) Pick a component $c \in \{1, 2, ..., K\}$ from $Cat(\pi)$ with $\pi = [\pi_1, \pi_2, ..., \pi_K]$; (2) Draw a sample z from the picked Gaussian distribution $\mathcal{N}\left(\mu_c, diag(\sigma_c^2)\right)$; (3) Use $g_\theta(z)$ to decode the sample z into an observable $\hat{x}$. The process of generating data in BMSH can be described as follows: (1) Choose a component c from $Cat(\pi)$; (2) Sample a latent vector from the chosen distribution $Bernoulli(\gamma_c)$; (3) Inject data-dependent noise into z, and draw z' from $\mathcal{N}(z, diag(\sigma_c^2))$; (4) Then use decoder $g_\theta(z')$ to reconstruct $\hat{x}$.

distribution $\mathcal{N}\left(\mu_c, \text{diag}\left(\sigma_c^2\right)\right)$. Thus, the document $\mathcal{D}$ is modelled as

$$p(\mathcal{D}, z, c) = p_\theta(\mathcal{D}|z)p(z|c)p(c), \tag{4}$$

where $p(z|c) = \mathcal{N}\left(\mu_c, \text{diag}\left(\sigma_c^2\right)\right)$, $p(c) = \text{Cat}(\pi)$ and $p_\theta(\mathcal{D}|z)$ is defined the same as (2).

To train the model, we seek to optimize the lower bound of the log-likelihood

$$\mathcal{L} = E_{q_\phi(z,c|x)}\left[\log \frac{p_\theta(\mathcal{D}|z)p(z|c)p(c)}{q_\phi(z, c|x)}\right], \tag{5}$$

where $q_\phi(z, c|x)$ is the approximate posterior distribution of $p(z, c|x)$ parameterized by ϕ; here x could be any representation of the documents, like the bag-of-words, TFIDF etc. For the sake of tractability, $q_\phi(z, c|x)$ is further assumed to maintain a factorized form, i.e., $q_\phi(z, c|x) = q_\phi(z|x)q_\phi(c|x)$. Substituting it into the lower bound gives

$$\begin{aligned}\mathcal{L} =& \mathbb{E}_{q_\phi(z|x)}\left[\log p_\theta(\mathcal{D}|z)\right] - KL\left(q_\phi(c|x)||p(c)\right) \\ & - \mathbb{E}_{q_\phi(c|x)}\left[KL\left(q_\phi(z|x)||p(z|c)\right)\right].\end{aligned} \tag{6}$$

For simplicity, we assume that $q_\phi(z|x)$ and $q_\phi(c|x)$ take the forms of Gaussian and categorical distributions, respectively, and the distribution parameters are defined as the outputs of neural networks. The entire model, including the generative and inference arms, is illustrated in Figure 1(a). Using the properties of Gaussian and categorical distributions, the last two terms in (6) can be expressed in a closed form. Combining with the reparameterization trick in stochastic gradient variational bayes (SGVB) estimator (Kingma and Welling, 2013), the lower bound $\mathcal{L}$ can be optimized w.r.t. model parameters $\{\theta, \pi, \mu_k, \sigma_k, \phi\}$ by error backpropagation and SGD algorithms directly.

Given a document x, its hashing code can be obtained through two steps: 1) mapping x to its latent representation by $z = \mu_\phi(x)$, where the $\mu_\phi(x)$ is the encoder mean $\mu_\phi(\cdot)$; 2) thresholding z into binary form. As suggested in (Wang et al., 2013; Chaidaroon et al., 2018; Chaidaroon and Fang, 2017) that when hashing a batch of documents, we can use the median value of the elements in z as the critical value, and threshold each element of z into 0 and 1 by comparing it to this critical value. For presentation conveniences, the proposed semantic hashing model with a Gaussian mixture priors is referred as GMSH.

2.3 Semantic Hashing by Imposing Bernoulli Mixture Priors

To avoid the separate casting step used in GMSH, inspired by NASH (Shen et al., 2018), we further propose a *S*emantic *H*ashing model with a *B*ernoulli *M*ixture prior (BMSH). Specifically, we replace the Gaussian mixture prior in GMSH with the following Bernoulli mixture prior

$$p(z) = \sum_{k=1}^{K} \pi_k \cdot \text{Bernoulli}\left(\gamma_k\right), \tag{7}$$

where $\gamma_k \in [0,1]^m$ represents the probabilities of z being 1. Effectively, the Bernoulli mixture prior, in addition to generating discrete samples, plays a similar role as Gaussian mixture prior, which make the samples drawn from different components have different patterns. The samples from the Bernoulli mixture can be generated by first choosing a component $c \in \{1, 2, \cdots, K\}$ from $\text{Cat}(\pi)$ and then drawing a sample from the chosen distribution $\text{Bernoulli}(\gamma_c)$. The entire model can be described as $p(\mathcal{D}, z, c) = p_\theta(\mathcal{D}|z)p(z|c)p(c)$, where $p_\theta(\mathcal{D}|z)$ is defined the same as (2), and $p(c) = \text{Cat}(\pi)$ and $p(z|c) = \text{Bernoulli}(\gamma_c)$.

Similar to GMSH, the model can be trained by maximizing the variational lower bound, which maintains the same form as (6). Different from GMSH, in which $q_\phi(z|x)$ and $p(z|c)$ are both in a Gaussian form, here $p(z|c)$ is a Bernoulli distribution by definition, and thus $q_\phi(z|x)$ is assumed to be the Bernoulli form as well, with the probability of the i-th element z_i taking 1 defined as

$$q_\phi(z_i = 1|x) \triangleq \sigma\left(g_\phi^i(x)\right) \tag{8}$$

for $i = 1, 2, \cdots, m$. Here $g_\phi^i(\cdot)$ indicates the i-th output of a neural network parameterized by ϕ. Similarly, we also define the posterior regarding which component to choose as

$$q_\phi(c = k|x) = \frac{\exp\left(h_\phi^k(x)\right)}{\sum_{i=1}^K \exp\left(h_\phi^i(x)\right)}, \tag{9}$$

where $h_\phi^k(x)$ is the k-th output of a neural network parameterized by ϕ. With denotation $\alpha_i = q_\phi(z_i = 1|x)$ and $\beta_k = q_\phi(c = k|x)$, the last two terms in (6) can be expressed in close-form as

$$KL\left(q_\phi(c|x)||p(c)\right) = \sum_{c=1}^K \beta_c \log \frac{\beta_c}{\pi},$$

$$\mathbb{E}_{q_\phi(c|x)}\left[KL\left(q_\phi(z|x)||p(z|c)\right)\right]$$
$$= \sum_{c=1}^K \beta_c \sum_{i=1}^m \left(\alpha_i \log \frac{\alpha_i}{\gamma_c^i} + (1-\alpha_i) \log \frac{1-\alpha_i}{1-\gamma_c^i}\right),$$

where γ_c^i denotes the i-th element of γ_c.

Due to the Bernoulli assumption for the posterior $q_\phi(z|x)$, the commonly used reparameterization trick for Gaussian distribution cannot be used to directly estimate the first term $\mathbb{E}_{q_\phi(z|x)}\left[\log p_\theta(\mathcal{D}|z)\right]$ in (6). Fortunately, inspired by the straight-through gradient estimator in (Bengio et al., 2013), we can parameterize the i-th element of binary sample z from $q_\phi(z|x)$ as

$$z_i = 0.5 \times \left(sign\left(\sigma(g_\phi^i(x)) - \xi_i\right) + 1\right), \tag{10}$$

where $sign(\cdot)$ the is the sign function, which is equal to 1 for nonnegative inputs and -1 otherwise; and $\xi_i \sim \text{Uniform}(0, 1)$ is a uniformly random sample between 0 and 1.

The reparameterization method used above can guarantee generating binary samples. However, backpropagation cannot be used to optimize the lower bound $\mathcal{L}$ since the gradient of $sign(\cdot)$ w.r.t. its input is zero almost everywhere. To address this problem, the straight-through(ST) estimator (Bengio et al., 2013) is employed to estimate the gradient for the binary random variables, where the derivative of z_i w.r.t ϕ is simply approximated by $0.5 \times \frac{\partial \sigma(g_\phi^i(x))}{\partial \phi}$. Thus, the gradients can then be backpropagated through discrete variables. Similar to NASH (Shen et al., 2018), data-dependent noises are also injected into the latent variables when reconstructing the document x so as to obtain more robust binary representations. The entire model of BMSH, including generative and inference parts, is illustrated in Figure 1(b).

To understand how the mixture-prior model works differently from the simple prior model, we examine the main difference term $\mathbb{E}_{q_\phi(c|x)}\left[KL\left(q_\phi(z|x)||p(z|c)\right)\right]$ in (6), where $q_\phi(c|x)$ is the approximate posterior probability that indicates the document x is generated by the c-th component distribution with $c \in \{1, 2, \cdots, K\}$. In the mixture-prior model, the approximate posterior $q_\phi(z|x)$ is compared to all mixture components $p(z|c) = \mathcal{N}\left(\mu_c, \text{diag}(\sigma_c^2)\right)$. The term $\mathbb{E}_{q_\phi(c|x)}\left[KL\left(q_\phi(z|x)||p(z|c)\right)\right]$ can be understood as the average of all these KL-divergences weighted by the probabilities $q_\phi(c|x)$. Thus, comparing to the simple-prior model, the mixture-prior model is endowed with more flexibilities, allowing the documents to be regularized by different mixture components according to their context.

2.4 Extensions to Supervised Hashing

When label information is available, it can be leveraged to yield more effective hashing codes since labels provide extra information about the similarities of documents. Specifically, a mapping from the latent representation z to the cor-

responding label y is learned for each document. The mapping encourages latent representations of documents with the same label to be close in the latent space, while those with different labels to be distant. A classifier built from a two-layer MLP is employed to parameterize this mapping, with its cross-entropy loss denoted by $\mathcal{L}_{dis}(z, y)$. Taking the supervised objective into account, the total loss is defined as

$$\mathcal{L}_{total} = -\mathcal{L} + \alpha \mathcal{L}_{dis}(z, y), \tag{11}$$

where $\mathcal{L}$ is the lower bound arising in GMSH or BMSH model; α controls the relative weight of the two losses. By examining the total loss $\mathcal{L}_{total}$, it can be seen that minimizing the loss encourages the model to learn a representation z that accounts for not only the unsupervised content similarities of documents, but also the supervised similarities from the extra label information.

3 Related Work

Existing hashing methods can be categorized into data independent and data dependent methods. A typical example of data independent hashing is the local-sensitive hashing (LSH) (Datar et al., 2004). However, such method usually requires long hashing codes to achieve satisfactory performance. To yield more effective hashing codes, more and more researches focus on data dependent hashing methods, which include unsupervised and supervised methods. Unsupervised hashing methods only use unlabeled data to learn hash functions. For example, spectral hashing (SpH) (Weiss et al., 2009) learns the hash function by imposing balanced and uncorrelated constraints on the learned codes. Iterative quantization (ITQ) (Gong et al., 2013) generates the hashing codes by simultaneously maximizing the variance of each binary bit and minimizing the quantization error. In (Zhang et al., 2010), the authors proposed to decompose the learning procedure into two steps: first learning hashing codes for documents via unsupervised learning, then using ℓ binary classifiers to predict the ℓ-bit hashing codes. Since the labels provide useful guidance in learning effective hash functions, supervised hashing methods are proposed to leverage the label information. For instance, binary reconstruction embedding (BRE) (Kulis and Darrell, 2009) learns the hash function by minimizing the reconstruction error between the original distances and the hamming distances of the corresponding hashing codes. Supervised hashing with kernels (KSH) (Liu et al., 2012) is a kernel-based method, which utilizes the pairwise information between samples to generate hashing codes by minimizing the hamming distances on similar pairs and maximizing those on dissimilar pairs.

Recently, VDSH (Chaidaroon and Fang, 2017) proposed to use a VAE to learn the latent representations of documents and then use a separate stage to cast the continuous representations into binary codes. While fairly successful, this generative hashing model requires a two-stage training. NASH (Shen et al., 2018) proposed to substitute the Gaussian prior in VDSH with a Bernoulli prior to tackle this problem, by using a straight-through estimator (Bengio et al., 2013) to estimate the gradient of neural network involving the binary variables. This model can be trained in an end-to-end manner. Our models differ from VDSH and NASH in that mixture priors are employed to yield better hashing codes, whereas only the simplest priors are used in both VDSH and NASH.

4 Experiments

4.1 Experimental Setups

Datasets Three public benchmark datasets are used in our experiments. $i)$ $Reuters21578$: A dataset consisting of 10788 news documents from 90 different categories; $ii)$ $20Newsgroups$: A collection of 18828 newsgroup posts that are divided into 20 different newsgroups; $iii)$ TMC: A dataset containing the air traffic reports provided by NASA, which includes 21519 training documents with 22 labels.

Training Details We experiment with the four models proposed in this paper, i.e., GMSH and BMSH for unsupervised hashing, and GMSH-S and BMSH-S for supervised hashing. The same network architectures as VDSH and NASH are used in our experiments to admit a fair comparison. Specifically, a two-layer feed-forward neural network with 500 hidden units and ReLU activation function is employed as the encoder and the extra classifier in the supervised case, while the decoder is the same as that stated in (2). Similar to VDSH and NASH (Chaidaroon and Fang, 2017; Shen et al., 2018), the TFIDF feature of a document is used as the input to the encoder. The Adam optimizer (Kingma and Ba, 2014) is used in the training of our models, and its learning rate is

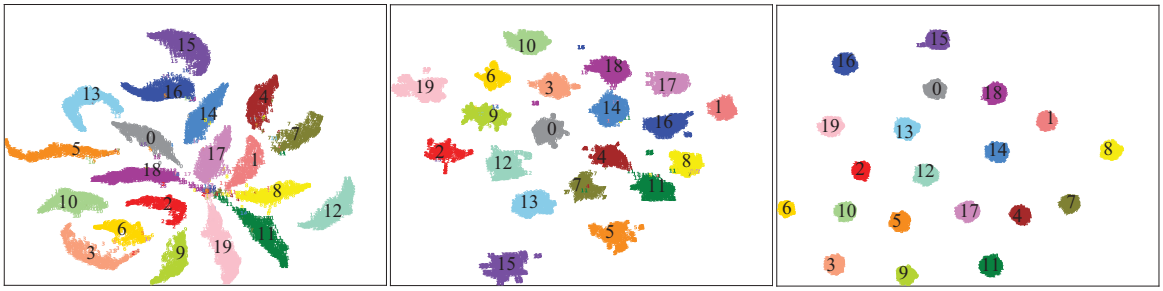
set to be 1×10^{-3}, with a decay rate of 0.96 for every 10000 iterations. The component number K and the parameter α in (11) are determined based on the validation set.

Baselines For unsupervised semantic hashing, we compare the proposed GMSH and BMSH with the following models: locality sensitive hashing (LSH), stack restricted boltzmann machines (S-RBM), spectral hashing (SpH), self-taught hashing (STH), variational deep semantic hashing (VDSH) and neural architecture for semantic hashing(NASH). For supervised semantic hashing, we also compare GMSH-S and BMSH-S with the following baselines: supervised hashing with kernels (KSH) (Liu et al., 2012), semantic hashing using tags and topic modeling (SHTTM) (Wang et al., 2013), supervised VDSH and supervised NASH.



Evaluation Metrics For every document from the testing set, we retrieve similar documents from the training set based on the hamming distance between their hashing codes. For each query, 100 closest documents are retrieved, among which the documents sharing the same label as the query are deemed as the relevant results. The ratio between the number of relevant ones and the total number, which is 100, is calculated as the similarity search precision. The averaged value over all testing documents is then reported. The retrieval precisions under the cases of 16 bits, 32 bits, 64 bits, 128 bits hashing codes are evaluated, respectively.

4.2 Performance Evaluation of Unsupervised Semantic Hashing

Table 1 shows the performance of the proposed and baseline models on three datasets under the unsupervised setting, with the number of hashing bits ranging from 16 to 128. From the experimental results, it can be seen that GMSH outperforms previous models under all considered scenarios on both TMC and Reuters. It also achieves better performance on 20Newsgroups when the length of hashing codes is large, e.g. 64 or 128. Comparing to VDSH using the simple Gaussian prior, the proposed GMSH using a Gaussian mixture prior exhibits better retrieval performance overall. This strongly demonstrates the benefits of using mixture priors on the task of semantic hashing. One possible explanation is that the mixture prior enables the documents from different categories to be regularized by different distributions, guiding the model to learn more distinguishable representations for documents from different categories. It can be further observed that among all methods, BMSH achieves the best performance under different datasets and hashing codes length consistently. This may be attributed to the imposed Bernoulli mixture prior, which offers both the ad-

vantages of producing more distinguishable codes with a mixture prior and end-to-end training enabled by a Bernoulli prior. BMSH integrates the merits of NASH and GMSH, and thus is more suitable for the hashing task.

Figure 2 shows how retrieval precisions vary with the number of hashing bits on the three datasets. It can be observed that as the number increases from 32 to 128, the retrieval precisions of most previous models tend to decrease. This phenomenon is especially obvious for VDSH, in which the precisions on all three datasets drop by a significant margin. This interesting phenomenon has been reported in previous works (Shen et al., 2018; Chaidaroon and Fang, 2017; Wang et al., 2013; Liu et al., 2012), and the reason could be overfitting since the model with long hashing codes is more likely to overfitting (Chaidaroon and Fang, 2017; Shen et al., 2018). However, it can be seen that our model is more robust to the number of hashing bits. When the number is increased to 64 or 128, the performance of our models is kept almost unchanged. This may be also attributed to the mixture priors imposed in our models, which can regularize the models more effectively.

4.3 Performance Evaluation of Supervised Semantic Hashing

We evaluate the performance of supervised hashing in this section. Table 2 shows the performances of different supervised hashing models on three datasets under different lengths of hashing codes. We observe that all of the VAE-based generative hashing models (i.e VDSH, NASH, GMSH and BMSH) exhibit better performance, demonstrating the effectiveness of generative models on the task of semantic hashing. It can be also seen that BMSH-S achieves the best performance, suggesting that the advantages of Bernoulli mixture priors can also be extended to the supervised scenarios.

To gain a better understanding about the relative

performance gain of the four proposed models, the retrieval precisions of GMSH, BMSH, GMSH-S and BMSH-S using 32-bit hashing codes on the three datasets are plotted together in Figure 4. It can be obviously seen that GMSH-S and BMSH-S outperform GMSH and BMSH by a substantial margin, respectively. This suggests that the proposed generative hashing models can also leverage the label information to improve the hashing codes' quality.

4.4 Impacts of the Component Number

To investigate the impacts of component number, experiments are conducted for GMSH and BMSH under different values of K. For demonstration convenience, the length of hashing codes is fixed to 32. Table 3 shows the precisions of top 100 retrieved documents when the number of components K is set to different values. We can see that the retrieval precisions of the proposed models, especially the BMSH, are quite robust to this parameter. For BMSH, the difference between the best and worst precisions on the three datasets are 0.0123, 0.0052 and 0.0134, respectively, which are small comparing to the gains that BMSH has achieved. One exception is the performance of GMSH on 20Newsgroups dataset. However, as seen from Table 3, as long as the number K is not too small, the performance loss is still acceptable. It is worth noting that the worst performance of GMSH on 20Newsgroups is 0.4708, which is still better than VDSH's 0.4327 as in Table 1. For the BMSH model, the performance is stable across all the considered datasets and K values.

4.5 Visualization of Learned Embeddings

To understand the performance gains of the proposed models better, we visualize the learned representations of VDSH-S, GMSH-S and BMSH-S on 20Newsgroups dataset. UMAP (McInnes et al., 2018) is used to project the 32-dimensional latent representations into a 2-dimensional space, as shown in Figure 3. Each data point in the figure denotes a document, with each color representing one category. The number shown with the color is the ground truth category ID. It can be observed from Figure 3 (a) and (b) that more embeddings are clustered correctly when the Gaussian mixture prior is used. This confirms the advantages of using mixture priors in the task of hashing. Furthermore, it is observed that the latent embeddings learned by BMSH-S can be clustered almost perfectly. In contrast, many embeddings are found to be clustered incorrectly for the other two models. This observation is consistent with the conjecture that mixture prior and end-to-end training are both useful for semantic hashing.

5 Conclusions

In this paper, deep generative models with mixture priors were proposed for the tasks of semantic hashing. We first proposed to use a Gaussian mixture prior, instead of the standard Gaussian prior in VAE, to learn the representations of documents. A separate step was then used to cast the continuous latent representations into binary hashing codes. To avoid the requirement of a separate casting step, we further proposed to use the Bernoulli mixture prior, which offers the advantages of both mixture prior and the end-to-end training. Comparing to strong baselines on three public datasets, the experimental results indicate that the proposed methods using mixture priors outperform existing models by a substantial margin. Particularly, the semantic hashing model with Bernoulli mixture prior (BMSH) achieves state-of-the-art results on all the three datasets considered in this paper.

Abstract

Retrieval of relevant vectors produced by representation learning critically influences the efficiency in natural language processing (NLP) tasks. In this paper we demonstrate an efficient method for searching vectors via a typical non-metric matching function: inner product. Our method, which constructs an approximate Inner Product Delaunay Graph (**IPDG**) for top-1 Maximum Inner Product Search (MIPS), transforms retrieving the most suitable latent vectors into a graph search problem with great benefits of efficiency. Experiments on data representations learned for different machine learning tasks verify the outperforming effectiveness and efficiency of the proposed IPDG.

1 Introduction

With the popularity of representation learning methods, such as Word2vec (Mikolov et al., 2013a), words are represented as real-valued embedding vectors in the semantic space. Therefore, retrieval of similar word embeddings is one of the most basic operations in natural language processing with wide applicability in synonym extraction (Yoon et al., 2017), sentence alignment (Levy et al., 2017), polysemous word learning (Sun et al., 2017) and semantic search for documents related to a query.

In this work, we address on efficient retrieval of similar word embeddings via inner product (dot product) similarity. Inner product is a general semantic matching function with applications in neural probabilistic language models (Bengio et al., 2003), machine translation (Gao et al., 2014), question answering (Lee et al., 2015), and attention mechanisms (Vaswani et al., 2017). For normalized vectors, inner product is equivalent to cosine similarity, which is a common semantic textual similarity utilized in semantic classification and search (Sahami and Heilman, 2006; Ramage et al., 2009; Agirre et al., 2012; Huang et al., 2013; Liu et al., 2015; Faruqui et al., 2016; Sultan et al., 2016; Köper and im Walde, 2018; Gong et al., 2018), Relation Extraction (RE) (Plank and Moschitti, 2013) and text coherence evaluation (Putra and Tokunaga, 2017). For un-normalized vectors, although cosine similarity is still widely applied, the final matching scores of word embeddings are usually weighted (Acree et al., 2016; Srinivas et al., 2010) by ranking-based coefficients (e.g., the side information), which transforms the problem back to search via inner product (see Eq. (2)).

Formally, retrieving the most similar word with the inner product ranking function is a *Maximum Inner Product Search* (**MIPS**) problem. MIPS is a continuously addressed topic (Bachrach et al., 2014; Shrivastava and Li, 2014; Kalantidis and Avrithis, 2014; Shrivastava and Li, 2015; Guo et al., 2016; Wu et al., 2017), and it has non-trivial differences with traditional *Approximate Nearest Neighbor Search* (ANNS) (Friedman et al., 1975, 1977; Indyk and Motwani, 1998) problems. ANNS is an optimization problem of finding the close points to the query point in a given set. Usually, the "close" means smaller in metric distances such as cosine or Euclidean distance, which have obvious geometrical implications. However, inner product is a typical non-metric measure, which distinguishes MIPS from traditional ANNS problems. Thus, methods designed for ANNS may have performance limitations in MIPS. For NLP tasks, such as retrieving relevant word embeddings by cosine and Euclidean distances, different ANNS methods have been studied (Sugawara et al., 2016). To our best knowledge, there is little literature on MIPS for retrieving word or language representations.

Currently, search on graph methods, such as *Hierarchical Navigable Small World graphs* (HNSW), is regarded as the state-of-the-art ANNS method (Malkov and Yashunin, 2018). Performance evaluation has demonstrated that HNSW is

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5236–5246,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

able to strongly outperform other methods ANNS benchmarks for metric distances. Meanwhile, the graph structure also has the flexibility of defining measures on edges, making HNSW feasible for MIPS. Morozov et al (Morozov and Babenko, 2018) conduct HNSW for MIPS and achieve positive results and also they introduce concepts of Delaunay Graph to explain similarity graph based methods for MIPS. Nevertheless, the link between HNSW and Delaunay Graph is still tenuous. Although global optima of MIPS will be retrieved by Delaunay Graph, there are little evidence showing that HNSW approximates proper Delauny Graph for inner product. How to provide a solid graph-based MIPS method is still an open question.

In this paper, we propose a new search on graph method, namely Inner Product Delaunay Graph (**IPDG**), for MIPS. Our key contributions can be summarized as follows:

- Design an edge selection algorithm specifically for inner product that reduces useless edges on graph and thus improves the searching efficiency.
- Propose a two rounds graph construction algorithm for effectively approximating Delaunay Graph under inner product.
- Empirically evaluate the effectiveness and efficiency. Provide a state-of-the-art MIPS method for similarity search in word embedding datasets.

The organization of this paper is as below: in the next section, we will introduce the research background. In Section 3, the approximate Inner Product Delaunay Graph (IPDG) will be introduced. For Section 4, we explore the effectiveness and efficiency of IPDG in maximum inner product word retrieval and compare it with state-of-the-art MIPS methods. Section 5 concludes the whole paper.

2 Background

In this section, we will first introduce the definition of *Maximum Inner Product Search* (MIPS) problem and review state-of-the-art methods for MIPS. Later a theoretical solution for MIPS by searching on the Delaunay Graphs will be summarized.

2.1 Problem Statement

In machine learning tasks, embedding methods such as Word2vec (Mikolov et al., 2013a,b), Glove (Pennington et al., 2014) or deep collaborative filtering (Xu et al., 2018) learn representations of data as dense distributed real-value vectors. Formally, for latent space $X \subset \mathbb{R}^d$, given an arbitrary query vector $q \in X$ and a set of vectors $S = \{x_1, \ldots, x_n\} \subset X$, vector similarity is defined as a continuous symmetric matching function, $f : X \times X \to \mathbb{R}$. The goal of similar vector retrieval is to find:

$$\arg\max_{x \in S} f(x, q). \tag{1}$$

In our paper, we specially discuss the non-metric similarity measure, inner product:

$$f(x, q) = x^\top q, \quad x, q \in X = \mathbb{R}^d \backslash \{0\}.$$

Without loss of the generality, we can always assume $\|q\| = 1$. We are not interested in the zero vector since its inner product with any vector is always zero. The problem in Eq. (1) with respect to the inner product is often referred to as *Maximum Inner Product Search* (MIPS) in literature.

The weighted cosine ANNS problem can also be viewed as the MIPS problem. We consider a data set $S = \{(z_i, w_i) : i \in [n]\}$ where w_i is an real scalar and z_i is a vector.

$$w \cos(z, q) = w \frac{z^\top q}{\|z\|\|q\|} = \frac{wz}{\|z\|}^\top \frac{q}{\|q\|}, \tag{2}$$

where $\|q\| = 1$. As can be seen, weighted ANNS w.r.t. cosine similarity is equivalent to MIPS by letting $x_i = w_i z_i / \|z_i\|$.

2.2 Related Works

Previous approaches for *Maximum Inner Product Search* (**MIPS**) can be mainly categorized into: (1) reducing MIPS to ANNS; (2) non-reduction methods. Reduction methods add wrappers on indexed data and queries asymmetrically and reduce the MIPS problem to ANNS in metric spaces (Shrivastava and Li, 2015; Bachrach et al., 2014). For example, given the query q, the indexed data $S = \{x_1, ..., x_n\}$ and $\Phi = \max_i ||x_i||$, the wrapper can be defined as:

$$P(x) = [x/\Phi; \sqrt{1 - ||x||^2/\Phi^2}], \tag{3}$$

$$Q(q) = [q; 0]. \tag{4}$$

It is not difficult to prove that searching on the new data by cosine or ℓ_2-distance is equal to search on the original data by inner product. Recently, researchers found that methods above can be improved further, based on the observation of the long tail distribution in data norms (Huang et al., 2018;

Yan et al., 2018). New approaches are proposed by adding wrappers for each norm range, such as **Range-LSH** (Yan et al., 2018). With reductions like the above one, any ANNS methods can be applied for MIPS. However, it was shown that there are performance limitations for the reduction MIPS methods (Morozov and Babenko, 2018).

Recently, more and more non-reduction methods are proposed, specifically for MIPS. Guo et al. proposed an MIPS method based on **Product Quantization (PQ)** (Guo et al., 2016). Yu et al. used an upper bound of inner product as the approximation of MIPS and designed a greedy search algorithm to find this approximation, called **Greedy-MIPS** (Yu et al., 2017). Graph-based non-reduction MIPS method, **ip-NSW**, was firstly introduced in Morozov and Babenko (2018) and the theoretical basis for conducting MIPS by similarity graph was also provided. Continuing of the advantages of similarity graph based methods for ANNS, ip-NSW showed superior performance for MIPS.

2.3 Delaunay Graph

Delaunay Graph plays an important role in the similarity search. The properties and construction of ℓ^2-Delaunay Graph have been considered in literature (Aurenhammer, 1991; Cignoni et al., 1998). Indeed, one can generalize the definition to any real binary function, including inner product.

Definition 2.1. The *Voronoi cell* R_i with respect to f and x_i is the set

$$R_i := \{q \in X : f(x_i, q) \geq f(x, q) \text{ for all } x \in S\}.$$

Moreover, $x \in S$ is an *extreme* point if it is associated with a nonempty Voronoi cell.

Definition 2.2. The *Delaunay Graph* G with respect to f and S is an undirected graph with vertices S satisfying $\{x_i, x_j\} \in G$ if and only if $R_i \cap R_j \neq \emptyset$.

An example of Voronoi cells and corresponding Delaunay Graph in inner product space is shown in Figure 1. Regions in different colors correspond to Voronoi cells for extreme points (red ones). Delaunay Graph connects extreme points. Different from metric similarities (e.g. ℓ^2-norm), the Voronoi cells of some data points with respect to inner product are possibly empty. By Definition 2.2, a data point is isolated (i.e., have no incident edges) if its Voronoi cell is empty. As we can see in Figure 1, there are many isolated points (blue ones). The

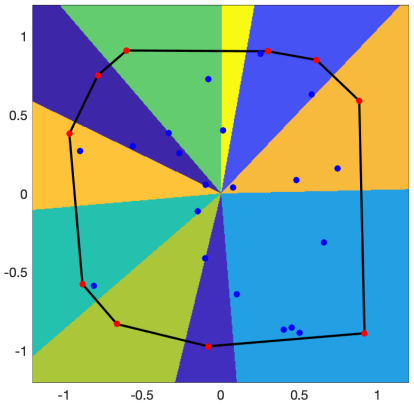

Figure 1: This shows the relation between Delaunay Graph and Voronoi cells in inner product space. The red dots are *extreme* points of each Voronoi cell. Delaunay Graph connects extreme points with black edges. If we search on this dataset, every query has a maximum inner product with one of these extreme points (i.e., red ones).

proportion of extreme points is relatively small in general. And Theorem 2.1 will show that only extreme points can achieve a maximum inner product score for any nonzero query.

The definition of an extreme point is equivalent to the one in (Barber et al., 1996), i.e., $x \in S$ is extreme if and only if x is on the boundary of the convex hull of S. In the two dimensional cases, the edges form the boundary of the convex hull, which is also shown in Figure 1.

2.4 Search on Delaunay Graph

Searching on the Delaunay Graph is demonstrated effective for similarity search (Morozov and Babenko, 2018). In the inner product case, given any query vector $q \in X$, we start from an extreme point, then move to its neighbor that has a larger inner product with q. We repeat this step until getting an extreme point has a larger inner product with q than all its neighbors and then we return it. It can be demonstrated this returned local optimum is actually the global optimum.

Generally, for any searching measure f, if the corresponding Voronoi cells are connected, then the local optimum returned by the greedy search is also the global optimum. Formally the statement can be summarized as below. The proof can be found in Morozov and Babenko (2018).

Theorem 2.1. Suppose f satisfies that the Voronoi cells R_i with respect to any subsets of S (including S itself) are connected on X, and G is the Delaunay Graph with respect to f and some S, then for $q \in X$, a local maximum in the greedy search starting

from an extreme point, that is, $x_i \in S$ satisfies

$$f(x_i, q) \geq \max_{x \in N(x_i)} f(x, q) \quad (5)$$
$$\text{where} \quad N(x_i) = \{x \in S : \{x_i, x\} \in G\}$$

is a global maximum.

Suppose the assumptions (i.e., connected Voronoi cells) in Theorem 2.1 hold, we say searching on Delaunay Graph can find the global maximum. It is easy to check that the assumptions hold for the inner product case since the Voronoi cells w.r.t. the inner product are either empty or a convex cone, so they are connected. Then we can claim that searching on Delaunay Graph in inner product, the vector in S that has the maximum inner product with the query vector will be retrieved.

3 Inner Product Delaunay Graph

Although the Delaunay Graph has demonstrated its potentials in similarity search, the direct construction of the Delaunay Graph in large scale and high dimensional datasets is unfeasible due to the exponentially growing number of edges in high dimension. To remedy this issue, practical algorithms usually approximate Delaunay Graphs. In this section, we will present the new proposed algorithm for constructing approximate Delaunay Graph in inner product space, namely Inner Product Delaunay Graph (IPDG). Two key features of our algorithm will be introduced first: i) edge selection specifically for inner product; and ii) the two rounds graph construction. And then we will conduct a case study on the toy dataset to show the effectiveness of IPDG in constructing better approximate Delaunay Graphs for inner product.

3.1 Edge Selection for Inner Product

To balance the effectiveness (retrieval of the nearest neighbor) and the efficiency (complete the process within limit time) of the retrieval, some empirical tricks are usually applied in previous search on graph methods: a) use directed edges instead of undirected edges; b) restrict the degree of outgoing edges for each node; and c) select more diverse outgoing edges (Malkov and Yashunin, 2018; Morozov and Babenko, 2018).

Specifically, for the inner product case, ip-NSW proposed in (Morozov and Babenko, 2018) applies all tricks listed above (although the authors did not mention it in the paper, the implementation did inherit all features from HNSW). We found that the edge selection method is vital for the trade-off of effectiveness and efficiency in searching. However, the existing edge selection techniques used in HNSW and ip-NSW are actually designed for metric distances, which are inapplicable for the non-metric measure, e.g., inner product.

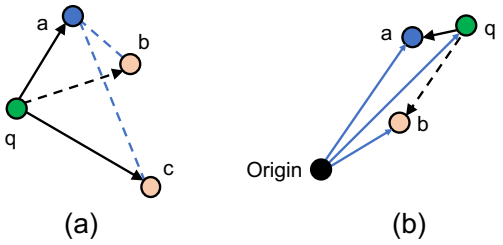

Figure 2: The example of edge selection used in constructing approximate Delaunay Graph. (a) the selection method for metric spaces used in HNSW and ip-NSW. c is selected while b is abandoned since it is not diverse from a. (b) the edge selection in IPDG. b will be ignored because a is a "super" point of it, which has been selected.

As shown in Figure 2 (a), the edge selection for metric spaces works as below: for each new inserting node (or edge updating node) q and its nearest neighbor set (candidates) from Algorithm 2, a directed edge from q to the nearest neighbor a is constructed first. For other candidates, say b, the edge selection algorithm will check whether:

$$dis(q, b) < dis(a, b), \quad (6)$$

where $dis(\cdot, \cdot)$ is the distance of two vectors, such as ℓ_2-distance or angular distance. If it is true, there will be an edge from q to b, otherwise, b will be abandoned in the selection. By this way, in a restricted degree, the new inserting node will have diverse outgoing neighbors. As shown in Figure 2 (a), b is not selected while c is selected.

It is obvious that the edge selection method for metric spaces is not suitable for inner product. As presented in Figure 2 (b), although $q^\top b > a^\top b$ (corresponding to $dis(q, b) < dis(a, b)$), b should not be selected, since $a^\top b > b^\top b$ and for any query vector q' with all positive elements, we have $q'^\top a > q'^\top b$. This means that b is dispensable in the top-1 MIPS task and the edge from q to b should not be constructed. To solve this issue, we propose a new edge selection method by checking whether:

$$b^\top b > a^\top b. \quad (7)$$

If it is true, we will select b. Otherwise, we will skip b since a is a "super" point of b and b is dispensable. In this way, each inserting node will trend to connect with extreme points but not other short norm

vectors. The detailed algorithm is summarized in Algorithm 1 Lines $17-28$.

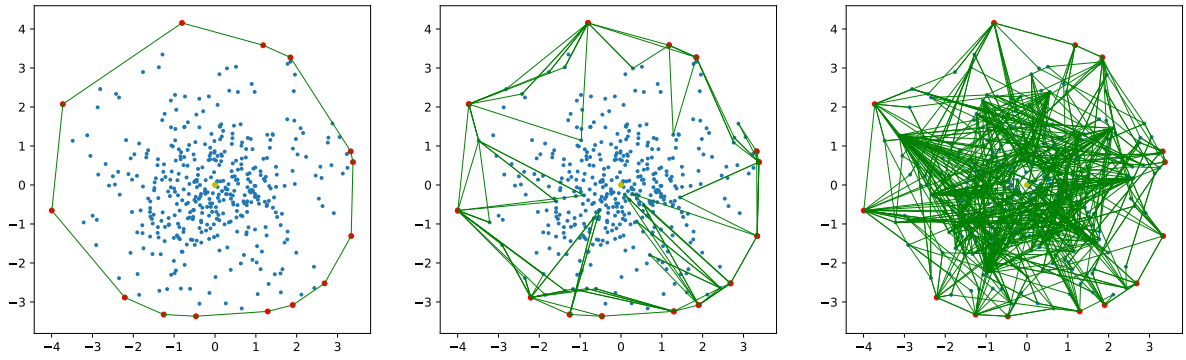
Algorithm 1 IPDG Construction

1: **Input:** dataset S, the size of candidate size N, maximum outgoing degree of graph M.
2: Initialize graph $G = \emptyset$. $round = 0$
3: **while** $round < 2$ **do**
4: $round = round + 1$
5: **for** each x in S **do**
6: $A \leftarrow$ GREEDY_SEARCH(x, G, N).
7: $B \leftarrow$ EDGE_SELECTION(A, M).
8: Add edges $\overrightarrow{xy}$ to G for every $y \in B$.
9: **for** each y in B **do** ▷ Edge Updating
10: $C \leftarrow \{z \in S : \overrightarrow{yz} \in G\} \cup \{x\}$.
11: $D \leftarrow$ EDGE_SELECTION(C, M).
12: Remove original outgoing edges of y, and add edges $\overrightarrow{yz}$ to G for $z \in D$.
13: **end for**
14: **end for**
15: **end while**
16: **Output:** graph G.
17: **function** EDGE_SELECTION(A, M)
18: $B = \emptyset$.
19: **for** $y \in A$ **do**
20: **if** $y^\top y \geq \max_{z \in B} y^\top z$ **then**
21: $B = B \cup \{y\}$.
22: **end if**
23: **if** $|B| \geq M$ **then**
24: Break.
25: **end if**
26: **end for**
27: **Output:** B.
28: **end function**

3.2 Two-Round Construction

Based on the new edge selection method introduced above (and the reverse edge updating, see Algorithm 1 Lines $9-13$), nodes with larger norms will have higher probabilities to be selected as outgoing neighbors. So extreme points of the dataset will have more incoming edges and non-extremes points will more likely have no incoming edges in general. This is consistent with the true Delaunay Graphs in inner product space as previously shown in Figure 1.

However, at beginning of the graph construction, relatively "super" points are not true extreme points. Vectors coming in later may be better candidates (i.e., true extreme points). This issue will damage the overall graph quality and affect the final searching performance. A straightforward method may probably help: inserting data points with larger norms first. We tried this trick but it did not work well. The reason is that high norm points are not necessarily extreme points. Norms of extreme points for some Voronoi cells may be relatively small. The top large norm points may be just from one or a few Voronoi cells. In high dimensional data, it is difficult to find true extreme points. Alternatively, we design a two rounds construction algorithm to solve this issue and exploit the additional round construction to update edges, especially for nodes inserted in the beginning. In this way, the graph construction algorithm can detect extreme points automatically. We tried to conduct this two rounds construction method for ip-NSW too, but there are no significant improvements.



We share the graph construction algorithm for IPDG, including the edge selection function in Algorithm 1. After the graph being constructed, we perform MIPS via a greedy search algorithm presented in Algorithm 2. The greedy search algorithm is also used in the graph construction for candidates collecting.

Algorithm 2 GREEDY_SEARCH(q, G, N)

1: **Input:** The query q, the index graph G, the size of candidate set N.
2: Randomly choose a node with outgoing edges, say y. $A \leftarrow \{y\}$. Mark y as checked and the rest as unchecked. ▷
In the practical implementation, A is a priority queue for efficiency. We note A as a set here to simplify the expression.
3: **while** not all nodes in G are checked **do**
4: $A \leftarrow A \cup \{z \in S : \overrightarrow{yz} \in G, y \in A, z \text{ unchecked}\}$
5: Mark nodes in A as checked.
6: $A \leftarrow$ top N candidates in $A \cup Z$ in descending order of inner product with q.
7: **if** A does not update **then**
8: Break.
9: **end if**
10: **end while**
11: **Output:** A.

3.3 A Toy Example

To further explain the differences between the proposed method and previous state-of-the-art, ip-NSW, we conduct a case study on a toy example

(a) (b) (c)

Figure 3: This is a toy example for approximate inner product Delaunay Graph construction (green lines are edges here) and red dots are $extreme$ points too. (a) is the true Delaunay Graph. (b) is an approximation by IPDG. (c) is built by ip-NSW. Note that IPDG and ip-NSW construct directed edges instead of undirected ones for the efficiency consideration. Only edges for nodes with incoming edges are shown in (b) and (c).

data which is shown in Figure 3. We randomly generate 400 two dimensional vectors following distribution Normal$(0, I_2)$. Figure 3 (a) shows the true Delaunay Graph for inner product. Red nodes correspond to extreme points of this dataset. Figure 3 (b) and (c) are graphs built by the proposed IPDG and ip-NSW, respectively. The parameter N is set to 10 and M is set to 2 for both algorithms in this study. Note that graphs built by IPDG and ip-NSW are directed graphs. To give better showing out, we only keep edges corresponding to nodes with incoming edges and other edges are ignored. Nodes without incoming edges will not be visited and do not affect the searching process, thus can be removed after the graph construction. As can be seen, the graph built by IPDG is more like the true Delaunay Graph and is more efficient for MIPS, while the graph built by ip-NSW have too many useless edges as shown in Figure 3 (c).

4 Experiments

In this section, we evaluate the proposed IPDG by comparing it with state-of-the-art MIPS methods.

4.1 Datasets

We used the following three pre-trained embeddings to investigate the performance of IPDG in MIPS for similar word searching. For each word embedding datasets, we random select 10000 vectors as queries and others as the base data.

fastTextEn and **fastTextFr** are 300 dimensional English and French word embeddings trained on Wikipedia using fastText (Joulin et al., 2016).

GloVe50 are 50 dimensional word embeddings trained on Wikipedia2014 and Gigaword5 using GloVe (Pennington et al., 2014).

As most state-of-the-art MIPS algorithms evaluate their performance on recommendation datasets, we also benchmark IPDG on three recommendation datasets: Amazon Movie (**Amovie**), **Yelp** and **Netflix**. We use the Matrix Factorization (MF) method in (Hu et al., 2008) to obtain latent vectors of user and item. Then, in the retrieval process, user vectors are regarded as queries and the item vector that has the highest inner product score with each query should be returned by the MIPS algorithm.

Datasets	Dimension	# Base Data
fastTextEn	300	989873
fastTextFr	300	1142501
GloVe	50	1183514
Amovie	64	104708
Yelp	64	25815
Netflix	50	17770

Table 1: Statistics of the datasets.

Statistics of the six datasets are listed in Table 1. They vary in dimension (300, 64 and 50), sources (recommendation ratings, word documents) and extraction methods (fastText, GloVe and MF), which is sufficient for fair comparison. The ground truth is the top-1 nearest neighbor by inner product.

4.2 Baselines

In this paper, we compare IPDG with state-of-the-art MIPS methods. Firstly, reduction methods can be baselines. Some popular ANNS open source platforms utilize the reduction trick to solve MIPS, such as Annoy[1]. As introduced in Section 2.2, with reductions, any ANNS methods can be applied for

[1]https://github.com/spotify/annoy

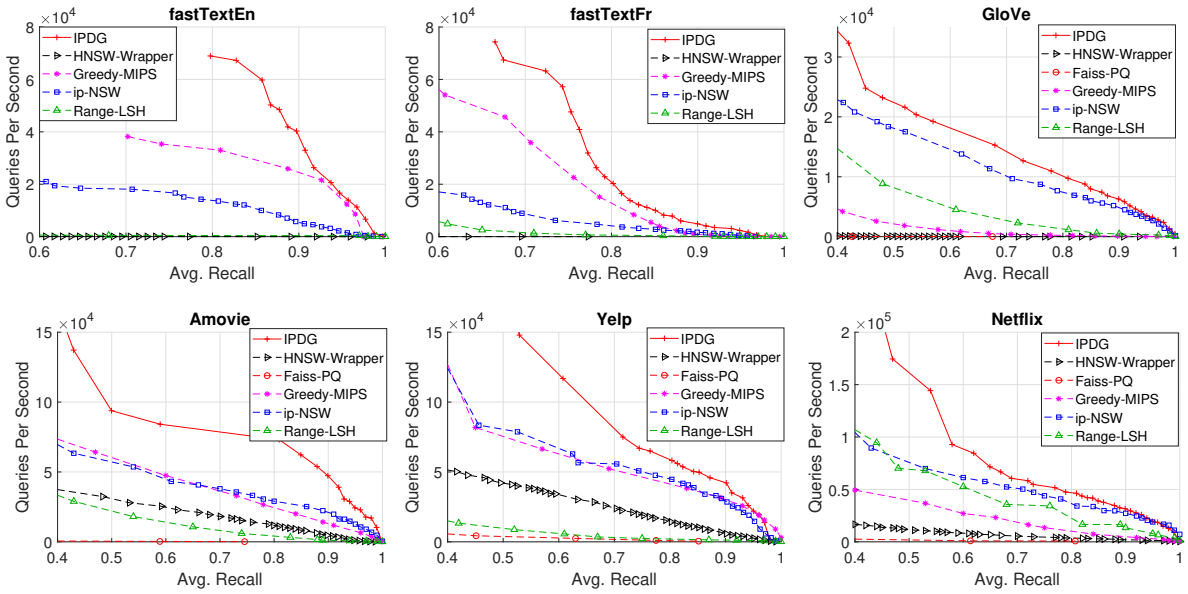


Figure 4: Recall vs. Time curves of for all methods in top-1 MIPS. Results for Faiss-PQ on fastTextEn and fastTextFr are not shown since they cannot produce recalls greater than 0.6. Best results are in upper right corners.

MIPS. In this line, we choose HNSW (Malkov and Yashunin, 2018) (referred to as **HNSW-Wrapper**) as the baseline and neglect other alternatives since HNSW is usually regarded as the most promising method for ANNS in metric spaces. We exploit the original implementation of HNSW[2] and add the wrapper introduced in Section 2.2.

Range-LSH (Yan et al., 2018) is also an reduction MIPS method and considers norm distribution of the data. The original implementation[3] is used.

Faiss-PQ[4] is a popular open source ANNS platform from Facebook, which is mainly implemented by Product Quantization (PQ) techniques. It contains MIPS as one component.

Greedy-MIPS is an MIPS algorithm from Yu et al. (2017). We use the original implementation[5].

ip-NSW is a state-of-the-art MIPS algorithm proposed in (Morozov and Babenko, 2018).[6].

4.3 Experimental Settings

There are two popular ways to evaluate ANNS/MIPS algorithms: i) **Recall vs. Time**; ii) **Recall vs. Computations**. Recall vs. Time reports the number of queries an algorithm can process per second at each recall level. Recall vs. Computations reports the amount/percentage of pairwise distance/similarity computations that the ANNS/MIPS algorithm costs at each recall level. Both evaluation indicators have their own pros and cons. Recall vs. Time is straightforward but it may introduce bias in implementation. Recall vs. Computations is beyond implementation but it does not consider the cost of different index structures. We will show both of these perspectives in the following experiments for the comprehensive evaluation.

All comparing methods have tunable parameters. In order to present a fair comparison, we vary all parameters over a fine grid for all methods. For each algorithm in each experiment, we will have multiple points scattered on the plane. To plot curves, we first find out the best result, $\max_x$, along with the x-axis (i.e., Recall). Then 100 buckets are produced by splitting the range from 0 to max_x evenly. For each bucket, the best result along the y-axis (e.g., the biggest amount of queries per second or the lowest percentage of computations) is chosen. If there are no data points in the bucket, the bucket will be ignored. In this way, we shall have multiple pairs of data for drawing curves. All time-related experiments were performed on a 2X 3.00 GHz 8-core i7-5960X CPU server with 32GB memory.

4.4 Experimental Results

We first show experimental results for all comparison algorithms from the view of Recall vs. Time, which are shown in Figure 4. Overall, the proposed method IPDG performs consistently and significantly better than baselines on all six datasets. As

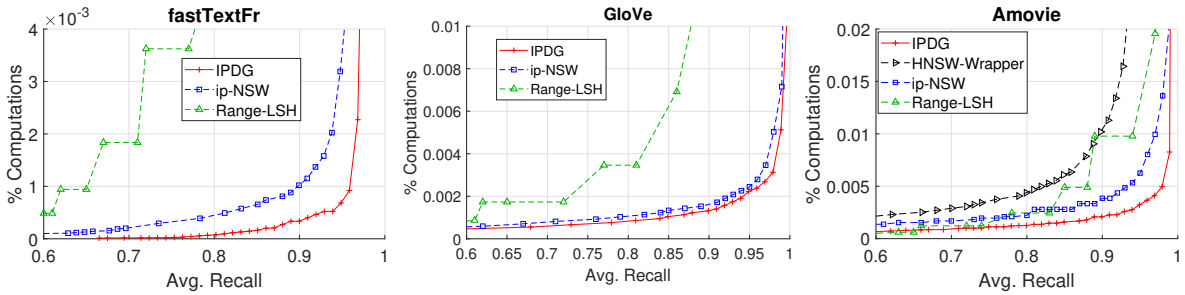

Figure 5: Recall vs. Computations curves in top-1 MIPS. Note that it is unable to show results for HNSW-Wrapper on fastTextFr and Glove in the showing scope. Best results are in lower right corners.

can be seen, some baselines show promising performance on partial datasets but they may work much worse on other datasets. For example, on lower dimensional datasets (i.e., the last four figures of Figure 4), ip-NSW work well but it fails on high dimensional datasets (i.e., fastTextEn and fastTextFr). Greedy-MIPS shows advantages on high dimensional datasets while becomes worse on some lower dimensional datasets, such as Netflix and GloVe. Among all methods, only IPDG works consistently well on all datasets which shows its effectiveness and robustness. Range-LSH performs badly in these experiments. The main reason is that Range-LSH does not have a good "budget" setting, similar to the budget in Greedy-MIPS and the N_{search} parameter in graph-based methods. HNSW-Wrapper does not work comparably with IPDG either, especially on word embedding datasets. On some recall levels, say higher than 0.5, searching by HNSW-Wrapper is extremely slow (see the first three figures). It is clear that HNSW-Wrapper is far from state-of-the-art in challenging MIPS tasks, such as larger or higher dimensional vector datasets. The PQ based method, Faiss-PQ, works badly on all datasets since quantization codes can speedup the retrieval while may largely reduce the search performance, especially for the challenging top-1 MIPS problem. Note that results for Faiss-PQ on fastTextEn and fastTextFr are not shown in Figure 4 since they cannot produce recalls greater than 0.6.

We also show experimental results by Recall vs. Computations in Figure 5. Greedy-MIPS and Faiss-PQ cannot be evaluated from this view and the other four methods are explored here. Due to the limited space, only results on partial datasets are represented. As can be seen, only IPDG and ip-NSW work consistently well on all shown datasets. HNSW-Wrapper and Range-LSH work comparably with the other two methods on the recommendation dataset, Amovie, while performs much worse on the word embedding dataset, fastTextFr and GloVe. It is even unable to show the result for HNSW-Wrapper on fastTextFr and Glove in the showing scope. For IPDG and ip-NSW, they share similar index structures, it is fair to compare their computation amount for each query. To get a similar recall, IPDG requires much less inner product computation. For example, on fastTextFr, to reach the recall at 95%, ip-NSW requires about 0.3% computations while IPDG only needs 0.07% computations. This also demonstrates the efficiency of vector inner product retrieval by IPDG.

4.5 More Comparison with ip-NSW

Datasets	ip-NSW	IPDG
fastTextEn	144339 (14.6%)	100138 (10.1%)
fastTextFr	378875 (33.2%)	250750 (21.9%)
GloVe	622080 (52.6%)	437378 (37.0%)
Amovie	32434 (31.0%)	12985 (12.4%)
Yelp	5224 (20.2%)	1871 (7.2%)
Netflix	17154 (96.5%)	14867 (83.7%)

Table 2: Number and percentage of nodes with incoming edges for graphs built by ip-NSW and IPDG.

In this section, we will conduct a study by comparing the proposed IPDG and its closely related method ip-NSW on the index graph quality. The evaluation measure is the number of nodes with incoming edges. Intuitively, only extreme points of each dataset are useful for top-1 MIPS retrieval. Non-extreme points could be ignored in graph construction (i.e., without incoming edges so will not be visited in searching). Results for $N = 100$ and $M = 16$ are shown in Table 2. As can be seen, the graphs built by IPDG have much fewer nodes with incoming edges, which is consistent with the toy example introduced above. The reason can be

explained as below. The finely designed edge selection method in IPDG trends to select extreme points as outgoing neighbors for each newly inserted node or each edge updating node (see Algorithm 1 Lines $9-13$). Meanwhile, extreme points will have more opportunities to keep incoming edges in the edge updating and the second round graph construction. While non-extreme points will lose their incoming edges in these processes.

5 Conclusion and Future Work

Fast similarity search for data representations via inner product is a crucial and challenging task since it is one of the basic operations in machine learning algorithms and recommendation methods. To remedy this issue, we propose a search on graph method, namely Inner Product Delaunay Graph (IPDG), for Maximum Inner Product Search (MIPS) in embedded latent vectors. IPDG provides a better approximation to Delaunay Graphs for inner product than previous methods and is more efficient for the MIPS task. Experiments on extensive benchmarks demonstrate that IPDG outperforms previous state-of-the-art MIPS methods in retrieving latent vectors under inner product.

In this paper, we improve the top-1 MIPS performance by graph-based index. In the future, we will try to move the state-of-the-art frontier further, not only for top-1 MIPS but also for top-n, $n > 1$, MIPS results. Besides of metric measures (e.g., ℓ_2-distance and cosine similarity) and inner product, more complicated measures has been studied, for example (Tan et al., 2019). It would be interesting to adopt these measures in NLP tasks. Another promising direction is to adopt a GPU-based system for fast ANNS or MIPS, which has been shown highly effective for generic ANNS tasks (Li et al., 2012; Johnson et al., 2017; Zhao et al., 2019). Developing GPU-based algorithms for MIPS is still a topic which has not been fully explored.
