To demonstrate the effectiveness of different strategies for augmenting the training data for ADR phrase detection, we compare our proposed approach with the following techniques:

- **CRF+SelfTraining (Usami et al., 2011):** A simple semi-supervised learning technique, where we train a similar conditional-random field phrase detection model as described before, but we apply the trained model on a set of randomly selected unlabeled sentences from UGC (i.e. we used 500 samples). The sentences containing newly annotated ADRs are added to the initial training data and are used to re-train the phrase detection model.
- **CRF+Doc2vec:** CRF model trained on data expanded using an embedding-based strategy. Instead of generating new content SC using VAE, we use Doc2vec (Le and Mikolov, 2014) which is inspired by word2vec (Mikolov et al., 2013) to find sentences similar to the labeled content LC.

4.4 Training

For training the Variational Autoencoder described in Section 3.1, we set the word dropout to 0.5, the learning rate to 0.001 and we used GRU (Cho et al., 2014) for both the encoder and the decoder. For labeling the newly generated sentences, we used word embeddings as described in (Mikolov et al., 2013). For Twitter we used pre-trained word embeddings trained on Twitter as described in (Godin et al., 2015). Since these pre-trained word embeddings did not perform well on the Reddit dataset, we trained a custom word embedding on all our Reddit data. We trained the skip-gram *word2vec* (300 dimension) model on the whole Reddit unlabeled collection.

Table 4: Performance of the different ADR detection techniques on the Twitter and Reddit test sets.

Technique	Precision	Recall	Fscore
QuickUMLS	.47	.34	.39
CRF	.67	.42	.51
BLSTM-RNN	.61	**.87**	.72
CRF+VAE	.68	.49	.57
BLSTM-RNN+VAE	**.71**	.85	**.77**

(a) Twitter

Technique	Precision	Recall	Fscore
QuickUMLS	.14	.21	17
CRF	**.72**	.47	.57
BLSTM-RNN	.67	.28	.39
CRF+VAE	.69	**.52**	**.60**
BLSTM-RNN+VAE	.63	.29	.40

(b) Reddit

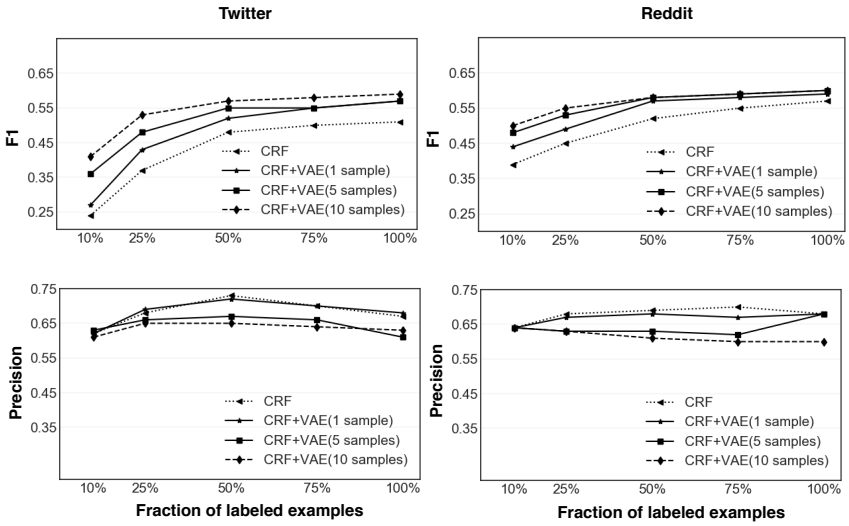

Figure 2: Average *F1* and *Precision* for *CRF* and *CRF+VAE* techniques, trained using different fractions of manually annotated examples and varying number of samples generated using VAE. Tested on the *Twitter* test set (on the left) and on the *Reddit* test set (on the right).

5 Results and Discussions

5.1 Comparison with ADR Detectors

In the first experiment, we compare our approach (i.e. trained with 100% of the labeled training data with 1 sample generated for each sample in the LC) against different ADR detector techniques described in Section 4.3. Table 4 reports precision, and recall and F1-measure, of all the baselines in comparison to proposed approach CRF+VAE in *Twitter* and *Reddit* dataset. We make the following observations: *QuickUMLS* is outperformed by all the other methods. The result shows that dictionary based approaches are not able to cover concepts that do not have a reference in UMLS dictionary, and produce false positives by labeling irrelevant words such as "maybe", "energy", "condition", "illness", or "worse" as positive.

The difference in performance between CRF and CRF+VAE shows the advantage brought by the sentence generation (VAE) and sentence annotation step of our approach. To highlight that our method can be combined with any supervised phrase detection technique, we combined our proposed technique with the BLSTM-RNN. BLSTM-RNN outperforms CRF in Twitter dataset; note that the model was designed to detect ADRs from the Twitter dataset. The results show that independent of the methodology used for training an ADR detector (e.g. CRF or BLSTM-RNN), expanding training data with VAE improves the overall performance. However due to the large amount of time required for training the BLSTM-RNN and the unstable prediction performance of its model on the test set (Cocos et al., 2017), the remaining experiments just focus on CRF for training ADR detector.

5.2 Effects of Training Data Size on CRF+VAE

For a given dataset (*Twitter* and *Reddit*), we created smaller subsets of the training data (i.e. 10%, 25%, 50%, 75%, 100%) to simulate the effect of limited training data availability. The subsets are randomly selected, and experiments are repeated 10 times for each size setting. We then train a CRF algorithm and different variants of our CRF+VAE (i.e. with different subsets of training data and different size of newly generated content for each labeled sample) and compare their performance. In

particular, the core advantage of our approach is that we are able to generate any number of additional training data samples. Therefore, we test different settings where we generate an extra 1, 5, or 10 artificial sentences for each labeled sentence in the training set. The experiments are conducted 10 times for each setting.

Figure 2 summarizes the average performance achieved for *Twitter* and *Reddit* datasets. The results show that by using the VAE to expand the training data, it is possible to obtain higher F-scores for both datasets. In Addition, we can show that by increasing the number of artificially generated samples (i.e. 5 and 10 samples), we can achieve a considerable F-score boost up to (+.17) and (+.12) for Twitter and Reddit (i.e. with just 10% of the labeled samples). We did not observe any significant improvement with more than 10 samples. This limitation is likely due to our constraint to generate sentences similar to the existing annotated sentences instead of radically new ones - a limitation chosen to allow us to perform reliable label propagation which would be hard for sentences too different. The results also show that by generating 1 sample using VAE but only using 50% of the training data, we can obtain comparable results to using the 100% of the labeled training data without VAE. When generating more training samples (i.e. 10 samples), our approach can achieve comparable performance with only the 25% of the initial labeled set. As shown in Figure 2, the effect of VAE expansion is greater the smaller the training data set is, thus VAE is used most efficiently to reduce the training costs of ADR detection significantly while maintaining quality. Note that all the improvements of CRF+VAE over CRF are statistically significant using paired t-test (i.e. p-value$<$0.05). When artificially expanding training data, recall is often improved at the cost of precision. This is demonstrated by the performance of CRF+Doc2Vec (Table 5). However, even using CRF+VAE (1 sample) shows higher F-score than CRF without notable loss of precision. This positive behaviour can be attributed to the larger number of positive and negative examples which helps to maintain the generalisation capabilities of the ADR detector while refining the quality of its recognition.

5.3 Comparison of Data Expansion Techniques

In the third experiment, we compare the performance of CRF+VAE against the two other automatic training data expansion techniques CRF+SelfTraining and CRF+Doc2Vec. As in the previous experiment, we use 10%, 25%, 50%, 75% and 100% of the training data. For the sake of brevity, we only report the best performance[9] achieved by these techniques in Table 5.

CRF+SelfTraining keeps the precision high but compared to CRF+Doc2Vec and CRF+VAE, it is not able to increase the recall significantly. Its low recall can be attributed to treating some terms incorrectly as negative instance examples. This is due to relying only on the output of the trained model for labeling the training data for the next iteration. We observe that CRF+VAE achieves better precision and comparable recall to CRF+Doc2Vec with the Twitter dataset, while achieving similar performance in the Reddit dataset in terms of F-score, but with higher precision. This underlines that artificially generating new similar training sentences can outperform discovering existing similar training sentences using Doc2Vec similarity. The results show that our approach in general performs better in the Twitter dataset. This can likely be attributed to the differences in the structure between the two datasets. Each tweet contains on average 8 words, while each Reddit sentence contains on average 17 words. Also, VAEs have shown to perform better on shorter sentences (Semeniuta et al., 2017).

6 Qualitative Analysis

In this section we tested CRF+VAE approach on *Twitter* and *Reddit* test sets and manually inspect all the posts containing false positive and negatives to understand the reasons for the prediction errors.

False Positives. Manual inspection of the posts reveal that most of the false positives are due to 1) Mis-recognizing *indications* as an ADR, i.e. an illness for which the drug has been prescribed is recognized as an adverse drug reaction (Chowdhury et al., 2018). For instance in the two posts *"I started effexor after having pretty severe postpartum depression"* and *"depression hurts cymbalta can help"*, `depression` is labeled as ADR even though it is an *indication*. However,

[9]The Self-training configuration has been run for ten iterations; we report the iteration with best performance.

Table 5: Average Precision/Recall/F1 with standard deviation in parenthesis for CRF, CRF+SelfTraining, CRF+Doc2Vec and CRF+VAE on Twitter and Reddit datasets. The experiments are conducted 10 times for each setting.

Datasets	%Labeled samples	CRF	CRF+SelfTraining	CRF+Doc2Vec	CRF+VAE
Twitter	10	62(.1)/.15(.05)/.24(.07)	.65(.05)/.27(.05)/.38(.06)	.57(.09)/.30(.04)/.39(.04)	.61(.10)/.32(.04)/.41(.04)
	25	68(.06)/.25(.03)/.37(.04)	.66(.05)/.32(.02)/.43(.02)	.62(.03)/.42(.03)/.50(.03)	.65(.04)/.44(.03)/.53(.02)
	50	73(.02)/.35(.02)/.48(.02)	70(.03)/.37(.03)/.48(.03)	.65(.04)/.50(.01)/.56(.01)	.65(.01)/.51(.02)/.57(.01)
	75	70(.02)/.39(.01)/.50(.02)	68(.02)/.40(.02)/.51(.02)	.66(.02)/.52(.02)/.58(.01)	.67(.02)/.51(.03)/.58(.02)
	100	.67/.42/.51	.67/.41/.51	.61/.57/.59	.64/.56/.60
Reddit	10	.64(.06)/.28(.05)/.38(.05)	.64(.05)/.29(.05)/.40(.04)	.62(0.04)/.42(.04)/.50(0.3)	.64(.03)/.41(.04)/.50(.03)
	25	.68(.03)/.34(.03)/.45(.03)	.68(.03)/.34(.04)/.45(.03)	.61(.02)/.51(.02)/.55(.02)	.63(.02)/.48(.01)/.55(.01)
	50	.69(.02)/.42(.03)/.52(.02)	.69(.02)/.43(.04)/.53(.02)	.57(.02)/.60(.01)/.59(.01)	.61(.01)/.56(.02)/.59(.01)
	75	.70(.01)/.46(.02)/.55(.01)	.70(.01)/.46(.02)/.55(.01)	.56(.01)/.62(.01)/.59(.01)	.60(.01)/.59(.01)/.60(.01)
	100	.72/.47/.57	.71/.46/.57	.57/.64/.61	.60/.62/.61

`depression` commonly occur as ADR as well in other posts, which might be the cause for this error (Chowdhury et al., 2018); 2) Ignoring negative verbs. As an example the word `manic` in *"The only one that didn't make me manic, Wellbrutin"* and `vomiting` in *"@uclaibd I never had bleeding or vomiting just a lot of fatigue"* are detected as ADRs due to the structure of the posts. However the model was not able to distinguish the negative verbs; 3) Mis-labeling ADR-related words as an ADR: For instance in the post *"temperature would start to rise, depression weakens"* the word `depression` was recognized as ADR; 4) Mistakes in manual annotation in the test data. For instance in the Tweet *"Ive had no appetite since I started on prozac"*, the annotators did not annotate *no appetite* as an ADR. However, our model was able to predict it correctly as an ADR, but due to this mistake in test data is considered a false positive.

False Negatives. False negatives are likely to occur in posts that are ambigious or overly complex. For example, in the post *"Im just wondering if its safe to take tramadol 15h after vyanse and if promethazine and melatonin would lower my chances of a seizure"* the word `seizure` was not detected as an ADR. It must be noted how, in this specific case, even human annotators debated if seizure is indeed an ADR of tramadol, or an indication of vyanse. In another example *"Am I the only one that grinds the shit out of their teeth on Vyvanse"*. The expression `grinds the shit out of their teeth` is a long description of the slang ADR *teeth grind*, which has been described in a very unstructured and informal way. This is hard to handle for phrase detectors like CRF as some level of abstraction would be necessary to deal with this.

7 Conclusion

In this paper, we have demonstrated an approach for augmenting training data for detecting mentions of Adverse Drug Reactions from social media text in a very cost-efficient manner. We introduced a technique which expands human-labeled training sets with a large number of artificially generated training samples. The benefit of our training data generation technique is greater the smaller the manually created training data set is. Therefore, it is used most efficiently to reduce the manual training costs of ADR detection while maintaining quality (e.g., in our experiments, we can maintain quality even when reducing manually provided training data by 75%). Furthermore, we could show that our approach generally works better on Twitter data. We assume that this can be explained by Reddit forum posts using significantly richer, longer, and more complex sentences. VAEs are known to work more effectively with shorter sentences than with longer ones. This work is only one of the initial steps towards automated adverse drug effect analytics on social data. The next step would be to interpret the semantics of the extracted slang ADRs, and linking them to medical ontologies to allow for further structured analysis.

Acknowledgments

We thank Dr. Gerhard Mulder for his wonderful collaboration in annotating the Reddit dataset.

Deep Reinforcement Learning-based Text Anonymization against Private-Attribute Inference

Ahmadreza Mosallanezhad **Ghazaleh Beigi** **Huan Liu**

Abstract

User-generated textual data is rich in content and has been used in many user behavioral modeling tasks. However, it could also leak user private-attribute information that they may not want to disclose such as age and location. User's privacy concerns mandate data publishers to protect privacy. One effective way is to anonymize the textual data. In this paper, we study the problem of textual data anonymization and propose a novel Reinforcement Learning-based Text Anonymizor, RLTA, which addresses the problem of private-attribute leakage while preserving the utility of textual data. Our approach first extracts a latent representation of the original text w.r.t. a given task, then leverages deep reinforcement learning to automatically learn an optimal strategy for manipulating text representations w.r.t. the received privacy and utility feedback. Experiments show the effectiveness of this approach in terms of preserving both privacy and utility.

1 Introduction

Social media users generate a tremendous amount of data such as profile information, network connections and online reviews and posts. Online vendors use this data to understand users preferences and further predict their future needs. However, user-generated data is rich in content and malicious attackers can infer users' sensitive information. AOL search data leak in 2006 is an example of privacy breaches which results in users re-identification according to the published AOL search logs and queries (Pass et al., 2006). Therefore, these privacy concerns mandate that data be anonymized before publishing. Recent research has shown that textual data alone may contain sufficient information about users' private-attributes that they do not want to disclose such as age, gender, location, political views and sexual orientation (Mukherjee and Liu, 2010; Volkova et al., 2015). Little attention has been paid to protect users textual information (Li et al., 2018; Zhang et al., 2018; Anandan et al., 2012; Saygin et al., 2006).

Anonymizing textual information comes at the cost of losing utility of data for future applications. Some existing work shows the degraded quality of textual information (Anandan et al., 2012; Zhang et al., 2018; Saygin et al., 2006). Another related problem setting is when the latent representation of the user generated texts is shared for different tasks. It is very common to use recurrent neural networks to create a representation of user generated text to use for different machine learning tasks. Hitaj el al. show text representations can leak users' private information such as location (Hitaj et al., 2017). This work aims to anonymize users' textual information against private-attribute inference attacks.

Adversarial learning is the state-of-the-art approach for creating a privacy preserving text embedding (Li et al., 2018; Coavoux et al., 2018). In these methods, a model is trained to create a text embedding, but we cannot control the privacy-utility balance. Recent success of reinforcement learning (RL) (Paulus et al., 2017; Sun and Zhang, 2018) shows a feasible alternative: by leveraging reinforcement learning, we can include feedback of attackers and utility in a reward function that allows for the control of the privacy-utility balance. Furthermore, an RL agent can perturb parts of an embedded text for preserving both utility and privacy, instead of retraining an embedding as in adversarial learning. Therefore, we propose a novel Reinforcement Learning-based Text Anonymizer, namely, RLTA, composed of two main components: 1) an attention based task-aware text representation learner to extract latent embedding representation of the original text's content w.r.t. a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2360–2369, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

given task, and 2) a deep reinforcement learning based privacy and utility preserver to convert the problem of text anonymization to a one-player game in which the agent's goal is to learn the optimal strategy for text embedding manipulation to satisfy both privacy and utility. The Deep Q-Learning algorithm is then used to train the agent capable of changing the text embedding w.r.t. the received feedback from the privacy and utility subcomponents.

We investigate the following challenges: 1) How could we extract the textual embedding w.r.t. a given task? 2) How could we perturb the extracted text embedding to ensure that user private-attribute information is obscured? and 3) How could we preserve the utility of text embedding during anonymization? Our main contributions are: (1) we study the problem of text anonymization by learning a reinforced task-aware text anonymizer, (2) we corporate a data-utility task-aware checker to ensure that the utility of textual embeddings is preserved w.r.t. a given task, and (3) we conduct experiments on real-world data to demonstrate the effectiveness of RLTA in an important natural language processing task.

2 Related Work

Reinforcement Learning (RL) has applications in natural language processing and recommendation systems. For example, a recent paper (Paulus et al., 2017) combines RL with a supervised method to get a readable and informative article summary. Another work uses RL to solve the problem of adversarial generative models for text generation (Shi et al., 2018). Sun et al. also uses RL in a recommendation system which recommends items according to the users' feedbacks and preferences (Sun and Zhang, 2018)

Textual data is rich in content and recent research has shown that users' private-attributes can be easily inferred from the text (Beretta et al., 2015; Mukherjee and Liu, 2010; Volkova et al., 2015), however, few papers consider user privacy w.r.t. such data. Anandan et al. (2012) introduce t-Plausibility which uses an information theoretic based approach to sanitize documents heuristically. This method does not preserves the utility of data during anonymization process. Another work focuses on leveraging differential privacy (Dwork et al., 2017) to make the extracted Term Frequency Inverse Document (TF-IDF) textual vectors private (Zhang et al., 2018). It has been shown that TF-IDF cannot accurately capture semantic meaning of the text which can hurt its usefulness for different tasks (Lan et al., 2005).

Two recent similar works Li et al. (2018); Coavoux et al. (2018) convert textual data anonymization into a minimax problem. These works use the idea of adversarial learning to create a text embedding which satisfies utility and protects users against private-attribute leakage. Our scenario is similar to the work of (Li et al., 2018) as they have considered several attribute-inference attackers as adversaries to create a privacy-preserving text embedding. (Beigi et al., 2019b,a) propose a method for privacy preserving text representation. In this method, they try to add noise to an existing text representation in a way that it does not change the meaning of the text and it preserves the user's private attributes.

Our work is different from the existing works. First, we consider the task that the textual information will be used for and protect users against leakage of private-attributes. Second, we incorporate deep RL to anonymize the extracted text embedding by receiving privacy and utility feedbacks and automatically learning the optimal strategy for proper manipulation of text embeddings.

3 Problem Statement

Let $\mathcal{X} = \{x_1, x_2, ..., x_N\}$ denotes a set of N documents and each document x_i is composed of a sequence of words. We denote $\mathbf{v}_i \in R^{d\times 1}$ as the embedded representation of the original document x_i. Let $\mathcal{P} = \{p_1, p_2, ..., p_m\}$ denotes a set of m private-attributes that users do not want to disclose such as age, gender, location, etc. The goal of reinforced task-aware text anonymizer is to learn an embedding representation of each document and then anonymize it such that 1) users privacy is preserved by preventing any potential attacker to infer users' private-attribute information from the textual embedding data, and 2) utility of the text embedding is maintained for a given task $\mathcal{T}$ which incorporates such data, e.g., classification. In this paper, we study the following problem:

Problem 3.1. Given a set of documents $\mathcal{X}$, set of private-attributes $\mathcal{P}$, and given task $\mathcal{T}$, learn an anonymizer f that can learn a private embedded representation $\mathbf{v}_i$ from the original document x_i so that, 1) the adversary cannot infer the targeted user's private-attributes $\mathcal{P}$ from the private

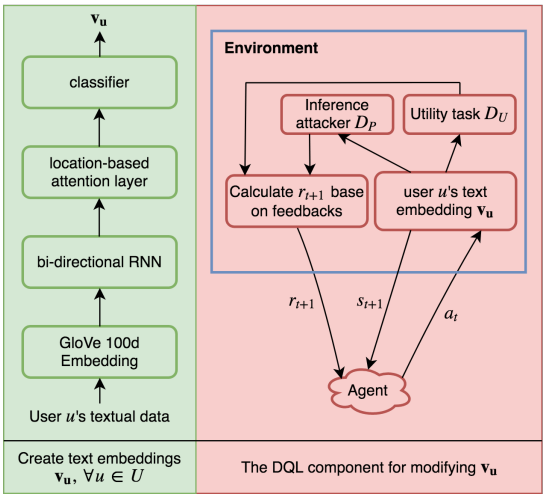

Figure 1: The architecture of RLTA method

text representation $\mathbf{v}_i$, and 2) the generated private representation $\mathbf{v}_i$ is good for the given task $\mathcal{T}$. The problem can be formally defined as:

$$\mathbf{v}_i = f(x_i, \mathcal{P}, \mathcal{T}) \tag{1}$$

Due to the success of Reinforcement Learning (Shi et al., 2018; Paulus et al., 2017), we use RL to address the aforementioned problem. RL (Sutton and Barto, 2018) formulates the problem within the framework of Markov Decision Process (MDP), and learns an action-selection policy based on past observations of transition data. An MDP is defined by state space $S = \{s\}$, action space $A = \{a\}$, transition probability function $P : S \times A \times S \to [0, 1]$ and reward function $r : S \times A \times S \to R$.

4 Proposed Method

We discuss the reinforced task-aware text anonymizer framework. The input of this private system is the user generated text, and the output is a privacy-preserving text representation. As in Figure. 1, this framework consists of two major components: 1) an attention based task-aware text representation learner, and 2) a deep RL based privacy and utility preserver. The text representation learner aims to extract the embedded representation of a document w.r.t. a given task by minimizing the task's loss function. Then, the deep RL preserver manipulates the embedded text representation by learning the optimal strategy so that both privacy and utility of the embedded representation are preserved. It includes two sub-components: 1) private-attribute inference attacker D_P, and 2) data-utility task-aware checker D_U. The former seeks to infer user private-attribute information based on their embedded text representation. The latter incorporates the given manipulated embedded text representation for a given task $\mathcal{T}$ and investigates the usefulness of the latent representation for $\mathcal{T}$.

The RL component then utilizes the feedback of the two sub-components to guide the data manipulation process by ensuring that the new text embedding does not leak user private-attributes by confusing the adversary in D_P and the changes made to the representation does not destroy the semantic meaning for $\mathcal{T}$.

4.1 Extracting Textual Embedding

Let $x = \{w_1, ..., w_m\}$ be a document with m words. Attention mechanism has shown to be effective in capturing embedding of textual information w.r.t. a given task (Pennington et al.; Vaswani et al., 2017). It allows the model to attend to different parts of the given original document at each step and then learns what to attend based on the input document and what it has produced as embedding representation so far, as shown in Figure. 1.

We use a bi-directional recurrent neural network (RNN) to encode the given document into an initial embedding representation. RNN has been shown to be effective for summarizing and learning semantic of unstructured noisy short texts (Cho et al., 2014; Shang et al., 2015). We use GloVe 100d (Pennington et al.) to exchange each word w_i with its corresponding word vector, note that different dimensionality can be used. This process produces a matrix of text $x' \in \mathcal{R}^{m*100}$.

We employ the gated recurrent unit (GRU) as the cell type to build the RNN, which is designed in a manner to have a more persisted memory (Cho et al., 2014). The bi-directional GRU will read the text forward and backwards, then outputs two hidden states $\mathbf{h_t^{fw}}, \mathbf{h_t^{bw}}$ and an output $\mathbf{o_t}$. We then concatenate two hidden states as the initial encoded embedding of the given original document:

$$\mathbf{H_t} = Concat(\mathbf{h_t^{fw}}, \mathbf{h_t^{bw}}) \tag{2}$$

After calculating the initial context vector $\mathbf{H_t}$, we seek to pinpoint specific information within the $\mathbf{H_t}$, which helps the classifier to predict the labels with higher confidence (Luong et al., 2015) We use the location-based attention layer based on the work of Luong et al. (2015). The attention layer calculates a vector $\mathbf{a_t}$ including a weight for each

element in the $\mathbf{H_t}$, showing the importance of that element. The context vector $\mathbf{v_t}$ is calculated:

$$\mathbf{v_t} = \sum_{i=1}^{m} a_{t,i}\mathbf{H_i} \quad (3)$$

The vector $\mathbf{v_t}$ is then fed to a neural network classifier for the given utility task. Classification is one of the common tasks for textual data. Based on the output of the classifier and loss function, we update the three networks so that the output of the attention layer is an useful context that can be used for a utility task (Ranzato et al., 2015).

4.2 Reinforced Task-Aware Text Anonymizer

Here, we discuss the details of the second component which seeks to preserve privacy and utility.

4.2.1 Protecting Private-Attributes

Textual information is rich in content and publishing textual embedding representation without proper anonymization leads to privacy breach and revealing the private-attributes of an individual such age, gender and location. It is thus essential to protect the textual information before publishing it. The goal of our model is to manipulated learned embedded representation such that any potential adversary cannot infer users' private-attribute information. However, a challenge is that the text anonymizer does not know the adversary's attack model. To address this challenge, we add a private-attribute inference attacker D_P sub-component to our text anonymizer. This sub-component learns a classifier that can accurately identify the private information of users from their embedded text representations $\mathbf{v_u}$. We incorporate this sub-component to understand how the textual embedded representation should be anonymized to obfuscate the private information.

Inspired by the success of RL (Kaelbling et al., 1996; Mnih et al., 2013; Van Hasselt et al., 2016), we model this problem using RL to automatically learn how to anonymize the text representations w.r.t. the private-attribute inference attacker. In our RL model, one agent is trained to change a randomly selected text embedding representation. Then, the agent keeps interacting with the environment and changes the text embedding accordingly based on its current state and received rewards so that the private-attribute inference attacker cannot correctly identify user's private-attribute information given his embedding. In this part, we define the main four parts of RL environment in our problem, i.e., environment, state, action and reward.

- **Environment:** Environment in our problem includes the private-attribute inference attackers D_P and the text embedding $\mathbf{v_u}$. Note that D_P is trained beforehand.
- **State:** State describes the current situation. Here, state is the current text embedding vector $\mathbf{v_{u,t}}$ which reflects the results of the agents' actions on $\mathbf{v_u}$ up to time t.
- **Actions:** Action is define as selecting one element such as $v_{u,k}$ in text embedding vector $\mathbf{v_u} = \{v_{u,1}, ..., v_{u,m}\}$ and changing it to a value near -1, 0 or 1. This results in $3.m$ actions where m is the size of the embedding vector.

  Changing value to near *1*: In this action, the agent changes the value of $v_{u,k}$ to a value between 0.9 to 1.0. As $v_{u,k}$ will be multiplied by a classifier's weight, the output will be the weight as is. In another word, the value $v_{u,k}$ will become important to the classifier.

  Changing value to near *0*: In this action the $v_{u,k}$ will be changed to a value between -0.01 to 0.01. This action makes $v_{u,k}$ seem neutral and unimportant to a classifier as it will result in a 0 when multiplied by a weight.

  Changing value to near *-1*: In this action, the agent changes $v_{u,k}$ to a value between -1.0 to -0.9. This action will make $v_{u,k}$ important to a classifier, but, in a negative way.
- **Reward:** Reward in our problem is defined based on how successfully the agent obfuscated the private-attribute information against the attacker so far. In particular, we defined the reward function at state s_{t+1} according to the confidence of private-attribute inference attacker C_{p_k} for private-attribute p_k given the resultant text embedding at state s_{t+1}, i.e., $\mathbf{v_{t+1}}$. Considering the classifier's input data as $\mathbf{v_u}$ and its correct label as i, we define the confidence for a multi-class classifier as the difference between the probability of actual value of the private-attribute and the minimum probability of other values of the private-attribute:

$$C_{p_k} = Pr(l = i|\mathbf{v_u}) - \min_j Pr(l = j|\mathbf{v_u}) \quad (4)$$

  Where l indicates label. For each private-attribute attacker p_k, the confidence score C_{p_k} is

within the range $[-1, 1]$. Positive value demonstrates that the attacker has predicted private-attribute accurately, and negative value indicates that the attacker was not able to infer user's private-attribute. According to this definition, the reward will be positive if action a_t has caused information hiding, and will be negative if the action a_t was not able to hide sensitive information. Having confidence of private-attribute inference attackers, reward function at state s_{t+1} is defined as:

$$r_{t+1}(s_{t+1}) = -\sum_{p_k \in D_P} C_{p_k}(s_{t+1}) \quad (5)$$

The reward r_t is calculated according to the state s_{t+1} which associated with the transition of agent from state s_t after applying action a_t. Note that the goal of agent is to maximize the amount of received rewards so that the mean of rewards r over time $t \in [0, T]$ (T is the terminal time) will be positive and above 0.

4.2.2 Preserving Utility of Text Embedding

Thus far, we have discussed how to 1) learn textual embeddings from the given original document w.r.t. the given task, and 2) prevent leakage of private-attribute information by developing a reinforcement learning environment which incorporates a private-attribute inference attacker and manipulates the initial given text embedding accordingly to fool the attacker. However, data obfuscation comes at the cost of data utility loss. Utility is defined as the quality of the given data for a given task. Neglecting the utility of the text embedding while manipulating it, may destroy the semantic meaning of the text data for the given task. Classification is one of the common tasks. In order to preserve the utility of data, we need to ensure that preserving privacy of data does not destroy the semantic meaning of the text embedding representation w.r.t. the given task. We approach this challenge by changing the agent's reward function w.r.t. the data utility. We add a utility sub-component, i.e., classifier D_U, to the reinforcement learning environment which its goal is to assess the quality of resultant embedding representation. We use the confidence of the classifier for the given task to measure the utility of embedding representation using the text embedding vector $\mathbf{v_u}$ the its correct label i.

$$C = Pr(l = i|\mathbf{v_u}) - \min_j Pr(l = j|\mathbf{v_u}) \quad (6)$$

The agent can then use the feedback from the utility classifier to make decision when taking actions. We thus modify the reward function in order to incorporate the confidence of utility sub-component. Reward function at state s_{t+1} can be defined as:

$$\begin{aligned} r_{t+1}(s_{t+1}) =& \alpha C_{D_U}(s_{t+1}) - \\ & -(1-\alpha)\sum_{p_k \in D_P} C_{p_k}(s_{t+1}) - \mathcal{B} \end{aligned} \quad (7)$$

where C_{D_U} and C_{p_k} represent the confidence of utility sub-component and private-attribute inference attacker, respectively. Moreover, $\mathcal{B}$ demonstrates a baseline reward which forces the agent to reach a minimum reward value. The coefficient α also control the amount of contribution from both private-attribute inference and utility sub-components in the Eq. 7.

4.3 Optimization Algorithm

Given the formulation of states and actions, we aim to learn the optimal strategy via manipulating text representations w.r.t. the private-attribute attackers and utility sub-component feedbacks. We manipulate the text embeddings by repeatedly choosing an action a_t given current state s_t, and then applying actions on current state to transit to the new one s_{t+1}. The agent then receives reward r_{t+1} as a consequence of interacting with the environment. The goal of agent is to manipulate text embedding $v_{u,k}$ in a way that maximizes its reward according to Eq. 7. Moreover, the agent updates its action selection policy $\pi(s)$ so that it can achieve the maximum reward over time.

In RLTA we use Deep Q-Learning which is a variant of Q-Learning. In this algorithm the goal is to find the following function:

$$Q^*(s_t, a_t) = \mathrm{E}_{s_{t+1}}[r_{t+1} + \gamma \max_{a'} Q^*(s_{t+1}, a')] \quad (8)$$

where $Q(s, a)$ corresponds to the Q-function for extracting actions and it is defined as the expected return based on state s and action a. Moreover, $Q^*(s, a)$ denotes the optimal action-value Q-function which has the maximum expected return using the optimal policy $\pi(s)$. Rewards are also discounted by a factor of γ per time step. The agent keeps interacting with the environment till it reaches the terminal time T.

Since it is not feasible to estimate $Q^*(s, a)$ in Eq.8, we use a function approximator to estimate the state-action value function $Q^*(s, a) \approx$

Algorithm 1 The Learning Process of RLTA

$Q(s, a; \theta)$. Given neural networks as excellent function approximators (Cybenko, 1989), we lverage a deep neural network function approximator with parameters θ, or a Deep Q-Network (DQN) (Mnih et al., 2013) by minimizing the following:

$$L(\theta) = \mathrm{E}_{s_t, a_t, r_{t+1}, s_{t+1}}[(y - Q(s, a; \theta))^2] \quad (9)$$

in which y is the target for the current iteration:

$$y = \mathrm{E}_{s_{t+1}}[r_{t+1} + \gamma \max_{a'} Q(s_{t+1}, a'; \theta^p)] \quad (10)$$

θ^p is the parameters from the previous iteration.

We update the DQN according to the derivation of Eq. 9 with respect to the parameter θ:

$$\begin{aligned} \nabla_\theta L(\theta) = \mathrm{E}_{s_t, a_t, r_{t+1}, s_{t+1}}[(r \\ + \gamma \max_{a'} Q(s_{t+1}, a'; \theta^p) \\ - Q(s_t, a_t; \theta)) \nabla_\theta Q(s_t, a_t; \theta)] \end{aligned} \quad (11)$$

Algorithm 1 shows the optimization process.

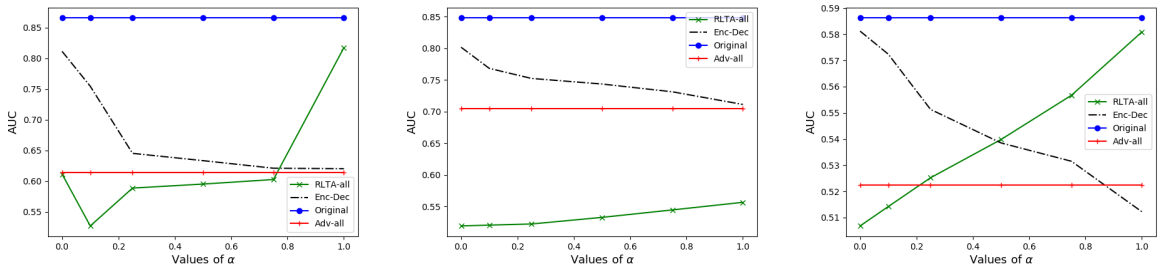
5 Experiments

Experiments are designed to answer the following questions: **Q1**(*Privacy*): How well RLTA can obscure users' private-attribute information? **Q2**(*Utility*): How well RLTA can preserve utility of the textual data w.r.t. the given task? **Q3**(*Privacy-Utility Relation*): How does improving user privacy affects loss of utility?

To answer the first question (**Q1**), we use investigate the robustness of resultant text embedding against private-attribute inference attacks. We consider two private-attribute information, i.e., location and gender. To answer the second question (**Q2**), we report experimental results w.r.t. a well-known task, sentiment analysis. Sentiment analysis has many applications in user-behavioral modeling and Web (Zafarani et al., 2014). In particular, we predict sentiment of the given textual embedding. To answer the final question (**Q3**), we examine the privacy improvement against utility loss.

5.1 Data

We use a real-world dataset from Trustpilot (Hovy et al., 2015). This dataset includes user reviews along with users private-attribute information such as location and gender. We remove non-English reviews based on LANGID.py[1] (Lui and Baldwin, 2012) and only keep reviews classified as English. Then, we consider English reviews associated with location of US and UK and create a subset of data with $10k$ users. Each review is associated with a rating score. We consider the review's sentiment as positive if its rating score is $\{4, 5\}$ and consider it as negative if rating is $\{1, 2, 3\}$



5.2 Implementation Details

For extracting the initial textual embedding, we use a bi-directional RNNs which their hidden sizes are set to 25. This makes the size of the final hidden vector $\mathbf{H_t}$ as 50. We also use a logistic regression with a linear network as the classifier in the attention mechanism. We use a 3-layer network for the Deep Q-network, i.e., input, hidden and output layers. Dimensions of the input and hidden layers are set to 50 and 700, respectively. Dimension of the last layer, i.e., output, is also set as 150. This layer outputs the state-action values which we execute the action with the best value.

For each of the private-attribute attackers and utility sub-components, we use feed-forward network with a single hidden layer with dimension of 100 which gets the textual embedding as input and uses a $Softmax$ function as output.

We first train both private-attribute inference attacker D_P and utility sub-component D_U on the training set. These sub-components do not change after that. Then, we train an agent on each selected data for 5000 episodes. The reward discount for agents is $\gamma = 0.99$ and batch size $b = 32$. We also set the terminal time $T = 25$. We run RLTA for 5 times and select the best agent based on the cumulative reward. We also vary α as $\alpha = \{0, 0.25, 0.5, 0.75, 1\}$. The higher values of

Figure 2: AUC scores for private-attribute and sentiment prediction tasks for different values of α. Lower AUC for private-attribute inference attacks shows higher privacy, while higher AUC for the sentiment prediction task indicates higher utility.

α indicate more utility contribution in RLTA.

5.3 Experimental Design

We use 10-fold cross validation of RLTA for evaluating both private-attribute inference attacker and an utility task with the following baselines:

- **ORIGINAL:** This baseline is a variant of proposed RLTA which does not change the original user text embeddings $\mathbf{v_u}$ and publishes it as is.
- **ADV-ALL:** This adversarial method has two main components, i.e., generator and discriminator, and creates a text representation that has high quality for a given task, but has poor quality for inferring private-attributes (Li et al., 2018).
- **ENC-DEC:** Using an auto-encoder is one of the effective methods to create a text embedding (Nallapati et al., 2016). We modify this simple method to create a privacy-preserving text embedding. This method gets the original text x and outputs a re-constructed text $\bar{x}$. The following loss function is used to train the model. After training, we use the encoder's output as the text representation $\mathbf{v_u}$ (Cho et al., 2014).

$$loss = -\sum_{x \in X} \log Pr(\bar{x}|x) + \quad (12)$$
$$+ \alpha((\sum_{p_k} C_{p_k}) - C_{D_U})$$

In which α is the privacy budget.

To examine the privacy of final text embedding, we apply the trained private-attribute attacker sub-component D_P to the output of each method to evaluate the users' privacy. We consider two private attributes, i.e., location and gender. We then compute the attacker's AUC. Lower attacker's AUC indicates that textual embeddings have higher privacy after anonymization against the private-attribute inference attacker. We also report experimental results w.r.t. the utility. In particular, we predict sentiment (positive and negative) of the given textual embedding by applying trained utility sub-component D_U to the resultant text embedding from test set for each method. We then compute AUC score for sentiment prediction task. Higher values of AUC demonstrate that the utility of textual embedding has been preserved.

5.4 Experimental Results

We answer the three question **Q1**, **Q2** and **Q3** to evaluate our proposed method RLTA.We use a natural language processing task, sentiment prediction, using a three layer neural network.

Privacy (Q1). Figure. 2 (a-b) demonstrates the results of private-attribute inference attack w.r.t. gender and location attributes. The lower the value of AUC is, the more privacy user has in terms of obscuring private attributes. We also report the performance of RLTA for different values of α.

We observe that ORIGINAL is not robust against private-attribute inference attack for both gender and location attributes. This confirms leakage of users private information from their textual data. Moreover, RLTA has significantly lower AUC score for both gender and location attributes in comparison to other methods. This demonstrates the effectiveness of RL for obfuscating private attributes. In RLTA, the AUC score for private-attribute inference attack increases for both attributes with the increase of α which shows the degradation in user privacy. The reason is because of the fact that agent pays less attention to privacy by increasing the value of α.

In the ENC-DEC method, as the value of α increases, the encoder tries to generate a text representation that is prune to inference attacks but it

does not lose its utility w.r.t. the given task D_U. The results show that as α increases, the AUC of inference attackers will decrease.

Utility (Q2). To answer the second question, we investigate the utility of embeddings w.r.t. sentiment prediction. Results for different values of α are demonstrated in Figure. 2(c). The higher the value of the AUC is, the higher utility is preserved.

The ORIGINAL approach has the highest AUC score which shows the utility of the text embeddings before any anonymization. We observe that the results for RLTA is comparable to the ORIGINAL approach which shows that RLTA preserves the utility of text embedding. Moreover, RLTA outperforms ADV-ALL which confirms the effectiveness of reinforced task-aware text anonymization approach in preserving utility of the textual embeddings. We also observe that the AUC of RLTA w.r.t. sentiment prediction task increases with the increase of value of α. This is because with the increase of α, the agent pays more attention to the feedbacks of utility sub-component.

We also observe a small utility loss after applying RLTA when $\alpha = 1$. This is because the agent keeps changing the text embedding until it reaches the terminal time. These changes result in loss of utility even when the $\alpha = 1$.

Finally, in the ENC-DEC method, as both utility and attackers have the same importance, trying to preserving privacy would result in huge utility loss as we increase the value of α.

Privacy-Utility Relation (Q3). Results show that the ORIGINAL achieves the highest AUC score for both utility task and private-attribute inference attack. This shows that ORIGINAL has the highest utility which comes at the cost of significant user privacy loss. However, comparing results of privacy and utility for $\alpha = 0.5$, we observe RLTA has achieved the lowest AUC score for attribute inference attacks in comparison to other baselines, thus has the highest privacy. It also reaches the higher utility level in comparison to the ADV-ALL. RLTA also has comparable utility results to the ORIGINAL approach. We also observe that increasing the α reduces the performance of RLTA in terms of privacy but increases its performance for utility. However, with $\alpha = 1$, RLTA preserves both user privacy and utility in comparison to ORIGINAL, ENC-DEC, and ADV-ALL.

Method	Location	Gender	Utility
ORIGINAL	84.77	86.54	58.57
ENC-DEC	71.55	58.35	53.78
ADV-ALL	70.37	57.15	52.15
RLTA	53.34	56.41	54.83
RLTA-GEN	56.64	**55.02**	**56.67**
RLTA-LOC	**52.04**	56.64	54.13

Table 1: Impact of different private-attribute inference attackers on RLTA when $\alpha = 0.5$. With $\alpha = 0.5$, privacy and utility will contribute equally.

5.4.1 Impact of Different Components

Here, we investigate the impact of different private-attribute inference attackers. We define two variants of our proposed model, RLTA-GEN and RLTA-LOC. In each of these variants, we train the agent in RLTA w.r.t. the one of private-attribute attackers, e.g., RLTA-GEN is trained to solely hide *gender* attribute. For this experiment we set $\alpha = 0.5$ as in this case privacy and utility sub-components contribute equally during training phase (Eq. 7). Results are shown in Table 1.

RLTA-LOC and RLTA-GEN have the best performance amongst all methods in obfuscating location and gender private-attributes, respectively. Results show that using RLTA-LOC could also help improve privacy on gender and likewise for (RLTA-GEN) in comparison to other approaches.

RLTA-GEN performs better in terms of utility, in comparison to RLTA which incorporates both gender and location attackers. Moreover, results show that both RLTA-GEN and RLTA-LOC have better utility than other baselines.

To sum-up, these results indicate that although using one private-attribute attacker in the training process can help in preserving more utility, it can compromise obscuring other private-attributes.

Parameter Analysis: Our proposed method RLTA has an important parameter α to change the level of privacy and utility. We illustrate the effect of this parameter by changing it as $\alpha \in \{0.0, 0.1, 0.25, 0.5, 0.75, 1.0\}$. According to the Figure 2, when the α parameter increases, the privacy loss will decrease, but, the utility loss will increase. This shows the utility and the privacy have an association with each other. Hence, the more privacy loss decreases, the utility loss increases. Choosing the right value for α depends on the application and usage of this method. According to the results, choosing $\alpha = 0.5$ would result in a balanced privacy-utility. In some applications where the privacy of users are important and critical, we can set the α parameter above 0.5.

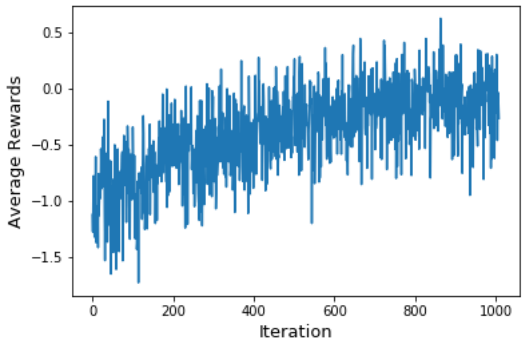

Figure 3: The average of agent's rewards

On the other hand, if the users privacy is not top priority, this parameter can be set to a lower value than 0.5 which although it does not protect users' private attribute as good as when $\alpha >= 0.5$, but it does protect users' private attribute at a reasonable level.

5.4.2 Rewards Convergence

To evaluate the convergence of rewards, we consider agent's reward during training phase for each episode, shown in Figure. 3. The result indicates that agent's average reward is low at the beginning and then it increases afterward. This is because agent performs many random actions at the beginning to explore the action state space. We also observe that after several episodes, the reward converges to the baseline reward $\mathcal{B}$. This confirms that the agent has learned a proper action selection policy $\pi(s)$ to preserve both utility and privacy by satisfying the objectives of Eq. 7.

6 Conclusion

In this paper, we propose a deep reinforcement learning based text anonymization, RLTA, which creates a text embedding such that does not leak user's private-attribute information while preserving its utility w.r.t. a given task. RLTA has two main components: (1) an attention based task-aware text representation learner, and (2) a deep RL based privacy and utility preserver. Our results illustrate the effectiveness of RLTA in preserving privacy and utility. One future direction is to generate privacy preserving text rather than embeddings. We also adopt deep Q-learning to train the agent. A future direction is to apply different RL algorithms and investigate how it impacts results. It would be also interesting to adopt RLTA for other types of data.

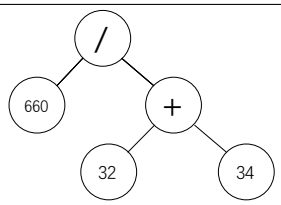
Abstract

Automatically solving math word problems is an interesting research topic that needs to bridge natural language descriptions and formal math equations. Previous studies introduced end-to-end neural network methods, but these approaches did not efficiently consider an important characteristic of the equation, i.e., an abstract syntax tree. To address this problem, we propose a tree-structured decoding method that generates the abstract syntax tree of the equation in a top-down manner. In addition, our approach can automatically stop during decoding without a redundant stop token. The experimental results show that our method achieves single model state-of-the-art performance on Math23K, which is the largest dataset on this task.

1 Introduction

Math word problem (MWP) solving is the task of obtaining a solution from math problems that are described in natural language. One example of MWP is illustrated in Figure 1. Early approaches rely on either predefined rules or statistical machine learning-based methods to map the problems into several predefined templates in classification style or retrieval style. The major drawback of these approaches is that they are inflexible for new templates and require extra effort to design rules, features and templates.

Modeling the tree structure of math equations has been considered as an important factor when building models for MWP. As shown in Figure 1, each equation could be transformed into an abstract syntax tree (AST). Roy and Roth (2017) built an expression tree and combined two classifiers for quantity relevance prediction and operator classification. Koncel-Kedziorski et al. (2015) designed a template ranking function based on the AST of the equations. However, these approaches are based on traditional methods and require feature engineering.



Problem	The distance between the two places A and B is 660 km, the car starting from A drives 32 km/h, and the car starting from B drives 34 km/h. The two cars are starting from the two places at the same time in inverse direction. How many hours later would the two cars meet?
Equation	x = 660 / (32 + 34)
Prefix	x = / 660 + 32 34
Answer	10
AST	

Figure 1: One example of MWP. Problem refers to the natural language descriptions. Equation refers to the formal math equation. Prefix refers to the prefix notation of the equation. Answer refers to the final quantity solution. AST refers to the AST of the equation.

Recently, the appearance of large-scale datasets and the development of neural generative models have opened a new research line for MWP. Wang et al. (2017) cast this task as a sequence generation problem and used a sequence-to-sequence (seq2seq) model to learn the mapping from natural language text to a math equation. Recent approaches use the Reverse Polish notation, also called suffix notation of equations in which operators follow their operands to implicitly model the tree structure (Wang et al., 2018a; Chiang and Chen, 2018). However, these studies lost sight of important information of the math equation ASTs

[*] This denotes equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2370–2379, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(e.g., parent and siblings of each node), despite of their promising results. Thus, their model has to use extra effort to memorize various pieces of auxiliary information such as the sibling node of the current step and learn the implicit tree structure in the sequence.

Meanwhile, in similar tasks such as semantic parsing and code generation, which also try to convert natural language into a well-formed executable tree structured output, they first decode the function or operator at the root node before decoding the variables. Such top-down decoding matches with the Polish notation, also called the prefix order of the AST of math equations, shown in Figure 1. Human also does reasoning and reference in a similar order, usually first determines the function before filling in the variables, but not the inverse. Thus we present a top-down hierarchical sequence-to-tree (seq2tree) model which explicitly models the tree structure. This decoder considers the prefix order of the equation and feeds the information of the parent and sibling nodes during decoding.

Another advantage of this system is that it can use a stack to monitor the decoding process and automatically end. By pushing in new generated nodes to the stack and popping out the completed subtrees, the decoding process can naturally end when the tree is completed and the stack is empty. There is no need for a special redundant end-of-sequence (EOS) token which is used in ordinary text sequence generation. Without the EOS token, the model has a higher possibility to generate valid equation answers.

In summary, the contributions of this work are as follows:

1. We design a hierarchical seq2tree model that can better capture information of the AST of the equation.

2. We are the first to use prefix order decoding for MWP.

3. We abandon the EOS token for end-to-end equation generation.

4. Our model outperforms previous systems for solving math word problems. On the large-scale dataset Math23K, we achieve state-of-the-art single model performance.

2 Related Work

Our work synthesizes two strands of research, which are math word problems and seq2tree encoder-decoder architectures.

2.1 Math Word Problems

Early approaches hand engineered rule-based systems to solve MWPs (Mukherjee and Garain, 2008). The rules could only cover a limited domain of problems, while math word problems are flexible in real-world settings.

There are currently three major research lines in solving MWPs. The first research line maps a problem text into logical forms, and then uses the logical forms to obtain the equation (Shi et al., 2015; Roy and Roth, 2015; Huang et al., 2017; Roy and Roth, 2018). Shi et al. (2015) defined a Dolphin language to connect math word problems and logical forms. The major drawback is that it requires extra human annotation for the logic forms.

Another research line uses either a retrieval or classification model to maintain a template, and then fills in the slots with quantities. Kushman et al. (2014) first introduced the idea of 'equation template'. For example, x = 6*7 and x = 10*5 belong to the same template x = n_1*n_2. They collected the first dataset of this task, ALG514, which contained 514 samples. They brought out a two-step pipeline model, which first used a classifier to select a template and then mapped the numbers into the slots. One major drawback is that it cannot solve problems beyond the templates in the training data. This two-step pipeline model was further extended with tree-based features, ranking style retrieval models and so on (Upadhyay and Chang, 2017; Roy and Roth, 2017). Huang et al. (2016) released the first large-scale dataset Dophin18K and trained a similar system on it.

The third research line directly generates the equation. Hosseini et al. (2014) cast the problem into a State Transition Diagram of verbs and trained a binary classifier that could solve problems with only add and minus operators. Wang et al. (2017) first used a seq2seq model to directly generate the equation template and released a Chinese high-quality large-scale dataset, Math23K. Reinforcement learning was used to further improve the seq2seq framework. Wang et al. (2018b) first extended the seq2seq model by decoding the suffix order sequence of the equations. Wang et al. (2018a) introduced equation normalization techniques that leverage the duplicated template problem. Chiang and Chen (2018) used the copy

mechanism to improve the semantic representation of quantities. However, in these work the model needs extra effort to learn the implicit tree structure and memorize tree information in the sequence. Wang et al. (2019) proposed a two-step pipeline method that first generates a template with unknown operators, and then uses a recursive neural network to combine tree structure information and predict the operators. However, the topology of the AST is determined in the first step without tree structure information. To our best knowledge, we are the first to explicitly give the model guidance of parent and sibling nodes.

2.2 Seq2Tree Architectures

Seq2Tree-style encoder-decoder is mainly used in two fields both of which try to bridge natural language and a tree structured output.

Semantic parsing is the task that translates natural language text to formal meaning logical forms or structured queries. Code generation maps a piece of program description to programming language source code. Dong and Lapata (2016) first used recurrent neural networks (RNNs) based seq2tree for semantic parsing and out performed the seq2seq model. One drawback is that their generation is at token level so it cannot guarantee the result is syntactically correct. Grammar rules were used to solve this problem. Another drawback is that they needed special tokens for predicting branches, which are not necessary for MWPs because all operators are binary operators. The similar framework is also used in code generation (Zhang et al., 2016; Yin and Neubig, 2017). Alvarez-Melis and Jaakkola (2017) presented doubly recurrent neural networks to predict tree topology explicitly. Rabinovich et al. (2017) presented a abstract syntax network that combines edge information for code generation. Convolution neural networks (CNNs) were used for code generation decoding because the output program is much longer than semantic parsing and MWPs, and RNNs suffer from the long dependency problem (Sun et al., 2018).

3 Model

Our model consists of two stages as shown in Figure 2: the encoder stage that encodes the input natural language into a sequence of representation vectors and the decoder stage that receives these vectors and decodes the AST of the equation with the help of an auxiliary stack.

Equation	x = 130 * (1 - 0.8)
Quantities	n_1: 130, n_2: 0.8
Template	n_1 * (1 - n_2)
Prefix template	* n_1 - 1 n_2

Table 1: One example of prefix template

3.1 Preprocessing

Significant Number Identification A Significant Number Identification (SNI) unit is used for reducing the noise in the input numbers. Significance refers to whether the number appears in the equation. In MWPs, it is very common that the input text contains irrelevant numbers, such as date or descriptive text such as 'third grade student'. We follow Wang et al. (2017) and simply use whether the numbers appear in the equation as gold labels and build an LSTM-based binary classification model to determine the significance of the input numbers. The accuracy of this unit is 99% and thus it can efficiently reduce the noise.

Prefix Order Equation Template For the output equations, we first turn them into prefix order equation templates before using them to train the model. In Table 1 we show one example of prefix templates. Given a problem-equation pair, we first build the mapping between numbers in the problem and equation, n_i denotes the ith number in the problem after SNI. We use this mapping to convert the equation into a template by replacing the numbers with n_i tokens, and at last convert the template into prefix order.

To be noticed, equations can be mapped to more than one AST. For example, $n1 + n2 + n3$ could be mapped to an AST with either the first $+$ or the second $+$ as the root node, and in that case the prefix order notation would also be different. We assume the first operator is the root node of the AST here. Further details are shown in the appendix.

Equation Normalization One math word problem can be solved by different but equivalent equations, which bring noise during training. For example, 10 - (8 + 5) and 10 - 8 - 5 are equivalent, but the templates $n_1 - (n_2 + n_3)$ and $n_1 - n_2 - n_3$ are different. This problem is called the equation duplication problem. We follow Wang et al. (2018a) and use several rules for equation normalization

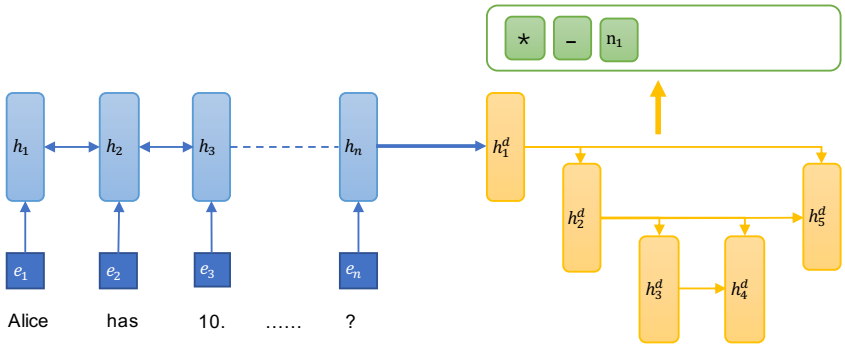


Figure 2: Framework of our seq2tree model. The blue blocks refer to the encoder. The yellow blocks refer to the decoder. The green blocks refer to the auxiliary stack.

to alleviate the equation duplication problem. The rules are listed below.

- If one long equation template could be converted into a shorter one, then it should be shortened. For example, $n_1+n_2+n_3+n_3-n_3$ and $n_1+n_2+n_3$ are equivalent. In this case the former one should be normalized as the latter one.
- The order of number tokens in the template should follow their occurrence order in the problem text as much as possible. For example, $n_1+n_3+n_2$ should be normalized as $n_1+n_2+n_3$.

3.2 Encoder

Bi-directional Long Short Term Memory Network (BiLSTM) is an efficient method to encode sequential information. Formally, given an input math word problem sentence $x = \{x_t\}_{t=1}^{n}$, we first embed each word into a vector e_t. Then these embeddings are fed into a BiLSTM layer to model the sequential information.

$$h_t = (LSTM(h_{t-1}^f, e_t); LSTM(h_{t-1}^b, e_t)), \quad (1)$$

where h_t is the concatenation of the hidden states h_t^f and h_t^b, which are from both forward and backward LSTMs. These representation vectors are then fed into the following decoder stage.

3.3 Tree-structured Decoder

For decoding, we follow Dong and Lapata (2016) and build a top-down hierarchical tree-structured decoder. However, their model is built for semantic parsing and some components are unnecessary and redundant for equation template decoding. Benefited by the fact that operator nodes must have two children and number nodes must be leaf nodes, we build a decoder which is specialized for math equation AST, as shown in Figure 3. It extends a vanilla sequence-based LSTM decoder by using tree-based information feeding as the input, and also an auxiliary stack to help the model know which is the next token to decode and automatically end the decoding process without a special token.

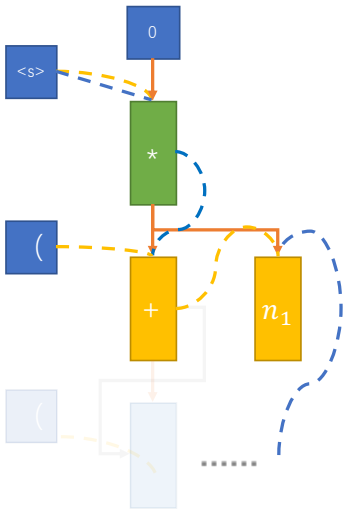

Figure 3: Framework of the tree structured decoder. The yellow dotted line refers to sibling feeding. The blue dotted line refers to previous token feeding. The orange solid line refers to parent feeding. The dotted line means it uses embedding information, while the solid line means it uses the hidden state information.

3.3.1 Tree-based Information Feeding

The input of each time step consists of three parts: parent feeding, sibling feeding and previous token feeding.

The parent feeding h^{parent} refers to using the LSTM hidden state of the parent node as the input when decoding children nodes, which is shown as

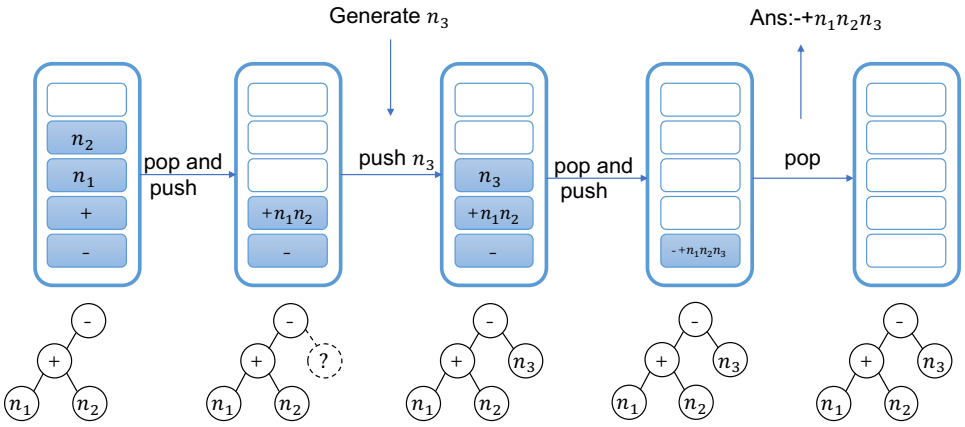

Figure 4: One example of tree-structured decoding with the auxiliary stack.

the orange solid line in Figure 3. This can let the model be informed of the parent node status. For the root node, this part of the input is padded as zeros.

The sibling feeding $e^{sibling}$ refers to using the embedding of the left sibling node as the input when decoding the right sibling node, which is shown as the yellow dotted line in Figure 3. This can let the model be informed whether we are decoding the left or right sibling. For the root node, we use a special token $\langle s \rangle$ for sibling feeding. For the left-most node, we use a special token (for sibling feeding.

The previous token feeding e^{prev} refers to using the previous token in prefix order as the input when decoding the next token, which is shown as the blue dot line in Figure 3. This can let the model be informed of what part is already decoded by the tree. For the root node, we also use the special token $\langle s \rangle$ for previous token feeding.

At time step t, the input e_t^d of the LSTM unit is the concatenation of these three components.

$$e_t^d = (h^{parent}; e^{sibling}; e^{prev}). \quad (2)$$

3.3.2 Tree-Structured LSTM

The tree-structured decoder uses LSTM to generate the equation template in a top-down manner, as the grey solid line in Figure 3, and use an auxiliary stack to guide the decoding process. Given the input e_t^d shown in the previous section, we generate the output token y_t with one LSTM layer and one Multi-layer Perceptron (MLP) layer.

$$h_t^d = LSTM(h_{t-1}^d, e_t^d) \quad (3)$$

$$y_t = argmax(MLP(h_t^d)) \quad (4)$$

Algorithm 1: The algorithm of using the auxiliary stack to guide tree decoding.

Input: Encoder Output h_n
Output: The Predicted Prefix Notation Equation $Equa^p = \{s_i^p\}_{i=1}^{n_2}$

initialize empty stack S and list $Equa^p$;
while *$S.size!=1$ or $S.top$ is not quantity* **do**
  generate token y_t;
  tmp = S.top;
  S.push(y_t);
  if *y_t is quantity* **then**
    while *tmp is a quantity* **do**
      subtree t = S.top[3];
      S.pop;S.pop;S.pop;
      tmp = S.top;S.push(t);
$Equa^p$ = S.pop;

As shown in Algorithm 1 and Figure 3, if the predicted token y_t is an operator, then we predict the left child node of the operator and push this token into the stack S. If the predicted token y_t is a quantity, we check the stack to determine which is the next token that needs to be decoded. If the top of the stack is an operator, then we push y_t into the stack and go on to decode the right sibling node of the current node. If the top of S is a quantity, we follow Algorithm 1 to find the next position to decode. We push y_t to the stack and pop out the top three tokens, which should be $\langle op \rangle \langle num \rangle \langle num \rangle$. These three tokens form a subtree t and we regard this subtree t as one quantity unit in the following process. Then we examine the status of the stack again, if the top of the stack is still a number, we push t back to the stack and continue until the top of the stack is not a quantity. When the loop stops,

if the top of the stack is an operator, we push back t and continue to decode the operator's right child node, and if the stack is empty, the decoding process ends because the AST is completed. Here we still push back the tree unit to the stack and treat the status that only one number is in the stack as the ending condition, which refers to line 2 in Algorithm 1. In this way the condition that the first generated token is the answer number can be unified. With the help of this stack, we can guide the decoding process, including which token to generate next and when to stop naturally without any special tokens.

We show one example of the decoding process with the an auxiliary stack in Figure 4. The upper half part shows the status of the stack, where the solid blocks stand for the inserted tokens. The lower half part shows the status of the AST during decoding, where the solid line stands for the generated nodes and the dotted line stands for the node that should be generated in the next step. The decoder first generates $-$, $+$, n_1 and n_2 and forms a complete subtree in the AST. This subtree $+$, n_1 and n_2 is then popped out of the stack and $+n_1n_2$ are pushed back as one unit. The model then continues to predict the sibling node of the subtree's root node, which is the dotted line circle in Figure 4. The top three tokens of the stack now form a complete subtree again and is popped out of the stack. The stack is now empty, we push it back and the stack only contains one number unit, then the decoding process ends and the equation template is popped out.

3.3.3 Attention Mechanism

An attention mechanism has shown its effectiveness in various natural language processing tasks. We extend the decoder with an attention mechanism by adjusting Equation 4. Instead of directly using the hidden state h_t^d to predict the output token y_t, we consider relevant information from the input vectors to better predict y_t. Formally, given the LSTM hidden state h_t^d and the encoder outputs $\{h_t\}_{t=1}^n$, we calculate the attention weights α_t^i and attention vector s_t as follows:

$$s_t = \sum_{i=1}^{n} \alpha_t^i \cdot h_i = \sum_{i=1}^{n} \frac{exp(h_i \cdot h_t^d)}{\sum_{j=1}^{n} exp(h_j \cdot h_t^d)} \cdot h_i \quad (5)$$

In lieu of Equation 4, we use the attention vector s_t, which considers relevance of the encoder information to predict the output token y_t.

4 Experiments

To demonstrate the effectiveness of our model, we conduct experiments on the Math23K dataset. Our method achieves the state-of-the-art (SOTA) single model performance and also exceeds the previous ensemble model SOTA.

4.1 Dataset

Math23K Math23K is one large-scale Chinese MWP dataset that contains 23,162 math problems and math equation solutions. The questions are elementary school level. Every question is linear and contains only one unknown variable.

Although there are other large-scale datasets such as Dolphin18K and AQuA, which are in English, they either contain many small typos (e.g., using x to represent $*$) or contain wrong answers and templates. Other datasets such as ALG514 and MAWPS are much more smaller. Therefore, we decide to conduct experiments on Math23K, which is the only large-scale, clean and high-quality dataset.

4.2 Implementation Details

The embedding vectors are pretrained on the training set with the word2vec algorithm. The dimension of the embedding is 128. We use a two-layer BiLSTM with the hidden size 512 for the encoder. The decoder is a two-layer LSTM with 1024 hidden size. We use a teacher forcing ratio of 0.83 during training. We use cross entropy as the loss function and Adam to optimize the parameters. We also use dropout to avoid over-fitting. The batch size is 128.

4.3 Results

Table 2 shows the results of our system and other novel systems of MWP on the Math23k test set. The retrieval-style models compare a question in the test set with the questions in the training set, choose the template that has the highest similarity, and then fill in the numbers into the template (Upadhyay and Chang, 2017; Robaidek et al., 2018). The classification-style models train a classifier to select an equation template, and then map the numbers into the template (Kushman et al., 2014). For retrieval and classification models, we use the results of Robaidek et al. (2018). The generation models use end-to-end style encoder-decoder systems to generate an equation template and then fill in the numbers.

Model		Acc
Retrieval	Cosine (Robaidek et al., 2018)	23.8%
	Jaccard (Robaidek et al., 2018)	47.2%
Classification	Self-Attention (Robaidek et al., 2018)	56.8%
	Bi-LSTM (Robaidek et al., 2018)	57.9%
Generation	DNS (Wang et al., 2017)	58.1%
	BiLSTM+Suffix+EN (Wang et al., 2018a)	66.7%
	Semantically-Aligned† (Chiang and Chen, 2018)	65.8%
	T-RNN (Wang et al., 2019)	66.9%
	Ours	**69.0%**
Ensemble	DNS+Retrieval (Wang et al., 2017)	64.7%

+ Parent Feeding	68.1 %
Full Model	**69.5%**

Table 3: Ablation study on Math23K by removing modules.

Model	Invalid Templates
EOS as terminator	1.3%
Stack as terminator	**0.2%**

Table 4: Ablation study on Math23K by using different terminating methods.

Wang et al. (2017) proposed a DNS model, which used seq2seq with SNI to generate an equation template. Wang et al. (2018a) proposed a BiLSTM+Suffix+EN model, which extends the DNS model by decoding the suffix notation and applies equation normalization. Chiang and Chen (2018) introduced a copy mechanism to generate equation templates in a semantically-aligned manner. T-RNN (Wang et al., 2019) extends the BiLSTM+Suffix+EN model by first generating a template with unknown operators and then filling in the operators with a Recursive Neural Network. The ensemble models use bagging to combine the results of different models.

Our seq2tree model is also a generation-style model. As shown in Table 2, we achieve state-of-the-art single model performance on the test set, and even better results than all the previous ensemble models, which can demonstrate the effectiveness of our proposed method.

5 Analysis and Discussion

5.1 Ablation Study

To get better insight into our seq2tree system, we conduct ablation study on Math23K development set, which is shown in Table 3. The prefix baseline denotes the model that removes parent feeding and sibling feeding, but only uses previous token feeding for the input. Thus, this model loses parent and sibling information and falls into a linear seq2seq model based on the prefix notation. The prefix baseline performs competitive results compared to previous single model SOTA (66.9%), which proves the effectiveness of top-down decoding. Parent feeding and sibling feeding separately improve the baseline model by 1.1% and 1.0%, demonstrating the importance of informing the model of AST structure information.

In Table 4, we also report the percentage of invalid templates by using different terminating methods. We remove the auxiliary stack and use a special end-of-sentence (EOS) token, which was used in previous studies to terminate the decoding process (Wang et al., 2017, 2018a). We can see that using the stack as a terminator can let the model generate very low percentage of invalid templates and outperforms the EOS method.

Problem	A person is taking a trip from A to B. He took a train for n_1 of the trip the first day. He took a bus and travelled for n_2 km the second day. He still needs to travel for n_3 of the total distance. How far is it from A to B?
Gold	**suffix order**: x = n_1 1 n_2 - n_3 - / **prefix order**: x = / n_1 - - 1 n_2 n_3
Prediction	**BiLSTM+Suffix+EN**: n_1 n_2 - n_3 / (error) **Ours**: / n_1 - - 1 n_2 n_3 (correct)

Table 6: Accuracy of different question domains on Math23K.

5.2 Case Study

Here we give an example that is improved by our tree-structured decoding system. As shown in Figure 5, in the gold equation of this example, there is a long distance between two pairs of parent-child nodes n_1 and $/$ and also 1 and $-$. The BiLSTM+Suffix+EN model failed to capture the relationship between these two pairs of parent-child nodes and caused an error. Our model has a better ability to capture the relation between pairs of parent-child nodes even if there is a long distance between them in the notation.

5.3 Error Analysis

In Table 5, we show the results of how the accuracy changes as the template becomes longer. We can see that our model's performance becomes very low when the equation becomes longer. This shows that our model has limitations at predicting long templates. This is because longer templates often match with more complex questions which are more difficult to solve. Thus, this model still has room for improvement on reasoning, inference and semantic understanding. Meanwhile, only a few examples in Math23K match with complex templates, so introducing data augmentation techniques or constructing a new dataset with more complex examples may further improve the model's performance.

In Table 6, we examine the performance of the model in different question domains. MWPs in the same domain usually share similar logic, while there is an obvious difference between questions across different domains. Accurately detecting the question domain is very laborious, so we do this experiment by simply detecting frequent keywords of each domain in the question. We show further details in the appendix. The results show that the performance of the model has obvious variance among different domains and limitations in some domains such as solid geometry. This is because these domains require complicated external knowledge for solving these questions, such as $S_{circle} = \pi r^2$. It is difficult for the model to automatically summarize these kinds of information with only supervision of the equation templates. Adding external knowledge for this task may further improve the model.

6 Conclusion

We proposed a sequence-to-tree generative model to improve template generation for solving math word problems. The hierarchical top-down tree-structure decoder can use the information of the abstract syntax tree of an equation during decoding. With the help of an auxiliary stack, this

decoding process can end without any redundant special tokens. Our model achieves state-of-the-art results on the large-scale dataset, Math23k, demonstrating the effectiveness of our approach.

A Prefix Notation Algorithm

Algorithm 2: The algorithm of converting ordinary equations to its prefix notation.

Input: The Ordinary Equation String $Equa = \{s_i\}_{i=1}^{n_1}$

Output: The Prefix Notation Equation String $Equa^p = \{s_i^p\}_{i=1}^{n_2}$

initialize empty stack S and list $Equa_{inv}^p$;
for $i \leftarrow n_1$ ***to*** 1 **do**
  if s_i *is quantity* **then**
    $Equa_{inv}^p$.append(s_i);
  else if s_i *is*) **then**
    S.push(s_i);
  else if s_i *is operator* **then**
    while *True* **do**
      if s_i *is prior to* S.*top or* S.*top is*) *or* S *is empty* **then**
        S.push(s_i);
        break;
      else
        $Equa_{inv}^p$.append(S.top);
        S.pop();
  else if S.*top is (* **then**
    while S.*top is not)* **do**
      $Equa_{inv}^p$.append(S.top);
      S.pop();
    S.pop()
$Equa^p$ = $Equa_{inv}^p$.inverse()

Here we show the details of the converting algorithm. The input is the ordinary equation string and the output is the prefix notation of the equation.

B Domain Keywords

We show the table of the keywords for each domain. These keywords were manually collected by observation.

Domain	Keywords
Distance & Speed	速 度,千 米,路 程,相距,全程
Tracing	相 遇,相 对,相 反,相背,相向
Engineering	工程,零件,工程队,公路,修路
Interval	利润
Circle	半径,圆,直径,周长
Plane Geometry	三角形,正方形,长方形,边长
Profit	间隔,隔
Solid Geometry	体 积,侧 面 积,横 截面,表面积,圆柱,长方体
Interest Rate	利息,利率
Production	超产,减产

Table 7: The list of keywords in the domain specific studies.

PullNet: Open Domain Question Answering with Iterative Retrieval on Knowledge Bases and Text

Haitian Sun Tania Bedrax-Weiss William W. Cohen
Google Research
{haitiansun,tbedrax,wcohen}@google.com

Abstract

We consider open-domain question answering (QA) where answers are drawn from either a corpus, a knowledge base (KB), or a combination of both of these. We focus on a setting in which a corpus is supplemented with a large but incomplete KB, and on questions that require non-trivial (e.g., "multi-hop") reasoning. We describe PullNet, an integrated framework for (1) learning what to retrieve and (2) reasoning with this heterogeneous information to find the best answer. PullNet uses an iterative process to construct a question-specific subgraph that contains information relevant to the question. In each iteration, a graph convolutional network (graph CNN) is used to identify subgraph nodes that should be expanded using retrieval (or "pull") operations on the corpus and/or KB. After the subgraph is complete, another graph CNN is used to extract the answer from the subgraph. This retrieve-and-reason process allows us to answer multi-hop questions using large KBs and corpora. PullNet is weakly supervised, requiring question-answer pairs but not gold inference paths. Experimentally PullNet improves over the prior state-of-the art, and in the setting where a corpus is used with incomplete KB these improvements are often dramatic. PullNet is also often superior to prior systems in a KB-only setting or a text-only setting.

1 Introduction

Open domain Question Answering (QA) is the task of finding answers to questions posed in natural language, usually using text from a corpus (Dhingra et al., 2017; Joshi et al., 2017; Dunn et al., 2017), or triples from a knowledge base (KB) (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Yih et al., 2015). Both of these approaches have limitations. Even the largest KBs are incomplete (Min et al., 2013), which limits recall of a KB-based QA system. On the other hand, while a large corpus may contain more answers than a KB, the diversity of natural language makes corpus-based QA difficult (Chen et al., 2017; Welbl et al., 2018; Kwiatkowski et al., 2019; Yang et al., 2018).

In this paper we follow previous research (Sawant et al., 2019; Sun et al., 2018) in deriving answers using both a corpus and a KB. We focus on tasks in which questions require compositional (sometimes called "multi-hop") reasoning, and a setting in which the KB is incomplete, and hence must be supplemented with information extracted from text. We also restrict ourselves in this paper to answers which correspond to KB entities. For this setting, we propose an integrated framework for (1) *learning what to retrieve*, from either a corpus, a KB, or a combination, and (2) *combining this heterogeneous information* into a single data structure that allows the system to reason and find the best answer. In prior work, this approach was termed an *early fusion* approach, and shown to improve over *late fusion* methods, in which two QA systems, one corpus-based and one KB-based, are combined in an ensemble.

Our system, PullNet, builds on the GRAFT-Net[1] (Sun et al., 2018) early fusion system. GRAFT-Net uses heuristics to build a question-specific subgraph which contains sentences from the corpus, and entities and facts from the KB. A graph CNN (Kipf and Welling, 2016; Li et al., 2016; Schlichtkrull et al., 2017) variant is then used to reason over this graph and select an answer. However, as we will show experimentally, GRAFT-Net's heuristics often produce subgraphs that are far from optimal–often they are much larger than necessary, and sometimes do not contain the answer.

Like GRAFT-Net, PullNet also uses a reason-

[1] Graphs of Relations Among Facts and Text Networks.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2380–2390, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing process based on a graph CNN to find answers. However, PullNet *learns* how to construct the subgraph, rather than using an *ad hoc* subgraph-building strategy. More specifically, PullNet relies on a small set of retrieval operations, each of which expands a graph node by retrieving new information from the KB or the corpus. PullNet learns when and where to apply these "pull" operations with another graph CNN classifier. The "pull" classifier is weakly supervised, using question-answer pairs.

The end result is a learned iterative process for subgraph construction, which begins with a small subgraph containing only the question text and the entities which it contains, and gradually expands the subgraph to contain information from the KB and corpus that are likely to be useful. The incremental question-guided subgraph construction process results in high-recall subgraphs that are much smaller than the ones created heuristically, making the final answer extraction process easier. The process is especially effective for multi-hop questions, which naively would require expanding the subgraph to include all corpus and KB elements that are k hops away from the question.

PullNet improves over the current state-of-the-art for KB-only QA on several benchmark datasets, and is superior to, or competitive with, corpus-only QA on several others. For multi-hop questions, this improvement is often dramatic. For instance, MetaQA (Zhang et al., 2018) contains multi-hop questions based on a small movie KB, originally associated with the WikiMovies dataset (Miller et al., 2016). In a KB-only setting, PullNet improves hits-at-one performance for 3-hop MetaQA questions from 62.5% to 91.4%. Perhaps more interestingly, PullNet obtains performance of 85.2% hits-at-one with a KB from which half of the triples have been removed, if that KB is supplemented with a corpus. We note that this result improves by 7% (absolute improvement) over a pure corpus-based QA system, and by more than 25% over a pure KB-based QA system. In a similar incomplete-KB setting, PullNet improves over GRAFT-Net by 6.8% on the ComplexWebQuestions dataset (Talmor and Berant, 2018).

2 Related Work

This paper has focused on QA for multi-hop questions using large KBs and text corpora as the information sources from which answers can be drawn. The main technical contribution is an iterative question-guided retrieval mechanism that retrieves information from KBs, corpora, or combinations of both, which makes it possible to follow long paths of reasoning on large KB.

A long line of QA models have been developed which answer questions based on a single passage of text (Dhingra et al., 2016; Yu et al., 2018; Seo et al., 2016; Gao et al., 2018; Liu et al., 2017; Devlin et al., 2018). Generally, these "reading comprehension" systems are operated by encoding the passage and question into an embedding space, and due to memory limitations cannot be applied to a large corpus instead of a short passage. To address this limitation a number of systems have been designed which use a "retrieve and read" pipeline (Chen et al., 2017; Dhingra et al., 2017; Joshi et al., 2017; Dunn et al., 2017; Wang et al., 2018, 2017), in which a retrieval system with high recall is piped into a reading comprehension system that can find the answer. An alternative approach is "phrase-indexed" QA (Seo et al., 2018), where embedded phrases in a document are indexed and searched over. Existing systems are also not able to use both KB and text for QA. They also differ from PullNet in using only a single round of retrieval; however, for questions that require multi-hop reasoning, it is difficult for a single retrieval step to find the relevant information.

SplitQA (Talmor and Berant, 2018) is a text-based QA system that decomposes complex questions (e.g., with conjunction or composition) into simple subquestions, and performs retrieval sequentially for the subquestions. Although it uses iterative retrieval for multi-hop questions, unlike PullNet, SplitQA does not also use a KB as an information source. Also, SplitQA has been applied only to the Complex WebQuestions dataset, so it is unclear how general this approach is.

There has also been much work on QA from KBs alone, often using methods based on memory networks (Sukhbaatar et al., 2015), semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005) or reinforcement learning Das et al. (2017). Extending such KB-based work to also use text, however, is non-trivial. Another line of QA work from text and KBs is exemplified by AQQU (Bast and Haussmann, 2015) and its successors (Sawant et al., 2019). These systems focus on questions (e.g. SimpleWebQuestions), that can

be interpreted as identifying an entity based on a relationship and related entity, plus additional restrictions described in text, and it is unclear how to extend such approaches to multi-hop questions.

GRAFT-Net (Sun et al., 2018) supports multi-hop reasoning on both KBs and text by introducing a question subgraph built with facts and text, and uses a learned graph representation (Kipf and Welling, 2016; Li et al., 2016; Schlichtkrull et al., 2017; Scarselli et al., 2009) to perform the reasoning required to select the answer. We use the same representation and reasoning scheme as GRAFT-Net, but do not require that the entire graph be retrieved in a single step. In our experimental comparisons, this gives significant performance gains for multi-hop reasoning tasks.

Combinations of KBs and text have also been used for relation extraction and Knowledge Base Completion (KBC) (Lao et al., 2012; Toutanova et al., 2015; Das et al., 2017). The QA task differs from KBC in that in QA, the inference process must be conditioned on a natural-language question, which leads to different constraints on which methods can be used.

3 The PullNet Model

PullNet retrieves from two "knowledge sources", a text corpus and a KB. Given a question, PullNet will use these to construct a *question subgraph* that can be used to answer the question. The question subgraph is constructed iteratively. Initially the subgraph depends only on the question. PullNet then iteratively expands the subgraph by choosing nodes from which to "pull" information about, from the KB or corpus as appropriate. The question subgraph is heterogeneous, and contains both entities, KB triples, and entity-linked text.

In this section, we will first introduce notation defining the heterogeneous graph structure we use. Then we will introduce the general iterative retrieval process. Finally, we will discuss the retrieval operations used on the corpus and KB, and the classification operations on the graph which determine where to perform the retrievals.

3.1 The Question Subgraph

A *question subgraph* for question q, denoted $\mathcal{G}_q = \{\mathcal{V}, \mathcal{E}\}$, is a hetogeneous graph that contains information from both the text corpus and the KB relevant to q. Let $\mathcal{V}$ denote the set of vertices, which we also call nodes. Following GRAFT-Net (Sun et al., 2018), there are three types of nodes: entity nodes $\mathcal{V}_e$, text nodes $\mathcal{V}_d$, and fact nodes $\mathcal{V}_f$, with $\mathcal{V} = \mathcal{V}_e \cup \mathcal{V}_d \cup \mathcal{V}_f$. An entity node $v_e \in \mathcal{V}_e$ represents an entity from the knowledge base. A text node $v_d \in \mathcal{V}_d$ represents a document from the corpus, with a sequence of tokens denoted $(w_1, \ldots, w_{|d|})$. In this paper, a document is always a single sentence, to which an entity linker (Ji et al., 2014) has been applied to detect and ground entity mentions. A fact node $v_f \in \mathcal{V}_f$ represents a triplet (v_s, r, v_o) from the KB, with subject and objects $v_s, v_o \in \mathcal{V}_e$ and relation r. Let $\mathcal{E}$ denote the set of edges between nodes. An edge connects a fact node v_f and an entity node v_e iff fact v_f has v_e as its subject or object. An edge connects a text node v_d with entity node v_e iff the entity is mentioned in the text.

3.2 Iterative subgraph construction

3.2.1 Overview

We start with a question subgraph $\mathcal{G}_q^0 = \{\mathcal{V}^0, \mathcal{E}^0\}$ where $\mathcal{V}^0 = \{e_{q_i}\}$ is the list of entities in the question and $\mathcal{E}^0$ is an empty set. We iteratively expand the question subgraph $\mathcal{G}_q^0$ until it contains the information required to answer the question.

Algorithm 1 PullNet

1: Initialize question graph G_q^0 with question q and question entities, with $\mathcal{V}^0 = \{e_{q_i}\}$ and $\mathcal{E}^0 = \emptyset$.
2: **for** $t = 1, \cdots, T$ **do**
3: Classify the entity nodes in the graph and select those with probability larger than ϵ
$\{v_{e_i}\} = \texttt{classify_pullnodes}\,(G_q^t, k)$
4: **for all** v_e in $\{v_{e_i}\}$ **do**
5: Perform pull operation on selected entity nodes
$\{v_{d_i}\} = \texttt{pull_docs}\,(v_e, q)$
$\{v_{f_i}\} = \texttt{pull_facts}\,(v_e, q)$
6: **for all** v_d in $\{v_{d_i}\}$ **do**
7: Extract entities from new document nodes
$\{v_{e(d)_i}\} = \texttt{pull_entities}\,(v_d)$
8: **for all** v_f in $\{v_{f_i}\}$ **do**
9: Extract head and tail of new fact nodes
$\{v_{e(f)_i}\} = \texttt{pull_headtail}\,(v_f)$
10: Add new nodes and edges to question graph
$G_q^{t+1} = \texttt{update}\,(G_q^t)$
11: Select entity node in final graph that is the best answer
$v_{\text{ans}} = \texttt{classify_answer}\,(G_q^T)$

The algorithm is shown in Alg 1. Briefly, we expand the graph in T iterations. In each iteration, we choose entities whose probability is larger than ϵ to expand, and then for each selected entity,

we retrieve a set of related documents, and also a set of related facts. The new documents are then passed through an entity-linking system to identify entities that occur in them, and the head and tail entities of each fact are also extracted. The last stage in each iteration is to update the question graph by adding all these new edges. After the T-th iteration of expansion, an additional classification step is applied to the final question subgraph to predict the answer entity.

3.2.2 Pull Operations

Pull operations either retrieve information from a knowledge source, or extract entities from a fact or document.

The two extraction operations are relatively simple. The `pull_entities(`v_d`)` operation inputs a document node v_d, calls an entity linker and returns all entities mentioned in v_d. The `pull_headtail(`v_f`)` operation inputs a fact node v_f and returns the subject and object entity of fact v_f.

The retrieval operations are more complex. The `pull_docs(`v_e, q`))` operation retrieves relevant documents from the corpus. We use an IDF-based retrieval system, Lucene (McCandless et al., 2010) and assume that all sentences have been entity-linked prior to being indexed. The retrieved documents are constrained to link to entity v_e, and are ranked by their IDF similarity to the question q. Only the top N_d ranked documents are returned.

The `pull_facts(`v_e, q`)` operation retrieves the top N_f facts from the KB about entity v_e. The retrieved facts are constrained to have v_e as their subject or object, and are ranked based on the similarity $S(r, q)$ between the fact's relation r and the question q. Since it is not obvious how to assess relevance of a fact to a question q, we learn $S(r, q)$ as follows. Let h_r be an embedding of relation r, which is looked up from an embedding table, and let $q = (w_1, \ldots, w_{|q|})$ be the sequence of words for question q. Similarity is defined as the dot-product of the last-state LSTM representation for q with the embedding for r. This dot-product is then passed through a sigmoid function to bring it into a range of $[0, 1]$: as we explain below, we will train this similarity function as a classifier which predicts which retrieved facts are relevant to the question q. The final ranking method for facts is

$$h_q = \text{LSTM}(w_1, \ldots, w_{|q|}) \in \mathbb{R}^n$$
$$S(r, q) = \text{sigmoid}(h_r^T \, h_q)$$

3.2.3 Classify Operations

Two types of `classify` operations are applied to the nodes in a subgraph G_q^t. These operations are applied only to the entity nodes in the graph, but they are based on node representations computed by the graph CNN, so the non-entity nodes and edges also affect the classification results.

During subgraph construction, the `classify_pullnodes(`G_q^t`)` operation returns the probability entity node v_e should be expanded in the next iteration. We choose the k nodes with the highest probability in each iteration. After the subgraph is complete, the `classify_answer(`G_q^t`)` operation predicts whether an entity node answers the question. The highest-scoring entity node is returned as the final answer.

We use the same CNN architecture used by GRAFT-Net (Sun et al., 2018) for classification. GRAFT-Net supports node classification on heterogeneous graphs containing facts, entities, and documents. GRAFT-Net differs from other graph CNN implementations in using special mechanisms to distribute representations across different types of nodes and edges: notably, document nodes are represented with an LSTM encoding, extended by mechanisms that allow the representations for entity nodes v_e to be passed into a document v_d that mentions v_e, and mechanisms that allow the LSTM hidden states associated with an entity mention to be passed out of v_d to the associated entity node v_e.

3.2.4 The Update Operation

The `update` operation takes the question subgraph G_q^{t-1} from the previous iteration and updates it by adding the newly retrieved entity nodes $\{v_{e(f)_i}\} \cup \{v_{e(d)_i}\}$, the text nodes $\{v_{d_i}\}$, and the fact nodes $\{v_{f_i}\}$. It also updates the set of edges $\mathcal{E}$ based on the definitions of Section 3.1. Note that some new edges are derived when pull operations are performed on text and fact nodes, but other new edges may connect newly-added nodes with nodes that already exist in the previous subgraph.

3.3 Training

To train PullNet, we assume that we only observe question and answer pairs, i.e., the actual inference chain required to answer the question is latent. We thus need to use weak supervision to train the classifiers described above.

To train these models, we form an approximation of the ideal question subgraph for question q as follows. Note that in training, the answer entities are available. We use these to find all shortest paths in the KB between the question entities and answer entities. Each entity e that appears in such a shortest path will be marked as a *candidate intermediate entities*. For each candidate intermediate entity e we record its minimal distance t_e from the question nodes.

When we train the `classify_pullnodes` classifier in iteration t, we treat as positive examples only those entities e' that are connected to a candidate intermediate entity e with distance $e_t = t+1$. Likewise in training the similarity function $S(h_r, q)$ we treat as positive relations leading to candidate intermediate entities e at distance $e_t = t + 1$. This encourages the retrieval to focus on nodes that lie on shortest paths to an answer.

In training we use a variant of teacher forcing. We pull from all entity nodes with a predicted score larger than some threshold ϵ, rather than only the top k nodes. If, during training, a candidate intermediate entity is not retrieved in iteration t_e, we add it to the graph anyway. The values T and ϵ are hyperparameters, but here we always pick for T the maximum length of the inference chain needed to ensure full coverage of the answers.

We use the same classifier in the retrieval step as in answer selection, except that we change the last fully-connected layer. The classifiers used for retrieval in the different iterations are identical.

The learned parts of the model are implemented in PyTorch, using an ADAM optimizer (Kingma and Ba, 2014), and the full retrieval process of Alg 1 is performed on each minibatch.

4 Experiments and Results

4.1 Datasets

MetaQA (Zhang et al., 2018) contains more than 400k single and multi-hop (up to 3-hop) questions in the domain of movies. The questions were constructed using the knowledge base provided with the WikiMovies (Miller et al., 2016) dataset. We use the "vanilla" version of the queries[2] We use the KB and text corpus supplied with the WikiMovies dataset, and use exact match on surface forms to perform entity linking. The KB used here is relatively small, with about 43k entities and 135k triples.

WebQuestionsSP (Yih et al., 2015) contains 4737 natural language questions that are answerable using Freebase.[3] The questions require up to 2-hop reasoning from knowledge base, and 1-hop reasoning using the corpus. We use Freebase as our knowledge base but for ease of experimentation restrict it to a subset of Freebase which contains all facts that are within 2-hops of any entity mentioned in the questions of WebQuestionsSP. We also exclude a few "very common" entities, e.g. the ones that describe the hierarchical structure of KB. This smaller KB contains 43 million facts and 12 million entities. We use Wikipedia as our corpus and use a simple entity-linker: we link entities by exact matching to any surface form annotated the FACC1 dataset (Gabrilovich et al., 2013).[4]

Complex WebQuestions 1.1 (Complex WebQ) (Talmor and Berant, 2018) is generated from WebQuestionsSP by extending the question entities or adding constraints to answers, in order to construct multi-hop questions.[5] There are four types of question: composition (45%), conjunction (45%), comparative (5%), and superlative (5%). The questions require up to 4-hops of reasoning on the KB and thr 2-hops on corpus. We use the same KB and corpus as for WebQuestionsSP.

	Train	Dev	Test
MetaQA 1-hop	96,106	9,992	9,947
MetaQA 2-hop	118,980	14,872	14,872
MetaQA 3-hop	114,196	14,274	14,274
WebQuestionsSP	2,848	250	1,639
Complex WebQ	27,623	3,518	3,531

Table 1: Statistics of all datasets.

4.2 Tasks

We explored several different QA settings: complete KB only, corpus only, incomplete KB only, and incomplete KB paired with the corpus.

In the *complete KB only* setting, the answer always exists in knowledge base: for all of these datasets, this is true because the questions were crowd-sourced to enforce this conditions. This is the easiest setting for QA, but arguably unrealistic, since with a more natural distribution of ques-

[2]For this version, the 1-hop questions in MetaQA are exactly the same as WikiMovies.

[3]We use the same train/dev/test splits as GRAFT-Net (Sun et al., 2018).

[4]If two overlapping spans are possible matches, we match only the longer of them.

[5]We use Complex WebQuestions v1.1, where the author re-partition the train/dev/test data to prevent the leakage of information.

tions, a KB is likely to be incomplete. In the *text only* setting we use only the corpus. In the *incomplete KB* setting, we simulate KB-based QA on an incomplete KB by randomly discarding some of the triples in the KB: specifically, we randomly drop a fact from the knowledge base with probability $p = 50\%$. This setting is presented mainly as a baseline for the *incomplete KB plus text setting*, where we pair the same incomplete knowledge base with the corpus. In principle this allows a learned QA system to adopt many different hybrid strategies: e.g., for 1-hop queries, a model "back off" to text when the KB is missing information, while in more complex queries, reasoning can involve combining inferences done with text and inferences done with KB triples.

Comment. One point to note is that our training procedure is based on finding shortest paths in a complete KB, and we use this same procedure on the incomplete KB setting. Thus the weak training that we use should, in the incomplete-KB settings, be viewed as a form of weak supervision, with labels that are intermediate in informativeness between pure distant training (with only question-answer pairs) and gold inference paths (a setting that has been extensively investigated on some of these datasets, in particular WebQuestionsSP).

4.3 Baselines

We choose Key-Value Memory Networks (Miller et al., 2016) and GRAFT-Net (Sun et al., 2018) as our baseline models: to the best of our knowledge, these are the only ones that can use both text and KBs for question answering. However, both models are limited by the number of facts and text that can fit into memory. Thus, we create a separate retrieval process as a pre-processing step, which will be discussed below.

Key-Value Memory Networks (KVMem) (Miller et al., 2016) maintain a memory table which stores KB facts and text encoded into key-value pairs. Our encoding of KB facts is the same as is presented in Miller et al. (2016). For text, we use an bi-directional LSTM to encode the text for the key and take the entities mentioned in the text as values. Our implementation shows comparable performance on the WikiMovies (MetaQA 1-hop) dataset, as shown in Table 3.

For **GRAFT-Net** (Sun et al., 2018), we use the implementation published by the author;[6] however, we retrieve data with a simpler process, as described in Section 4.4.

[6] https://github.com/OceanskySun/GraftNet

	WikiM-KB	WikiM-KB (50%)
MetaQA-1hop	0.995 / 9.17	0.544 / 4.58
MetaQA-2hop	0.983 / 47.3	0.344 / 28.6
MetaQA-3hop	0.923 / 459.2	0.522 / 316.6
	Freebase	Freebase (50%)
WebQuestionsSP	0.927 / 1876.9	0.485 / 1212.5
ComplexWebQ	0.644 / 1948.7	0.542 / 1849.2

Table 2: Retrieval results (recall / # entities in graph) on MetaQA ($m = 500$), and WebQuestionsSP and Complex WebQuestions with Freebase ($m = 2000$).

4.4 Subgraph Retrieval for Baseline Models

Text is retrieved (non-iteratively) using IDF-based similarity to the question. It is not obvious how to perform KB retrieval: we would like to retrieve as many facts as possible to maximize the recall of answers, but it is infeasible to take all facts that are within k-hops of question entities since the number grows exponentially. Based on prior work in the database community on sampling from graphs (Leskovec and Faloutsos, 2006) and local partitioning (Andersen et al., 2006a), we ran an approximate version of personalized PageRank (aka random walk with reset) to find the KB entities closest to the entities in the question—specifically, we used the PageRank-Nibble algorithm (Andersen et al., 2006b) with $\epsilon = 1e^{-6}$ and the picked the m top-scoring entities.[7] We then eliminate all top-m entities that are more than k-hops of the question entities, and finally, retrieve all facts from the KB connecting retrieved entities.

The results for several tasks are shown in Table 2, which gives the answer recall, and the average number of entities retrieved. For the smaller MetaQA KB with $m = 500$, the retrieval method finds high-coverage graphs when the KB is complete. For ComplexWebQuestions, even with $m = 2000$, the recall is 64%—which is expected, since retrieving relevant entities for a multi-hop question from a KB with millions of entities is difficult.

4.5 Main Results

4.5.1 MetaQA

The experimental results for MetaQA are shown in Table 3. For 1-hop questions (which is identical to the WikiMovies dataset), PullNet is comparable

[7] Notice that in this process we do not use answer entities which are of course not available at test time.

	MetaQA (1-hop) / wikimovies				MetaQA (2-hop)				MetaQA (3-hop)			
	KB	Text	50% KB	50% KB + Text	KB	Text	50% KB	50%KB + Text	KB	Text	50% KB	50% KB + Text
KV-Mem*	96.2	75.4	(63.6)	75.7	82.7	7.0	(41.8)	48.4	48.9	19.5	(37.6)	35.2
GRAFT-Net*	97.0	82.5	(64.0)	91.5	94.8	36.2	(52.6)	69.5	77.7	40.2	(59.2)	66.4
PullNet (Ours)	97.0	84.4	(65.1)	92.4	**99.9**	**81.0**	(52.1)	**90.4**	**91.4**	**78.2**	(59.7)	**85.2**
KV-Mem	93.9	76.2	–	–	–	–	–	–	–	–	–	–
GRAFT-Net	96.8	**86.6**	(68.0)	**92.6**	–	–	–	–	–	–	–	–
VRN	**97.5**	–	–	–	89.9	–	–	–	62.5	–	–	–

Table 3: Hits@1 on MetaQA compared to baseline models. Number below the double line are from original papers: KV-Mem (KB) (Miller et al., 2016), KV-Mem (Text) (Watanabe et al., 2017), GRAFT-Net (Sun et al., 2018), and VRN (Zhang et al., 2018). *Reimplemented or different retrieval process.

to the state-of-the-art.[8] We also see that our simplified retrieval pipeline has slightly lower performance than the original (Sun et al., 2018) method. However, for multi-hop questions, PullNet generally shows a large improvement over the baseline models. In the KB-only setting, the absolute performance improvement over the best previously published results is 10 points for 2-hop and almost 30 points for 3-hop questions—and there are even larger improvements relative to the baseline models in the settings using text. In the incomplete KB plus text setting, PullNet also consistently improves over either the text-only or incomplete-KB-only setting.[9] This supports our claim that PullNet is able to effectively combine a KB and text.[10]

4.5.2 WebQuestionsSP

Table 4 presents similar results on the WebQuestionsSP dataset. PullNet improves over GRAFT-Net in the incomplete KB plus text setting, and the addition of text to the incomplete KB also improves performance for PullNet.

4.5.3 Complex WebQuestions

Complex WebQuestions contains multi-hop questions against Freebase: intuitively, one would expect that single-shot retrieval of facts and text would not be able to always find sufficient information to answer such questions. Table 5 shows our results for Complex WebQuestions on the development set. As expected, PullNet shows significant improvement over GRAFT-Net and KV-Mem on all four settings. Once again we see some improvement when pairing the incomplete knowledge base with text, compared to using the incomplete knowledge base only or the text only.

	KB	Text	50% KB	50% KB + Text
KV-Mem*	46.7	23.2	(32.7)	31.6
GRAFT-Net*	66.4	24.9	(48.2)	49.7
PullNet (Ours)	**68.1**	24.8	(50.3)	**51.9**
GRAFT-Net	67.8	**25.3**	(47.7)	49.9
NSM	69.0 (F1)	–	–	–

Table 4: Hits@1 on WebQuestionsSP compared to baseline models. Number below the double line are from the original papers: GRAFT-Net (Sun et al., 2018), and NSM (Liang et al., 2017) (which only reports F1 in their paper). * Reimplemented or different retrieval process.

	KB	Text (Wikipedia)	50% KB	50% KB + Text
KV-Mem*	21.1	7.4	(14.8)	15.2
GRAFT-Net*	32.8	10.6	(26.1)	26.9
PullNet (Ours)	**47.2**	**13.1**	(31.5)	**33.7**
		(Snippets)		
SplitQA	–	34.2	–	–
PullNet (Ours)	45.9	29.7	–	–

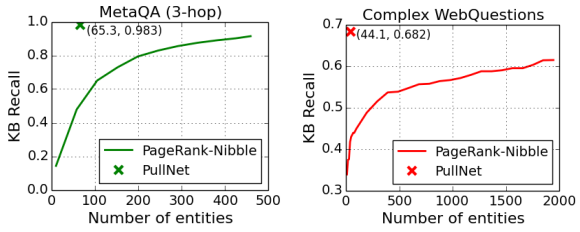
Table 5: Hits@1 on Complex WebQuestions compared to baseline models. Above the double line results are on the dev set, below on the test set. *Reimplemented or different retrieval process.

Researchers are only allowed limited submissions on the Complex WebQuestions test set, however, some results for the test set are shown in Table 5. On the test set, our model has 45.9% Hits@1 in the KB only setting and 13.8% Hits@1 (not listed in Table 5) in the text only setting with Wikipedia corpus, which are comparable to the dev set results.

For completeness, we also compare to SplitQA (Talmor and Berant, 2018). SplitQA decomposes a multi-hop question into several simpler sub-questions, and sends each sub-question to the Google search engine. In then applies a reading comprehension model to these web snippets to find answers. The snippet corpus is made available

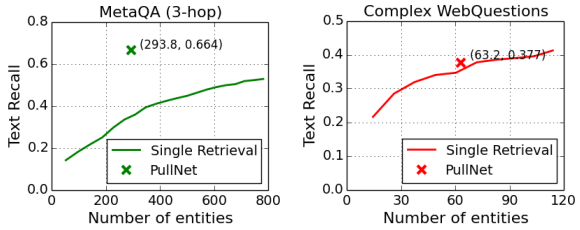
[8] 6.7% questions in Wikimovies are ambiguous, e.g. questions about movies with remakes without specifying years.

[9] The implement KB results are parenthesized because it presented only to compare against the incomplete KB plus text setting.



[10] Although we do not repeat the results here, we note that prior work (Sun et al., 2018) showed GRAFT-Net outperforms "late fusion" approaches for combining information: in late fusion, two QA systems are ensembled together, one which uses the incomplete KB, and one which uses the text.

with the Complex WebQuestions dataset, but it is arguably biased toward the SplitQA model, since it was collected specifically to support it, and also relies on non-reproducible, non-open-source components. With this corpus our model has 4.5% lower Hits@1 than SplitQA. However, using the KB, PullNet has much better performance than SplitQA, with an absolute gain of 11.7%.



4.6 Additional Results

4.6.1 Retrieval Performance of PullNet

In Figure 1a we compare the retrieval performance of PullNet to that of PageRank-Nibble on multi-hop questions with a complete KB, on two multi-hop problems, varying the number of entities retrieved by PageRank-Nibble. PullNet retrieves far fewer entities but obtains higher recall.

(a) Recall of graphs retrieved by PageRank-Nibble compared with PullNet.

(b) Recall of a single round of retrieval with Apache Lucene compared with PullNet.

Figure 1: Retrieval performance on different datasets.

In Figure 1b we evaluate the effectiveness of iterative retrieval for multi-hop questions on a text corpus. PullNet, with multiple iterations of retrieval, greatly outperfoms a single iteration of IDF-based retrieval on 3-hop MetaQA, and slighly outperforms IDF on Complex WebQuestions.

Figure 2 shows the recall of question subgraphs on 3-hop MetaQA questions as training proceeds. Performance of the retrieval components of PullNet converges relatively quickly, with recall saturating after 10-20,000 examples (about 10-20% of a single epoch).

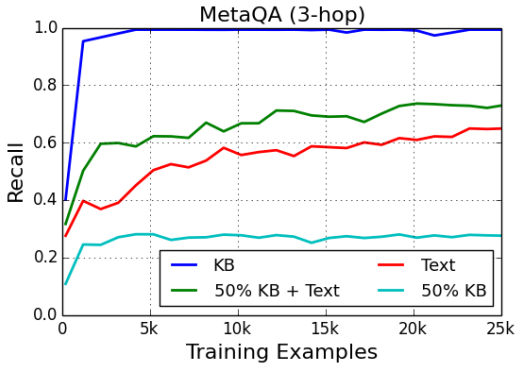


Figure 2: Recall of question subgraph on MetaQA 3-hop questions.

4.6.2 Training Time

PullNet's algorithm is quite different from prior systems, since learning and retrieval are interleaved: in most prior systems, including GRAFT-Net, retrieval is performed only once, before learning. Intuitively, interleaving learning with the relatively slow operation of retrieval is potentially slower; on the other hand, PullNet's final question subgraph is smaller than GRAFT-Net, which makes learning potentially faster.

To study these issues, we plot the Hits@1 performance of learned model versus wall clock time in Figure 3. This experiment is run on Complex WebQuestions in the KB-only setting, using one high-end GPU.[11] GRAFT-Net takes an average of 31.9 minutes per epoch, while PullNet takes an average of 114 minutes per epoch, about 3.5 times slower.

As the graph shows, initially PullNet's performance is better, since GRAFT-Net cannot start learning until the preprocessing finishes. GRAFT-Net's faster learning speed then allows it to dominates for some time. GRAFT-Net reaches its peak in about 3.6 hours. PullNet passes GRAFT-Net after around 6 hours (about 3 epochs for PullNet).

5 Conclusions

PullNet is a novel integrated QA framework for (1) learning what to retrieve from a KB and/or corpus and (2) reasoning with this heterogeneous data to find the best answer. Unlike prior work, PullNet uses an iterative process to construct a question-specific subgraph that contains information relevant to the question. In each iteration, a

[11] To be fair to GRAFT-Net, we used a fast in-memory implementation of PageRank-Nibble (based on SciPy sparse matrices), which takes about 40 minutes.

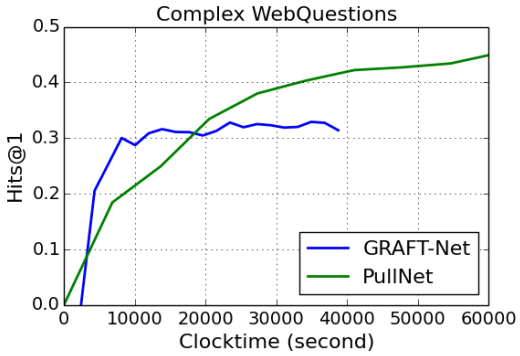

Figure 3: Performance of PullNet and GRAFT-Net under wall clock training time.

graph CNN is used to identify subgraph nodes that should be expanded using "pull" operations on the corpus and/or KB. This iterative process makes it possible to retrieve a small graph that contains just the information relevant to a multi-hop question.

Experimentally PullNet improves over the prior state-of-the-art for the setting in which questions are answered with a corpus plus an incomplete KB, or in settings in which questions need "multi-hop" reasoning. Sometimes the performance improvements are dramatic: e.g., an improvement from 62.5% Hits@1 to 91.4% Hits@1 for 3-hop MetaQa with a KB, or improvements from 32.8% to 47.2% for Complex WebQuestions with a KB.

Abstract

Understanding narratives requires reading between the lines, which in turn, requires interpreting the likely causes and effects of events, even when they are not mentioned explicitly. In this paper, we introduce COSMOS QA, a large-scale dataset of 35,600 problems that require commonsense-based reading comprehension, formulated as multiple-choice questions. In stark contrast to most existing reading comprehension datasets where the questions focus on factual and literal understanding of the context paragraph, our dataset focuses on reading between the lines over a diverse collection of people's everyday narratives, asking such questions as *"what might be the possible reason of ...?"*, or *"what would have happened if ..."* that require reasoning beyond the exact text spans in the context. To establish baseline performances on COSMOS QA, we experiment with several state-of-the-art neural architectures for reading comprehension, and also propose a new architecture that improves over the competitive baselines. Experimental results demonstrate a significant gap between machine (68.4%) and human performance (94%), pointing to avenues for future research on commonsense machine comprehension. Dataset, code and leaderboard is publicly available at https://wilburone.github.io/cosmos.

P1: It's a very humbling experience when you need someone to dress you every morning, tie your shoes, and put your hair up. Every menial task takes an unprecedented amount of effort. It made me appreciate Dan even more. But anyway I shan't dwell on this (I'm not dying after all) and not let it detract from my lovely 5 days with my friends visiting from Jersey.

Q: *What's a possible reason the writer needed someone to dress him every morning?*

A: The writer doesn't like putting effort into these tasks.
✓ **B: The writer has a physical disability.**
C: The writer is bad at doing his own hair.
D: None of the above choices.

P2: A woman had topped herself by jumping off the roof of the hospital she had just recently been admitted to. She was there because the first or perhaps latest suicide attempt was unsuccessful. She put her clothes on, folded the hospital gown and made the bed. She walked through the unit unimpeded and took the elevator to the top floor.

Q: *What would have happened to the woman if the staff at the hospital were doing their job properly?*

✓ **A: The woman would have been stopped before she left to take the elevator to the top floor and she would have lived.**
B: She would have been ushered to the elevator with some company.
C: She would have managed to get to the elevator quicker with some assistance.
D: None of the above choices.

Figure 1: Examples of COSMOS QA. (✓ indicates the correct answer.) Importantly, (1) the correct answer is not explicitly mentioned anywhere in the context paragraph, thus requiring reading between the lines through commonsense inference and (2) answering the question correctly requires reading the context paragraph, thus requiring reading comprehension and *contextual* commonsense reasoning.

1 Introduction

Reading comprehension requires not only understanding what is stated explicitly in text, but also *reading between the lines*, i.e., understanding what is not stated yet obviously true (Norvig, 1987).

For example, after reading the first paragraph in Figure 1, we can understand that the writer is not a child, yet needs someone to dress him or her every morning, and appears frustrated with the current situation. Combining these clues, we can infer that the plausible reason for the writer being dressed by other people is that he or she may have a physical disability.

As another example, in the second paragraph of Figure 1, we can infer that the woman was admitted to a psychiatric hospital, although not mentioned explicitly in text, and also that the job of the hospital staff is to stop patients from committing suicide. Furthermore, what the staff should

[*]The work has been done during the author's internship in AI2.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2391–2401, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

have done, in the specific situation described, was to stop the woman from taking the elevator.

There are two important characteristics of the problems presented in Figure 1. First, the correct answers are not explicitly mentioned anywhere in the context paragraphs, thus requiring reading between the lines through commonsense inference. Second, selecting the correct answer requires reading the context paragraphs. That is, if we were not provided with the context paragraph for the second problem, for example, the plausible correct answer could have been B or C instead.

In this paper, we focus on reading comprehension that requires *contextual* commonsense reasoning, as illustrated in the examples in Figure 1. Such reading comprehension is an important aspect of how people read and comprehend text, and yet, relatively less studied in the prior machine reading literature. To support research toward commonsense reading comprehension, we introduce COSMOS QA (**Co**mmon**s**ense **M**achine C**o**mprehen**s**ion), a new dataset with $35,588$ reading comprehension problems that require reasoning about the causes and effects of events, the likely facts about people and objects in the scene, and hypotheticals and counterfactuals. Our dataset covers a diverse range of everyday situations, with $21,886$ distinct contexts taken from blogs of personal narratives.

The vast majority (93.8%) of our dataset requires contextual commonsense reasoning, in contrast with existing machine comprehension (MRC) datasets such as SQuAD (Rajpurkar et al., 2016), RACE (Lai et al., 2017), Narrative QA (Kočiskỳ et al., 2018), and MCScript (Ostermann et al., 2018), where only a relatively smaller portion of the questions (e.g., 27.4% in MCScript) require commonsense inference. In addition, the correct answer cannot be found in the context paragraph as a text span, thus we formulate the task as multiple-choice questions for easy and robust evaluation. However, our dataset can also be used for generative evaluation, as will be demonstrated in our empirical study.

To establish baseline performances on COSMOS QA, we explore several state-of-the-art neural models developed for reading comprehension. Furthermore, we propose a new architecture variant that is better suited for commonsense-driven reading comprehension. Still, experimental results demonstrate a significant gap between machine (68.4% accuracy) and human performance (94.0%). We provide detailed analysis to provide insights into potentially promising research directions.

2 Dataset Design

2.1 Context Paragraphs

We gather a diverse collection of everyday situations from a corpus of personal narratives (Gordon and Swanson, 2009) from the Spinn3r Blog Dataset (Burton et al., 2009). Appendix A provides additional details on data pre-processing.

2.2 Question and Answer Collection

We use Amazon Mechanical Turk (AMT) to collect questions and answers. Specifically, for each paragraph, we ask a worker to craft at most two questions that are related to the context and require commonsense knowledge. We encourage the workers to craft questions from but not limited to the following four categories:

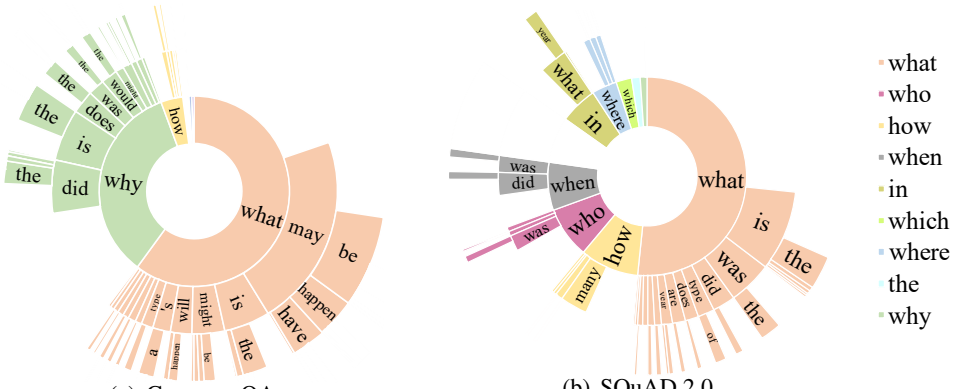
Causes of events: What may (or may not) be the plausible reason for an event?

Effects of events: What may (or may not) happen before (or after, or during) an event?

Facts about entities: What may (or may not) be a plausible fact about someone or something?

Counterfactuals: What may (or may not) happen if an event happens (or did not happen)?

These 4 categories of questions literally cover all 9 types of social commonsense of Sap et al. (2018). Moreover, the resulting commonsense also aligns with 19 ConceptNet relations, e.g., *Causes*, *HasPrerequisite* and *MotivatedByGoal*, covering about 67.8% of ConceptNet types. For each question, we also ask a worker to craft at most two correct answers and three incorrect answers. We paid workers $0.7 per paragraph, which is about $14.8 per hour. Appendix B provides additional details on AMT instructions.



2.3 Validation

We create multiple tasks to have humans verify the data. Given a paragraph, a question, a correct answer and three incorrect answers,[1] we ask AMT workers to determine the following sequence of questions: (1) whether the paragraph is inappropriate or nonsensical, (2) whether the question is

[1] If a question is crafted with two correct answers, we will create two question sets with each correct answer and the same three incorrect answers.

	Train	Dev	Test	All
# Questions (Paragraphs)	25,588 (13,715)	3,000 (2,460)	7,000 (5,711)	35,588 (21,866)
Ave./Max. # Tokens / Paragraph	69.4 / 152	72.6 / 150	73.1 / 149	70.3/ 152
Ave./Max. # Tokens / Question	10.3 / 34	11.2 / 28	11.2 / 29	10.6 / 34
Ave./Max. # Tokens / Correct Answer	8.0 / 40	9.7 / 41	9.7 / 36	8.5 / 41
Ave./Max. # Tokens / Incorrect Answer	7.6 / 40	9.1 / 38	9.1 / 36	8.0 / 40
Percentage of Unanswerable Questions	5.9%	8.7%	8.4%	6.7%

Table 1: Statistics of training, dev and test sets of COSMOS QA.

(a) COSMOS QA (b) SQuAD 2.0

Figure 2: Distribution of trigram prefixes of questions in COSMOS QA and SQuAD 2.0

nonsensical or not related to the paragraph, (3) whether they can determine the most plausible correct answer, (4) if they can determine the correct answer, whether the answer requires commonsense knowledge, and (5) if they can determine the correct answer, whether the answer can be determined without looking at the paragraph.

We follow the same criterion as in Section 2.2 and ask 3 workers to work on each question set. Workers are paid $0.1 per question. We consider as valid question set where at least two workers correctly picked the intended answer and all of the workers determined the paragraph/question/answers as satisfactory. Finally we obtain 33,219 valid question sets in total.

2.4 Unanswerable Question Creation

With human validation, we also obtain a set of questions for which workers can easily determine the correct answer without looking at the context or using commonsense knowledge. To take advantage of such questions and encourage AI systems to be more consistent with human understanding, we create unanswerable questions for COSMOS QA. Specifically, from validation outputs, we collect 2,369 questions for which at least two workers correctly picked the answer and at least on worker determined that it is answerable without looking at the context or requires no common sense. We replace the correct choice of these questions with a "None of the above" choice.

To create false negative training instances, we randomly sample 70% of questions from the 33,219 good question sets and replace their least challenging negative answer with "None of the above". Specifically, we fine-tune three BERT[2] next sentence prediction models on COSMOS: BERT($A|P,Q$), BERT($A|P$), BERT($A|Q$), where P, Q, A denotes the paragraph, question, and answer. BERT($A|\triangle$) denotes the possibility of an answer A being the next sentence of $\triangle$. The least challenging negative answer is determined by

$$A^{'} = \arg\min\Big(\sum_{\forall \triangle \subseteq \{P,Q\}} \text{BERT}(A|\triangle)\Big)$$

2.5 Train / Dev / Test Split

We finally obtain 35,588 question sets for our COSMOS dataset. To ensure that the development and test sets are of high quality, we identify a group of workers who excelled in the generation task for question and answers, and randomly sample 7K question sets authored by these excellent workers as test set, and 3K question sets as development set. The remaining questions are all used as training set. Table 1 shows dataset statistics.

[2]Through the whole paper, BERT refers to the pre-trained BERT large uncased model from https://github.com/huggingface/pytorch-pretrained-BERT

2.6 Data Analysis

Figure 2 compares frequent trigram prefixes in COSMOS and SQuAD 2.0 (Rajpurkar et al., 2018). Most of the frequent trigram prefixes in COSMOS, e.g., *why*, *what may happen*, *what will happen* are almost absent from SQuAD 2.0, which demonstrates the unique challenge our dataset contributes. We randomly sample 500 answerable questions to manually categorize according to their contextual commonsense reasoning types. Figure 3 shows representative examples. Table 2 shows the distribution of the question types.

- **Pre-/post-conditions:** causes/effects of an event.
- **Motivations:** intents or purposes.
- **Reactions:** possible reactions of people or objects to an event.
- **Temporal events:** what events might happen before or after the current event.
- **Situational facts:** facts that can be inferred from the description of a particular situation.
- **Counterfactuals:** what might happen given a counterfactual condition.
- **Other:** other types, e.g., cultural norms.

Type	Percentage (%)
MRC w/o commonsense	6.2
MRC w/ commonsense	93.8
Pre-/Post- Condition	27.2
Motivation	16.0
Reaction	13.2
Temporal Events	12.4
Situational Fact	23.8
Counterfactual	4.4
Other	12.6

Table 2: The distribution of contextual commonsense reasoning types in COSMOS.

3 Model

3.1 BERT with Multiway Attention

Multiway attention (Wang et al., 2018a; Zhu et al., 2018) has been shown to be effective in capturing the interactions between each pair of input paragraph, question and candidate answers, leading to better context interpretation, while BERT fine-tuning (Devlin et al., 2018) also shows its prominent ability in commonsense inference. To further enhance the context understanding ability of BERT fine-tuning, we perform multiway bidirectional attention over the BERT encoding output. Figure 4 shows the overview of the architecture.

Encoding with Pre-trained BERT Given a paragraph, a question, and a set of candidate answers, the goal is to select the most plausible correct answer from the candidates. We formulate the input paragraph as $P = \{p_0, p_1, ..., p_n\}$, the question as $Q = \{q_0, q_1, ..., q_k\}$ and a candidate answer as $A = \{a_0, a_1, ..., a_s\}$, where p_i, q_i and a_i is the i-th word of the paragraph, question and candidate answer respectively. Following (Devlin et al., 2018), given the input P, Q and A, we apply the same tokenizer and concatenate all tokens as a new sequence $\big[\text{[CLS]}, P, \text{[SEP]}, Q, \text{[SEP]}, A, \text{[SEP]}\big]$, where [CLS] is a special token used for classification and [SEP] is a delimiter. Each token is initialized with a vector by summing the corresponding token, segment and position embedding from pre-trained BERT, and then encoded into a hidden state. Finally we get $[\mathbf{H}_{cls}, \mathbf{H}_P, \mathbf{H}_Q, \mathbf{H}_A]$ as encoding output.

Multiway Attention To encourage better context interpretation, we perform multiway attention over BERT encoding output. Taking the paragraph P as an example, we compute three types of attention weights to capture its correlation to the question, the answer, and both the question and answer, and get question-attentive, answer-attentive, and question and answer-attentive paragraph representations

$$\tilde{\mathbf{H}}_P = \mathbf{H}_P \boldsymbol{W}_t + \boldsymbol{b}_t$$
$$\mathbf{M}_P^Q = \text{Softmax}(\tilde{\mathbf{H}}_P \mathbf{H}_Q^\top)\mathbf{H}_Q$$
$$\mathbf{M}_P^A = \text{Softmax}(\tilde{\mathbf{H}}_P \mathbf{H}_A^\top)\mathbf{H}_A$$
$$\mathbf{M}_P^{QA} = \text{Softmax}(\tilde{\mathbf{H}}_P \mathbf{H}_{QA}^\top)\mathbf{H}_{QA}$$

where $\boldsymbol{W}_t$ and $\boldsymbol{b}_t$ are learnable parameters. Next we fuse these representations with the original encoding output of P

$$\mathbf{F}_P^Q = \sigma([\mathbf{H}_P \mathbf{M}_P^Q : \mathbf{H}_P - \mathbf{M}_P^Q]\boldsymbol{W}_P + \boldsymbol{b}_P)$$
$$\mathbf{F}_P^A = \sigma([\mathbf{H}_P \mathbf{M}_P^A : \mathbf{H}_P - \mathbf{M}_P^A]\boldsymbol{W}_P + \boldsymbol{b}_P)$$
$$\mathbf{F}_P^{QA} = \sigma([\mathbf{H}_P \mathbf{M}_P^{QA} : \mathbf{H}_P - \mathbf{M}_P^{QA}]\boldsymbol{W}_P + \boldsymbol{b}_P)$$

where $[:]$ denotes concatenation operation. $\boldsymbol{W}_P$, $\boldsymbol{b}_P$ are learnable parameters for fusing paragraph representations. σ denotes ReLU function.

Finally, we apply column-wise max pooling on $[\mathbf{F}_P^Q : \mathbf{F}_P^A : \mathbf{F}_P^{QA}]$ and obtain the new paragraph representation $\mathbf{F}_P$. Similarly, we can also obtain a new representation $\mathbf{F}_Q$ and $\mathbf{F}_A$ for Q and A respectively. We use $\mathbf{F} = [\mathbf{F}_P : \mathbf{F}_Q : \mathbf{F}_A]$ as the

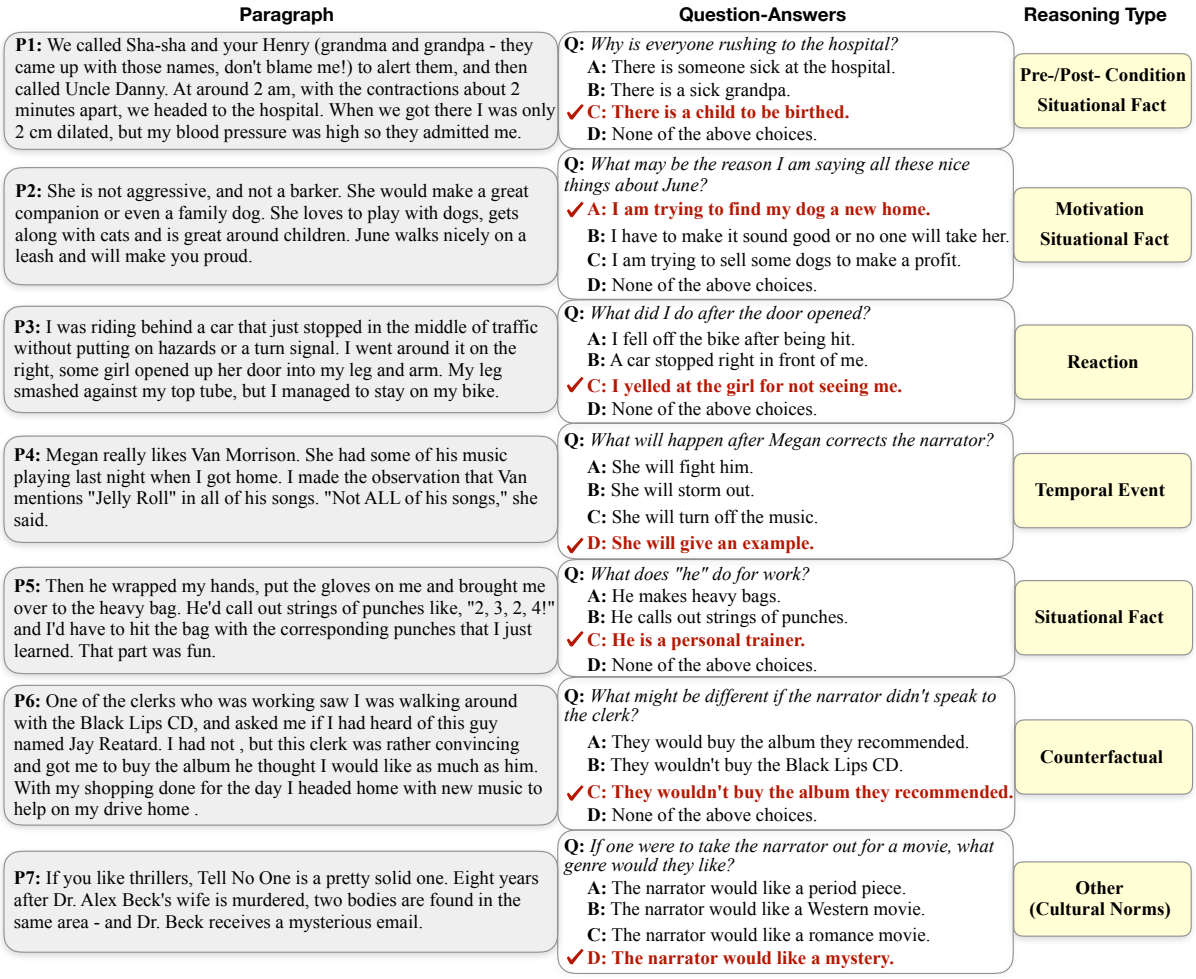


Figure 3: Examples of each type of commonsense reasoning in COSMOS QA. (✓ indicates the correct answer.)

overall vector representation for the set of paragraph, question and a particular candidate answer.

Classification For each candidate answer A_i, we compute the loss as follows:

$$L(A_i|P,Q) = -\log \frac{\exp(\boldsymbol{W}_f^\top \mathbf{F}_i)}{\sum_{j=1}^{4} \exp(\boldsymbol{W}_f^\top \mathbf{F}_j))}$$

4 Experiments

4.1 Baseline Methods

We explore two categories of baseline methods: reading comprehension approaches and pre-trained language model based approaches.

Sliding Window (Richardson et al., 2013) measures the similarity of each candidate answer with each window with m words of the paragraph.

Stanford Attentive Reader (Chen et al., 2016) performs a bilinear attention between the question and paragraph for answer prediction.

Gated-Attention Reader (Dhingra et al., 2017) performs multi-hop attention between the question and a recurrent neural network based paragraph encoding states.

Co-Matching (Wang et al., 2018b) captures the interactions between question and paragraph, as well as answer and paragraph with attention.

Commonsense-RC (Wang et al., 2018a) applies three-way unidirectional attention to model interactions between paragraph, question, and answers.

GPT-FT (Radford et al., 2018) is based on a generative pre-trained transformer language model, following a fine-tuning step on COSMOS QA.

BERT-FT (Devlin et al., 2018) is a pre-trained bidirectional transformer language model following a fine-tuning step on COSMOS QA.

DMCN (Zhang et al., 2019a) performs dual attention between paragraph and question/answer over BERT encoding output.

Human Performance To get human performance on COSMOS QA, we randomly sample 200 question sets from the test set, and ask 3 workers

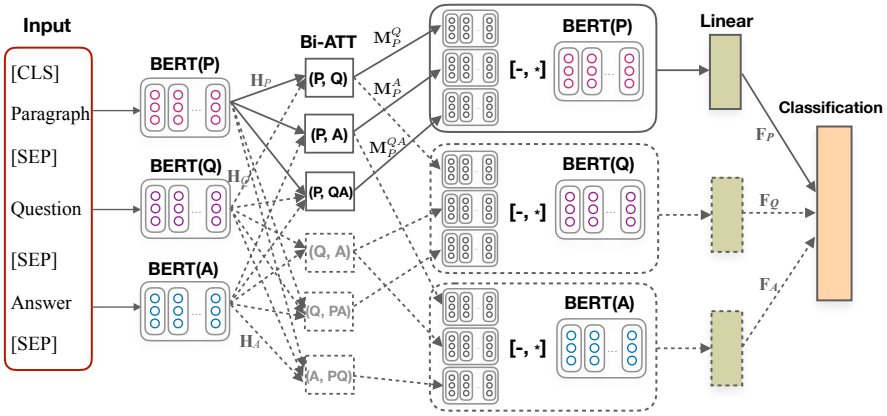

Figure 4: Architecture overview of BERT with multiway attention: Solid lines and blocks show the learning of multiway attentive context paragraph representation.

Model	Att(P, Q)	Att(P, A)	Att(Q, A)	Pre-training LM	Dev	Test
Sliding Window (Richardson et al., 2013)	✗	✗	✗	✗	25.0	24.9
Stanford Attentive Reader (Chen et al., 2016)	UD	✗	✗	✗	45.3	44.4

from AMT to select the most plausible correct answer. Each worker is paid $0.1 per question set. We finally combine the predictions for each question with majority vote.

4.2 Results and Analysis

Table 3 shows the characteristics and performance of varying approaches and human performance.[3]

Most of the reading comprehension approaches apply attention to capture the correlation between paragraph, question and each candidate answer and tend to select the answer which is the most semantically closed to the paragraph. For example, in Figure 5, the Commonsense-RC baseline mistakenly selected the choice which has the most overlapped words with the paragraph without any commonsense reasoning. However, our analysis shows that more than 83% of correct answers in COSMOS QA are not stated in the given paragraphs, thus simply comparing the semantic relatedness doesn't work well.

Pre-trained language models with fine-tuning achieve more than 20% improvement over reading comprehension approaches. By performing attention over BERT-FT, the performance is further improved, which demonstrates our assumption that incorporating interactive attentions can further enhance the context interpretation of BERT-FT. For example, in Figure 5, BERT-FT mistakenly selected choice A which can be possibly entailed by the paragraph. However, by performing multiway attention to further enhance the interactive comprehension of context, question and answer, our approach successfully selected the correct answer.

5 Discussion

5.1 Ablation Study

Model	Dev Acc (%)	Test Acc (%)
BERT-FT (A|P, Q)	66.2	67.1
BERT-FT (A|P)	63.5	64.5
BERT-FT (A|Q)	56.2	55.9
BERT-FT (A)	40.3	40.3

Table 4: Ablation of Paragraphs (P) or Questions (Q)

Many recent studies have suggested the importance of measuring the dataset bias by checking

[3] Appendix C shows the implementation details.

P: I cleaned the two large bottom cupboards and threw a ton of old stuff away. Dustin's parents like to drop off boxes of food like we're refugees or something. It's always appreciated, and some of it is edible. Most of what I threw away was from last year when Dustin's great-aunt was moving into her new apartment home (retirement center) and they cleaned out her pantry.

Q: *What is the most likely reason that I decided to clean the cupboards ?*

✗ **A:** I was getting tired of having food in the house.

✓ **B: We were getting more food and needed to create room.**

✗ **C:** Dustin and I split up and I need to get rid of his old stuff.

D: None of the above choices.

Figure 5: Prediction comparison between our approach (B) with Commonsense-RC (C) and BERT-FT (A).

the model performance based on partial information of the problem (Gururangan et al., 2018; Cai et al., 2017). Therefore, we report problem ablation study in Table 4 using BERT-FT as a simple but powerful straw man approach. Most notably, ablating questions does not cause significant performance drop. Further investigation indicates that this is because the high-level question types, e.g., *what happens next*, *what happened before*, are not diverse, so that it is often possible to make a reasonable guess on what the question may have been based on the context and the answer set. Ablating other components of the problems cause more significant drops in performance.

5.2 Knowledge Transfer Through Fine-tuning

Recent studies (Howard and Ruder, 2018; Min et al., 2017; Devlin et al., 2018) have shown the benefit of fine-tuning on similar tasks or datasets for knowledge transfer. Considering the unique challenge of COSMOS, we explore two related multiple-choice datasets for knowledge transfer: RACE (Lai et al., 2017), a large-scale reading comprehension dataset, and SWAG (Zellers et al., 2018), a large-scale commonsense inference dataset. Specifically, we first fine-tune BERT on RACE or SWAG or both, and directly test on COSMOS to show the impact of knowledge transfer. Furthermore, we sequentially fine-tune BERT on both RACE or SWAG and COSMOS. As Table 5 shows, with direct knowledge transfer, RACE provides significant benefit than SWAG since COSMOS requires more understanding of the interaction between paragraph, question and each candidate answer. With sequentially fine-tuning, SWAG provides better performance, which indicates that with fine-tuning on SWAG, BERT can obtain better commonsense inference ability, which is also beneficial to COSMOS.

Model	Dev Acc	Test Acc
BERT-FT$_{\text{SWAG}}$	28.9	28.5
BERT-FT$_{\text{RACE}}$	42.0	42.5
BERT-FT$_{\text{RACE+SWAG}}$	44.2	45.1
BERT-FT$_{\text{SWAG}\rightarrow\text{Cosmos}}$	67.8	68.9
BERT-FT$_{\text{RACE}\rightarrow\text{Cosmos}}$	67.4	68.2
BERT-FT$_{\text{RACE+SWAG}\rightarrow\text{Cosmos}}$	67.1	68.7

Table 5: Knowledge transfer through fine-tuning. (%)

P1: A woman had topped herself by jumping off the roof of the hospital she had just recently been admitted to. She was there because the first or perhaps latest suicide attempt was unsuccessful. She put her clothes on, folded the hospital gown and made the bed. She walked through the unit unimpeded and took the elevator to the top floor.

Q: *What would have happened to the woman if the staff at the hospital were doing their job properly?*

✓ **A: The woman would have been stopped before she left to take the elevator to the top floor and she would have lived.**

B: She would have been ushered to the elevator with some company.

✗ **C: She would have managed to get to the elevator quicker with some assistance.**

D: None of the above choices.

P2: Like me, she had no family or friends who could help with childcare. So like me, she found a daycare center that met her part-time needs. In sharp contrast to my job as a (gasp!) writer for the evil MSM, her nursing job was deemed by the other moms to be useful and worthwhile --in fact, worth putting her baby into daycare for "just a few hours, what harm could it do?"

Q: *What would happened if she could not find a daycare?*

✓ **A: She would try to find a babysitter.**

B: She would take the baby to work.

✗ **C: She would leave the baby alone at home.**

D: None of the above choices.

P3: My head hurts. I had so much fun at a chat with some scrap friends last Saturday night that I forgot to sleep. I ended up crawling into bed around 7AM.

Q: *What may have happened if she did n't chat to her scrap friends ?*

A: She would have done some scrap thing at home.

✓ **B: She would not have gotten up with a headache.**

✗ **C: She would have been lonely and stayed up all night.**

D: None of the above choices.

Figure 6: Examples errors of our approach. (✓ indicates correct answers and ✗ shows prediction errors.)

5.3 Error Analysis

We randomly select 100 errors made by our approach from the dev set, and identify 4 phenomena:

Complex Context Understanding: In 30% of the errors, the context requires complicated cross-sentence interpretation and reasoning. Taking P1 in Figure 6 as an example, to correctly predict the answer, we need to combine the context information that *the woman attempted to suicide before but failed*, *she made the bed since she determined to leave*, and *she took the elevator and headed to the roof*, and infer that *the woman was attempting to suicide again*.

Inconsistent with Human Common Sense: In

33% of the errors, the model mistakenly selected the choice which is not consistent with human common sense. For example, in P2 of Figure 6, both choice A and choice C could be potentially correct answers. However, from human common sense, *it's not safe to leave a baby alone at home*.

Multi-turn Commonsense Inference: 19% of the errors are due to multi-turn commonsense inference. For example, in P3 of Figure 6, the model needs to first determine the cause of *headache* is that *she chatted with friends and forgot to sleep* using common sense. Further, with counterfactual reasoning, if *she didn't chat to her friends*, then *she wouldn't have gotten up with a headache*.

Unanswerable Questions: 14% of the errors are from unanswerable questions. The model cannot handle "None of the above" properly since it cannot be directly entailed by the given paragraph or the question. Instead, the model needs to compare the potential of all the other candidate choices.

5.4 Generative Evaluation

In real world, humans are usually asked to perform contextual commonsense reasoning without being provided with any candidate answers. To test machine for human-level intelligence, we leverage a state-of-the-art natural language generator GPT2 (Radford et al., 2019) to automatically generate an answer by reading the given paragraph and question. Specifically, we fine-tune a pre-trained GPT2 language model on all the $[Paragraph, Question, Correct\ Answer]$ of COSMOS training set, then given each $[Paragraph, Question]$ from test set, we use GPT2-FT to generate a plausible answer. We automatically evaluate the generated answers against human authored correct answers with varying metrics in Table 6. We also create a AMT task to have 3 workers select all plausible answers among 4 automatically generated answers and a "None of the aboce" choice for 200 question sets. We consider an answer as correct only if all 3 workers determined it as correct. Figure 7 shows examples of automatically generated answers by pre-trained GPT2 and GPT2-FT as well as human authored correct answers. We observe that by fine-tuning on COSMOS, GPT2-FT generates more accurate answers. Although intuitively there may be multiple correct answers to the questions in COSMOS QA, our analysis shows that more than 84% of generated correct answers identified by human are semantically consistent with the gold answers in COSMOS, which demonstrates that COSMOS can also be used as a benchmark for generative commonsense reasoning. Appendix E shows more details and examples for generative evaluation.

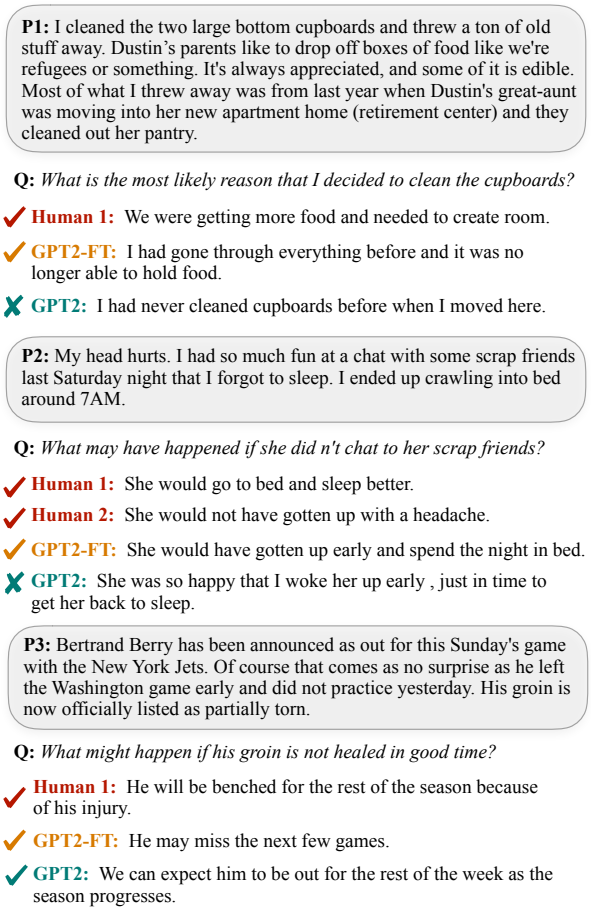

Figure 7: Examples of human authored correct answers, and automatically generated answers by pre-trained GPT2 and GPT2-FT. (✓indicates the answer is correct while ✗shows that the answer is incorrect.)

Metrics	GPT2	GPT2-FT
BLEU (Papineni et al., 2002)	10.7	21.0
METEOR (Banerjee and Lavie, 2005)	7.2	8.6
ROUGE-L (Lin, 2004)	13.9	22.1
CIDEr (Vedantam et al., 2015)	0.05	0.17

ARC	7.8K	QA	MC	N/A	Web	✗	-
CommonsenseQA	12.2K	QA	MC	N/A	MTurk/Web	✗	100%
ReCoRD	121K	PQA	Span	News	Automatic	✓	75.0%
COSMOS	31.8K	PQA	MC	Webblog	MTurk	✓	93.8%

Table 7: Comparison of the COSMOS QA to other multiple-choice machine reading comprehension datasets: P: contextual paragraph, Q: question, A: answers, MC: Multiple-choice, and - means unknown.

2016), NEWSQA (Trischler et al., 2017), SearchQA (Dunn et al., 2017), NarrativeQA (Kočiskỳ et al., 2018), ProPara (Mishra et al., 2018), CoQA (Reddy et al., 2018), ReCoRD (Zhang et al., 2018), MCTest (Richardson et al., 2013), RACE (Lai et al., 2017), CNN/Daily Mail (Hermann et al., 2015), Children's Book Test (Hill et al., 2015), and MCScript (Ostermann et al., 2018). Most these datasets focus on relatively explicit understanding of the context paragraph, thus a relatively small or unknown fraction of the dataset requires commonsense reasoning, if at all.

A notable exception is ReCoRD (Zhang et al., 2018) that is designed specifically for challenging reading comprehension with commonsense reasoning. COSMOS complements ReCoRD with three unique challenges: (1) our context is from webblogs rather than news, thus requiring commonsense reasoning for *everyday events* rather than *news-worthy events*. (2) All the answers of ReCoRD are contained in the paragraphs and are assumed to be entities. In contrast, in COSMOS, more than 83% of answers are *not* stated in the paragraphs, creating unique modeling challenges. (3) COSMOS can be used for *generative* evaluation in addition to multiple-choice evaluation.

There also have been other datasets focusing specifically on question answering with commonsense, such as CommonsenseQA (Talmor et al., 2018) and Social IQa (Sap et al., 2019), and various other types of commonsense inferences (Levesque et al., 2012; Rahman and Ng, 2012; Gordon, 2016; Rashkin et al., 2018; Roemmele et al., 2011; Mostafazadeh et al., 2017; Zellers et al., 2018). The unique contribution of COSMOS is combining reading comprehension with commonsense reasoning, requiring *contextual* commonsense reasoning over considerably more complex, diverse, and longer context. Table 7 shows comprehensive comparison among the most relevant datasets.

There have been a wide range of attention mechanisms developed for reading comprehension datasets (Hermann et al., 2015; Kadlec et al., 2016; Chen et al., 2016; Dhingra et al., 2017; Seo et al., 2016; Wang et al., 2018b). Our work investigates various state-of-the-art approaches to reading comprehension, and provide empirical insights into the design choices that are the most effective for contextual commonsense reasoning required for COSMOS.

7 Conclusion

We introduced COSMOS QA, a large-scale dataset for machine comprehension with contextual commonsense reasoning. We also presented extensive empirical results comparing various state-of-the-art neural architectures to reading comprehension, and demonstrated a new model variant that leads to the best result. The substantial headroom (25.6%) between the best model performance and human encourages future research on contextual commonsense reasoning.

Abstract

We propose a system that finds the strongest supporting evidence for a given answer to a question, using passage-based question-answering (QA) as a testbed. We train evidence agents to select the passage sentences that most convince a pretrained QA model of a given answer, if the QA model received those sentences instead of the full passage. Rather than finding evidence that convinces one model alone, we find that agents select evidence that generalizes; agent-chosen evidence increases the plausibility of the supported answer, as judged by other QA models and humans. Given its general nature, this approach improves QA in a robust manner: using agent-selected evidence (i) humans can correctly answer questions with only ∼20% of the full passage and (ii) QA models can generalize to longer passages and harder questions.

1 Introduction

There is great value in understanding the fundamental nature of a question (Chalmers, 2015). Distilling the core of an issue, however, is time-consuming. Finding the correct answer to a given question may require reading large volumes of text or understanding complex arguments. Here, we examine if we can automatically discover the underlying properties of problems such as question answering by examining how machine learning models learn to solve that task.

We examine this question in the context of passage-based question-answering (QA). Inspired by work in interpreting neural networks (Lei et al., 2016), we have agents find a subset of the passage (i.e., supporting evidence) that maximizes a QA model's probability of a particular answer. Each agent (one agent per answer) finds the sentences that a QA model regards as strong evidence for its answer, using either exhaustive search or learned prediction. Figure 1 shows an example.

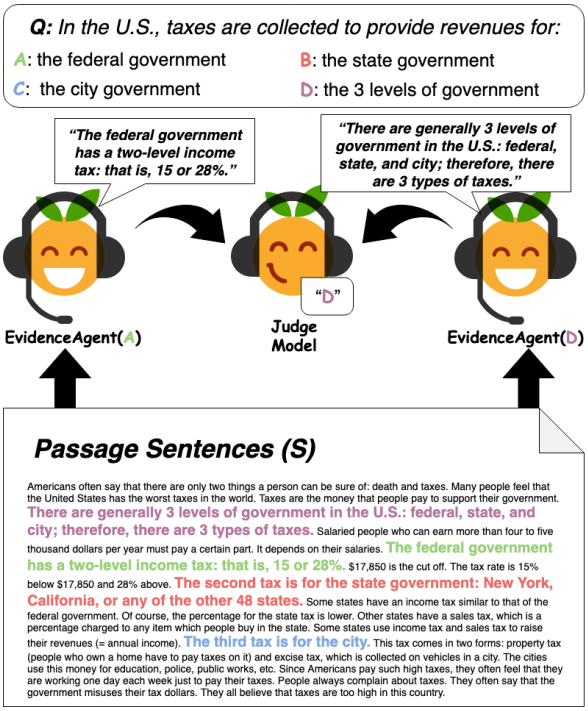

Figure 1: Evidence agents quote sentences from the passage to convince a question-answering judge model of an answer.

To examine to what extent evidence is general and independent of the model, we evaluate if humans and other models find selected evidence to be valid support for an answer too. We find that, when provided with evidence selected by a given agent, both humans and models favor that agent's answer over other answers. When human evaluators read an agent's selected evidence in lieu of the full passage, humans tend to select the agent-supported answer.

Given that this approach appears to capture some general, underlying properties of the problem, we examine if evidence agents can be used to assist human QA and to improve generalization of other QA models. We find that humans can accurately answer questions on QA benchmarks, based

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2402–2411, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

on evidence for each possible answer, using only 20% of the sentences in the full passage. We observe a similar trend with QA models: using only selected evidence, QA models trained on short passages can generalize more accurately to questions about longer passages, compared to when the models use the full passage. Furthermore, QA models trained on middle-school reading comprehension questions generalize better to high-school exam questions by answering only based on the most convincing evidence instead of the full passage. Overall, our results suggest that learning to select supporting evidence by having agents try to convince a judge model of their designated answer improves QA in a general and robust way.

2 Learning to Convince Q&A Models

Figure 1 shows an overview of the problem setup. We aim to find the passage sentences that provide the most convincing evidence for each answer option, with respect to a given QA model (the *judge*). To do so, we are given a sequence of passage sentences $S = [S(1), \ldots, S(m)]$, a question Q, and a sequence of answer options $A = [A(1), \ldots, A(n)]$. We train a judge model with parameters ϕ to predict the correct answer index i^* by maximizing $p_\phi(\text{answer} = i^* | S, Q, A)$.

Next, we assign each answer $A(i)$ to one evidence agent, $\textsc{Agent}(i)$. $\textsc{Agent}(i)$ aims to find evidence $E(i)$, a subsequence of passage sentences S that the judge finds to support $A(i)$. For ease of notation, we use set notation to describe $E(i)$ and S, though we emphasize these are ordered sequences. $\textsc{Agent}(i)$ aims to maximize the judge's probability on $A(i)$ when conditioned on $E(i)$ instead of S, i.e., $\text{argmax}_{E(i) \subseteq S} p_\phi(i | E(i), Q, A)$. We now describe three different settings of having agents select evidence, which we use in different experimental sections (§4-6).

Individual Sequential Decision-Making Since computing the optimal $E(i)$ directly is intractable, a single $\textsc{Agent}(i)$ can instead find a reasonable $E(i)$ by making T sequential, greedy choices about which sentence to add to $E(i)$. In this setting, the agent ignores the actions of the other agents. At time t, $\textsc{Agent}(i)$ chooses index $e_{i,t}$ of the sentence in S such that:

$$e_{i,t} = \underset{1 \le e' \le |S|}{\text{argmax}}\, p_\phi(i | \{S(e')\} \cup E(i, t-1), Q, A), \quad (1)$$

where $E(i,t)$ is the subsequence of sentences in S that $\textsc{Agent}(i)$ has chosen until time step t, i.e., $E(i,t) = \{S(e_{i,t})\} \cup E(i, t-1)$ with $E(i,0) = \varnothing$ and $E(i) = E(i,T)$. It is a no-op to add a sentence $S(e_{i,t})$ that is already in the selected evidence $E(i, t-1)$. The individual decision-making setting is useful for selecting evidence to support one particular answer.

Competing Agents: Free-for-All Alternatively, multiple evidence agents can compete at once to support unique answers, by each contributing part of the judge's total evidence. Agent competition is useful as agents collectively select a pool of question-relevant evidence that may serve as a summary to answer the question. Here, each of $\textsc{Agent}(1), \ldots, \textsc{Agent}(n)$ finds evidence that would convince the judge to select its respective answer, $A(1), \ldots, A(n)$. $\textsc{Agent}(i)$ chooses a sentence $S(e_{i,t})$ by conditioning on all agents' prior choices:

$$e_{i,t} = \underset{1 \le e' \le |S|}{\text{argmax}}\, p_\phi(i | \{S(e')\} \cup E(*, t-1), Q, A),$$

where $E(*, t-1) = \cup_{j=1}^{n} E(j, t-1)$.

Agents simultaneously select a sentence each, doing so sequentially for t time steps, to jointly compose the final pool of evidence. We allow an agent to select a sentence previously chosen by another agent, but we do not keep duplicates in the pool of evidence. Conditioning on other agents' choices is a form of interaction that may enable competing agents to produce a more informative total pool of evidence. More informative evidence may enable a judge to answer questions more accurately without the full passage.

Competing Agents: Round Robin Lastly, agents can compete round robin style, in which case we aggregate the outcomes of all $\binom{n}{2}$ pairs of answers $\{A(i), A(j)\}$ competing. Any given $\textsc{Agent}(i)$ participates in $n-1$ rounds, each time contributing half of the sentences given to the judge. In each one-on-one round, two agents select a sentence each at once. They do so iteratively multiple times, as in the free-for-all setup. To aggregate pairwise outcomes and compute an answer i's probability, we average its probability over all rounds involving $\textsc{Agent}(i)$:

$$\frac{1}{n-1} \sum_{j=1}^{n} \mathbb{1}(i \neq j) * p_\phi(i | E(i) \cup E(j), Q, A)$$

2.1 Judge Models

The judge model is trained on QA, and it is the model that the evidence agents need to convince. We aim to select diverse model classes, in order to: (i) test the generality of the evidence produced by learning to convince different models; and (ii) to have a broad suite of models to evaluate the agent-chosen evidence. Each model class assigns every answer $A(i)$ a score, where the predicted answer is the one with the highest score. We use this score $L(i)$ as a softmax logit to produce answer probabilities. Each model class computes $L(i)$ in a different manner. In what follows, we describe the various judge models we examine.

TFIDF We define a function $\text{BoW}_{\text{TFIDF}}$ that embeds text into its corresponding TFIDF-weighted bag-of-words vector. We compute the cosine similarity of the embeddings for two texts $\mathbf{X}$ and $\mathbf{Y}$:

$$\text{TFIDF}(\mathbf{X}, \mathbf{Y}) = \cos(\text{BoW}_{\text{TFIDF}}(\mathbf{X}), \text{BoW}_{\text{TFIDF}}(\mathbf{Y}))$$

We define two model classes that select the answer most similar to the input passage sentences: $L(i) = \text{TFIDF}(S, [Q; A(i)])$, and $L(i) = \text{TFIDF}(S, A(i))$.

fastText We define a function BoW_{FT} that computes the average bag-of-words representation of some text using *fastText* embeddings (Joulin et al., 2017). We use 300-dimensional *fastText* word vectors pretrained on Common Crawl. We compute the cosine similarity between the embeddings for two texts $\mathbf{X}$ and $\mathbf{Y}$ using:

$$\text{fastText}(\mathbf{X}, \mathbf{Y}) = \cos(\text{BoW}_{\text{FT}}(\mathbf{X}), \text{BoW}_{\text{FT}}(\mathbf{Y}))$$

This method has proven to be a strong baseline for evaluating the similarity between two texts (Perone et al., 2018). Using this function, we define a model class that selects the answer most similar to the input passage context: $L(i) = \text{fastText}(S, A(i))$.

BERT $L(i)$ is computed using the multiple-choice adaptation of BERT (Devlin et al., 2019; Radford et al., 2018; Si, 2019), a pre-trained transformer network (Vaswani et al., 2017). We fine-tune all BERT parameters during training. This model predicts $L(i)$ using a trainable vector v and BERT's first token embedding: $L(i) = v^\top \cdot \text{BERT}([S; Q; A(i)])$.

We experiment with both the $\text{BERT}_{\text{BASE}}$ model (12 layers) and $\text{BERT}_{\text{LARGE}}$ (24 layers). For training details, see Appendix B.

Predicting	**Loss**	**Target**
Search	*CE*	$S(e_{i,t})$

$\Delta p(i)$	*MSE*	$p_\phi(i \vert \{S(e')\} \cup E(i,t), Q, A)$ $-p_\phi(i \vert E(i,t), Q, A)$

Table 1: The loss functions and prediction targets for three learned agents. *CE*: cross entropy. *MSE*: mean squared error. e' takes on integer values from 1 to $|S|$.

2.2 Evidence Agents

In this section, we describe the specific models we use as evidence agents. The agents select sentences according to Equation 1, either exactly or via function approximation.

Search agent $\text{AGENT}(i)$ at time t chooses the sentence $S(e_{i,t})$ that maximizes $p_\phi(i|S(i,t), Q, A)$, after exhaustively trying each possible $S(e_{i,t}) \in S$. Search agents that query TFIDF or fastText models maximize TFIDF or fastText scores directly (i.e., $L(i)$, rather than $p_\phi(i|S(i,t), Q, A)$).

Learned agent We train a model to predict how a sentence would influence the judge's answer, instead of directly evaluating answer probabilities at test time. This approach may be less prone to selecting sentences that exploit hard-to-predict quirks in the judge; humans may be less likely to find such sentences to be valid evidence for an answer (discussed in §4.1). We define several loss functions and prediction targets, shown in Table 1. Each forward pass, agents predict one scalar per passage sentence via end-of-sentence token positions. We optimize these predictions using Adam (Kingma and Ba, 2015) on one loss from Table 1. For $t > 1$, we find it effective to simply predict the judge model at $t = 1$ and use this distribution for all time steps during inference. This trick speeds up training by enabling us to precompute prediction targets using the judge model, instead of querying it constantly during training.

We use $\text{BERT}_{\text{BASE}}$ for all learned agents. Learned agents predict the $\text{BERT}_{\text{BASE}}$ judge, as it is more efficient to compute than $\text{BERT}_{\text{LARGE}}$. Each agent $\text{AGENT}(i)$ is assigned the answer $A(i)$ that it should support. We train one learned agent to find evidence for an arbitrary answer i. We condition $\text{AGENT}(i)$ on i using a binary indicator when predicting $L(i)$. We add the indicator to BERT's first token segment indicator and embed it

into vectors γ and β; for each timestep's features f from BERT, we scale and shift f element-wise: $(\gamma * f) + \beta$ (Perez et al., 2018; Dumoulin et al., 2018). See Appendix B for training details.

Notably, learning to convince a judge model does not require answer labels to a question. Even if the judge only learns from a few labeled examples, evidence agents can learn to model the judge's behavior on more data and out-of-distribution data without labels.

3 Experimental Setup

3.1 Evaluating Evidence Agents

Evaluation Desiderata An ideal evidence agent should be able to find evidence for its answer w.r.t. a judge, regardless (to some extent) of the specific answer it defends. To appropriately evaluate evidence agents, we need to use questions with more than one defensible, passage-supported answer per question. In this way, an agent's performance will not depend disproportionately on the answer it is to defend, rather than its ability to find evidence.

Multiple-choice QA: RACE and DREAM For our experiments, we use RACE (Lai et al., 2017) and DREAM (Sun et al., 2019), two multiple-choice, passage-based QA datasets. Both consist of reading comprehension exams for Chinese students learning English; teachers explicitly designed answer options to be plausible (even if incorrect), in order to test language understanding. Each question has 4 total answer options in RACE and 3 in DREAM. Exactly one option is correct. DREAM consists of 10K informal, dialogue-based passages. RACE consists of 100K formal, written passages (i.e., news, fiction, or well-written articles). RACE also divides into easier, middle school questions (29%) and harder, high school questions (71%).

Other datasets we considered Multiple-choice passage-based QA tasks are well-suited for our purposes. Multiple-choice QA allows agents to support clear, dataset-curated possible answers. In contrast, Sugawara et al. (2018) show that 5-20% of questions in extractive, span-based QA datasets have only one valid candidate option. For example, some "when" questions are about passages with only one date. Sugawara et al. argue that multiple-choice datasets such as RACE do not have this issue, as answer candidates are manually created. In preliminary experiments on SQuAD (Rajpurkar et al., 2016), we found that agents could only learn to convince the judge model when supporting the correct answer (one answer per question).

Judge Model	RACE	DREAM
Random	25.0	33.3
TFIDF$(S, [Q; A])$	32.6	44.4
TFIDF(S, A)	31.6	44.5
fastText(S, A)	30.4	38.4
$\text{BERT}_{\text{BASE}}$	65.4	61.0
$\text{BERT}_{\text{LARGE}}$	69.4	64.9
Human Adult*	94.5	98.6

Table 2: RACE and DREAM test accuracy of various judge models using the full passage. Our agents use these models to find evidence. The models cover a spectrum of QA ability. (*) reports ceiling accuracy from original dataset papers.

3.2 Training and Evaluating Models

Our setup is not directly comparable to standard QA setups, as we aim to evaluate evidence rather than raw QA accuracy. However, each judge model's accuracy is useful to know for analysis purposes. Table 2 shows model accuracies, which cover a broad range. BERT models significantly outperform word-based baselines (TFIDF and fastText), and $\text{BERT}_{\text{LARGE}}$ achieves the best overall accuracy. No model achieves the estimated human ceiling for either RACE (Lai et al., 2017) or DREAM (Sun et al., 2019).

Our code is available at `https://github.com/ethanjperez/convince`. We build off AllenNLP (Gardner et al., 2018) using PyTorch (Paszke et al., 2017). For all human evaluations, we use Amazon Mechanical Turk via ParlAI (Miller et al., 2017). Appendix B describes preprocessing and training details.

4 Agents Select General Evidence

4.1 Human Evaluation of Evidence

Would evidence that convinces a model also be valid evidence to humans? On one hand, there is ample work suggesting that neural networks can learn similar patterns as humans do. Convolutional networks trained on ImageNet share similarities with the human visual cortex (Cadieu et al., 2014). In machine translation, attention learns to align foreign words with their native counterparts (Bahdanau et al., 2015). On the other hand, neural networks often do not behave as humans

	Evidence Sentence Selection Method	*How Often Human Selects Agent's Answer (%)*					
		RACE			***DREAM***		
			Agent Answer is			*Agent Answer is*	
		Overall	Right	Wrong	Overall	Right	Wrong
Baselines	No Sentence Given	25.0	52.5	15.8	33.3	43.3	28.4
	Human Selection	41.6	75.1	30.4	50.7	84.9	33.5
Search Agents querying...	TFIDF$(S, [Q; A(i)])$	33.5	69.6	21.5	41.7	68.8	28.1
	fastText$(S, A(i))$	37.1	74.2	24.7	41.5	75.6	24.5
	TFIDF$(S, A(i))$	38.0	71.4	26.9	43.4	75.2	27.6
	$\text{BERT}_{\text{BASE}}$	38.4	68.4	28.4	50.5	82.5	34.6
	$\text{BERT}_{\text{LARGE}}$	40.1	71.0	29.9	52.3	79.4	38.7
Learned Agents predicting...	Search	40.0	71.0	29.7	49.1	78.3	34.6
	$p(i)$	42.0	74.6	31.1	50.0	77.3	36.3
	$\Delta p(i)$	41.1	73.2	30.4	48.2	76.5	34.0

Table 3: *Human evaluation*: **Search Agents** select evidence by querying the specified judge model, and **Learned Agents** predict the strongest evidence w.r.t. a judge model ($\text{BERT}_{\text{BASE}}$); humans then answer the question using the selected evidence sentence (without the full passage). Most agents do on average find evidence for their answer, right or wrong. Agents are more effective at supporting right answers.

do. Neural networks are susceptible to adversarial examples—changes to the input which do or do not change the network's prediction in surprising ways (Szegedy et al., 2014; Jia and Liang, 2017; Ribeiro et al., 2018; Alzantot et al., 2018). Convolutional networks rely heavily on texture (Geirhos et al., 2019), while humans rely on shape (Landau et al., 1988). Neural networks trained to recognize textual entailment can rely heavily on dataset biases (Gururangan et al., 2018).

Human evaluation setup We use human evaluation to assess how effectively agents select sentences that also make humans more likely to provide a given answer, when humans act as the judge. Humans answer based only on the question Q, answer options A, and a single passage sentence chosen by the agent as evidence for its answer option $A(i)$ (i.e., using the "Individual Sequential Decision-Making" scheme from §2). Appendix C shows the interface and instructions used to collect evaluations. For each of RACE and DREAM, we use 100 test questions and collect 5 human answers for each $(Q, A(i))$ pair for each agent. We also evaluate a human baseline for this task, where 3 annotators select the strongest supporting passage sentence for each $(Q, A(i))$ pair. We report the average results across 3 annotators.

Humans favor answers supported by evidence agents when shown that agent's selected evidence, as shown in Table 3.[1] Without receiving any passage sentences, humans are at random chance at selecting the agent's answer (25% on RACE, 33% on DREAM), since agents are assigned an arbitrary answer. For all evidence agents, humans favor agent-supported answers more often than the baseline (33.5-42.0% on RACE and 41.7-50.5% on DREAM). For our best agents, the relative margin over the baseline is substantial. In fact, these agents select evidence that is comparable to human-selected evidence. For example, on RACE, humans select the target answer 41.6% when provided with human-selected evidence, compared to 42% evidence selected by the learned agent that predicts $p(i)$.

All agents support right answers more easily than wrong answers. On RACE, the learned agent that predicts $p(i)$ finds strong evidence more than twice as often for correct answers than for incorrect ones (74.6% vs. 31.1%). On RACE and DREAM both, BERT-based agents (search or learned agents) find stronger evidence than word-based agents do. Humans tend to find that BERT-based agents select valid evidence for an answer, right or wrong. On DREAM, word-based agents generally fail to find evidence for wrong answers compared to the no-sentence baseline (28.4% vs. 24.5% for a search-based fastText agent).

On RACE, learned agents that predict the $\text{BERT}_{\text{BASE}}$ judge outperform search agents that directly query the $\text{BERT}_{\text{BASE}}$ judge. This effect may occur if search agents find an adversarial sentence that unduly affects the judge's answer but that humans do not find to be valid evidence. Appendix A shows one such example. Learned agents may

[1] Appendix D shows results by question type.

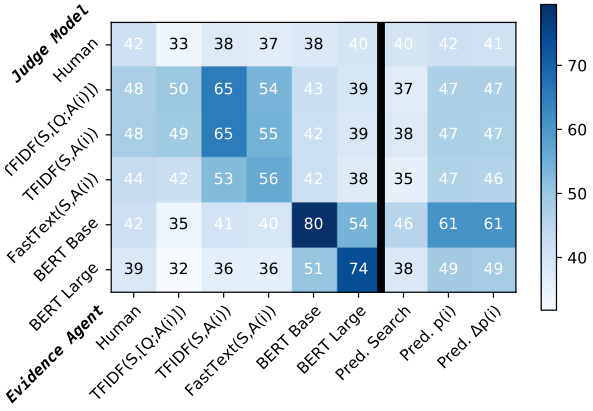

Figure 2: On RACE, how often each judge selects an agent's answer when given a single agent-chosen sentence. The black line divides learned agents (right) and search agents (left), with human evidence selection in the leftmost column. All agents find evidence that convinces judge models more often than a no-evidence baseline (25%). Learned agents predicting $p(i)$ or $\Delta p(i)$ find the most broadly convincing evidence.

have difficulty predicting such sentences, without directly querying the judge. Appendix E provides some analysis on why learned agents may find more general evidence than search agents do. Learned agents are most accurate at predicting evidence sentences when the sentences have a large impact on the judge model's confidence in the target answer, and such sentences in turn are more likely to be found as strong evidence by humans. On DREAM, search agents and learned agents perform similarly, likely because DREAM has 14x less training data than RACE.

4.2 Model Evaluation of Evidence

Evaluating an agent's evidence across models Beyond human evaluation, we test how general agent-selected evidence is, by testing this evidence against various judge models. We expect evidence agents to most frequently convince the model they are optimized to convince, by nature of their direct training or search objective. The more similar models are, the more we expect evidence from one model to be evidence to another. To some extent, we expect different models to rely on similar patterns to answer questions. Thus, evidence agents should sometimes select evidence that transfers to any model. However, we would not expect agent evidence to transfer to other models if models only exploit method-specific patterns.

Experimental setup Each agent selects one evidence sentence for each $(Q, A(i))$ pair. We test how often the judge selects an agent's answer, when given this sentence, Q, and A. We evaluate on all $(Q, A(i))$ pairs in RACE's test set. Human evaluations are on a 100 question subset of test.

Results Figure 2 plots how often each judge selects an agent's answer. Without any evidence, judge models are at random at choosing an agent's assigned answer (25%). All agents find evidence that convinces judge models more often than the no-evidence baseline. Learned agents that predict $p(i)$ or $\Delta p(i)$ find the evidence most broadly considered convincing; other judge models select these agents' supported answers over 46% of the time. These findings support that evidence agents find general structure despite aiming to convince specific methods with their distinct properties.

Notably, evidence agents are not uniformly convincing across judge models. All evidence agents are most convincing to the judge model they aim to convince; across any given agent's row, an agent's target judge model is the model which most frequently selects the agent's answer. Search agents are particularly effective at finding convincing evidence w.r.t. their target judge model, given that they directly query this model. More broadly, similar models find similar evidence convincing. We find similar results for DREAM (Appendix F).

5 Evidence Agents Aid Generalization

We have shown that agents capture method-agnostic evidence representative of answering a question (the strongest evidence for various answers). We hypothesize that QA models can generalize better out of distribution to more challenging questions by exploiting evidence agents' capability to understand the problem.

Throughout this section, using various train/test splits of RACE, we train a $\text{BERT}_{\text{BASE}}$ judge on easier examples (involving shorter passages or middle-school exams) and test its generalization to harder examples (involving longer passages or high-school exams). Judge training follows §2.1. We compare QA accuracy when the judge answers using (i) the full passage and (ii) only evidence sentences chosen by competing evidence agents. We report results using the round robin competing agent setup described in §2, as it resulted in higher generalization accuracy than free-for-all competition in preliminary experiments. Each competing agent selects sentences up to a fixed, maximum turn limit; we experiment with 3-6 turns per agent (6-12 total sentences for the judge), and we report the best result. We train learned agents (as de-

Train Data	Sentence Selection	*RACE* Sentences in Passage ≤ 12	*RACE* Sentences in Passage ≥ 27	*→DREAM* Sentences in Passage ≥ 27
All	Full Passage	64.7	60.0	71.2
RACE $\lvert S\rvert \leq 12$	None (Answer-only)	36.1	40.2	38.5
	Full Passage of Subset	57.4	44.1	65.0
	Random Sentences	49.2	44.7	48.2
	TFIDF$(S, [Q; A(i)])$	57.2	48.0	67.3
	fastText$(S, A(i))$	**57.7**	**50.2**	64.2
	TFIDF$(S, A(i))$	57.1	47.9	64.6
	Search over $\text{BERT}_{\text{BASE}}$	56.7	49.6	**68.9**
	Predict $\text{BERT}_{\text{BASE}}$ $p(i)$	56.7	50.0	66.9

Table 4: We train a judge on short RACE passages and test its generalization to long passages. The judge is more accurate on long passages when it answers based on only sentences chosen by competing agents (last 5 rows) instead of the full passage. BERT-based agents aid generalization even under test-time domain shift (from RACE to DREAM).

scribed in §2.2) on the full RACE dataset without labels, so these agents can model the judge using more data and on out-of-distribution data.

For reference, we evaluate judge accuracy on a subsequence of randomly sampled sentences; we vary the number of sentences sampled from 6-12 and report the best result. As a lower bound, we train an answer-only model to evaluate how effectively the QA model is using the passage sentences it is given. As an upper bound, we evaluate our $\text{BERT}_{\text{BASE}}$ judge trained on all of RACE, requiring no out-of-distribution generalization.

5.1 Generalizing to Longer Passages

We train a judge on RACE passages averaging 10 sentences long (all training passages each with $\leq$12 sentences); this data is roughly $\frac{1}{10}$th of RACE. We test the judge on RACE passages averaging 30 sentences long.

Results Table 4 shows the results. Using the full passage, the judge outperforms an answer-only BERT baseline by 4% (44.1% vs. 40.2%). When answering using the smaller set of agent-chosen sentences, the judge outperforms the baseline by 10% (50.2% vs. 40.2%), more than doubling its relative use of the passage. Both search and learned agents aid the judge model in generalizing to longer passages. The improved generalization is not simply a result of the judge using a shorter passage, as shown by the random sentence selection baseline (44.7%).

Train Data	Sentence Selection	*School Level* Middle	*School Level* High
All	Full Passage	70.8	63.2
Middle School only	None (Answer-only)	38.9	40.2
	Full Passage of Subset	66.2	50.7
	Random Sentences	54.8	47.0
	TFIDF$(S, [Q; A(i)])$	65.1	50.4
	fastText$(S, A(i))$	64.6	50.8
	TFIDF$(S, A(i))$	64.9	51.0
	Search over $\text{BERT}_{\text{BASE}}$	67.0	**53.0**
	Predict $\text{BERT}_{\text{BASE}}$ $p(i)$	**67.3**	51.9

Table 5: *Generalizing to harder questions*: We train a judge to answer questions with RACE's Middle School exam questions only. We test its generalization to High School exam questions. The judge is more accurate when using evidence agent sentences (last 5 rows) rather than the full passage.

5.2 Generalizing Across Domains

We examine if evidence agents aid generalization even in the face of domain shift. We test the judge trained on short RACE passages on long passages from *DREAM*. We use the same evidence agents from the previous subsection; the learned agent is trained on RACE only, and we do not fine-tune it on DREAM to test its generalization to finding evidence in a new domain. DREAM passages consist entirely of dialogues, use more informal language and shorter sentences, and emphasize general world knowledge and commonsense reasoning (Sun et al., 2019). RACE passages are more formal, written articles (e.g. news or fiction).

Results Table 4 shows that BERT-based evidence agents aid generalization even under domain shift. The model shows notable improvements for RACE → DREAM transfer when it predicts from BERT-based agent evidence rather than the full passage (65.0% vs. 68.9%). These results support that our best evidence agents capture something fundamental to the problem of QA, despite changes in e.g. content and writing style.

5.3 Generalizing to Harder Questions

Using RACE, we train a judge on middle-school questions and test it on high-school questions.

Results Table 5 shows that the judge generalizes to harder questions better by using evidence from either search-based BERT agents (53.0%) or learned BERT agents (51.9%) compared to using the full passage directly (50.7%) or to search-based TFIDF and fastText agents (50.4%-51.0%). Figure 3 shows that the improved generalization comes from questions the model originally gener-

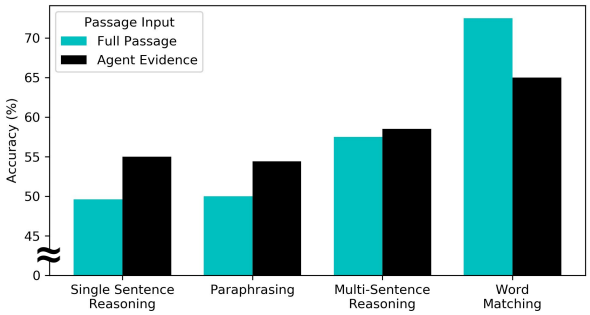

Figure 3: *Generalizing to harder questions by question type*: We train a judge on RACE Middle School questions and test its generalization to RACE High School questions. To predict the answer, the judge uses either the full passage or evidence sentences chosen by a BERT-based search agent. The worse the judge does on a question category using the full passage, the better it does when using the agent-chosen sentences.

alizes worse on. Simplifying the passage by providing key sentences may aid generalization by e.g. removing extraneous or distracting sentences from passages with more uncommon words or complex sentence structure. Such improvements come at the cost of accuracy on easier, word-matching questions, where it may be simpler to answer with the full passage as seen in training.

6 Evidence Agents Aid Human QA

As observed in §4.1, evidence agents more easily support right answers than wrong ones. Furthermore, evidence agents do aid QA models in generalizing systematically when all answer evidence sentences are presented at once. We hypothesize that when we combine all evidence sentences, humans prefer to choose the correct answer.

Human evaluation setup Evidence agents compete in a free-for-all setup (§2), and the human acts as the judge. We evaluate how accurately humans can answer questions based only on agent sentences. Appendix C shows the annotation interface and instructions. We collect 5 human answers for each of the 100 test questions.

Humans can answer using evidence sentences alone Shown in Table 6, humans correctly answer questions using many fewer sentences (3.3 vs. 18.2 on RACE, 2.4 vs. 12.2 on DREAM); they do so while maintaining 90% of human QA accuracy on the full passage (73.2% vs. 82.3% on RACE, 83.8% vs. 93.0% on DREAM). Evidence agents, however, vary in how effectively they aid human QA, compared to answer-agnostic evidence selection. On DREAM, humans answer with 79.1% accuracy using the sentences

Sentences Shown		***Human Acc. (%)***	
Selection Type	Selection Method	**RACE**	**DREAM**
Full Passage	Full Passage	82.3	93.0
No Passage	Answer-only	52.5	43.3
Subset (~20%)	Human Selection	**73.5**	82.3
Answer-Free	First n Sentences	61.8	68.5
Selection	TFIDF(S, Q)	69.2	77.5
	fastText(S, Q)	69.7	79.1
Search Agent	TFIDF$(S, [Q; A(i)])$	66.1	70.0
Selection	TFIDF$(S, A(i))$	73.2	77.0
	fastText$(S, A(i))$	73.2	77.3
	$\text{BERT}_{\text{BASE}}$	69.9	**83.8**
	$\text{BERT}_{\text{LARGE}}$	72.4	75.0
Learned Agent	Predicting Search	66.5	80.0
Selection	Predicting $p(i)$	71.6	77.8
	Predicting $\Delta p(i)$	65.7	81.5

Table 6: *Human accuracy using evidence agent sentences*: Each agent selects a sentence supporting its own answer. Humans answer the question given these agent-selected passage sentences only. Humans still answer most questions correctly, while reading many fewer passage sentences.

most similar to the question alone (via fastText), while achieving lower accuracy when using the $\text{BERT}_{\text{LARGE}}$ search agent's evidence (75.0%) and higher accuracy when using the $\text{BERT}_{\text{BASE}}$ search agent's evidence (83.8%). We explain the discrepancy by examining how effective agents are at supporting right vs. wrong answers (Table 3 from §4.1); $\text{BERT}_{\text{BASE}}$ is more effective than $\text{BERT}_{\text{LARGE}}$ at finding evidence for right answers (82.5% vs. 79.4%) and less effective at finding evidence for wrong answers (34.6% vs. 38.7%).

7 Related Work

Here, we discuss further related work, beyond that discussed in §4.1 on (dis)similarities between patterns learned by humans and neural networks.

Evidence Extraction Various papers have explored the related problem of extracting evidence or summaries to aid downstream QA. Wang et al. (2018a) concurrently introduced a neural model that extracts evidence specifically for the correct answer, as an intermediate step in a QA pipeline. Prior work uses similar methods to explain what a specific model has learned (Lei et al., 2016; Li et al., 2016; Yu et al., 2019). Others extract evidence to improve downstream QA efficiency over large amounts of text (Choi et al., 2017; Kratzwald and Feuerriegel, 2019; Wang et al., 2018b). More broadly, extracting evidence can facilitate fact verification (Thorne et al., 2018) and debate.[2]

[2]IBM Project Debater: www.research.ibm.com/artificial-intelligence/project-debater

Generic Summarization In contrast, various papers focus primarily on summarization rather than QA, using downstream QA accuracy only as a reward to optimize generic (question-agnostic) summarization models (Arumae and Liu, 2018, 2019; Eyal et al., 2019).

Debate Evidence extraction can be viewed as a form of debate, in which multiple agents support different stances (Irving et al., 2018; Irving and Askell, 2019). Chen et al. (2018) show that evidence-based debate improves the accuracy of crowdsourced labels, similar to our work which shows its utility in natural language QA.

8 Conclusion

We examined if it was possible to automatically distill general insights for passage-based question answering, by training evidence agents to convince a judge model of any given answer. Humans correctly answer questions while reading only 20% of the sentences in the full passage, showing the potential of our approach for assisting humans in question answering tasks. We examine how selected evidence affects the answers of humans as well as other QA models, and we find that agent-selected evidence is generalizable. We exploit these capabilities by employing evidence agents to facilitate QA models in generalizing to longer passages and out-of-distribution test sets of qualitatively harder questions.

Abstract

Open-domain question answering (OpenQA) aims to answer questions based on a number of unlabeled paragraphs. Existing approaches always follow the distantly supervised setup where some of the paragraphs are wrong-labeled (noisy), and mainly utilize the paragraph-question relevance to denoise. However, the paragraph-paragraph relevance, which may aggregate the evidence among relevant paragraphs, can also be utilized to discover more useful paragraphs. Moreover, current approaches mainly focus on the positive paragraphs which are known to contain the answer during training. This will affect the generalization ability of the model and make it be disturbed by the similar but irrelevant (distracting) paragraphs during testing. In this paper, we first introduce a ranking model leveraging the paragraph-question and the paragraph-paragraph relevance to compute a confidence score for each paragraph. Furthermore, based on the scores, we design a modified weighted sampling strategy for training to mitigate the influence of the noisy and distracting paragraphs. Experiments on three public datasets (Quasar-T, SearchQA and TriviaQA) show that our model advances the state of the art.

1 Introduction

Different from the traditional reading comprehension (RC) task, which aims to answer a question based on an off-the-peg paragraph, the reading paragraphs on OpenQA datasets are always collected via an information retrieval (IR) system. For example, given a question as shown in Figure 1, an OpenQA system usually coarsely retrieves paragraphs that are similar to the question. Therefore, the OpenQA model has to answer a question based on numerous paragraphs. As can be seen in Figure 1, some of the negative paragraphs are similar to the question whereas the answer string is missed, e.g. Paragraph4. We consider these paragraphs as distracting ones. Besides, in the distantly supervised setup (Mintz et al., 2009), it is postulated that the paragraphs that contain the answer string are ground truths, while even some of the positive paragraphs are wrong-labeled as they do not concern the question, e.g. Paragraph3. We consider these paragraphs as noisy ones. As a result, only Paragraph1 and Paragraph2 provide relevant answer to the question and the distracting and noisy paragraphs will prevent the model from identifying the correct answer.

Question: Who is Donald Duck's uncle ?
Answer: Scrooge
Paragraph1 (positive, relevant): Donald's maternal uncle Scrooge McDuck made his first appearance ...
Paragraph2 (positive, relevant): This story was reissued as a single record entitled "Donald Duck and Uncle Scrooge's Money Rocket" ...
Paragraph3 (positive, noisy): In Scrooge's stories, Donald Duck was cast as Scrooge's assistant ...
Paragraph4 (negative, distracting): Donald Duck is the uncle of Huey, Dewey, and Louie.

Figure 1: An example of OpenQA. The key information, answers in correct-labeled and wrong-labeled contexts are marked in blue, green and red respectively.

Recent OpenQA approaches always follow the retrieve-then-read pipeline and can be roughly divided into two categories: single-paragraph approaches (Joshi et al., 2017; Wang et al., 2018a) and multi-paragraph approaches (Chen et al., 2017; Clark and Gardner, 2018; Pang et al., 2019). Single-paragraph approaches mainly focus on the most relevant paragraph during reading. Multi-paragraph approaches apply a RC model to multiple paragraphs to extract the final answer. However, these approaches still face two major issues.

First, as described above, recent methods only consider the paragraph-question relevance in selecting paragraphs but neglect the paragraph-

*Corresponding author

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2412–2421, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

paragraph relevance, which can be exploited to associate relevant paragraphs that are useful to the downstream RC task. Second, some previous approaches only take into account the positive paragraphs, which are known to contain the answer string, at the training stage. This will make the model become too confident in heuristics or patterns that are only effective in positive paragraphs. As a result, the model will suffer from the problem of impaired generalization ability and be easily bewildered by the distracting paragraphs during testing. Such phenomenon has also been observed by Clark and Gardner (2018). Therefore, a more carefully-designed training strategy is needed.

To address the two issues, we first propose an attention based ranking model which utilizes both the question-paragraph and the paragraph-paragraph relevance to compute a more accurate confidence score for each paragraph. Through the multi-level attention mechanism, the model can utilize the word-level and sentence-level information between the paragraph and the question. Through the sentence-level self-attention mechanism, the model can aggregate the effective evidence among relevant paragraphs and thus increase their confidence scores.

Second, based on the confidence scores, we design a modified weighted sampling strategy to select training paragraphs, which simultaneously ameliorate the influence of the distracting and noisy paragraphs. Through "sampling", the model can be prevented from being too confident in heuristics that are only effective in positive paragraphs. Through "weighted", the model can be less affected by the noisy paragraphs. After that, we concatenate the selected paragraphs and feed them to a RC model to predict the final answer.

We evaluate our work on three distantly supervised OpenQA datasets including Quasar-T (Dhingra et al., 2017b), SearchQA (Dunn et al., 2017) and TriviaQA (Joshi et al., 2017). Empirical results show that our model is effective in improving the performance of OpenQA and advances the state of the art on all three datasets. We additionally perform an ablation study on our model to give insights into the contribution of each submodule. We will release our code on GitHub for further research explorations. [1]

2 Methodology

2.1 Task Definition

OpenQA aims to answer a question based on a number of paragraphs retrieved by IR systems. Formally, given a question containing m words $Q = \{q_1, q_2, ..., q_m\}$ and a set of retrieved paragraphs $D = \{P_1, P_2, ..., P_n\}$, where $P_i = \{p_i^1, p_i^2, ..., p_i^{|p_i|}\}$ is the i-th paragraph, $|p_i|$ is the number of words in the i-th paragraph, our model is supposed to extract the answer from the paragraph collection D.

2.2 Two-stage Framework

Figure 2 gives an overview of our OpenQA model which is composed of two modules including a **ranker** and a **reader**. The ranker is responsible to compute a confidence score for each paragraph. Based on the confidence scores, we design five strategies to select k paragraphs, which are then concatenated and passed to the reader. Note that k is a hyperparameter. Finally, a sub-phrase of the concatenated paragraph is predicted as the answer according to reader's output, which is the probability distribution of the start and end positions.

2.3 Paragraph Ranker

We adopt a ranker to produce a confidence score for each paragraph. The ranker is comprised of an encoding layer, a word-level matching layer, a sentence-level matching layer and a sentence-level decoding layer.

Encoding Layer

Given a paragraph $P_i = \{p_i^1, p_i^2, ..., p_i^{|p_i|}\}$ and a question $Q = \{q_1, q_2, ..., q_m\}$, we map each word into a vector by combining the following features:

Word Embeddings: We use pre-trained word vectors, GloVe (Pennington et al., 2014), to obtain the fixed embedding of each word.

Char Embeddings: We map the characters in a word into 20-dimensional vectors which are then passed to a convolutional layer and a max pooling layer to obtain a fixed-size vector of the word.

Common word: The feature is set to 1 if the word appears in both the question and the paragraph, and otherwise it is set to 0. Then the feature is mapped into a vector of fixed size.

By concatenating the above features, we obtain the encoded sequence of the paragraph $\mathbf{P}_i^{emb} = \{\mathbf{p}_i^t\}_{t=1}^{|p_i|} \in \mathbb{R}^{d_{emb} \times |p_i|}$ and the question $\mathbf{Q}^{emb} = \{\mathbf{q}^t\}_{t=1}^{m} \in \mathbb{R}^{d_{emb} \times m}$, where $|p_i|$ is the number

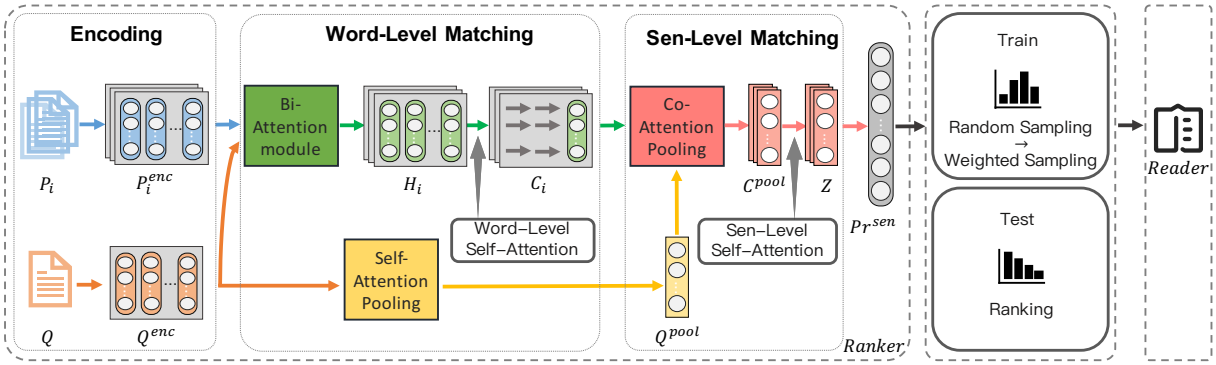

Figure 2: The framework of out model, which consists of a paragraph ranker (left) and a paragraph reader (right). The ranker first computes a confidence score for each paragraph and k paragraphs are selected through the ranking and sampling strategies. Then, the reader concatenates the selected paragraphs together and computes the start score and the end score for each word in the concatenated paragraph.

of words in the i-th paragraph. After that, a bi-directional LSTM is used to calculate a contextual encoding for each word in the paragraph and the question respectively:

$$\mathbf{P}_i^{enc} = BiLSTM(\mathbf{P}_i^{emb}) \in \mathbb{R}^{d_{hid} \times |p_i|} \quad (1)$$

$$\mathbf{Q}^{enc} = BiLSTM(\mathbf{Q}^{emb}) \in \mathbb{R}^{d_{hid} \times m} \quad (2)$$

Word-level Matching Layer

The word-level matching layer takes $\mathbf{P}_i^{enc}$ and $\mathbf{Q}^{enc}$ as inputs and produces a new question-aware representation $\mathbf{C}_i$ for each paragraph. Following Clark and Gardner (2018), we first perform bi-directional attention between the question $\mathbf{Q}^{enc}$ and the paragraph $\mathbf{P}_i^{enc}$, which gives rise to $\mathbf{H}_i$ for $\mathbf{P}_i^{enc}$, where $\mathbf{H}_i \in \mathbb{R}^{d_{hid} \times |p_i|}$. Next, we feed $\mathbf{H}_i$ to the self-attention layer and obtain $\mathbf{E}_i \in \mathbb{R}^{d_{hid} \times |p_i|}$. We strictly implement the steps as suggested by Clark and Gardner (2018). After that, we use a bi-directional LSTM to obtain a question-aware paragraph embedding for the paragraph P_i:

$$\mathbf{C}_i = BiLSTM(\mathbf{E}_i) \in \mathbb{R}^{d_{hid} \times |p_i|} \quad (3)$$

Sentence-level Matching Layer

Given $\mathbf{D}_c = \{\mathbf{C}_1, \mathbf{C}_2, ..., \mathbf{C}_n\}$ and $\mathbf{Q}^{enc}$, the sentence-level matching layer produces a sentence-level representation $\mathbf{Z}_i$ for each paragraph by effectively exploiting the paragraph-question and the paragraph-paragraph relevance. Firstly, we use self-attention pooling to obtain a fixed-size vector for the encoded question representation. Each position in the encoded question representation is assigned with a score computed using a two-layer multi-layer perception (MLP). This score is normalized and used to compute a weighted sum over the columns of the question representation:

$$\alpha = softmax(\mathbf{W}_2^T tanh(\mathbf{W}_1 \mathbf{Q}^{enc})) \in \mathbb{R}^m \quad (4)$$

$$\mathbf{Q}^{pool} = \sum_t \alpha_t \mathbf{Q}_{:t}^{enc} \in \mathbb{R}^{d_{hid}} \quad (5)$$

Here, α_t is the normalized score for the t-th word in the question and $\mathbf{W}_1 \in \mathbb{R}^{d_{hid} \times d_{hid}}$, $\mathbf{W}_2 \in \mathbb{R}^{d_{hid}}$ are trainable parameters for the MLP. Next, we utilize the co-attention pooling (CAP) to get the fixed-length summary vector for each paragraph. The score for each position in $\mathbf{C}_i$ is calculated by measuring the similarity between $\mathbf{C}_i$ and $\mathbf{Q}^{pool}$, based on which we can compute a weighted sum over the columns of the question-aware paragraph embedding $\mathbf{C}_i$:

$$\hat{\alpha} = softmax(\mathbf{Q}_{pool}^T \mathbf{C}_i) \in \mathbb{R}^{|p_i|} \quad (6)$$

$$\mathbf{C}_i^{pool} = \sum_t \hat{\alpha}_t \mathbf{C}_{i:t} \in \mathbb{R}^{d_{hid}} \quad (7)$$

$$\mathbf{C}^{pool} = \{\mathbf{C}_i^{pool}\}_{i=1}^n \in \mathbb{R}^{d_{hid} \times n} \quad (8)$$

where $\hat{\alpha}_t$ is the normalized score for the t-th position in $\mathbf{C}_i$. Let $\mathbf{C}^{pool}$ represent the sequence of summary vectors for all paragraphs. Afterwards, in order to make full use of the paragraph-paragraph relevance, we use the sentence-level self-attention (SSA) and a bi-directional LSTM to produce the sentence-level paragraph representation $\mathbf{Z}$. The SSA is calculated as:

$$\mathbf{A} = softmax(\mathbf{C}^{pool^T} \mathbf{C}^{pool}) \in \mathbb{R}^{n \times n} \quad (9)$$

$$\mathbf{U} = \mathbf{C}^{pool} \mathbf{A} \in \mathbb{R}^{d_{hid} \times n} \quad (10)$$

Here, A is the similarity matrix and A_{ij} indicates the similarity between $\mathbf{C}_{:i}^{pool}$ and $\mathbf{C}_{:j}^{pool}$. $\mathbf{U}_{:i}$

is the i-th column of $\mathbf{U}$ which is the representation of the i-th paragraph where information of all the retrieved paragraphs is encompassed. $\mathbf{U}$ and $\mathbf{C}^{pool}$ are concatenated together to yield $\mathbf{G}$, which is defined by

$$\mathbf{G}_{:i} = [\mathbf{C}^{pool}_{:i}; \mathbf{U}_{:i}; \mathbf{C}^{pool}_{:i} \circ \mathbf{U}_{:i}; \mathbf{C}^{pool}_{:i} - \mathbf{U}_{:i}] \in \mathbb{R}^{4d_{hid}} \tag{11}$$

where $\circ$ is element-wise multiplication, $-$ is element-wise subtraction, and $[;]$ is vector concatenation across rows. After that, a bi-directional LSTM is used to obtain the final sentence-level paragraph representation $\mathbf{Z}$:

$$\mathbf{Z} = BiLSTM(\mathbf{G}) \in \mathbb{R}^{d_{hid} \times n} \tag{12}$$

Sentence-level Decoding Layer

The sentence-level decoding layer, which consists of a linear layer and a sotfmax function, will produce a normalized score for each paragraph:

$$\mathbf{Pr}^{sen} = softmax(W_3^T \mathbf{Z}) \in \mathbb{R}^n \tag{13}$$

where $W_3 \in \mathbb{R}^{d_{hid}}$ is a trainable weight vector. $\mathbf{Pr}^{sen}_i$ is the i-th element of $\mathbf{Pr}^{sen}$ which represents the probability that the i-th paragraph contains the answer.

2.4 Ranking and Sampling Strategies

Based on the retrieved paragraphs and their confidence scores, we design five strategies to select paragraphs for the reader.

Ground Truth (GT) strategy simply chooses all positive paragraphs which contain the answer string as reading datasets and filters out the negative ones. Since we have to know which paragraph contains the answer string, this strategy can only be used while constructing the training set.

Random Sampling (RS) strategy samples k different paragraphs from all the retrieved paragraphs based on the uniform probability distribution. Different from the GT strategy, this strategy will include paragraphs, which do not contain an answer, in the training set. As a result, the RC model is prevented from becoming too confident in heuristics or patterns that are only effective when it is guaranteed that an answer string exists.

Ranking (RK) strategy selects k top-ranked paragraphs based on the confidence scores produced by the ranker. In this strategy, the ranker is expected to select more relevant paragraphs, providing a better start point for the reader to predict the final answer.

Weighted Sampling (WS) strategy samples k different paragraphs from all retrieved paragraphs based on the probability distribution generated by the ranker. This strategy is an improved version of RK. It hopes to consider the effects of the distracting paragraphs while filtering out the noisy ones.

RS→WS strategy is a combination of RS and WS. In the training process, in order to make full use of the dataset and mitigate the impact of the distracting paragraphs, we generate the initial training set for the reader via RS. After that, WS is applied to select paragraphs with higher accuracy, which reduces the influence of the distracting and noisy paragraphs.

During training, we can utilize all the five strategies to generate reading data, while in testing, considering that the paragraphs should be as clean as possible, we only use RK for paragraph selection. After that, we feed the selected paragraphs to the reader to generate the final answer.

2.5 Paragraph Reader

The reader is a traditional RC model, where the inputs are the k selected paragraphs $D^{top} = \{P_1, P_2, ..., P_k\}$ and we regard k as a hyperparameter. We concatenate these paragraphs together to obtain $\hat{P} = [P_1; P_2; ...; P_k]$ which aggregates the information from the selected paragraphs in word level. Given $\hat{P}$ and Q, the output of the reader, i.e, $\mathbf{Pr}^s, \mathbf{Pr}^e \in \mathbb{R}^{|\hat{P}|}$, are the probability distributions of the start index and the end index over the concatenated paragraph, where $|\hat{P}|$ is the number of words in the concatenated paragraph. Our reader is the same as in Clark and Gardner (2018) and we do not give the details here due to the space limitation. After that, we split $\mathbf{Pr}^s$ and $\mathbf{Pr}^e$ into k vectors according to the length of each paragraph and obtain $\{\mathbf{Pr}^s_1, \mathbf{Pr}^s_2, ..., \mathbf{Pr}^s_k\}$ and $\{\mathbf{Pr}^e_1, \mathbf{Pr}^e_2, ..., \mathbf{Pr}^e_k\}$, where $\mathbf{Pr}^s_i$/ $\mathbf{Pr}^e_i$ represent the start/end probabilities of the i-th paragraph.

2.6 Training and Testing

Our model is trained in two stages. We follow the distantly supervised setup that all the paragraphs that contain the answer span are ground truths.

For the ranker, each paragraph in $\{P_i\}_{i=1}^n$ is associated with a label $\mathbf{y}_i \in \{0, 1\}$, and $\mathbf{y}_i$ equals to 1 if the paragraph contains the answer string. We follow the S-Net (Tan et al., 2018) to design the loss function of the ranker. Given the paragraph

probabilities $\mathbf{Pr}^{sen} \in \mathbb{R}^n$, the ranker is trained by minimizing the loss:

$$\mathcal{L}_s = -\sum_{i=1}^{n}(\mathbf{y}_i log(\mathbf{Pr}_i^{sen}) + (1-\mathbf{y}_i) log(1-\mathbf{Pr}_i^{sen})) \tag{14}$$

For the reader, we first select k paragraphs based on the RS→WS strategy and then obtain the final scores $\mathbf{Pr}_i^s$ and $\mathbf{Pr}_i^e$ for each paragraph, where $\mathbf{Pr}_i^s(t)$/$\mathbf{Pr}_i^e(t)$ represent the start/end scores of the t-th word in the i-th paragraph. As described above, the answer string can appear multiple times in a paragraph. Therefore, The reader is trained using a summed objective function that optimizes the negative log probability of selecting any correct answer span:

$$\mathcal{L}_r = -(log(\sum_{i=1}^{k}\sum_{t=1}^{|a_i|}(\mathbf{Pr}_i^s(x_i^t))) + log(\sum_{i=1}^{k}\sum_{t=1}^{|a_i|}(\mathbf{Pr}_i^e(z_i^t)))) \tag{15}$$

where $\{(x_i^t, z_i^t)\}_{t=1}^{|a_i|}$ is the set of the start and end positions of the answer strings that appear in the paragraph P_i.

During testing, we first utilize the ranker to predict a confidence score for each retrieved paragraph and utilize the RK strategy to select k paragraphs. Next, the reader calculates the start and the end score of each word for all the selected paragraphs. Based on the reader-produced scores, there are two answer choosing methods:

MAX method is usually adopted in the traditional RC task. It simply chooses an answer span which has the maximum span score from all selected paragraphs. This span score is the product of the start score of the first word and the end score of the last word of the answer span.

SUM method first extracts an answer candidate A_i that has the maximum span score from each paragraph. Next, if the answer candidates from different paragraphs refer to the same answer, we will sum up the scores of these answer candidates and choose the answer candidate with the maximum score as the final prediction. The similar method has also been adopted by recent approaches (Wang et al., 2018b; Lin et al., 2018; Pang et al., 2019).

3 Experiments

3.1 Datasets and Baselines

We evaluate our model on three OpenQA datasets, namely Quasar-T (Dhingra et al., 2017b), SearchQA (Dunn et al., 2017) and the unfiltered version of TriviaQA (Joshi et al., 2017).

Quasar-T. It consists of 43K open-domain trivia question-answer pairs, and about 100 paragraphs are provided for each question-answer pair by using the Solr search engine.

SearchQA. It has a total of more than 140k question-answer pairs, and roughly 50 webpage snippets are provided by the Google search engine as background paragraphs for each question.

TriviaQA. It contains approximately 95K open-domain question–answer pairs. The unfiltered version of TriviaQA is used in our experiment.

To better demonstrate the effectiveness of our model, we carefully select some recent approaches as baselines, including traditional RC models, i.e., BIDAF (Seo et al., 2016) , DECAPROP (Tay et al., 2018), single-paragraph models, i.e., R3 (Wang et al., 2018a), confidence-based models, i.e., DrQA (Chen et al., 2017) , DS-QA (Lin et al., 2018), S-Norm (Clark and Gardner, 2018), HAS-QA (Pang et al., 2019), MSR (Das et al., 2019) and answer re-ranking models, i.e., Re-Ranker (Wang et al., 2018b), Joint (Wang et al., 2018c).

3.2 Implementation Details

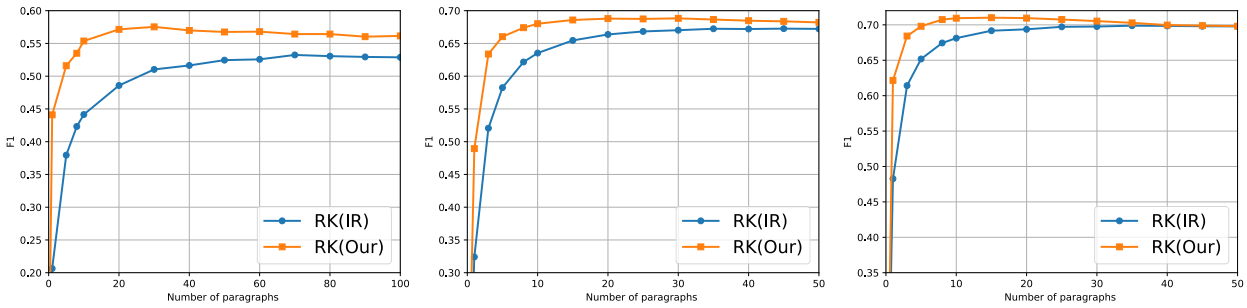
In the experiments, we adopt the same data preprocessing scheme as Clark and Gardner (2018). For the ranker, we use the 300-dimensional word embeddings pre-trained by GloVe (Pennington et al., 2014), which are fixed during training, and regard the 20-dimensional character embeddings as learnable parameters. The common word feature is mapped into a 4-dimensional vector and it is updated during training. We set the hidden size of LSTM to 150 and the number of LSTM layers to 1. We use Adam with learning rate 5e-4 to optimize the model. The batch size is set to 8 and dropout is applied to the outputs of all LSTM layers at a rate of 0.2. As for RS→WS, we first train the reader until convergence by RS. After that, we utilize WS to select paragraphs for training in order to further facilitate the performance of the reader. Our reader adopts the same hyperparameters as S-Norm (Clark and Gardner, 2018). While training the reader, the parameters of the ranker are fixed. The average length of paragraphs in TriviaQA is greater than that of Quasar-T and SearchQA, so we select 30, 30 and 15 paragraphs for Quasar-T, SearchQA and TriviaQA respectively.

Models	Quasar-T		SearchQA		TriviaQA		Average	
	EM	F1	EM	F1	EM	F1	EM	F1
BIDAF (Seo et al., 2016)	25.9	28.5	28.6	34.6	41.1	47.4	31.8	36.8
DECAPROP (Tay et al., 2018)	38.6	46.9	56.8	63.6	-	-	-	-
R3 (Wang et al., 2018a)	35.3	41.7	49.0	55.3	47.3	53.7	43.8	50.2
Re-Ranker (Wang et al., 2018b)	42.3	49.6	57.0	63.2	50.6	53.7	49.9	55.5
Joint (Wang et al., 2018c)	45.9	53.9	58.3	64.2	-	-	-	-
DrQA (Chen et al., 2017)	37.7	44.5	41.9	48.7	32.3	38.3	37.3	43.8
DS-QA (Lin et al., 2018)	42.2	49.3	58.8	64.5	48.7	56.3	49.9	56.7
S-Norm (Clark and Gardner, 2018)	38.6	45.4	59.8	67.1	61.3	67.2	53.2	59.9
HAS-QA (Pang et al., 2019)	43.2	48.9	62.7	68.7	63.6	68.9	56.5	62.1
MSR(BiDAF) (Das et al., 2019)	40.6	47.0	56.2	61.4	55.9	61.7	50.9	56.7
Our (RS, RK, MAX)	46.6	56.5	60.4	68.0	63.8	70.4	56.9	64.9
Our (RS→WS, RK, MAX)	48.2	57.5	61.1	68.8	64.6	71.0	57.9	65.7
Our (RS→WS, RK, SUM)	**48.6**	**57.8**	**62.9**	**69.8**	**65.2**	**71.3**	**58.9**	**66.3**

Table 1: Experimental results on three OpenQA datasets: Quasar-T, SearchQA and TriviaQA. The results of 'BIDAF', 'DrQA' and 'S-Norm' are replicated from Pang et al. (2019). The unfiltered version of TriviaQA does not provide the answer of the test set. Therefore, we follow previous works to report the results on the development set of TriviaQA. Average: The average score of the three datasets.

3.3 Overall Results

In this section, we focus on the performance of the whole model. Table 1 presents the F1 and Exact Match (EM) scores of our model and the baseline models. These evaluation metrics are widely-adopted for OpenQA. Our (RS, RK, MAX) model utilizes RS and RK to select paragraphs for training and testing respectively and uses MAX to generate answer.



Our (RS, RK, MAX) model achieves better results on most of the datasets compared to the baselines. The main reason is that RS can select distracting paragraph to train the reader, thereby preventing the reader from being too confident in patterns that are only effective in positive paragraphs. Besides, compared with the paragraph-question relevance, the paragraph-paragraph relevance can further enhance the evidence among the relevant paragraphs. By jointly considering those relevance, RK can select more relevant paragraphs during testing to provide a better start point for the reader.

Our (RS→WS, RK, MAX) model consistently outperforms Our (RS, RK, MAX) model across the three datasets. The improvement is attributed to the adoption of the weighted sampling strategy. In the first stage of training, RS prevents excessive focus on the positive paragraphs. On this basis, WS further alleviates the influence of noisy paragraphs in the second stage without hurting the model's generalization ability.

We can observe that the SUM method (Wang et al., 2018b) helps our model better extract the correct answer. As we discussed, different from the traditional RC task, the answer string will appear multiple times in different paragraphs in OpenQA. By summing up the answer span scores which refer to the same answer candidate, we can extract a more accurate answer.

On SearchQA dataset, Our (RS→WS, RK, MAX) model achieves a close performance compared to HAS-QA model. 35% of the paragraphs in the development set of SearchQA contain the answer string, and for Quasar-T and TriviaQA the percentage of such paragraphs in the development set are 13% and 29% respectively. This indicates that SearchQA contains more positive paragraphs than other datasets. Since our model is better at filtering out the irrelevant data, the improvement in SearchQA is not as significant as in other datasets. However, Our (RS→WS, RK, SUM) model still achieves the SOTA result by adopting the SUM method and HAS-QA, which is a strong baseline, also adopts the similar method.

In the following sections, we give further analyses about the ranker, the selection strategies, the hyperparameter, the case study and the ablation study of our model.

(a) Quasar-T (b) SearchQA (c) TriviaQA

Figure 3: Impact of the number of the selected paragraphs during testing on Quasar-T, SearchQA and TriviaQA. RK (IR), RK (Our): Utilizing a information retrieval model with BM25 or our ranker to select top k paragraphs.

	Quasar-T			SearchQA		
Models	**Top1**	**Top3**	**Top5**	**Top1**	**Top3**	**Top5**

Table 3: The performance of different training selection strategies on Quasar-T, SearchQA and TriviaQA.

3.4 Performance of the Ranker

We separately evaluate our ranker by comparing it with a typical IR model [2] and SOTA models which also have a ranking submodule to select paragraphs, i.e. DS-QA (Lin et al., 2018), R3 (Wang et al., 2018a), FSE (Zhang et al., 2018), MSR (Das et al., 2019). This evaluation simply focuses on whether the ground-truth appears in the Top 1, 3, 5 paragraphs. We follow the previous works to report the results on Quasar-T and SearchQA. As shown in Table 2, we can observe that our ranker surpasses the IR model with a large margin. The result implies that, the question-paragraph relevance is effective in selecting the relevant paragraphs. Compared with R3, DS-QA, FSE and MSR, which also adopt a neural network to select paragraphs, our model still works better. It suggests that exploiting the paragraph-question and paragraph-paragraph relevance with multi-level attention and self-attention mechanisms can further improve the performance of the ranker.

3.5 Performance of Selection Strategies

In this section, we compare the performance of different selection strategies for training. For fair comparison, a common scheme for testing is applied, where we use RK to select testing paragraphs and MAX to extract the answer. As shown in Table 3, the performance of RS is much better than GT and RK. The reason is that both GT and RK tend to train the reader on the positive paragraphs which inevitably impairs the generalization ability of the reader. It demonstrates that mainly choosing the positive paragraphs for training will hurt the performance of the model. Compared with RS, WS leads to a slight improvement thanks to the denoising effect. However, WS still reveals a bias toward the positive paragraphs during training, which may explain for the reason why the improvement is trivial. We can see that RS→WS gains the best score on three datasets. The reason is that the RS→WS strategy can not only ameliorates the influences of the distracting paragraphs but also filter out the noisy paragraphs to further strengthen our model.

3.6 Impact of the Number of Paragraphs

In order to further investigate the influences of different rankers and the hyperparameter k during testing, we compare the final performance of RK (Our) with that of RK (IR). We utilize RS→WS to select paragraphs for training and and extract answers through the MAX method.

[2]The IR model ranks the paragraph with BM25

Question: Who was born on Krypton ?
Answer: Superman
5 top-ranked paragraphs selected by our ranker:
P1 (positive, relevant) : With a premise that taps into adolescent fantasy, Superman is born Kal-El on the alien planet Krypton, before being rocketed to Earth as an infant by his scientist father moments before the planet exploded.
P2 (positive, relevant) : The original story of Superman relates that he was born Kal-El on the planet Krypton, before being rocketed to Earth as an infant by his scientist father Jor-El, moments before Krypton's destruction.
P3 (positive, relevant) : Superman was born on the planet Krypton and was sent to Earth by his father moments before his planet exploded.
P4 (positive, relevant) : As of the early 1960s, (this story has undergone many revisions) Superman was born as Kal-el on the planet Krypton.
P5 (positive, relevant) : Superman was born Kal-El on the planet Krypton.
5 top-ranked paragraphs selected by RKN:
P1 (positive, noisy) : Television in the pilot episode of the 1950s television program Adventures of Superman Jor-El, portrayed by Robert Rockwell, was Krypton 's leading scientist, who tried to warn the ...
P2 (negative, distracting) : They did not tell anyone of his alien origins, letting family and friends believe he was born on the farm as their biological son, whom they named Clark Joseph Kent.
P3 (positive, relevant) : "Superman will be the only Kryptonian who survived the destruction of Krypton"- John Byrne on The Man of Steel.
P4 (positive, noisy) : In 1985, writer Alan Moore gave a somewhat darker glimpse into the world of Krypton in his story "For the Man Who Has Everything" (in Superman Annual), the premise being an ...
P5 (positive, noisy) : George Reeves, star of the Adventures of Superman television series, born in 1914.

Table 4: An example from Quasar-T to illustrate the necessity of the paragraph-paragraph relevance. The key information, answers in correct-labeled and wrong-labeled contexts are marked in blue, green and red respectively. RKN: a naive version of our ranker which only utilizes the paragraph-question relevance.

RK (Our) and RK (IR) denote utilizing our ranker and a typical IR model, respectively, to select the k top-ranked paragraphs for testing. As shown in Figure 3, it is obvious that the performance of the two models first increases and then remains stable or reduces as k rises on three datasets. As the number of paragraphs increases, the chances are better that the answer is included in these paragraphs. However, the difficulty and running time for the reader also increase. As can be seen in Figure 3, the peak value of our ranker exceeds that of the IR model on three datasets, suggesting that our ranker can discover more useful and relevant paragraphs during testing, providing a better start point for the reader to predict the final answer.

3.7 Case Study

Table 4 shows an example from Quasar-T. The second row contains 5 top-ranked paragraphs which are produced by our ranker and the paragraphs in the third row are selected by a naive version of our ranker (RKN) which replaces the co-attention pooling (CAP) with max pooling for $\mathbf{C}_i$ and removes the sentence-level self-attention (SSA). For the question "Who was born on Krypton?", our ranker can select more related paragraphs and all of them support "Superman" as the answer. These paragraphs are inherently relevant to each other and provide enhanced evidence for the correct answer. However, most of the paragraphs in the third row are noisy and distracting, even though some of them are related to the question to some extent. Compared with RKN, which only uses the paragraph-question relevance, our completed ranker can further utilize the paragraph-paragraph relevance to aggregate the evidence among relevant paragraphs, thereby increasing their confidence scores. As a result, the reader is provided with more useful paragraphs to enhance the performance of our model.

Models	P@1	P@3	P@5	EM	F1	ΔF1

3.8 Ablation Study

Finally, we conduct an ablation study to analyze the effect of all proposed methods and report the results on Quasar-T. As shown in Table 5, we evaluate the performance of the ranker according to the precision at 1, 3 and 5. In comparison with the evaluation which assesses whether the ground-truth appears in the top-ranked paragraphs, this metric can better evaluate the performance of the ranker, as we expect to find as many relevant paragraphs in the k top-ranked paragraphs as possible. We start with our completed model

which utilizes RS→WS to select 30 paragraphs for training and RK to select 30 top-ranked paragraphs for testing. As shown in Table 5, the '-SUM' denotes using MAX to choose the answer and the performance drop indicates that SUM can further enhance our model. Replacing RS→WS with RK for training accounts for a 2.1% performance drop, which demonstrates the effectiveness of our proposed selection strategy. The '-CAP' means replacing the co-attention pooling with max pooling for $\mathbf{C}_i$ and the '-SSA' means removing the sentence-level self-attention , and from the results, we can see that both paragraph-question and paragraph-paragraph relevance are integral to our model. The '-ranker' denotes replacing our ranker with the IR model in training and testing stages. The replacement accounts for a performance drop of 5.2%, which illustrates the indispensable role of our ranker in the final architecture.

4 Related Work

Most recent OpenQA approaches extract answer from distantly supervised paragraphs which are retrieved from the web (Chen et al., 2017; Dhingra et al., 2017a; Buck et al., 2018).

The interest of research roughly falls into two categories, namely the single-paragraph approaches and the multi-paragraph approaches, both of which follow the retrieve-then-read pipeline. Single-paragraph approaches (Joshi et al., 2017; Wang et al., 2018a) select a most relevant paragraph from all the retrieved paragraphs and then feed it to a RC model to extract the answer. The dependence on a single paragraph renders the RC model vulnerable to selection errors and a large amount of information in the remaining paragraphs is consequently being neglected.

Multi-paragraph approaches can be further divided into answer-rerank methods and confidence-based methods. For answer-rerank methods, Wang et al. (2018b) adopted a single-paragraph approach to extract an answer candidate from each retrieved paragraph and then used an extra neural network to rerank the candidates. Wang et al. (2018c) jointly trained the candidates extraction and reranking steps with reinforcement learning to further improve the performance. But these methods still rely heavily on the candidates extraction results.

Chen et al. (2017) proposed the first confidence method which retrieved multiple paragraphs with an IR system and applied a RC model to each paragraph for extracting the answer with the highest confidence. Das et al. (2019) introduced a new framework to make use of the result of the reader for improved paragraph retrieval. However, these models suffer from the problem of impaired generalization ability as a result of too much focus on the positive paragraphs in training. Clark and Gardner (2018) presented a new method, S-Norm. They used the sampling strategy and the shared-norm objective function to teach the model to ignore non-answer containing paragraphs. However, the retrieved paragraphs are always noisy and this will hurt the performance of the model.

Zhang et al. (2018) and Lee et al. (2018) adopted a neural network to rank the retrieved paragraphs. Lin et al. (2018) and Pang et al. (2019) also ranked the paragraphs and took into account both the ranking results and the scores produced by the reader to predict the final answer. However, they mainly utilize the paragraph-question relevance to rank the paragraphs and train the reader mainly on the positive paragraphs.

5 Conclusion

In this paper, we tackle the issues caused by the noisy and distracting paragraphs on OpenQA via ranking and sampling. By jointly considering the question-paragraph and the paragraph-paragraph relevance, our ranking model can calculate a more accurate confidence score for each paragraph. Through the modified weighted sampling strategy, our model can make full use of the dataset and mitigate the influence of the distracting and noisy paragraphs. Experimental results on three challenging public OpenQA datasets (Quasar-T, SearchQA and TriviaQA) show that our model advances the state of the art.

Abstract

Bilinear diagonal models for knowledge graph embedding (KGE), such as DistMult and ComplEx, balance expressiveness and computational efficiency by representing relations as diagonal matrices. Although they perform well in predicting atomic relations, composite relations (relation paths) cannot be modeled naturally by the product of relation matrices, as the product of diagonal matrices is commutative and hence invariant with the order of relations. In this paper, we propose a new bilinear KGE model, called BlockHolE, based on block circulant matrices. In BlockHolE, relation matrices can be non-commutative, allowing composite relations to be modeled by matrix product. The model is parameterized in a way that covers a spectrum ranging from diagonal to full relation matrices. A fast computation technique is developed on the basis of the duality of the Fourier transform of circulant matrices.

1 Introduction

Large-scale knowledge graphs (Nickel et al., 2016a) are indispensable resources for knowledge-intensive applications such as question answering, dialog systems, and distantly supervised relation extraction. A knowledge graph is a collection of *triplets* (s, r, o) representing the fact that (binary) relation r holds between subject entity s and object entity o. Although efforts continue to enrich existing knowledge graphs with more facts, many facts are still missing (Nickel et al., 2016a). Knowledge graph completion (KGC) aims to automatically detect missing facts in an *incomplete* knowledge graph, and has become an active field of research in recent years.

Knowledge graph embedding (KGE) is a promising approach to KGC. It embeds entities and relations in vector space, and defines a *scoring function* $\phi(s, r, o)$ to evaluate the degree of factuality of a given triplet (s, r, o) in terms of vector operations.

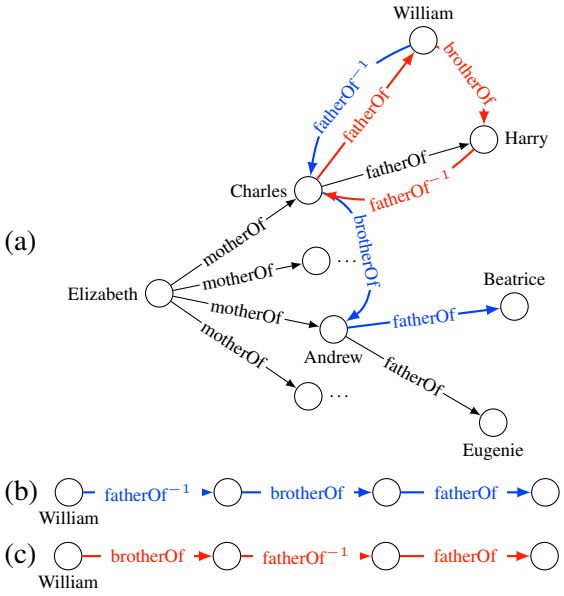

Figure 1: (a) A knowledge graph and (b,c) two relation paths starting from William.

Bilinear KGE models are a popular choice for a scoring function, along with those based on translation and neural networks. RESCAL (Nickel et al., 2011) adopts a generic bilinear form as the scoring function, given by $\phi_{\text{RESCAL}}(s, r, o) = \mathbf{e}_s^{\mathrm{T}} \mathbf{R}_r \mathbf{e}_o$. In this formula, $\mathbf{e}_s, \mathbf{e}_o$ are the n-dimensional vector embeddings of entities s and o, respectively, and $\mathbf{R}_r$ is the $n \times n$ matrix embedding of relation r. Some of the more recent models have constrained the relation matrices to be diagonal. DistMult (Yang et al., 2015) and ComplEx (Trouillon et al., 2016) are two such diagonal models. HolE (Nickel et al., 2016b) does not use diagonal relation matrices, but has been shown (Hayashi and Shimbo, 2017) to be isomorphic to ComplEx. These models have a smaller number of parameters than RESCAL, making them less prone to overfit-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2422–2430, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ting, and the performance is usually better.

While all these models were designed with a specific task of KGC in mind, i.e., computing the factuality of triplets, another important task on knowledge graphs was pursued by Guu et al. (2015) and Lin et al. (2015). This latter task, called *path query answering (path QA)*, is to answer composite queries that consist of a cascade of relations, as opposed to an atomic relation. See Figure 1 for instance. A query "Is Beatrice a child of a paternal uncle of William?" can be answered by predicting the truth value of the triplet (William, fatherOf^{-1}/brotherOf/fatherOf, Beatrice) where fatherOf^{-1}/brotherOf/fatherOf is a binary relation not present in the knowledge graph as a relation (edge) label but is composed of a cascade of three atomic relations.[1] Composite queries are also called *path queries*, as they can be represented as paths in a knowledge graph; see, e.g., the blue line in Figure 1(a). Notice however that some of the edges in the path may be missing due to the incompleteness of the knowledge graph; even in such circumstances, the model must ideally be able to answer path queries correctly.

Guu et al. (2015) extended the existing KGE approaches to path QA. For example, to answer a general path query $(s, r_1/\ldots/r_k, o)$ with RESCAL, a composite relation $r_1/\cdots/r_k$ is modeled by matrix product $\mathbf{R}_{r_1}\cdots\mathbf{R}_{r_k}$, and the score for the given query is modeled by $\mathbf{e}_s^{\mathrm{T}}\mathbf{R}_{r_1}\cdots\mathbf{R}_{r_k}\mathbf{e}_o$. This formulation is also applicable to DistMult and ComplEx, which use diagonal relation matrices. In diagonalized models, however, relation matrices are *commutative*, in the sense that $\mathbf{R}_r\mathbf{R}_{r'} = \mathbf{R}_{r'}\mathbf{R}_r$ for any pair of relations r, r'.

Commutativity of relation matrices was not recognized as an issue in the past research because the main focus was on predicting the truth value of atomic triplets. However, when path queries are concerned, commutativity poses a problem. Consider, for example, a relation sequence

$$\text{fatherOf}^{-1}/\text{brotherOf}/\text{fatherOf}$$

and its permutation

$$\text{brotherOf}/\text{fatherOf}^{-1}/\text{fatherOf}.$$

Although these are two distinct paths (cf. Figure 1(b, c)), in bilinear models with commutative relation matrices, they are represented by the same product of relation matrices, which thereby makes the truth values of these permutated queries indistinguishable by their scores.

Drawing on the observation above, this paper proposes a new KGE model called BlockHolE, wherein relations are represented by block circulant matrices. This makes relation matrices non-commutative, and thus it does not suffer from the issues arising from commutativity, yet in general manages to reduce the number of parameters compared with RESCAL. It can be interpreted as a generalization of HolE and ComplEx, and also subsumes RESCAL as an extreme case. We report experimental results in both path and atomic QA tasks.

[1] We regard inverse relations (e.g., fatherOf^{-1}) also as atomic relations.

Symbol	Description
$\mathbb{R}, \mathbb{C}$	sets of real/complex numbers
$[\mathbf{v}]_j$	jth component of vector $\mathbf{v}$
$[\mathbf{M}]_{jk}$	(j,k)-component of matrix $\mathbf{M}$
$\mathbf{M}^{\mathrm{T}}$	transpose of $\mathbf{M}$
$\overline{\mathbf{M}}$	conjugate of $\mathbf{M}$
$\odot$	componentwise (Hadamard) product
$*$	circular convolution
$\star$	circular correlation
$\mathrm{Re}(x)$	real part of complex number x
$\mathrm{diag}(\mathbf{v})$	diagonal matrix with main diagonal $\mathbf{v}$
$\mathrm{circ}(\mathbf{v})$	circulant matrix determined by $\mathbf{v}$
$\langle \mathbf{x}, \mathbf{y}, \mathbf{z} \rangle$	sum of the componentwise products of $\mathbf{x}, \mathbf{y}, \mathbf{z}$
$\mathbf{F}$	discrete Fourier matrix
$\mathcal{E}$	set of entities
$\mathcal{R}$	set of relations
$\mathcal{F}$	set of observed facts (triplets)
$\mathcal{F}^*$	set of ground truth facts
$\mathcal{G}(\mathcal{F})$	Knowledge graph induced by facts $\mathcal{F}$

Table 1: List of symbols. See Secs. 2 and 3 for detail.

2 Notation and preliminaries

We first introduce symbols and notation used in this paper, followed by some preliminaries on circulant matrices, circular convolution, correlation, and Fourier transform. The summary of symbols can be found in Table 1.

Let $\mathbb{R}$ be the set of reals, and $\mathbb{C}$ be the set of complex numbers. Let $[\mathbf{v}]_j$ denote the jth component of vector $\mathbf{v}$, and let $[\mathbf{M}]_{jk}$ the (j,k) element of matrix $\mathbf{M}$. For a complex number z, vector $\mathbf{z}$, and matrix $\mathbf{Z}$, let $\overline{z}$, $\overline{\mathbf{z}}$, and $\overline{\mathbf{Z}}$ denote their complex conjugate, respectively.

Let $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$ be n-dimensional (real or complex) vectors. Let $\mathrm{diag}(\mathbf{x})$ denote an $n \times n$ diagonal matrix with the main diagonal components given by $\mathbf{x}$. We write $\mathbf{x} \odot \mathbf{y}$ to denote the componentwise product of $\mathbf{x}$ and $\mathbf{y}$; i.e., $\mathbf{x} \odot \mathbf{y} = \mathrm{diag}(\mathbf{x})\mathbf{y}$, or

$[\mathbf{x} \odot \mathbf{y}]_i = [\mathbf{x}]_i[\mathbf{y}]_i$, $i = 1, \ldots, n$. We also write $\langle \mathbf{x}, \mathbf{y}, \mathbf{z} \rangle = \mathbf{x}^{\mathrm{T}} \operatorname{diag}(\mathbf{y})\mathbf{z} = \sum_{i=1}^{n} [\mathbf{x}]_i[\mathbf{y}]_i[\mathbf{z}]_i$.

For n-dimensional real vectors[2] $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, $\mathbf{x} * \mathbf{y}$ and $\mathbf{x} \star \mathbf{y}$ denote *circular convolution* and *circular correlation*, respectively defined by

$$[\mathbf{x} * \mathbf{y}]_i = \sum_{j=1}^{n} [\mathbf{x}]_{i-j+1}[\mathbf{y}]_j,$$

$$[\mathbf{x} \star \mathbf{y}]_i = \sum_{j=1}^{n} [\mathbf{x}]_{j-i+1}[\mathbf{y}]_j, \quad i = 1, \ldots, n,$$

where vector indices that do not fall in the range $1, \ldots, n$ must be interpreted by $0 = n, -1 = n - 1, \ldots, -n + 1 = 1$.

For n-dimensional real vector $\mathbf{v} \in \mathbb{R}^n$, let

$$\operatorname{circ}(\mathbf{v}) = \begin{bmatrix} [\mathbf{v}]_1 & [\mathbf{v}]_n & \cdots & [\mathbf{v}]_3 & [\mathbf{v}]_2 \\ [\mathbf{v}]_2 & [\mathbf{v}]_1 & [\mathbf{v}]_n & & [\mathbf{v}]_3 \\ \vdots & [\mathbf{v}]_2 & [\mathbf{v}]_1 & \ddots & \vdots \\ [\mathbf{v}]_{n-1} & & \ddots & \ddots & [\mathbf{v}]_n \\ [\mathbf{v}]_n & [\mathbf{v}]_{n-1} & \cdots & [\mathbf{v}]_2 & [\mathbf{v}]_1 \end{bmatrix}$$

be an operation that converts a vector $\mathbf{v}$ to a circulant matrix of size $n \times n$.

A circulant matrix $\operatorname{circ}(\mathbf{v}) \in \mathbb{R}^{n \times n}$ can be diagonalized as $\operatorname{circ}(\mathbf{v}) = \mathbf{F}^{-1} \operatorname{diag}(\mathbf{F}\mathbf{v})\mathbf{F}$, where $\mathbf{F} \in \mathbb{C}^{n \times n}$ is the discrete Fourier matrix of order n. Also, circular convolution and correlation can be written in terms of $\operatorname{circ}(\cdot)$: $\mathbf{x} * \mathbf{y} = \operatorname{circ}(\mathbf{x})\mathbf{y}$, and $\mathbf{x} \star \mathbf{y} = \operatorname{circ}(\mathbf{x})^{\mathrm{T}}\mathbf{y}$. It follows that

$$\mathbf{x} * \mathbf{y} = \mathbf{F}^{-1}(\mathbf{F}\mathbf{x} \odot \mathbf{F}\mathbf{y}), \tag{1}$$

$$\mathbf{x} \star \mathbf{y} = \mathbf{F}^{-1}(\overline{\mathbf{F}\mathbf{x}} \odot \mathbf{F}\mathbf{y}). \tag{2}$$

These equations imply that circular convolution and correlation can be computed in time $O(n \log n)$ using the fast Fourier transform (FFT).

3 Knowledge graph embedding using bilinear maps

A *knowledge graph* is a labeled multigraph $(\mathcal{E}, \mathcal{R}, \mathcal{F})$, where $\mathcal{E}$ is the set of entities (or vertices), $\mathcal{R}$ is the set of relation labels (or edge labels), and $\mathcal{F} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ defines the observed instances of binary relations over entities (or labeled edges). An item $(s, r, o) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is called a *triplet*, with s and o called its *subject* and *object*, respectively. For every entity in $e \in \mathcal{E}$, it is assumed that $\mathcal{F}$ contains at least one triplet (s, r, o) with $s = e$ or $o = e$; likewise, for every relation in $r \in \mathcal{R}$, $\mathcal{F}$ is assumed to contain at least one triplet (s, r, o). Because $\mathcal{F}$ determines the sets $\mathcal{E}$ and $\mathcal{R}$ of entities and relations, we write $\mathcal{G}(\mathcal{F})$ to denote the knowledge graph $(\mathcal{E}, \mathcal{R}, \mathcal{F})$ determined by $\mathcal{F}$.

Aside from observed triplets $\mathcal{F}$, we also assume the presence of a set $\mathcal{F}^* \supset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ of *(ground truth) facts*, which is a strict superset of $\mathcal{F}$, i.e., $\mathcal{F} \subset \mathcal{F}^*$. Thus, $\mathcal{F}^*$ is not fully observable.

3.1 Knowledge graph completion

Knowledge graph completion (KGC) is the task of identifying the set of ground truth facts $\mathcal{F}^*$ from observed facts $\mathcal{F} \subset \mathcal{F}^*$ (or equivalently, $\mathcal{G}(\mathcal{F}^*)$ from $\mathcal{G}(\mathcal{F})$).

A popular approach to KGC is to design a *scoring function* $\phi(s, r, o)$ quantifying how likely a triplet (s, r, o) is true. This scoring function is learned from the observed triplets $\mathcal{F}$, in a way that it generalizes well to unobserved triplets $\mathcal{F}^* \backslash \mathcal{F}$; i.e., the score must be high for both observed and unobserved facts, and it must be low for nonfactual triplets.

In *knowledge graph embedding* (KGE)–based approaches to KGC, the scoring function $\phi(s, r, o)$ is defined in terms of the embeddings of entities and relations; i.e., s, r, and o are embedded as objects in a vector space, and ϕ is defined in terms of some operations over these objects.

3.2 Bilinear models for knowledge graph embedding

Below, we describe some of the popular KGE models that use bilinear maps to define scoring functions.

3.2.1 RESCAL

RESCAL (Nickel et al., 2011) provides the most general form of bilinear scoring function.

$$\phi_{\text{RESCAL}}(s, r, o) = \mathbf{e}_s^{\mathrm{T}} \mathbf{R}_r \mathbf{e}_o, \tag{3}$$

where $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^n$ are the vector embeddings of entities s and o, respectively, and $\mathbf{R}_r \in \mathbb{R}^{n \times n}$ is the matrix representing relation r. Thus, n^2 parameters are required per relation, which is not only a computational burden but also the cause of overfitting during training (Kazemi and Poole, 2018).

3.2.2 DistMult

DistMult (Yang et al., 2015) is a model obtained by restricting the relation matrices $\mathbf{R}_r$ of RESCAL

[2] Generally, circular convolution, circular correlation, and circulant matrices are defined over $\mathbb{C}^n$. However, in this paper, it suffices to define them over $\mathbb{R}^n$.

to diagonal; i.e., $\mathbf{R}_r = \mathrm{diag}(\mathbf{w}_r)$, $\mathbf{w}_r \in \mathbb{R}^n$. The scoring function is thus

$$\begin{aligned}\phi_{\text{DistMult}}(s, r, o) &= \mathbf{e}_s{}^{\mathrm{T}} \,\mathrm{diag}(\mathbf{w}_r)\mathbf{e}_o \\ &= \langle \mathbf{w}_r, \mathbf{e}_s, \mathbf{e}_o \rangle. \end{aligned} \tag{4}$$

Although the number of parameters is reduced considerably, the scoring function (4) is symmetric with respect to the entities, i.e., $\phi_{\text{DistMult}}(s, r, o) = \phi_{\text{DistMult}}(o, r, s)$. This is a severe limitation because most real-world relations are non-symmetric.

3.2.3 ComplEx: Complex embedding

The *complex embedding* (ComplEx) (Trouillon et al., 2016) represents entities and relations as n-dimensional vectors as in DistMult, but their components are complex-valued.

The scoring function of ComplEx is given by

$$\begin{aligned}\phi_{\text{ComplEx}}(s, r, o) &= \mathrm{Re}(\mathbf{e}_s{}^{\mathrm{T}} \,\mathrm{diag}(\mathbf{w}_r)\overline{\mathbf{e}_o}) \\ &= \mathrm{Re}(\langle \mathbf{w}_r, \mathbf{e}_s, \overline{\mathbf{e}_o} \rangle),\end{aligned}$$

where $\mathbf{e}_s, \mathbf{e}_o, \mathbf{w}_r \in \mathbb{C}^n$ are the embeddings of s, o, and r, respectively. The number of parameters in ComplEx is $2n|\mathcal{E}| + 2n|\mathcal{R}|$, and the score is computable in time linear in the dimension of vector space. Unlike DistMult, ComplEx can model non-symmetric relations, since $\phi(s, r, o) \neq \phi(o, r, s)$ in general.

3.2.4 HolE: Holographic embedding

The *holographic embedding* (HolE) (Nickel et al., 2016b) uses circular correlation to define a scoring function

$$\phi_{\text{HolE}}(s, r, o) = \mathbf{w}_r^{\mathrm{T}}(\mathbf{e}_s \star \mathbf{e}_o), \tag{5}$$

where $\mathbf{w}_r, \mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^n$ are n-dimensional real vectors representing relation r, and entities s and o, respectively. HolE has only n parameters per relation, and it can model non-symmetric relations since $\phi_{\text{HolE}}(s, r, o) \neq \phi_{\text{HolE}}(o, r, s)$ in general. Computing circular correlation requires $O(n \log n)$ time if FFT is employed. Eq. (5) is not a bilinear form, but it has been shown (Hayashi and Shimbo, 2017) that HolE is isomorphic to ComplEx, and thus any model in HolE can be converted to an equivalent model in ComplEx, and vice versa.

4 Path question answering over a knowledge graph

4.1 Path query answering

Let $\mathcal{F}^*$ be the set of ground truth facts, and let $\mathcal{G}(\mathcal{F}^*) = (\mathcal{E}, \mathcal{R}, \mathcal{F}^*)$ be its induced knowledge graph. For k relations $r_1, \ldots, r_k \in \mathcal{R}$, we call $r_1/\ldots/r_k$ a *relation path* of length k. When $k = 1$, the relation path is *atomic*; otherwise, it is *composite*. Let $s, o \in \mathcal{E}$. We say a *path query* $(s, r_1/\ldots/r_k, o)$ holds (or "is true") in $\mathcal{G}(\mathcal{F}^*)$ (or with respect to $\mathcal{F}^*$) if

$$\exists e_1, \ldots, e_{k-1} \in \mathcal{E} \;\; \forall j = 1, \ldots, k \quad (e_{j-1}, r_j, e_j) \in \mathcal{F}^*,$$

where $e_0 = s$ and $e_k = o$. *Path query answering* (path QA) is the task of predicting the truth value of path queries with respect to the unobserved set $\mathcal{F}^*$ of ground truth facts, when its incomplete subset $\mathcal{F} \subset \mathcal{F}^*$ is only available. In other words, we want to predict that $(s, r_1/\ldots/r_k, o)$ is true if a path from s to o exists in $\mathcal{G}(\mathcal{F}^*)$, although some of the edges that constitute the path may be missing in the observed graph $\mathcal{G}(\mathcal{F})$.

For atomic path queries (i.e., those with length $k = 1$), path QA reduces to that of knowledge graph completion introduced in Section 3.1. Thus, it is natural to address general path QA by extending the scoring function $\phi(s, r, o)$ of KGC methods so that composite relation $r_1/\ldots/r_k$ is allowed in place of atomic relation r; i.e., by defining $\phi(s, r_1/\ldots/r_k, o)$. Previous work (Guu et al., 2015) explored this direction, which is also pursued in the rest of this paper.

4.2 Issues in existing KGE models applied to path QA

We now discuss the extension of existing bilinear KGE models to path QA. We begin with RESCAL, which is the most general among existing bilinear models. In RESCAL, if we assume $\mathbf{R}_r^{\mathrm{T}}\mathbf{e}_s \approx \mathbf{e}_o$ for true triplets (s, r, o), we can model path QA as computing

$$\begin{aligned}&\phi_{\text{RESCAL}}(s, r_1/\ldots/r_k, o) \\ &\qquad = \mathbf{e}_s^{\mathrm{T}}\mathbf{R}_{r_1}\cdots\mathbf{R}_{r_k}\mathbf{e}_o. \end{aligned} \tag{6}$$

As seen in this formula, a composite relation is represented by the product of the matrices for atomic relations (Guu et al., 2015).

Likewise, DistMult and ComplEx can also be used for path QA, by computing

$$\begin{aligned}&\phi_{\text{DistMult}}(s, r_1/\ldots/r_k, o) \\ &\qquad = \mathbf{e}_s^{\mathrm{T}}\,\mathrm{diag}(\mathbf{w}_{r_1})\cdots\mathrm{diag}(\mathbf{w}_{r_k})\mathbf{e}_o,\end{aligned}$$

and

$$\phi_{\text{ComplEx}}(s, r_1/\ldots/r_k, o) = \text{Re}(\mathbf{e}_s^{\text{T}} \,\text{diag}(\mathbf{w}_{r_1}) \cdots \text{diag}(\mathbf{w}_{r_k}) \overline{\mathbf{e}_o}),$$

respectively. However, because diagonal matrices are commutative, the score of $(s, r_1/\ldots/r_k, o)$ is equal to any path query in which $r_1, \cdots, r_k$ are permutated, such as $(s, r_k/r_{k-1}/\ldots/r_1, o)$. That is, because $\phi(s, r_1/\ldots/r_k, o) = \phi(s, r_k/r_{k-1}/\ldots/r_1, o)$, their truth values cannot be distinguished by the magnitude of scores. More recent bilinear models such as ANALOGY[3] (Liu et al., 2017) and SimplE (Kazemi and Poole, 2018) also represent relations by diagonal matrices, and thus they can only model commutative relation paths. Moreover, for SimplE, which represents subject and object entities in different vector spaces, it is not clear how it can be applied to path QA.

In the translation-based model TransE (Bordes et al., 2013), the scoring function is given by[4]

$$\phi_{\text{TransE}}(s, r, o) = -||\mathbf{e}_s + \mathbf{w}_r - \mathbf{e}_o||_2^2. \quad (7)$$

Guu et al. (2015) extended this function for a path query by

$$\phi_{\text{TransE}}(s, r_1/\ldots/r_k, , o) = -\|\mathbf{e}_s + \mathbf{w}_{r_1} + \cdots + \mathbf{w}_{r_k} - \mathbf{e}_o\|_2^2. \quad (8)$$

Thus, a composite relation is represented as the sum of the embedding vectors for its constituent atomic relations. Unfortunately, Eq. (8) is also invariant with the permutation of relations $r_1, \ldots, r_k$, and their order is not respected.

5 Knowledge graph embedding with block circulant matrices

5.1 BlockHolE

In this section, we propose a bilinear KGE model suitable for path QA. In this model, the relation matrices are non-commutative. It thus respects the order of relations in a path query. Further, it has a smaller number of parameters than RESCAL in general. To be specific, our model constrains the relation matrices to be block circulant.

A matrix is *block circulant* if it can be written in the form

$$\begin{bmatrix} \mathbf{W}^{(11)} & \cdots & \mathbf{W}^{(1b)} \\ \vdots & \ddots & \vdots \\ \mathbf{W}^{(b1)} & \cdots & \mathbf{W}^{(bb)} \end{bmatrix}, \quad (9)$$

where each $\mathbf{W}^{(ij)} = \text{circ}(\mathbf{w}^{(ij)})$, $i, j = 1, \ldots, b$, is a circulant matrix determined by $\mathbf{w}^{(ij)} \in \mathbb{R}^m$. Thus, if the dimension of the matrix in Eq. (9) is $n \times n$, we have $n = bm$. A block circulant matrix is non-commutative when $b \geq 2$; i.e., for two block circulant matrices $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{bm \times bm}$, $\mathbf{A} \neq \mathbf{B}$, $\mathbf{AB} \neq \mathbf{BA}$ in general.

Substituting a block circulant matrix of Eq. (9) for matrix $\mathbf{R}_r$ in the bilinear scoring function (Eq. (3)) yields

$$\phi_{\text{BlockHolE}}(s, r, o) = \mathbf{e}_s^{\text{T}} \mathbf{R}_r \mathbf{e}_o = \overbrace{[\mathbf{e}_s^{(1)\text{T}} \cdots \mathbf{e}_s^{(b)\text{T}}]}^{\mathbf{e}_s^{\text{T}}} \overbrace{\begin{bmatrix} \mathbf{W}_r^{(11)} & \cdots & \mathbf{W}_r^{(1b)} \\ \vdots & \ddots & \vdots \\ \mathbf{W}_r^{(b1)} & \cdots & \mathbf{W}_r^{(bb)} \end{bmatrix}}^{\mathbf{R}_r} \overbrace{\begin{bmatrix} \mathbf{e}_o^{(1)} \\ \vdots \\ \mathbf{e}_o^{(b)} \end{bmatrix}}^{\mathbf{e}_o}, \quad (10)$$

where $\mathbf{e}_s^{(i)}, \mathbf{e}_o^{(i)} \in \mathbb{R}^m$, and $\mathbf{W}_r^{(ij)} = \text{circ}(\mathbf{w}_r^{(ij)}) \in \mathbb{R}^{m \times m}$, $i, j = 1, \ldots, b$. Recall that $n = bm$, and thus $\mathbf{e}_s, \mathbf{e}_o \in \mathbb{R}^n$, $\mathbf{R}_r \in \mathbb{R}^{n \times n}$. Using equalities $\mathbf{x}^{\text{T}}(\mathbf{y} * \mathbf{z}) = \mathbf{y}^{\text{T}}(\mathbf{x} \star \mathbf{z})$ (Nickel et al., 2016b) and $\text{circ}(\mathbf{x})\mathbf{y} = \mathbf{x} * \mathbf{y}$ to rewrite Eq. (10), we have

$$\begin{aligned} \phi_{\text{BlockHolE}}(s, r, o) &= [\mathbf{e}_s^{(1)\text{T}} \ldots \mathbf{e}_s^{(b)\text{T}}] \begin{bmatrix} \sum_{j=1}^b \mathbf{w}_r^{(1j)} * \mathbf{e}_o^{(j)} \\ \vdots \\ \sum_{j=1}^b \mathbf{w}_r^{(bj)} * \mathbf{e}_o^{(j)} \end{bmatrix} \\ &= \sum_{i=1}^b \mathbf{e}_s^{(i)\text{T}} \left(\sum_{j=1}^b \mathbf{w}_r^{(ij)} * \mathbf{e}_o^{(j)} \right) \\ &= \sum_{i,j=1}^b \mathbf{w}_r^{(ij)\text{T}} \left(\mathbf{e}_o^{(j)} \star \mathbf{e}_s^{(i)} \right). \quad (11) \end{aligned}$$

We call this model *BlockHolE*, after the fact that it reduces to HolE when $b = 1$; cf. Eq. (5). Also, BlockHolE is identical to b-dimensional RESCAL when $m = 1$ (or equivalently $b = n$).

The number of parameters in BlockHolE is $bm|\mathcal{E}| + b^2 m|\mathcal{R}|$ (or $n|\mathcal{E}| + bn|\mathcal{R}|$), and naive

[3] We categorize ANALOGY as a diagonal model because each 2×2 block diagonal element of its relation matrices can be substituted by a single equivalent complex-valued component.

[4] The original TransE defines a *penalty* function, which gives a smaller value if a triplet is more likely to be true. We thus changed the sign to make it a scoring function in Eq. (7).

computation of Eq. (11) takes time $O(b^2 m \log m)$ using FFT. However, we can make this computation faster by exploiting the duality of the Fourier transform, as shown below.

5.2 Fast computation in complex space

Using a similar technique used by Hayashi and Shimbo (2017) to show the equivalence of ComplEx and HolE, we can eliminate Fourier transform to speed up the computation of BlockHolE scores. We first rewrite Eq. (11) as follows:

$$\begin{aligned}
&\phi_{\text{BlockHolE}}(s,r,o) \\
&\quad = \sum_{i,j=1}^{b} \mathbf{w}_r^{(ij)\mathrm{T}}(\mathbf{e}_o^{(j)} \star \mathbf{e}_s^{(i)}) \\
&\quad = \sum_{i,j=1}^{b} \mathbf{w}_r^{(ij)\mathrm{T}}\mathbf{F}^{-1}(\overline{\mathbf{F}\mathbf{e}_o^{(j)}} \odot \mathbf{F}\mathbf{e}_s^{(i)}) \\
&\quad = \frac{1}{m}\sum_{i,j=1}^{b} (\overline{\mathbf{F}\mathbf{w}_r^{(ij)}})^{\mathrm{T}}(\overline{\mathbf{F}\mathbf{e}_o^{(j)}} \odot \mathbf{F}\mathbf{e}_s^{(i)}) \\
&\quad = \frac{1}{m}\sum_{i,j=1}^{b} \mathrm{Re}(\langle \mathbf{F}\mathbf{w}_r^{(ij)}, \overline{\mathbf{F}\mathbf{e}_s^{(i)}}, \mathbf{F}\mathbf{e}_o^{(j)}\rangle),
\end{aligned}$$

where $\mathbf{F}$ is the discrete Fourier matrix. Here we used Eq. (1) to derive the second equation, and $\mathbf{F}^{-1} = (1/m)\overline{\mathbf{F}}^{\mathrm{T}}$ to derive the third. Defining complex vectors $\mathbf{w}'^{(ij)}_r = (1/m)\mathbf{F}\mathbf{w}_r^{(ij)}$, $\mathbf{e}'^{(i)}_s = \overline{\mathbf{F}\mathbf{e}_s^{(i)}}$, and $\mathbf{e}'^{(j)}_o = \overline{\mathbf{F}\mathbf{e}_o^{(j)}}$ yields

$$\begin{aligned}
&\phi_{\text{BlockHolE}}(s,r,o) \\
&\quad = \sum_{i,j=1}^{b} \mathrm{Re}\left(\langle \mathbf{w}'^{(ij)}_r, \mathbf{e}'^{(i)}_s, \overline{\mathbf{e}'^{(j)}_o}\rangle\right). \quad (12)
\end{aligned}$$

On the basis of Eq. (12), we train $\mathbf{e}'^{(i)}_k \in \mathbb{C}^m$ directly in complex space (i.e., the Fourier domain) instead of $\mathbf{e}_k^{(j)} \in \mathbb{R}^m$ and use it as the vector embedding of entity k, for all $k \in \mathcal{E}$; similarly, $\mathbf{w}'^{(ij)}_r \in \mathbb{C}^m$ is directly trained in complex space to represent relation $r \in \mathcal{R}$. The number of parameters in this model is $2n|\mathcal{E}| + 2bn|\mathcal{R}|$, and Eq. (12) can be computed in $O(bn)$ time. Typically, we set $b \ll n$. For instance, in the experiment of Section 6, we set $b = 2$ and $m = 50$, and thus $n = bm = 100$. In this case, factor b is negligible and the computational complexity is linear in n.

		WN11	FB13
Base	Train	112,581	316,232
	Valid	2,609	5,908
	Test	10,544	23,733
Path	Train	2,129,539	6,266,058
	Valid	11,277	27,163
	Test-Deduction	24,749	77,883
	Test-Induction	21,828	31,674

Table 2: Dataset provided by Guu et al. (2015).

5.3 Modeling path QA

BlockHolE can be used in path QA as follows. First, for any $\ell \in \mathcal{E}$ and $r \in \mathcal{R}$, let

$$\begin{aligned}
\mathbf{e}'^{\mathrm{T}}_\ell &= [\mathbf{e}'^{(1)\mathrm{T}}_\ell \cdots \mathbf{e}'^{(b)\mathrm{T}}_\ell], \\
\mathbf{W}'_r &= \begin{bmatrix} \mathrm{diag}(\mathbf{w}'^{(11)}_r) & \cdots & \mathrm{diag}(\mathbf{w}'^{(1b)}_r) \\ \vdots & \ddots & \vdots \\ \mathrm{diag}(\mathbf{w}'^{(b1)}_r) & \cdots & \mathrm{diag}(\mathbf{w}'^{(bb)}_r) \end{bmatrix}.
\end{aligned}$$

Then, Eq. (12) can be rewritten as

$$\phi_{\text{BlockHolE}}(s,r,o) = \mathrm{Re}\left(\mathbf{e}'^{\mathrm{T}}_s \mathbf{W}'_r \overline{\mathbf{e}'}_o\right),$$

and we can compute the score of relation paths by

$$\begin{aligned}
&\phi_{\text{BlockHolE}}(s, r_1/\ldots/r_k, o) \\
&\qquad = \mathrm{Re}(\mathbf{e}'^{\mathrm{T}}_s \mathbf{W}'_{r_1} \ldots \mathbf{W}'_{r_k} \overline{\mathbf{e}'_o}).
\end{aligned}$$

Since $\mathbf{W}'_{r_i}\mathbf{W}'_{r_j} \neq \mathbf{W}'_{r_j}\mathbf{W}'_{r_i}$ for $b \geq 2$, this scoring function respects the order of relations in $r_1/\ldots/r_k$.

6 Experiments

In this section, we report the results of empirical evaluation investigating the commutativity property of bilinear KGE models on the path QA task. As expected, the proposed BlockHolE model, which uses non-commutative relation matrices, outperformed commutative bilinear KGE models.

6.1 Dataset and evaluation protocol

The comparison of KGE models was performed in two path QA tasks: (i) ranking and (ii) binary classification tasks.

6.1.1 Path QA ranking

For the path QA ranking task, we adopted the same protocol and dataset used by Guu et al. (2015). Table 2 shows the statistics of their dataset. The dataset consists of two parts, "Base" and "Path".

	WN11						FB13					
	Base		Deduction		Induction		Base		Deduction		Induction	
	P@10	MQ	P@10	MQ	P@10	MQ	P@10	MQ	P@10	MQ	P@10	MQ
DistMult	45.6	83.0	33.5	97.7	29.6	79.8	62.7	91.6	63.6	86.4	59.3	86.5
ComplEx	60.9	83.1	68.7	99.2	46.1	79.7	76.8	93.0	71.5	90.0	70.5	88.9
RESCAL	51.8	74.2	43.2	97.9	51.2	76.8	65.2	91.1	66.9	88.4	69.8	89.0
$b = 2, m = 25$	**80.9**	**83.4**	**70.2**	**99.5**	**54.9**	**81.0**	**79.2**	**93.2**	**75.0**	**91.5**	**71.3**	**90.0**
$b = 4, m = 25$	80.5	75.6	69.3	99.2	54.5	77.4	76.2	92.1	72.1	90.5	70.9	89.5

Table 3: Path QA ranking result: Comparing BlockHolE ($b = 2, m = 25$ and $b = 4, m = 25$) to other bilinear models. The dimension of the embedding space for DistMult, ComplEx and RESCAL was set to $n = 50$ as the result of grid search.

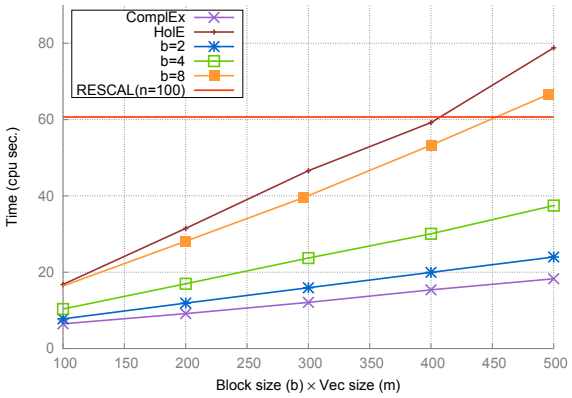

Figure 2: CPU run time per epoch of BlockHolE on WN11 Base with single CPU thread.

The Base part only contains facts (i.e., path queries with $k = 1$), and thus it is essentially for evaluating KGC performance. Its training samples constitute the observed facts $\mathcal{F}$, and the facts in the entire Base part (training/validation/test sets) make the ground truth facts $\mathcal{F}^*$.

The Path part contains path queries sampled from the same $\mathcal{F}$ and $\mathcal{F}^*$ as the Base part. The test samples in the Path part is divided into "deduction" and "induction" sets. In the "deduction" set, test samples were sampled from the Base training graph $\mathcal{G}(\mathcal{F})$. By contrast, in the "induction" set, the test samples were chosen from the ground truth graph $\mathcal{G}(\mathcal{F}^*)$ such that none of them have a corresponding path in $\mathcal{G}(\mathcal{F})$. Thus, the "induction" set is intended to measure how well a model generalizes to unobserved paths, whereas the "deduction" set is to test its ability to faithfully encode the observed training graph.

At the time of evaluation, for each a test sample $(s, r_1/\ldots/r_k, o)$, a *candidate set*

$$\mathcal{T}(r_k) = \{t : \exists h \in \mathcal{E}\ (h, r_k, t) \in \mathcal{F}^*\},$$

was first computed. In other words, the candidates are the entities for which r_k (i.e., the last relation in the test query) takes as its object at least once in $\mathcal{F}^*$. Then, for each compared model, we made the ranking of the candidates entities in $\mathcal{T}(r_k)$ by the score $\phi(s, r_1/\ldots/r_k, e)$, where ϕ is learned by the model from the training set.

The quality of the ranking was measured by two evaluation metrics: averaged mean quantile (MQ) and P@10 (percentage of correct answers ranked in the top 10). For $q = s/p$ where $p = r_1/\ldots/r_k$, the correct answer set $[\![q]\!]$ is the set of all entities that can be reached from s by traversing p over $\mathcal{G}(\mathcal{F}^*)$. Formally, let $[\![s]\!] = \{s\}$, and the answer set can be recursively defined: $[\![q/r]\!] = \{t : \exists h \in [\![q]\!], (h, r, t) \in \mathcal{F}^*\}$. With these definitions, MQ is computed by the following formula:

$$\frac{|\{o' | o' \in \mathcal{N}(q) : \phi(s, p, o') \leq \phi(s, p, o)\}|}{|\mathcal{N}(q)|}, \quad (13)$$

where $\mathcal{N}(q) = \mathcal{T}(r_k) \setminus [\![q]\!]$ is the set of incorrect answers. Eq. (13) cannot be computed for queries with which $\mathcal{T}(r_k) = [\![q]\!]$, and these queries were excluded from evaluation. For further details, see the original paper by Guu et al. (2015).

6.1.2 Path QA classification

In the path QA classification task, we simply report classification accuracy. After the scoring function ϕ was trained with logistic regression, a path query $q = (s, r_1/\ldots/r_k, o)$ was classified as true if $\phi(q) \geq 0$, or false otherwise.

Since the test and validation sets of Path in Table 2 contain only correct queries, we sampled negative ones by the following procedure: For a correct query $q = (s, r_1/\ldots/r_k, o)$ $(k \geq 2)$, we generated its reverse relation path query $q' = (s, r_k/r_{k-1}/\ldots/r_1, o)$. If q' does not exist in $\mathcal{G}(\mathcal{F}^*)$, we used it as a negative.

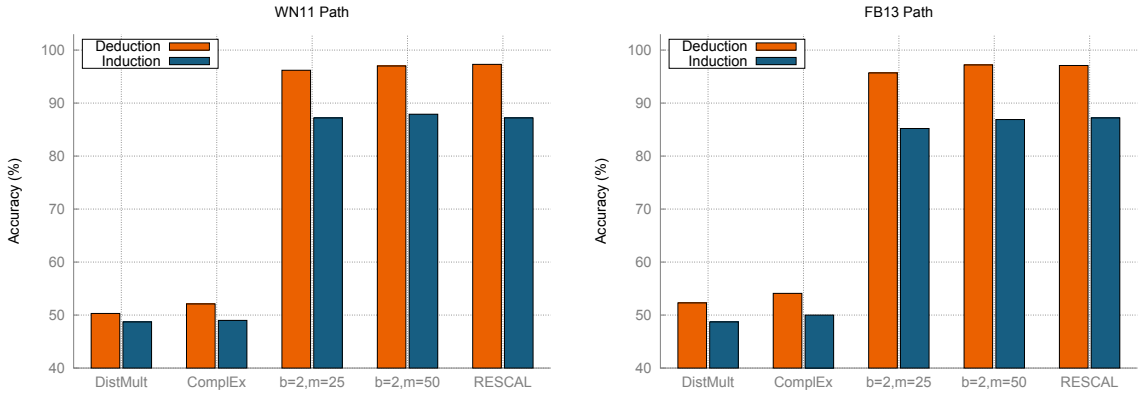

Figure 3: Path QA classification result comparing BlockHolE ($b = 2, m = 25$ and $b = 2, m = 50$) to DistMult, ComplEx and RESCAL models (all with $n = 50$ as the result of grid search).

6.2 Experiment setup

We compared BlockHolE with state-of-the-art bilinear KGE models: DistMult, RESCAL and ComplEx. We have implemented BlockHolE in Java. BlockHolE reduces to ComplEx when $b = 1$, and with the imaginary parts of parameters set to 0, it reduces to RESCAL when $m = 1$ and to DistMult when $b = 1$. For a fair run time comparison, however, we separately implemented RESCAL using jblas-1.2.4 for matrix computation. Through all experiments, we optimized the logistic loss with L2 regularization on the parameters Θ:

$$\min_{\Theta} \sum_{(q,y)\in\mathcal{D}} \log\{1 + \exp(-y\phi(q;\Theta))\} + \lambda||\Theta||_2^2$$

where y denotes the truth value of a query q in a training data $\mathcal{D}$. Given a correct query $q = (s, r_1/\ldots/r_k, o)$, we generated negative samples by replacing o with an entity randomly sampled from $\mathcal{E}$.

We selected the hyperparameters via grid search such that on the validation set they maximize classification accuracy in the path QA classification task and MQ in the path QA ranking task. For all models except BlockHolE, all combinations of $\lambda \in \{0.0001, 0\}$, learning rate $\eta \in \{0.005, 0.01, 0.025, 0.05\}$, and the embedding size $n \in \{50, 100, 150, 200\}$ were tried during grid search. For BlockHolE, all combinations of $(b, m) \in \{(2, 25), (2, 50), (2, 100), (4, 25), (4, 50), (8, 25)\}$, $\lambda \in \{0.0001, 0\}$ and $\eta \in \{0.005, 0.01, 0.025, 0.05\}$ were tried. The maximum number of training epochs was set to 500. The number of negatives generated per positive sample was 5 during training.

Label	Relation Path	ComplEx	BlockHolE
+	*/parents/religion/*	96.7	100.0
-	*/religion/parents/*	3.3	100.0

Table 4: Classification accuracy on selected queries.

6.3 Results

6.3.1 Path QA ranking

Table 3 shows the results on the path QA ranking data. BlockHolE outperforms other bilinear KGE models considerably both on deductive and inductive test settings. These results strongly suggest that BlockHolE is more expressive in modeling path QA than DistMult and ComplEx, while effectively reducing redundant parameters in RESCAL which can cause model overfitting. Figure 2 shows the empirical scalability of BlockHolE. When b is small, BlockHolE scales linearly in the dimension $n = bm$ of the embedding space.

6.3.2 Path QA classification

Figure 3 shows the accuracy of path QA classification. DistMult and ComplEx were considerably worse than BlockHolE and RESCAL for both WN11 and FB13. This result confirms our claim: The non-commutativity of relation matrices plays a critical role in modeling path QA. The performance of BlockHolE ($b = 2, m = 25$) was comparable to that of RESCAL but the former was 12 times faster.

6.4 Analysis

The accuracies of BlockHolE and RESCAL on the path QA classification task were markedly better than those of DistMult and ComplEx. We analyzed the results further. We extracted all queries from

$\mathcal{G}(\mathcal{F}^*)$ of FB13 that consist of an interpretable relation path */parents/religion/* where $*$ denotes "can match any relation path". For such queries $(s, */\text{parents}/\text{religion}/*, o)$, we also generated meaningless queries $(s, */\text{religion}/\text{parents}/*, o)$ as negatives. Table 4 shows the classification accuracies of ComplEx and BlockHolE ($b = 2, m = 25$). The results clearly show that ComplEx cannot correctly answer the negative queries at all due to the lack of the non-commutative property.

7 Summary

In this paper, we have pointed out the problems of existing bilinear KGE models in path QA, and proposed a new model that overcomes these problems. This model, called BlockHolE, represents relations as block circulant matrices. As a result, it respects the order of relations in path queries, while enjoying linear-time computation of scoring functions when the number b^2 of blocks is sufficiently small. It generalizes HolE/ComplEx, and it can also be interpreted as an interpolation between RESCAL and HolE/ComplEx. Its effectiveness was shown empirically in path QA.

Our proposal can be useful in not only path QA but also many tasks such as associative rule mining (Yang et al., 2015), path regularization (Lin et al., 2015), and more complex QA (Hamilton et al., 2018), in which composite relations need to be embedded as a vector. Other future directions include reducing the increased parameters in the proposed block circulant matrices, such as by using multiplicative L1 regularization for ComplEx (Manabe et al., 2018).

Abstract

We tackle the task of question generation over knowledge bases. Conventional methods for this task neglect two crucial research issues: 1) the given predicate needs to be expressed; 2) the answer to the generated question needs to be definitive. In this paper, we strive toward the above two issues via incorporating diversified contexts and answer-aware loss. Specifically, we propose a neural encoder-decoder model with multi-level copy mechanisms to generate such questions. Furthermore, the answer aware loss is introduced to make generated questions corresponding to more definitive answers. Experiments demonstrate that our model achieves state-of-the-art performance. Meanwhile, such generated question can express the given predicate and correspond to a definitive answer.

1 Introduction

Question Generation over Knowledge Bases (KBQG) aims at generating natural language questions for the corresponding facts on KBs, and it can benefit some real applications. Firstly, KBQG can automatically annotate question answering (QA) datasets. Secondly, the generated questions and answers will be able to augment the training data for QA systems. More importantly, KBQG can improve the ability of machines to actively ask questions on human-machine conversations (Duan et al., 2017; Sun et al., 2018). Therefore, this task has attracted more attention in recent years (Serban et al., 2016; Elsahar et al., 2018).

Specifically, KBQG is the task of generating natural language questions according to the input facts from a knowledge base with triplet form, like <subject, predicate, object>. For example, as illustrated in Figure 1, KBQG aims at generating a question "Which city is Statue of Liberty located in?" (Q3) for the input factual triplet

Input	<Statue of Liberty, location/containedby, ***New York City***>		
Output	Matching Predicate	Definite Answer	Question
Q1	×	-	Who **created** the Statue of Liberty?
Q2	√	×	**Where** is Statue of Liberty in?
Q3	√	√	Which ***city*** is Statue of Liberty **located** in?

Figure 1: Examples of KBQG. We aims at generating questions like Q3 which expresses (matches) the given predicate and refers to a definitive answer.

"<Statue of Liberty, location/containedby[1], New York City>". Here, the generated question is associated to the subject "*Statue of Liberty*" and the predicate `fb:location/containedby`) of the input fact, and the answer corresponds to the object "*New York City*".

As depicted by Serban et al. (2016), KBQG is required to transduce the triplet fact into a question about the subject and predicate, where the object is the correct answer. Therefore, it is a key issue for KBQG to correctly understand the knowledge symbols (subject, predicate and object in the triplet fact) and then generate corresponding text descriptions. More recently, some researches have striven toward this task, where the behind intuition is to construct implicit associations between facts and texts. Specifically, Serban et al. (2016) designed an encoder-decoder architecture to generate questions from structured triplet facts. In order to improve the generalization for KBQG, Elsahar et al. (2018) utilized extra contexts as input via distant supervisions (Mintz et al., 2009), then a decoder is equipped with attention and part-of-speech (POS) copy mechanism to generate questions. Finally, this model obtained significant improvements. Nevertheless, we observe that there are still two important research issues (RIs) which are not processed well or even neglected.

[1]We omit the domain of the predicate for sake of brevity.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2431–2441,

RI-1: *The generated question is required to* ***express the given predicate*** *in the fact*. For example in Figure 1, Q1 does not express (match) the predicate (`fb:location/containedby`) while it is expressed in Q2 and Q3. Previous work (Elsahar et al., 2018) usually obtained predicate textual contexts through distant supervision. However, the distant supervision is noisy or even wrong (e.g. "X is the husband of Y" is the relational pattern for the predicate `fb:marriage/spouse`, so it is wrong when "X" is a woman). Furthermore, many predicates in the KB have no predicate contexts. We make statistic in the resources released by Elsahar et al. (2018), and find that only 44% predicates have predicate textual context[2]. Therefore, it is prone to generate error questions from such without-context predicates.

RI-2: *The generated question is required to contain a* ***definitive answer***. A definitive answer means that one question only associates with a determinate answer rather than alternative answers. As an example in Figure 1, Q2 may contain ambiguous answers since it does not express the refined answer type. As a result, different answers including "*United State*", "*New York City*", etc. may be correct. In contrast, Q3 refers to a definitive answer (the object "*New York City*" in the given fact) by restraining the answer type to a city. We believe that Q3, which expresses the given predicate and refers to a definitive answer, is a better question than Q1 and Q2. In previous work, Elsahar et al. (2018) only regarded a most frequently mentioned entity type as the textual context for the subject or object in the triplet. In fact, most answer entities have multiple types, where the most frequently mentioned type tends to be universal (e.g. a broad type "administrative region" rather than a refined type "US state" for the entity "*New York*"). Therefore, generated questions from Elsahar et al. (2018) may be difficult to contain definitive answers.

To address the aforementioned two issues, we exploit more **diversified contexts** for the given facts as textual contexts in an encoder-decoder model. Specifically, besides using predicate contexts from the distant supervision utilized by Elsahar et al. (2018), we further leverage the domain, range and even topic for the given predicate as contexts, which are off-the-shelf in KBs (e.g. the range and the topic for the predicate `fb:location/containedby` are "location" and "containedby", respectively[1]). Therefore, 100% predicates (rather than 44%[2] of those in Elsahar et al.) have contexts. Furthermore, in addition to the most frequently mentioned entity type as contexts used by Elsahar et al. (2018), we leverage the type that best describes the entity as contexts (e.g. a refined entity type[3] "US state" combines a broad type "administrative region" for the entity "New York"), which is helpful to refine the entity information. Finally, in order to make full use of these contexts, we propose context-augmented fact encoder and multi-level copy mechanism (KB copy and context copy) to integrate diversified contexts, where the multi-level copy mechanism can copy from KB and textual contexts simultaneously. For the purpose of further making generated questions correspond to definitive answers, we propose the **answer-aware loss** by optimizing the cross-entropy between the generated question and answer type words, which is beneficial to generate precise questions.

We conduct experiments on an open public dataset. Experimental results demonstrate that the proposed model using diversified textual contexts outperforms strong baselines (+4.5 BLEU4 score). Besides, it can further increase the BLEU score (+5.16 BLEU4 score) and produce questions associated with more definitive answers by incorporating answer-aware loss. Human evaluations complement that our model can express the given predicate more precisely.

In brief, our main contributions are as follows:

(1) We leverage diversified contexts and multi-level copy mechanism to alleviate the issue of incorrect predicate expression in traditional methods.

(2) We propose an answer-aware loss to tackle the issue that conventional methods can not generate questions with definitive answers.

(3) Experiments demonstrate that our model achieves state-of-the-art performance. Meanwhile, such generated question can express the given predicate and refer to a definitive answer.

2 Task Description

We leverage textual contexts concerned with the triplet fact to generate questions over KBs. The

[2]We map the "prop_text_evidence.csv" file to the "property.vocab" file in Elsahar et al. (2018)

[3]We obtain such representative entity types through the predicate `fb:topic/notable_types` in freebase.

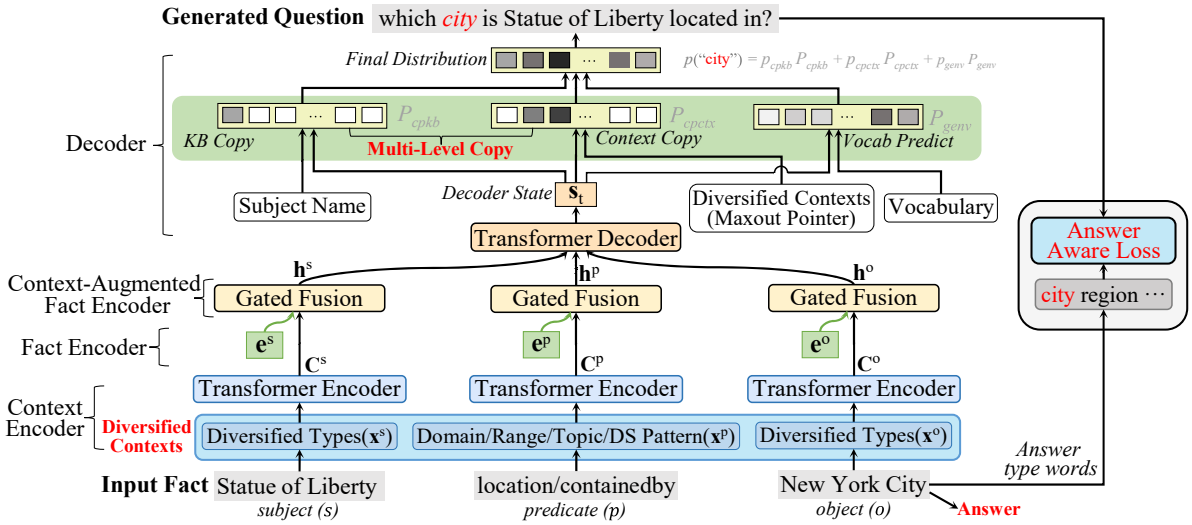

Figure 2: Overall structure of the proposed model for KBQG. A **context encoder** is firstly employed to encode each textual context (Sec. 3.1), where "Diversified Types" represents the subject (object) context, and "DS pattern" denotes the relational pattern from distant supervisions. At the same time, a **fact encoder** transforms the fact into low-dimensional representations (Sec. 3.2). The above two encoders are aggregated by the **context-augmented fact encoder** (Sec. 3.3). Finally, the aggregated representations are fed to the **decoder** (Sec. 3.4), where the decoder leverages multi-level copy mechanism (KB copy and context copy) to generate target question words.

task of KBQG can be formalized as follows:

$$P(Y|F) = \prod_{t=1}^{|Y|} P(y_t|y_{<t}, F, C) \quad (1)$$

where $F = (s, p, o)$ represents the subject (s), predicate (p) and object (o) of the input triplet, $C = \{\mathbf{x}^s, \mathbf{x}^p, \mathbf{x}^o\}$ denotes a set of additional textual contexts, $Y = (y_1, y_2, ..., y_{|Y|})$ is the generated question, $y_{<t}$ represents all previously generated question words before time step t.

3 Methodology

Our model extends the encoder-decoder architecture (Cho et al., 2014b) with three encoding modules and two copy mechanisms in the decoder. The model overview is shown in Figure 2 along with its caption. It should be emphasized that we additionally design an answer-aware loss to make the generated question associated with a definitive answer (Sec. 3.5.2).

3.1 Context Encoder

Inspired by the great success of transformer (Vaswani et al., 2017) in sequence modeling (Shen et al., 2018), we adopt a transformer encoder to encode each textual context separately. Take the subject context $\mathbf{x}^s$ as an example, $\mathbf{x}^s = (x_1^s, x_2^s, ..., x_{|s|}^s)$ is concatenated from diversified types for the subject, and x_i^s is the i-th token in the subject context, $|s|$ stands for the length of the subject context. Firstly, $\mathbf{x}^s$ is mapped into a query matrix $\mathbf{Q}$, where $\mathbf{Q}$ is constructed by summing the corresponding token embeddings and segment embeddings. Similar to BERT (Devlin et al., 2019), segment embeddings are the same for tokens of $\mathbf{x}^s$ but different for that of $\mathbf{x}^p$ (predicate context) or $\mathbf{x}^o$ (object context). Based on the query matrix, transformer encoder works as follows:

$$\mathbf{Q}_j = \mathbf{Q}\mathbf{W}_j^Q, \mathbf{K}_j = \mathbf{K}\mathbf{W}_j^K, \mathbf{V}_j = \mathbf{V}\mathbf{W}_j^V \quad (2)$$

$$head_j = \text{softmax}(\mathbf{Q}_j\mathbf{K}_j^T/\sqrt{d/h})\mathbf{V}_j \quad (3)$$

$$\mathbf{H}^s = \text{Concat}(head_1, head_2, ..., head_h)\mathbf{W}_0 \quad (4)$$

$$\mathbf{N}^s = \text{LayerNorm}(\mathbf{Q} + \mathbf{H}^s) \quad (5)$$

$$\mathbf{C}^s = \max(0, \mathbf{N}^s\mathbf{W}_1 + b_1)\mathbf{W}_2 + b_2 \quad (6)$$

where $\mathbf{K}$ and $\mathbf{V}$ are the key matrix and value matrix, respectively. It is called self-attention because $\mathbf{K}$ and $\mathbf{V}$ are equal to the query matrix $\mathbf{Q} \in \mathbb{R}^{|s|,d}$ in the encoding stage, where d represents the number of hidden units. And h denotes the number of the heads in multi-head attention mechanism of the transformer encoder. It first projects the input matrixes ($\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$) into subspaces h times mapped by different linear projections $\mathbf{W}_j^Q$, $\mathbf{W}_j^K$, $\mathbf{W}_j^V \in \mathbb{R}^{|s|,d/h}$ ($j = 1, 2, ..., h$) in Equation 2. And then h projections perform the scaled dot-product attention to obtain the representation of each head in parallel (Equation 3). Representa-

tions for all parallel heads are concatenated together in Equation 4. After residual connection, layer normalization (Equation 5) and feed forward operation (Equation 6), we can obtain the subject context matrix $\mathbf{C}^s = \{\mathbf{c}_1^s, \mathbf{c}_2^s, ..., \mathbf{c}_{|s|}^s\} \in \mathbb{R}^{|s|,d}$.

Similarly, $\mathbf{C}^p$ and $\mathbf{C}^o$ are obtained from the same transformer encoder for the predicate and object, respectively.

3.2 Fact Encoder

In contrast to general Sequence-to-Sequence (Seq2Seq) model (Sutskever et al., 2014), the input fact is not a word sequence but instead a structured triplet $F = (s, p, o)$. We employ a fact encoder to transform each atom in the fact into a fixed embedding, and the embedding is obtained from a KB embedding matrix. For example, the subject embedding $\mathbf{e}^s \in \mathbb{R}^d$ is looked up from the KB embedding matrix $\mathbf{E}_f \in \mathbb{R}^{k,d}$, where k represents the size of KB vocabulary, and the size of KB embedding is equal to the number of hidden units (d) in Equation 3. Similarly, the predicate embedding $\mathbf{e}^p$ and the object embedding $\mathbf{e}^o$ are mapped from the KB embedding matrix $\mathbf{E}_f$, where $\mathbf{E}_f$ is pre-trained using *TransE* (Bordes et al., 2013) to capture much more fact information in previous work (Elsahar et al., 2018). In our model, $\mathbf{E}_f$ can be pre-trained or randomly initiated (Details in Sec. 4.7.1).

3.3 Context-Augmented Fact Encoder

In order to combine both the context encoder information and the fact encoder information, we propose a context-augmented fact encoder which applies the gated fusion unit (Gong and Bowman, 2018) to integrate the context matrix and the fact embedding. For example, the subject context matrix $\mathbf{C}^s = \{\mathbf{c}_1^s, \mathbf{c}_2^s, ..., \mathbf{c}_{|s|}^s\}$ and the subject embedding vector $\mathbf{e}^s$ are integrated by the following gated fusion:

$$\mathbf{f} = \tanh(\mathbf{W}_f[\mathbf{c}^s, \mathbf{e}^s]) \quad (7)$$

$$\mathbf{g} = \text{sigmoid}(\mathbf{W}_g[\mathbf{c}^s, \mathbf{e}^s]) \quad (8)$$

$$\mathbf{h}^s = \mathbf{g} \odot \mathbf{f} + (1 - \mathbf{g}) \odot \mathbf{e}^s \quad (9)$$

where $\mathbf{c}^s$ is an attentive vector from $\mathbf{e}^s$ to $\mathbf{C}^s$, which is similar to Zhao et al. (2018). The attentive vector $\mathbf{c}^s$ is combined with original subject embedding $\mathbf{e}^s$ as a new enhanced representation $\mathbf{f}$ (Equation 7). And then a learnable gate vector, $\mathbf{g}$ (Equation 8), controls the information from $\mathbf{c}^s$ and $\mathbf{e}^s$ to the final augmented subject vector $\mathbf{h}^s \in \mathbb{R}^d$ (Equation 9), where $\odot$ denotes the element-wise multiplication. Similarly, the augmented predicate vector $\mathbf{h}^p$ and the augmented object vector $\mathbf{h}^o$ are calculated in the same way. Finally, the context-augmented fact representation $\mathbf{H}_f \in \mathbb{R}^{3,d}$ is the concatenation of augmented vectors as follows:

$$\mathbf{H}_f = [\mathbf{h}^s; \mathbf{h}^p; \mathbf{h}^o] \quad (10)$$

3.4 Decoder

The decoder aims at generating a question word sequence. As shown in Figure 2, we also exploit the transformer as the basic block in our decoder. Then we use a multi-level copy mechanism (KB copy and context copy), which allows copying from KBs and textual contexts.

Specifically, we first map the input of the decoder into an embedding representation by looking up word embedding matrix, then we use position embedding (Vaswani et al., 2017) to enhance sequential information. Compared with the transformer encoder in Sec. 3.1, transformer decoder has an extra sub-layer: a fact multi-head attention layer, which is similar to Equation 2-6, where the query matrix is initiated with previous decoder sub-layer while both the key matrix and the value matrix are the augmented fact representation $\mathbf{H}_f$. After feedforward and multiple transformer layers, we obtain the decoder state $\mathbf{s}_t$ at time step t, and then $\mathbf{s}_t$ could be leveraged to generate the target question sequence word by word.

As depicted in Figure 2, we propose multi-level copy mechanism to generate question words. At each time step t, given decoder state $\mathbf{s}_t$ together with input fact F, textual contexts C and vocabulary V, the probabilistic function for generating any target question word y_t is calculated as:

$$P(y_t|\mathbf{s}_t, y_{t-1}, F, C) = p_{genv} P_{genv}(y_t|\mathbf{s}_t, V) + p_{cpkb} P_{cpkb}(y_t|\mathbf{s}_t, F) + p_{cpctx} P_{cpctx}(y_t|\mathbf{s}_t, C) \quad (11)$$

$$p_{genv}, p_{cpkb}, p_{cpctx} = \text{softmax}([\mathbf{s}_t, \mathbf{y}_{t-1}]) \quad (12)$$

where $genv$, $cpkb$ and $cpctx$ denote the vocab generation mode, the KB copy mode and the context copy mode, respectively. In order to control the balance among different modes, we employ a 3-dimensional switch probability in Equation 12, where $\mathbf{y}_{t-1}$ is the embedding of previous generated word, $P_\cdot(\cdot|\cdot)$ indicates the probabilistic score function for generated target word of each mode. In the three probability score functions, P_{vocab} is typically performed by a $softmax$ classifier over

a fixed vocabulary V based on the word embedding similarity, and the details of P_{cpkb} and P_{cpctx} are in the following.

3.4.1 KB Copy

Previous study found that most questions contain the subject name or its aligns in SimpleQuestion (Petrochuk and Zettlemoyer, 2018). However, the predicate name and object name hardly appear in the question. Therefore, we only copy the subject name in the KB copy, where $P_{cpkb}(y_t|\mathbf{s}_t, f)$, the probability of copying the subject name, is calculated by a neural network function with a multilayer perceptron (MLP) projected from $\mathbf{s}_t$.

3.4.2 Context Copy

Elsahar et al. (2018) demonstrated the effectiveness of POS copy for the context. However, such a copy mechanism heavily relies on POS tagging. Inspired by the CopyNet (Gu et al., 2016), we directly copy words in the textual contexts C, and it does not rely on any POS tagging. Specifically, the input sequence χ for the context copy is the concatenation of all words in the textual contexts C. Unfortunately, χ is prone to contain repeated words because it consists of rich contexts for subject, predicate and object. The repeated words in the input sequence tend to cause repetition problems in output sequences (Tu et al., 2016). We adopt the maxout pointer (Zhao et al., 2018) to address the repetition problem. Instead of summing all the probabilistic scores for repeated input words, we limit the probabilistic score of repeated words to their maximum score as Equation 13:

$$P_{cpctx}(y_t|.)=\begin{cases}\max\limits_{m,\, where\ \chi_m=y_t} sc_{t,m} & y_t \in \chi \\ 0 & otherwise\end{cases} \quad (13)$$

where χ_m represents the m-th token in the input context sequence χ, $sc_{t,m}$ is the probabilistic score of generating the token χ_m at time step t, and $sc_{t,m}$ is calculated by a softmax function over χ.

3.5 Learning

3.5.1 Question-Aware Loss

It is totally differential for our model to obtain question words, and it can be optimized in an end-to-end manner by back-propagation. Given the input fact F, additional textual context C and target question word sequence Y, the object function is to optimize the following negative log-likelihood:

$$\mathcal{L}_{ques_loss}=\frac{-1}{|Y|}\sum_{t=1}^{|Y|}\log[P(y_t|\mathbf{s}_t,y_{t-1},F,C)] \quad (14)$$

The question-aware loss $\mathcal{L}_{ques_loss}$ does not require any additional labels to optimize because the three modes share a same softmax classifier to keep a balance (Equation 12), and they can learn to coordinate each other by minimizing $\mathcal{L}_{ques_loss}$.

3.5.2 Answer-Aware loss

It is able to generate questions similar to the labeled questions by optimizing the question-aware loss $\mathcal{L}_{ques_loss}$. However, there is an ambiguous problem in the annotated questions where the questions have alternative answers rather than determinate answers (Petrochuk and Zettlemoyer, 2018). In order to make generated questions correspond to definitive answers, we propose a novel answer-aware loss. By answer-aware loss, we aim at generating an answer type word in the question, which contributes to generating a question word matching the answer type. Formally, the answer-aware loss is in the following:

$$\mathcal{L}_{ans_loss} = \min_{a_n, a_n \in A} \min_{y_t, y_t \in Y} H_{a_n, y_t} \quad (15)$$

where $A = \{a_n\}_{n=1}^{|A|}$ is a set of answer type words. We treat object type words as the answer type words because the object is the answer. H_{a_n,y_t} denotes the cross entropy between the answer type word a_n and the generated question word y_t. Finally, the minimum cross entropy is regarded as the answer-aware loss $\mathcal{L}_{ans_loss}$. Optimizing $\mathcal{L}_{ans_loss}$ means that the model aims at generating an answer type word in the generated question sequence. For example, the model tends to generate Q3 rather than Q2 in Figure 1, because Q3 contains an answer type word—"city". Similarly, $\mathcal{L}_{ans_loss}$ could be optimized in an end-to-end manner, and it can integrate $\mathcal{L}_{ques_loss}$ by a weight coefficient λ to the total loss as follows:

$$\mathcal{L}_{total_loss} = \mathcal{L}_{ques_loss} + \lambda \mathcal{L}_{ans_loss} \quad (16)$$

4 Experiment

4.1 Experimental Settings

4.1.1 Experimental Data Details

We conduct experiments on the SimpleQuestion dataset (Bordes et al., 2015), and there

are 75910/10845/21687 question answering pairs (QA-pairs) for training/validation/test. In order to obtain **diversified contexts**, we additionally employ domain, range and topic of the predicate to improve the coverage of predicate contexts. In this way, 100% predicates (rather than 44%[2] of those in Elsahar et al.) have contexts. For the subject and object context, we combine the most frequently mentioned entity type (Elsahar et al., 2018) with the type that best describe the entity[3]. The KB copy needs subject names as the copy source, and we map entities with their names similar to those in Mohammed et al. (2018). The data details are in Appendix A and submitted Supplementary Data.

4.1.2 Evaluation Metrics

Following (Serban et al., 2016; Elsahar et al., 2018), we adopt some word-overlap based metrics (WBMs) for natural language generation including BLEU-4 (Papineni et al., 2002), ROUGE_L (Lin, 2004) and METEOR (Denkowski and Lavie, 2014). However, such metrics still suffer from some limitations (Novikova et al., 2017). Crucially, it might be difficult for them to measure whether generated questions that express the given predicate and refer to definitive answers. To better evaluate generated questions, we run two further evaluations as follows.

(1) ***Predicate identification***: Following Mohammed et al. (2018), we employ annotators to judge whether the generated question expresses the given predicate in the fact or not. The score for predicate identification is the percentage of generated questions that express the given predicate.

(2) ***Answer coverage***: We define a novel metric called answer coverage to identify whether the generated question refers to a definitive answer. Specifically, answer coverage is obtained by automatically calculating the percentage of questions that contain answer type words, and answer type words are object contexts (entity types for the object are regarded as answer type words).

Furthermore, it is hard to automatically evaluate the naturalness of generated questions. Following Mohammed et al. (2018), we adopt human evaluation to measure the naturalness by a score of 0-5.

4.1.3 Comparison with State-of-the-arts

We compare our model with following methods.

(1) *Template*: A baseline in Serban et al. (2016), it randomly chooses a candidate fact F_c in the training data to generate the question, where F_c shares the same predicate with the input fact.

(2) *Serban et al. (2016)*: We compare our methods with the single placeholder model, which performs best in Serban et al. (2016).

(3) *Elsahar et al. (2018)*: We compare our methods with the model utilizing copy actions, the best performing model in Elsahar et al. (2018). Although this model is designed to a zero-shot setting (for unseen predicates and entity type), it has good abilities to generate better questions (on known or unknown predicates and entity types) represented in the additional context input and SPO copy mechanism.

4.1.4 Implementation Details

To make our model comparable to the comparison methods, we keep most parameter values the same as Elsahar et al. (2018). We utilize RMSProp algorithm with a decreasing learning rate (0.001), batch size (200) to optimize the model. The size of KB embeddings is 200, and KB embeddings are pre-trained by TransE (Bordes et al., 2013). The word embeddings are initialized by the pre-trained Glove word vectors[4] with 200 dimensions. In the transformer, we set the hidden units d to 200, and we employ 4 paralleled attention head and a stack of 5 identical layers. We set the weight (λ) of the answer-aware loss to 0.2.

4.2 Overall Comparisons

Model	BLEU4	ROUGE_L	METEOR
Template	31.36	*	33.12
Serban et al. (2016)	33.32	*	35.38
Elsahar et al. (2018)	36.56	58.09	34.41
Our Model	41.09	68.68	47.75
Our $\text{Model}_{\text{ans_loss}}$	**41.72**	**69.31**	**48.13**

Table 1: Overall comparisons on the test data, where "ans_loss" represents answer-aware loss.

In Table 1, we compare our model with the typical baselines on word-overlap based metrics. It is evident that our model is remarkably better than baselines on all metrics, where the BLEU4 score increases 4.53 compared with the strongest baseline (Elsahar et al., 2018). Especially, incorporating answer-aware loss (the last line in Table 1) further improves the performance (+5.16 BLEU4).

4.3 Performances on Predicate Identification

To evaluate the ability of our model on predicate identification, we sample 100 generated question-

[4]http://nlp.stanford.edu/data/glove.6B.zip

Model	Pred. Identification
Serban et al. (2016)	53.5
Elsahar et al. (2018)	71.5
Our Model$_{\text{ans_loss}}$	**75.5**

Table 2: Performances on predicate identification.

s from each model, and then two annotators are employed to judge whether the generated question expresses the given predicate. The Kappa for inter-annotator statistics is 0.611, and p-value for all scores is less than 0.005. As shown in Table 2, we can see that our model has a significant improvement in the predicate identification.

4.4 Performances on Answer Coverage — The Effectiveness of Answer-Aware Loss

Model	λ	BLEU4	Ans$_{\text{cov}}$
Elsahar et al. (2018)	0	36.56	59.49
Our Model	0	41.09	61.65
Our Model$_{\text{ans_loss}}$	0.05	41.55	62.27
Our Model$_{\text{ans_loss}}$	0.2	**41.72**	64.23
Our Model$_{\text{ans_loss}}$	0.5	41.57	**65.50**
Our Model$_{\text{ans_loss}}$	1.0	41.34	65.25

Table 3: Performances on answer coverage, where "Ans$_{\text{cov}}$" denotes the metric of answer coverage. "λ" is the weight of the answer-aware loss in Equation 16.

Table 3 reports performances on BLUE4 and answer coverage (Ans$_{\text{cov}}$). We can obtain that:

(1) When answer-aware loss is not leveraged ($\lambda = 0$), advantages of performance are obvious in our model. Note that the answer coverage is 55.23 on the human-labeled questions. Although our model does not explicitly capture answer information, it still obtains a high answer coverage, which may be because our diversified contexts contain rich answer type words.

(2) To demonstrate the effectiveness of answer-aware loss, we set the weight of answer-aware loss (λ) to 0.05/0.2/0.5/1.0 (the last four lines in Table 3). It can be seen that our model, incorporating answer-aware loss, has a significant improvement on answer coverage while there is no performance degradation on BLEU4 compared with $\lambda = 0$, which indicates that answer-aware loss contributes to generating better questions. Especially, the generated questions are more precise because they refer to more definitive answers with high Ans$_{\text{cov}}$.

(3) It tends to correspond to alternative answers (object in the triplet fact) for some predicates such as `fb:location/containedby`, while other predicates (e.g. `fb:person/gender`) may refer to a definitive answer. To investigate our model, by incorporating answer-aware loss, does not generate an answer type word in a mandatory way, we found 20.5% predicate corresponds to the generated questions without answer type words when our model obtains the highest Ans$_{\text{cov}}$ (λ=0.5), and it is very close to 21.7% for the one in human-annotated questions. This demonstrates that the answer-aware loss does not force all predicates to generate questions with answer type words.

4.5 Ablation Study

Model	BLEU4	ROUGE$_{\text{L}}$	METEOR
Our Model$_{\text{ans_loss}}$	**41.72**	**69.31**	**48.13**
w/o context copy	41.27	68.36	47.54
w/o KB copy	41.04	68.66	47.72
w/o answer-aware loss	41.09	68.68	47.75
w/o diversified contexts	40.53	68.52	47.66

Table 4: Ablation study by removing the main components, where "w/o" means without, and "w/o diversified contexts" represents that diversified contexts are replaced by contexts used in Elsahar et al. (2018).

In order to validate the effectiveness of model components, we remove some important components in our model, including context copy, KB copy, answer-aware loss and diversified contexts. The results are shown in Table 4. We can see that removing any component brings performance decline on all metrics. It demonstrates that all these components are useful. Specifically, the last line in Table 4, replacing diversified contexts with contexts used in Elsahar et al. (2018), has more obvious performance degradation.

4.6 Performances on Naturalness

Model	Naturalness
Serban et al. (2016)	2.96
Elsahar et al. (2018)	2.23
Our Model$_{\text{ans_loss}}$	**3.56**

Table 5: Performances on naturalness.

Human evaluation is important for generated questions. Following Elsahar et al. (2018), we sample 100 questions from each system, and then two annotators measure the naturalness by a score of 0-5. The Kappa coefficient for inter-annotator is 0.629, and p-value for all scores is less than 0.005. As shown in Table 5, Elsahar et al. (2018) perform poorly on naturalness, while our model obtains the

highest score on naturalness, which demonstrates our model can deliver more natural questions than baselines.

4.7 Discussion

4.7.1 Without Pre-trained KB Embeddings

Model	TransE	BLEU4	ROUGE_L	METEOR
Elsahar et al. (2018)	True	36.56	58.09	34.41
Elsahar et al. (2018)	False	33.67	55.57	33.20
Our $\text{Model}_{\text{ans_loss}}$	True	41.72	69.31	48.13
Our $\text{Model}_{\text{ans_loss}}$	False	41.55	68.59	47.52

Table 6: Performances of whether using the pre-trained KB embedding by transE.

Pre-trained KB embeddings may provide rich structured relational information among entities. However, it heavily relies on large-scale triplets, which is time and resource-intensive. To investigate the effectiveness of pre-trained KB embedding for KBQG, we report the performance of KBQG whether using pre-trained KB embeddings by simply applying TransE. Table 6 shows that the performance of KBQG is degraded without TransE embeddings. In comparison, Elsahar et al. (2018) obtain obvious degradation on all metrics while there is only a slight decline in our model. We believe that it may owe to the context-augmented fact encoder since our model drops to 40.87 on the BLEU4 score without context-augmented fact encoder and transE embeddings.

4.7.2 The Effectiveness of Generated Questions for Enhancing Question Answering over Knowledge Bases

Data Type	Accuracy
human-labeled data	68.97
+ gen_data (Serban et al., 2016)	68.53
+ gen_data (Elsahar et al., 2018)	69.13
+ gen_data (Our $\text{Model}_{\text{ans_loss}}$)	**69.57**

Table 7: Performances of generated questions for QA.

Previous experiments demonstrate that our model can deliver more precise questions. To further prove the effectiveness of our model, we will see how useful the generated questions are for training a question answering system over knowledge bases. Specifically, we combine human-labeled data with the same amount of model-generated data to a typical QA system (Mohammed et al., 2018). The accuracy of QA is shown in Table 7. We can observe that adding generative questions may weaken the performance of QA (drop from 68.97 to 68.53 in Table 7). Our generated questions achieve the best performance on the QA system. It indicates that our model generates more precise question and has improved QA performances greatly.

4.7.3 Speed

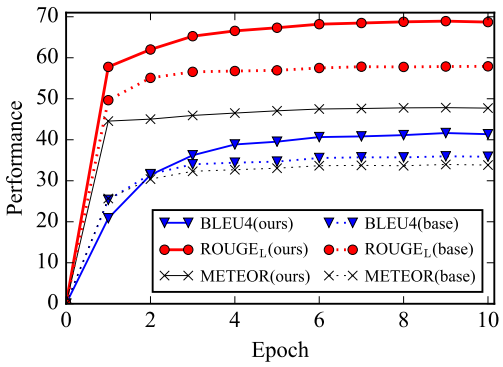

Figure 3: Performance on valid data through epochs, where "base" is the method in Elsahar et al. (2018).

In order to further explore the convergence speed, we plot the performances on valid data through epochs in Figure 3. Our model has much more information to learn, and it may have a bad impact on the convergence speed. Nevertheless, our model can copy KB elements and textual context simultaneously, which may accelerate the convergence speed. As demonstrated in Figure 3, our model achieves the best performances on almost epochs. After about 6 epochs, performances on our model become stable and convergent.

4.7.4 Case Study

Figure 4 lists referenced question and generated questions by different models. It can be seen that our generated questions can better express the target predicate such as ID 1 (marked as underline). In ID 2, although all questions express the target predicate correctly, only our question refers to a definitive answer since it contains an answer type word "city" (marked as **bold**). It should be emphasized that the questions, generated by our method with answer-aware loss, do not always contain answer type words (ID 1 and 3).

5 Related Work

Our work is inspired by a large number of successful applications using neural encoder-decoder

ID	Model	Question

Figure 4: Examples of questions by different models.

frameworks on NLP tasks such as machine translation (Cho et al., 2014a) and dialog generation (Vinyals and Le, 2015). Our work is also inspired by the recent work for KBQG based on encoder-decoder frameworks. Serban et al. (2016) first proposed a neural network for mapping KB facts into natural language questions. To improve the generalization, Elsahar et al. (2018) introduced extra contexts for the input fact, which achieved significant performances. However, these contexts may make it difficult to generate questions that express the given predicate and associate with a definitive answer. Therefore, we focus on the two research issues: expressing the given predicate and referring to a definitive answer for generated questions.

Moreover, our work also borrows the idea from copy mechanisms. Point network (Vinyals et al., 2015) predicted the output sequence directly from the input, and it can not generate new words while CopyNet (Gu et al., 2016) combined copying and generating. Bao et al. (2018) proposed to copy elements in the table (KB). Elsahar et al. (2018) exploited POS copy action to better capture textual contexts. To incorporate advantages from above copy mechanisms, we introduce KB copy and context copy which can copy KB element and textual context, and they do not rely on POS tagging.

6 Conclusion and Future Work

In this paper, we focus on two crucial research issues for the task of question generation over knowledge bases: generating questions that express the given predicate and refer to definitive answers rather than alternative answers. For this purpose, we present a neural encoder-decoder model which integrates diversified off-the-shelf contexts and multi-level copy mechanisms. Moreover, we design an answer-aware loss to generate questions that refer to definitive answers. Experiments show that our model achieves state-of-the-art performance on automatic and manual evaluations.

For future work, we investigate error cases by analyzing the error distributions of 100 examples. We find that most generated questions (51%) are judged by the human to correctly express the input facts, but they unfortunately obtain low scores on the widely used metrics. It implies that it is still intractable to evaluate generated questions. Although we additionally evaluate on predicate identification and answer coverage, these metrics may be coarse and deserve further study.

Abstract

We consider the problem of conversational question answering over a *large-scale* knowledge base. To handle huge entity vocabulary of a large-scale knowledge base, recent neural semantic parsing based approaches usually decompose the task into several subtasks and then solve them sequentially, which leads to following issues: 1) errors in earlier subtasks will be propagated and negatively affect downstream ones; and 2) each subtask cannot naturally share supervision signals with others. To tackle these issues, we propose an innovative multi-task learning framework where a pointer-equipped semantic parsing model is designed to resolve coreference in conversations, and naturally empower joint learning with a novel type-aware entity detection model. The proposed framework thus enables shared supervisions and alleviates the effect of error propagation. Experiments on a large-scale conversational question answering dataset containing 1.6M question answering pairs over 12.8M entities show that the proposed framework improves overall F1 score from 67% to 79% compared with previous state-of-the-art work.

1 Introduction

Recent decades have seen the development of AI-driven personal assistants (e.g., Siri, Alexa, Cortana, and Google Now) that often need to answer factorial questions. Meanwhile, large-scale knowledge base (KB) like DBPedia (Auer et al., 2007) or Freebase (Bollacker et al., 2008) has been built to store world's facts in a structure database, which is used to support open-domain question answering (QA) in those assistants.

Neural semantic parsing based approach (Jia and Liang, 2016; Reddy et al., 2014; Dong and Lapata, 2016; Liang et al., 2016; Dong and Lapata, 2018; Guo et al., 2018) is gaining rising attention for knowledge-based question answer (KB-QA) in recent years since it does not rely on handcrafted features and is easy to adapt across domains. Traditional approaches usually retrieve answers from a small KB (e.g., small table) (Jia and Liang, 2016; Xiao et al., 2016) and are difficult to handle large-scale KBs. Many recent neural semantic parsing based approaches for KB-QA take a stepwise framework to handle this issue. For example, Liang et al. (2016), Dong and Lapata (2016), and Guo et al. (2018) first use an entity linking system to find entities in a question, and then learn a model to map the question to logical form based on that. Dong and Lapata (2018) decompose the semantic parsing process into two stages. They first generate a rough sketch of logical form based on low-level features, and then fill in missing details by considering both the question and the sketch.

However, these stepwise approaches have two issues. First, errors in upstream subtasks (e.g., entity detection and linking, relation classification) are propagated to downstream ones (e.g., semantic parsing), resulting in accumulated errors. For example, case studies in previous works (Yih et al., 2015; Dong and Lapata, 2016; Xu et al., 2016; Guo et al., 2018) show that entity linking error is one of the major errors leading to wrong predictions in KB-QA. Second, since models for the subtasks are learned independently, the supervision signals cannot be shared among the models for mutual benefits.

To tackle issues mentioned above, we propose a novel multi-task semantic parsing framework for KB-QA. Specifically, an innovative pointer-equipped semantic parsing model is first designed for two purposes: 1) built-in pointer network toward positions of entity mentions in the question

can naturally empower multi-task learning with conjunction of upstream sequence labeling subtask, i.e., entity detection; and 2) it explicitly takes into account the context of entity mentions by using the supervision of the pointer network. Besides, a type-aware entity detection method is proposed to produce accurate entity linking results, in which, a joint prediction space combining entity detection and entity type is employed, and the predicted type is then used to filter entity linking results during inference phase.

The proposed framework has certain merits.

First, since the two subtasks, i.e., pointer-equipped semantic parsing and entity detection, are closely related, learning them within a single model simultaneously makes the best of supervisions and improves performance of KB-QA task.

Second, considering entity type prediction is crucial for entity linking, our joint learning framework combining entity mention detection with type prediction leverages contextual information, and thus further reduces errors in entity linking.

Third, our approach is naturally beneficial to coreference resolution for conversational QA due to rich contextual features captured for entity mention, compared to previous works directly employing low-level features (e.g., mean-pooling over word embeddings) as the representation of an entity. This is verified via our experiments in §4.2.

We evaluate the proposed framework on the CSQA (Saha et al., 2018) dataset, which is the largest public dataset for complex conversational question answering over a large-scale knowledge base. Experimental results show that the overall F1 score is improved by 12.56% compared with strong baselines, and the improvements are consistent for all question types in the dataset.

2 Task Definition

In this work, we target the problem of conversational question answering over a large-scale knowledge base. Formally, in training data, question U denotes an user utterance from a dialog, which is concatenated dialog history for handling ellipsis or coreference in conversations, and the question is labeled with its answer A. Besides, "IOB" (Insider-Outside-Beginning) tagging and entities linking to KB are also labeled for entity mentions in U to train an entity detection model.

We employ a neural semantic parsing based approach to tackle the problem. That is, given a question, a semantic parsing model is used to produce a logical form which is then executed on the KB to retrieve an answer. We decompose the approach into two subtasks, i.e., entity detection for entity linking and semantic parsing for logical form generation. The former employs IOB tagging and corresponding entities as supervision, while the latter uses a gold logical form as supervision, which may be obtained by conducting intensive BFS[1] over KB if only final answers (i.e., weak supervision) are provided.

3 Approach

This section begins with a description of grammars and logic forms used in this work. Then, the proposed model is presented, and finally, model's training and inference are introduced.

[1] Breadth-first search with limited buffer (Guo et al., 2018)

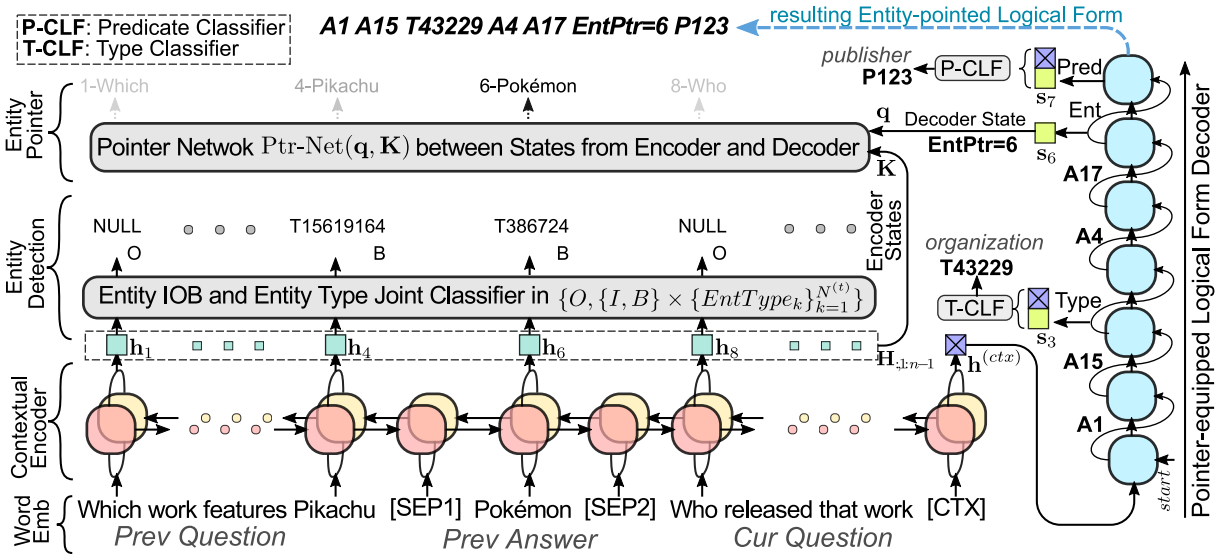

Figure 1: Proposed **M**ulti-t**a**sk **S**emantic **P**arsing (MaSP) model. Note that P* and T* are predicate and entity type ids in Wikidata where entity type id originally starts with Q but is replaced with T for clear demonstration.

3.1 Grammar and Logical Form

Grammar We use similar grammars and logical forms as defined in Guo et al. (2018), with minor modification for better adaptation to the CSQA dataset. The grammars are briefly summarized in Table 1, where each operator consists of three components: semantic category, a function name, and a list of arguments with specified semantic categories. Semantic categories can be classified into two groups here w.r.t. the ways for instantiation: one is referred to as *entry* semantic category (i.e., $\{e, p, tp, u_num\}$ for entities, predicates, types, numbers) whose instantiations are constants parsed from a question, and another is referred to as *intermediate* semantic category (i.e., $\{start, set, num, bool\}$) whose instantiation is the output of an operator execution.

Logical Form A KB-executable logical form is intrinsically formatted as an ordered tree where the root is the semantic category $start$, each child node is constrained by the nonterminal (i.e., the un-instantiated semantic category in parenthesis) of its parent operator, and leaf nodes are instantiated entry semantic categories, i.e., constants.

To make the best of well-performed sequence to sequence (seq2seq) models (Vaswani et al., 2017; Bahdanau et al., 2015) as a base for semantic parsing, we represent a tree-structured logical form as a sequence of operators and constants via depth-first traversal over the tree. Note, given guidance of grammars, we can recover corresponding tree structure from a sequence-formatted logical form.

3.2 Proposed Model

The structure of our proposed **M**ulti-t**a**sk **S**mantic **P**arsing (MaSP) model is illustrated in Figure 1. The model consists of four components: i.e., word embedding, contextual encoder, entity detection and pointer-equipped logical form decoder.

3.2.1 Embedding and Contextual Encoder

To handle ellipsis or coreference in conversations, our model takes current user question combined with dialog history as the input question U. In particular, all those sentences are concatenated with a *[SEP]* separated, and then a special token *[CTX]* is appended. We apply wordpiece tokenizing (Wu et al., 2016) method, and then use a word embedding method (Mikolov et al., 2013) to transform the tokenized question to a sequence of low-dimension distributed embeddings, i.e., $\boldsymbol{X} = [\boldsymbol{x_1}, \cdots, \boldsymbol{x_n}] \in \mathbb{R}^{d_e \times n}$ where d_e denotes embedding size and n denotes question length.

Given word embeddings $\boldsymbol{X}$, we use stacked two-layer multi-head attention mechanism in the Transformer (Vaswani et al., 2017) with learnable positional encodings as an encoder to model contextual dependencies between tokens, which results in context-aware representations $\boldsymbol{H} = [\boldsymbol{h_1}, \cdots, \boldsymbol{h_n}] \in \mathbb{R}^{d_e \times n}$. And, contextual embedding for token *[CTX]* is used as the semantic representation for entire question, i.e., $\boldsymbol{h^{(ctx)}} \triangleq \boldsymbol{h_n}$

3.2.2 Pointer-Equipped Decoder

Given contextual embeddings $\boldsymbol{H}$ of a question, we employ stacked two-layer masked attention mechanism in (Vaswani et al., 2017) as the decoder to produce sequence-formatted logical forms.

In each decoding step, the model first predicts a token from a small decoding vocabulary $\mathbb{V}^{(dec)}$ = $\{start, end, e, p, tp, u_num, \text{A1}, \cdots, \text{A21}\}$, where $start$ and end indicate the start and end of decoding, $A1, \cdots, A21$ are defined in Table 1, and e, p, tp and u_num denote entity, predicate, type and number entries respectively. A neural classifier is established to predict current decoding token, which is formally denoted as

$$\boldsymbol{p_j^{(tk)}} = \text{softmax}(\text{FFN}(\boldsymbol{s_j}; \theta^{(tk)})), \quad (1)$$

where $\boldsymbol{s_j}$ is decoding hidden state of current (i.e., j-th) step, $\text{FFN}(\cdot;\theta)$ denotes a θ-parameterized two-layer feed forward network with an activation function inside, and $\boldsymbol{p_j^{(tk)}} \in \mathbb{R}^{|\mathbb{V}^{(dec)}|}$ is a predicted distribution over $\mathbb{V}^{(dec)}$ to score candidates[2].

Then, a $\text{FFN}(\cdot)$ or a pointer network (Vinyals et al., 2015) is utilized to predict instantiation for entry semantic category (i.e., e, p, tp or u_num in $\mathbb{V}^{(vec)}$) if it is necessary.

- For predicate p and type tp, two parameter-untied $\text{FFN}(\cdot)$ are used as

$$\boldsymbol{p_j^{(p)}} = \text{softmax}(\text{FFN}([\boldsymbol{s_j}; \boldsymbol{h^{(ctx)}}]; \theta^{(p)})), \quad (2)$$

$$\boldsymbol{p_j^{(t)}} = \text{softmax}(\text{FFN}([\boldsymbol{s_j}; \boldsymbol{h^{(ctx)}}]; \theta^{(t)})), \quad (3)$$

  where $\boldsymbol{h^{(ctx)}}$ is semantic embedding of entire question, $\boldsymbol{s_j}$ is current hidden state, $\boldsymbol{p_j^{(p)}} \in \mathbb{R}^{N^{(p)}}$ and $\boldsymbol{p_j^{(t)}} \in \mathbb{R}^{N^{(t)}}$ are predicted distributions over the predicate and type instantiation candidates respectively, and $N^{(p)}$ and $N^{(t)}$ are the numbers of distinct predicates and types in the knowledge base.

- For entity e and number u_num, two parameter-untied pointer-networks (Vinyals et al., 2015) with learnable bilinear layer are employed to point toward the targeted entity[3] and number, which are defined as follows.

$$\boldsymbol{p_j^{(e)}} = \text{softmax}(\boldsymbol{s_j^T W^{(e)} H}_{:,1:n-1}), \quad (4)$$

$$\boldsymbol{p_j^{(n)}} = \text{softmax}(\boldsymbol{s_j^T W^{(n)} H}_{:,1:n-1}), \quad (5)$$

  where $\boldsymbol{H}_{:,1:n-1}$ is contextual embedding of tokens in the question except *[CTX]*, $\boldsymbol{W^{(e)}}$ and $\boldsymbol{W^{(n)}}$ are weights of pointer-network for entity and number, $\boldsymbol{p_j^{(e)}}, \boldsymbol{p_j^{(n)}} \in \mathbb{R}^{n-1}$ are the resulting distributions over positions of input question, and n is the length of the question.

The pointer network is also used for semantic parsing in (Jia and Liang, 2016), where the pointer aims at copying out-of-vocabulary words from a question over small-scale KB. Different from that, the pointer used here aims at locating the targeted entity and number in a question, which has two advantages. First, it handles the coreference problem by considering the context of entity mentions in the question. Second, it solves the problem caused by huge entity vocabulary, which reduces the size of decoding vocabulary from several million (i.e., the number of entities in KB) to several dozen (i.e., the length of the question).

3.2.3 Entity Detection and Linking

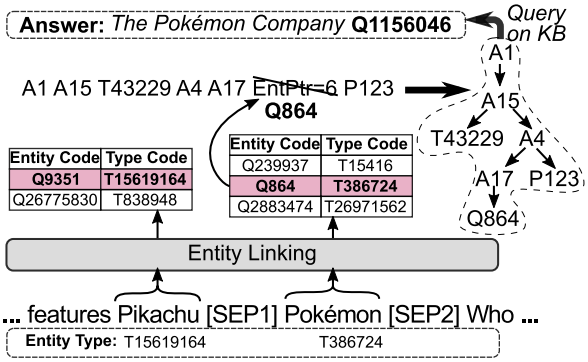

Figure 2: Transformation from entity-pointed logical form to KB-executable logical form for KB querying.

To map the pointed positions to entities in KB, our model also detects entity mentions for the input question, as shown as the "Entity Detection" part of Figure 1.

We observe that multiple entities in a large-scale KB usually have same entity text but different types, leading to named entity ambiguity. Therefore, we design a novel type-aware entity detection module in which the prediction is fulfilled in a joint space of IOB tagging and corresponding entity type for disambiguation. Particularly, the prediction space is defined as $\mathbb{E} = \{O, \{I, B\} \times \{ET_k\}_{k=1}^{N^{(t)}}\}$ where ET_k stands for the k-th entity type label, $N^{(t)}$ denotes number of distinct entity types in KB, and $|\mathbb{E}| = 2 \times N^{(t)} + 1$.

[2]Superscript in bracket denotes the type instead of index.
[3]Toward the first one if entity consists of multiple words.

The prediction for both entity IOB tagging and entity type is formulated as

$$\boldsymbol{p_i^{(ed)}}=\text{softmax}(\text{FFN}(\boldsymbol{h_i};\theta^{(ed)})),\forall i\in[1,n-1] \quad (6)$$

where $\boldsymbol{h_i}$ is the contextual embedding of the i-th token in the question, and $\boldsymbol{p_i^{(ed)}} \in \mathbb{R}^{|\mathbb{E}|}$ is the predicted distribution over $\mathbb{E}$.

Given the predicted IOB labels and entity types, we take the following steps for entity linking. First, the predicted IOB labels are used to locate all entities in the question and return corresponding entity mentions. Second, an inverted index built on the KB is leveraged to find entity candidates in KB based on each entity mention. Third, the jointly predicted entity types are used to filter out the candidates with unwanted types, and the remaining entity with the highest inverted index score is selected to substitute the pointer. This process is shown as the bottom part of Figure 2.

During inference phase, the final logical form is derived by replacing entity pointers in entity-pointed logical form from §3.2.2 with entity linking results, and is then executed on the KB to retrieve an answer for the question, as shown as the top part of Figure 2.

3.3 Learning and Inference

Model Learning During the training phase, we first search gold logical forms for questions in training data over KB if only weak supervision is provided. Then we conduct multi-task learning for semantic parsing and entity detection. The final loss is defined as

$$L = \alpha L^{(sp)} + L^{(ed)}, \quad (7)$$

where $\alpha > 0$ is a hyperparameter for a tradeoff between semantic parsing and entity detection, and $L^{(sp)}$ and $L^{(ed)}$ are negative log-likelihood losses of semantic parsing and entity detection defined as follows.

$$L^{(sp)} = -\frac{1}{|\mathcal{D}|}\sum_{\mathcal{D}}\frac{1}{m}\sum_{j=1}^{m}\log \boldsymbol{p_j^{(tk)}}_{[tk'=y_j^{(tk)}]} \quad (8)$$
$$+\sum_{c\in\{p,t,e,n\}} I_{(y_j^{(tk)}=c)} \log \boldsymbol{p_j^{(c)}}_{[c'=y_j^{(c)}]}$$

$$L^{(ed)} = -\frac{1}{|\mathcal{D}|}\sum_{\mathcal{D}}\frac{1}{n-1}\sum_{i=1}^{n-1}\log \boldsymbol{p_i^{(ed)}}_{[ed'=y_i^{(ed)}]} \quad (9)$$

In the two equations above, $y_j^{(tk)}$ is gold label for decoding token in $\mathbb{V}^{(dec)}$; $y_j^{(p)}, y_j^{(t)}, y_j^{(e)}$ and $y_j^{(n)}$ are gold labels for predicate, type, entity position and number position for instantiation; $\boldsymbol{p_j^{(tk)}}$, $[\boldsymbol{p_j^{(c)}}]_{c\in\{p,t,e,n\}}$, and $\boldsymbol{p_j^{(ed)}}$ are defined in Eq.(1-6) respectively; and m denotes the decoding length.

Here, we use a single model to handle two subtasks simultaneously, i.e., semantic parsing and entity detection. This multi-task learning framework enables each subtask to leverage supervision signals from the others, and thus improves the final performance for KB-QA.

Grammar-Guided Inference The grammars defined in Table 1 are utilized to filter illegal operators out in each decoding step. An operator is legitimate if its left-hand semantic category in the definition is identical to the leftmost nonterminal (i.e., un-instantiated semantic category) in the incomplete logical form parsed so far. In particular, the decoding of a logical form begins with the semantic category $start$. During decoding, the proposed semantic parsing model recursively rewrites the leftmost nonterminal in the logical form by 1) applying a legitimate operator for an intermediate semantic category, or 2) instantiation for one of entity, predicate, type or number for an entry semantic category. The decoding process for the parsing terminates until no nonterminals remain.

Furthermore, beam search is also incorporated to boost the performance of the proposed model during the decoding. And, the early stage execution is performed to filter out illegal logical forms that lead to empty intermediate result.

4 Experiments

4.1 Experimental Settings

Dataset We evaluated the proposed approach on Complex Sequential Question Answering (CSQA) dataset[4] (Saha et al., 2018), which is the largest dataset for conversational question answering over large-scale KB. It consists of about 1.6M question-answer pairs in ∼200K dialogs, where 152K/16K/28K dialogs are used for train/dev/test. Questions are classified as different types, e.g., simple, comparative reasoning, logical reasoning questions. Its KB is built on Wikidata[5] in a form of (subject, predicate, object), and consists of 21.2M triplets over 12.8M entities, 3,054 distinct entity types, and 567 distinct predicates.

Table 2: Comparisons with baselines on CSQA. The last column consists of differences between MaSP and D2A.

Training Setups We leveraged a BFS method to search valid logical forms for questions in training data. The buffer size in BFS is set to 1000. Both embedding and hidden sizes in the model are set to $300D$, and no pretrained embeddings are loaded for initialization, and the positional encodings are randomly initialized and learnable. The head number of multi-head attention is 6 and activation function inside $\mathrm{FFN}(\cdot)$ is $\mathrm{Gelu}(\cdot)$ (Hendrycks and Gimpel, 2016). We used Adam (Kingma and Ba, 2015) to optimize the loss function defined in Eq.(7) where α is set to 1.5, and learning rate is set to 10^{-4}. The training batch size is 128 for 6 epochs. And we also employed learning rate warmup within the first 1% steps and linear decay within the rest. The source codes are available at `https://github.com/taoshen58/MaSP`.

Evaluation Metrics We used the same evaluation metrics as Saha et al. (2018) and Guo et al. (2018). F1 score (i.e., precision and recall) is used to evaluate the question whose answer is comprised of entities, and accuracy is used to measure the question whose answer type is boolean or number.

Baselines There are few works targeting conversational question answering over a large-scale knowledge base. HRED+KVmem (Saha et al., 2018) and D2A (Guo et al., 2018) are two typical approaches, and we compared them with our proposed approach. Particularly, HRED+KVmem is a memory network (Sukhbaatar et al., 2015; Li et al., 2017) based seq2seq model, which combines HRED model (Serban et al., 2016) with key-value memory network (Miller et al., 2016). D2A[6] is a memory augmented neural symbolic model for semantic parsing in KB-QA, which introduces dialog memory manager to handle ellipsis and coreference problems in conversations.

4.2 Model Comparisons

We compared our approach (denoted as MaSP) with HRED+KVmem and D2A in Table 2. As shown in the table, the semantic parsing based D2A significantly outperforms the memory network based text generation approach (HRED+KVmem), which thus poses a strong baseline. Further, our proposed approach (MaSP) achieves a new state-of-the-art performance, where the overall F1 score is improved by $\sim$12%. Besides, the improvement is consistent for all question types, which ranges from 2% to 25%.

There are two possible reasons for this significant improvement. First, our approach predicts entities more accurately, where the accuracy of entities in final logical forms increases from 55% to 72% compared with D2A. Second, the proposed pointer-equipped logical form decoder in the multi-task learning framework handles coreference better. For instance, given an user question with history, "*What is the parent organization of that one? // Did you mean Polydor Records ? // No, I meant Deram Records. Could you tell me the answer for that?*" with coreference, D2A produces "(*find* {*Polydor Records*}, *owned by*)" and in contrast our approach produces "(*find* {*Deram Records*}, *owned by*)". This also explains the substantial improvement for *Simple Question (Coreferenced)* and *Clarification*[7].

[6]Overall score of D2A reported in this paper is superior to that in the original paper since our re-implemented grammars for CSQA achieve a better balance between the simple and non-simple question types. For rational and fair comparisons, we report re-run results for D2A in this paper.

[7]In CSQA, the performance of *Clarification* closely depends on F1 score for next question, 88% of which belong to

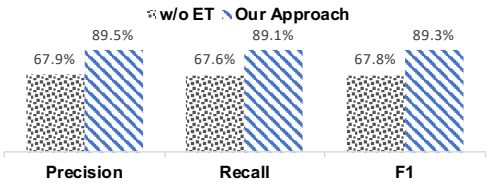

Figure 3: Performance of entity linking. "w/o ET" denotes removing entity type filtering.

We also observed that the improvement of MaSP over D2A for some question types is relatively small, e.g., 1.73% for logical reasoning questions. A possible reason is that there are usually more than one entities are needed to compose the correct logical form for logical reasoning questions, and our current model is too shallow to parse the multiple entities. Hence, we adopted deeper model and employed BERT (Devlin et al., 2018) as the encoder (latter in §4.4), and found that the performance of logical reasoning questions is improved by 10% compared to D2A.

4.3 Ablation Study

Methods	Ours	w/o ET	w/o Multi	w/o Both
Question Type	F1	F1	F1	F1
Overall	79.26%	70.42%	76.73%	68.22%
Clarification	80.79%	68.01%	66.30%	54.64%
Comparative	68.90%	66.35%	61.12%	58.04%
Logical	69.04%	62.63%	67.81%	62.51%
Quantitative	73.75%	73.75%	64.56%	64.55%
Simple (Co-ref)	76.47%	64.94%	74.35%	63.15%
Simple (Direct)	85.18%	75.24%	84.93%	75.19%
Simple (Ellipsis)	83.73%	78.45%	82.66%	77.44%
Question Type	Accu	Accu	Accu	Accu
Verification	60.63%	45.40%	60.43%	45.02%
Quantitative	43.39%	39.70%	37.84%	43.39%
Comparative	22.26%	19.08%	18.24%	22.26%

Table 3: Ablation study. "w/o ET" stands for removing entity type prediction in Entity Detection of §3.2.3; "w/o Multi" stands for learning two subtasks separately in our framework; and "w/o Both" stands for a combination of "w/o ET" and "w/o Multi".

There are two aspects leading to performance improvement, i.e., predicting entity type in entity detection to filter candidates, and multi-task learning framework. We conducted an ablation study in Table 3 for in-depth understanding of their effects.

Effect of Entity Type Prediction (w/o ET) First, the entity type prediction was removed from the entity detection task, which results in 9% drop of overall F1 score. We argue that the performance of the KB-QA task is in line with that of entity linking. Hence, we separately evaluated the entity linking task on the test set. As illustrated in Figure 3, both precision and recall of entity linking drop significantly without filtering the entity linking results w.r.t. the predicted entity type, which verifies our hypothesis above.

Simple Question(Coreference) .

Accuracy	Ours	w/o Multi
Entity pointer	79.8%	79.3%
Predicate	96.9%	96.3%
Type	86.8%	84.1%
Number	89.1%	88.3%
Operators	79.4%	78.7%

Table 4: Prediction accuracy on each component composing the pointer-equipped logical form.

Effect of Multi-Task Learning (w/o Multi) Second, to measure the effect of multi-task learning, we evaluated the KB-QA task when the two subtasks, i.e., pointer-equipped semantic parsing and entity detection, are learned separately. As shown in Table 3, the F1 score for every question type consistently drops in the range of 3% to 14% compared with that with multi-task learning. We further evaluated the effect of multi-task learning on each subtask. As shown in Table 4, the accuracy for each component of the pointer-equipped logical form drops with separate learning. Meanwhile, we found 0.1% F1 score reduction (99.4% vs. 99.5%) for entity detection subtask compared to the model without multi-task learning, which only poses a negligible effect on the downstream task. To sum up, the multi-task learning framework increases the accuracy of the pointer-based logical form generation while keeping a satisfactory performance of entity detection, and consequently improves the final question answering performance.

Note that, considering a combination of removing the entity type filter and learning two subtasks separately (i.e., w/o Both in Table 3), the proposed framework will degenerate to a model that is similar to Coarse-to-Fine semantic parsing model, another state-of-the-art KB-QA model over small-scale KB (Dong and Lapata, 2018). Therefore, an improvement of 11% of F1 score also verifies the advantage of our proposed framework.

4.4 Model Setting Analysis

As introduced in §4.1 and evaluated in §4.2, the proposed framework is built on a relatively shal-

Methods	Vanilla	w/ BERT	w/ Large Beam
Question Type	F1	F1	F1
Overall	79.26%	80.60%	81.55%
Clarification	80.79%	79.46%	83.37%
Comparative	68.90%	65.99%	69.34%
Logical	69.04%	77.53%	69.41%
Quantitative	73.75%	70.43%	73.75%
Simple (Co-ref)	76.47%	77.95%	79.03%
Simple (Direct)	85.18%	86.40%	88.28%
Simple (Ellipsis)	83.73%	84.82%	86.96%
Question Type	Accuracy	Accuracy	Accuracy
Verification	60.63%	63.85%	61.96%
Quantitative	43.39%	47.14%	44.22%
Comparative	22.26%	25.28%	22.70%

Table 5: Comparisons with different experimental settings. "Vanilla" stands for standard settings of our framework, i.e, MaSP. "w/ BERT" stands for incorporating BERT. And "w/ Large Beam" stands for increasing beam search size from 4 to 8.

low neural network, i.e., stacked two-layer multi-head attention, which might limit its representative ability. Hence, in this section, we further exploited the performance of the proposed framework by applying more sophisticated strategies.

As shown in Table 5, we first replaced the encoder with pre-trained BERT base model (Devlin et al., 2018) and fine-tuned parameters during the training phase, which results in 1.3% F1 score improvement over the vanilla one. Second, we increased beam search size from 4 to 8 during the decoding in the inference phase for the standard settings, which leads to 2.3% F1 score increase.

4.5 Error Analysis

We randomly sampled 100 examples with wrong logical forms or incorrect answers to conduct an error analysis, and found that the errors mainly fall into the following categories.

Entity Ambiguity Leveraging entity type as a filter in entity linking significantly reduces errors caused by entity ambiguity, but it is still possible that different entities with same text belong to the same type, due to coarse granularity of the entity type, which results in filtering invalidity. For example, it is difficult to distinguish between two persons whose names are both *Bill Woods*.

Wrong Predicted Logical Form The predicted components (e.g., operators, predicates and types) composing the logical form would be inaccurate, leading to a wrong answer to the question or an un-executable logical form.

Spurious Logical Form We took a BFS method to search gold logical forms for questions in training set, which inevitably generates spurious (incorrect but leading to correct answers coincidentally) logical forms as training signals. Take the question "*Which sexes do King Harold, Queen Lillian and Arthur Pendragon possess*" as an example, a spurious logical form only retrieves the genders of "*King Harold*" and "*Queen Lillian*", while it gets correct answers for the question. Spurious logical forms accidentally introduce noises into training data and thus negatively affect the performance of KB-QA.

5 Related Work

Our work is aligned with semantic parsing based approach for KB-QA. Traditional semantic parsing systems typically learn a lexicon-based parser and a scoring model to construct a logical form given a natural language question (Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Zettlemoyer and Collins, 2009; Kwiatkowski et al., 2011; Andreas et al., 2013; Artzi and Zettlemoyer, 2013; Zhao and Huang, 2014; Long et al., 2016). For example, Zettlemoyer and Collins (2009) and Artzi and Zettlemoyer (2013) learn a CCG parser, and Long et al. (2016) develop a shift-reduce parser to construct logical forms.

Neural semantic parsing approaches have been gaining rising attention in recent years, eschewing the need for extensive feature engineering (Jia and Liang, 2016; Ling et al., 2016; Xiao et al., 2016). Some efforts have been made to utilize the syntax of logical forms (Rabinovich et al., 2017; Krishnamurthy et al., 2017; Cheng et al., 2017; Yin and Neubig, 2017). For example, Dong and Lapata (2016) and Alvarez-Melis and Jaakkola (2017) leverage an attention-based encoder-decoder framework to translate a natural language question to tree-structured logical form.

Recently, to handle huge entity vocabulary existing in a large-scale knowledge base, many works take a stepwise approach. For example, Liang et al. (2016), Dong and Lapata (2016), and Guo et al. (2018) first process questions using a name entity linking system to find entity candidates, and then learn a model to map a question to a logical form based on the candidates. Dong and Lapata (2018) decompose the task into two stages: first, a sketch of the logical form is predicted, and then a full logical form is generated with consid-

ering both the question and the predicted sketch.

Our proposed framework also decomposes the task into multiple subtasks but is different from existing works in several aspects. First, inspired by pointer network (Vinyals et al., 2015), we replace entities in a logical form with the starting positions of their mentions in the question, which can be naturally used to handle coreference problem in conversations. Second, the proposed pointer-based semantic parsing model can be intrinsically extended to jointly learn with entity detection for fully leveraging all supervision signals. Third, we alleviate entity ambiguity problem in entity detection & linking subtask, by incorporating entity type prediction into entity mention IOB labeling to filter out the entities with unwanted types.

6 Conclusion

We studied the problem of conversational question answering over a *large-scale* knowledge base, and proposed a multi-task learning framework which learns for type-aware entity detection and pointer-equipped logical form generation simultaneously. The multi-task learning framework takes full advantage of the supervisions from all subtasks, and consequently increases the performance of final KB-QA problem. Experimental results on a large-scale dataset verify the effectiveness of the proposed framework. In the future, we will test our proposed framework on more datasets and investigate potential approaches to handle spurious logical forms for weakly-supervised KB-QA.

BiPaR: A Bilingual Parallel Dataset for Multilingual and Cross-lingual Reading Comprehension on Novels

Yimin Jing , Deyi Xiong* and **Yan Zhen**
School of Computer Science and Technology, Soochow University, Suzhou, China
{yymmjing,corezhen}@gmail.com
dyxiong@suda.edu.cn

Abstract

This paper presents *BiPaR*, a **bi**lingual **pa**rallel novel-style machine **r**eading comprehension (MRC) dataset, developed to support multilingual and cross-lingual reading comprehension. The biggest difference between BiPaR and existing reading comprehension datasets is that each triple (Passage, Question, Answer) in BiPaR is written parallelly in two languages. We collect 3,667 bilingual parallel paragraphs from Chinese and English novels, from which we construct 14,668 parallel question-answer pairs via crowdsourced workers following a strict quality control procedure. We analyze BiPaR in depth and find that BiPaR offers good diversification in prefixes of questions, answer types and relationships between questions and passages. We also observe that answering questions of novels requires reading comprehension skills of coreference resolution, multi-sentence reasoning, and understanding of implicit causality, etc. With BiPaR, we build monolingual, multilingual, and cross-lingual MRC baseline models. Even for the relatively simple monolingual MRC on this dataset, experiments show that a strong BERT baseline is over 30 points behind human in terms of both EM and F1 score, indicating that BiPaR provides a challenging testbed for monolingual, multilingual and cross-lingual MRC on novels. The dataset is available at https://multinlp.github.io/BiPaR/.

1 Introduction

Machine reading comprehension is to evaluate how well computer systems understand natural language texts, where machines read a given text passage and answer questions about the passage. It has been regarded as a crucial technology for many applications such as question answering, dialogue systems (Nguyen et al., 2016; Chen et al., 2017; Liu et al., 2018; Wang et al., 2018) and so on. In order to enable machine to understand texts, large-scale reading comprehension datasets have been developed, such as CNN/Daily Mail (Hermann et al., 2015), SQuAD (Rajpurkar et al., 2016), MS MACRO (Nguyen et al., 2016), hotpotQA (Yang et al., 2018), CoQA (Reddy et al., 2019), etc.

Figure 1: Illustration of BiPaR with the monolingual, multilingual and cross-lingual MRC on the dataset.

The majority of such datasets, unfortunately, are only for monolingual text understanding. To the best of our knowledge, there is no publicly available bilingual parallel reading comprehension dataset, which is exactly what BiPaR is mainly developed for, as illustrated in Figure 1. BiPaR

produces over 14K Chinese-English parallel questions from nearly 4K bilingual parallel novel passages with consecutive word spans from these passages as answers, following SQuAD (Rajpurkar et al., 2016). Table 1 shows that BiPaR has two significant differences in comparison with existing datasets: (1) each (Passage, Question, Answer) triple is bilingual parallel, and (2) passages and questions are from novels. BiPaR's bilinguality and novel-based questions provide an interesting corner and unexplored territory for MRC.

With an in-depth analysis on the manually created questions, we observe that answering these novel-style questions requires challenging skills: coreference resolution, multi-sentence reasoning, and understanding of implicit causality, etc. Further monolingual MRC experiments on BiPaR demonstrate that, the English BERT_large model (Devlin et al., 2019) achieves an F1 score of 56.5%, which is 35.4 points behind human performance (91.9%), and the Chinese BERT_Base model achieves an F1 score of 64.1%, which is 28.0 points behind human performance (92.1%), indicating there is a huge gap to be bridged for MRC on novels.

More interestingly, the bilinguality of BiPaR supports multilingual and cross-lingual MRC tasks on this dataset in addition to the traditional monolingual MRC. It is more cost-effective to build a single model that can handle machine reading comprehension on multiple languages, than building multiple MRC systems, one reading system for each language. Different from previous multilingual QA systems that are trained on independently developed datasets of different languages and domains, we are able to train a single multilingual MRC model to do MRC on different languages, by exploring BiPaR that is built parallelly on two different languages with alignments between triples of (Passage, Question, Answer) of the two languages, as shown in Figure 1.

Yet another interesting task that we can do with BiPaR is cross-lingual reading comprehension. We define two types of cross-lingual MRC on BiPaR: (1) using questions in one language to find answers from passages written in another language and (2) finding answers from passages of two different languages for questions in one language. The former is in essence similar to the early cross-lingual question answering (CLQA) (Aceves-Pérez et al., 2008; Peñas et al., 2009; Pérez et al., 2009). The intuitive approaches to CLQA are to translate the questions into the document's language (Sutcliffe et al., 2005; de Pablo-Sánchez et al., 2005; Aceves-Pérez et al., 2007), which, however, suffers from translation errors. The BiPaR dataset provides a potential opportunity for building cross-lingual MRC that does not rely on machine translation.

To summarize, our contributions are threefold:

- We build the BiPaR, the first publicly available bilingual parallel dataset for MRC. The passages are novel paragraphs, originally written in Chinese or English and then translated into the other language. The questions are manually constructed undergoing a strict quality control procedure.
- We conduct an in-depth analysis on BiPaR, which reveals that MRC on novels is very challenging, requiring skills of coreference resolution, inter-sentential reasoning, implicit causality understanding, etc.
- We build monolingual, multilingual and cross-lingual MRC baseline models on BiPaR and provides baseline results as well as human performance on this dataset.

2 Related Work

MRC Datasets and Models Large-scale cloze-style datasets, such as CNN/Daily Mail (Hermann

et al., 2015), have been automatically developed in the early days of MRC. Several neural network models have been proposed and tested on these datasets, such as ASReader (Kadlec et al., 2016), StanfordAttentiveReader (Chen et al., 2016), AoAReader (Cui et al., 2017), etc. However, Chen et al. (2016) argue that such datasets may be noisy due to the automatic data creation method and co-reference errors. Rajpurkar et al. (2016) propose SQuAD, a dataset created from English Wikipedia, where questions are manually generated by crowdsourced workers, and answers are spans in the Wikipedia passages. Along with the development of this dataset, a variety of neural MRC models have been proposed, such as BiDAF (Seo et al., 2016), R-NET (Wang et al., 2017), ReasonNet (Shen et al., 2017), DCN (Xiong et al., 2016), QANet (Yu et al., 2018), SAN (Liu et al., 2018), etc. Recent years have witnessed substantial progress made on this dataset. However, there are some limitations on SQuAD, which lie in that questions are created based on single passages, that answers are limited to a single span in passages, and that most questions can be answered from a single supporting sentence without requiring multi-sentence reasoning (Chen, 2018). To address these limitations, a number of datasets have be built recently, such as MS MARCO (Nguyen et al., 2016), DuReader (He et al., 2018), TriviaQA (Joshi et al., 2017), RACE (Lai et al., 2017), NarrativeQA (Kocisky et al., 2018), SQuAD2.0 (Rajpurkar et al., 2018), hotpotQA (Yang et al., 2018), CoQA (Reddy et al., 2019), etc. These datasets and models are only for monolingual text understanding. By contrast, BiPaR, following these efforts of creating challenging MRC datasets, aims at setting up a new benchmark dataset for MRC on novels and bilingual/cross-lingual MRC.

Multilingual MRC and Datasets Previous studies on multilingual MRC are very limited. Asai et al. (2018) propose a multilingual MRC system by translating the target language into a pivot language via runtime machine translation. They still rely on SQuAD to train the MRC model of the pivot language. No multilingual MRC dataset is created except that a Japanese and French test set is created by manually translating the test set of SQuAD into the two languages.

Multilingual/Cross-lingual QA Answering questions in multiple languages or retrieving answers from passages that are written in a language different from questions is an important capability for QA systems. To achieve this goal, QA@CLEF[1] has organized a series of public evaluations for multilingual/cross-lingual QA (Magnini et al., 2006). Widely-used approaches to multilingual/cross-lingual QA are to build monolingual QA systems and then adapt them to multilingual/cross-lingual settings via machine translation (Lin et al., 2005). Such QA systems are prone to being affected by machine translation errors. Hence, various techniques have been proposed to reduce the errors of the machine translation module (Sutcliffe et al., 2005; de Pablo-Sánchez et al., 2005; Aceves-Pérez et al., 2007).

3 Dataset Creation

In this section, we elaborate on the three stages of our dataset creation process: collecting bilingual parallel passages, crowdsourcing question-answer pairs on those passages, and constructing multiple answers for the development and test set.

3.1 Bilingual Parallel Passage Collection

We select bilingual parallel passages from six Chinese and English novels with different topics, including Chinese martial arts, science fictions, fantasy literature, etc. These novels are either written in Chinese and translated into English or vice versa. Automatic paragraph alignments between Chinese and English are available for these novels. The number of words in each Chinese passage in parallel passages is limited in the range of $[120, 600]$, to make the passage not too short or too long for crowdsourced workers to construct questions. As some of bilingual parallel passages are very difficult to understand and create parallel questions, we need to consider the appropriateness of these passages. The following rules are used to select bilingual parallel passages:

- The Chinese passage shall not contain poetry, couplets, or classical Chinese words/phrases.
- The passage shall not contain too much dialogue, where speakers are difficult to recognize without global context.
- The Chinese passage shall not contain full-passage description of Kongfu fighting. Such

[1] http://www.clef-initiative.eu/track/qaclef

descriptions on fighting are hard to translate in a direct way into a target language (i.e., English in this dataset).

- In order to ensure the correct alignments of Chinese and English passages, if an English passage has over 10 words fewer than its Chinese counterpart, such automatically aligned bilingual passages shall not be selected as they are normally not translations of each other.

Following these selection rules, we finally collect 3,667 bilingual parallel passages. Table 2 provides the number of selected passages from each novel.

3.2 Question-Answer Pair Crowdsourcing

We then ask our bilingual crowdsourced workers to create questions and answers on these collected passages. We develop a crowdsourcing annotation system and 150 bilingual workers, 3 bilingual reviewers and 1 expert participate in the data annotation process. The collected bilingual parallel passages are divided into 150 groups and randomly assigned to the bilingual workers. They will create bilingual parallel questions and find corresponding answers to the questions after reading the bilingual parallel passages. Particularly, we encourage workers to create questions according to the following rules:

- For each parallel passage, at least three bilingual question-answer pairs are to be created.
- If the answers in Chinese and English are not parallel (i.e., not translations of each other), the corresponding questions shall be deleted and new questions shall be created.
- Answers have to be consecutive spans in passages.
- If possible, questions of how and why are preferred.
- It is not suggested to directly copy words from passages for creating questions.

In order to guarantee the quality of created question-answer pairs, we use a strict quality control procedure during data annotation. In particular, 30% annotated data from each group are randomly sampled and passed to the three reviewers who will review all answers created by the workers and correct answers if they consider they are wrong. Then, 5% of the reviewed data will be further sampled from each reviewer. The sampled data will be checked again by the expert. If the accuracy is lower than 95%, the corresponding workers and reviewers need to revise the answers again. This quality control loop is executed three times.

Novels	#Parallel Passages	#Avg EN/ZH tokens
I	1,948	251.3/195.9
II	75	223.3/194.6
III	490	206.4/190.1
IV	245	175.1/188.9
V	87	190.7/189.8
VI	822	202.4/212.3
Total	3,667	227.3/198.2

Table 2: Statistics on the selected passages (I: *The Duke of the Mount Deer* /《鹿鼎记》, II: *Demi-Gods and Semi-Devils* /《天龙八部》, III: *The Three-Body Problem* /《三体》, IV: *The Great Gatsby* /《了不起的盖茨比》, V: *The Old Man and the Sea* /《老人与海》, VI: *Harry Potter* /《哈利波特》).

At last, we collect 14,668 question-answer pairs along with their corresponding passages. We randomly partition the annotated data into a training set (with 11,668 QA pairs), a development set (1,500 QA pairs), and a test set (1,500 QA pairs).

3.3 Multiple Answers Construction

In order to make evaluation more robust, we ask crowdsourced workers to create at least two additional answers for each question in the development and test sets, similar to SQuAD (Rajpurkar et al., 2016). But differently, we make the answers from the crowdsourced workers visible to each other, and encourage them to annotate different but reasonable answers. The reason for creating multiple amswers is that we often encounter situations where multiple answers are correct. Consider the following example from SQuAD[2]:

P: Official corporal punishment, often by caning, remains commonplace in schools in some Asian, African and Caribbean countries. For details of individual countries see School corporal punishment.

Q:What countries is corporal punishment still a normal practice?

The ground truth answers of the question are *some Asian, African and Caribbean countries /*

[2]https://rajpurkar.github.io/SQuAD-explorer/explore/1.1/dev/

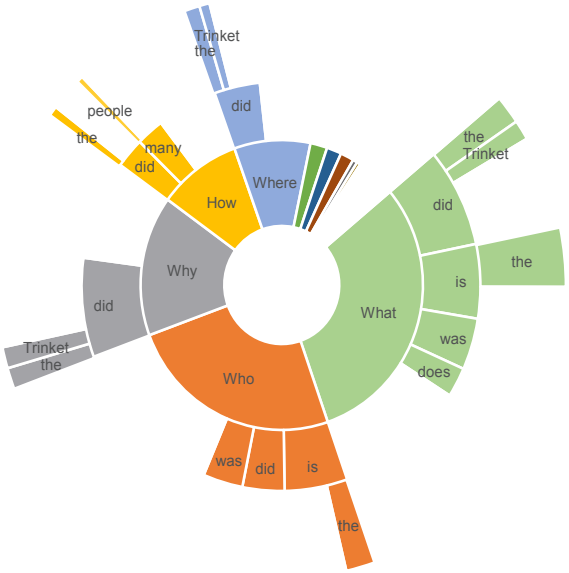

Figure 2: Visualization of the distribution of trigram prefixes of questions in BiPaR.

Asian, African and Caribbean. The prediction of BERT (Devlin et al., 2019) ensemble model is *Asian, African and Caribbean countries*. In fact, the machine-predicted result is also correct. However, it will be considered as a wrong answer if the exact match metric is used since the answer is not in the ground truth answer list. Such cases can be avoided if multiple reasonable answers are annotated.

4 Dataset Analysis

In this section, we analyze the the types of questions and answers, the relationships of questions with passages as well as reading skills covered in BiPaR. Due to the bilingual parallelism of BiPaR, we choose the English part of the dataset for analyses.

4.1 Prefixes of Questions

Figure 2 shows the distribution of trigram prefixes of questions in BiPaR. Unlike SQuAD (Rajpurkar et al., 2018) where nearly half of questions are dominated by *what* questions, the question type distribution in BiPaR is of better dispersion over multiple question types. In particular, BiPaR has 15.6% *why* and 9.5% *how* questions. Since in the novel texts, causality is usually not represented by explicit expressions such as "why", "because", and "the reason for", answering these questions in BiPaR requires the MRC models to understand implicit causality (Section 4.3). The *why* and *how* questions, which account for considerable proportions, undoubtedly make BiPaR a very challenging MRC dataset.

Answer Type	%	Examples
Person	23	Trinket
Location	13	the floor
Date	6	Saturday morning
Verb phrase	2	wash her face
Yes/No	2	-
Adjective	3	jade-green
Event	2	Quidditch practice
Other proper noun	4	a pinch of Floo powder
Common noun	8	secret vault
Description	37	wand backfired

Table 3: Statistics on answer types in BiPaR.

4.2 Answers Types

We sample 100 examples from the development set, and present the types of answers in Table 3. As is shown, BiPaR covers a broad range of answer types, which matches our analysis on questions contribution. Moreover, we find that a large number of questions require some descriptive sentences to answer (37%), which are generally complete sentences or summary statements, etc (See the third example in Table 4). These answers are usually corresponding to *what/why/how* questions, for instances:

1) ***What*** *is Ding Yi doing?*
2) ***Why*** *is fighting so much less fun?*
3) ***How*** *did the protagonist treat her?*

4.3 Relationships of Questions with Passages and Reading Comprehension Skills

In order to assess how difficult to answer questions in BiPaR, we further analyze the relationships between questions and corresponding passages as well as reading comprehension skills required to detect answers for BiPaR questions. We sample 100 samples from the development set and annotate them with various reasoning phenomena as shown in Table 4.

Inspired by Reddy et al. (2019), we group questions into several categories in terms of their relationships with passages. If a question contains more than one content word that appears in the passage, we label it as *lexical match*. These account for 49.0% of all the questions. One might think that if a lot of words in a question overlap with those in a passage, the answer may be easily detected from the matched sentence in the passage. However, this is not the case at all in BiPaR. As the first example in Table 4 shows, the question is almost the same to the sentence in passage. However, the answer is far away from the matched

Phenomenon	Example	%
	Relationship between a question and its passage	
Lexical match	$\mathbf{P}_{en}$: ... **Doublet** flew into the attack, flailing around her like the wind. She was too small to reach the bodies of her enemies, ...jabbing the Vital Points on the riders' legs. $\mathbf{P}_{zh}$: ... **双儿**出手如风，只是敌人骑在马上，她身子又矮，打不到敌人，... 便戳中敌人腿上的穴道。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: Who did jab the Vital Points on the riders' legs? / 谁戳中敌人腿上的穴道?	49
Paraphrasing	$\mathbf{P}_{en}$: ... Getting very difficult ter find anyone fer **the Dark Arts job**. $\mathbf{P}_{zh}$: ... 现在找一个**黑魔法防御术课老师**很困难，人们都不大想干，觉得这工作不吉利。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: What occupation do people avoid? / 人们不愿从事什么职业?	27
Summary	$\mathbf{P}_{en}$: ... As soon as he opened the door to Ding Yi's brand-new three-bedroom apartment, ... **The apartment was unfinished, with only a few pieces of furniture and little decoration, and the huge living room seemed very empty. The most eye-catching object was the pool table in the corner**. $\mathbf{P}_{zh}$: ... 推开丁仪那套崭新的三居室的房门，... 看到**房间还没怎么装修，也没什么家具和陈设，宽大的客厅显得很空，最显眼的是客厅一角摆放的一张台球桌**。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: What does Ding Yi's three-bedroom look like now? / 丁仪的三居室现在是什么样?	24
	Reading comprehension skills required to answer questions	
Coreference resolution	$\mathbf{P}_{en}$: Trying hard to bear all this in mind, Harry took a ... he opened his mouth and immediately swallowed a lot of hot ash."D-**Dia-gon Alley**," he coughed. $\mathbf{P}_{zh}$: 哈利拼命把这些都记在心里，... 他一张嘴，马上吸了一大口滚烫的烟灰。"对一**对角巷**。"他咳着说。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: Where did Harry go? / 哈利去了哪儿?	31
Multi-sentence reasoning	$\mathbf{P}_{en}$: and heard a woman's voice cry out from within it: 'Stop! Lay down your arms! We should all be friends here!' ... The cart stopped in front of them, and out jumped—**Fang Yi**. $\mathbf{P}_{zh}$: 车中一个女子声音叫道："是自己人，别动手！" ... 小车驶别跟前，车中跃出一人，正是**方怡**。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: Who did stop the conflict? / 是谁制止了冲突?	32
Implicit causality	$\mathbf{P}_{en}$: Harry, however, was shaken awake several hours earlier than he would have liked by Oliver Wood, Captain of the Gryffindor Quidditch team."Whassamatter?" said Harry groggily. "**Quidditch practice**" said Wood. $\mathbf{P}_{zh}$: 哈利一早就被格兰芬多魁地奇队队长奥利弗伍德摇醒了，他本来还想再睡几个小时的。"什一什么事？"哈利迷迷糊糊地说。"**魁地奇训练**"伍德说。 $\mathbf{Q}_{en}$-$\mathbf{Q}_{zh}$: Why did Oliver Wood shake Harry awake? / 奥利弗伍德为什么要摇醒哈利?	17

Table 4: Question categories and reading comprehension skills covered in BiPaR. Bold words are answers while underlined words indicate coreference resolution.

sentence. Actually, correctly answering this question requires very complicated reading comprehension skills, such as multi-sentence reasoning, ellipsis/co-reference resolution, etc. We've found 43 examples of this case among the 49 lexical-match samples.

If there is no lexical match between a question and the corresponding passage but we can find a semantically matched sentence to the question from the passage, we regard this case as *paraphrasing*. Such questions account for 27.0% of the questions. Interestingly, we find questions in BiPaR that are not found in other datasets. We refer to these questions as *summary* questions, which account for 24% of the sampled questions. In order to answer these questions, MRC models need to read the entire passage to detect summative statements. Examples of the summary questions are:

1) What is the situation of the Old Majesty?

2) What features does Oboi's bedroom show?

In addition, we also analyze the reading comprehension skills required to answer questions. We find that *coreference resolution*, *multi-sentence reasoning* and *implicit causality understanding* frequently appear in answering questions in BiPaR. What deserves our special attention here is the implicit causality, which rarely appears in other datasets. For some questions, it is crucial to understand causality that is not represented by explicit expressions such as "why", "because", and "the reason for". As demonstrated in the last example in Table 4, to correctly answer the question, we must understand the implicit causality: *Quidditch practice* $\longrightarrow$ *Harry, however, was shaken awake several hours earlier than he would have liked by Oliver Wood, Captain of the Gryffindor Quidditch team.*

5 MRC Task Formulation on BiPaR

With aligned passage-question-answer triples, we can define three MRC tasks (monolingual, multilingual and cross-lingual) with seven different forms on this dataset, as demonstrated in Figure 1. Since our goal is to provide benchmark results on this new dataset, we either directly train state-of-the-art MRC models on these tasks or use a straightforward way to adapt existing approaches to the defined tasks in this paper. We leave new approaches, especially those for

multilingual and cross-lingual MRC to our future work.

Monolingual MRC: (P_{en}, Q_{en}, A_{en}) or (P_{zh}, Q_{zh}, A_{zh}). With these two monolingual MRC forms, we can investigate the performance variation of the same MRC model trained on two different languages with equivalent training instances. In our experiments, we directly train off-the-shelf MRC models on the two monolingual tasks to evaluate their performance on Chinese and English.

Multilingual MRC: (P_{en}, Q_{en}, A_{en}, P_{zh}, Q_{zh}, A_{zh}). Similar to multilingual neural machine translation (Johnson et al., 2017), we can build a single MRC model to handle MRC of multiple languages on BiPaR. In our benchmark test, we directly mix training instances of the two languages into a single training set. Correspondingly, the two vocabularies are also combined into one vocabulary for both languages. After that, we train MRC models on this language-mixed dataset to endow them with the multilingual comprehension capacity.

Cross-lingual MRC: The first two forms of cross-lingual MRC are (P_{en}, Q_{zh}, A_{en}) or (P_{zh}, Q_{en}, A_{zh}), in which we use questions in one language to extract answers from passages written in another language. The other two forms are (P_{en}, P_{zh}, Q_{zh}, A_{zh}, A_{en}) or (P_{zh}, P_{en}, Q_{en}, A_{en}, A_{zh}), in which we use questions written in one language to extract answers from passages written in multiple languages. For the first two forms of cross-lingual MRC, we use Google Translate[3] to translate questions into the language of passages, and then treat them as a monolingual MRC task. For the second two forms of cross-lingual MRC, such as (P_{zh}, P_{en}, Q_{en}, A_{en}, A_{zh}), we first obtain A_{en} through a monolingual MRC model, then use the word alignment tool fast_align[4] to obtain the aligned A_{zh} from P_{zh}. Alternative approaches that do not rely on machine translation or word alignments for the cross-lingual MRC tasks are to directly build cross-lingual MRC models on language-mixed training instances constructed from BiPaR or to explore multi-task learning on multiple languages (Dong et al., 2015).

[3]https://translate.google.com/

[4]https://github.com/clab/fast_align

6 Experiments

We carried out experiments with state-of-the-art MRC models on BiPaR to provide machine results for these 7 MRC tasks defined above. We also provide human performance on the monolingual tasks and demonstrate the performance trajectory of human and machine in answering BiPaR questions.

6.1 Evaluation Metric

Like evaluations on other extraction-based datasets, we used EM and F1 to evaluate model accuracy on BiPaR. Particularly, we used the evaluation program of SQuAD1.1 for the English dataset in BiPaR, and the evaluation program[5] of CMRC2018 for the Chinese dataset in BiPaR.

6.2 Human Performance Evaluation

In order to assess human performance on BiPaR, we hired three other bilingual crowdsourced workers to independently answer questions (both Chinese and English) on the test set which contains three answers per question as described in Section 3.3. We then calculated the average results of the three human workers as the final human performance on this dataset, which are shown in Table 5.

6.3 Baseline models

We adapted the following state-of-the-art models to the dataset and MRC tasks as described in Section 4.

DrQA[6]**:** DrQA (Chen et al., 2017) is a simple but effective neural network model for reading comprehension.

BERT[7]**:** BERT (Devlin et al., 2019) is a strong method for pre-training language representations, which obtains the state-of-the-art results on many reading comprehension datasets. We used the multilingual model of BERT trained on multiple languages for the evaluation of our multilingual MRC task.

6.4 Experimental Setup

All the baselines were tested using their default hyper-parameters except BERT. We only changed the batch size to 8 for BERT_base and 6 for BERT_large due to the memory limit of our

DrQA	27.00/39.29	37.40/53.11	28.00/42.49	36.60/53.34	21.93/34.45	27.53/41.08	7.00/18.63	4.07/16.64
BERT_base	41.40/55.03	**48.87/64.09**	38.33/51.20	49.00/64.06	32.80/46.36	**39.87/53.10**	5.73/21.08	7.67/20.69
BERT_large	**42.53/56.48**	-	-		**37.53/51.51**	-	5.60/22.29	-
Human	80.50/91.93	81.50/92.12						

Table 5: Results (EM/F1 score) of models and humans on the development and the test data of BiPaR. 1-7 indicate the seven different MRC tasks on BiPaR: (P_{en}, Q_{en}, A_{en}), (P_{zh}, Q_{zh}, A_{zh}), (P_{en}, Q_{en}, A_{en}, P_{zh}, Q_{zh}, A_{zh}), (P_{en}, Q_{zh}, A_{en}), (P_{zh}, Q_{en}, A_{zh}), (P_{en}, P_{zh}, Q_{zh}, A_{zh}, A_{en}), (P_{zh}, P_{en}, Q_{en}, A_{en}, A_{zh}). For the 6th and 7th task, we mainly explored the word-alignment method. Hence, EM and F1 scores were evaluated on A_{en} or A_{zh}.

GPUs[8]. We used spaCy[9] to tokenize sentences and generate part-of-speech and named entity tags that were used to train the DrQA model. We downloaded Chinese models[10] for spaCy to preprocess Chinese datasets. The 300-dimensional Glove word embeddings trained from 840B Web crawl data (Pennington et al., 2014) were used as our pre-trained English word embeddings while the 300-dimensional SGNS word embeddings trained from mixed-sources data (Li et al., 2018) as our pre-trained Chinese word embeddings.

6.5 Evaluation Results

Table 5 presents the results of the models on the development and the test data. As BERT_large is currently not available for Chinese, results on the tasks that need to use BERT_large on Chinese are not provided.

BERT vs. Human: In the monolingual MRC task, the English BERT_large model achieves an F1 score of 56.5%, which is 35.4 points behind human performance (91.9%), and the Chinese BERT_base model achieves an F1 score of 64.1%, which is 28.0 points behind human performance (92.1%), indicating that these tasks are difficult to accomplish with current state-of-the-art models. We also tested the English BERT_large model on a subset of the SQuAD data, which contains the same number of training instances as BiPaR. The F1 score is 86.5%, much more higher than that on BiPaR. This further suggests that BiPaR provides a very challenging dataset for MRC.

English vs. Chinese: On the monolingual and cross-lingual tasks, Chinese results are almost better than the English results of the same MRC model. This does not mean that Chinese MRC is easier than English. One possible reason for this may be that novels originally written in Chinese contribute to 68.5% passages of BiPaR. In the future, we plan to make the dataset more balanced between the two languages.

Monolingual vs. Multilingual: For the DrQA model, we observe that the multilingual training significantly improves the performance on English comparing with the monolingual training with only the English dataset. However, we do not observe this trend on BERT. This suggests that more should be explored on the multilingual MRC setting. We believe that BiPaR opens a door to new MRC approaches that are devoted to using a single model to handle MRC on multiple languages.

Monolingual vs. Cross-lingual: The two simple strategies via machine translation and word alignments for the cross-lingual MRC perform very bad on the four forms of cross-lingual tasks compared to the monolingual task. For (P_{en}, Q_{zh}, A_{en}) and (P_{zh}, Q_{en}, A_{zh}), the major problem is the low-quality translations of questions, especially for questions from martial arts novels. For the other two cross-lingual tasks, word alignment errors directly result in wrong answers found in passages

[8]The original batch sizes used in BERT_base/BERT_large are 12/24.

of the other language.

6.6 Analysis of BERT and Human in Answering Different BiPaR Questions

Table 6 presents a fine-grained comparison analysis of BERT_base and human results on the English and Chinese monolingual task in terms of both answer types and question categories defined in Section 4.3. We observe that humans have absolute advantages over machines in all answer types and reasoning phenomena. However, humans exhibit different capabilities on answering different questions. They perform worse on answering paraphrasing questions, questions with description answers and questions requiring reading comprehension skills of multi-sentence reasoning than answering other questions.

The performance of BERT_base on questions with description answers is much worse than other questions, e.g., questions with person/location answers. As described in Section 4.2, descriptive answers are often complete sentences or summary statements, which are very long and difficult for machines to detect.

In terms of the relationships between questions and passages, it is clearly observed that the BERT MRC model achieves better performance on answering lexical-match questions than answering paraphrasing and summary questions. In BiPaR, we have more than 50% questions that are paraphrasing and summary questions as described in Section 4.3. Answering them requires a deep understanding of both questions and passages.

As described in Section 4.3, BiPaR produces questions that involve higher-order reading comprehension skills, such as co-reference resolution, multi-sentence reasoning, and understanding of implicit causality. It can be seen from Table 6 that the BERT model is worse on multi-sentence reasoning and implicit causality than co-reference resolution.

Type	BERT_base	Human
Answer Type		
Non-description	61.97/63.22	91.72/95.10
Description	44.77/54.34	91.87/94.72
Question Category		
Lexical Match	58.69/69.01	96.09/96.73
Paraphrasing	54.34/49.84	85.49/91.36
Summary	50.73/52.76	90.03/95.39
Coreference res.	52.35/58.97	91.78/98.11
Multi-sentence rea.	44.91/45.81	87.22/95.31
Implicit causality	39.31/57.63	92.54/91.28

Table 6: Fine-grained results in terms of different answer types and question categories on the monolingual task. The left side of the slash is the F1 score on the English data, while the right is on Chinese. All F1 scores are calculated on the 100 questions as described in Section 4.3.

7 Conclusion and Future Work

In this paper, we have presented the BiPaR, a bilingual parallel machine reading comprehension dataset on novels. From bilingual parallel passages of Chinese and English novels, we manually created diversified parallel questions and answers of different types via crowdsourced workers with a multi-layer quality control system. Although BiPaR is an extractive MRC dataset, in-depth analyses demonstrate that the dataset is very challenging for state-of-the-art MRC models (performing far behind human) as reading comprehension skills of co-reference resolution, inter-sentential reasoning are needed to answer BiPaR questions. We further define seven types of MRC tasks supported by BiPaR and build baseline models of monolingual, multilingual and cross-lingual MRC on BiPaR.

BiPaR can be extended in several ways. First, we would like to create more parallel triples by adding more novels to make instances more balanced between the two languages. Second, we want to create questions with non-extractive answers. Third, we are also interested in adding multi-passage questions or questions based on the entire novels to BiPaR.

Abstract

Recent progress in pretraining language models on large textual corpora led to a surge of improvements for downstream NLP tasks. Whilst learning linguistic knowledge, these models may also be storing relational knowledge present in the training data, and may be able to answer queries structured as "fill-in-the-blank" cloze statements. Language models have many advantages over structured knowledge bases: they require no schema engineering, allow practitioners to query about an open class of relations, are easy to extend to more data, and require no human supervision to train. We present an in-depth analysis of the relational knowledge already present (without fine-tuning) in a wide range of state-of-the-art pretrained language models. We find that (i) without fine-tuning, BERT contains relational knowledge competitive with traditional NLP methods that have some access to oracle knowledge, (ii) BERT also does remarkably well on open-domain question answering against a supervised baseline, and (iii) certain types of factual knowledge are learned much more readily than others by standard language model pretraining approaches. The surprisingly strong ability of these models to recall factual knowledge without any fine-tuning demonstrates their potential as unsupervised open-domain QA systems. The code to reproduce our analysis is available at https://github.com/facebookresearch/LAMA.

1 Introduction

Recently, pretrained high-capacity language models such as ELMo (Peters et al., 2018a) and BERT (Devlin et al., 2018a) have become increasingly important in NLP. They are optimised to either predict the next word in a sequence or some masked word anywhere in a given sequence (*e.g.* "Dante was born in [MASK] in the year 1265."). The parameters of these models appear to store vast amounts of linguistic knowledge (Peters et al., 2018b; Goldberg, 2019; Tenney et al., 2019) useful for downstream tasks. This knowledge is usually accessed either by conditioning on latent context representations produced by the original model or by using the original model weights to initialize a task-specific model which is then further fine-tuned. This type of knowledge transfer is crucial for current state-of-the-art results on a wide range of tasks.

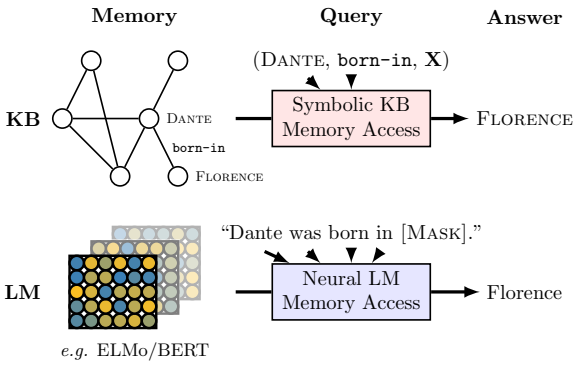

Figure 1: Querying knowledge bases (KB) and language models (LM) for factual knowledge.

In contrast, knowledge bases are effective solutions for accessing annotated gold-standard relational data by enabling queries such as (DANTE, born-in, **X**). However, in practice we often need to *extract* relational data from text or other modalities to populate these knowledge bases. This requires complex NLP pipelines involving entity extraction, coreference resolution, entity linking and relation extraction (Surdeanu and Ji, 2014)—components that often need supervised data and fixed schemas. Moreover, errors can easily propagate and accumulate throughout the pipeline. Instead, we could attempt to query neural language models for relational data by asking them to fill in masked tokens in sequences like "Dante was born

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2463–2473, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

in [MASK]", as illustrated in Figure 1. In this setting, language models come with various attractive properties: they require no schema engineering, do not need human annotations, and they support an open set of queries.

Given the above qualities of language models as potential representations of relational knowledge, we are interested in the relational knowledge already present in pretrained *off-the-shelf* language models such as ELMo and BERT. How much relational knowledge do they store? How does this differ for different types of knowledge such as facts about entities, common sense, and general question answering? How does their performance without fine-tuning compare to symbolic knowledge bases automatically extracted from text? Beyond gathering a better general understanding of these models, we believe that answers to these questions can help us design better unsupervised knowledge representations that could transfer factual and commonsense knowledge reliably to downstream tasks such as commonsense (visual) question answering (Zellers et al., 2018; Talmor et al., 2019) or reinforcement learning (Branavan et al., 2011; Chevalier-Boisvert et al., 2018; Bahdanau et al., 2019; Luketina et al., 2019).

For the purpose of answering the above questions we introduce the *LAMA* (LAnguage Model Analysis) probe, consisting of a set of knowledge sources, each comprised of a set of facts. We define that a pretrained language model *knows* a fact (SUBJECT, `relation`, OBJECT) such as (DANTE, `born-in`, FLORENCE) if it can successfully predict masked objects in cloze sentences such as "Dante was born in ____" expressing that fact. We test for a variety of types of knowledge: relations between entities stored in Wikidata, common sense relations between concepts from ConceptNet, and knowledge necessary to answer natural language questions in SQuAD. In the latter case we manually map a subset of SQuAD questions to cloze sentences.

Our investigation reveals that (i) the largest BERT model from Devlin et al. (2018b) (BERT-large) captures (accurate) relational knowledge comparable to that of a knowledge base extracted with an off-the-shelf relation extractor and an oracle-based entity linker from a corpus known to express the relevant knowledge, (ii) factual knowledge can be recovered surprisingly well from pretrained language models, however, for some relations (particularly *N*-to-*M* relations) performance is very poor, (iii) BERT-large consistently outperforms other language models in recovering factual and commonsense knowledge while at the same time being more robust to the phrasing of a query, and (iv) BERT-large achieves remarkable results for open-domain QA, reaching 57.1% precision@10 compared to 63.5% of a knowledge base constructed using a task-specific supervised relation extraction system.

2 Background

In this section we provide background on language models. Statistics for the models that we include in our investigation are summarized in Table 1.

2.1 Unidirectional Language Models

Given an input sequence of tokens $\mathbf{w} = [w_1, w_2, \ldots, w_N]$, unidirectional language models commonly assign a probability $p(\mathbf{w})$ to the sequence by factorizing it as follows

$$p(\mathbf{w}) = \prod_t p(w_t \,|\, w_{t-1}, \ldots, w_1). \qquad (1)$$

A common way to estimate this probability is using neural language models (Mikolov and Zweig, 2012; Melis et al., 2017; Bengio et al., 2003) with

$$p(w_t \,|\, w_{t-1}, \ldots, w_1) = \text{softmax}(\mathbf{W}\mathbf{h}_t + \mathbf{b}) \qquad (2)$$

where $\mathbf{h}_t \in \mathbb{R}^k$ is the output vector of a neural network at position t and $\mathbf{W} \in \mathbb{R}^{|\mathcal{V}| \times k}$ is a learned parameter matrix that maps $\mathbf{h}_t$ to unnormalized scores for every word in the vocabulary $\mathcal{V}$. Various neural language models then mainly differ in how they compute $\mathbf{h}_t$ given the word history, *e.g.*, by using a multi-layer perceptron (Bengio et al., 2003; Mikolov and Zweig, 2012), convolutional layers (Dauphin et al., 2017), recurrent neural networks (Zaremba et al., 2014; Merity et al., 2016; Melis et al., 2017) or self-attention mechanisms (Radford et al., 2018; Dai et al., 2019; Radford et al., 2019).

fairseq-fconv: Instead of commonly used recurrent neural networks, Dauphin et al. (2017) use multiple layers of gated convolutions. We use the pretrained model in the fairseq[1] library in our study. It has been trained on the WikiText-103 corpus introduced by Merity et al. (2016).

[1] https://github.com/pytorch/fairseq

Model	Base Model	#Parameters	Training Corpus	Corpus Size
fairseq-fconv (Dauphin et al., 2017)	ConvNet	324M	WikiText-103	103M Words
Transformer-XL (large) (Dai et al., 2019)	Transformer	257M	WikiText-103	103M Words
ELMo (original) (Peters et al., 2018a)	BiLSTM	93.6M	Google Billion Word	800M Words
ELMo 5.5B (Peters et al., 2018a)	BiLSTM	93.6M	Wikipedia (en) & WMT 2008-2012	5.5B Words
BERT (base) (Devlin et al., 2018a)	Transformer	110M	Wikipedia (en) & BookCorpus	3.3B Words
BERT (large) (Devlin et al., 2018a)	Transformer	340M	Wikipedia (en) & BookCorpus	3.3B Words

Table 1: Language models considered in this study.

Transformer-XL: Dai et al. (2019) introduce a large-scale language model based on the Transformer (Vaswani et al., 2017). Transformer-XL can take into account a longer history by caching previous outputs and by using relative instead of absolute positional encoding. It achieves a test perplexity of 18.3 on the WikiText-103 corpus.

2.2 Bidirectional "Language Models"[2]

So far, we have looked at language models that predict the next word given a history of words. However, in many downstream applications we mostly care about having access to contextual representations of words, *i.e.*, word representations that are a function of the entire context of a unit of text such as a sentence or paragraph, and not only conditioned on previous words. Formally, given an input sequence $\mathbf{w} = [w_1, w_2, \ldots, w_N]$ and a position $1 \leq i \leq N$, we want to estimate $p(w_i) = p(w_i \mid w_1, \ldots, w_{i-1}, w_{i+1}, \ldots, w_N)$ using the left and right context of that word.

ELMo: To estimate this probability, Peters et al. (2018a) propose running a forward and backward LSTM (Hochreiter and Schmidhuber, 1997), resulting in $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ which consequently are used to calculate a forward and backward language model log-likelihood. Their model, ELMo, uses multiple layers of LSTMs and it has been pretrained on the Google Billion Word dataset. Another version of the model, ELMo 5.5B, has been trained on the English Wikipedia and monolingual news crawl data from WMT 2008-2012.

BERT: Instead of a standard language model objective, Devlin et al. (2018a) propose to sample positions in the input sequence randomly and to learn to fill the word at the masked position. To this end, they employ a Transformer architecture and train it on the BookCorpus (Zhu et al., 2015) as well as a crawl of English Wikipedia. In addition to this pseudo language model objective, they use an auxiliary binary classification objective to predict whether a particular sentence follows the given sequence of words.

[2]Contextual representation models (Tenney et al., 2019) might be a better name, but we keep calling them language models for simplicity.

3 Related Work

Many studies have investigated pretrained word representations, sentence representations, and language models. Existing work focuses on understanding linguistic and semantic properties of word representations or how well pretrained sentence representations and language models transfer linguistic knowledge to downstream tasks. In contrast, our investigation seeks to answer to what extent pretrained language models store factual and commonsense knowledge by comparing them with symbolic knowledge bases populated by traditional relation extraction approaches.

Baroni et al. (2014) present a systematic comparative analysis between neural word representation methods and more traditional count-based distributional semantic methods on lexical semantics tasks like semantic relatedness and concept categorization. They find that neural word representations outperform count-based distributional methods on the majority of the considered tasks. Hill et al. (2015) investigate to what degree word representations capture semantic meaning as measured by similarity between word pairs.

Marvin and Linzen (2018) assess the grammaticality of pretrained language models. Their dataset consists of sentence pairs with a grammatical and an ungrammatical sentence. While a good language model should assign higher probability to the grammatical sentence, they find that LSTMs do not learn syntax well.

Another line of work investigates the ability of pretrained sentence and language models to transfer knowledge to downstream natural language understanding tasks (Wang et al., 2018). While such an analysis sheds light on the transfer-learning

abilities of pretrained models for understanding short pieces of text, it provides little insight into whether these models can compete with traditional approaches to representing knowledge like symbolic knowledge bases.

More recently, McCoy et al. (2019) found that for natural language inference, a model based on BERT learns to rely heavily on fallible syntactic heuristics instead of a deeper understanding of the natural language input. Peters et al. (2018b) found that lower layers in ELMo specialize on local syntactic relationships, while higher layers can learn to model long-range relationships. Similarly, Goldberg (2019) found that BERT captures English syntactic phenomena remarkably well. Tenney et al. (2019) investigate to what extent language models encode sentence structure for different syntactic and semantic phenomena and found that they excel for the former but only provide small improvements for tasks that fall into the latter category. While this provides insights into the linguistic knowledge of language models, it does not provide insights into their factual and commonsense knowledge.

Radford et al. (2018) introduce a pretrained language model based on the Transformer which they termed generative pretraining (GPTv1). The first version of GPT (Radford et al., 2018) has been trained on the Book Corpus (Zhu et al., 2015) containing 7000 books. The closest to our investigation is the work by Radford et al. (2019) which introduces GPTv2 and investigates how well their language model does zero-shot transfer to a range of downstream tasks. They find that GPTv2 achieves an F_1 of 55 for answering questions in CoQA (Reddy et al., 2018) and 4.1% accuracy on the Natural Questions dataset (Kwiatkowski et al., 2019), in both cases without making use of annotated question-answer pairs or an information retrieval step. While these results are encouraging and hint at the ability of very large pretrained language models to memorize factual knowledge, the large GPTv2 model has not been made public and the publicly available small version achieves less than 1% on Natural Questions (5.3 times worse than the large model). Thus, we decided to not include GPTv2 in our study. Similarly, we do not include GPTv1 in this study as it uses a limited lower-cased vocabulary, making it incompatible to the way we assess the other language models.

4 The LAMA Probe

We introduce the *LAMA* (LAnguage Model Analysis) probe to test the factual and commonsense knowledge in language models. It provides a set of knowledge sources which are composed of a corpus of facts. Facts are either subject-relation-object triples or question-answer pairs. Each fact is converted into a cloze statement which is used to query the language model for a missing token. We evaluate each model based on how highly it ranks the ground truth token against every other word in a fixed candidate vocabulary. This is similar to ranking-based metrics from the knowledge base completion literature (Bordes et al., 2013; Nickel et al., 2016). Our assumption is that models which rank ground truth tokens high for these cloze statements have more factual knowledge. We discuss each step in detail next and provide considerations on the probe below.

4.1 Knowledge Sources

To assess the different language models in Section 2, we cover a variety of sources of factual and commonsense knowledge. For each source, we describe the origin of fact triples (or question-answer pairs), how we transform them into cloze templates, and to what extent aligned texts exist in Wikipedia that are known to express a particular fact. We use the latter information in supervised baselines that extract knowledge representations directly from the aligned text.

4.1.1 Google-RE

The Google-RE corpus[3] contains ~60K facts manually extracted from Wikipedia. It covers five relations but we consider only three of them, namely "place of birth", "date of birth" and "place of death". We exclude the other two because they contain mainly multi-tokens objects that are not supported in our evaluation. We manually define a template for each considered relation, *e.g.*, "[S] was born in [O]" for "place of birth". Each fact in the Google-RE dataset is, by design, manually aligned to a short piece of Wikipedia text supporting it.

4.1.2 T-REx

The T-REx knowledge source is a subset of Wikidata triples. It is derived from the T-REx

[3] https://code.google.com/archive/p/relation-extraction-corpus/

dataset (Elsahar et al., 2018) and is much larger than Google-RE with a broader set of relations. We consider 41 Wikidata relations and subsample at most 1000 facts per relation. As with the Google-RE corpus, we manually define a template for each relation (see Table 3 for some examples). In contrast to the Google-RE knowledge source, T-REx facts were automatically aligned to Wikipedia and hence this alignment can be noisy. However, Elsahar et al. (2018) report an accuracy of 97.8% for the alignment technique over a test set.

4.1.3 ConceptNet

ConceptNet (Speer and Havasi, 2012) is a multilingual knowledge base, initially built on top of Open Mind Common Sense (OMCS) sentences. OMCS represents commonsense relationships between words and/or phrases. We consider facts from the English part of ConceptNet that have single-token objects covering 16 relations. For these ConceptNet triples, we find the OMCS sentence that contains both the subject and the object. We then mask the object within the sentence and use the sentence as template for querying language models. If there are several sentences for a triple, we pick one at random. Note that for this knowledge source there is no explicit alignment of facts to Wikipedia sentences.

4.1.4 SQuAD

SQuAD (Rajpurkar et al., 2016) is a popular question answering dataset. We select a subset of 305 context-insensitive questions from the SQuAD development set with single token answers. We manually create cloze-style questions from these questions, *e.g.*, rewriting "Who developed the theory of relativity?" as "The theory of relativity was developed by ____". For each question and answer pair, we know that the corresponding fact is expressed in Wikipedia since this is how SQuAD was created.

4.2 Models

We consider the following pretrained case-sensitive language models in our study (see Table 1): fairseq-fconv (*Fs*), Transformer-XL large (*Txl*), ELMo original (*Eb*), ELMo 5.5B (*E5B*), BERT-base (*Bb*) and BERT-large (*Bl*). We use the natural way of generating tokens for each model by following the definition of the training objective function.

Assume we want to compute the generation for the token at position t. For unidirectional language models, we use the network output ($\mathbf{h}_{t-1}$) just before the token to produce the output layer softmax. For ELMo we consider the output just before ($\overrightarrow{\mathbf{h}}_{t-1}$) for the forward direction and just after ($\overleftarrow{\mathbf{h}}_{t+1}$) for the backward direction. Following the loss definition in (Peters et al., 2018a), we average forward and backward probabilities from the corresponding softmax layers. For BERT, we mask the token at position t, and we feed the output vector corresponding to the masked token ($\mathbf{h}_t$) into the softmax layer. To allow a fair comparison, we let models generate over a unified vocabulary, which is the intersection of the vocabularies for all considered models (~21K case-sensitive tokens).

4.3 Baselines

To compare language models to canonical ways of using off-the-shelf systems for extracting symbolic knowledge and answering questions, we consider the following baselines.

Freq: For a subject and relation pair, this baseline ranks words based on how frequently they appear as objects for the given relation in the test data. It indicates the upper bound performance of a model that always predicts the same objects for a particular relation.

RE: For the relation-based knowledge sources, we consider the pretrained Relation Extraction (RE) model of Sorokin and Gurevych (2017). This model was trained on a subcorpus of Wikipedia annotated with Wikidata relations. It extracts relation triples from a given sentence using an LSTM-based encoder and an attention mechanism. Based on the alignment information from the knowledge sources, we provide the relation extractor with the sentences known to express the test facts. Using these datasets, RE constructs a knowledge graph of triples. At test time, we query this graph by finding the subject entity and then rank all objects in the correct relation based on the confidence scores returned by RE. We consider two versions of this procedure that differ in how the entity linking is implemented: $\mathbf{RE}_n$ makes use of a naïve entity linking solution based on exact string matching, while $\mathbf{RE}_o$ uses an oracle for entity linking in addition to string matching. In other words, assume we query for the object o of a test subject-relation fact (s, r, o) expressed in a sentence x. If RE has extracted any triple (s', r, o') from that sen-

tence x, s' will be linked to s and o' to o. In practice, this means RE can return the correct solution o if *any* relation instance of the right type was extracted from x, regardless of whether it has a wrong subject or object.

DrQA: Chen et al. (2017) introduce DrQA, a popular system for open-domain question answering. DrQA predicts answers to natural language questions using a two step pipeline. First, a TF/IDF information retrieval step is used to find relevant articles from a large store of documents (e.g. Wikipedia). On the retrieved top k articles, a neural reading comprehension model then extracts answers. To avoid giving the language models a competitive advantage, we constrain the predictions of DrQA to single-token answers.

4.4 Metrics

We consider rank-based metrics and compute results per relation along with mean values across all relations. To account for multiple valid objects for a subject-relation pair (*i.e.*, for N-M relations), we follow Bordes et al. (2013) and remove from the candidates when ranking at test time all other valid objects in the training data other than the one we test. We use the mean precision at k ($P@k$). For a given fact, this value is 1 if the object is ranked among the top k results, and 0 otherwise.

4.5 Considerations

There are several important design decisions we made when creating the LAMA probe. Below we give more detailed justifications for these decisions.

Manually Defined Templates For each relation we manually define a template that queries for the object slot in that relation. One can expect that the choice of templates has an impact on the results, and this is indeed the case: for some relations we find both worse and better ways to query for the same information (with respect to a given model) by using an alternate template. We argue that this means we are measuring a *lower* bound for what language models know. We make this argument by analogy with traditional knowledge bases: they only have a *single* way of querying knowledge for a specific relation, namely by using the relation id of that relation, and this way is used to measure their accuracy. For example, if the relation ID is `works-For` and the user asks for `is-working-for`, the accuracy of the KG would be 0.

Single Token We only consider single token objects as our prediction targets. The reason we include this limitation is that multi-token decoding adds a number of additional tuneable parameters (beam size, candidate scoring weights, length normalization, n-gram repetition penalties, etc.) that obscure the knowledge we are trying to measure. Moreover, well-calibrated multi-token generation is still an active research area, particularly for bidirectional models (see *e.g.* Welleck et al. (2019)).

Object Slots We choose to *only* query object slots in triples, as opposed to subject or relation slots. By including reverse relations (e.g. `contains` and `contained-by`) we can also query subject slots. We do not query relation slots for two reasons. First, surface form realisations of relations will span several tokens, and as we discussed above, this poses a technical challenge that is not in the scope of this work. Second, even if we could easily predict multi-token phrases, relations can generally be expressed with many different wordings, making it unclear what the gold standard pattern for a relation should be, and how to measure accuracy in this context.

Intersection of Vocabularies The models that we considered are trained with different vocabularies. For instance, ELMo uses a list of ~800K tokens while BERT considers only ~30K tokens. The size of the vocabulary can influence the performance of a model for the LAMA probe. Specifically, the larger the vocabulary the harder it would be to rank the gold token at the top. For this reason we considered a common vocabulary of ~21K case-sensitive tokens that are obtained from the intersection of the vocabularies for all considered models. To allow a fair comparison, we let every model rank only tokens in this joint vocabulary.

5 Results

We summarize the main results in Table 2, which shows the mean precision at one (P@1) for the different models across the set of corpora considered. In the remainder of this section, we discuss the results for each corpus in detail.

Google-RE We query the LMs using a standard cloze template for each relation. The base and large versions of BERT both outperform all other models by a substantial margin. Furthermore, they

Table 2: Mean precision at one (P@1) for a frequency baseline (Freq), DrQA, a relation extraction with naïve entity linking (RE_n), oracle entity linking (RE_o), fairseq-fconv (Fs), Transformer-XL large (Txl), ELMo original (Eb), ELMo 5.5B (E5B), BERT-base (Bb) and BERT-large (Bl) across the set of evaluation corpora.

obtain a 2.2 and 2.9 respective average accuracy improvement over the oracle-based RE baseline. This is particularly surprising given that with the gold-aligned Google-RE source we know for certain that the oracle RE baseline has seen at least one sentence expressing each test fact. Moreover, the RE baseline was given substantial help through an entity linking oracle.

It is worth pointing out that while BERT-large does better, this does not mean it does so for the right reasons. Although the aligned Google-RE sentences are likely in its training set (as they are part of Wikipedia and BERT has been trained on Wikipedia), it might not "understand" them to produce these results. Instead, it could have learned associations of objects with subjects from co-occurrence patterns.

T-REx The knowledge source derived from Google-RE contains relatively few facts and only three relations. Hence, we perform experiments on the larger set of facts and relations in T-REx. We find that results are generally consistent with Google-RE. Again, the performance of BERT in retrieving factual knowledge are close to the performance obtained by automatically building a knowledge base with an off-the-shelf relation extraction system and oracle-based entity linking. Broken down by relation type, the performance of BERT is very high for 1-to-1 relations (*e.g.*, *capital of*) and low for N-to-M relations.

Note that a downstream model could learn to make use of knowledge in the output representations of a language model even if the correct answer is not ranked first but high enough (*i.e.* a hint

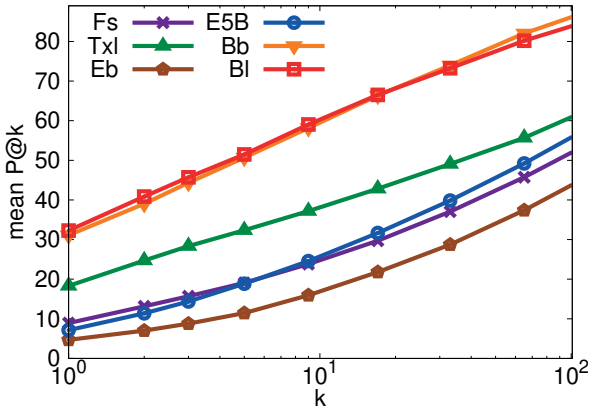

Figure 2: Mean P@k curve for T-REx varying k. Base-10 log scale for X axis.

about the correct answer can be extracted from the output representation). Figure 2 shows the mean P@k curves for the considered models. For BERT, the correct object is ranked among the top ten in around 60% of the cases and among the top 100 in 80% of the cases.

To further investigate why BERT achieves such strong results, we compute the Pearson correlation coefficient between the *P@1* and a set of metrics that we report in Figure 3. We notice, for instance, that the number of times an object is mentioned in the training data positively correlates with performance while the same is not true for the subject of a relation. Furthermore, the log probability of a prediction is strongly positively correlated with P@1. Thus, when BERT has a high confidence in its prediction, it is often correct. Performance is also positively correlated with the cosine similarity between subject and object vectors, and

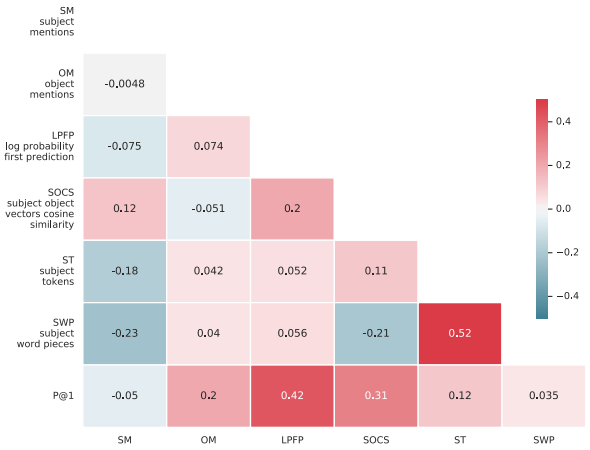

Figure 3: Pearson correlation coefficient for the P@1 of the BERT-large model on T-REx and a set of metrics: SM and OM refer to the number of times a subject and an object are mentioned in the BERT training corpus[4]respectively; LPFP is the log probability score associated with the first prediction; SOCS is the cosine similarity between subject and object vectors (we use spaCy[5]); ST and SWP are the number of tokens in the subject with a standard tokenization and the BERT WordPiece tokenization respectively.

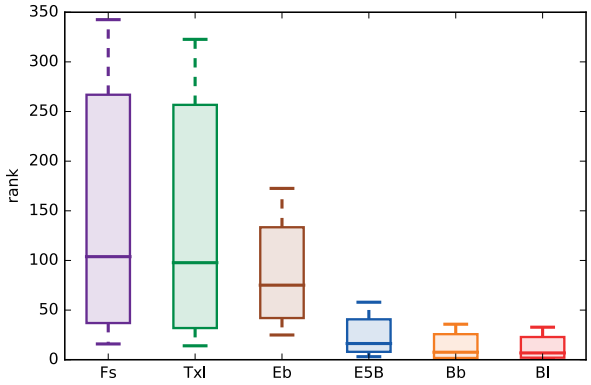

Figure 4: Average rank distribution for 10 different mentions of 100 random facts per relation in T-REx. ELMo 5.5B and both variants of BERT are least sensitive to the framing of the query but also are the most likely to have seen the query sentence during training.

slightly with the number of tokens in the subject.

Table 3 shows randomly picked examples for the generation of BERT-large for cloze template queries. We find that BERT-large generally predicts objects of the correct type, even when the predicted object itself is not correct.

To understand how the performance of a pretrained language model varies with different ways of querying for a particular fact, we analyze a maximum of 100 random facts per relation for which we randomly select 10 aligned sentences in Wikipedia from T-REx.[6] In each of the sentences, we mask the object of the fact, and ask the model to predict it. For several of our language models this also tests their ability to memorize and recall sentences from the training data since as the models have been trained on Wikipedia (see Table 1).

Figure 4 shows the average distribution of the rank for ten queries per fact. The two BERT models and ELMo 5.5B exhibit the lowest variability while ranking the correct object close to the top on average. Surprisingly, the performance of ELMo original is not far from BERT, even though this model did not see Wikipedia during training. Fairseq-fconv and Transformer-XL experience a higher variability in their predictions. Note that BERT and ELMo 5.5B have been trained on a larger portion of Wikipedia than fairseq-fconv and Transformer-XL and may have seen more sentences containing the test queries during training.

ConceptNet The results on the ConceptNet corpus are in line with those reported for retrieving factual knowledge in Google-RE and T-REx. The BERT-large model consistently achieves the best performance, and it is able to retrieve commonsense knowledge at a similar level to factual knowledge. The lower half of Table 3 shows generations by BERT-large for randomly sampled examples. Some of the concepts generated by the language models are surprisingly reasonable in addition to being syntactically correct.

SQuAD Next we evaluate our system on open-domain cloze-style question answering and compare against the supervised DrQA model. Table 2 shows a performance gap between BERT-large and the DrQA open-domain QA system on our cloze SQuAD task. Again, note that the pretrained language model is completely unsupervised, it is not fine-tuned, and it has no access to a dedicated information retrieval system. Moreover, when comparing DrQA and BERT-large in terms of P@10, we find that gap is remarkably small (57.1 for BERT-large and 63.5 for DrQA).

6 Discussion and Conclusion

We presented a systematic analysis of the factual and commonsense knowledge in publicly available pretrained language models *as is* and found

[5]The original training corpus is not available, we created our version using the same sources.

	P264	Joe Cocker is represented by music label ____.	Capitol	EMI [-2.6] , BMG [-2.6] , Universal [-2.8] , **Capitol [-3.2]** , Columbia [-3.3]
	P276	London Jazz Festival is located in ____.	London	**London [-0.3]** , Greenwich [-3.2] , Chelsea [-4.0] , Camden [-4.6] , Stratford [-4.8]
	P127	Border TV is owned by ____.	ITV	Sky [-3.1] , **ITV [-3.3]** , Global [-3.4] , Frontier [-4.1] , Disney [-4.3]
	P103	The native language of Mammootty is ____.	Malayalam	**Malayalam [-0.2]** , Tamil [-2.1] , Telugu [-4.8] , English [-5.2] , Hindi [-5.6]
	P495	The Sharon Cuneta Show was created in ____.	Philippines	Manila [-3.2] , **Philippines [-3.6]** , February [-3.7] , December [-3.8] , Argentina [-4.0]
ConceptNet	AtLocation	You are likely to find a overflow in a ____.	drain	sewer [-3.1] , canal [-3.2] , toilet [-3.3] , stream [-3.6] , **drain [-3.6]**
	CapableOf	Ravens can ____.	fly	**fly [-1.5]** , fight [-1.8] , kill [-2.2] , die [-3.2] , hunt [-3.4]
	CausesDesire	Joke would make you want to ____.	laugh	cry [-1.7] , die [-1.7] , **laugh [-2.0]** , vomit [-2.6] , scream [-2.6]
	Causes	Sometimes virus causes ____.	infection	disease [-1.2] , cancer [-2.0] , **infection [-2.6]** , plague [-3.3] , fever [-3.4]
	HasA	Birds have ____.	feathers	wings [-1.8] , nests [-3.1] , **feathers [-3.2]** , died [-3.7] , eggs [-3.9]
	HasPrerequisite	Typing requires ____.	speed	patience [-3.5] , precision [-3.6] , registration [-3.8] , accuracy [-4.0] , **speed [-4.1]**
	HasProperty	Time is ____.	finite	short [-1.7] , passing [-1.8] , precious [-2.9] , irrelevant [-3.2] , gone [-4.0]
	MotivatedByGoal	You would celebrate because you are ____.	alive	happy [-2.4] , human [-3.3] , **alive [-3.3]** , young [-3.6] , free [-3.9]
	ReceivesAction	Skills can be ____.	taught	acquired [-2.5] , useful [-2.5] , learned [-2.8] , combined [-3.9] , varied [-3.9]
	UsedFor	A pond is for ____.	fish	swimming [-1.3] , fishing [-1.4] , bathing [-2.0] , **fish [-2.8]** , recreation [-3.1]

Table 3: Examples of generation for BERT-large. The last column reports the top five tokens generated together with the associated log probability (in square brackets).

that BERT-large is able to recall such knowledge better than its competitors and at a level remarkably competitive with non-neural and supervised alternatives. Note that we did *not* compare the ability of the corresponding architectures and objectives to capture knowledge in a given body of text but rather focused on the knowledge present in the weights of existing pretrained models that are being used as starting points for many researchers' work. Understanding which aspects of data our commonly-used models and learning algorithms are capturing is a crucial field of research and this paper complements the many studies focused on the learned linguistic properties of the data.

We found that it is non-trivial to extract a knowledge base from text that performs on par to directly using pretrained BERT-large. This is despite providing our relation extraction baseline with only data that is likely expressing target facts, thus reducing potential for false negatives, as well as using a generous entity-linking oracle. We suspected BERT might have an advantage due to the larger amount of data it has processed, so we added Wikitext-103 as additional data to the relation extraction system and observed no significant change in performance. This suggests that while relation extraction performance might be difficult to improve with more data, language models trained on ever growing corpora might become a viable alternative to traditional knowledge bases extracted from text in the future.

In addition to testing future pretrained language models using the LAMA probe, we are interested in quantifying the variance of recalling factual knowledge with respect to varying natural language templates. Moreover, assessing multi-token answers remains an open challenge for our evaluation setup.

Acknowledgments

We would like to thank the reviewers for their thoughtful comments and efforts towards improving our manuscript. In addition, we would like to acknowledge three frameworks that were used in our experiments: AllenNLP[7], Fairseq[8] and the Hugging Face PyTorch-Transformers[9] library.

Abstract

Numerical reasoning, such as addition, subtraction, sorting and counting is a critical skill in human's reading comprehension, which has not been well considered in existing machine reading comprehension (MRC) systems. To address this issue, we propose a numerical MRC model named as NumNet, which utilizes a numerically-aware graph neural network to consider the comparing information and performs numerical reasoning over numbers in the question and passage. Our system achieves an EM-score of 64.56% on the DROP dataset, outperforming all existing machine reading comprehension models by considering the numerical relations among numbers.

1 Introduction

Machine reading comprehension (MRC) aims to infer the answer to a question given the document. In recent years, researchers have proposed lots of MRC models (Chen et al., 2016; Dhingra et al., 2017; Cui et al., 2017; Seo et al., 2017) and these models have achieved remarkable results in various public benchmarks such as SQuAD (Rajpurkar et al., 2016) and RACE (Lai et al., 2017). The success of these models is due to two reasons: (1) Multi-layer architectures which allow these models to read the document and the question iteratively for reasoning; (2) Attention mechanisms which would enable these models to focus on the part related to the question in the document.

However, most of existing MRC models are still weak in numerical reasoning such as addition, subtraction, sorting and counting (Dua et al., 2019), which are naturally required when reading financial news, scientific articles, etc. Dua et al. (2019) proposed a numerically-aware QANet (NAQANet) model, which divides the answer generation for numerical MRC into three types: (1) extracting spans; (2) counting; (3) addition or subtraction over numbers. NAQANet makes a pioneering attempt to answer numerical questions but still does not explicitly consider numerical reasoning.

To tackle this problem, we introduce a novel model NumNet that integrates numerical reasoning into existing MRC models. A key problem to answer questions requiring numerical reasoning is how to perform numerical comparison in MRC systems, which is crucial for two common types of questions:

(1) **Numerical Comparison**: The answers of the questions can be directly obtained via performing numerical comparison, such as sorting and comparison, in the documents. For example, in Table 1, for the first question, if the MRC system knows the fact that "$49 > 47 > 36 > 31 > 22$", it could easily extract that the second longest field goal is 47-yard.

(2) **Numerical Condition**: The answers of the questions cannot be directly obtained through simple numerical comparison in the documents, but often require numerical comparison for understanding the text. For example, for the second question in Table 1, an MRC system needs to know which age group made up more than 7% of the population to count the group number.

Hence, our NumNet model considers numerical comparing information among numbers when answering numerical questions. As shown in Figure 1, NumNet first encodes both the question and passages through an encoding module consisting of convolution layers, self-attention layers and feed-forward layers as well as a passage-question attention layer. After that, we feed the question and passage representations into a numerically-aware graph neural network (NumGNN) to further

Question	Passage	Answer
What is the second longest field goal made?	... The Seahawks immediately trailed on a scoring rally by the Raiders with kicker *Sebastian Janikowski nailing a 31-yard field goal* ... Then in the third quarter *Janikowski made a 36-yard field goal*. Then *he made a 22-yard field goal* in the fourth quarter to put the Raiders up 16-0 ... The Seahawks would make their only score of the game with kicker *Olindo Mare hitting a 47-yard field goal*. However, they continued to trail as *Janikowski made a 49-yard field goal*, followed by RB Michael Bush making a 4-yard TD run.	47-yard
How many age groups made up more than 7% of the population?	Of Saratoga Countys population in 2010, *6.3%* were between ages of 5 and 9 years, *6.7%* between 10 and 14 years, 6.5% between 15 and 19 years, *5.5%* between 20 and 24 years, *5.5%* between 25 and 29 years, *5.8%* between 30 and 34 years, *6.6%* between 35 and 39 years, *7.9%* between 40 and 44 years, *8.5%* between 45 and 49 years, *8.0%* between 50 and 54 years, *7.0%* between 55 and 59 years, *6.4%* between 60 and 64 years, and *13.7%* of age 65 years and over ...	5

Table 1: Example questions from the DROP dataset which require numerical comparison. We highlight the relevant parts in the passage to infer the answer.

integrate the comparison information among numbers into their representations. Finally, we utilize the numerically-aware representation of passages to infer the answer to the question.

The experimental results on a public numerical MRC dataset DROP (Dua et al., 2019) show that our NumNet model achieves significant and consistent improvement as compared to all baseline methods by explicitly performing numerical reasoning over numbers in the question and passage. In particular, we show that our model could effectively deal with questions requiring sorting with multi-layer NumGNN. The source code of our paper is available at `https://github.com/ranqiu92/NumNet`.

2 Related Work

2.1 Machine Reading Comprehension

Machine reading comprehension (MRC) has become an important research area in NLP. In recent years, researchers have published a large number of annotated MRC datasets such as CNN/Daily Mail (Hermann et al., 2015), SQuAD (Rajpurkar et al., 2016), RACE (Lai et al., 2017), TriviaQA (Joshi et al., 2017) and so on. With the blooming of available large-scale MRC datasets, a great number of neural network-based MRC models have been proposed to answer questions for a given document including Attentive Reader (Kadlec et al., 2016), BiDAF (Seo et al., 2017), Interactive AoA Reader (Cui et al., 2017), Gated Attention Reader (Dhingra et al., 2017), R-Net (Wang et al., 2017a), DCN (Xiong et al., 2017), QANet (Yu et al., 2018), and achieve promising results in most existing public MRC datasets.

Despite the success of neural network-based MRC models, researchers began to analyze the data and rethink to what extent we have solved the problem of MRC. Some works (Chen et al., 2016; Sugawara et al., 2018; Kaushik and Lipton, 2018) classify the reasoning skills required to answer the questions into the following types: (1) Exact matching/Paraphrasing; (2) Summary; (3) Logic reasoning; (4) Utilizing external knowledge; (5) Numerical reasoning. They found that most existing MRC models are focusing on dealing with the first three types of questions. However, all these models suffer from problems when answering the questions requiring numerical reasoning. To the best of our knowledge, our work is the first one that *explicitly* incorporates numerical reasoning into the MRC system. The most relevant work to ours is NAQANet (Dua et al., 2019), which adapts the output layer of QANet (Yu et al., 2018) to support predicting answers based on counting and addition/subtraction over numbers. However, it does not consider numerical reasoning explicitly during encoding or inference.

2.2 Arithmetic Word Problem Solving

Recently, understanding and solving arithmetic word problems (AWP) has attracted the growing interest of NLP researchers. Hosseini et al. (2014) proposed a simple method to address arithmetic word problems, but mostly focusing on subsets of problems which only require addition and subtraction. After that, Roy and Roth (2015) proposed an algorithmic approach which could handle arithmetic word problems with multiple steps and operations. Koncel-Kedziorski et al. (2015) further

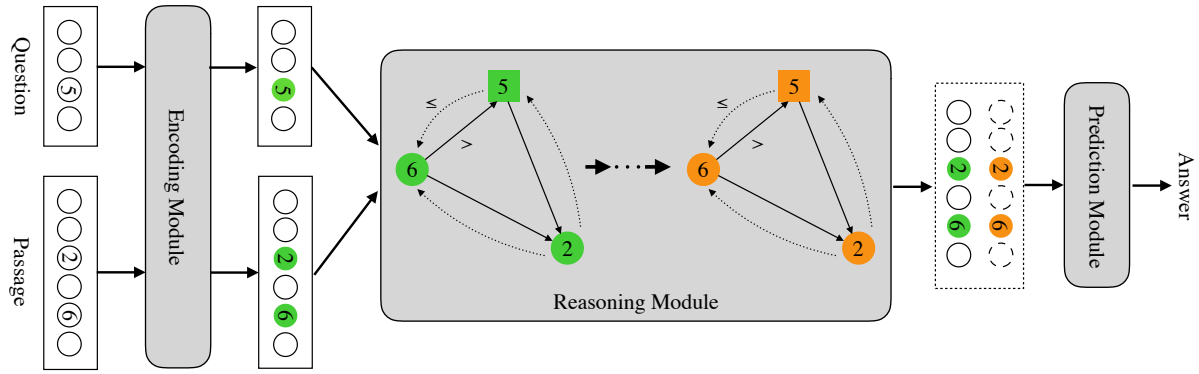

Figure 1: **The framework of our NumNet model.** Our model consists of an encoding module, a reasoning module and a prediction module. The numerical relations between numbers are encoded with the topology of the graph. For example, the edge pointing from "6" to "5" denotes "6" is greater than "5". And the reasoning module leverages a numerically-aware graph neural network to perform numerical reasoning on the graph. As numerical comparison is modeled explicitly in our model, it is more effective for answering questions requiring numerical reasoning such as addition, counting, or sorting over numbers.

formalized the AWP problem as that of generating and scoring equation trees via integer linear programming. Wang et al. (2017b) and Ling et al. (2017) proposed sequence to sequence solvers for the AWP problems, which are capable of generating unseen expressions and do not rely on sophisticated manual features. Wang et al. (2018) leveraged deep Q-network to solve the AWP problems, achieving a good balance between effectiveness and efficiency. However, all the existing AWP systems are only trained and validated on small benchmark datasets. Huang et al. (2016) found that the performance of these AWP systems sharply degrades on larger datasets. Moreover, from the perspective of NLP, MRC problems are more challenging than AWP since the passages in MRC are mostly real-world texts which require more complex skills to be understood. Above all, it is nontrivial to adapt most existing AWP models to the MRC scenario. Therefore, we focus on enhancing MRC models with numerical reasoning abilities in this work.

3 Methodology

In this section, we will introduce the framework of our model NumNet and provide the details of the proposed numerically-aware graph neural network (NumGNN) for numerical reasoning.

3.1 Framework

An overview of our model NumNet is shown in Figure 1. We compose our model with encoding module, reasoning module and prediction module. Our major contribution is the reasoning module, which leverages a NumGNN between the encoding module and prediction module to explicitly consider the numerical comparison information and perform numerical reasoning. As NAQANet has been shown effective for handling numerical MRC problem (Dua et al., 2019), we leverage it as our base model and mainly focus on the design and integration of the NumGNN in this work.

Encoding Module Without loss of generality, we use the encoding components of QANet and NAQANet to encode the question and passage into vector-space representations. Formally, the question Q and passage P are first encoded as:

$$\boldsymbol{Q} = \texttt{QANet-Emb-Enc}(Q), \quad (1)$$
$$\boldsymbol{P} = \texttt{QANet-Emb-Enc}(P), \quad (2)$$

and then the passage-aware question representation and the question-aware passage representation are computed as:

$$\bar{\boldsymbol{Q}} = \texttt{QANet-Att}(\boldsymbol{P}, \boldsymbol{Q}), \quad (3)$$
$$\bar{\boldsymbol{P}} = \texttt{QANet-Att}(\boldsymbol{Q}, \boldsymbol{P}), \quad (4)$$

where $\texttt{QANet-Emb-Enc}(\cdot)$ and $\texttt{QANet-Att}(\cdot)$ denote the "stacked embedding encoder layer" and "context-query attention layer" of QANet respectively. The former consists of convolution, self-attention and feed-forward layers. The latter is a passage-question attention layer. $\bar{\boldsymbol{Q}}$ and $\bar{\boldsymbol{P}}$ are used by the following components.

Reasoning Module First we build a heterogeneous directed graph $\mathcal{G} = (\boldsymbol{V}; \boldsymbol{E})$, whose nodes

($\boldsymbol{V}$) are corresponding to the numbers in the question and passage, and edges ($\boldsymbol{E}$) are used to encode numerical relationships among the numbers. The details will be explained in Sec. 3.2.

Then we perform reasoning on the graph based on a graph neural network, which can be formally denoted as:

$$\boldsymbol{M}^Q = \texttt{QANet-Mod-Enc}(\boldsymbol{W}^M \bar{\boldsymbol{Q}}), \quad (5)$$
$$\boldsymbol{M}^P = \texttt{QANet-Mod-Enc}(\boldsymbol{W}^M \bar{\boldsymbol{P}}), \quad (6)$$
$$\boldsymbol{U} = \texttt{Reasoning}(\mathcal{G}; \boldsymbol{M}^Q, \boldsymbol{M}^P), \quad (7)$$

where $\boldsymbol{W}^M$ is a shared weight matrix, $\boldsymbol{U}$ is the representations of the nodes corresponding to the numbers, $\texttt{QANet-Mod-Enc}(\cdot)$ is the "model encoder layer" defined in QANet which is similar to $\texttt{QANet-Emb-Enc}(\cdot)$, and the definition of $\texttt{Reasoning}(\cdot)$ will be given in Sec. 3.3.

Finally, as $\boldsymbol{U}$ only contains the representations of numbers, to tackle span-style answers containing non-numerical words, we concatenate $\boldsymbol{U}$ with $\boldsymbol{M}^P$ to produce numerically-aware passage representation $\boldsymbol{M}_0$. Formally,

$$\boldsymbol{M}_0^{\text{num}}[i] = \begin{cases} \boldsymbol{U}[I(i)] & \text{if } w_i^p \text{ is a number} \\ \boldsymbol{0} \end{cases},$$
$$\boldsymbol{M}_0' = \boldsymbol{W}_0[\boldsymbol{M}^P; \boldsymbol{M}^{\text{num}}] + \boldsymbol{b}_0, \quad (8)$$
$$\boldsymbol{M}_0 = \texttt{QANet-Mod-Enc}(\boldsymbol{M}_0'), \quad (9)$$

where $[\cdot;\cdot]$ denotes matrix concatenation, $\boldsymbol{W}[k]$ denotes the k-th column of a matrix $\boldsymbol{W}$, $\boldsymbol{0}$ is a zero vector, $I(i)$ denotes the node index corresponding to the passage word w_i^p which is a number, $\boldsymbol{W}_0$ is a weight matrix, and $\boldsymbol{b}_0$ is a bias vector.

Prediction Module Following NAQANet (Dua et al., 2019), we divide the answers into four types and use a unique output layer to calculate the conditional answer probability $\Pr(\text{answer}|\text{type})$ for each type :

- *Passage span*: The answer is a span of the passage, and the answer probability is defined as the product of the probabilities of the start and end positions.
- *Question span*: The answer is a span of the question, and the answer probability is also defined as the product of the probabilities of the start and end positions.
- *Count*: The answer is obtained by counting, and it is treated as a multi-class classification problem over ten numbers (0-9), which covers most of the *Count* type answers in the DROP dataset.
- *Arithmetic expression*: The answer is the result of an arithmetic expression. The expression is obtained in three steps: (1) extract all numbers from the passage; (2) assign a sign (plus, minus or zero) for each number; (3) sum the signed numbers [1].

Meanwhile, an extra output layer is also used to predict the probability $\Pr(\text{type})$ of each answer type. At training time, the final answer probability is defined as the joint probability over all feasible answer types, i.e., $\sum_{\text{type}} \Pr(\text{type}) \Pr(\text{answer}|\text{type})$. Here, the answer type annotation is not required and the probability $\Pr(\text{type})$ is learnt by the model. At test time, the model first selects the most probable answer type greedily and then predicts the best answer accordingly.

Without loss of generality, we leverage the definition of the five output layers in (Dua et al., 2019), with $\boldsymbol{M_0}$ and $\boldsymbol{Q}$ as inputs. Please refer to the paper for more details due to space limitation.

Comparison with NAQANet The major difference between our model and NAQANet is that NAQANet does not have the reasoning module, i.e., $\boldsymbol{M}_0$ is simply set as $\boldsymbol{M}^P$. As a result, numbers are treated as common words in NAQANet except in the prediction module, thus NAQANet may struggle to learn the numerical relationships between numbers, and potentially cannot well generalize to unseen numbers. However, as discussed in Sec. 1, the numerical comparison is essential for answering questions requiring numerical reasoning. In our model, the numerical relationships are explicitly represented with the topology of the graph and a NumGNN is used to perform numerical reasoning. Therefore, our NumNet model can handle questions requiring numerical reasoning more effectively, which is verified by the experiments in Sec. 4.

3.2 Numerically-aware Graph Construction

We regard all numbers from the question and passage as nodes in the graph for reasoning [2] . The

[1] As few samples require multiplication/division expression in the DROP dataset, we simply adapt the module proposed (Dua et al., 2019) and leave multiplication/division expression handling as future work.

[2] As a number in the question may serve as a critical comparison condition (refer to the second example in Table 1),

set of nodes corresponding to the numbers occurring in question and passage are denoted as $\boldsymbol{V}^Q$ and $\boldsymbol{V}^P$ respectively. And we denote all the nodes as $\boldsymbol{V} = \boldsymbol{V}^Q \cup \boldsymbol{V}^P$, and the number corresponding to a node $v \in \boldsymbol{V}$ as $n(v)$.

Two sets of edges are considered in this work:

- **Greater Relation Edge ($\overrightarrow{\boldsymbol{E}}$)**: For two nodes $v_i, v_j \in \boldsymbol{V}$, a directed edge $\overrightarrow{e}_{ij} = (v_i, v_j)$ pointing from v_i to v_j will be added to the graph if $n(v_i) > n(v_j)$, which is denoted as solid arrow in Figure 1.

- **Lower or Equal Relation Edge ($\overleftarrow{\boldsymbol{E}}$)**: For two nodes $v_i, v_j \in \boldsymbol{V}$, a directed edge $\overleftarrow{e}_{ij} = (v_j, v_i)$ will be added to the graph if $n(v_i) \leq n(v_j)$, which is denoted as dashed arrow in Figure 1.

Theoretically, $\overrightarrow{\boldsymbol{E}}$ and $\overleftarrow{\boldsymbol{E}}$ are complement to each other . However, as a number may occur several times and represent different facts in a document, we add a distinct node for each occurrence in the graph to prevent potential ambiguity. Therefore, it is more reasonable to use both $\overrightarrow{\boldsymbol{E}}$ and $\overleftarrow{\boldsymbol{E}}$ in order to encode the equal information among nodes.

3.3 Numerical Reasoning

As we built the graph $\mathcal{G} = (\boldsymbol{V}, \boldsymbol{E})$, we leverage NumGNN to perform reasoning, which is corresponding to the function $\texttt{Reasoning}(\cdot)$ in Eq. 7. The reasoning process is as follows:

Initialization For each node $v_i^P \in \boldsymbol{V}^P$, its representation is initialized as the corresponding column vector of $\boldsymbol{M}^P$. Formally, the initial representation is $\boldsymbol{v}_i^P = \boldsymbol{M}^P[I^P(v_i^P)]$, where $I^P(v_i^P)$ denotes the word index corresponding to v_i^P. Similarly, the initial representation $\boldsymbol{v}_j^Q$ for a node $v_j^Q \in \boldsymbol{V}^Q$ is set as the corresponding column vector of $\boldsymbol{M}^Q$. We denote all the initial node representations as $\boldsymbol{v}^0 = \{\boldsymbol{v}_i^P\} \cup \{\boldsymbol{v}_j^Q\}$.

One-step Reasoning Given the graph $\mathcal{G}$ and the node representations $\boldsymbol{v}$, we use a GNN to perform reasoning in three steps:

(1) **Node Relatedness Measure**: As only a few numbers are relevant for answering a question generally, we compute a weight for each node to by-pass irrelevant numbers in reasoning. Formally, the weight for node v_i is computed as:

$$\alpha_i = \text{sigmoid}(\boldsymbol{W}_v \boldsymbol{v}[i] + b_v), \tag{10}$$

we also add nodes for them in the graph.

where $\boldsymbol{W}_v$ is a weight matrix, and b_v is a bias.

(2) **Message Propagation**: As the role a number plays in reasoning is not only decided by itself, but also related to the context, we propagate messages from each node to its neighbors to help to perform reasoning. As numbers in question and passage may play different roles in reasoning and edges corresponding to different numerical relations should be distinguished, we use relation-specific transform matrices in the message propagation. Formally, we define the following propagation function for calculating the forward-pass update of a node:

$$\widetilde{\boldsymbol{v}}_i' = \frac{1}{|\mathcal{N}_i|} \left(\sum_{j \in \mathcal{N}_i} \alpha_j \boldsymbol{W}^{\mathtt{r}_{ji}} \boldsymbol{v}[j] \right), \tag{11}$$

where $\widetilde{\boldsymbol{v}}_i'$ is the message representation of node v_i, $\mathtt{r}_{ji}$ is the relation assigned to edge e_{ji}, $\boldsymbol{W}^{\mathtt{r}_{ji}}$ are relation-specific transform matrices, and $\mathcal{N}_i = \{j | (v_j, v_i) \in \boldsymbol{E}\}$ is the neighbors of node v_i.

For each edge e_{ji}, $\mathtt{r}_{ji}$ is determined by the following two attributes:

- Number relation: $>$ or $\leq$;

- Node types: the two nodes of the edge corresponding to two numbers that: (1) both from the question (q-q); (2) both from the passage (p-p); (3) from the question and the passage respectively (q-p); (4) from the passage and the question respectively (p-q).

Formally, $\mathtt{r}_{ij} \in \{>, \leq\} \times \{\text{q-q}, \text{p-p}, \text{q-p}, \text{p-q}\}$.

(3) **Node Representation Update**: As the message representation obtained in the previous step only contains information from the neighbors, it needs to be fused with the node representation to combine with the information carried by the node itself, which is performed as:

$$\boldsymbol{v}_i' = \text{ReLU}(\boldsymbol{W}_f \boldsymbol{v}_i + \widetilde{\boldsymbol{v}}_i' + \boldsymbol{b}_f), \tag{12}$$

where $\boldsymbol{W}_f$ is a weight matrix, and $\boldsymbol{b}_f$ is a bias vector.

We denote the entire one-step reasoning process (Eq. 10-12) as a single function

$$\boldsymbol{v}' = \texttt{Reasoning-Step}(\mathcal{G}, \boldsymbol{v}). \tag{13}$$

As the graph $\mathcal{G}$ constructed in Sec. 3.2 has encoded the numerical relations via its topology, the reasoning process is numerically-aware.

Multi-step Reasoning By single-step reasoning, we can only infer relations between adjacent nodes. However, relations between multiple nodes may be required for certain tasks, e.g., sorting. Therefore, it is essential to perform multi-step reasoning, which can be done as follows

$$\boldsymbol{v}^t = \texttt{Reasoning-Step}(\boldsymbol{v}^{t-1}), \qquad (14)$$

where $t \geq 1$. Suppose we perform K steps of reasoning, $\boldsymbol{v}^K$ is used as $\boldsymbol{U}$ in Eq. 7.

4 Experiments

4.1 Dataset and Evaluation Metrics

We evaluate our proposed model on DROP dataset (Dua et al., 2019), which is a public numerical MRC dataset. The DROP dataset is constructed by crowd-sourcing, which asks the annotators to generate question-answer pairs according to the given Wikipedia passages, which require numerical reasoning such as addition, counting, or sorting over numbers in the passages. There are $77,409$ training samples, $9,536$ development samples and $9,622$ testing samples in the dataset.

In this paper, we adopt two metrics including Exact Match (EM) and numerically-focused F1 scores to evaluate our model following Dua et al. (2019). The numerically-focused F1 is set to be 0 when the predicted answer is mismatched for those questions with the numeric golden answer.

4.2 Baselines

For comparison, we select several public models as baselines including **semantic parsing models**:

- Syn Dep (Dua et al., 2019), the neural semantic parsing model (KDG) (Krishnamurthy et al., 2017) with Stanford dependencies based sentence representations;
- OpenIE (Dua et al., 2019), KDG with open information extraction based sentence representations;
- SRL (Dua et al., 2019), KDG with semantic role labeling based sentence representations;

and **traditional MRC models**:

- BiDAF (Seo et al., 2017), an MRC model which utilizes a bi-directional attention flow network to encode the question and passage;
- QANet (Yu et al., 2018), which utilizes convolutions and self-attentions as the building blocks of encoders to represent the question and passage;
- BERT (Devlin et al., 2019), a pre-trained bidirectional Transformer-based language model which achieves state-of-the-art performance on lots of public MRC datasets recently;

and **numerical MRC models**:

- NAQANet (Dua et al., 2019), a numerical version of QANet model.
- NAQANet+, an enhanced version of NAQANet implemented by ourselves, which further considers real number (e.g. "2.5"), richer arithmetic expression, data augmentation, etc. The enhancements are also used in our NumNet model and the details are given in the supplemental material.

4.3 Experimental Settings

In this paper, we tune our model on the development set and use a grid search to determine the optimal parameters. The dimensions of all the representations (e.g., $\boldsymbol{Q}$, $\boldsymbol{P}$, $\boldsymbol{M}^Q$, $\boldsymbol{M}^P$, $\boldsymbol{U}$, $\boldsymbol{M}'_0$, $\boldsymbol{M}_0$ and $\boldsymbol{v}$) are set to 128. If not specified, the reasoning step K is set to 3. Since other parameters have little effect on the results, we simply follow the settings used in (Dua et al., 2019).

We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.8$, $\beta_2 = 0.999$, $\epsilon = 10^{-7}$ to minimize the objective function. The learning rate is 5×10^{-4}, L2 weight decay λ is 10^{-7} and the maximum norm value of gradient clipping is 5. We also apply exponential moving average with a decay rate 0.9999 on all trainable variables. The model is trained with a batch size of 16 for 40 epochs. Passages and questions are trimmed to 400 and 50 tokens respectively during training, and trimmed to $1,000$ and 100 tokens respectively during prediction [3].

4.4 Overall Results

The performance of our NumNet model and other baselines on DROP dataset are shown in Table 2. From the results, we can observe that:

(1) Our NumNet model achieves better results on both the development and testing sets on DROP dataset as compared to semantic parsing-based models, traditional MRC models and even numerical MRC models NAQANet and NAQANet+. The reason is that our NumNet model can make full use of the numerical comparison information over

[3] Trimming passages/questions introduces little impact because it only affects about 8% of the samples.

Method	Dev		Test	
	EM	F1	EM	F1

Table 2: Overall results on the development and test set. The evaluation metrics are calculated as the maximum over a golden answer set. All the results except "NAQANet+" and "NumNet" are obtained from (Dua et al., 2019).

numbers in both question and passage via the proposed NumGNN module.

(2) Our implemented NAQANet+ has a much better performance compared to the original version of NAQANet. It verifies the effectiveness of our proposed enhancements for baseline.

4.5 Effect of GNN Structure

In this part, we investigate the effect of different GNN structures on the DROP development set. The results are shown in Table 3. The "Comparison", "Number" and "ALL" are corresponding to the comparing question subset [4], the number-type answer subset, and the entire development set, respectively [5]. If we replace the proposed numerically-aware graph (Sec. 3.2) with a fully connected graph, our model fallbacks to a traditional GNN, denoted as "GNN" in the table. Moreover, "- question num" denotes the numbers in the question is not included in the graph, and "- $\leq$ type edge" and "- $>$ type edge" denote edges of $\leq$ and $>$ types are not adopted respectively.

[4]We find that many comparing questions in the DROP dataset are biased, of which the answers are the former candidates in the questions. Hence, we employ crowdsourced workers to identify and rewrite all comparing questions to construct an enhanced development set. Specially, for those comparing questions containing answer candidates, we also ask the crowdsourced workers to swap the candidates manually to enlarge the dataset.

[5]Note that the "ALL" result is not the average of "Comparison" and "Number". It is the performance on the entire development set which also includes questions of selection type, coreference resolution type, etc.

Method	Comparison		Number		ALL	
	EM	F1	EM	F1	EM	F1
GNN	69.86	75.91	67.77	67.78	61.90	65.16
NumGNN	74.53	80.36	69.74	69.75	64.54	68.02
- question num	74.84	80.24	68.42	68.43	63.78	67.17
- $\leq$ type edge	74.89	80.51	68.48	68.50	63.66	67.06
- $>$ type edge	74.86	80.19	68.77	68.78	63.64	66.96

Table 3: Performance with different GNN structure. "Comparison", "Number" and "ALL" denote the comparing question subset, the number-type answer subset, and the entire development set, respectively.

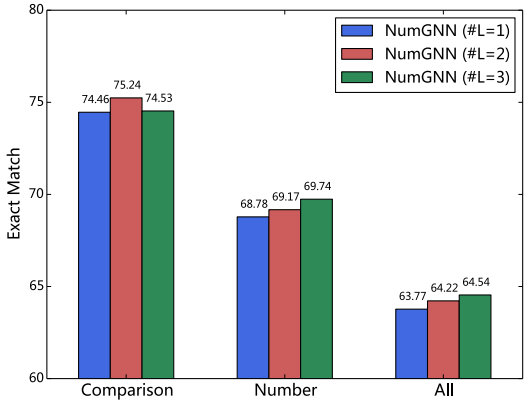

Figure 2: Effect of GNN layer numbers (# L).

As shown in Table 3, our proposed NumGNN leads to statistically significant improvements compared to traditional GNN on both EM and F1 scores especially for comparing questions. It indicates that considering the comparing information over numbers could effectively help the numerical reasoning for comparing questions. Moreover, we find that the numbers in the question are often related to the numerical reasoning for answering the question, thus considering numbers in questions in NumGNN achieves better performance. And the results also justify that encoding "greater relation" and "lower or equal relation" simultaneously in the graph also benefits our model.

4.6 Effect of GNN Layer Number

The number of NumGNN layers represents the numerical reasoning ability of our models. A K-layer version has the ability for K-step numerical inference. In this part, we additionally perform experiments to understand the values of the numbers of NumGNN layers. From Figure 2, we could observe that:

(1) The 2-layer version of NumNet achieves the best performance for the comparing questions. From careful analysis, we find that most compar-

Table 5: Typical error examples. Row 1: the answer is multiple nonadjacent spans; Row 2: Intermediate numbers are involved in reasoning.

ing questions only require at most 2-step reasoning (e.g., "*Who was the second oldest player in the MLB, Clemens or Franco?*"), and therefore the 3-layer version of NumNet is more complex but brings no gains for these questions.

(2) The performance of our NumNet model on the overall development set is improved consistently as the number of GNN layers increases. The reason is that some of the numerical questions require reasoning over many numbers in the passage, which could benefit from the multi-step reasoning ability of multi-layer GNN. However, further investigation shows that the performance gain is not stable when $K \geq 4$. We believe it is due to the intrinsic over smoothing problem of GNNs (Li et al., 2018).

4.7 Case Study

We further give some examples to show why incorporating comparing information over numbers in the passage could help numerical reasoning in MRC in Table 4. For the first case, we observe that NAQANet+ gives a wrong prediction, and we find that NAQANet+ will give the same prediction for the question "*Which age group is smaller: under the age of 18 or 18 and 24?*". The reason is that NAQANet+ cannot distinguish which one is larger for 10.1% and 56.2%. For the second case, NAQANet+ cannot recognize the second longest field goal is 22-yard and also gives a wrong prediction. For these two cases, our NumNet model could give the correct answer through the numeric reasoning, which indicates the effectiveness of our NumNet model.

4.8 Error Analysis

To investigate how well our NumNet model handles sorting/comparison questions and better understand the remaining challenges, we perform an error analysis on a random sample of NumNet predictions. We find that:

(1) Our NumNet model can answer about 76% of sorting/comparison questions correctly, which indicates that our NumNet model has achieved numerical reasoning ability to some extend.

(2) Among the incorrectly answered sorting/comparison questions, the most ones (26%) are those whose golden answers are multiple nonadjacent spans (row 1 in Table 5), and the second most ones (19%) are those involving comparison with an intermediate number that does not literally occur in the document/question but has to be de-

rived from counting or arithmetic operation (row 1 in Table 5).

4.9 Discussion

By combining the numerically-aware graph and the NumGNN together, our NumNet model achieves the numerical reasoning ability. On one hand, the numerically-aware graph encodes numbers as nodes and relationships between them as the edges, which is required for numerical comparison. On the other hand, through one-step reasoning, our NumGNN could perform comparison and identify the numerical condition. After multiple-step reasoning, our NumGNN could further perform sorting.

However, since the numerically-aware graph is pre-defined, our NumNet is not applicable to the case where an intermediate number has to be derived (e.g., from arithmetic operation) in the reasoning process, which is a major limitation of our model.

5 Conclusion and Future Work

Numerical reasoning skills such as addition, subtraction, sorting and counting are naturally required by machine reading comprehension (MRC) problems in practice. Nevertheless, these skills are not taken into account explicitly for most existing MRC models. In this work, we propose a numerical MRC model named NumNet which performs explicit numerical reasoning while reading the passages. To be specific, NumNet encodes the numerical relations among numbers in the question and passage into a graph as its topology, and leverages a numerically-aware graph neural network to perform numerical reasoning on the graph. Our NumNet model outperforms strong baselines with a large margin on the DROP dataset.

In the future, we will explore the following directions: (1)As we use a pre-defined reasoning graph in our model, it is incapable of handling reasoning process which involves intermediate numbers that not presented in the graph. How to incorporate dynamic graph into our model is an interesting problem. (2) Compared with methods proposed for arithmetic word problems (AWPs), our model has better natural language understanding ability. However, the methods for AWPs can handle much richer arithmetic expressions. Therefore, how to combine both of their abilities to develop a more powerful numerical MRC model is an interesting future direction. (3) Symbolic reasoning plays a crucial role in human reading comprehension. Our work integrates numerical reasoning, which is a special case of symbolic reasoning, into traditional MRC systems. How to incorporate more sophisticated symbolic reasoning abilities into MRC systems is also a valuable future direction.

Abstract

We present Unicoder, a universal language encoder that is insensitive to different languages. Given an arbitrary NLP task, a model can be trained with Unicoder using training data in one language and directly applied to inputs of the same task in other languages. Comparing to similar efforts such as Multilingual BERT (Devlin et al., 2018) and XLM (Lample and Conneau, 2019), three new cross-lingual pre-training tasks are proposed, including cross-lingual word recovery, cross-lingual paraphrase classification and cross-lingual masked language model. These tasks help Unicoder learn the mappings among different languages from more perspectives. We also find that doing fine-tuning on multiple languages together can bring further improvement. Experiments are performed on two tasks: cross-lingual natural language inference (XNLI) and cross-lingual question answering (XQA), where XLM is our baseline. On XNLI, 1.8% averaged accuracy improvement (on 15 languages) is obtained. On XQA, which is a new cross-lingual dataset built by us, 5.5% averaged accuracy improvement (on French and German) is obtained.

Introduction

Data annotation is expensive and time-consuming for most of NLP tasks. Recently, pre-trained models, such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2018) and GPT (Radford et al., 2018), have shown strong capabilities of transferring knowledge learned from large-scale text corpus to specific NLP tasks with limited or no training data. But they still cannot handle tasks when training and test instances are in different languages.

Motivated by this issue, some efforts have been made, such as Multilingual BERT (Devlin et al., 2018) and XLM (Lample and Conneau, 2019), for cross-lingual tasks. Multilingual BERT trains a BERT model based on multilingual Wikipedia, which covers 104 languages. As its vocabulary contains tokens from all languages, Multilingual BERT can be used to cross-lingual tasks directly. XLM further improves Multilingual BERT by introducing a translation language model (TLM). TLM takes a concatenation of a bilingual sentence pair as input and performs masked language model based on it. By doing this, it learns the mappings among different languages and performs good on the XNLI dataset.

However, XLM only uses a single cross-lingual task during pre-training. At the same time, Liu et al. (2019) has shown that multi-task learning can further improve a BERT-style pre-trained model. So we think more cross-lingual tasks could further improve the resulting pre-trained model for cross-lingual tasks. To verify this, we propose Unicoder, a universal language encoder that is insensitive to different languages and pre-trained based on 5 pre-training tasks. Besides masked language model and translation language model, 3 new cross-lingual pre-training tasks are used in the pre-training procedure, including cross-lingual word recovery, cross-lingual paraphrase classification and cross-lingual masked language model. Cross-lingual word recovery leverage attention matrix between bilingual sentence pair to learn the cross-lingual word alignment relation. Cross-lingual paraphrase classification takes two sentences from different languages and classify whether they have same meaning. This task could learn the cross-lingual sentence alignment relation. Inspired by the successful of monolingual pre-training on long text (Radford et al., 2018; Devlin et al., 2018), we propose cross-lingual masked language model whose input is document written by multiple languages. We also find that doing fine-tuning on multiple languages together can

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2485–2494, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

bring further improvement. For the languages without training data, we use machine translated data from rich-resource languages.

Experiments are performed on cross-lingual natural language inference (XNLI) and cross-lingual question answering (XQA), where both Multilingual BERT and XLM are considered as our baselines. On XNLI, 1.8% averaged accuracy improvement (on 15 languages) is obtained. On XQA, which is a new cross-lingual dataset built by us, 5.5% averaged accuracy improvement (on French and German) is obtained.

In short, our contributions are 4-fold. First, 3 new cross-lingual pre-training tasks are proposed, which can help to learn a better language-independent encoder. Second, a cross-lingual question answering (XQA) dataset is built, which can be used as a new cross-lingual benchmark dataset. Third, we verify that by fine-tuning multiple languages together, significant improvements can be obtained. Fourth, on the XNLI dataset, new state-of-the-art results are achieved.

Related work

Monolingual Pre-training Recently, pretraining an encoder by language model (Radford et al., 2018; Peters et al., 2018; Devlin et al., 2018) and machine translation (McCann et al., 2017) have shown significant improvement on various natural language understanding (NLU) tasks, like tasks in GLUE (Wang et al., 2018). The application scheme is to fine-tune the pre-trained encoder on single sentence classification task or sequential labeling task. If the tasks have multiple inputs, just concatenate them into one sentence. This approach enables one model to be generalized to different language understanding tasks. Our approach also is contextual pre-training so it could been applied to various NLU tasks.

Cross-lingual Pre-training Cross-lingual Pretraining is a kind of transfer learning with different source and target domain (Pan and Yang, 2010). A high-quality cross-lingual representation space is assumed to effectively perform the cross-lingual transfer. Mikolov et al. (2013) has been applied small dictionaries to align word representations from different languages and it is sufficient to align different languages with orthogonal transformation (Xing et al., 2015), even without parallel data (Lample et al., 2018). Following the line of previous work, the word alignment also could be applied to multiple languages (Ammar et al., 2016). Artetxe and Schwenk (2018) use multilingual machine translation to train a multilingual sentence encoder and use this fixed sentence embedding to classify XNLI. We take these ideas one step further by producing a pre-trained encoder instead of word embedding or sentence embedding.

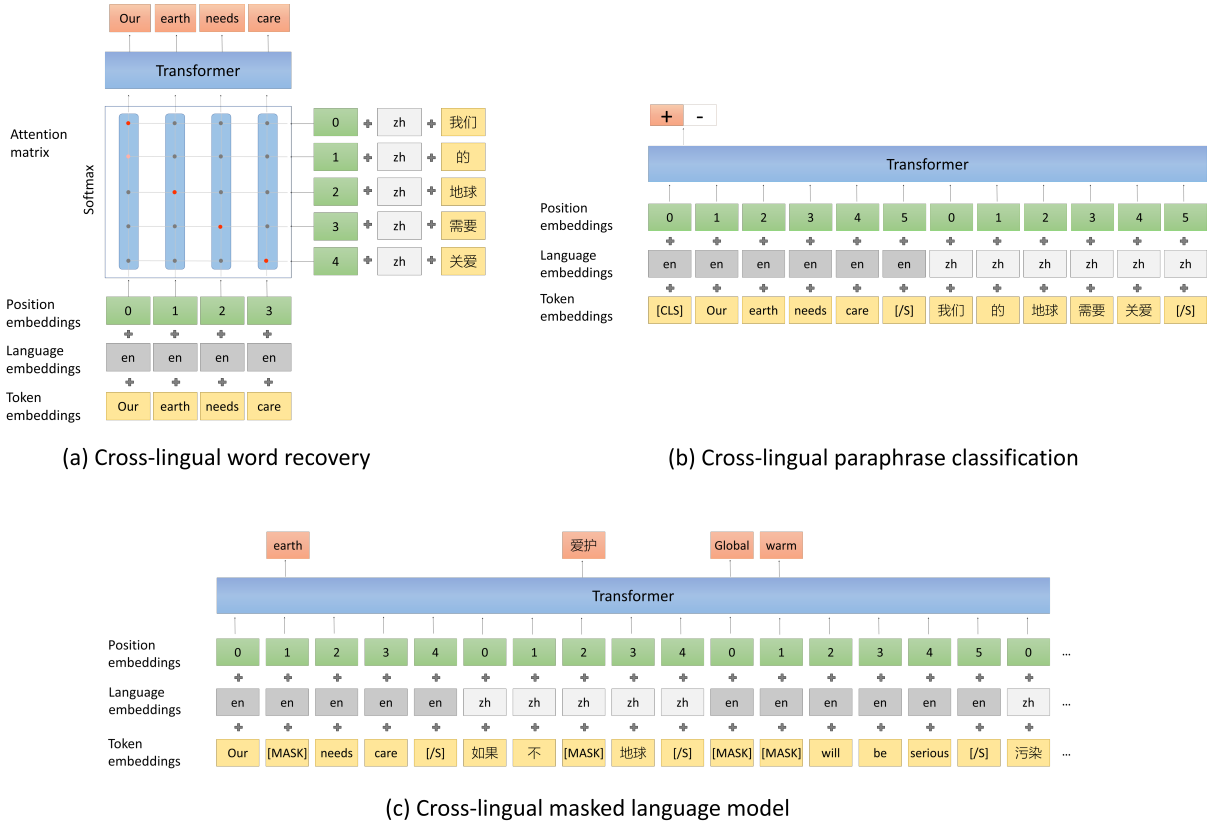
Our work is based on two recent pre-trained cross-lingual encoders: multilingual BERT [1] (Devlin et al., 2018) and XLM (Lample and Conneau, 2019). Multilingual BERT trains masked language model (MLM) with sharing vocabulary and weight for all 104 languages. But each training sample is monolingual document. Keeping the same setting, XLM proposed a new task TLM, which uses a concatenation of the parallel sentences into one sample for masked language modeling. Besides these two tasks, we proposed three new cross-lingual pre-training tasks for building a better language-independent encoder.

Approach

This section will describe details of Unicoder, including tasks used in the pre-training procedure and its fine-tuning strategy.

Model Structure

Unicoder follows the network structure of XLM (Lample and Conneau, 2019). A shared vocabulary is constructed by running the Byte Pair Encoding (BPE) algorithm (Sennrich et al., 2016) on corpus of all languages. We also down sample the rich-resource languages corpus, to prevent words of target languages from being split too much at the character level.



Pre-training Tasks in Unicoder

Both masked language model and translation language model are used in Unicoder by default, as they have shown strong performance in XLM.

Motivated by Liu et al. (2019), which shows that pre-trained models can be further improved by involving more tasks in pre-training, we introduce three new cross-lingual tasks in Unicoder. All training data for these three tasks are acquired from the existing large-scale high-quality machine translation corpus.

Cross-lingual Word Recovery Similar to translation language model, this task also aims to let the

[1] https://github.com/google-research/bert/blob/master/multilingual.md

(a) Cross-lingual word recovery

(b) Cross-lingual paraphrase classification

(c) Cross-lingual masked language model

Figure 1: Unicoder consists of three cross-lingual pre-training tasks: (a) The cross-lingual word recovery model is to learn word relation from different languages (b) The cross-lingual paraphrase classification is to classify whether two sentences from different languages are paraphrase. (c) The cross-lingual masked language model is to train masked language model with cross-lingual document.

pre-trained model learn the underlying word alignments between two languages. It is mainly motivated by the attention matrix used in the neural machine translation Bahdanau et al. (2014) task.

Formally, given a bilingual sentence pair (X, Y), where $X = (x_1, x_2, ..., x_m)$ is a sentence with m words from language s, $Y = (y_1, y_2, ..., y_n)$ is a sentence with n words from language t, this task first represents each x_i as $x_i^t \in R^h$ by all word embeddings of Y:

$$x_i^t = \sum_{j=1}^{n} softmax(A_{ij}) y_j^t \quad (1)$$

where $x_i^s \in R^h$ and $y_j^t \in R^h$ denote the word embeddings of x_i and y_j respevtively, h denotes the word embedding dimension, $A \in R^{m \times n}$ is an attention matrix calculated by:

$$A_{ij} = W[x_i^s, y_j^t, x_i^s \odot y_j^t] \quad (2)$$

$W \in R^{3*h}$ is a trainable weight and $\odot$ is element-wise multiplication. Then, Unicoder takes $X^t = (x_1^t, x_2^t, ..., x_n^t)$ as input, and tries to predict the original word sequence X.

Similar to translation language model in XLM, this task is based on the bilingual sentence pairs as well. However, as it doesn't use the original words as input, we can train this task by recovering all words at the same time. The model structure of this task is illustrated in Figure 1.a.

Cross-lingual Paraphrase Classification This task takes two sentences from different languages as input and classifies whether they are with the same meaning. Like the next sentence prediction task in BERT, we concatenate two sentences as a sequence and input it to Unicoder. The representation of the first token in the final layer will be used for the paraphrase classification task. This procedure is illustrated in Figure 1.b.

We created the cross-lingual paraphrase classification dataset from machine translation dataset. Each bilingual sentence pair (X, Y) servers as a positive sample. For negative samples, the most straight forward method is to replace Y to a ran-

dom sampled sentence from target language. But this will make the classification task too easy. So we introduce the hard negative samples followed Guo et al. (2018). First, we train a light-weight paraphrase model with random negative samples. Then we use this model to select sentence with high similarity score to X but doesn't equal to Y as hard negative samples. We choose DAN (Iyyer et al., 2015) as the light model. We create positive and negative samples in 1:1.

Cross-lingual Masked Language Model Previous successful pre-training language model (Devlin et al., 2018; Radford et al., 2018) is conducted on document-level corpus rather than sentence-level corpus. The language model perplexity on document also is much lower than sentence (Peters et al., 2018). So we propose cross-lingual masked language model, whose input is come from cross-lingual document.

Cross-lingual document is a sequence of sentences, and the sentences are written with different languages. In most case, people won't write cross-lingual document. But we found that a large proportion of aligned sentence pairs in machine translation are extracted from parallel documents, such as MultiUN corpus and OpenSubtitles corpus. In other words, these MT corpus are document-level corpus in which each sentence and its translation is well aligned. We construct cross-lingual document by replacing the sentences with even index to its translation as illustrated in Figure 1.c. We truncate the cross-lingual document by 256 sequence length and feed it to Unicoder for masked language modeling.

Multi-language Fine-tuning

A typical setting of cross-lingual language understanding is only one language has training data, but the test is conducted on other languages. We denote the language has training data as source language, and other languages as target languages. A scalable way (Conneau et al., 2018) to address this problem is through Cross-lingual TEST, in which a pre-trained encoder is trained on data in source language and directly evaluated on data in target languages.

There are two other machine translation methods that make training and test belong to the same language. TRANSLATE-TRAIN translates the source language training data to a target language and fine-tunes on this pseudo training data. TRANSLATE-TEST fine-tunes on source language training data, but translates the target language test data to source language and test on it.

Inspired by multi-task learning (Liu et al., 2018, 2019) for improving pre-trained model, we propose a new fine-tuning strategy Multi-language Fine-tuning. We propose to fine-tune on both the source language training data and pseudo target language training data. If there are multiple target languages, we will fine-tune on all of them at same time.

Different languages may have totally different vocabulary and syntax. But our experiments show that in most cases, joint fine-tuning multiple languages could bring huge improvement. Only in just a few cases, this may harm the performance.

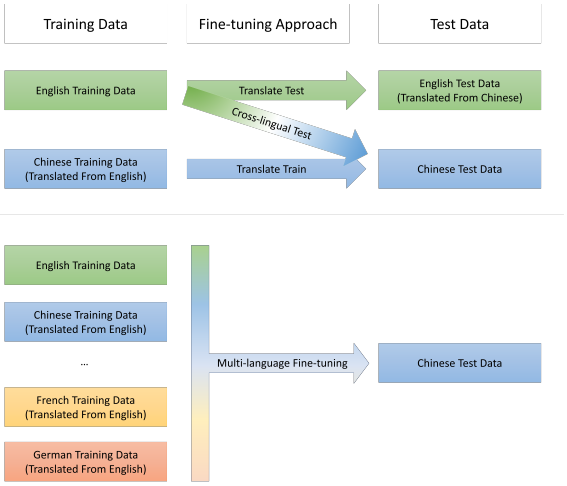


Figure 2: Currently cross-lingual fine-tuning has three baseline approaches, they could be defined based on their training data and test data. Suppose we target to test on Chinese data, Translate-train is to train on Chinese training data which is translated from English and test on Chinese test data; Translate-Test is to train on English training data and test on English test data which is translated from Chinese; Cross-lingual test is to train in English training data and test on Chinese test data. Multi-language fine-tuning is to train on English training data and multiple other languages training data which are translated from English, then test on Chinese Test data.

Experiment

In this section, we describe the data processing and training details. Then we compare the Unicoder with the current state of the art approaches on two tasks: XNLI and XQA.

Data Processing

Our model is pre-trained on 15 languages, including English(en), French(fr), Spanish(es), German(de), Greek(el), Bulgarian(bg), Russian(ru), Turkish(tr), Arabic(ar), Vietnamese(vi), Thai(th), Chinese(zh), Hindi(hi), Swahili(sw) and Urdu(ur). For MLM, we use the Wikipedia from these languages. The other four tasks need MT dataset. We use same MT dataset as Lample and Conneau (2019) which are collected from MultiUN (Eisele and Chen, 2010), IIT Bombay corpus (Kunchukuttan et al., 2017), OpenSubtitles 2018, EUbookshop corpus and GlobalVoices. In the MT corpus, 13 of 14 languages (except IIT Bombay corpus) are from parallel document and could be used to train cross-lingual document language model. The number of data we used is reported at table 1.

For tokenization, we follows the line of Koehn et al. (2007); Chang et al. (2008) for each language. We use byte-pair encoding (BPE) to process the corpus and build vocabulary.

Table 1: Sentence number we used in pre-training.

Training Details

Model Structure Our Unicoder is a 12-layer transformer with 1024 hidden units, 16 heads, GELU activation (Hendrycks and Gimpel, 2017). we set dropout to 0.1. The vocabulary size is 95,000.

Pre-training details To reduce pre-training time, we initialize our model from XLM (Lample and Conneau, 2019). We pretrain Unicoder with five tasks including MLM\TLM and our three cross-lingual tasks. In each step, we iteratively train these five tasks. A batch for these tasks is available in 15 languages, and we sample several languages with equal probability. And we use batch size 512 by gradient accumulation. We train our model with the Adam optimizer (Kingma and Ba, 2015), and learning rate starts from $1e-5$ with invert square root decay (Vaswani et al., 2017). We run our pretraining experiments on a single server with 8 V100 GPUs and use FP16 to save the memory.

The max sequence length of MLM and cross-lingual language model is 256. For the other three tasks with two sentences as input, we set the max sequence length to 128 so the sum of them is 256.

Fine-tuning details For fine-tuning stage, we use same optimizer and learning rate as pre-training. We set the batch size to 32.

Experimental evaluation

XNLI: Cross-lingual Natural Language Inference Natural Language Inference(NLI) takes two sentences as input and determines whether one entails the other, contradicts it or neither (neutral). XNLI is NLI defined on 15 languages. Each language contains 5000 human annotated development and test set. Only English has training data, which is a crowd-sourced collection of 433k sentence pairs from MultiNLI (Williams et al., 2018). The performance is evaluated by classification accuracy.

We report the results of XNLI in Table 2, by comparing our Unicoder model with four baselines: Conneau et al. (2018) uses LSTM as sentence encoder and constraints bilingual sentence pairs have similar embedding. The other baselines are pre-training based approaches. Multilingual BERT (Devlin et al., 2018) is to train masked language model on multilingual Wikipedia. And Artetxe and Schwenk (2018) is pre-trained with machine translation model and takes the MT encoder to produce sentence embedding. XLM (Lample and Conneau, 2019) explores masked language model on multilingual Wikipedia, using translation language model on MT bilingual sentence pair for pre-training in addition.

Based on the result, we could find our pre-training model Unicoder obtains the best result in every fine-tuning setting. In TRANSLATE-TRAIN, TRANSLATE-TEST and Cross-lingual TEST, Unicoder obtains 76.9%, 74.9% and 75.4% accuracy on average, respectively. In Multi-language Fine-tuning, Unicoder outper-

Table 2: Test accuracy on the 15 XNLI languages. This table is organized by fine-tuning and test approaches. TRANSLATE-TRAIN is to machine translate English training data to target language and fine-tune with this translated data; TRANSLATE-TEST is machine translate target language test data to English, the fine-tuning is conducted on English; Cross-lingual TEST is to fine-tune on English and directly test on target language; Multi-language Fine-tune is to fine-tune on machine translated training data on all languages.

forms XLM by 0.7%. By translating the English training data to target language, both TRANSLATE-TRAIN and Multi-language Fine-tuning can outperform other fine-tuning approaches on average no matter what encoder is used. Our Multi-language Fine-tuning approach is even better than TRANSLATE-TRAIN. With this approach, XLM is been improved by 1.1% and Unicoder is been improved by 1.6%.

By Combining Unicoder and Multi-language Fine-tuning, Unicoder achieves an new state of the art with 78.5%. It obtains 1.8% accuracy gain compared to previous state of the art, XLM fine-tuned with TRANSLATE-TRAIN.

XQA: Cross-lingual Question Answering We proposed a new dataset XQA. Question Answering takes a question and an answer as input, then classify whether the answer is relevant to question. Each answer is a short passage. XQA contains three languages including English, French and German. Only English have training data. The training data cover various domains, such as health, tech, sports, etc. The English training data contains millions of samples and each languages has 500 test data.

Keeping the same experimental setup as XNLI, we also evaluate Unicoder on XQA and set XLM fine-tuned on our dataset as baseline with their published code. We split 5K data from training dataset as development data to do model selection. The results are shown in Table 3.

	en	fr	de	average

formance 69.7% on XQA. Compared to XLM + TRANSLATE-TRAIN baseline, we have 5.5% gain.

Analysis

In this section, we provide ablation analysis for different variants of our approaches and elucidate some interesting aspects of Unicoder. Sec. 5.1 is the ablation study of each cross-lingual pre-training task. It also shows the impact of Multi-language Fine-tuning. Sec. 5.2 explores the impact of language numbers. Additionally, Sec. 5.3 analyzes the relation between English and other language by joint fine-tune on two languages. Then we further explore the relation between any language pair (Sec. 5.4).

Ablation Study

To examine the utility of our new cross-lingual pre-training tasks, we conducted ablation study on XNLI dataset. For these three cross-lingual pre-training tasks, we remove them and only pre-train on other tasks. To this end, we fine-tune the Unicoder with Multi-language Fine-tuning. The results are present at Table 2.

Ablation experiments for each factor showed that removing any tasks will lead to performance drop. Comparing Unicoder with XLM, We can draw several conclusions from the results in Table 2. First, the cross-lingual paraphrase classification has least drop compared to others and removing the word recovery task hurts performance significantly. For example, in the case of XNLI, using just the Cross-lingual Language Model and Paraphrase Classification improves test accuracy on average by 0.4%. And integrating with Word Recovery model allows Unicoder to learn a better representation improves the average accuracy another 0.3%. Second, Multi-language fine-tuning is helpful to find the relation between languages, we will analyze it below. Table 2 and Table 3 both show it can bring a significant boost in cross-lingual language understanding performance. With the help of Multi-language fine-tuning, Unicoder is been improved by 1.6% of accuracy on XNLI and 3.3% on XQA.

The relation between language number and fine-tuning performance

In Table 2, we proved that Multi-language Fine-tuning with 15 languages is better than TRANSLATE-TRAIN who only fine-tune on 1 language. In this sub-section, we try more setting to analysis the relation between language number and fine-tuning performance.

In this experiment, only English has human labeled training data, the other languages use machine translated training data from English. The experiment is conducted on 6 languages which are the languages of MT corpus Multilingual United Nations (MultiUN).

We have four settings: **1 language** is equals to TRANSLATE-TRAIN, the pre-trained model is fine-tuned on target language. **2 languages** is to fine-tune on English and target language. For English, we report the average result when fine-tune with other 5 languages, respectively. **6 languages** is to fine-tune on 6 selected languages of this experiment. **15 languages** is to fine-tune on all 15 languages our model support, and report the results on 6 languages. This setting is equals to last row of Table 2.

The results are shown at Table 4. In most languages, we could find that the more languages we used in fine-tuning, the better the performance. Chinese and Russian have two numbers don't follow this trend. But 15 languages always outperform 1 language for each languages.

The most surprising result is English could be improved by Multi-language Fine-tuning even it

Table 6: Result of joint fine-tuning two languages. This table reports the result on English and average accuracy of 15 languages on XNLI. The last row means Unicoder only fine-tunes on English.

The relation between English and other languages

In this experiment, we joint fine-tune English and one language. With this experiment, we could test the relation between English and other languages since all languages have equal position in the pre-training and fine-tuning.

We report the performance on English and average of 15 languages. First, we could find most of the average results are improved by joint fine-tuning two languages. Only Vietnamese(vi) and Urdu(ur) lead to performance drop. Secondly, the improvement on English is not stable. French(fr) and Spanish(es) could improve English performance. But Vietnamese(vi) and Thai(th) lead to a big drop.

The relation between different languages

So as to better understand the relation between different languages, we fine-tune Unicoder on one language and test on all 15 languages. The results are shown in Table 5. The numbers in the diagonal correspond to the TRANSLATE-TRAIN result reported in Table 2.

We observe that the Unicoder can transfer knowledge from one language to another language. We could find that fine-tune on one language often lead to best performance on this language, except Greek(el) and Urdu(ur). In fact, TRANSLATE-TRAIN of Urdu even harm the performance. Urdu also have worst generation ability to other languages. Russian(ru) has best generalization ability, even better than source language

English.

We also could find that transfer between English(en), Spanish(es) and French(fr) is easier that other languages. The MT system between these languages also outperform other languages (Conneau et al., 2018).

Conclusion

We have introduced the Unicoder which is insensitive to different languages. We pre-train Unicoder with three new cross-lingual tasks, including cross-lingual word recovery, cross-lingual paraphrase classification and cross-lingual masked language model. We also proposed a new Multi-language Fine-tuning approach. The experiments on XNLI and XQA proved Unicoder could bring large improvements. and our approach become new state of the art on XNLI and XQA. We also did experiments to show that the more languages we used in fine-tuning, the better the results. Even rich-resource language also could been improved.

Addressing Semantic Drift in Question Generation for Semi-Supervised Question Answering

Shiyue Zhang **Mohit Bansal**

{shiyue, mbansal}@cs.unc.edu

Abstract

Text-based Question Generation (QG) aims at generating natural and relevant questions that can be answered by a given answer in some context. Existing QG models suffer from a "semantic drift" problem, i.e., the semantics of the model-generated question drifts away from the given context and answer. In this paper, we first propose two semantics-enhanced rewards obtained from downstream question paraphrasing and question answering tasks to regularize the QG model to generate semantically valid questions. Second, since the traditional evaluation metrics (e.g., BLEU) often fall short in evaluating the quality of generated questions, we propose a QA-based evaluation method which measures the QG model's ability to mimic human annotators in generating QA training data. Experiments show that our method achieves the new state-of-the-art performance w.r.t. traditional metrics, and also performs best on our QA-based evaluation metrics. Further, we investigate how to use our QG model to augment QA datasets and enable semi-supervised QA. We propose two ways to generate synthetic QA pairs: generate new questions from existing articles or collect QA pairs from new articles. We also propose two empirically effective strategies, a data filter and mixing mini-batch training, to properly use the QG-generated data for QA. Experiments show that our method improves over both BiDAF and BERT QA baselines, even without introducing new articles.[1]

1 Introduction

In contrast to the rapid progress shown in Question Answering (QA) tasks (Rajpurkar et al., 2016; Joshi et al., 2017; Yang et al., 2018), the task of Question Generation (QG) remains understudied and challenging. However, as an important dual task to QA, QG can not only be used to augment QA datasets (Duan et al., 2017), but can also be applied in conversation and education systems (Heilman and Smith, 2010; Lindberg et al., 2013). Furthermore, given that existing QA models often fall short by doing simple word/phrase matching rather than true comprehension (Jia and Liang, 2017), the task of QG, which usually needs complicated semantic reasoning and syntactic variation, should be another way to encourage true machine comprehension (Lewis and Fan, 2019). Recently, we have seen an increasing interest in the QG area, with mainly three categories: Text-based QG (Du et al., 2017; Zhao et al., 2018), Knowledge-Base-based QG (Reddy et al., 2017; Serban et al., 2016), and Image-based QG (Li et al., 2018; Jain et al., 2017). Our work focuses on the Text-based QG branch.

Context: ...during the age of enlightenment, philosophers such as **john locke** advocated the principle in their writings, whereas others, such as thomas hobbes, strongly opposed it. montesquieu was one of the foremost supporters of separating the legislature, the executive, and the judiciary...
Gt: who was an advocate of separation of powers? **Base**: who opposed the principle of enlightenment? **Ours**: who advocated the principle in the age of enlightenment?

Table 1: An examples of the "semantic drift" issue in Question Generation ("Gt" is short for "ground truth").

Current QG systems follow an attention-based sequence-to-sequence structure, taking the paragraph-level context and answer as inputs and outputting the question. However, we observed that these QG models often generate questions that semantically drift away from the given context and answer; we call this the "semantic drift" problem. As shown in Table 1, the baseline QG model generates a question that has almost contrary semantics with the ground-truth question, and the generated phrase "the principle of en-

lightenment" does not make sense given the context. We conjecture that the reason for this "semantic drift" problem is because the QG model is trained via teacher forcing only, without any high-level semantic regularization. Hence, the learned model behaves more like a question language model with some loose context constraint, while it is unaware of the strong requirements that it should be closely grounded by the context and should be answered by the given answer. Therefore, we propose two semantics-enhanced rewards to address this drift: **QPP** and **QAP**. Here, **QPP** refers to **Q**uestion **P**araphrasing **P**robability, which is the probability of the generated question and the ground-truth question being paraphrases; **QAP** refers to **Q**uestion **A**nswering **P**robability, which is the probability that the generated question can be correctly answered by the given answer. We regularize the generation with these two rewards via reinforcement learning. Experiments show that these two rewards can significantly improve the question generation quality separately or jointly, and achieve the new state-of-the-art performance on the SQuAD QG task.

Next, in terms of QG evaluation, previous works have mostly adopted popular automatic evaluation metrics, like BLEU, METEOR, etc. However, we observe that these metrics often fall short in properly evaluating the quality of generated questions. First, they are not always correlated to human judgment about answerability (Nema and Khapra, 2018). Second, since multiple questions are valid but only one reference exists in the dataset, these traditional metrics fail to appropriately score question paraphrases and novel generation (shown in Table 2). Therefore, we introduce a QA-based evaluation method that directly measures the QG model's ability to mimic human annotators in generating QA training data, because ideally, we hope that the QG model can act like a human to ask questions. We compare different QG systems using this evaluation method, which shows that our semantics-reinforced QG model performs best. However, this improvement is relatively minor compared to our improvement on other QG metrics, which indicates improvement on typical QG metrics does not always lead to better question annotation by QG models for generating QA training set.

Further, we investigate how to use our best QG system to enrich QA datasets and perform semi-supervised QA on SQuADv1.1 (Rajpurkar et al., 2016). Following the back-translation strategy that has been shown to be effective in Machine Translation (Sennrich et al., 2016) and Natural Language Navigation (Fried et al., 2018; Tan et al., 2019), we propose two methods to collect synthetic data. First, since multiple questions can be asked for one answer while there is only one human-labeled ground-truth, we make our QG model generate new questions for existing context-answer pairs in SQuAD training set, so as to enrich it with paraphrased and other novel but valid questions. Second, we use our QG model to label new context-answer pairs from new Wikipedia articles. However, directly mixing synthetic QA pairs with ground-truth data will not lead to improvement. Hence, we introduce two empirically effective strategies: one is a data filter based on QAP (same as the QAP reward) to filter out examples that have low probabilities to be correctly answered; the other is a "mixing mini-batch training" strategy that always regularizes the training signal with the ground-truth data. Experiments show that our method improves both BiDAF (Seo et al., 2016; Clark and Gardner, 2018) and BERT (Devlin et al., 2018) QA baselines by 1.69/1.27 and 1.19/0.56 absolute points on EM/F1, respectively; even without introducing new articles, it can bring 1.51/1.13 and 0.95/0.13 absolute improvement, respectively.

2 Related Works

Question Generation Early QG studies focused on using rule-based methods to transform statements to questions (Heilman and Smith, 2010; Lindberg et al., 2013; Labutov et al., 2015). Recent works adopted the attention-based sequence-to-sequence neural model (Bahdanau et al., 2014) for QG tasks, taking answer sentence as input and outputting the question (Du et al., 2017; Zhou et al., 2017), which proved to be better than rule-based methods. Since human-labeled questions are often relevant to a longer context, later works leveraged information from the whole paragraph for QG, either by extracting additional information from the paragraph (Du and Cardie, 2018; Song et al., 2018; Liu et al., 2019) or by directly taking the whole paragraph as input (Zhao et al., 2018; Kim et al., 2018; Sun et al., 2018). A very recent concurrent work applied the large-scale language model pre-training strategy for QG and

also achieved a new state-of-the-art performance (Dong et al., 2019). However, the above models were trained with teacher forcing only. To address the exposure bias problem, some works applied reinforcement learning taking evaluation metrics (e.g., BLEU) as rewards (Song et al., 2017; Kumar et al., 2018). Yuan et al. (2017) proposed to use a language model's perplexity (R_{PPL}) and a QA model's accuracy (R_{QA}) as two rewards but failed to get significant improvement. Their second reward is similar to our QAP reward except that we use QA probability rather than accuracy as the probability distribution is more smooth. Hosking and Riedel (2019) compared a set of different rewards, including R_{PPL} and R_{QA}, and claimed none of them improved the quality of generated questions. For QG evaluation, even though some previous works conducted human evaluations, most of them still relied on traditional metrics (e.g., BLEU). However, Nema and Khapra (2018) pointed out the existing metrics do not correlate with human judgment about answerability, so they proposed "Q-metrics" that mixed traditional metrics with an "answerability" score. In our work, we will show QG results on traditional metrics, Q-metrics, as well as human evaluation, and also propose a QA-based QG evaluation.

Question Generation for QA As the dual task of QA, QG has been often proposed for improving QA. Some works have directly used QG in QA models' pipeline (Duan et al., 2017; Dong et al., 2017; Lewis and Fan, 2019). Some other works enabled semi-supervised QA with the help of QG. Tang et al. (2017) applied the "dual learning" algorithm (He et al., 2016) to learn QA and QG jointly with unlabeled texts. Yang et al. (2017) and Tang et al. (2018) followed the GAN (Goodfellow et al., 2014) paradigm, taking QG as a generator and QA as a discriminator, to utilize unlabeled data. Sachan and Xing (2018) proposed a self-training cycle between QA and QG. However, these works either reduced the ground-truth data size or simplified the span-prediction QA task to answer sentence selection. Dhingra et al. (2018) collected 3.2M cloze-style QA pairs to pre-train a QA model, then fine-tune with the full ground-truth data which improved a BiDAF-QA baseline. In our paper, we follow the back-translation (Sennrich et al., 2016) strategy to generate new QA pairs by our best QG model to augment SQuAD training set. Further, we introduce a data filter to remove poorly generated examples and a mixing mini-batch training strategy to more effectively use the synthetic data. Similar methods have also been applied in some very recent concurrent works (Dong et al., 2019; Alberti et al., 2019) on SQuADv2.0. The main difference is that we also propose to generate new questions from existing articles without introducing new articles.

3 Question Generation

3.1 Base Model

We first introduce our base model which mainly adopts the model architecture from the previous state-of-the-art (Zhao et al., 2018). The differences are that we introduce two linguistic features (POS & NER), apply deep contextualized word vectors, and tie the output projection matrix with the word embedding matrix. Experiments showed that with these additions, our base model results surpass the results reported in Zhao et al. (2018) with significant margins. Our base model architecture is shown in the upper box in Figure 1 and described as follow. If we have a paragraph $p = \{x_i\}_{i=1}^{M}$ and an answer a which is a sub-span of p, the target of the QG task is to generate a question $q = \{y_j\}_{j=1}^{N}$ that can be answered by a based on the information in p.

Embedding The model first concatenates four word representations: word vector, answer tag embedding, Part-of-Speech (POS) tag embedding, and Name Entity (NER) tag embedding, i.e., $e_i = [w_i, a_i, p_i, n_i]$. For word vectors, we use the deep contextualized word vectors from ELMo (Peters et al., 2018) or BERT (Devlin et al., 2018). The answer tag follows the BIO[2] tagging scheme.

Encoder The output of the embedding layer is then encoded by a two-layer bi-directional LSTM-RNNs, resulting in a list of hidden representations H. At any time step i, the representation h_i is the concatenation of $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$.

$$\begin{aligned} \overrightarrow{h}_i &= \overrightarrow{LSTM}([e_i; \overrightarrow{h}_{i-1}]) \\ \overleftarrow{h}_i &= \overleftarrow{LSTM}([e_i; \overleftarrow{h}_{i+1}]) \\ H &= [\overrightarrow{h_i}, \overleftarrow{h_i}]_{i=1}^{M} \end{aligned} \quad (1)$$

[2] "B", for "Begin", tags the start token of the answer span; "I", for "Inside", tags other tokens in the answer span; "O", for "Other", tags other tokens in the paragraph.

Self-attention A gated self-attention mechanism (Wang et al., 2017) is applied to H to aggregate the long-term dependency within the paragraph. α_i is an attention vector between h_i and each element in H; u_i is the self-attention context vector for h_i; h_i is then updated to f_i using u_i; a soft gate g_i decides how much the update is applied. $\hat{H} = [\hat{h}_i]_{i=1}^{M}$ is the output of this layer.

$$
\begin{aligned}
u_i = H\alpha_i, \alpha_i = softmax(H^T W^u h_i) \\
f_i = tanh(W^f[h_i; u_i]) \\
g_i = sigmoid(W^g[h_i; u_i]) \\
\hat{h}_i = g_i * f_i + (1 - g_i) * h_i
\end{aligned} \tag{2}
$$

Decoder The decoder is another two-layer unidirectional LSTM-RNN. An attention mechanism dynamically aggregates $\hat{H}$ at each decoding step to a context vector c_j which is then used to update the decoder state s_j.

$$
\begin{aligned}
c_j = \hat{H}\alpha_j, \alpha_j = softmax(\hat{H}^T W^a s_j) \\
\tilde{s}_j = tanh(W^c[c_j; s_j]) \\
s_{j+1} = LSTM([y_j; \tilde{s}_j])
\end{aligned} \tag{3}
$$

The probability of the target word y_j is computed by a maxout neural network.

$$
\begin{aligned}
\tilde{o}_j = tanh(W^o[c_j; s_j]) \\
o_j = [max\{\tilde{o}_{j,2k-1}, \tilde{o}_{j,2k}\}]_k \\
p(y_j|y_{<j}) = softmax(W^e o_j)
\end{aligned} \tag{4}
$$

In practice, we keep the weight matrix W^e the same as the word embedding matrix and fix it during training. Furthermore, we apply the same "maxout pointer" proposed by Zhao et al. (2018) to enable the model to copy words from input.

3.2 Semantics-Reinforced Model

To address the "semantic drift" problem shown in Table 1, we propose two semantics-enhanced rewards to regularize the generation to focus on generating semantically valid questions.

QPP Reward To deal with the "exposure bias" problem, many previous works directly used the final evaluation metrics (e.g., BLEU) as rewards to train the generation models (Rennie et al., 2017; Paulus et al., 2017). However, these metrics sometimes fail to evaluate equally to question paraphrases and thus provide inaccurate rewards. Hence, we propose to use a pre-trained question paraphrasing classification (QPC) model

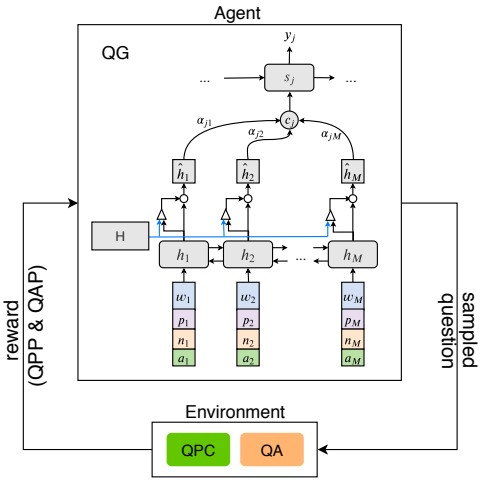

Figure 1: The architecture of our semantics-reinforced QG model.

to provide paraphrasing probability as a reward. Since paraphrasing is more about semantic similarity than superficial word/phrase matching, it treats question paraphrases more fairly (Example 1 in Table 2). Therefore, we first train a QPC model with Quora Question Pairs dataset. Next, we take it as an environment, and the QG model will interact with it during training to get the probability of the generated question and the ground-truth question being paraphrases as the reward.

QAP Reward Two observations motivate us to introduce QAP reward. First, in a paragraph, usually, there are several facts relating to the answer and can be used to ask questions. Neither the teacher forcing or the QPP reward can favor this kind of novel generation (Example 2 in Table 2). Second, we find semantically-drifted questions are usually unanswerable by the given answer. Therefore, inspired by the dual learning algorithm (He et al., 2016), we propose to take the probability that a pre-trained QA model can correctly answer the generated question as a reward, i.e., $p(a^*|q^s; p)$, where a^* is the ground-truth answer and q^s is a sampled question. Using this reward, the model can not only gets positive rewards for novel generation but also be regularized by the answerability requirement. Note that, this reward is supposed to be carefully used because the QG model can cheat by greedily copying words in/near the answer to the generated question. In this case, even though high QAPs are achieved, the model loses the question generation ability.

Policy Gradient To apply these two rewards, we use the REINFORCE algorithm (Williams, 1992)

Example 1: Fail to score equally to paraphrases	BLEU4	Q-BLEU1	QPP	QAP
Context: ...the university first offered graduate degrees , in the form of a master of arts (ma) , in the the **1854** – 1855 academic year ... Gt: in what year was a master of arts course first offered ?

Gen2: when did the observer begin to show a conservative bias ?	15.03	21.11	13.44	77.15

Table 2: Two examples of where QPP and QAP improve in question quality evaluation.

to learn a generation policy p_θ defined by the QG model parameters θ. We minimize the loss function $L_{RL} = -E_{q^s \sim p_\theta}[r(q^s)]$, where q^s is a sampled question from the model's output distribution. Due to the non-differentiable sampling procedure, the gradient is approximated using a single sample with some variance reduction baseline b:

$$\bigtriangledown_\theta L_{RL} = -(r(q^s) - b) \bigtriangledown_\theta log p_\theta(q^s) \quad (5)$$

We follow the effective SCST strategy (Rennie et al., 2017) to take the reward of greedy search result q^g as the baseline, i.e. $b = r(q^g)$. However, only using this objective to train QG will result in poor readability, so we follow the mixed loss setting (Paulus et al., 2017): $L_{mixed} = \gamma L_{RL} + (1 - \gamma) L_{ML}$. In practice, we find the mixing ratio γ for QAP reward should be lower, i.e., it needs more regularization from teacher forcing, so that it can avoid the undesirable cheating issue mentioned above. Furthermore, we also apply the multi-reward optimization strategy (Pasunuru and Bansal, 2018) to train the model with two mixed losses alternately with an alternate rate $n : m$, i.e., train with L^{qpp}_{mixed} for n mini-batches, then train with L^{qap}_{mixed} for m mini-batches, repeat until convergence. n and m are two hyper-parameters.

$$\begin{aligned} L^{qpp}_{mixed} &= \gamma^{qpp} L^{qpp}_{RL} + (1 - \gamma^{qpp}) L_{ML} \\ L^{qap}_{mixed} &= \gamma^{qap} L^{qap}_{RL} + (1 - \gamma^{qap}) L_{ML} \end{aligned} \quad (6)$$

Experiments show that these two rewards can significantly improve the QG performance separately or jointly, and we achieve new state-of-the-art QG performances, see details in Section 6.

3.3 QA-Based QG Evaluation

Inspired by the idea that "a perfect QG model can replace humans to ask questions", we introduce a QA-based evaluation method that measures the quality of a QG model by its ability to mimic human annotators in labeling training data for QA models. The evaluation procedure is described as follows. First, we sample some unlabeled Wikipedia paragraphs with pre-extracted answer spans from HarvestingQA dataset (Du and Cardie, 2018). Second, we make a QG model act as an "annotator" to annotate a question for each answer span. Third, we train a QA model using this synthetic QA dataset. Lastly, we use the QA model's performance on the original SQuAD development set as the evaluation for this QG model. The higher this QA performance is, the better the QG model mimics a human's question-asking ability. We believe that this method provides a new angle to evaluate QG model's quality and also a more reliable way to choose QG models to conduct data augmentation and semi-supervised QA.

4 Semi-Supervised Question Answering

Since one of the major goals of developing QG systems is to generate new QA pairs and augment QA datasets, we investigate how to use our QG system to act as a question annotator, collect new QA pairs, and conduct semi-supervised QA. Figure 2 illustrates the overall procedure of our semi-supervised QA approach.

4.1 Synthetic Data Generation

To generate synthetic QA pairs, we follow the effective "back translation" approach proposed in Neural Machine Translation (NMT) (Sennrich et al., 2016). In NMT, the back translation method first obtains synthetic source sentences by running a pre-trained target-to-source translation model on a monolingual dataset of the target language; then, it combines the synthetic and ground-truth translation pairs to train the desired source-to-target translation model. Similarly, in the QA scenario,

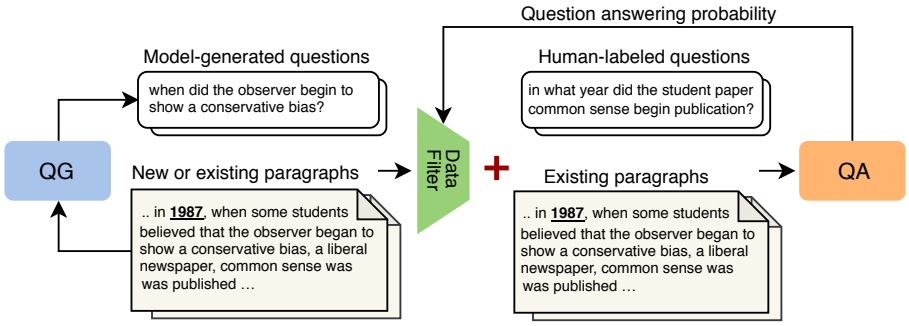

Figure 2: Semi-supervised QA: First, a trained QG model generates questions from new or existing paragraphs building up a synthetic QA dataset; Second, a data filter filters out low-QAP synthetic examples and augment the rest to human-labeled QA pairs; Lastly, the QA model is trained with the enlarged QA dataset.

the paragraph/answer can be viewed as the "target sentence", while the question can be taken as the "source sentence". One tricky difference is that even if the paragraphs can be easily obtained from Wikipedia, there are no answer span labels. Therefore, we use two sources to generate questions from, as discussed below.

Generate from Existing Articles In SQuAD (Rajpurkar et al., 2016), each context-answer pair only has one ground-truth question. However, usually, multiple questions can be asked. The diversity lies in question paraphrasing and different facts in the context that can be used to ask the question. Therefore, without introducing new Wikipedia articles, we make our QG model generate diverse questions for the existing context-answer pairs in SQuAD training set by keeping the all beam search outputs for each example.

Generate from New Articles To use unlabeled Wikipedia articles for data augmentation, an automatic answer extractor is indispensable. Some previous works have proposed methods to detect key phrases from a paragraph and automatically extract potential answer spans (Yang et al., 2017; Du and Cardie, 2018; Subramanian et al., 2018). Instead of building up our answer extractor, we directly take advantage of the released HarvestingQA dataset. It contains 1.2M synthetic QA pairs, in which both the answer extractor and the QG model were proposed by Du and Cardie (2018). We use their paragraphs with answer span labels but generate questions with our QG models, and only use their questions for comparison.

4.2 Synthetic Data Usage

In practice, we find that directly mixing the synthetic data with the ground-truth data does not improve QA performance. We conjecture the reason is that some poor-quality synthetic examples mislead the learning process of the QA model. Therefore, we propose two empirical strategies to better utilize synthetic data.

QAP Data Filter In "self-training" literature, similar issues have been discussed that using model-labeled examples to train the model will amplify the model's error. Later works proposed co-training or tri-training that uses two or three models as judges and only keeps examples that all models agree on (Blum and Mitchell, 1998; Zhou and Li, 2005). Sachan and Xing (2018) also designed question selection oracles based on curriculum learning strategy in their QA-QG self-training circle. In this paper, we simply design a data filter based on our QAP measure (same definition as the QAP reward) to filter poor-quality examples. We think if one question-answer pair has a low QAP, i.e., the probability of the answer given the question is low, it is likely to be a mismatched pair. Hence, we filter synthetic examples with $QAP < \epsilon$, where ϵ is a hyper-parameter that we will tune for different synthetic datasets.

Mixing Mini-Batch Training When conducting semi-supervised learning, we do not want gradients from ground-truth data are overwhelmed by synthetic data. Previous works (Fried et al., 2018; Dhingra et al., 2018) proposed to first pre-train the model with synthetic data and then fine-tune it with ground-truth data. However, we find when the synthetic data size is small (e.g., similar size as the ground-truth data), catastrophic forgetting

[3]They actually used the reversed dev-test setup as opposed to the original setup used in Du et al. (2017) and Du and Cardie (2018) (see Section 3.1 in Zhao et al. (2018)). Thus, we also conducted the reversed dev-test setup and our QPP&QAP model yields BLEU4/METEOR/ROUGE-L=20.76/24.20/48.91.

	BLEU4	METEOR	ROUGE-L	Q-BLEU1	QPP	QAP
Du and Cardie (2018)	15.16	19.12	–	–	–	–
Zhao et al. (2018)[3]	16.38	20.25	44.48	–	–	–
Our baseline (w. ELMo)	17.00	21.44	45.89	47.80	27.29	45.15
+ BLEU4	17.72	22.13	46.52	49.07	27.09	45.96
+ METEOR	17.84	22.41	46.18	49.09	26.70	46.52
+ ROUGE-L	17.78	22.28	46.51	49.23	27.06	46.31
+ QPP	18.25	22.62	46.45	49.59	**28.13**	47.63
+ QAP	18.12	22.52	46.45	49.27	27.49	**48.76**
+ QPP&QAP	**18.37**	**22.65**	**46.68**	**49.63**	28.03	48.37

Table 3: The performance of different QG models.

will happen during fine-tuning, leading to similar results as using ground-truth data only. Thus, we propose a "mixing mini-batch" training strategy, where for each mini-batch we combine half mini-batch ground-truth data with half mini-batch synthetic data, which keeps the data mixing ratio to 1:1 regardless of what the true data size ratio is. In this way, we can have the training process generalizable to different amounts of synthetic data and keep the gradients to be regularized by ground-truth data.

5 Experiment Setup

Datasets For QG, we use the most commonly used SQuAD QG dataset first used by (Du et al., 2017). For QA-based QG evaluation, we obtain unlabeled paragraph and answer labels from HarvestingQA (Du and Cardie, 2018), and have different QG systems to label questions. For semi-supervised QA, we use SQuADv1.1 (Rajpurkar et al., 2016) as our base QA task, and split the original development set in half as our development and test set respectively. Plus, we make our QG model generate new questions from both SQuAD and HarvestingQA. We will sample 10% – 100% examples from HarvestingQA which are denoted by H1-10 in our experiments.

Evaluation Metrics For QG, we first adopt 3 traditional metrics (BLEU4/METEOR/ROUGE-L). Second, we apply the new Q-BLEU1 metric proposed by (Nema and Khapra, 2018). Moreover, we conduct a pairwise **human evaluation** between our baseline and QPP&QAP model on MTurk. We gave the annotators a paragraph with an answer bold in context and two questions generated by two models (randomly shuffled). We asked them to decide which one is better or non-distinguishable. For both QA-based QG evaluation and semi-supervised QA, we follow the standard evaluation method for SQuAD to use Exact Match (EM) and F1.

QPP&QAP	Our baseline	Tie
160	131	9

Table 4: Pairwise human evaluation between our baseline and QPP&QAP multi-reward model.

Data	Du and Cardie	Our baseline	QPP & QAP
H1	53.20/65.47	55.06/67.83	**55.89/68.26**
H2	53.40/66.28	56.23/**69.23**	**56.69**/69.19
H3	53.12/65.57	**57.14**/69.39	57.05/**70.17**
S+H1	71.16/80.75	71.94/81.26	**72.20/81.44**
S+H2	72.02/81.00	72.03/81.38	**72.22/81.81**
S+H3	71.48/81.02	72.61/81.46	**72.69/82.22**

Table 5: The QA-based evaluation results for different QG systems. The two numbers of each item in this table are the EM/F1 scores. All results are the performance on our QA test set. "S" is short for "SQuAD".

More details about datasets, evaluation metrics, human evaluation setup, and model implement details are provided in the Appendix.

6 Results

6.1 Question Generation

Baselines First, as shown in Table 3, our baseline QG model obtains a non-trivial improvement over previous best QG system (Zhao et al., 2018) which proves the effectiveness of our newly introduced setups: introduce POS/NER features, use deep contexturalized word vectors (from ELMo or BERT), and tie output projection matrix with non-trainable word embedding matrix. Second, we apply three evaluation metrics as rewards to deal with the exposure bias issue and improve performance. All the metrics are significantly[4] ($p < 0.001$) improved except QPP, which supports that high traditional evaluation metrics do not always correlate to high semantic similarity.

[4]The significance tests in this paper are conducted following the bootstrap test setup (Efron and Tibshirani, 1994).

	Filter	Data Size[5]	EM	F1
H1 only	$\epsilon = 0.0$	120k	54.55	67.91
	$\epsilon = 0.2$	84k	61.18	71.65
	$\epsilon = 0.4$	69k	**61.97**	**72.48**
	$\epsilon = 0.6$	55k	60.38	70.51
	$\epsilon = 0.8$	40k	57.47	66.48
SQuAD+H1	$\epsilon = 0.0$	207k	72.97	82.18
	$\epsilon = 0.2$	171k	73.88	82.72
	$\epsilon = 0.4$	156k	73.47	82.62
	$\epsilon = 0.6$	142k	**73.96**	**82.81**
	$\epsilon = 0.8$	127k	73.65	82.77

Table 6: The effect of QAP-based synthetic data filter. We filter out the synthetic data with $QAP < \epsilon$. All results are the performance on our QA development set.

Semantics-Reinforced Models As shown in Table 3, when using QAP and QQP separately, all metrics are significantly ($p < 0.001$) improved over our baseline and all metrics except ROUGE-L are significantly ($p < 0.05$) improved over the models using traditional metrics as rewards. After applying multi-reward optimization, our model performs consistently best on BLEU4/METEOR/ROUGE-L and Q-BLEU1. Notably, using one of these two rewards will also improve the other one at the same time, but using both of them achieves a good balance between these two rewards without exploiting either of them and results in the consistently best performance on other metrics, which is a new state-of-the-art result. **Human Evaluation Results:** Table 4 shows the MTurk anonymous human evaluation study, where we do a pairwise comparison between our baseline and QPP&QAP model. We collected 300 responses in total, 160 of which voted the QPP&QAP model's generation is better, 131 of which favors the baseline model, and 9 of which selected non-distinguishable.

QA-Based Evaluation As shown in Table 5, we compare three QG systems using QA-based evaluation on three different amounts of synthetic data and their corresponding semi-supervised QA setups (without filter). It can be observed that both our baseline and our best QG model can significantly improve the synthetic data's QA performance, which means they can act as better "annotators" than the QG model proposed by Du and Cardie (2018). However, our best QG model only has a minor improvement over our baseline model, which means significant improvement over QG metrics does not guarantee significant better question annotation ability.

6.2 Semi-Supervised Question Answering

Effect of the data filter As shown in Table 6, when using synthetic data only, adding the data filter can significantly improve QA performance. In terms of semi-supervised QA, the improvement is relatively smaller, due to the regularization from ground-truth data, but still consistent and stable.

Semi-Supervised QA results Table 7 demonstrates the semi-supervised QA results. Without introducing new articles, we keep beam search outputs as additional questions. It can be seen that using beam search with beam size 10 (+Beam10) improves the BiDAF-QA baseline by 1.51/1.13 absolute points on the testing set. With introducing new articles, the best performance (+H8) improves the BiDAF-QA baseline by 1.69/1.27 absolute points on the testing set. We also combine the two best settings (Beam10+H8), but it does not perform better than using them separately.

We conduct two ablation studies on the development set. First, we compare beam search with

[5] "Data Size" counts the total number of examples in training set (after filter). In Table 8, "New Data Size" only counts # examples generated from articles outside SQuAD.

	BLEU4	METEOR	ROUGE-L	Q-BLEU1	QPP	QAP	QA-Eval (H1)

Table 10: The results of our semi-supervised QA method using a stronger BERT-QA model.

different beam sizes and diverse beam search (Li et al., 2016), but all of them perform similarly. Second, increasing the size of synthetic data from H1 to H10, the performance saturates around H2-H4. We also observed that when using a big synthetic data, e.g., H10, the model converges even before all examples were used for training. Based on these results, we conjecture that there is an upper bound of the effect of synthetic data which might be limited by the QG quality. To further improve the performance, more diverse and tricky questions need to be generated. To show how QG models help or limit the QA performance, we include some synthetic QA examples in Appendix. Finally, we compare our semi-supervised QA methods with Dhingra et al. (2018). As shown in Table 8, with no or less new data injection, our methods achieve larger improvements over a stronger baseline than their method.

6.3 QG and QA Results with BERT

The Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) has recently improved a lot of NLP tasks by substantial margins. To verify if our improvements still hold on BERT-based baselines, we propose a BERT-QG baseline and test our two semantics-enhanced rewards; further, we conduct our semi-supervised QA method on a BERT-QA baseline.

BERT-QG Without modifying our QG model's architecture, we simply replaced ELMo used above with BERT. Table 9 shows that our BERT-QG baseline improves previous ELMo-QG baseline by a large margin; meanwhile, our QPP/QAP rewards significantly improve the stronger QG baseline and achieve the new state-of-the-art QG performance w.r.t both traditional metrics and QA-based QG evaluation. One difference is that the QAP-only model has the overall best performance instead of the multi-reward model. Note that, we also obtain the QPP and QAP rewards from BERT-based QPC and QA models, respectively.

BERT-QA Using our QAP-reinforced BERT-QG model, we apply the same semi-supervised QA method on a BERT-QA baseline. As shown in Table 10, though with smaller margins, our method improves the strong BERT-QA baseline by 1.19/0.56 absolute points on test set; even without introducing new articles, it obtains 0.95/0.13 absolute gains.

7 Conclusion

We proposed two semantics-enhanced rewards to regularize a QG model to generate semantically valid questions, and introduced a QA-based evaluation method that directly evaluates a QG model's ability to mimic human annotators in generating QA training data. Experiments showed that our QG model achieves new state-of-the-art performances. Further, we investigated how to use our QG system to augment QA datasets and conduct semi-supervised QA via two synthetic data generation methods along with a data filter and mixing mini-batch training. Experiments showed that our approach improves both BiDAF and BERT QA baselines even without introducing new articles.

Appendix

A Experiment Setup

A.1 Dataset

QG For QG, we use the SQuAD-based QG dataset[6] first introduced by Du et al. (2017) which was the most widely-used QG dataset in previous works (Song et al., 2018; Zhao et al., 2018; Du and Cardie, 2018; Kim et al., 2018; Sun et al., 2018). It was derived from SQuADv1.1 (Rajpurkar et al., 2016). Since the testing set is not open, they sampled 10% articles from the training set as the testing set, and the original development set is still used for validation.

For the QA-based QG evaluation, we obtain new paragraphs with pre-extracted answer spans from HarvestingQA (Du and Cardie, 2018). Without using their provided questions, we have different QG models act as "annotators" to generate questions, and then use the different QG-labeled synthetic datasets to train QA models. We use the same dev-test setup as described below.

[6] https://github.com/xinyadu/nqg/tree/master/data

QA For QA, we use SQuADv1.1 (Rajpurkar et al., 2016). Previous semi-supervised QA works sampled 10% from training set as the testing set (Yang et al., 2017; Dhingra et al., 2018). Since we want to use the full training set in semi-supervised QA setup without any data size reduction, we instead split the original development set in half for validation and testing respectively.

For semi-supervised QA, first, without introducing new articles, we generate new questions for SQuAD training set by keeping all beam search outputs. Second, with introducing new articles, we obtain new paragraphs with pre-extracted answer spans from HarvestingQA (Du and Cardie, 2018). Without using their provided questions, we use our best QG model to label questions. Meanwhile, we investigate the influence of synthetic data size, so we sample 10% to 100% examples from HarvestingQA, which are denoted as H1-H10 in our experiments.

A.2 Evaluation Metrics

QG First, we use three traditional automatic evaluation metrics: BLEU4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), ROUGE-L (Lin, 2004). Second, we adopt the new "Q-metrics" proposed by Nema and Khapra (2018), and we only use "Q-BLEU1" that was shown to have the highest correlation with human judgments on SQuAD. We also take the QPP and QAP rewards as two additional evaluation metrics. Further, we conduct a pairwise human comparison between our baseline and best QG models. Detailed human evaluation setup is described in the next section. For the QA-based QG evaluation, we use the same QA evaluation metrics as follows.

QA Following the standard evaluation method for SQuADv1.1 (Rajpurkar et al., 2016), we use Exact Match (EM) and F1 as two metrics.

A.3 Human Evaluation

We performed pairwise human evaluation between our baseline and the QPP&QAP multi-reward model on Amazon Mechanical Turk. We selected human annotators that are located in the US, have an approval rate greater than 98%, and have at least 10,000 approved HITs. We showed the annotators an input paragraph with the answer bold in the paragraph and two questions generated by two QG models (randomly shuffled to anonymize model identities). We then asked them to decide which one is better or choose "non-distinguishable" if they are equally good/bad. We give human three instructions about what is a good question: first, "answerability" – a good question should be answerable by the given answer; "making sense" – a good question should be making sense given the surrounding context; "overall quality" – a good question should be as fluent, non-ambiguous, semantically compact as possible. Ground-truth questions were not provided to avoid simple matching with ground-truth.

B Implementation Details

QG For ELMo-QG, we first tokenize and obtain the POS/NER tags by Standford Corenlp toolkit[7], then lower-case the entire dataset. We use 2-layer LSTM-RNNs for both encoder and decoder with hidden size 600. Dropout with a probability of 0.3 is applied to the input of each LSTM-RNN layer. We use the pre-trained character-level word embedding from ELMo (Peters et al., 2018) both as our word embedding and output-projection matrix, and keep it fixed. We use Adam (Kingma and Ba, 2014) as optimizer with learning rate 0.001 for teacher forcing and 0.00001 for reinforcement learning. Batch size is set to 32. For stability, we first pre-train the model with teacher forcing until convergence, then fine-tune it with the mixed loss. Hyper-parameters are tuned on development set: $\gamma^{qpp} = 0.99$, $\gamma^{qap} = 0.97$, and $n : m = 3 : 1$. We use beam search with beam size 10 for decoding and apply a bi-gram/tri-gram repetition penalty as proposed in Paulus et al. (2017).

For BERT-QG, we simply replace the ELMo used above to BERT (Devlin et al., 2018). To match with BERT's tokenization, we use the WordPiece tokenizer to tokenize each word obtained above and extend the POS/NER tags to each word piece. Decoder's word-piece outputs will be mapped to normal words by post-processing. Hyper-parameters are tuned on development set: $\gamma^{qpp} = 0.99$, $\gamma^{qap} = 0.97$, and $n : m = 1 : 3$.

QA For BiDAF-QA, we implement the BiDAF+Self-attention architecture proposed by Clark and Gardner (2018). We use GRUs for all RNN layers with hidden size 90 for GRUs and 180 for linear layers. Dropout with a probability of 0.2 is applied to the input of each GRU-RNN layer. We optimize the model using Adadelta with

batch size 64. We also add ELMo to both the input and output of the contextual GRU-RNN layer as proposed in (Peters et al., 2018). To match with QG model's setup, we also apply lower-case on QA datasets.

For BERT-QA, we use the pre-trained uncased BERT-base model[8] and fine-tune it on QA datasets.

QPC For ELMo-QPC, we follow the model architecture proposed by Conneau et al. (2017). First, two input questions are embedded with ELMo (Peters et al., 2018). Second, the embedded questions are encoded by two 2-layer bidirectional LSTM-RNNs separately with hidden size 512. Next, a max-pooling layer outputs the sentence embedding of each question, denoted by q_1 and q_2. Lastly, we input $[q_1, q_2, |q_1 - q_2|, q_1 * q_2]$ to an MLP to predict whether these two questions are paraphrases or not. This QPC model is trained using the Quora Question Pairs[9] dataset. We use Adam (Kingma and Ba, 2014) as optimizer with learning rate 0.0004 and batch size 64. This model obtained 86% accuracy on QQP development set.

For BERT-QPC, we also use the pre-trained uncased BERT-base model and fine-tune it on QQP dataset, which obtained 90% accuracy on QQP development set.

Abstract

In this paper, we focus on unsupervised domain adaptation for Machine Reading Comprehension (MRC), where the source domain has a large amount of labeled data, while only unlabeled passages are available in the target domain. To this end, we propose an Adversarial Domain Adaptation framework (AdaMRC), where (i) pseudo questions are first generated for unlabeled passages in the target domain, and then (ii) a domain classifier is incorporated into an MRC model to predict which domain a given passage-question pair comes from. The classifier and the passage-question encoder are jointly trained using adversarial learning to enforce domain-invariant representation learning. Comprehensive evaluations demonstrate that our approach (i) is generalizable to different MRC models and datasets, (ii) can be combined with pre-trained large-scale language models (such as ELMo and BERT), and (iii) can be extended to semi-supervised learning.

1 Introduction

Recently, many neural network models have been developed for Machine Reading Comprehension (MRC), with performance comparable to human in specific settings (Gao et al., 2019). However, most state-of-the-art models (Seo et al., 2017; Liu et al., 2018; Yu et al., 2018) rely on large amount of human-annotated in-domain data to achieve the desired performance. Although there exists a number of large-scale MRC datasets (Rajpurkar et al., 2016; Trischler et al., 2016; Bajaj et al., 2016; Zhang et al., 2018), collecting such high-quality datasets is expensive and time-consuming, which hinders real-world applications for domain-specific MRC.

Therefore, the ability to transfer an MRC model trained in a high-resource domain to other low-resource domains is critical for scalable MRC. While it is difficult to collect annotated question-answer pairs in a new domain, it is generally feasible to obtain a large amount of unlabeled text in a given domain. In this work, we focus on adapting an MRC model trained in a source domain to other new domains, where only unlabeled passages are available.

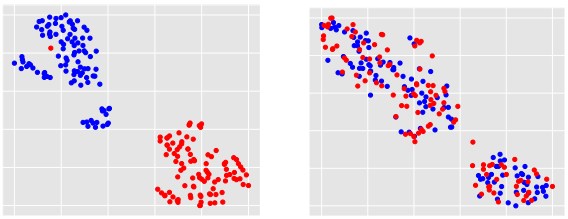
This domain adaptation issue has been a main challenge in MRC research, and the only existing work that investigated this was the two-stage synthesis network (SynNet) proposed in Golub et al. (2017). Specifically, SynNet first generates pseudo question-answer pairs in the target domain, and then uses the generated data as augmentation to fine-tune a pre-trained MRC model. However, the source-domain labeled data and target-domain pseudo data are directly combined without considering domain differences (see Figure 1(a), where the two feature distributions in two domains are independently clustered). Directly transfering a model from one domain to another could be counter-effective, or even hurt the performance of the pre-trained model due to domain variance.

To achieve effective domain transfer, we need to learn features that are discriminative for the MRC task in the source domain, while simultaneously indiscriminating with respect to the shift between source and target domains. Motivated by this, we propose *Adversarial Domain Adaptation for MRC* (AdaMRC), a new approach that utilizes adversarial learning to learn domain-invariant transferable representations for better MRC model adaptation across domains (see Figure 1(b), where the two feature distributions learned by AdaMRC are indistinguishable through adversarial learning).

Specifically, our proposed method first generates synthetic question-answer pairs given pas-

*Most of this work was done when the first author was an intern at Microsoft Dynamics 365 AI Research.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2510–2520, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics



sages in the target domain. Different from Golub et al. (2017), which only used pseudo question-answer pairs to fine-tune pre-trained MRC models, our AdaMRC model uses the passage and the generated pseudo-questions in the target domain, in addition to the human-annotated passage-question pairs in the source domain, to train an additional *domain classifier* as a discriminator. The passage-question encoder and the domain classifier are jointly trained via adversarial learning. In this way, the encoder is enforced to learn domain-invariant representations, which are beneficial for transferring knowledge learned from one domain to another. Based on this, an answer decoder is then used to decode domain-invariant representation into an answer span.

The proposed approach is validated on a set of popular benchmarks, including SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), and MS MARCO (Bajaj et al., 2016), using state-of-the-art MRC models including SAN (Liu et al., 2018) and BiDAF (Seo et al., 2017). Since pre-trained large-scale language models, such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), have shown strong performance to learn representations that are generalizable to various tasks, in this work, to further demonstrate the versatility of the proposed model, we perform additional experiments to demonstrate that AdaMRC can also be combined with ELMo and BERT to further boost the performance.

The main contributions of this paper are summarized as follows: (i) We propose AdaMRC, an adversarial domain adaptation framework that is specifically designed for MRC. (ii) We perform comprehensive evaluations on several benchmarks, demonstrating that the proposed method is generalizable to different MRC models and diverse datasets. (iii) We demonstrate that AdaMRC is also compatible with ELMo and BERT. (iv) We further extend the proposed framework to semi-supervised learning, showing that AdaMRC can also be applied to boost the performance of a pre-trained MRC model when a small amount of labeled data is available in the target domain.

2 Related Work

Machine Reading Comprehension The MRC task has recently attracted a lot of attention in the community. An MRC system is required to answer a question by extracting a text snippet within a given passage as the answer. A large number of deep learning models have been proposed to tackle this task (Seo et al., 2017; Xiong et al., 2017; Shen et al., 2017; Liu et al., 2018; Yu et al., 2018). However, the success of these methods largely relies on large-scale human-annotated datasets (such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016) and MS MARCO (Bajaj et al., 2016)).

(a) SynNet (b) AdaMRC

Figure 1: t-SNE plot of encoded feature representations from (a) SynNet (Golub et al., 2017) and (b) the proposed AdaMRC. We sampled 100 data points, each from the development set of the source and the target domains. Blue: SQuAD. Red: NewsQA.

Different from previous work that focused on improving the state of the art on particular MRC datasets, we study the MRC task from a different angle, and aim at addressing a critical yet challenging problem: how to transfer an MRC model learned from a high-resource domain to other low-resource domains in an unsupervised manner.

Although important for the MRC task, where annotated data are limited in real-life applications, this problem has not yet been well investigated. There were some relevant studies along this line. For example, Chung et al. (2018) adapted a pre-trained model to TOEFL and MCTest dataset, and Wiese et al. (2017) applied transfer learning to the biomedical domain. However, both studies assumed that annotated data in the target domain (either questions or question-answer pairs) are available.

To the best of our knowledge, SynNet (Golub et al., 2017) is the only work that also studied domain adaptation for MRC. Compared with SynNet, the key difference in our model is adversarial learning, which enables domain-invariant representation learning for better model adaptation to low-resource domains. Our approach is also related to multi-task learning (Xu et al., 2019; Caruana, 1997; Liu et al., 2015, 2019) and semi-supervised learning (Yang et al., 2017) for MRC.

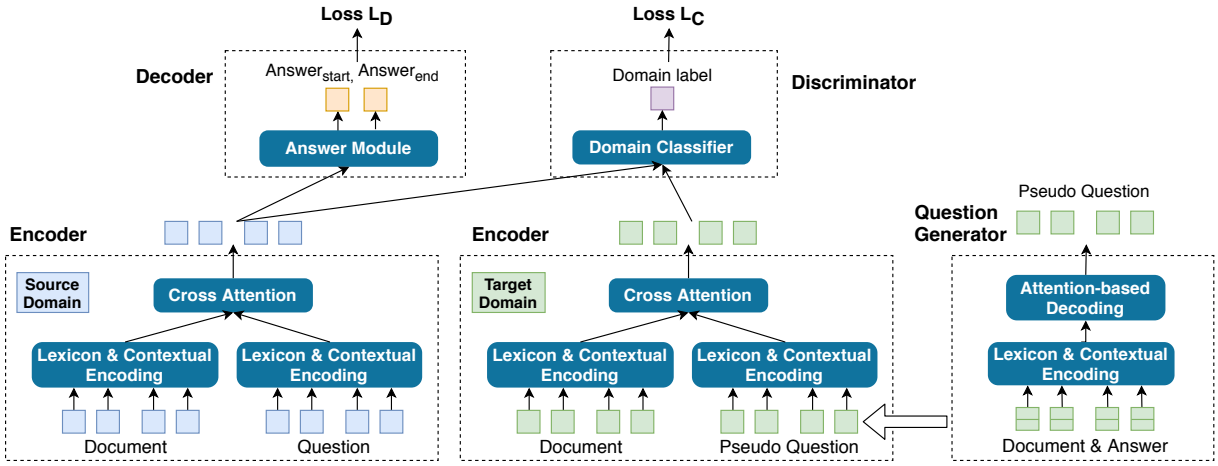


Figure 2: Illustration of the proposed AdaMRC model for unsupervised domain adaptation of MRC.

In this work, we focus on purely unsupervised domain adaptation.

Domain Adaptation Domain adaptation aims to make a machine learning model generalizable to other domains, especially without any annotated data in the target domain (or with only limited data) (Ganin and Lempitsky, 2015). One line of research on domain adaptation focuses on transiting the feature distribution from the source domain to the target domain (Gong et al., 2012; Long et al., 2015). Another school of research focuses on learning domain-invariant representations (Glorot et al., 2011) (e.g., via adversarial learning (Ganin et al., 2016; Tzeng et al., 2017)).

Domain adaptation has been successfully applied to many tasks, such as image classification (Tzeng et al., 2017), speech recognition (Doulaty et al., 2015), sentiment classification (Ganin et al., 2016; Li et al., 2017), machine translation (Johnson et al., 2017; Zoph et al., 2016), relation extraction (Fu et al., 2017), and paraphrase identification (Shah et al., 2018). Compared to these areas, the application to MRC presents additional challenges, since besides missing labeled data (*i.e.*, answer spans), the questions in the target domain are also unavailable. To our best knowledge, we are the first to investigate the usage of adversarial domain adaptation for the MRC task.

There are many prevailing unsupervised techniques for domain adaptation. Our proposed approach is inspired by the seminal work of Ganin et al. (2016) to validate its potential of solving domain adaptation problem on a new task, without any supervision for the target domain. There are also other more advanced methods, such as MMD-based adaptation (Long et al., 2017), residual transfer network (Long et al., 2016), and maximum classifier discrepancy (Saito et al., 2018) that can be explored for future work.

3 Problem Definition

The problem of unsupervised domain adaptation for MRC is defined as follows. First, let $S = \{p^s, q^s, a^s\}$ denote a labeled MRC dataset from the source domain s, where p^s, q^s and a^s represent the passage, the question, and the answer of a sample, respectively. An MRC model M^s, taking as input the passage $p^s = (p_1, p_2, ..., p_T)$ of length T and the question $q^s = (q_1, q_2, ..., q_{T'})$ of length T', is trained to predict the correct answer span $a^s = (a^s_{start}, a^s_{end})$, where a^s_{start}, a^s_{end} represent the starting and ending indexes of the answer in the passage p^s.

We assume that only unlabeled passages are available in the target domain t, *i.e.*, $T = \{p^t\}$, where p^t represents a passage. This is a reasonable assumption as it is easy to collect a large amount of unlabeled passages in a new domain. Given datasets S and T, the goal of unsupervised domain adaptation is defined as learning an MRC model M^t based on S and T to answer questions in the target domain t.

4 AdaMRC

As illustrated in Figure 2, AdaMRC consists of three main components: (i) *Question Generator* (Sec. 4.1), where pseudo question-answer pairs are generated given unlabeled passages in the target domain; (ii) *MRC Module* (Sec. 4.2), where

given an input document and a question, an answer span is extracted from the document; (*iii*) *Domain Classifier* (Sec. 4.3), where a domain label is predicted to distinguish a feature vector from either the source domain or the target domain.

Specifically, the MRC module is composed of an encoder and a decoder. The encoder with parameter θ_e embeds the input passage and the question into a feature vector. The decoder with parameter θ_d takes the feature vector as input to predict the answer span. The domain classifier with parameter θ_c takes the same feature vector as input to classify the domain label. All the parameters $(\theta_e, \theta_d, \theta_c)$ are jointly optimized, with the objective of training the encoder to correctly predict the answer span, but also simultaneously fool the domain classifier. In other words, the encoder learns to map text input into a feature space that is invariant to the switch of domains. The following sub-sections describe each module, with training details provided in Sec. 4.4.

4.1 Question Generation

First, we use an NER system to extract possible answer spans a^t from the passages p^t in the target domain, under the assumption that any named entity could be the potential answer of certain questions. Similar answer extraction strategy has been applied in Yang et al. (2017) in a semi-supervised-learning setting, while Golub et al. (2017) proposed to train an answer synthesis network to predict possible answers spans. We tried both methods, and empirically observed that a simple NER system provides more robust results, which is used in our experiments.

Now, we describe how the question generation (QG) model is trained. Given the passage $p^s = (p_1, p_2, ..., p_T)$ and answer $a^s = (a_{start}, a_{end})$ from the source domain, the QG model with parameter θ_{QG} learns the conditional probability of generating a question $q^s = (q_1, q_2, ..., q_{T'})$, *i.e.*, $P(q^s|p^s, a^s)$. We implement the QG model as a sequence-to-sequence model with attention mechanism (Bahdanau et al., 2015), and also apply the copy mechanism proposed in Gu et al. (2016); Gulcehre et al. (2016) to handle rare/unknown words.

Specifically, the QG model consists of a lexicon encoding layer, a BiLSTM contextual encoding layer, and an LSTM decoder. For lexicon encoding, each word token p_i of a passage is mapped into a concatenation of GloVe vectors (Pennington et al., 2014), part-of-speech (POS) tagging embedding, and named-entity-recognition (NER) embedding. We further insert answer information by appending an additional zero/one feature (similar to Yang et al. (2017)) to model the appearance of answer tokens in the passage. The output of the lexicon encoding layer is appended with CoVe vectors (McCann et al., 2017), and then passed to the Bidirectional LSTM contextual encoding layer, producing a sequence of hidden states. The decoder is another LSTM with attention and copy mechanism over the encoder hidden states. At each time step, the generation probability of a question token q_t is defined as:

$$P(q_t) = g_t P^v(q_t) + (1 - g_t) P^{copy}(q_t)\,, \quad (1)$$

where g_t is the probability of generating a token from the vocabulary, while $(1 - g_t)$ is the probability of copying a token from the passage. $P^v(q_t)$ and $P^{copy}(q_t)$ are defined as softmax functions over the words in the vocabulary and over the words in the passage, respectively. g_t, $P^v(q_t)$ and $P^{copy}(q_t)$ are functions of the current decoder hidden state.

4.2 MRC Module

Encoder The encoder in the MRC module contains lexicon encoding and contextual encoding, similar to the encoder used in the question generation module. It also includes a cross-attention layer for fusion. Specifically, the output of the lexicon encoder is appended with the CoVe vector and passed to the contextual encoding layer, which is a 2-layer Bidirectional LSTM that produces hidden states of the passage $H^p \in \mathbb{R}^{T \times 2m}$ and the question $H^q \in \mathbb{R}^{T' \times 2m}$, where m is the hidden size of the BiLSTM. We then use cross attention to fuse H^p and H^q, and construct a working memory of passage $M^p \in \mathbb{R}^{T \times 2m}$ (see Liu et al. (2018) for more details). The question memory $M^q \in \mathbb{R}^{2m}$ is constructed by applying self-attention on H^q.

Decoder The decoder, or answer module, predicts an answer span $a = (a_{start}, a_{end})$ given a passage p and a question q, by modeling the conditional probability $P(a|p, q)$. The initial state s_0 is set as M^q. Through T steps, a GRU (Cho et al., 2014) is used to generate a sequence of state vectors $s_t = \text{GRU}(s_{t-1}, x_t)$, where x_t is computed via attention between M^p and s_{t-1}. Two softmax layers are used to compute the distribution of

Algorithm 1 AdaMRC training procedure.

Input: source domain labeled data $S = \{p^s, q^s, a^s\}$, target domain unlabeled data $T = \{p^t\}$
Train the MRC model $\theta^s = (\theta_e^s, \theta_d^s)$ on source domain S;
Train the QG model θ_{QG} on source domain S;
Generate $T_{gen} = \{p^t, q^t, a^t\}$ using the QG model;
Initialize $\theta = (\theta_e, \theta_d, \theta_c)$ with θ^s;
for epoch $\leftarrow$ 1 to #epochs **do**
    Optimize θ on $S \cup T_{gen}$. Each minibatch is composed with k_s samples from S and k_t samples from T_{gen};
end for
Output: Model with the best performance on the target development set θ^*.

the start and the end of the answer span at each step given s_t, and the final prediction is the average prediction of all steps. Stochastic prediction dropout (Liu et al., 2018) is applied during training.

Note that we use SAN as an example MRC model in the proposed framework. However, our approach is compatible with any existing MRC models. In experiments, in order to demonstrate the versatility of the proposed model, we also conduct experiments with BiDAF (Seo et al., 2017).

4.3 Domain Classifier

The domain classifier takes the output of the encoder as input, including the aforementioned passage representation $M^p \in \mathbb{R}^{T \times 2m}$ and the self-attended question representation $M^q \in \mathbb{R}^{2m}$ from different domains, and predicts the domain label d by modeling the conditional probability $P(d|p, q)$. A self-attention layer is also applied to M^p to reduce its size to $M^{p'} \in \mathbb{R}^{2m}$. We then concatenate it with M^q, followed by a two-layer Multi-Layer Perceptron (MLP), $f(W[M^{p'}; M^q])$, and use a sigmoid function to predict the domain label.

4.4 Training

Algorithm 1 illustrates the training procedure of our proposed framework. We first train the question generation model θ_{QG} on the source domain dataset S by maximizing the likelihood of generating question q^s given passage p^s and answer a^s. Given the unlabeled dataset in the target domain, we extract candidate answers a^t on p^t and use θ_{QG} to generate pseudo questions q^t, and then compose a pseudo labeled dataset $T_{gen} = \{p^t, q^t, a^t\}$.

We initialize the MRC model θ for the target domain with the pre-trained MRC model θ^s from the source domain, and then fine-tune the model using both the source domain dataset S and the target domain dataset T_{gen}. The goal of the decoder θ_d is to predict $P(a|p, q)$. The objective function is denoted as:

$$L_D(\theta_e, \theta_d) = \frac{1}{|S|} \sum_{i=1}^{|S|} \log P(a^{(i)}|p^{(i)}, q^{(i)}) , \quad (2)$$

where the superscript (i) indicates the i-th sample. It is worthwhile to emphasize that unlike Golub et al. (2017), we only use source domain data to update the decoder, without using pseudo target domain data. This is because the synthetic question-answer pairs could be noisy, and directly using such data for decoder training may lead to degraded performance of the answer module, as observed both in Sachan and Xing (2018) and in our experiments.

The synthetic target domain data and source domain data are both used to update the encoder θ_e and the domain classifier θ_c. The classifier predicts a domain label d given the feature representation from the encoder. The objective function is:

$$L_C(\theta_e, \theta_c) = \frac{1}{N} \sum_{i=1}^{N} \log P(d^{(i)}|p^{(i)}, q^{(i)}) , \quad (3)$$

where $N = |S| + |T_{gen}|$. In order to learn *domain-invariant* representations from the encoder, we update θ_e to *maximize* the loss while updating θ_c to minimize the loss in an adversarial fashion. The overall objective function is defined as:

$$L(\theta_e, \theta_d, \theta_c) = L_D(\theta_e, \theta_d) - \lambda L_C(\theta_e, \theta_c) , \quad (4)$$

where λ is a trade-off parameter that balances the two terms.

To optimize our model, instead of alternately updating the adversaries like in GAN (Goodfellow et al., 2014), we use the gradient-reversal layer (Ganin and Lempitsky, 2015) to jointly optimize all the components, as suggested in Chen et al. (2018).

5 Experiments

5.1 Experimental Setting

Datasets We validate our proposed method on three benchmarks: SQuAD (Rajpurkar et al.,

Dataset	Domain	Train	Dev	Test
SQuAD (v1.1)	Wiki	87,600	10,570	–
NewsQA	News	92,549	5,166	5,165
MS MARCO (v1)	Web	82,430	10,047	9,650

Table 1: Statistics of the datasets.

2016), NewsQA (Trischler et al., 2016), and MS MARCO (Bajaj et al., 2016). The statistics of the datasets are provided in Table 1. Note that these datasets are all from different domains: SQuAD is from *Wikipedia*; NewsQA is from *CNN news*; and MS MARCO is from *web search log*.

Evaluation metrics For SQuAD and NewsQA, we report results on two evaluation metrics: Exact Match (**EM**), which measures the percentage of span predictions that match any of the ground truth answers exactly; and Macro-averaged **F1** score, which measures the average overlap between the prediction and the ground-truth answer. For MS MARCO, since the answer is free-formed, we use BLEU and ROUGE-L scores for evaluation.

Implementation details[1] We use spaCy[2] to generate POS and NER taggings, which are used in answer extraction and the lexicon encoding layer of the QG and MRC models. The QG model is fixed after trained on source-domain labeled data. The hidden size of the LSTM in the QG model is set to 125. Parameters of the SAN model follow Liu et al. (2018). The hidden size of the MLP layer in the domain classifier is set to 125. Both the QG and the MRC model are optimized via Adamax (Kingma and Ba, 2015) with mini-batch size set to 32. The learning rate is set to 0.002 and is halved every 10 epochs. To avoid overfitting, we set the dropout rate to 0.3. For each mini-batch, data are sampled from both domains, with k_s samples from the source domain and k_t samples from the target domain. We set $k_s : k_t = 2 : 1$ as default in our experiments. For the trade-off parameter λ, we gradually change it from 0 to 1, following the schedule suggested in Ganin and Lempitsky (2015).

5.2 Experimental Results

We implement the following baselines and models for comparison.

1. **SAN**: we directly apply the pre-trained SAN model from the source domain to answer questions in the target domain.
2. **SynNet+SAN**: we use SynNet[3] (Golub et al., 2017) to generate pseudo target-domain data, and then fine-tune the pre-trained SAN model.
3. **AdaMRC**: as illustrated in Algorithm 1.
4. **AdaMRC with GT questions**: the same as AdaMRC, except that the ground-truth questions in the target domain are used for training. This serves as an upper-bound of the proposed model.

Method	EM/F1
SQuAD → NewsQA	
SAN	36.68/52.79
SynNet + SAN	35.19/49.61
AdaMRC	**38.46/54.20**
AdaMRC with GT questions	39.37,54.63
NewsQA → SQuAD	
SAN	56.83/68.62
SynNet + SAN	50.34/62.42
AdaMRC	**58.20/69.75**
AdaMRC with GT questions	58.82/70.14
SQuAD → MS MARCO (BLEU-1/ROUGE-L)	
SAN	13.06/25.80
SynNet + SAN	12.52/25.47
AdaMRC	**14.09/26.09**
AdaMRC with GT questions	15.59/26.40
MS MARCO → SQuAD	
SAN	27.06/40.07
SynNet + SAN	23.67/36.79
AdaMRC	**27.92/40.69**
AdaMRC with GT questions	27.79/41.47

Table 2: Performance of AdaMRC compared with baseline models on three datasets, using SAN as the MRC model.

Table 2 summarizes the experimental results. We observe that the proposed method consistently outperforms SAN and the SynNet+SAN model on all datasets. For example, in the SQuAD→NewsQA setting, where the source-domain dataset is SQuAD and the target-domain dataset is NewsQA, AdaMRC achieves 38.46% and 54.20% in terms of EM and F1 scores, outperforming the pre-trained SAN by 1.78% (EM) and 1.41% (F1), respectively, as well as surpassing SynNet by 3.27% (EM) and 4.59% (F1), respectively. Similar improvements are also observed in NewsQA→SQuAD, SQuAD→MS MARCO and MS MARCO→SQuAD settings, which demonstrates the effectiveness of the proposed model.

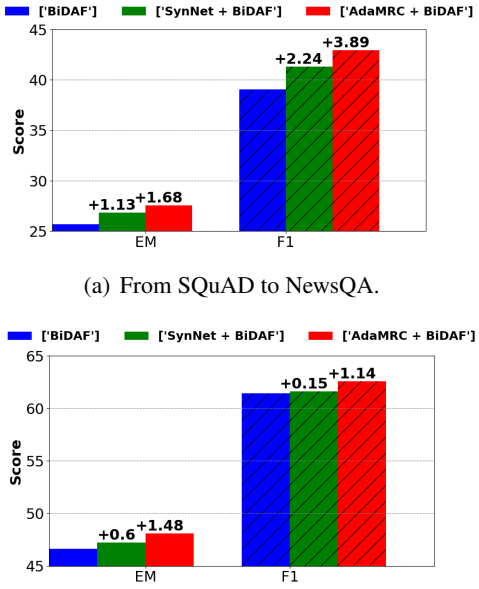
Interestingly, we find that the improvement on adaptation between SQuAD and NewsQA is greater than that between SQuAD and MS MARCO. Our assumption is that it is because

[1] Code will be released for easy access.

[2] https://spacy.io/

[3] The officially released code is used in our experiments: https://github.com/davidgolub/QuestionGeneration.

SQuAD and NewsQA datasets are more similar than SQuAD and MS MARCO, in terms of question style. For example, questions in MS MARCO are real web search queries, which are short and may have typos or abbreviations; while questions in SQuAD and NewsQA are more formal and well written. Furthermore, the ground-truth answers in MS MARCO are human-synthesized and usually much longer (16.4 tokens in average) than those in the other datasets, while our answer extraction process focuses on named entities (which are much shorter). We argue that extracting named entities as possible answers is still reasonable for most of the reading comprehension tasks such as SQuAD and NewsQA. The problem of synthesizing answers across different domains will be investigated in future work.



SynNet vs. pre-trained SAN baseline One observation is that SynNet performs worse than the pre-trained SAN baseline. We hypothesize that this is because the generated question-answer pairs are often noisy and inaccurate, and directly fine-tuning the answer module with synthetic data may hurt the performance, which is also observed in Sachan and Xing (2018), especially when a well-performed MRC model is used as the baseline. Note that we do observe improvements from SynNet+BiDAF over the pre-trained BiDAF model, which will be discussed in Sec. 6.2.

Comparing with upper-bound The "AdaMRC with GT questions" model (in Section 5.2) serves as the upper-bound of our proposed approach, where ground-truth questions are used instead of synthesized questions. By using ground-truth questions, performance is further boosted by around 1%. This suggests that our question generation model is effective as the margin is relatively small, yet it could be further improved. We plan to study if recent question generation methods (Du et al., 2017; Duan et al., 2017; Sun et al., 2018; Benmalek et al., 2019) could further help to close the performance gap in future work.

6 Analysis

6.1 Visualization

To demonstrate the effectiveness of adversarial domain adaptation, we visualize the encoded representation via t-SNE (Maaten and Hinton, 2008) in Figure 1. We observe that with AdaMRC, the two distributions of encoded feature representations are indistinguishable. Without AdaMRC, the two distributions are independently clustered by domain. We further use KL divergence for measuring distributional differences. The KL divergence of data samples between source and target domains, with and without domain adaptation, are 0.278, 0.433, respectively (smaller is better).

(a) From SQuAD to NewsQA.

(b) From NewsQA to SQuAD.

Figure 3: Performance of our proposed method compared with baselines, using BiDAF as the MRC model.

Method	EM/F1
SAN	32.35/42.62
AdaMRC + SAN	**33.61/44.16**
BiDAF	27.85/36.82
AdaMRC + BiDAF	**29.12/38.84**

Table 3: Performance on DuoRC, adapting from SelfRC (Wikipedia) to ParaphraseRC (IMDB).

6.2 Robustness of AdaMRC

Results on BiDAF To verify that our proposed framework is compatible to existing MRC models, we also apply our framework to the BiDAF model, which has different encoder and decoder structures compared to SAN. We follow the model architecture and parameter settings in Seo et al. (2017). As shown in Figure 3, the proposed AdaMRC model clearly outperforms both SynNet+BiDAF and pre-trained BiDAF model. We also observe that the improvement of AdaMRC over BiDAF is more significant than SAN. Our hypothesis is that since BiDAF is a weaker baseline than SAN, a higher performance improvement can be observed when the domain adaptation approach is applied to enhance the model. This experiment confirms that

Method	EM/F1
SAN	36.68/52.79
AdaMRC + SAN	**38.46/54.20**
SAN + ELMo	39.61/55.18
AdaMRC + SAN + ELMo	**40.96/56.25**
$\text{BERT}_{\text{BASE}}$	42.00/58.71
AdaMRC + $\text{BERT}_{\text{BASE}}$	**42.59/59.25**

Table 4: Results of using ELMo and BERT. Setting: adaptation from SQuAD to NewsQA.

Ratio	SAN	AdaMRC + SAN
0%	36.68/52.79	**38.46/54.20**
5%	47.61/62.69	**48.50/63.17**
10%	48.66/63.32	**49.64/63.94**
20%	50.75/64.80	**51.14/65.38**
50%	53.24/67.07	**53.34/67.30**
100%	**56.48/69.14**	56.29/68.97

Table 5: Semi-supervised domain adaptation experiment with varied labeling ratio on the target-domain dataset. Setting: adaptation from SQuAD to NewsQA.

our proposed approach is robust and can generalize to different MRC models.

Results on DuoRC We further test our model on the newly-released DuoRC dataset (Saha et al., 2018). This dataset contains two subsets: movie descriptions collected from *Wikipedia* (SelfRC) and from *IMDB* (ParaphraseRC). Although the two subsets are describing the same movies, the documents from Wikipedia are usually shorter (580 words in average), while the documents from IMDB are longer and more descriptive (926 words in average). We consider them as two different domains and perform domain adaptation from Wikipedia to IMDB. This experiment broadens our definition of domain.

In the DuoRC dataset, the same questions are asked on both Wikipedia and IMDB documents. Thus, question synthesis is not needed, and comparison with SynNet is not feasible. Note that the answers of the same question could be different in the two subsets (only 40.7% of the questions have the same answers in both domains). We preprocess the dataset and test the answer-span extraction task following Saha et al. (2018). Results are reported in Table 3. AdaMRC improves the performance over both SAN (1.26%, 1.54% in EM and F1) and BiDAF (1.27%, 2.02% in EM and F1). This experiment validates that our method can be applied to different styles of domain adaptation tasks as well.

6.3 AdaMRC with Pre-trained Language Models

To verify that our approach is compatible with large-scale pre-trained language models, we evaluate our model with ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). To apply ELMo to SAN, we use the model provided by AllenNLP[4], and append a 1024-dim ELMo vector to the contextual encoding layer, with dropout rate set to 0.5. For BERT, we experiment with the pre-trained $\text{BERT}_{\text{BASE}}$ uncased model[5] due to limited computational resources. We use the original design of finetuning BERT for the MRC task in Devlin et al. (2019), instead of combining BERT with SAN. Results are provided in Table 4. We observe that using ELMo and BERT improves both AdaMRC and the baseline model. However, the improvement over ELMo and BERT is relatively smaller than SAN. We believe this is because pre-trained language model provides additional domain-invariant information learned from external data, and therefore limits the improvement of domain-invariant feature learning in our model. However, it is worth noting that combining AdaMRC with BERT achieves the best performance, which validates that AdaMRC is compatible with data augmentation from external sources.

6.4 Semi-supervised Setting

As an additional experiment, we also evaluate the proposed AdaMRC framework for semi-supervised domain adaptation. We randomly sample k portion of labeled data from the target domain, and feed them to the MRC model. The ratio of labeled data ranges k from 0% to 100%. Table 5 shows that AdaMRC outperforms SAN. However, the gap is decreasing when the labeling ratio increases. When the ratio is 20% or smaller, there is noticeable improvement. When the ratio is set to 50%, the two methods result in similar performance. When the ratio is increased to 100%, *i.e.*, fully supervised learning, the performance of AdaMRC is slightly worse than SAN. This is possibly because in a supervised learning setting, the encoder is trained to preserve domain-specific feature information. The overall results suggest that our proposed AdaMRC is also effective in semi-supervised setting, when a small portion of target-domain data is provided.

*Refugee camps in eastern Chad house about 300,000 people who fled violence in the Darfur region of Sudan . The U.N. High Commissioner for Refugees said on Monday that more than **12,000** people have fled militia attacks over the last few days from Sudan 's Darfur region to neighboring Chad...*
Answer: 12,000
GT Question: How many have recently crossed to Chad?
Pseudo Question: How many people fled the Refugee region to Sudan?

*Sources say the classified materials were taken from the East Tennessee Technology Park . **Roy Lynn Oakley** , 67 , of Roane County , Tennessee , appeared in federal court in Knoxville on Thursday . Oakley was briefly detained for questioning in the case in January ...*
Answer: Roy Lynn Oakley
GT Question: Who is appearing in court ?
Pseudo Question: What is the name of the classified employee in Tennessee on East Tennessee ?

*The Kyrgyz order became effective on Friday when **President Kurmanbek Bakiyev** reportedly signed legislation that the parliament in Bishkek backed on Thursday , the Pentagon said . Pentagon spokesman Bryan Whitman said the Kyrgyz Foreign Ministry on Friday officially notified the U.S. Embassy in Bishkek that a 180-day withdrawal process is under way...*
Answer: President Kurmanbek Bakiyev
GT Question: Who is the President of Kyrgyzstan ?
Pseudo Question: What spokesman signed legislation that the parliament was signed legislation in 2011 ?

*A high court in northern India on Friday acquitted a wealthy businessman facing the death sentence for the killing of a teen in a case dubbed " the house of horrors . " Moninder Singh Pandher was sentenced to death by a lower court in February . The teen was **one of 19** victims – children and young women – in one of the most gruesome serial killings in India in recent years ...*
Answer: one of 19
GT Question:What was the amount of children murdered?
Pseudo Question: How many victims were in India?

Table 6: Examples of generated questions given input paragraphs and answers, comparing with the ground-truth human-written questions.

6.5 Examples of Generated Questions

The percentage of generated questions starting with "what", "who", "when" and "where" are 63.2%, 12.8%, 2.3%, and 2.1%, respectively. We provide several examples of generated questions in Table 6. We observe that the generated questions are longer than human-written questions. This is possibly due to the copy mechanism used in the question generation model, which enables directly copying words into the generated questions. On the one hand, the copy mechanism provides detailed background information for generating a question. However, if not copying correctly, the question could be syntactically incorrect. For instance, in the third example, "*signed legislation that the parliament*" is copied from the passage. The copied phrase is indeed describing the answer "*President Kurmanbek Bakiyev*"; however, the question is syntactically incorrect and the question generator should copy "*the parliament backed on Thursday*" instead.

There is generally good correspondence between the answer type and generated questions. For example, the question generator will produce "*What is the name of*" if the answer is about a person, and ask "*How many*" if the answer is a number. We also observe that the generated questions may encounter semantic errors though syntactically fluent. For instance, in the first example, the passage suggests that people fled *from* Sudan to Chad, while the generated question describes the wrong direction. However, overall we think that the current question generator provides reasonable synthesized questions, yet there is still large room to improve. The observation also confirms our analysis that the synthetic question-answer pairs could be noisy and inaccurate, thus could hurt the performance when fine-tuning the answer module with generated data.

7 Conclusion

In this paper, we propose a new framework, *Adversarial Domain Adaptation for MRC* (AdaMRC), to transfer a pre-trained MRC model from a source domain to a target domain. We validate our proposed framework on several datasets and observe consistent improvement over baseline methods. We verify the robustness of the proposed framework by applying it to different MRC models. Experiments also show that AdaMRC is compatible with pre-trained language model and semi-supervised learning setting. We believe our analysis provides insights that can help guide further research in this task.

Abstract

Commonsense and background knowledge is required for a QA model to answer many non-trivial questions. Different from existing work on knowledge-aware QA, we focus on a more challenging task of leveraging external knowledge to generate answers in natural language for a given question with context.

In this paper, we propose a new neural model, Knowledge-Enriched Answer Generator (KEAG), which is able to compose a natural answer by exploiting and aggregating evidence from all four information sources available: question, passage, vocabulary and knowledge. During the process of answer generation, KEAG adaptively determines when to utilize symbolic knowledge and which fact from the knowledge is useful. This allows the model to exploit external knowledge that is not explicitly stated in the given text, but that is relevant for generating an answer. The empirical study on public benchmark of answer generation demonstrates that KEAG improves answer quality over models without knowledge and existing knowledge-aware models, confirming its effectiveness in leveraging knowledge.

1 Introduction

Question Answering (QA) has come a long way from answer sentence selection, relational QA to machine reading comprehension. The next-generation QA systems can be envisioned as the ones which can read passages and write long and abstractive answers to questions. Different from extractive question answering, generative QA based on machine reading produces an answer in true natural language which does not have to be a sub-span in the given passage.

Most existing models, however, answer questions based on the content of given passages as the only information source. As a result, they may not be able to understand certain passages or to answer certain questions, due to the lack of commonsense and background knowledge, such as the knowledge about what concepts are expressed by the words being read (lexical knowledge), and what relations hold between these concepts (relational knowledge). As a simple illustration, given the passage:

State officials in Hawaii on Monday said they have once again checked and confirmed that President Barack Obama was born in Hawaii.

to answer the question: *Was Barack Obama born in the U.S.?*, one must know (among other things) that Hawaii is a state in the U.S., which is external knowledge not present in the text corpus.

Therefore, a QA model needs to be enriched with external knowledge properly to be able to answer many nontrivial questions. Such knowledge can be commonsense knowledge or factual background knowledge about entities and events that is not explicitly expressed but can be found in a knowledge base such as ConceptNet (Speer et al., 2016), Freebase (Pellissier Tanon et al., 2016) and domain-specific KBs collected by information extraction (Fader et al., 2011; Mausam et al., 2012). Thus, we aim to design a neural model that encodes pre-selected knowledge relevant to given questions, and that learns to include the available knowledge as an enrichment to given textual information.

In this paper, we propose a new neural architecture, Knowledge-Enriched Answer Generator (KEAG), specifically designed to generate natural answers with integration of external knowledge. KEAG is capable of leveraging symbolic knowledge from a knowledge base as it generates each word in an answer. In particular, we assume that each word is generated from one of the four information sources: 1. question, 2. passage, 3. vocabulary and 4. knowledge. Thus, we introduce the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2521–2530, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

source selector, a sentinel component in KEAG that allows flexibility in deciding which source to look to generate every answer word. This is crucial, since knowledge plays a role in certain parts of an answer, while in others text context should override the context-independent knowledge available in general KBs.

At each timestep, before generating an answer word, KEAG determines an information source. If the knowledge source is selected, the model extracts a set of facts that are potentially related to the given question and context. A stochastic fact selector with discrete latent variables then picks a fact based on its semantic relevance to the answer being generated. This enables KEAG to bring external knowledge into answer generation, and to generate words not present in the predefined vocabulary. By incorporating knowledge explicitly, KEAG can also provide evidence about the external knowledge used in the process of answer generation.

We introduce a new differentiable sampling-based method to learn the KEAG model in the presence of discrete latent variables. For empirical evaluation, we conduct experiments on the benchmark dataset of answer generation MARCO (Nguyen et al., 2016). The experimental results demonstrate that KEAG effectively leverages external knowledge from knowledge bases in generating natural answers. It achieves significant improvement over classic QA models that disregard knowledge, resulting in higher-quality answers.

2 Related Work

There have been several attempts at using machine reading to generate natural answers in the QA field. Tan et al. (2018) took a generative approach where they added a decoder on top of their extractive model to leverage the extracted evidence for answer synthesis. However, this model still relies heavily on the extraction to perform the generation and thus needs to have start and end labels (a span) for every QA pair. Mitra (2017) proposed a seq2seq-based model that learns alignment between a question and passage words to produce rich question-aware passage representation by which it directly decodes an answer. Gao et al. (2019) focused on product-aware answer generation based on large-scale unlabeled e-commerce reviews and product attributes. Furthermore, natural answer generation can be reformulated as query-focused summarization which is addressed by Nema et al. (2017).

The role of knowledge in certain types of QA tasks has been remarked on. Mihaylov and Frank (2018) showed improvements on a cloze-style task by incorporating commonsense knowledge via a context-to-commonsense attention. Zhong et al. (2018) proposed commonsense-based pre-training to improve answer selection. Long et al. (2017) made use of knowledge in the form of entity descriptions to predict missing entities in a given document. There have also been a few studies on incorporating knowledge into QA models without passage reading. GenQA (Yin et al., 2016) combines knowledge retrieval and seq2seq learning to produce fluent answers, but it only deals with simple questions containing one single fact. COREQA (He et al., 2017) extends it with a copy mechanism to learn to copy words from a given question. Moreover, Fu and Feng (2018) introduced a new attention mechanism that attends across the generated history and memory to explicitly avoid repetition, and incorporated knowledge to enrich generated answers.

Some work on knowledge-enhanced natural language (NLU) understanding can be adapted to the question answering task. CRWE (Weissenborn, 2017) dynamically integrates background knowledge in a NLU model in the form of free-text statements, and yields refined word representations to a task-specific NLU architecture that reprocesses the task inputs with these representations. In contrast, KBLSTM (Yang and Mitchell, 2017) leverages continuous representations of knowledge bases to enhance the learning of recurrent neural networks for machine reading. Furthermore, Bauer et al. (2018) proposed MHPGM, a QA architecture that fills in the gaps of inference with commonsense knowledge. The model, however, does not allow an answer word to come directly from knowledge. We adapt these knowledge-enhanced NLU architectures to answer generation, as baselines for our experiments.

3 Knowledge-aware Answer Generation

Knowledge-aware answer generation is a question answering paradigm, where a QA model is expected to generate an abstractive answer to a given question by leveraging both the contextual passage and external knowledge. More formally, given a knowledge base $\mathcal{K}$ and two sequences of input words: question

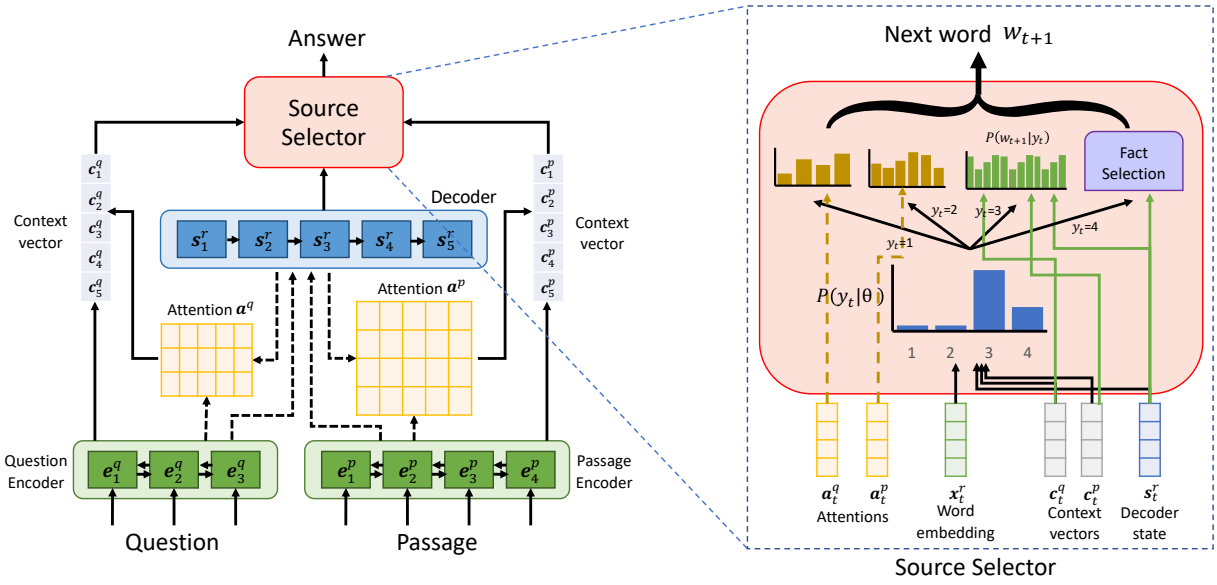

Figure 1: An overview of the architecture of KEAG (best viewed in color). A question and a passage both go through an extension of the sequence-to-sequence model. The outcomes are then fed into a source selector to generate a natural answer.

$q = \{w_1^q, w_2^q, \ldots, w_{N_q}^q\}$ and passage $p = \{w_1^p, w_2^p, \ldots, w_{N_p}^p\}$, the answer generation model should produce a series of answer words $r = \{w_1^r, w_2^r, \ldots, w_{N_r}^r\}$. The knowledge base $\mathcal{K}$ contains a set of facts, each of which is represented as a triple $f = (subject, relation, object)$ where $subject$ and $object$ can be multi-word expressions and $relation$ is a relation type, e.g., $(bridge, UsedFor, cross\ water)$.

3.1 Knowledge-Enriched Answer Generator

To address the answer generation problem, we propose a novel KEAG model which is able to compose a natural answer by recurrently selecting words at the decoding stage. Each of the words comes from one of the four sources: question q, passage p, global vocabulary $\mathcal{V}$, and knowledge $\mathcal{K}$. In particular, at every generation step, KEAG first determines which of the four sources to inspect based on the current state, and then generates a new word from the chosen source to make up a final answer. An overview of the neural architecture of KEAG is depicted in Figure 1.

3.2 Sequence-to-sequence model

KEAG is built upon an extension of the sequence-to-sequence attentional model (Bahdanau et al., 2015; Nallapati et al., 2016; See et al., 2017). The words of question q and passage p are fed one-by-one into two different encoders, respectively. Each of the two encoders, which are both bidirectional LSTMs, produces a sequence of encoder hidden states ($\mathbf{E}^q$ for question q, and $\mathbf{E}^p$ for passage p). In each timestep t, the decoder, which is a unidirectional LSTM, takes an answer word as input, and outputs a decoder hidden state $\mathbf{s}_t^r$.

We calculate attention distributions $\mathbf{a}_t^q$ and $\mathbf{a}_t^p$ on the question and the passage, respectively, as in (Bahdanau et al., 2015):

$$\mathbf{a}_t^q = \text{softmax}(\mathbf{g}^{q\intercal}\tanh(\mathbf{W}^q\mathbf{E}^q + \mathbf{U}^q\mathbf{s}_t^r + \mathbf{b}^q)), \quad (1)$$

$$\mathbf{a}_t^p = \text{softmax}(\mathbf{g}^{p\intercal}\tanh(\mathbf{W}^p\mathbf{E}^p + \mathbf{U}^p\mathbf{s}_t^r + \mathbf{V}^p\mathbf{c}^q + \mathbf{b}^p)), \quad (2)$$

where $\mathbf{g}^q$, $\mathbf{W}^q$, $\mathbf{U}^q$, $\mathbf{b}^q$, $\mathbf{g}^p$, $\mathbf{W}^p$, $\mathbf{U}^p$ and $\mathbf{b}^p$ are learnable parameters. The attention distributions can be viewed as probability distributions over source words, which tells the decoder where to look to generate the next word. The coverage mechanism is added to the attentions to avoid generating repetitive text (See et al., 2017). In Equation 2, we introduce $\mathbf{c}^q$, a context vector for the question, to make the passage attention aware of the question context. $\mathbf{c}^q$ for the question and $\mathbf{c}^p$ for the passage are calculated as follows:

$$\mathbf{c}_t^q = \sum_i a_{ti}^q \cdot \mathbf{e}_i^q, \qquad \mathbf{c}_t^p = \sum_i a_{ti}^p \cdot \mathbf{e}_i^p, \quad (3)$$

where $\mathbf{e}_i^q$ and $\mathbf{e}_i^p$ are an encoder hidden state for question q and passage p, respectively. The context vectors ($\mathbf{c}_t^q$ and $\mathbf{c}_t^p$) together with the attention distributions ($\mathbf{a}_t^q$ and $\mathbf{a}_t^p$) and the decoder state

($\mathbf{s}_t^r$) will be used downstream to determine the next word in composing a final answer.

4 Source Selector

During the process of answer generation, in each timestep, KEAG starts with running a source selector to pick a word from one source of the question, the passage, the vocabulary and the knowledge. The right plate in Figure 1 illustrates how the source selector works in one timestep during decoding.

If the question source is selected in timestep t, KEAG picks a word according to the attention distribution $\mathbf{a}_t^q \in \mathbb{R}^{N_q}$ over question words (Equation 1), where N_q denotes the number of distinct words in the question. Similarly, when the passage source is selected, the model picks a word from the attention distribution $\mathbf{a}_t^p \in \mathbb{R}^{N_p}$ over passage words (Equation 2), where N_p denotes the number of distinct words in the passage. If the vocabulary is the source selected in timestep t, the new word comes from the conditional vocabulary distribution $P_v(w|\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r)$ over all words in the vocabulary, which is obtained by:

$$P_v(w|\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r) = \text{softmax}(\mathbf{W}^v \cdot [\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r] + \mathbf{b}^v), \tag{4}$$

where $\mathbf{c}_t^q$ and $\mathbf{c}_t^p$ are context vectors, and $\mathbf{s}_t^r$ is a decoder state. $\mathbf{W}^v$ and $\mathbf{b}^v$ are learnable parameters.

To determine which of the four sources a new word w_{t+1} is selected from, we introduce a discrete latent variable $y_t \in \{1, 2, 3, 4\}$ as an indicator. When $y_t = 1$ or 2, the word w_{t+1} is generated from the distribution $P(w_{t+1}|y_t)$ given by:

$$P(w_{t+1}|y_t) = \begin{cases} \sum_{i:w_i = w_{t+1}} a_{ti}^q & y_t = 1 \\ \sum_{i:w_i = w_{t+1}} a_{ti}^p & y_t = 2. \end{cases} \tag{5}$$

If $y_t = 3$, KEAG picks word w_{t+1} according to the vocabulary distribution $P_v(w|\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r)$ given in Equation 4. Otherwise, if $y_t = 4$, the word w_{t+1} comes from the fact selector, which will be described in the coming section.

5 Knowledge Integration

In order for KEAG to integrate external knowledge, we first extract related facts from the knowledge base in response to a given question, from which we then pick the most relevant fact that can be used for answer composition. In this section, we present the two modules for knowledge integration: *related fact extraction* and *fact selection*.

5.1 Related Fact Extraction

Due to the size of a knowledge base and the large amount of unnecessary information, we need an effective way of extracting a set of candidate facts which provide novel information while being related to a given question and passage.

For each instance (q, p), we first extract facts with the subject or object that occurs in question q or passage p. Scores are added to each extracted fact according to the following rules:

- Score+4, if the subject occurs in q, *and* the object occurs in p.
- Score+2, if the subject *and* the object both occur in p.
- Score+1, if the subject occurs in q *or* p.

The scoring rules are set heuristically such that they model relative fact importance in different interactions. Next, we sort the fact triples in descending order of their scores, and take the top N_f facts from the sorted list as the related facts for subsequent processing.

5.2 Fact Selection

Figure 2 displays how a fact is selected from the set of related facts for answer completion. With the extracted knowledge, we first embed every related fact f by concatenating the embeddings of the subject $\mathbf{e}^s$, the relation $\mathbf{e}^r$ and the object $\mathbf{e}^o$. The embeddings of subjects and objects are initialized with pre-trained GloVe vectors (and average pooling for multiple words), when the words are present in the vocabulary. The fact embedding is followed by a linear transformation to relate subject $\mathbf{e}^s$ to object $\mathbf{e}^o$ with relation $\mathbf{e}^r$:

$$\mathbf{f} = \mathbf{W}^e \cdot [\mathbf{e}^s, \mathbf{e}^r, \mathbf{e}^o] + \mathbf{b}^e. \tag{6}$$

where $\mathbf{f}$ denotes fact representation, $[\cdot, \cdot]$ denotes vector concatenation, and $\mathbf{W}^e$ and $\mathbf{b}^e$ are learnable parameters. The set of all related fact representations $F = \{\mathbf{f}_1, \mathbf{f}_2, \ldots, \mathbf{f}_{N_f}\}$ is considered to be a short-term memory of the knowledge base while answering questions on given passages.

To enrich KEAG with the facts collected from the knowledge base, we propose to complete an answer with the most relevant fact(s) whenever it is determined to resort to knowledge during the process of answer generation. The most relevant fact is selected from the related fact set F based on the dynamic generation state. In this model, we introduce a discrete latent random variable $z_t \in$

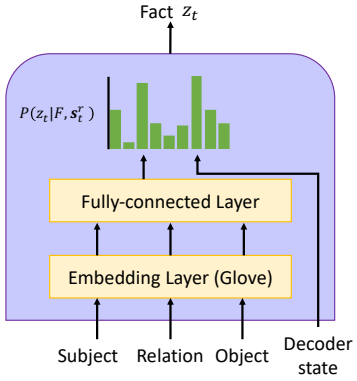

Figure 2: An overview of the fact selection module (best viewed in color)

$[1, N_f]$ to explicitly indicate which fact is selected to be put into an answer in timestep t. The model selects a fact by sampling a z_t from the discrete distribution $P(z_t|F, \mathbf{s}_t^r)$ given by:

$$P(z_t|\cdot) = \frac{1}{Z} \cdot \exp(\mathbf{g}^{f\intercal} \tanh(\mathbf{W}^f \mathbf{f}_{z_t} + \mathbf{U}^f \mathbf{s}_t^r + \mathbf{b}^f)), \tag{7}$$

where Z is the normalization term, $Z = \sum_{i=1}^{N_f} \exp(\mathbf{g}^{f\intercal} \tanh(\mathbf{W}^f \mathbf{f}_i + \mathbf{U}^f \mathbf{s}_t^r + \mathbf{b}^f))$, and $\mathbf{s}_t^r$ is the hidden state from the decoder in timestep t. $\mathbf{g}^f$, $\mathbf{W}^f$, $\mathbf{U}^f$ and $\mathbf{b}^f$ are learnable parameters.

The presence of discrete latent variables $\mathbf{z}$, however, presents a challenge to training the neural KEAG model, since the backpropagation algorithm, while enabling efficient computation of parameter gradients, does not apply to the non-differentiable layer introduced by the discrete variables. In particular, gradients cannot propagate through discrete samples from the categorical distribution $P(z_t|F, \mathbf{s}_t^r)$.

To address this problem, we create a differentiable estimator for discrete random variables with the Gumbel-Softmax trick (Jang et al., 2017). Specifically, we first compute the discrete distribution $P(z_t|F, \mathbf{s}_t^r)$ with class probabilities $\pi_1, \pi_2, \ldots, \pi_{N_f}$ by Equation 7. The Gumbel-Max trick (Gumbel, 1954) allows to draw samples from the categorical distribution $P(z_t|F, \mathbf{s}_t^r)$ by calculating one_hot$(\arg\max_i [g_i + \log \pi_i])$, where $g_1, g_2, \ldots, g_{N_f}$ are i.i.d. samples drawn from the Gumbel$(0, 1)$ distribution. For the inference of a discrete variable z_t, we approximate the Gumbel-Max trick by the continuous softmax function (in place of $\arg\max$) with temperature τ to generate a sample vector $\hat{\mathbf{z}}_t$:

$$\hat{z}_{ti} = \frac{\exp((\log(\pi_i) + g_i)/\tau)}{\sum_{j=1}^{N_f} \exp((\log(\pi_j) + g_j)/\tau)}. \tag{8}$$

When τ approaches zero, the generated sample $\hat{\mathbf{z}}_t$ becomes a one-hot vector. τ is gradually annealed over the course of training.

This new differentiable estimator allows us to backpropagate through $z_t \sim P(z_t|F, \mathbf{s}_t^r)$ for gradient estimation of every single sample. The value of z_t indicates a fact selected by the decoder in timestep t. When the next word is determined to come from knowledge, the model appends the object of the selected fact to the end of the answer being generated.

6 Learning Model Parameters

To learn the parameters θ in KEAG with latent source indicators $\mathbf{y}$, we maximize the log-likelihood of words in all answers. For each answer, the log-likelihood of the words is given by:

$$\log P(w_1^r, w_2^r, \ldots, w_{N_r}^r|\theta) = \sum_{t=1}^{N_r} \log P(w_t^r|\theta)$$

$$= \sum_{t=1}^{N_r} \log \sum_{y_t=1}^{4} P(w_{t+1}|y_t) P(y_t|\theta) \tag{9}$$

$$\geq \sum_{t=1}^{N_r} \sum_{y_t=1}^{4} P(y_t|\theta) \log P(w_{t+1}|y_t) \tag{10}$$

$$= \sum_{t=1}^{N_r} \mathbb{E}_{y_t|\theta}[\log P(w_{t+1}|y_t)], \tag{11}$$

where the word likelihood at each timestep is obtained by marginalizing out the latent source variable y_t. Unfortunately, direct optimization of Equation 9 is intractable, so we instead learn the objective function through optimizing its variational lower bound given in Equations 10 and 11, obtained from Jensen's inequality.

To estimate the expectation in Equation 11, we use Monte Carlo sampling on the source selector variables $\mathbf{y}$ in the gradient computation. In particular, the Gumbel-Softmax trick is applied to generate discrete samples $\hat{\mathbf{y}}$ from the probability $P(y_t|\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r, \mathbf{x}_t^r)$ given by:

$$P(y_t|\cdot) = \text{softmax}(\mathbf{W}^y \cdot [\mathbf{c}_t^q, \mathbf{c}_t^p, \mathbf{s}_t^r, \mathbf{x}_t^r] + \mathbf{b}^y), \tag{12}$$

where $\mathbf{x}_t^r$ is the embedding of the answer word in timestep t, $\mathbf{W}^y$ and $\mathbf{b}^y$ are learnable parameters. The generated samples are fed to $\log P(w_{t+1}|y_t)$ to estimate the expectation.

7 Experiments

We perform quantitative and qualitative analysis of KEAG through experiments. In our experi-

ments, we also study the impact of the integrated knowledge and the ablations of the KEAG model. In addition, we illustrate how natural answers are generated by KEAG with the aid of external knowledge by analyzing a running example.

7.1 Dataset and Evaluation Metrics

Given our objective of generating natural answers by document reading, the MARCO dataset (Nguyen et al., 2016) released by Microsoft is the best fit for benchmarking KEAG and other answer generation methods. We use the latest MARCO V2.1 dataset and focus on the "*Q&A + Natural Language Generation*" task in the evaluation, the goal of which is to provide the best answer available in natural language that could be used by a smart device / digital assistant.

In the MARCO dataset, the questions are user queries issued to the Bing search engine and the contextual passages are from real web documents. The data has been split into a training set (153,725 QA pairs), a dev set (12,467 QA pairs) and a test set (101,092 questions with unpublished answers). Since true answers are not available in the test set, we hold out the dev set for evaluation in our experiments, and test models for each question on its associated passages by concatenating them all together. We tune the hyper-parameters by cross-validation on the training set.

The answers are human-generated and not necessarily sub-spans of the passages, so the official evaluation tool of MARCO uses the metrics BLEU-1 (Papineni et al., 2002) and ROUGE-L (Lin, 2004). We use both metrics for our evaluation to measure the quality of generated answers against the ground truth.

For external knowledge, we use ConceptNet (Speer et al., 2016), one of the most widely used commonsense knowledge bases. Our KEAG is generic and thus can also be applied to other knowledge bases. ConceptNet is a semantic network representing words and phrases as well as the commonsense relationships between them. After filtering out non-English entities and relation types with few facts, we have 2,823,089 fact triples and 32 relation types for the model to consume.

7.2 Implementation Details

In KEAG, we use 300-dimensional pre-trained *Glove* word embeddings (Pennington et al., 2014) for initialization with update during training. The dimension of hidden states is set to 256 for every LSTM. The fact representation $\mathbf{f}$ has 500 dimensions. The maximum number of related facts N_f is set to be 1000. We use a vocabulary of 50K words (filtered by frequency). Note that the source selector enables KEAG to handle out-of-vocabulary words by generating a word from given text or knowledge.

At both training and test stages, we truncate a passage to 800 words, and limit the length of an answer to 120 words. We train on a single Tesla M40 GPU with the batch size of 16. At test time, answers are generated using beam search with the beam size of 4.

Table 1: Metrics of KEAG and QA models disregarding knowledge on the MARCO dataset.

7.3 Model Comparisons

Table 1 compares KEAG with the following state-of-the-art extractive/generative QA models, which do not make use of external knowledge:

1. **BiDAF** (Seo et al., 2017): A multi-stage hierarchical process that represents the context at different levels of granularity, and using the bi-directional attention flow mechanism for answer extraction
2. **BiDAF+Seq2Seq**: A BiDAF model followed by an additional sequence-to-sequence model for answer generation
3. **S-Net** (Tan et al., 2018): An extraction-then-synthesis framework to synthesize answers from extracted evidences
4. **S-Net+Seq2Seq**: An S-Net model followed by an additional sequence-to-sequence model for answer generation
5. **QFS** (Nema et al., 2017): A model that adapts the query-focused summarization model to answer generation
6. **VNET** (Wang et al., 2018): An MRC model that enables answer candidates from different

Model	Rouge-L	Bleu-1

Table 2: Metrics of KEAG and knowledge-enriched QA models on the MARCO dataset.

passages to verify each other based on their content representations

7. **gQA** (Mitra, 2017): A generative approach to question answering by incorporating the copying mechanism and the coverage vector

Table 1 shows the comparison of QA models in Rouge-L and Bleu-1. From the table we observe that abstractive QA models (e.g., KEAG) are consistently superior to extractive models (e.g., BiDAF) in answer quality. Therefore, abstractive QA models establish a strong base architecture to be enhanced with external knowledge, which motivates this work. Among the abstractive models, gQA can be viewed as a simplification of KEAG, which generates answer words from passages and the vocabulary without the use of knowledge. In addition, KEAG incorporates a stochastic source selector while gQA does not. The result that KEAG significantly outperforms gQA demonstrates the effectiveness of KEAG's architecture and the benefit of knowledge integration.

Table 2 shows the metrics of KEAG in comparison to those of the following state-of-the-art QA models that are adapted to leveraging knowledge:

1. **gQA w/ KBLSTM** (Yang and Mitchell, 2017): KBLSTM is a neural model that leverages continuous representations of knowledge bases to enhance the learning of recurrent neural networks for machine reading. We plug it into gQA to make use of external knowledge for natural answer generation.
2. **gQA w/ CRWE** (Weissenborn, 2017): CRWE is a reading architecture with dynamic integration of background knowledge based on contextual refinement of word embeddings by leveraging supplementary knowledge. We extend gQA with the refined word embedding for this model.
3. **MHPGM** (Bauer et al., 2018): A multi-hop reasoning QA model which fills in the gaps of inference with commonsense knowledge.

Model	Syntactic	Correct
gQA	3.78	3.54
gQA w/ KBLSTM	3.98	3.62
gQA w/ CRWE	3.91	3.69
MHPGM	4.10	3.81
KEAG	**4.18**	**4.03**

Table 3: Human evaluation of KEAG and state-of-the-art answer generation models. Scores range in $[1, 5]$.

From Table 2, it can be clearly observed that KEAG performs best with the highest Rouge-L and Bleu-1 scores among the knowledge-enriched answer generation models. The major difference between KEAG and the other models is the way of incorporating external knowledge into a model. *gQA w/ KBLSTM* and *gQA w/ CRWE* extend gQA with the module that consumes knowledge, and MHPGM incorporates knowledge with selectively-gated attention while its decoder does not leverage words from knowledge in answer generation. Different from these models, KEAG utilizes two stochastic selectors to determine when to leverage knowledge and which fact to use. It brings additional gains in exploiting external knowledge to generate abstractive answers.

Since neither Rouge-L nor Bleu-1 can measure the quality of generated answers in terms of their correctness and accuracy, we also conduct human evaluation on Amazon Mechanical Turk. The evaluation assesses the answer quality on grammaticality and correctness. We randomly select 100 questions from the dev set, and ask turkers for ratings in a Likert scale ($\in [1, 5]$) on the generated answers.

Table 3 reports the human evaluation scores of KEAG and state-of-the-art answer generation models. The KEAG model surpasses all the others in generating correct answers syntactically and substantively. In terms of syntactic correctness, KEAG and MHPGM both perform well thanks to their architectures of composing answer text and integrating knowledge. On the other hand, KEAG significantly outperforms all compared models in generating substantively correct answers, which demonstrates its power in exploiting external knowledge.

7.4 Ablation Studies

We conduct ablation studies to assess the individual contribution of every component in KEAG. Table 4 reports the performance of the full KEAG

Ablation	Rouge-L	Bleu-1
Full KEAG	**51.68**	**45.97**
✗ supplementary knowledge	49.98	44.59
✗ latent indicators $\mathbf{y}$	47.61	42.10
✗ source selector	38.33	36.75

Table 4: Ablation tests of KEAG.

model and its ablations.

We evaluate how much incorporating external knowledge as supplementary information contributes to natural answer generation by removing the supplementary knowledge and the corresponding fact selection module from KEAG's architecture. It can be seen that the knowledge component plays an important role in generating high-quality answers, with a drop to 49.98 on Rouge-L after the supplementary knowledge is removed.

To study the effect of our learning method, we further ablate the latent indicators $\mathbf{y}$, which leads to degradation to gQA except that the new model can select answer words from the question source while gQA cannot. Our learning method proves to be effective with a drop of about 5% on Rouge-L and about 6% on Bleu-1 after ablation.

Finally, for ablating the source selector, we have a new model that generates answer words from the vocabulary alone. It results in a significant drop to 38.33 on Rouge-L, confirming its effectiveness in generating natural answers.

7.5 Visualization and Interpretation

The source selector allows us to visualize how every word in an answer is generated from one of the sources of the question, passage, vocabulary and knowledge, which gives us insights about how KEAG works.

Table 5 visualizes a sample QA pair from KEAG and which source every word in the answer is selected from (indicated by the sample value of the source selector variable y_t). As exemplified in the table, the source distribution $P(y_t|\theta)$ varies over decoding timesteps. To answer the question, at each timestep, KEAG first selects a source based on the sample from $P(y_t|\theta)$, followed by generating an answer word from the selected source. It is observed that the in the generated answer the keyword *personality* comes from the knowledge source which relates psychopathy to personality. The answer word *psychopathy* is selected from the question source, which leads to a well-formed answer with a complete sentence. Another keyword *disorder*, on the other hand, comes from the passage source. This results from reading comprehension of the model on the passage. To generate a final answer in good form, KEAG picks the filler words *is* and *a* as well as the period "." from the vocabulary source. It makes the generated answer semantically correct and comprehensive.

Question	
What's psychopathy?	
Answer with source probabilities	
Question src	Psychopathy is a personality disorder.
Passage src	Psychopathy is a personality disorder.
Vocabulary src	Psychopathy is a personality disorder.
Knowledge src	Psychopathy is a personality disorder.
Answer colored by source	
Psychopathy is a personality disorder.	

Table 5: Visualization of a sample QA pair and the source of individual words in the answer. The **Answer with source probabilities** section displays a heatmap on answer words selected from the question, passage, vocabulary and knowledge, respectively. A slot with a higher source probability is highlighted in darker cyan. The **Answer colored by source** section shows the answer in which every word is colored based on the source it was actually selected from. Words in blue come from the question, red from the passage, green from the vocabulary, and orange from the knowledge. The visualization is best viewed in color.

8 Conclusion and Future Work

This paper presents a new neural model KEAG that is designed to bring symbolic knowledge from a knowledge base into abstractive answer generation. This architecture employs the source selector that allows for learning an appropriate tradeoff for blending external knowledge with information from textual context. The related fact extraction and stochastic fact selection modules are introduced to complete an answer with relevant facts.

This work opens up for deeper investigation of answer generation models in a targeted way, allowing us to investigate what knowledge sources are required for different domains. In future work, we will explore even tighter integration of symbolic knowledge and stronger reasoning methods.

Abstract

Answering multiple-choice questions in a setting in which no supporting documents are explicitly provided continues to stand as a core problem in natural language processing. The contribution of this article is two-fold. First, it describes a method which can be used to semantically rank documents extracted from Wikipedia or similar natural language corpora. Second, we propose a model employing the semantic ranking that holds the first place in two of the most popular leaderboards for answering multiple-choice questions: ARC Easy and Challenge. To achieve this, we introduce a self-attention based neural network that latently learns to rank documents by their importance related to a given question, whilst optimizing the objective of predicting the correct answer. These documents are considered relevant contexts for the underlying question. We have published the ranked documents so that they can be used off-the-shelf to improve downstream decision models.

1 Introduction

The article at hand devotes to the problem of answering multiple-choice questions where the input consists of an inquiry expressed solely in raw natural language along with a small set of candidate answers (usually 4) from which only one is correct. Moreover, we are targeting questions from a field of science (e.g. chemistry, biology) as they are distinctly more challenging to answer than regular questions (Clark et al., 2018). A relevant example of such a question is the following:

Which of the following is an example of a physical change? (A) Lighting a match (B) Breaking a glass (C) Burning of gasoline (D) Rusting of iron

An important characteristic of all solutions developed for this task is that they are not given explicitly any external information in the form of documents supporting the correct answer or semi-structured information. However, external information is highly desirable, especially domain and common-sense knowledge. Thus, most of the state of the art solutions (Pîrtoacă et al., 2018; Nicula et al., 2018; Ni et al., 2018; Zhang et al., 2018) are using a two-step architecture, as shown in Figure 1. In the first phase, an information retrieval (IR) engine *lexically* searches for relevant supporting paragraphs in Wikipedia and other corpora considered relevant for the task. Having extracted some pertinent paragraphs (usually only one per candidate answer), potentially containing relevant information, a machine learning model is employed in the second step to reason about tuples *(question, candidate answer, external information)*. Various downstream decision models are trained to infer whether the candidate answer is correct given the external information: transformers (Pan et al., 2019), attention models (Clark et al., 2018; Ni et al., 2018), or support vector machines (Clark et al., 2016).

However, it has been previously reported that a retrieval-based engine alone is not able to return relevant documents from the reference corpora (Pîrtoacă et al., 2018; Zhang et al., 2018). Depending on the dataset used as an external reference, about 50% of the questions have insufficient and irrelevant support from a standard retrieval model (Zhang et al., 2018). Therefore, the decision engine that relies on the quality of the supporting documents will be highly affected. Irrelevant documents disturb the training process since the models are trained on "wrong" (or noisy)

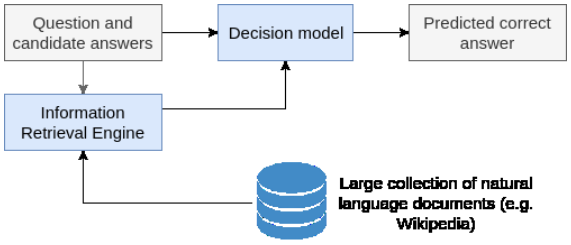

Figure 1: The general high-level architecture of a question answering system

data. As a result, the end-to-end performance of question answering (QA) systems decreases considerably. This article improves the current retrieval scheme by *semantically* ranking the retrieved documents, placing the most relevant ones at the top with a neural self-attention model.

We conduct our experiments on two significant datasets containing science-related multiple-choice questions collected from official examinations: ARC Easy and ARC Challenge (Clark et al., 2018). The former consists of easier questions, whereas the latter incorporates more difficult queries that require inference and external knowledge. In the results section, we are going to observe that our approach achieves state-of-the-art accuracy on both datasets whilst acknowledging their core difference stated by the large gap in the performance: about 28% difference in the accuracy between Easy and Challenge questions.

In this paper, we make the following important contributions:

1) We introduce a neural network architecture, called Attentive Ranker that latently learns to rank supporting documents at a semantic level. The classifier is trained to predict the correct answer to a multiple-choice question achieving state of the art accuracy on the two ARC datasets: Easy (72.30%) and Challenge (44.72%).

2) We show that the set of documents computed by our semantic ranking system can be off-the-shelf adopted by various downstream classifiers to boost their performance (by up to 7%).

2 Related Work

A lot of effort has been invested to extract more relevant external documents from natural language corpora to improve QA systems. One approach is to identify the essential terms in questions (Pîrtoacă et al., 2018; Khashabi et al., 2017) and use these terms to improve the quality of the extracted documents. Essential terms are particularly useful for long questions that are intentionally injected with noisy information by teachers to assess the reading comprehension of examined students (which is the case of the ARC dataset, collected indeed from examinations).

Pîrtoacă et al. (2018) propose a neural network architecture, with a small number of parameters, trained to annotate each term in the question with an essentialness score from 0 to 5. The architecture is based on LSTM units (Hochreiter and Schmidhuber, 1997) but with some pre-computed features added to the input to overcome the problem of small datasets: part of speech, a concreteness score for each term (Brysbaert et al., 2014), dependency relations from the parsing tree. The authors show that using the essential terms to extract documents improves the accuracy of multiple-choice QA systems by up to 4% on the ARC dataset (versus a standard IR approach). This highlights that more relevant documents are retrieved using essential terms.

In a similar spirit, Khashabi et al. (2017) report the importance of essential terms for the same multiple-choice QA task but on different datasets. They propose an essential term classifier in the form of a linear Support Vector Machine (SVM) trained on syntactic and semantic features extracted from the question. In total, about 120 types of features (with their combinations) are fed into the classifier. Incorporating the computed essential terms in the IR engine yields an increase in the number of questions correctly answered by up to 5% on the *REGENTS* and the *AI2PUBLIC* datasets[1].

Furthermore, Jansen et al. (2017) formulate the multiple-choice question answering problem into extracting answer justifications and then ranking them. A perceptron is trained to jointly rank the answers along together with their justifications considering the relevance of justifications as a latent variable. The ranking model is tested on a corpus of 1,000 primary school questions, answering 44% of the questions correctly, empirically showing that about 57% of the justifications are meaningful.

On another note, the state of the art downstream decision models are mainly based on transformers (Vaswani et al., 2017) and pre-retrained language models (Devlin et al., 2018; Radford et al., 2019).

[1] Available at http://allenai.org/data.html

Sun et al. (2018) present some reading strategies for machine reading comprehension such as back and forth reading or highlighting. These strategies are carried out by fine-tuning a generative transformer (GPT) (Radford, 2018). Their model was the state of the art approach on the ARC dataset (both Easy and Challenge) prior to our proposed model.

Previous work has shown that the performance of models on QA datasets drops dramatically when a document is not provided to support answering the question. Chen et al. (2017) proposed a model, called DrQA, that was trained on the SQuAD 1.1 dataset (Rajpurkar et al., 2016) to find the correct answer to open-domain questions. When a valid document is provided - guaranteed to contain the correct answer - the exact match (EM) score obtained by DrQA is 69.5. However, when the supporting document has to be retrieved from Wikipedia, by an information retrieval engine, the EM score drops to 27.1. This suggests that research has to be invested in improving retrieval strategies and candidate document ranking methods.

As this related work section suggests, the main direction currently approached for increasing the quality of the extracted documents is to employ essential term information in a form or another and blend this knowledge in the query sent to the retrieval engine. Our paper proposes a completely different strategy, which is based on semantically ranking the extracted documents using a neural network that learns to select the most meaningful and discriminative documents for a given question.

3 Proposed approach

We briefly describe how an IR engine is used to extract external information (e.g. supporting documents) from natural language resources like Wikipedia to support QA systems. Then, the paper continues with our proposed approach towards rectifying the shortcomings of the current retrieval-based extraction methods.

3.1 Extracting supporting documents

It is undeniable that external information is deeply required in some form or another for answering a given question. Humans capture that information by learning, by experiencing and from common-sense knowledge. For machine learning models, external information is injected as input during training. Given a question and a candidate answer, documents containing information relevant to each *(question, candidate answer)* pair are usually extracted from raw text corpora (Pîrtoacă et al., 2018, Nicula et al., 2018). For the example question mentioned earlier in this paper, a good supporting document would be the following one: *"When a glass is broken, a lot of small sharp glass pieces are formed and spread around."* Given this information, a decision component such as a neural network should be able to deduce that "*breaking a glass"* is indeed an "*example of a physical change"*, thus predicting the correct answer.

Natural language corpora like Wikipedia, ARC Corpus[2], or a large collection of science books crawled from the World Wide Web (Pîrtoacă et al., 2018) are split into articles, paragraphs, or even at the sentence level and then indexed using various search engines: Lucene (Białecki et al., 2012) or ElasticSearch (Gormley and Tong, 2015), to make the entire query process a lot faster. After the indexing phase is completed, queries are sent to the IR engine in the format *"question tokens" AND "answer tokens"*, thus retrieving documents that contain tokens from the question and tokens from the answer (at least one from each) which are, desirably, semantically relevant – and they should be up to one point, depending on the question difficulty and how it is formulated. Notice that for each candidate answer, a set of documents are retrieved and they will be used by some decision engine to derive if the candidate answer is correct or not. In some cases, no decision engine is used at all and the candidate answer with the highest matching score (for example, TF-IDF (Manning et al., 2010)) is predicted as the correct one. During this paper, we will refer to this simple approach as the "*IR baseline*".

In this paper, we will build upon the aforementioned IR baseline by adding a layer on the top of it, which is a neural network capable of latently learning to better rank the documents (as compared to the IR baseline).

[2] http://data.allenai.org/arc/arc-corpus/

3.2 Towards a better retrieval engine

An important problem of QA systems is the IR approach for extracting relevant documents. Using a token-based retrieval (Lucene, ElasticSearch) and keeping *the most relevant document* as dictated by a *lexical score* (e.g. TF-IDF, Okapi BM25 (Manning et al., 2010)) does not produce relevant supporting documents for a significant proportion of the questions (Zhang et al., 2018). Our work is a trade-off between the computational performance of such systems and the expressivity of semantic level retrieval. Our main research hypothesis is that semantically ranking the first N (e.g. $N = 100$ or 500) returned documents instead of sorting them by a lexical metric produces better results and delivers more meaningful documents for answering the question at hand. In other words, some better documents can be found in the first N (where N is a small number), but the best is not always the one with the highest lexical (e.g. TF-IDF) score. We are going to validate our hypothesis in the results section by showing that we can achieve state-of-the-art accuracy on both ARC Easy and Challenge, significantly improving the performance of the same decision model without the proposed semantic ranking.

In order to semantically discern relevant and irrelevant documents for a given question, we are designing a set of discriminators, each receiving a tuple *(question, candidate answer, and document)* and returning a confidence score. A higher score means that the document contains relevant information for answering the question, whereas a score equal to 0 signifies a document that can be ignored as it is noisy or unrelated. These discriminators are the core idea in our approach and they will be used further on to learn how to rank the documents. As will be expanded, these are deep learning models pre-trained to achieve some particular (semantically related) objective. In the next sections, various discriminators are illustrated, and, after that, we present how they are combined to produce the final ranking model.

3.3 Document relevance discriminator

This discriminator's purpose is to determine whether or not the document has any significance in answering the question at hand. It ignores the candidate answer and takes into account only the question and the document. The intuition is that some documents are clearly not helpful for the question as they do not contain any relevant information. For example, consider the question: "*How many electrons does a hydrogen atom have?*" and the following two possible extracted documents: "*The hydrogen atom is an electrically neutral atom, usually denoted using the symbol H.*", and "*The hydrogen is a chemical element with a single electron orbiting its nucleus.*" It is clear that the second context is relevant, whilst the first one is not that important. Therefore, in the ranking process, we should place the latter, lower in the list of candidate documents, because semantically it is not relevant for the question at hand, although it has a large TF-IDF score.

Model	Validation Accuracy
GRU with GloVe	59.04%
GRU with ELMo	60.90%
BERT Base	75.30%
BERT Large	80.43%

Table 1: Discriminative performance of the models on the adapted SQuAD 2.0 validation set

We have constructed this discriminator by training a neural network on an adapted version of the SQuAD 2.0 dataset (Rajpurkar et al., 2018). The network receives a question and a document as input and produces a score between 0 and 1, correlated with the significance of the document for the question.

The SQuAD 2.0 dataset has the following structure: a paragraph of raw text and a question targeting the information in the paragraph. The answer can be either a span from the paragraph or "*not answerable*", meaning that an answer cannot be deduced based solely on the information in the paragraph. Observe the duality of the task: a "*not answerable*" entry also means that the paragraph is not relevant to the question. This is the key insight that we are going to exploit. We adopted the SQuAD 2.0 dataset, but translated the task into a binary one: is the question answerable or not? Notice that if an answer exists, we pay no attention to the answer itself, the important fact being that the paragraph contains an answer for the question. The resulting dataset has about 100k questions where an answer exists and 50k questions with no valid answer in the given paragraph.

The dataset size is generous enough to enable training deep neural architectures. We have tried four different neural networks to play the role of a document relevance discriminator. The first model encodes the question and the document via 2 layers of independent Gated Recurrent Unit (GRU) cells

(Cho et al., 2014) with the words embedded into a 50-dimensional vector space using pre-trained GloVe word vectors (Pennington et al., 2014). Replacing GRU with Long-Short Term Memory (LSTM) cells (Hochreiter and Schmidhuber, 1997) gives similar performance but the training procedure is computationally more expensive. On top of the representations computed by the GRUs, we added 2 layers of feed-forward connections, the decision phase of the network.

In the second approach, we replaced the first layer of GRUs with the more expressive ELMo encoder (Peters et al., 2018). The other parts of the architecture have not been modified.

Last but not least, we deployed a pre-trained transformer, BERT (Devlin et al., 2018), both the base version with 12 layers and the large version with 24 layers of transformers. BERT is currently the state-of-the-art approach in multiple NLP tasks including open-domain question answering and reading comprehension (Devlin et al., 2018). We fine-tuned the model on the SQuAD 2.0 dataset, with the following hyperparameters: learning rate: 3e-5, warm-up steps: 10% (refer to the BERT paper (Devlin et al., 2018) for further details), sequence length: 425 tokens, batch size: 24 for BERT Large and 10 for BERT base. In order to fine-tune BERT Large, we employed one Tensor Processing Unit (TPU) for about 2 hours. The tokenization has been done following the recommendations in the original paper (Devlin et al., 2018) and the input to the network as the following structure: "*[CLS] question [SEP] supporting document [SEP]*".

These four different discriminators were trained with the objective of discerning between relevant and irrelevant supporting documents for a given question. Their binary accuracies are reported in Table 1. All models were trained on the modified SQuAD 2.0 train split and the performance is reported on the validation dataset. The effectiveness of the BERT Large model is much better than the others, as expected. Therefore, this fine-tuned model is chosen as the final document relevance discriminator (DRD).

3.4 Answer verifier discriminator

The purpose of the second discriminator is to probe whether the answer can be inferred to be correct given the supporting document. Of course, we want to rank documents taking into account if they can be used to find the correct answer. Please notice the core difference between the DRD and the answer verifier discriminator (ARD). The latter is also considering the answer at hand, whereas the former only examines the question and the given supporting document.

Training the discriminator is performed on the RACE (Reading Comprehension Dataset) which is also collected from English Examinations (Lai et al., 2017). The structure of the dataset is perfect for our situation. It contains multiple-choice questions with relevant supporting paragraphs for the correct answer. It is guaranteed that the answer can be deduced by understanding the information in the associated paragraph. We transform this dataset into tuples *(question, candidate answer, paragraph)* that are labeled either as negative, meaning that the answer cannot be verified using the paragraph (for incorrect answers), or as positive – reinforcing the fact that the paragraph can be used to infer that the answer is correct. The RACE dataset is extremely suitable in this situation as it always provides a paragraph that is relevant to the question. This is not the case for the ARC dataset, in which no supporting document is given – thus, one has to be extracted and it is not guaranteed to be always the "right" document.

We have fine-tuned the BERT Large model on the joined RACE middle-school and RACE high-school datasets, totaling near 100k questions with 28k documents. Each question generates 4 entries for the ARD: the 3 wrong answers generate 3 negative examples and the correct answer generates one positive example.

The hyperparameters used for fine-tuning BERT are similar to the DRD discriminator, with differences in the maximum sequence length (512 tokens for RACE vs. 425 tokens for SQuAD 2.0). These hyperparameters were found by trying multiple sensible assignments and selecting the best one according to the validation error. Results are reported in the next section on the test split.

Each tuple *(question, answer, and document)* is fed into the BERT model as: *"[CLS] question [SEP] answer [SEP] document [SEP]"*. The final accuracy of the model on the merged RACE middle and high test datasets is 68.28%.

As a remark, we want to highlight that both the DRD and ARD discriminators have been trained on different datasets than the final multiple choice QA model, which is trained and evaluated on the ARC Easy and Challenge datasets. Hence, our intuition was that transfer learning will succeed

even though there are some core differences in the nature of the datasets.

3.5 TF-IDF discriminator

We decided to also consider the TF-IDF score computed by Lucene as the third discriminator. This is a lexical (non-semantic) discriminator but it might helpful for simpler questions, especially the ones in the ARC Easy dataset.

3.6 Ranking architecture

We have described three discriminators whose purpose is to discern between relevant and useless documents extracted by the IR engine. As mentioned, our proposed approach is to retrieve the first N documents and then rank them taking into account a semantic criterion (as dictated by the pre-trained discriminators). In this section, we are going to describe a neural network that is latently learning to rank the extracted documents whilst selecting the correct answer to the question.

In the ARC dataset, more than 95% of the questions have exactly 4 candidate answers and only one is correct. For a given question and a candidate answer, we pass the extracted N documents though the set of discriminators obtaining a list of scores, one for each discriminator. These scores need to be combined into a final answer score by a mechanism, called Attentive Ranker, inspired from self-attention which we will describe in the next paragraphs.

As shown in Figure 2, each supporting document is associated with a list of scores computed by the discriminators. These scores are projected into a higher dimensional space using a learned projection matrix (we will denote by D the dimension of the projection space – in our experiments, $D = 32$). We then apply an attention mechanism over the semantically labeled documents to select the most relevant ones for a given candidate answer. Let A be a D x N matrix where each column is the encoding of a document after applying the set of discriminators and the projection step. As we are fetching N documents using the IR engine, matrix A has N columns. Notice that this matrix encodes all the information for a given candidate answer. Next, inspired by the self-attention mechanism (Vaswani et al., 2017), we developed a way to relate documents between each other in order to compute a global representation for them. First of all, we project each row of the matrix A into a key space (with M

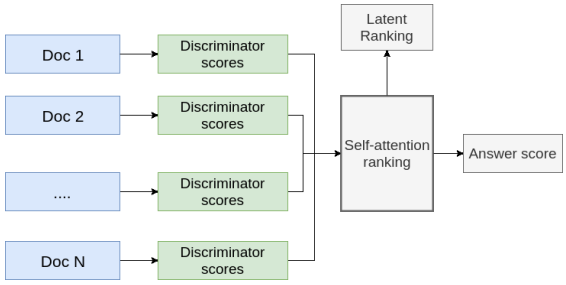

Figure 2: Applying discriminators for a candidate answer and ranking the documents

dimensions) whose purpose is to encode aspects about the quality (relevance) of the associated document (a column in matrix A):

$$K = \tanh(W_k A \oplus b_k) \quad (1)$$

where $A \in \mathbb{R}^{DxN}, W_k \in \mathbb{R}^{MxD}, b_k \in \mathbb{R}^M$ and by the $\oplus$ operator, we denote the addition of a vector to each column of a matrix (here and throughout the rest of the paper). Second, each column of matrix A is encoded into a value space (with Q dimensions), which is going to dictate the output of the attention mechanism:

$$V = \text{relu}(W_V A \oplus b_V) \quad (2)$$

where $W_V \in \mathbb{R}^{QxD}, b_V \in \mathbb{R}^Q$. The intuition is that the value space is dictating what the output of the attention should be, whereas the key space encodes necessary information about which elements (documents in our case) the network should pay attention to. Third, we normalize the key vectors using the softmax function:

$$P = softmax(W_P K \oplus b_P) \quad (3)$$

where $W_P \in \mathbb{R}^{1xM}, b_P \in \mathbb{R}$ and the bias is added to each element of $P \in \mathbb{R}^{1xN}$. As a result, the weights in P dictate to what extent the network should attend each document. The output of the layer is the weighted sum of the value vectors:

$$Y = VP^T \quad (4)$$

The same procedure is applied to all candidate answers and the attention weights are shared because we want to have the same representation regardless of the position of the answer in the candidate list (e.g. answer A, B, C, or D). Figure 2 shows the entire encoding procedure and how the attention network is applied.

Observe the fact that for each candidate answer a score (a vector with the dimension of the value space) is obtained by applying a general function. This score is further used to infer which of the four possible answers is, indeed, correct. This decision

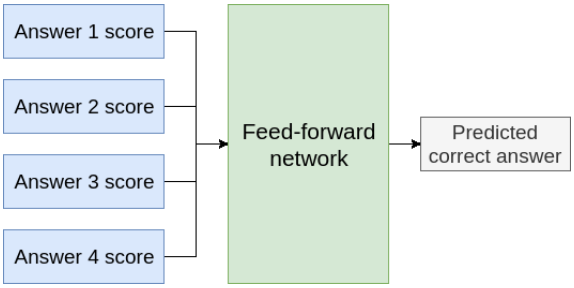

Figure 3: Applying discriminators for a candidate answer and ranking the documents

step is accomplished by a simple feed-forward network (Figure 3).

As a result, one can view this architecture as a feedback loop system. The neural network learns to predict the correct answer. In order to predict the correct answer, it is constrained to select more relevant documents. More relevant documents result in better classification, and so on. Thus, the proposed QA self-attention model, called Attentive Ranker, is jointly *Answering questions by learning to rank* and *Learning to rank by answering questions*.

In the following section, we highlight how the Attentive Ranker can improve QA systems by combining semantic information from a small number of supporting documents extracted with an IR engine.

4 Results

We report our model performance on two of the most important multiple-choice science questions datasets: ARC Easy and ARC Challenge (Table 2). During training, due to the small size of the datasets, we experienced a large variance in performance. To partially overcome this issue, we have trained the models a number of times with different random initialization and kept the weights producing the lowest validation loss as the final weights for the QA model.

We have used two knowledge bases in order to retrieve external supporting information: the ARC Corpus (Clark et al., 2018) which contains 14M science-related sentences and a book collection (Pîrtoacă et al., 2018) consisting of about 35 books crawled from online resources such as CK12[3]. Hereinafter, when we mention top N retrieved documents, it means that top $N / 2$ are fetched from ARC Corpus and $N / 2$ are extracted from the book collection, giving the two knowledge bases equal importance.

Dataset	Train	Dev	Test
ARC Easy	2,251	570	2,376
ARC Challenge	1,119	299	1,172

Table 2: Number of questions in the ARC dataset

Model	Accuracy
Random guess	25.00%
IR Solver	62.55%
Reading Strategies (previous SOTA)	68.90%
Attentive Ranker (ours)	***72.30%***

Table 3: Results on ARC Easy test

Model	Accuracy
Random guess	25.00%
BERT (our implementation)	40.00%
Reading Strategies	42.32%
BERT (previous SOTA - Microsoft)	44.62%
Attentive Ranker (ours)	***44.72%***

Table 4: Results on ARC Challenge test

Dataset	TFD	+DRD	+AVD
ARC Easy	63.89%	67.48%	72.30%
ARC Challenge	26.70%	34.16%	44.72%

Table 5: The impact of adding more discriminators on the test set accuracy

The ranking neural network is trained for about 50 epochs, batch size 128, with categorical cross entropy loss, optimized using Adam (Kingma and Ba, 2014).

First, it is important to observe the impact of the number of documents, N, on the model's performance (refer to Figure 4 and Figure 5). Considering more than one document improves the accuracy, thus verifying our initial assumption that relevant supporting documents can be found in the first N, but it is not always the case that the first one is the most relevant. As it can be observed in Figures 4 and 5, there is a large improvement in accuracy when increasing from 1 to 5 documents. The accuracy continues to increase for both ARC Easy and ARC Challenge until it reaches a maximum at about 40 documents. Thus, for the next experiments, we set the number of documents to 40 (20 from the ARC corpus and 20 from the science book collection).

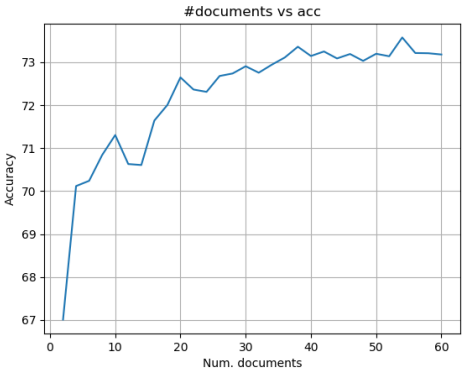

Figure 4: Performance vs. number of documents measured on the ARC Easy validation set

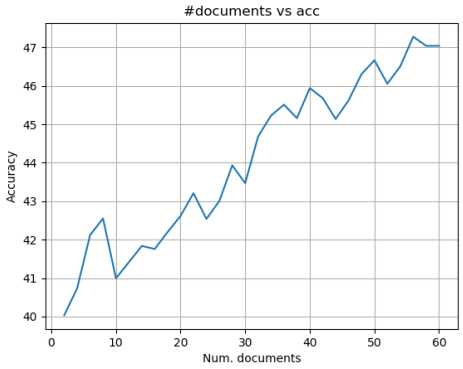

Figure 5: Performance vs. number of documents measured on the ARC Challenge validation set

Second, we verified the model performance on the ARC test sets in order to check how the model generalizes on unseen data and to compare it with other top models in the ARC public leaderboard (https://leaderboard.allenai.org/arc/submissions/public). A summary of the results is reported in Table 3 and Table 4. In both cases, our Attentive Ranker model outperforms the current state-of-the-art (SOTA) approach proving that, indeed, performing a semantic ranking is very effective for QA systems. For a fair comparison, we also reported BERT results as obtained in our implementation and training. The previous SOTA was held by a Microsoft implementation of BERT.

As an ablation study, we wanted to identify the contribution of the discriminators to the overall performance of the Attentive Ranker. We performed an experiment, where starting from the TF-IDF lexical discriminator, other discriminators are incrementally added to the scheme: document relevance discriminator (DRD) and answer verifier discriminator (AVD). The results are revealed in Table 5 where we measured the total number of

Dataset	# docs	Ranking	Accuracy (Δ)
Val.	Top 1	TF-IDF	35.59%
Val.	Top 1	Ours	***38.30% (+2.71)***

Table 7: Downstream model performance on the ARC Challenge dataset comparing ranking with Attentive Ranker vs. doc2vec

questions correctly answered in the ARC Easy and ARC Challenge test sets. The influence of both semantic-level discriminators (DRD, AVD) is fundamental: they increase the performance with up to 20%, both contributing to the end-to-end accuracy. Notice that the discriminators have a greater impact on the challenge questions as those are radically more difficult and require high-level reasoning to determine the correct answer (that is why the TF-IDF discriminator, which works at a lexical level, has a performance close to random).

One other examination that we enforced is to analyze whether the ranked documents that we computed (semantically sorted by our Attentive Ranker) are more relevant than the documents sorted by the TF-IDF metric. We fine-tuned a downstream BERT (Devlin et al., 2018) model that selects the most probable answer from the candidate list given a list of supporting documents. In the experiment split A, we fed this model with top N documents as ranked by the TF-IDF metric and in experiment split B we fed the model with top N documents as sorted by our ranking neural network (given the weights in the attention layer).

As we have previously shown, the ARC Challenge dataset is more eloquent for this type of semantical analysis due to the difficult questions it includes, thus, we use it for this investigation.

Table 6 shows that using documents ranked by our attentive neural network always leads to a performance increase in downstream models, compared to TF-IDF. On the validation set, the improvement is considerably higher (+7.79) due to a possible over-fitting of the hyperparameters during the Attentive Ranker's training.

We also investigated the ability of the Attentive Ranker to sort the retrieved documents as compared to document embeddings – which may be used to measure the similarity between a question and a candidate document. The question and the documents are embedded using doc2vec (Le and Mikolov, 2014) pre-trained on English Wikipedia. Then, the documents are sorted by their cosine distance to the question. Therefore, the documents that are cosine-closest to a question should be more relevant in answering that question as they are more similar to the question in the doc2vec embeddings space. We would like to note that this approach, although reasonable, may suffer from a subtle problem: the question and the documents have different structures and it may be difficult for an embedding function to capture similarities defined as relevance: "the document is helpful in answering the question". Table 7 illustrates the performance of a downstream model (BERT) in answering the questions when fed with top N (1 or 10) documents as ranked by Attentive Ranker or doc2vec. In all cases, the Attentive Ranker provided more relevant documents than doc2vec, to the BERT-based decision layer. On another hand, doc2vec yields better accuracies than the simple TF-IDF metric.

Our hypothesis that the Attentive Ranker is suitable to rank the retrieved documents by their semantic value to the question is confirmed. Therefore, we decided to make the ranked set of documents public[4], in order to be used by other models. Please refer to the GitHub repository for instructions on how to use the ranked documents. In the same repository, one can find the source code and the full set of trained models.

5 Conclusion

In this paper, we highlighted an important problem with many of the current approaches developed for multiple-choice question answering tasks. To overcome the poor performance of the IR engines used to retrieve supporting documents for *(question, candidate answer)* pairs, we described a method that semantically ranks the extracted supporting documents. For this, we proposed an attention-based neural network that latently learns to rank supporting documents by their relevance in answering the given question. The Attentive Ranker architecture depends on the existence of semantic discriminators which are pre-trained to distinguish between relevant and pointless documents. Our proposed model achieves state-of-the-art accuracy on two significant datasets: ARC Easy (72.30%) and ARC Challenge (44.72%).

Furthermore, we have shown that just replacing TF-IDF sorted documents with documents provided by our enhanced ranking method, highly improves the accuracy of various downstream decision models, by up to 7% in our experiments. Therefore, we have made the ranked documents public and further research can benefit from it.

Heidelberg, Germany
{mihaylov,frank}@cl.uni-heidelberg.de

Abstract

In this work, we propose to use linguistic annotations as a basis for a *Discourse-Aware Semantic Self-Attention* encoder that we employ for reading comprehension on narrative texts. We extract relations between discourse units, events and their arguments as well as coreferring mentions, using available annotation tools. Our empirical evaluation shows that the investigated structures improve the overall performance (up to +3.4 *Rouge-L*), especially intra-sentential and cross-sentential discourse relations, sentence-internal semantic role relations, and long-distance coreference relations. We show that dedicating self-attention heads to intra-sentential relations and relations connecting neighboring sentences is beneficial for finding answers to questions in longer contexts. Our findings encourage the use of discourse-semantic annotations to enhance the generalization capacity of self-attention models for reading comprehension.

1 Introduction

Transformer-based self-attention models (Vaswani et al., 2017) have been shown to work well on many natural language tasks that require large-scale training data, such as Machine Translation (Vaswani et al., 2017; Dai et al., 2019), Language Modeling (Radford et al., 2018a; Devlin et al., 2019; Dai et al., 2019; Radford et al., 2019) or Reading Comprehension (Yu et al., 2018), and can even be trained to perform surprisingly well in several multi-modal tasks (Kaiser et al., 2017b).

Recent work (Strubell et al., 2018) has shown that for downstream semantic tasks with much smaller datasets, such as Semantic Role Labeling (SRL) (Palmer et al., 2005), self-attention models greatly benefit from the use of linguistic information such as dependency parsing annotations. Motivated by this work, we examine to what extent we can use discourse and semantic information to extend self-attention-based neural models for a higher-level task such as Reading Comprehension.

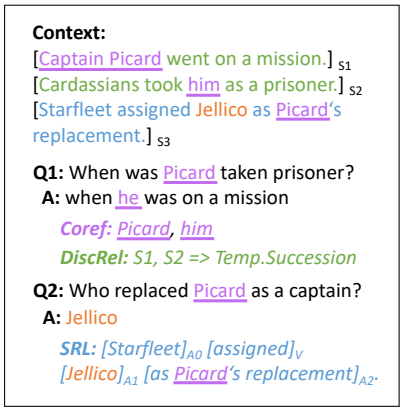

Figure 1: Motivational example: context and questions with required discourse and semantic annotations.

Reading Comprehension is a task that requires a model to answer natural language questions, given a text as context: a paragraph or even full documents. Many datasets have been proposed for the task, starting with a small multi-choice dataset (Richardson et al., 2013), large-scale automatically created cloze-style datasets (Hermann et al., 2015; Hill et al., 2016) and big manually annotated datasets such as Onishi et al. (2016); Rajpurkar et al. (2016); Joshi et al. (2017); Kocisky et al. (2018). Previous research has shown that some datasets are not challenging enough, as simple heuristics work well with them (Chen et al., 2016; Weissenborn et al., 2017b; Chen et al., 2017). In this work we focus on the recent NarrativeQA (Kocisky et al., 2018) dataset that was designed not to be easy to answer and that requires a model to read narrative stories and answer questions about them.

In terms of model architecture, previous work in reading comprehension and question answer-

Figure 2: Example on different discourse-semantic annotations: DiscRel (Dicourse Relations) (NE - Non-Explicit), SRL (Semantic Role Labeling), Coref (Co-reference resolution). The distinct horizontal lines show the interaction between the tokens: Coref - full context, SRL - single sentence, Non-Explicit DR - two neighbouring sentences.

ing has focused on integrating external knowledge (linguistic and/or knowledge-based) into recurrent neural network models using Graph Neural Networks (Song et al., 2018), Graph Convolutional Networks (Sun et al., 2018; De Cao et al., 2019), attention (Das et al., 2017; Mihaylov and Frank, 2018; Bauer et al., 2018) or pointers to coreferent mentions (Dhingra et al., 2017).

In contrast, in this work we examine the impact of *discourse-semantic annotations* (Figure 1) in a *self-attention architecture*. We build on the QANet (Yu et al., 2018) model by modifying the encoder of its self-attention modeling layer. In particular, we *specialize self-attention heads to focus on specific discourse-semantic annotations*, such as, e.g., an ARG1 relation in SRL, a CAUSATION relation holding between clauses in shallow discourse parsing, or coreference relations holding between entity mentions.

Our contributions are the following:

- To our knowledge we are the first to explicitly introduce discourse information into a neural model for reading comprehension.
- We design a *Discourse-Aware Semantic Self-Attention* mechanism, an extension to the standard self-attention models – without significant increase of computation complexity.
- We analyze the impact of different discourse and semantic annotations for narrative reading comprehension and report improvements of up to 3.4 *Rouge-L* over the base model.
- We perform empirical fine-grained evaluation of the discourse-semantic annotations on specific question types and context size.

Code and data will be available at https://github.com/Heidelberg-NLP/discourse-aware-semantic-self-attention.

2 Discourse-aware Semantic Annotations

Understanding narrative stories requires the ability to identify events and their participants and to identify how these events are related in discourse (e.g., by *causation, contrast*, or *temporal sequence*) (Mani, 2012). Our aim is to extract structured knowledge about these phenomena from long texts and to integrate this information in a neural self-attention model, in order to examine to what extent such knowledge can enhance the efficiency of a strong reading comprehension model applied to NarrativeQA.

Specifically, we enhance self-attention with knowledge about entity coreference (Coref), their participation in events (SRL) and the relation between events in narrative discourse (Shallow Discourse Parsing (Xue et al., 2016), DR).

All these linguistic information types are *relational* in nature. For integrating relational knowledge into the self-attention mechanism, we follow a two-step approach: i) we extract such relations from a multi-sentence paragraph and *project them down to the token level*, specifically to the tokens of the text fragments that they involve; ii) we design a neural self-attention model that *uses the interaction information between these tokens in a multi-head self-attention module*.

To be able to map the extracted linguistic knowledge to paragraph tokens, we need annotations that are easy to map to token level (see Figure 2). This can be achieved with tools for annotation of span-based Semantic Role Labeling, Coreference Resolution, and Shallow Discourse Parsing.

Events and Their Participants Relations between characters in a story are expressed in text through their participation in states or actions in which they fill a particular event argument with a specific semantic role (see Figure 2). For annotation of events and their participants we use the state-of-the-art SRL system of He et al. (2017) as

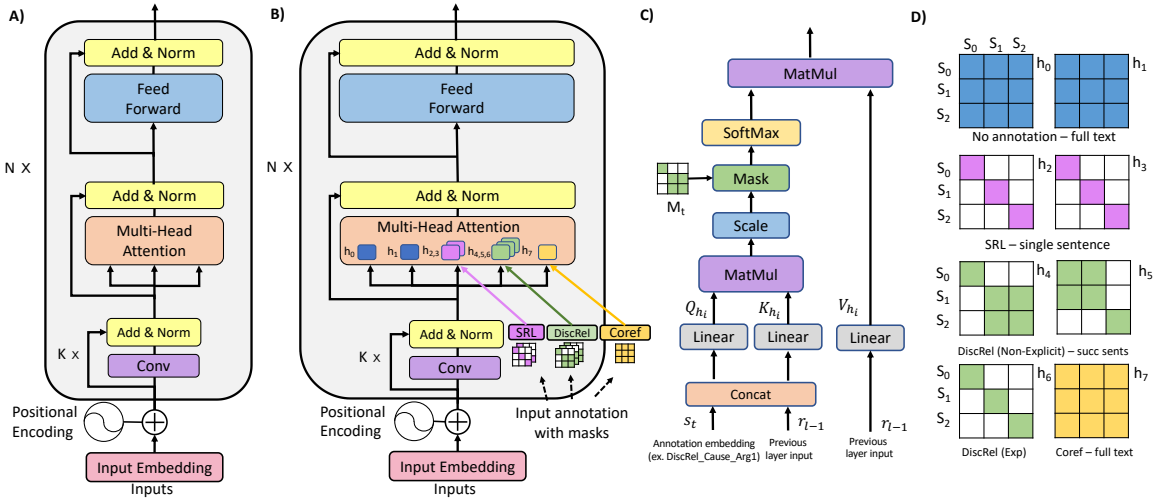

Figure 3: A) Base Multi-Head Self-Attention Encoder Block, B) Discourse-Aware Semantic Self-Attention (DASSA) Encoder Block , C) Single Attention Head with disource/semantic Information, D) Example of attention scope masks for different attention heads and different information.

implemented in AllenNLP (Gardner et al., 2018). The system splits paragraphs into sentences and tokens, performs POS (part of speech tagging) and for each verb token V it predicts semantic tags such as ARG0, ARG1 (Argument Role 0, 1 of verb V), etc. When several argument-taking predicates are realized in a sentence, we obtain more than single semantic argument structure, and each token in the sentence can be involved in the argument structure of more than one verb. We refer to these annotations as different semantic views (Khashabi et al., 2018a), e.g., 'semantic view for verb 1'. Different self-attention heads will be able to attend to individual semantic views.

Coreference Resolution Narrative texts abound of entity mentions that refer to the same entity in the discourse. We hypothesize that by directing the self-attention to this specific coreference information, we can encourage the model to focus on tokens that refer to the same entity mention. Although token-based self-attention models are able to attend over wide-ranged context spans, we hypothesize that it will be beneficial to allow the model to focus directly on the parts of the text that refer to the same entity. For coreference annotation we use the *medium* size model from the neuralcoref spaCy extension available at https://github.com/huggingface/neuralcoref. For each token we give as information the label of the corresponding coreference cluster (see Figure 2) that it belongs to. Therefore, tokens from the same coreference cluster get the same label as input.

Discourse Relations In narrative texts, events are connected by discourse relations such as *causation, temporal succession*, etc. (Mani, 2012). In this work we adopt the 15 fine-grained discourse relation sense types from the annotation scheme of the Penn Discourse Tree Bank (PDTB) (Prasad et al., 2008). For producing discourse relation annotations we use the discourse relation sense disambiguation system from Mihaylov and Frank (2016) which is trained on the data provided by the CoNLL Shared Task on Shallow Discourse Parsing (Xue et al., 2016). In this annotation scheme discourse relations are divided into two main types: *Explicit* and *Non-Explicit*. *Explicit* relations are usually connected with an explicit *discourse connective*, such as *because, but, if*. *Non-Explicit*[1] relations are not explicitly marked with a discourse connective and the arguments are usually contained in two consecutive sentences (see Figure 2). To extract explicit discourse relations we take into account only arguments that are in the same sentence. We consider as separate arguments (ARG1 and ARG2) text sequences that are on the left and right of an explicit discourse connective (CONN): ex. '[Jeff went home]$_{ARG1_CCR}$ [because]$_{CONN}$ [he was hungry.]$_{ARG2_CCR}$, where CCR is Contingency.Cause.Reason'. To provide *Non-Explicit* discourse relation sense annotations, we annotate every consecutive pair of sentences with a predicted discourse relation sense type.

[1] *Non-Explicit* relations include *Implicit*, *AltLex* and *EntRel* relation from PDTB. See Xue et al. (2016) for details.

3 A Discourse-Aware Semantic Self-Attention Neural Model

3.1 QANet

As a base reading comprehension model we use QANet (Yu et al., 2018). QANet is a standard token-based self-attention model with the following components, which are common across many recent models: *1. Input Embedding Layer* uses pre-trained word embeddings and convolutional character embeddings; *2. Encoder Layer* consists of stacked *Encoder Blocks* (see Figure 3, A) based on *Multi-Head Self-Attention* (Vaswani et al., 2017) and *depth-wise separable convolution* (Chollet, 2016; Kaiser et al., 2017a); *3. Context-to-Query Attention Layer* is a standard layer, that builds a token-wise attention-weighted question-aware context representation; *4. Modeling Layer* has the same structure as 2. above but uses as input the output of layer 3.; *5. Output layer* is used for prediction of *start* and *end* answer pointers. For detailed information about these layers, please refer to Yu et al. (2018). In this work we replace the standard *Multi-Head Self-Attention* with *Discourse-Aware Semantic Self-Attention*, using several different semantic and discourse annotation types. We describe this below and explain the differences to the standard *Encoder Block*.

3.2 Discourse-Aware Semantic Self-Attention

In Figure 3 we show the difference between the Base Multi-Head Self-Attention Encoder Block A) and the Discourse-Aware Semantic Self-Attention Encoder Block B). Both consist of $\text{positional-encoding} + \text{convolutional-layer} \times K + \text{multi-head-self-attention} + \text{feed-forward layer}$. The difference is that B is provided additional inputs that are used by multi-head self-attention. The multi-head self-attention is a concatenation of outputs from multiple single self-attention heads h_i followed by a linear layer. A single head of the extended multi-head self-attention is shown in Figure 3C and is formally defined as

$$a_{h_i} = \text{mask_softmax}\left(\frac{Q_{h_i}K_{h_i}^T}{\sqrt{d_h}}, M_t\right)V_{h_i} \quad (1)$$

$$Q_{h_i} = W_{h_i}^Q[r_{l-1}; s_t] \in \mathbb{R}^{n\times d_h} \quad (2)$$

$$K_{h_i} = W_{h_i}^K[r_{l-1}; s_t] \in \mathbb{R}^{n\times d_h} \quad (3)$$

$$V_{h_i} = W_{h_i}^V r_{l-1} \in \mathbb{R}^{n\times d_h} \quad (4)$$

, where Q_{h_i}, K_{h_i}, V_{h_i} are components of the query-key-value attention and $\sqrt{d_h}$ is used for weight scaling as originally proposed in Vaswani et al. (2017). $W_{h_i}^Q$, $W_{h_i}^K$, $W_{h_i}^V$ are weights, specific for head $h_i, i \in 1..H$ [2], r_{l-1} is the input from the previous encoder block, s_t is an embedding vector for the linguistic annotation type t ('SRL_Arg1', 'DiscRel_Cause.Reason_Arg2', etc.), a_{h_i} is the output of head h_i. M_t is a sentence-wise attention mask as shown in Figure 3D. s_t and M_t are the main difference compared to the standard self-attention (Figure 3C).

In principle, representing edges of a graph (e.g., the V-ARG1 role from SRL) requires memory of $n^2 d_h H$, where n is the length of the context, which would be a bottleneck for computation on a GPU with limited memory (8-16GB). Instead, we adopt a strategy where the *relation* is represented as a *source and target node* and an *attention scope* (one sentence for SRL; two sentences for DR (Non-Exp); full context for Coref). The latter is controlled using the attention mask. The combination of flat token labels and mask reduces the maximum memory required for representing the information in the knowledge-enhanced head to $2nd_hH$. The attention masks, which we use for reducing the attention scope of the different semantic and discourse annotations, are shown in Figure 3D. These masks ensure that the corresponding attention heads will only attend to tokens from the corresponding scope (SRL: single sentence; DR (NonE): two sentences, etc.). The attention masks are symmetric to the matrix diagonal. Therefore, they can easily be computed 'on-the-fly' given only the sentence boundaries (corresponding to the horizontal lines in Figure 2).

To reduce the model memory further and still benefit from the full-context self-attention, we use the *Discourse-Aware Semantic Self-Attention* encoder (Figure 3B) only for blocks [1,3,5] of the *Modeling Layer* that consists of 7 stacked encoder blocks (indexed 0 to 6). Blocks [0,2,6] are set as the base encoders that look at the entire context (Figure 3A).

4 Data and Task Description

NarrativeQA We perform experiments with the NarrativeQA (Kocisky et al., 2018) reading comprehension dataset. This dataset requires understanding of narrative stories (English) in order to provide answers for a given question. It offers two

[2] Number of heads H=8 as in original QANet specification if not specified otherwise.

sub-tasks: (i) answering questions about a long narrative summary (up to 1150 tokens) of a book or movie, or (ii) answering questions about entire books or movie scripts of lengths up to 110k tokens. We are focusing on the summary setting (i) and refer to the summary as *document* or *context*. The dataset contains 1572 documents in total, devided into *Train* (1102 docs, 32.7k questions), *Dev* (115 documents, 3.5k questions) and *Test* (355 documents, 10.5k questions) sets.

Generative QA as Span Prediction An interesting aspect of the NarrativeQA dataset is that in contrast to most other RC datasets, the two answers provided for each question are written by human annotators. Therefore, answers typically differ in form from the context passages that license them. To map the human-generated answers to answer candidate spans from the context, we use *Rouge-L* (Lin, 2004) to calculate a similarity score between token n-grams from the provided answer and token n-grams from candidate answers selected from the context (we select candidate spans of the same length as the given answer). If two answer candidates have the same *Rouge-L* score, we calculate the score between the candidates' surrounding tokens (window size: 15 tokens to the left and right) and the question tokens, and choose the candidate with the higher score. We retrieve the best candidate answer span for each answer and use the candidate with the higher *Rouge-L* score as supervision for training. We refer to this method for answer retrieval as *Oracle (Ours)*.

5 Related Work

Reading Comprehension with Knowledge Recent work has proposed different approaches for integrating external knowledge into neural models for the high-level downstream tasks reading comprehension (RC) and question answering (QA). One line of work leverages external knowledge from knowledge bases for RC (Xu et al., 2016; Weissenborn et al., 2017a; Ostermann et al., 2018; Mihaylov and Frank, 2018; Bauer et al., 2018; Wang et al., 2018b) and QA (Das et al., 2017; Sun et al., 2018; Tandon et al., 2018). These approaches make use of implicit (Weissenborn et al., 2017a) or explicit (Mihaylov and Frank, 2018; Sun et al., 2018; Bauer et al., 2018) attention-based knowledge aggregation or leverage features from knowledge base relations (Wang et al., 2018b). Another line of work builds on linguistic knowledge from downstream tasks, such as coreference resolution (Dhingra et al., 2017) or notions of co-occurring candidate mentions (De Cao et al., 2019) and OpenIE triples (Khot et al., 2017) into RNN-based encoders. Recently, several pre-trained language models (Peters et al., 2018; Radford et al., 2018b; Devlin et al., 2019) have been shown to incrementally boost the performance of well-performing models for several short paragraph reading comprehension tasks (Peters et al., 2018; Devlin et al., 2019) and question answering (Sun et al., 2019), as well as many tasks from the GLUE benchmark (Wang et al., 2018a). Approaches based on BERT (Devlin et al., 2019) usually perform best when the weights are fine-tuned for the specific training task. Earlier, many papers that do not use self-attention models or even neural methods have also tried to use semantic parse labels (Yih et al., 2016), or annotations from upstream tasks (Khashabi et al., 2018b).

Self-Attention Models in NLP Vanilla self-attention models (Vaswani et al., 2017) use positional encoding, sometimes combined with local convolutions (Yu et al., 2018) to model the token order in text. Although they are scalable due to their recurrence-free nature, most self-attention models do not well work when trained with fixed-length context, due to the fact that they often learn global token positions observed during training, rather than relative. To address this issue, Shaw et al. (2018) proposes relative position encoding to model the distance between tokens in the context. Dai et al. (2019) address the problem of moving beyond fixed-length context by adding recurrence to the self-attention model. Dai et al. (2019) argue that the fixed-length segments used for language modeling hurt the performance due to the fact that they do not respect sentence or any other semantic boundaries. In this work we also support the claim that the lack of semantic, and also discourse *boundaries* is an issue, and therefore we aim to introduce structured linguistic information into the self-attention model. We hypothesize that the lack of local discourse context is a problem for answering narrative questions, where the answer is contained inside the same sentence, or neighbouring sentences and therefore, by offering discourse-level semantic structure to the attention heads, offer ways to restrict, or focus the model to wider or narrower structures, depending on what is needed

for specific questions.

Self-attention architectures can be seen as graph architectures (imagine the token (node) interactions as adjacency matrix) and are applied to graph problems (Veličković et al., 2018; Li et al., 2019). Therefore, in very recent work Koncel-Kedziorski et al. (2019) have used a self-attention encoder as a graph encoder for text generation, in a dual encoder model. A dual-encoder model similar to Koncel-Kedziorski et al. (2019) is suitable for a setting where the input is knowledge from a graph knowledge-base. For a text-based setting like ours, where word order is important and the tokens are part of semantic arguments, an approach that tries to encode linguistic information in the same architecture (Strubell et al., 2018) is more appropriate. Therefore our method is most related to LISA (Strubell et al., 2018), which uses joint multi-task learning of POS and Dependency Parsing to inject syntactic information for Semantic Role Labeling. In contrast, we do not use multi-task learning, but directly encode semantic information extracted by pre-processing with existing tools.

NarrativeQA The summary setting of the NarrativeQA dataset (Kocisky et al., 2018) has in the past been addressed with attention mechanisms by the following models: *BiAtt + MRU* (Tay et al., 2018a) is similar to *BiDAF* (Seo et al., 2017). It is bi-attentive (attends form context-to-query and vice versa) but enhanced with a MRU (Multi-Range Reasoning Units). MRU is a compositional encoder that splits the context tokens into ranges (n-grams) of different sizes and combines them in summed n-gram representations and fully-connected layers. *DecaProp* (Tay et al., 2018b) is a neural architecture for reading comprehension, that densely connects all pairwise layers, modeling relationships between passage and query across all hierarchical levels. Bauer et al. (2018) observed that some of the questions require external commonsense knowledge and developed *MHPGM-NOIC* - a *seq2seq* generative model with a copy mechanism that also uses commonsense knowledge and ELMo (Peters et al., 2018) contextual representations. Hu et al. (2018b) used an implementation of Reinforced Mnemonic Reader (*RMR*) (Hu et al., 2018a). They also proposed *RMR + A2D*, a novel teacher-student attention distillation method to train a model to mirror the behavior of the ensemble model *RMR (Ens)*.

6 Experiments and Results

In this section we describe the experiments and results of our proposed model in different configurations. We compare the results of different models using overall results (Table 1) on the dataset, but also the performance for different question types (Figure 4) and context sizes (Figure 5).

6.1 Overall Results

Table 1 compares our baselines and proposed model to prior work. We report results for *Bleu-1*, and *Rouge-L* scores. The first section lists results on the NarrativeQA dataset as reported in **Kocisky et al. (2018)**. *Oracle (original)* uses the gold answers as queries to match a token sequence (with the answer length) in the context that

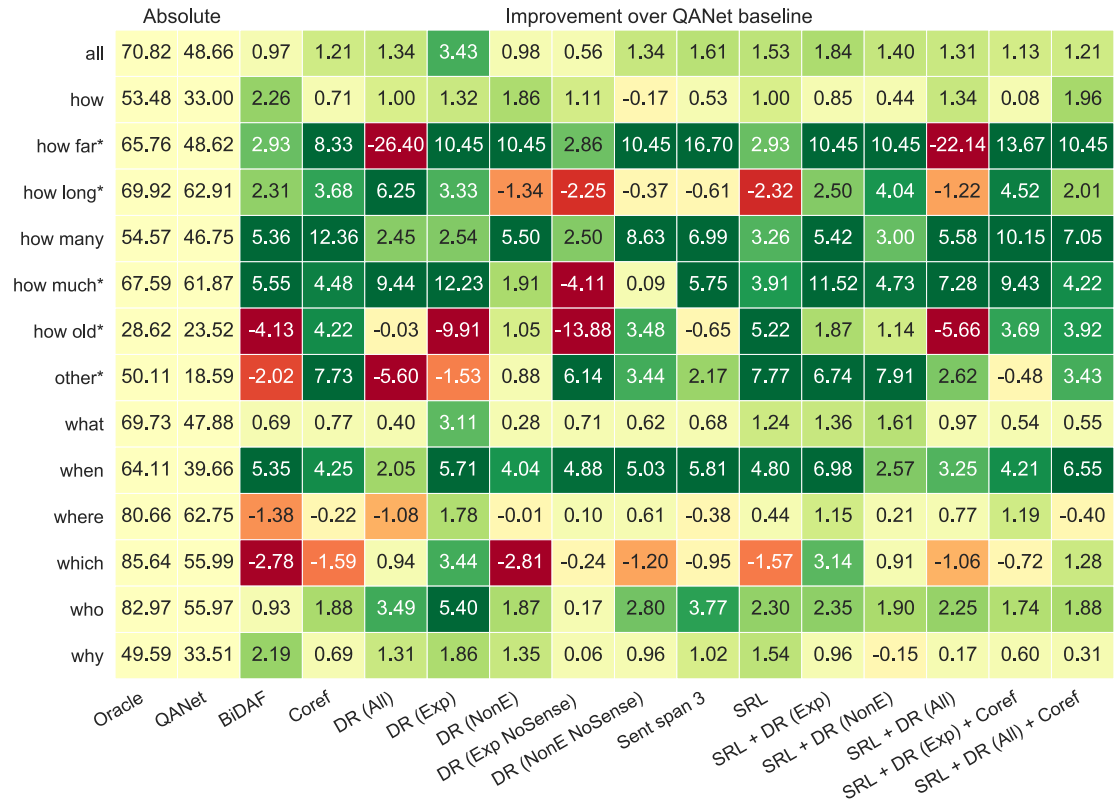

Figure 4: Rouge-L performance per Question Type on the NarrativeQA *Test* set. The first two columns represent *Absolute* values. The rest are improvements over the QANet baseline model (i) by BiDAF and (ii) configurations of QANet with linguistic information. Question types with * have less than 100 instances in the *Test* set.

has the highest *Rouge-L*. In contrast, using *Oracle (Ours)*, described in Section 4, we report a +11 *Rouge-L* score improvement (Table 1: **This work**). The Oracle performance in this setting is important since the produced annotations are used for training of the span-prediction systems, and is considered upper-bound.[3] *Seq2Seq (no context)* is an encoder-decoder RNN model trained only on the question. *ASR* is a version of the Attention Sum Reader (Kadlec et al., 2016) implemented as a pointer-generator that reads the question and points to words in the context that are contained in the answer. *BiDAF* is Bi-Directional Attention Flow (Seo et al., 2017) trained either with the *Oracle (original)* or *Oracle (ours)*. The models from **Previous Work** are described in Section 5. In the last section of Table 1 we present the results of our experiments (**This work**). Here, *BiDAF* and *QANet* are implementations available in the AllenNLP framework (Gardner et al., 2018). In the last two rows we give the results of QANet extended with the proposed Discourse-Aware Semantic Self-Attention, using intra-sentential, *Explicit* discourse relations (*DR (Exp)*, EMA is Exponential Moving Average).

[3]The previous work that uses span-prediction models do not report their *Oracle* model used for training supervision.

6.2 Fine-grained Evaluation

We further analyze the performance of different configurations of our model by conducting fine-grained evaluation in view of question types (Figure 4) and context length (Figure 5).

We define a range of system configurations using attention heads enhanced with different combinations of linguistic annotation types, including *Explicit* (referred to as Exp or E) and *Non-Explicit* (NonE, NE), *Discourse Relations* (DiscRel, DR), *Semantic Role Labeling* (SRL), and *Coreference* (Coref), and configurations without any such additional information (*No*). We also experiment with a setting where instead of using specific discourse relation types (such as DiscRel_Exp_Cause_Arg1), we only identify that a token is part of **any** (NoSense) discourse relation (e.g., DiscRel_Exp_Arg1) or simply a multi-sentence attention span *Sent span 3* with labels *Sent1*, *Sent2*, *Sent3* for each sentence. This is

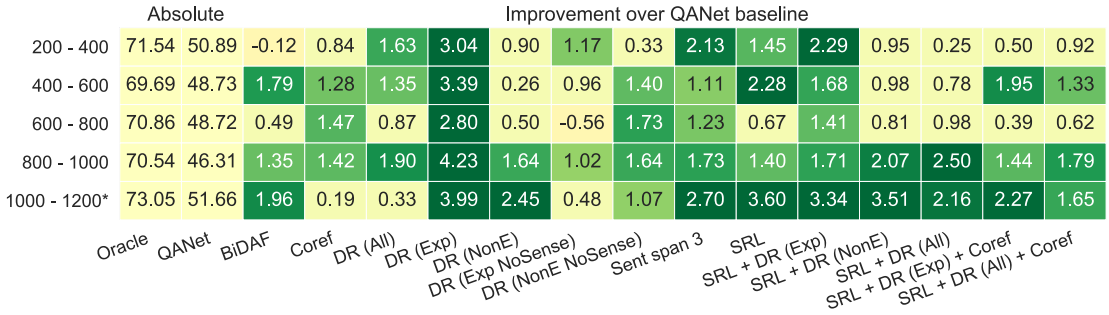

Figure 5: Rouge-L performance by context length on the NarrativeQA *Test* set. The first two columns represent *Absolute* values. The rest are improvements over the QANet baseline model (i) by BiDAF and (ii) different configurations of QANet with linguistic information. Rows with * have less than 100 instances in the *Test* set.

to examine whether the type of discourse relation is important or rather the attention scope (intra-sentential, cross-sentence - 2, 3 neighbouring sentences, full context).

Question Type Different question types might profit from different linguistic annotation types. We thus examine the performance of different question types, and analyze how it correlates with the presence of specific Semantic Self-Attention signals. We classify the questions into question types using a simple heuristic based on the question words as an indicator of their type (*How / Where / Why / Who / What ...)*, and calculate the average *Rouge-L* for each such questions type. The resulting scores are displayed in Figure 4. In the first two columns of the figure, we report the *Oracle* score and the baseline (QANet) score. In the remaining columns we report (i) the improvement over the QANet baseline of BiDAF, and (ii) of our models with different combinations of discourse-aware semantic self-attention. In the first row we report the score for each of the models on *all* questions. We observe that best performing models on *all* questions are the ones that include *Explicit* DR, and/or SRL. In terms of hardness, *how* and *why* questions usually have the lowest score. This not surprising since *Oracle* performance is also low. For these type of questions, the RNN-based encoder (BiDAF) and self-attention with DR (Exp) or DR (NonE) perform best. Almost all models with additional linguistic information improve over the baseline on *when* questions, lead by the SRL+DR (Exp) and SRL + DR (All) + Coref. *What* questions are improved most by DR (Exp) and SRL alone or when combined. *Who* questions gain most from discourse relations and all models that contain SRL.

Context Length In Figure 5 we present the performance on documents of different lengths, in number of tokens. All presented models are trained on the examples from the *Train* set with context up to 800 tokens. Again, the models DR (Exp) and SRL+DR (Exp) show clear improvement across all context lengths. It is clear that all models show improvement over length *800-1000*. This supports our hypothesis that discourse information is required for generalizing to longer contexts. One reason is that some of the questions can be answered with a local context (one-two sentences) which are better represented given short discourse scope (one-three sentences) or long dependencies given coreference.

In the evaluation of multiple model configurations we notice that in some cases a single discourse/semantic type (e.g. DR (Exp)) performs better than in combination with others (e.g. SRL+DR (Exp)). We hypothesize that the reason is that the linguistic annotations work well in combination with free *No* attention heads (see Table 2). Currently, we place multiple annotations on the same *Encoder Block* which reduces the number of free attention heads. For instance, for SRL+DR (Exp), each knowledge-enhanced encoder block has 3 SRL + 2 DR (Exp) + 3 No heads. In future work we plan to use different annotation heads per *Encoder Block (EB)*: e.g., *EB0* has 3 SRL + 5 No; *EB1* has 2 DR (Exp) + 6 No; etc.

Success and Failure Examples In Figures 6, 7, 8 we show examples of context[4] and questions, together with the answers from human annotators and some of the examined models.[5] We provide

[4]The part that contains the correct answer.

[5]For easier reading, we color the gold, correct, and wrong answers and underline the mentions of different characters.

Context	Although he terrifies the fairies when he first arrives , Peter quickly gains favour with them . He amuses them with his human ways and agrees to play the panpipes at the fairy dances . Eventually , Queen Mab grants him the wish of his heart , and he decides to return home to his mother .
Question	After scaring the fairies, how does Peter win them over ?
Human 1: he agrees to play the panpipes at all of the fairy dances.; **Human 2:** He amuses them with his human ways and plays the pipes at their dances.; **Oracle:** human ways and agrees to play the panpipes at the fairy dances ; **QANet:** gains favour ; **DR (Exp), DR (NE):** quickly gains favour with them; **Coref, SRL, SRL+DR(Exp):** He amuses them with his human ways and agrees to play the panpipes; **SRL+DR(NE):** He amuses them with his human ways and agrees to play the panpipes at the fairy dances	
Rationale: To find the correct answer we need to know that (i) 'gains favor' is a synonym to 'win' in this context (commonsense); (ii) the following (2nd) sentence is the reason for the previous (1st) (DR - the model fails in this case) (iii) 'them' are 'the fairies', 'he' is Peter (Coref)	

Figure 6: Example of positive impact of SRL and Coref and negative impact from discourse relations (DR).

Context	Jacob frequently visits Jeff and Kenny , who are serving time in a juvenile hall . Jacob initially threatens them , until eventually Jeff commits suicide . Jacob befriends Kenny , soon learning he has an early release and is illegally moving to New Mexico .
Question	Why does Jeff committ suicide ?
Human 1: Jacob threatened them; **Human 2:** He is threatened by Jacob.; **Oracle:** site which he says is ; **QANet:** Jeff and Kenny , who are serving time in a juvenile hall; **DR (Exp), DR (NE), SRL, SRL+DR(Exp), SRL+DR(NE):** Jacob initially threatens them ,; **Coref:** Jacob initially threatens them , until eventually Jeff commits suicide . Jacob befriends Kenny , soon learning he has an early release and is illegally moving to New Mexico	
Rationale: To find the correct answer we need to understand that 'until eventually' suggests that the suicide of Jeff is caused by Jacob threatening 'them' (DR) and that Jeff is part of 'them' (Coref).	

Figure 7: Example of positive impact of SRL and Coref, and discourse relations (DR).

Context	The four orphan children of the house , Edward , Humphrey , Alice and Edith , are believed to have died in the flames . However , they are saved by Jacob Armitage , a local verderer , who hides them in his isolated cottage and disguises them as his grandchildren . Under Armitage 's guidance , the children from an aristocratic lifestyle to that of simple foresters .
Question	Who rescues the children from fire at Arnwood ?
Human 1, Human 2: Jacob Armitage; **Oracle:** Jacob Armitage; **DR (Exp), DR (NE), Coref:** Jacob Armitage; **QANet, SRL, SRL+DR(Exp):** Pablo; **SRL+DR(NE):** Patience	
Rationale: To find the correct answer we need to understand at least that 'they' are 'the children' (Coref) and 'who did what to whom' in the context (SRL).	

Figure 8: Example of positive impact of Coref and DR and negative impact from SRL.

a hypothetical rationale of what we would need to answer the question. [6]

7 Conclusion and Future Work

In this work we use linguistic annotations as a basis for a *Discourse-Aware Semantic Self-Attention* encoder that we employ for reading comprehension on narrative texts.

The provided annotations of discourse relations, events and their arguments as well as coreferring mentions, are using available annotation tools. Our empirical evaluation shows that discourse-semantic annotations combined with self-attention yields significant (+3.43 *Rouge-L*) improvement over QANet's token-based self-attention when applied to NarrativeQA reading comprehension. We analyzed the impact of different semantic annotation types on specific question types and context regions. We find, for instance, that SRL greatly improves *who* and *when* questions, and that discourse relations improve also the performance on *why* and *where* questions. While all examined annotation types contribute, particularly strong and constant gains are seen with intra-sentential DR (all context ranges), followed by SRL (short to mid-sized contexts). Coreference shows positive, but weaker impact, mostly in mid-sized contexts. A promising future direction would be to include additional external knowledge such as commonsense and world knowledge, and learn all annotations jointly with the downstream task.

Acknowledgments This work has been supported by the German Research Foundation as part of the Research Training Group Adaptive Preparation of Information from Heterogeneous Sources (AIPHES) under grant No. GRK 1994/1. We thank NVIDIA Corporation for donating GPUs used in this research.

[6] The examples are selected from NarrativeQA *Test*, in such a way, that they depict the strength and weaknesses of the different models, corresponding to the empirical evaluation on Figure 4 and they fit in the space limit.

Revealing the Importance of Semantic Retrieval for Machine Reading at Scale

Yixin Nie **Songhe Wang** **Mohit Bansal**

Abstract

Machine Reading at Scale (MRS) is a challenging task in which a system is given an input query and is asked to produce a precise output by "reading" information from a large knowledge base. The task has gained popularity with its natural combination of information retrieval (IR) and machine comprehension (MC). Advancements in representation learning have led to separated progress in both IR and MC; however, very few studies have examined the relationship and combined design of retrieval and comprehension at different levels of granularity, for development of MRS systems. In this work, we give general guidelines on system design for MRS by proposing a simple yet effective pipeline system with special consideration on hierarchical semantic retrieval at both paragraph and sentence level, and their potential effects on the downstream task. The system is evaluated on both fact verification and open-domain multi-hop QA, achieving state-of-the-art results on the leaderboard test sets of both FEVER and HOTPOTQA. To further demonstrate the importance of semantic retrieval, we present ablation and analysis studies to quantify the contribution of neural retrieval modules at both paragraph-level and sentence-level, and illustrate that intermediate semantic retrieval modules are vital for not only effectively filtering upstream information and thus saving downstream computation, but also for shaping upstream data distribution and providing better data for downstream modeling.[1]

1 Introduction

Extracting external textual knowledge for machine comprehensive systems has long been an important yet challenging problem. Success requires not only precise retrieval of the relevant information sparsely restored in a large knowledge source but also a deep understanding of both the selected knowledge and the input query to give the corresponding output. Initiated by Chen et al. (2017), the task was termed as Machine Reading at Scale (MRS), seeking to provide a challenging situation where machines are required to do both semantic retrieval and comprehension at different levels of granularity for the final downstream task.

Progress on MRS has been made by improving individual IR or comprehension sub-modules with recent advancements on representative learning (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018). However, partially due to the lack of annotated data for intermediate retrieval in an MRS setting, the evaluations were done mainly on the final downstream task and with much less consideration on the intermediate retrieval performance. This led to the convention that upstream retrieval modules mostly focus on getting better coverage of the downstream information such that the upper-bound of the downstream score can be improved, rather than finding more exact information. This convention is misaligned with the nature of MRS where equal effort should be put in emphasizing the models' joint performance and optimizing the relationship between the semantic retrieval and the downstream comprehension subtasks.

Hence, to shed light on the importance of semantic retrieval for downstream comprehension tasks, we start by establishing a simple yet effective hierarchical pipeline system for MRS using Wikipedia as the external knowledge source. The system is composed of a term-based retrieval module, two neural modules for both paragraph-level retrieval and sentence-level retrieval, and a neural downstream task module. We evaluated the system on two recent large-scale open do-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2553–2566, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

main benchmarks for fact verification and multi-hop QA, namely FEVER (Thorne et al., 2018) and HOTPOTQA (Yang et al., 2018), in which retrieval performance can also be evaluated accurately since intermediate annotations on evidences are provided. Our system achieves the start-of-the-art results with 45.32% for answer EM and 25.14% joint EM on HOTPOTQA (8% absolute improvement on answer EM and doubling the joint EM over the previous best results) and with 67.26% on FEVER score (3% absolute improvement over previously published systems).

We then provide empirical studies to validate design decisions. Specifically, we prove the necessity of both paragraph-level retrieval and sentence-level retrieval for maintaining good performance, and further illustrate that a better semantic retrieval module not only is beneficial to achieving high recall and keeping high upper bound for downstream task, but also plays an important role in shaping the downstream data distribution and providing more relevant and high-quality data for downstream sub-module training and inference. These mechanisms are vital for a good MRS system on both QA and fact verification.

2 Related Work

Machine Reading at Scale First proposed and formalized in Chen et al. (2017), MRS has gained popularity with increasing amount of work on both dataset collection (Joshi et al., 2017; Welbl et al., 2018) and MRS model developments (Wang et al., 2018; Clark and Gardner, 2017; Htut et al., 2018). In some previous work (Lee et al., 2018), paragraph-level retrieval modules were mainly for improving the recall of required information, while in some other works (Yang et al., 2018), sentence-level retrieval modules were merely for solving the auxiliary sentence selection task. In our work, we focus on revealing the relationship between semantic retrieval at different granularity levels and the downstream comprehension task. To the best of our knowledge, we are the first to apply and optimize neural semantic retrieval at both paragraph and sentence levels for MRS.

Automatic Fact Checking: Recent work (Thorne and Vlachos, 2018) formalized the task of automatic fact checking from the viewpoint of machine learning and NLP. The release of FEVER (Thorne et al., 2018) stimulates many recent developments (Nie et al., 2019; Yoneda et al., 2018; Hanselowski et al., 2018) on data-driven neural networks for automatic fact checking. We consider the task also as MRS because they share almost the same setup except that the downstream task is verification or natural language inference (NLI) rather than QA.

Information Retrieval Success in deep neural networks inspires their application to information retrieval (IR) tasks (Huang et al., 2013; Guo et al., 2016; Mitra et al., 2017; Dehghani et al., 2017). In typical IR settings, systems are required to retrieve and rank (Nguyen et al., 2016) elements from a collection of documents based on their relevance to the query. This setting might be very different from the retrieval in MRS where systems are asked to select facts needed to answer a question or verify a statement. We refer the retrieval in MRS as *Semantic Retrieval* since it emphasizes on semantic understanding.

3 Method

In previous works, an MRS system can be complicated with different sub-components processing different retrieval and comprehension sub-tasks at different levels of granularity, and with some sub-components intertwined. For interpretability considerations, we used a unified pipeline setup. The overview of the system is in Fig. 1.

To be specific, we formulate the MRS system as a function that maps an input tuple $(q, \mathbf{K})$ to an output tuple $(\hat{y}, \mathbf{S})$ where q indicates the input query, $\mathbf{K}$ is the textual KB, $\hat{y}$ is the output prediction, and $\mathbf{S}$ is selected supporting sentences from Wikipedia. Let $\mathbf{E}$ denotes a set of necessary evidences or facts selected from $\mathbf{K}$ for the prediction. For a QA task, q is the input question and $\hat{y}$ is the predicted answer. For a verification task, q is the input claim and $\hat{y}$ is the predicted truthfulness of the input claim. For all tasks, $\mathbf{K}$ is Wikipedia.

The system procedure is listed below:

(1) Term-Based Retrieval: To begin with, we used a combination of the TF-IDF method and a rule-based keyword matching method[2] to narrow the scope from whole Wikipedia down to a set of related paragraphs; this is a standard procedure in MRS (Chen et al., 2017; Lee et al., 2018; Nie et al., 2019). The focus of this step is to efficiently select a candidate set $\mathbf{P_I}$ that can cover the information as much as possible ($\mathbf{P_I} \subset \mathbf{K}$) while keeping the

[2]Details of term-based retrieval are in Appendix.

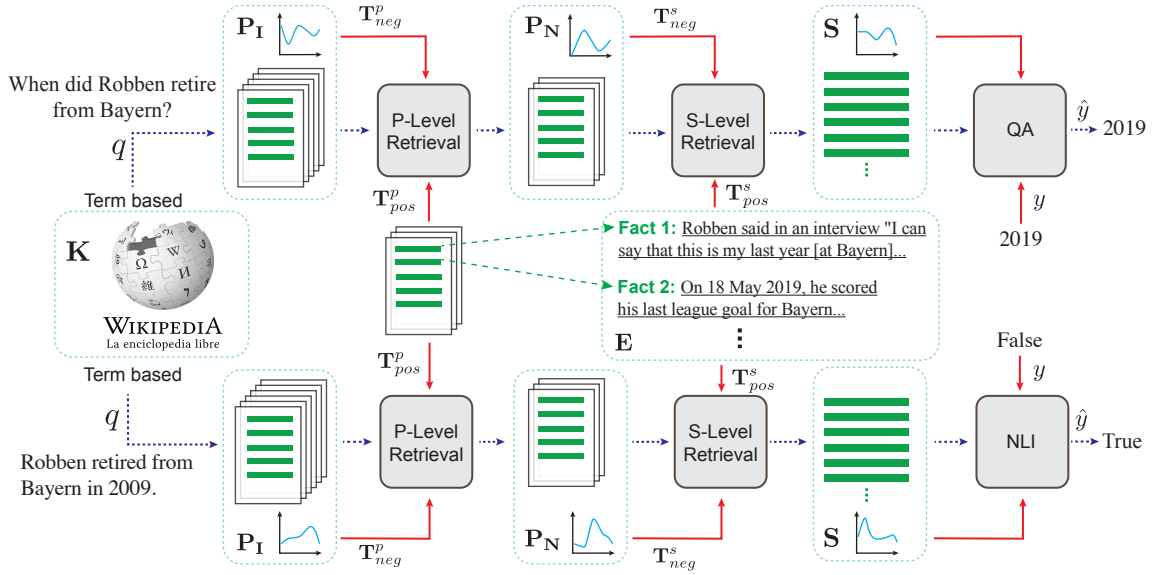

Figure 1: System Overview: blue dotted arrows indicate the inference flow and the red solid arrows indicate the training flow. Grey rounded rectangles are neural modules with different functionality. rounded rectangles. The two retrieval modules were trained with all positive examples from annotated ground truth set and negative examples sampled from the direct upstream modules. Thus, the distribution of negative examples is subjective to the quality of the upstream module.

size of the set acceptable enough for downstream processing.

(2) Paragraph-Level Neural Retrieval: After obtaining the initial set, we compare each paragraph in $\mathbf{P_I}$ with the input query q using a neural model (which will be explained later in Sec 3.1). The outputs of the neural model are treated as the relatedness score between the input query and the paragraphs. The scores will be used to sort all the upstream paragraphs. Then, $\mathbf{P_I}$ will be narrowed to a new set $\mathbf{P_N}$ ($\mathbf{P_N} \subset \mathbf{P_I}$) by selecting top k_p paragraphs having relatedness score higher than some threshold value h_p (going out from the P-Level grey box in Fig. 1). k_p and h_p would be chosen by keeping a good balance between the recall and precision of the paragraph retrieval.

(3) Sentence-Level Neural Retrieval: Next, we select the evidence at the sentence-level by decomposing all the paragraphs in $\mathbf{P_N}$ into sentences. Similarly, each sentence is compared with the query using a neural model (see details in Sec 3.1) and obtain a set of sentences $\mathbf{S} \subset \mathbf{P_N}$ for the downstream task by choosing top k_s sentences with output scores higher than some threshold h_s (S-Level grey box in Fig. 1). During evaluation, $\mathbf{S}$ is often evaluated against some ground truth sentence set denoted as $\mathbf{E}$.

(4) Downstream Modeling: At the final step, we simply applied task-specific neural models (e.g., QA and NLI) on the concatenation of all the sentences in $\mathbf{S}$ and the query, obtaining the final output $\hat{y}$.

In some experiments, we modified the setup for certain analysis or ablation purposes which will be explained individually in Sec 6.

3.1 Modeling and Training

Throughout all our experiments, we used **BERT-Base** (Devlin et al., 2018) to provide the state-of-the-art contextualized modeling of the input text.[3]

Semantic Retrieval: We treated the neural semantic retrieval at both the paragraph and sentence level as binary classification problems with models' parameters updated by minimizing binary cross entropy loss. To be specific, we fed the query and context into BERT as:

$$[CLS]\ Query\ [SEP]\ Context\ [SEP]$$

We applied an affine layer and sigmoid activation on the last layer output of the $[CLS]$ token which is a scalar value. The parameters were updated with the objective function:

$$\mathcal{J}_{retri} = -\sum_{i \in \mathbf{T}^{p/s}_{pos}} \log(\hat{p}_i) - \sum_{i \in \mathbf{T}^{p/s}_{neg}} \log(1 - \hat{p}_i)$$

[3]We used the pytorch BERT implementation in https://github.com/huggingface/pytorch-pretrained-BERT.

where $\hat{p}_i$ is the output of the model, $\mathbf{T}_{pos}^{p/s}$ is the positive set and $\mathbf{T}_{neg}^{p/s}$ is the negative set. As shown in Fig. 1, at sentence level, ground-truth sentences were served as positive examples while other sentences from upstream retrieved set were served as negative examples. Similarly at the paragraph-level, paragraphs having any ground-truth sentence were used as positive examples and other paragraphs from the upstream term-based retrieval processes were used as negative examples.

QA: We followed Devlin et al. (2018) for QA span prediction modeling. To correctly handle yes-or-no questions in HOTPOTQA, we fed the two additional "*yes*" and "*no*" tokens between $[CLS]$ and the $Query$ as:

$$[CLS]\ yes\ no\ Query\ [SEP]\ Context\ [SEP]$$

where the supervision was given to the second or the third token when the answer is "yes" or "no", such that they can compete with all other predicted spans. The parameters of the neural QA model were trained to maximize the log probabilities of the true start and end indexes as:

$$\mathcal{J}_{qa} = -\sum_i \left[\log(\hat{y}_i^s) + \log(\hat{y}_i^e)\right]$$

where $\hat{y}_i^s$ and $\hat{y}_i^e$ are the predicted probability on the ground-truth start and end position for the ith example, respectively. It is worth noting that we used ground truth supporting sentences plus some other sentences sampled from upstream retrieved set as the context for training the QA module such that it will adapt to the upstream data distribution during inference.

Fact Verification: Following Thorne et al. (2018), we formulate downstream fact verification as the 3-way natural language inference (NLI) classification problem (MacCartney and Manning, 2009; Bowman et al., 2015) and train the model with 3-way cross entropy loss. The input format is the same as that of semantic retrieval and the objective is $\mathcal{J}_{ver} = -\sum_i \mathbf{y}_i \cdot \log(\hat{\mathbf{y}}_i)$, where $\hat{\mathbf{y}}_i \in \mathbf{R^3}$ denotes the model's output for the three verification labels, and $\mathbf{y}_i$ is a one-hot embedding for the ground-truth label. For verifiable queries, we used ground truth evidential sentences plus some other sentences sampled from upstream retrieved set as new evidential context for NLI. For non-verifiable queries, we only used sentences sampled from upstream retrieved set as context because those queries are not associated with ground truth evidential sentences. This detail is important for the model to identify non-verifiable queries and will be explained more in Sec 6. Additional training details and hyper-parameter selections are in the Appendix (Sec. A; Table 6).

It is worth noting that each sub-module in the system relies on its preceding sub-module to provide data both for training and inference. This means that there will be upstream data distribution misalignment if we trained the sub-module in isolation without considering the properties of its precedent upstream module. The problem is similar to the concept of internal covariate shift (Ioffe and Szegedy, 2015), where the distribution of each layer's inputs changes inside a neural network. Therefore, it makes sense to study this issue in a joint MRS setting rather than a typical supervised learning setting where training and test data tend to be fixed and modules being isolated. We release our code and the organized data both for reproducibility and providing an off-the-shelf testbed to facilitate future research on MRS.

4 Experimental Setup

MRS requires a system not only to retrieve relevant content from textual KBs but also to poccess enough understanding ability to solve the downstream task. To understand the impact or importance of semantic retrieval on the downstream comprehension, we established a unified experimental setup that involves two different downstream tasks, i.e., multi-hop QA and fact verification.

4.1 Tasks and Datasets

HOTPOTQA: This dataset is a recent large-scale QA dataset that brings in new features: (1) the questions require finding and reasoning over multiple documents; (2) the questions are diverse and not limited to pre-existing KBs; (3) it offers a new comparison question type (Yang et al., 2018). We experimented our system on HOTPOTQA in the fullwiki setting, where a system must find the answer to a question in the scope of the entire Wikipedia, an ideal MRS setup. The sizes of the train, dev and test split are 90,564, 7,405, and 7,405. More importantly, HOTPOTQA also provides human-annotated sentence-level supporting facts that are needed to answer each question. Those intermediate annotations enable evaluation on models' joint ability on both fact retrieval

and answer span prediction, facilitating our direct analysis on the explainable predictions and its relations with the upstream retrieval.

FEVER: The Fact Extraction and VERification dataset (Thorne et al., 2018) is a recent dataset collected to facilitate the automatic fact checking. The work also proposes a benchmark task in which given an arbitrary input claim, candidate systems are asked to select evidential sentences from Wikipedia and label the claim as either SUPPORT, REFUTE, or NOT ENOUGH INFO, if the claim can be verified to be true, false, or non-verifiable, respectively, based on the evidence. The sizes of the train, dev and test split are 145,449, 19,998, and 9,998. Similar to HOTPOTQA, the dataset provides annotated sentence-level facts needed for the verification. These intermediate annotations could provide an accurate evaluation on the results of semantic retrieval and thus suits well for the analysis on the effects of retrieval module on downstream verification.

As in Chen et al. (2017), we use Wikipedia as our unique knowledge base because it is a comprehensive and self-evolving information source often used to facilitate intelligent systems. Moreover, as Wikipedia is the source for both HOTPOTQA and FEVER, it helps standardize any further analysis of the effects of semantic retrieval on the two different downstream tasks.

4.2 Metrics

Following Thorne et al. (2018); Yang et al. (2018), we used annotated sentence-level facts to calculate the F1, Precision and Recall scores for evaluating sentence-level retrieval. Similarly, we labeled all the paragraphs that contain any ground truth fact as ground truth paragraphs and used the same three metrics for paragraph-level retrieval evaluation. For HOTPOTQA, following Yang et al. (2018), we used exact match (EM) and F1 metrics for QA span prediction evaluation, and used the joint EM and F1 to evaluate models' joint performance on both retrieval and QA. The joint EM and F1 are calculated as: $P_j = P_a \cdot P_s; R_j = R_a \cdot R_s; F_j = \frac{2P_j \cdot R_j}{P_j + R_j}; \text{EM}_j = \text{EM}_a \cdot \text{EM}_s$, where P, R, and EM denote precision, recall and EM; the subscript a and s indicate that the scores are for answer span and supporting facts.

For the FEVER task, following Thorne et al. (2018), we used the Label Accuracy for evaluating downstream verification and the Fever Score for joint performance. Fever score will award one point for each example with the correct predicted label only if all ground truth facts were contained in the predicted facts set with at most 5 elements. We also used Oracle Score for the two retrieval modules. The scores were proposed in Nie et al. (2019) and indicate the upperbound of final FEVER Score at one intermediate layer assuming all downstream modules are perfect. All scores are averaged over examples in the whole evaluation set.

5 Results on Benchmarks

We chose the best system based on the dev set, and used that for submitting private test predictions on both FEVER and HOTPOTQA[4].

As can be seen in Table 1, with the proposed hierarchical system design, the whole pipeline sys-

[4]Results can also be found at the leaderboard websites for the two datasets: https://hotpotqa.github.io and https://competitions.codalab.org/competitions/18814

tem achieves new start-of-the-art on HOTPOTQA with large-margin improvements on all the metrics. More specifically, the biggest improvement comes from the EM for the supporting fact which in turn leads to doubling of the joint EM on previous best results. The scores for answer predictions are also higher than all previous best results with ∼8 absolute points increase on EM and ∼9 absolute points on F1. All the improvements are consistent between test and dev set evaluation.

Similarly for FEVER, we showed F1 for evidence, the Label Accuracy, and the FEVER Score (same as benchmark evaluation) for models in Table 2. Our system obtained substantially higher scores than all previously published results with a ∼4 and ∼3 points absolute improvement on Label Accuracy and FEVER Score. In particular, the system gains 74.62 on the evidence F1, 22 points greater that of the second system, demonstrating its ability on semantic retrieval.

Previous systems (Ming Ding, 2019; Yang et al., 2018) on HOTPOTQA treat supporting fact retrieval (sentence-level retrieval) just as an auxiliary task for providing extra model explainability. In Nie et al. (2019), although they used a similar three-stage system for FEVER, they only applied one neural retrieval module at sentence-level which potentially weaken its retrieval ability. Both of these previous best systems are different from our fully hierarchical pipeline approach. These observations lead to the assumption that the performance gain comes mainly from the hierarchical retrieval and its positive effects on downstream. Therefore, to validate the system design decisions in Sec 3 and reveal the importance of semantic retrieval towards downstream, we conducted a series of ablation and analysis experiments on all the modules. We started by examining the necessity of both paragraph and sentence retrieval and give insights on why both of them matters.

6 Analysis and Ablations

Intuitively, both the paragraph-level and sentence-level retrieval sub-module help speeding up the downstream processing. More importantly, since downstream modules were trained by sampled data from upstream modules, both of neural retrieval sub-modules also play an implicit but important role in controlling the immediate retrieval distribution i.e. the distribution of set $\mathbf{P_N}$ and set $\mathbf{S}$ (as shown in Fig. 1), and providing better inference data and training data for downstream modules.

6.1 Ablation Studies

Setups: To reveal the importance of neural retrieval modules at both paragraph and sentence level for maintaining the performance of the overall system, we removed either of them and examine the consequences. Because the removal of a module in the pipeline might change the distribution of the input of the downstream modules, we re-trained all the downstream modules accordingly. To be specific, in the system without the paragraph-level neural retrieval module, we re-trained the sentence-level retrieval module with negative sentences directly sampled from the term-based retrieval set and then also re-trained the downstream QA or verification module. In the system without the sentence-level neural retrieval module, we re-train the downstream QA or verification module by sampling data from both ground truth set and retrieved set directly from the paragraph-level module. We tested the simplified systems on both FEVER and HOTPOTQA.

Results: Table 3 and 4 shows the ablation results for the two neural retrieval modules at both paragraph and sentence level on HOTPOTQA and FEVER. To begin with, we can see that removing paragraph-level retrieval module significantly reduces the precision for sentence-level retrieval and the corresponding F1 on both tasks. More importantly, this loss of retrieval precision also led to substantial decreases for all the downstream scores on both QA and verification task in spite of their higher upper-bound and recall scores. This indicates that the negative effects on downstream module induced by the omission of paragraph-level retrieval can not be amended by the sentence-level retrieval module, and focusing semantic retrieval merely on improving the recall or the upper-bound of final score will risk jeopardizing the performance of the overall system.

Next, the removal of sentence-level retrieval module induces a ∼2 point drop on EM and F1 score in the QA task, and a ∼15 point drop on FEVER Score in the verification task. This suggests that rather than just enhance explainability for QA, the sentence-level retrieval module can also help pinpoint relevant information and reduce the noise in the evidence that might otherwise distract the downstream comprehension

Table 4: Ablation over the paragraph-level and sentence-level neural retrieval sub-modules on FEVER. "LA"=Label Accuracy; "FS"=FEVER Score; "Orcl." is the oracle upperbound of FEVER Score assuming all downstream modules are perfect. "L-F1 (S/R/N)" means the classification f1 scores on the three verification labels: SUPPORT, REFUTE, and NOT ENOUGH INFO.

module. Another interesting finding is that without sentence-level retrieval module, the QA module suffered much less than the verification module; conversely, the removal of paragraph-level retrieval neural induces a 11 point drop on answer EM comparing to a ∼9 point drop on Label Accuracy in the verification task. This seems to indicate that the downstream QA module relies more on the upstream paragraph-level retrieval whereas the verification module relies more on the upstream sentence-level retrieval. Finally, we also evaluate the F1 score on FEVER for each classification label and we observe a significant drop of F1 on NOT ENOUGH INFO category without retrieval module, meaning that semantic retrieval is vital for the downstream verification module's discriminative ability on NOT ENOUGH INFO label.

6.2 Sub-Module Change Analysis

To further study the effects of upstream semantic retrieval towards downstream tasks, we change training or inference data between intermediate layers and then examine how this modification will affect the downstream performance.

6.2.1 Effects of Paragraph-level Retrieval

We fixed $h_p = 0$ (the value achieving the best performance) and re-trained all the downstream parameters and track their performance as k_p (the number of selected paragraph) being changed from 1 to 12. The increasing of k_p means a potential higher coverage of the answer but more noise in the retrieved facts. Fig. 2 shows the results. As can be seen that the EM scores for supporting fact retrieval, answer prediction, and joint performance increase sharply when k_p is changed from 1 to 2. This is consistent with the fact that at least two paragraphs are required to ask each question in HOTPOTQA. Then, after the peak, every score decrease as k_p becomes larger except the recall of supporting fact which peaks when $k_p = 4$. This indicates that even though the neural sentence-level retrieval module poccesses a certain level of ability to select correct facts from noisier upstream information, the final QA module is more sensitive to upstream data and fails to maintain the overall system performance. Moreover, the reduction on answer EM and joint EM suggests that it might be risky to give too much information for downstream modules with a unit of a paragraph.

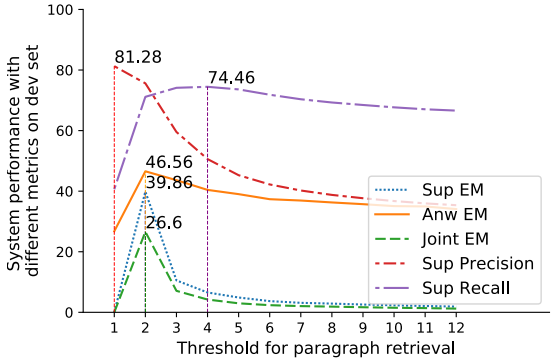

Figure 2: The results of EM for supporting fact, answer prediction and joint score, and the results of supporting fact precision and recall with different values of k_p at paragraph-level retrieval on HOTPOTQA.

6.2.2 Effects of Sentence-level Retrieval

Similarly, to study the effects of neural sentence-level retrieval module towards downstream QA and verification modules, we fixed k_s to be 5 and set h_s ranging from 0.1 to 0.9 with a 0.1 interval.

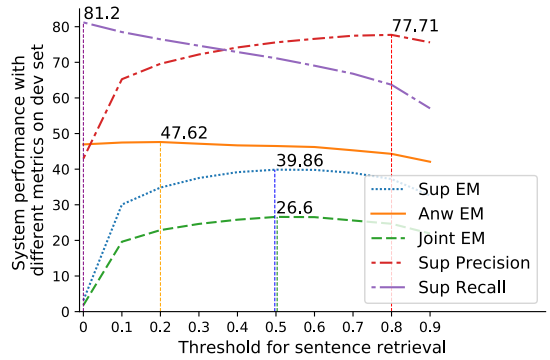

Figure 3: The results of EM for supporting fact, answer prediction and joint score, and the results of supporting fact precision and recall with different values of h_s at sentence-level retrieval on HOTPOTQA.

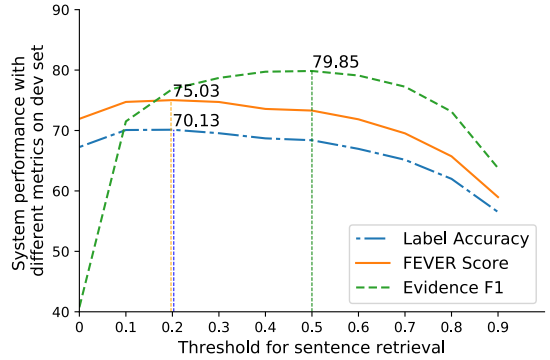

Figure 4: The results of Label Accuracy, FEVER Score, and Evidence F1 with different values of h_s at sentence-level retrieval on FEVER.

Then, we re-trained the downstream QA and verification modules with different h_s value and experimented on both HOTPOTQA and FEVER.

Question Answering: Fig. 3 shows the trend of performance. Intuitively, the precision increase while the recall decrease as the system becomes more strict about the retrieved sentences. The EM score for supporting fact retrieval and joint performance reaches their highest value when $h_s = 0.5$, a natural balancing point between precision and recall. More interestingly, the EM score for answer prediction peaks when $h_s = 0.2$ and where the recall is higher than the precision. This misalignment between answer prediction performance and retrieval performance indicates that unlike the observation at paragraph-level, the downstream QA module is able to stand a certain amount of noise at sentence-level and benefit from a higher recall.

Fact Verification: Fig. 4 shows the trends for Label Accuracy, FEVER Score, and Evidence F1 by modifying upstream sentence-level threshold h_s. We observed that the general trend is similar to that of QA task where both the label accuracy and FEVER score peak at $h_s = 0.2$ whereas the retrieval F1 peaks at $h_s = 0.5$. Note that, although the downstream verification could take advantage of a higher recall, the module is more sensitive to sentence-level retrieval comparing to the QA module in HOTPOTQA. More detailed results are in the Appendix.

Answer Type	Total	Correct	Acc. (%)
Person	50	28	56.0
Location	31	14	45.2
Date	26	13	50.0
Number	14	4	28.6
Artwork	19	7	36.8
Yes/No	17	12	**70.6**
Event	5	2	40.0
Common noun	11	3	27.3
Group/Org	17	6	35.3
Other PN	20	9	45.0
Total	200	98	49.0

Table 5: System performance on different answer types. "PN"= Proper Noun

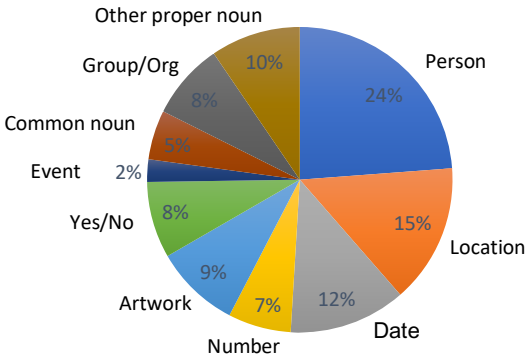

Figure 5: Proportion of answer types.

6.3 Answer Breakdown

We further sample 200 examples from HOTPOTQA and manually tag them according to several common answer types (Yang et al., 2018). The proportion of different answer types is shown in Figure 5. The performance of the system on each answer type is shown in Table 5. The most frequent answer type is 'Person' (24%) and the least frequent answer type is 'Event' (2%). It is also interesting to note that the model performs the best in Yes/No questions as shown in Table 5, reaching an accuracy of 70.6%.

Question: Wojtek Wolski played for what team based in the Miami metropolitan area?
GT Answer: Florida Panthers

GT Facts:
[**Florida Panthers,0**]: The Florida Panthers are a professional ice hockey team based in the Miami metropolitan area. (*P-Score* : 0.99; *S-Score* : 0.98)
[**Wojtek Wolski,1**]: In the NHL, he has played for the Colorado Avalanche, Phoenix Coyotes, New York Rangers, Florida Panthers, and the Washington Capitals. (*P-Score* : 0.98; *S-Score* : 0.95)

Distracting Fact:
[**History of the Miami Dolphins,0**]: The Miami Dolphins are a professional American football franchise based in the Miami metropolitan area. (*P-Score* : 0.56; *S-Score* : 0.97)

Wrong Answer : The Miami Dolphins

Figure 6: An example with a distracting fact. P-Score and S-Score are the retrieval score at paragraph and sentence level respectively. The full pipeline was able to filter the distracting fact and give the correct answer. The wrong answer in the figure was produced by the system without paragraph-level retrieval module.

6.4 Examples

Fig. 6 shows an example that is correctly handled by the full pipeline system but not by the system without paragraph-level retrieval module. We can see that it is very difficult to filter the distracting sentence after sentence-level either by the sentence retrieval module or the QA module.

Above findings in both FEVER and HOTPOTQA bring us some important guidelines for MRS: (1) A paragraph-level retrieval module is imperative; (2) Downstream task module is able to undertake a certain amount of noise from sentence-level retrieval; (3) Cascade effects on downstream task might be caused by modification at paragraph-level retrieval.

7 Conclusion

We proposed a simple yet effective hierarchical pipeline system that achieves state-of-the-art results on two MRS tasks. Ablation studies demonstrate the importance of semantic retrieval at both paragraph and sentence levels in the MRS system. The work can give general guidelines on MRS modeling and inspire future research on the relationship between semantic retrieval and downstream comprehension in a joint setting.

P-Level Retri.	64	3	{2, 5}	{5e-3, 0.01, 0.1, 0.5}
S-Level Retri.	128	3	{2, 5}	[0.1-0.5]
QA	32	5	-	-
Verification	32	5	-	-

Table 6: Hyper-parameter selection for the full pipeline system. h and k are the retrieval filtering hyper-parameters mentioned in the main paper. P-level and S-level indicate paragraph-level and sentence-level respectively. "{}" means values enumerated from a set. "[]" means values enumerated from a range with interval=0.1 "BS."=Batch Size "# E."=Number of Epochs

The hyper-parameters were chosen based on the performance of the system on the dev set. The hyper-parameters search space is shown in Table 6 and the learning rate was set to 10^{-5} in all experiments.

B Term-Based Retrieval Details

FEVER We used the same key-word matching method in Nie et al. (2019) to get a candidate set for each query. We also used TF-IDF (Chen et al., 2017) method to get top-5 related documents for each query. Then, the two sets were combined to get final term-based retrieval set for FEVER. The mean and standard deviation of the number of the retrieved paragraph in the merged set were 8.06 and 4.88.

HOTPOTQA We first used the same procedure on FEVER to get an initial candidate set for each query in HOTPOTQA. Because HOTPOTQA requires at least 2-hop reasoning for each query, we

h_p	S-Level Retrieval				Answer		Joint

Table 7: Detailed Results of downstream sentence-level retrieval and question answering with different values of h_s on HOTPOTQA.

then extract all the hyperlinked documents from the retrieved documents in the initial candidate set, rank them with TF-IDF (Chen et al., 2017) score and then select top-5 most related documents and add them to the candidate set. This gives the final term-based retrieval set for HOTPOTQA. The mean and standard deviation of the number of the retrieved paragraph for each query in HOTPOTQA were 39.43 and 16.05.

C Detailed Results

- The results of sentence-level retrieval and downstream QA with different values of h_s on HOTPOTQA are in Table 7.
- The results of sentence-level retrieval and downstream verification with different values of h_s on FEVER are in Table 8.
- The results of sentence-level retrieval and downstream QA with different values of k_p on HOTPOTQA are in Table 9.

D Examples and Case Study

We further provide examples, case study and error analysis for the full pipeline system. The examples are shown from Tables 11, 12, 13, 14, 15. The examples show high diversity on the semantic level and the error occurs often due to the system's failure of extracting precise (either wrong, surplus or insufficient) information from KB.

Abstract

We introduce PubMedQA, a novel biomedical question answering (QA) dataset collected from PubMed abstracts. The task of PubMedQA is to answer research questions with yes/no/maybe (e.g.: *Do preoperative statins reduce atrial fibrillation after coronary artery bypass grafting?*) using the corresponding abstracts. PubMedQA has 1k expert-annotated, 61.2k unlabeled and 211.3k artificially generated QA instances. Each PubMedQA instance is composed of (1) a question which is either an existing research article title or derived from one, (2) a context which is the corresponding abstract without its conclusion, (3) a long answer, which is the conclusion of the abstract and, presumably, answers the research question, and (4) a yes/no/maybe answer which summarizes the conclusion. PubMedQA is the first QA dataset where reasoning over biomedical research texts, especially their quantitative contents, is required to answer the questions. Our best performing model, multi-phase fine-tuning of BioBERT with long answer bag-of-word statistics as additional supervision, achieves 68.1% accuracy, compared to single human performance of 78.0% accuracy and majority-baseline of 55.2% accuracy, leaving much room for improvement. PubMedQA is publicly available at https://pubmedqa.github.io.

1 Introduction

A long-term goal of natural language understanding is to build intelligent systems that can reason and infer over natural language. The question answering (QA) task, in which models learn how to answer questions, is often used as a benchmark for quantitatively measuring the reasoning and inferring abilities of such intelligent systems.

While many large-scale annotated general domain QA datasets have been introduced (Rajpurkar et al., 2016; Lai et al., 2017; Kočiskỳ et al., 2018; Yang et al., 2018; Kwiatkowski et al., 2019), the largest annotated biomedical QA dataset, BioASQ (Tsatsaronis et al., 2015) has less than 3k training instances, most of which are simple factual questions. Some works proposed automatically constructed biomedical QA datasets (Pampari et al., 2018; Pappas et al., 2018; Kim et al., 2018), which have much larger sizes. However, questions of these datasets are mostly factoid, whose answers can be extracted in the contexts without much reasoning.

Question:
Do preoperative statins reduce atrial fibrillation after coronary artery bypass grafting?
Context:
(Objective) Recent studies have demonstrated that statins have pleiotropic effects, including anti-inflammatory effects and atrial fibrillation (AF) preventive effects [...]
(Methods) 221 patients underwent CABG in our hospital from 2004 to 2007. 14 patients with preoperative AF and 4 patients with concomitant valve surgery [...]
(Results) The overall incidence of postoperative AF was 26%. ***Postoperative AF was significantly lower in the Statin group compared with the Non-statin group (16% versus 33%, p=0.005).*** Multivariate analysis demonstrated that independent predictors of AF [...]
Long Answer:
(Conclusion) Our study indicated that preoperative statin therapy seems to reduce AF development after CABG.
Answer: yes

Figure 1: An instance (Sakamoto et al., 2011) of PubMedQA dataset: Question is the original question title; Context includes the structured abstract except its conclusive part, which serves as the Long Answer; Human experts annotated the Answer yes. Supporting fact for the answer is ***highlighted***.

In this paper, we aim at building a biomedical QA dataset which (1) has substantial instances with some expert annotations and (2) requires reasoning over the contexts to answer the questions. For this, we turn to the PubMed[1], a search engine providing access to over 25 million references of

biomedical articles. We found that around 760k articles in PubMed use questions as their titles. Among them, the abstracts of about 120k articles are written in a structured style – meaning they have subsections of "Introduction", "Results" etc. Conclusive parts of the abstracts, often in "Conclusions", are the authors' answers to the question title. Other abstract parts can be viewed as the contexts for giving such answers. This pattern perfectly fits the scheme of QA, but modeling it as abstractive QA, where models learn to generate the conclusions, will result in an extremely hard task due to the variability of writing styles.

Interestingly, more than half of the question titles of PubMed articles can be briefly answered by yes/no/maybe, which is significantly higher than the proportions of such questions in other datasets, e.g.: just 1% in Natural Questions (Kwiatkowski et al., 2019) and 6% in HotpotQA (Yang et al., 2018). Instead of using conclusions to answer the questions, we explore answering them with yes/no/maybe and treat the conclusions as a long answer for additional supervision.

To this end, we present PubMedQA, a biomedical QA dataset for answering research questions using yes/no/maybe. We collected all PubMed articles with question titles, and manually labeled 1k of them for cross-validation and testing. An example is shown in Fig. 1. The rest of yes/no/answerable QA instances compose of the unlabeled subset which can be used for semi-supervised learning. Further, we automatically convert statement titles of 211.3k PubMed articles to questions and label them with yes/no answers using a simple heuristic. These artificially generated instances can be used for pre-training. Unlike other QA datasets in which questions are asked by crowd-workers for existing contexts (Rajpurkar et al., 2016; Yang et al., 2018; Kočiskỳ et al., 2018), in PubMedQA contexts are generated to answer the questions and both are written by the same authors. This consistency assures that contexts are perfectly related to the questions, thus making PubMedQA an ideal benchmark for testing scientific reasoning abilities.

As an attempt to solve PubMedQA and provide a strong baseline, we fine-tune BioBERT (Lee et al., 2019) on different subsets in a multi-phase style with additional supervision of long answers. Though this model generates decent results and vastly outperforms other baselines, it's still much worse than the single-human performance, leaving significant room for future improvements.

2 Related Works

Biomedical QA: Expert-annotated biomedical QA datasets are limited by scale due to the difficulty of annotations. In 2006 and 2007, TREC[2] held QA challenges on genomics corpus (Hersh et al., 2006, 2007), where the task is to retrieve relevant documents for 36 and 38 topic questions, respectively. QA4MRE (Peñas et al., 2013) included a QA task about Alzheimer's disease (Morante et al., 2012). This dataset has 40 QA instances and the task is to answer a question related to a given document using one of five answer choices. The QA task of BioASQ (Tsatsaronis et al., 2015) has phases of (a) retrieve question-related documents and (b) using related documents as contexts to answer yes/no, factoid, list or summary questions. BioASQ 2019 has a training set of 2,747 QA instances and a test set of 500 instances.

Several large-scale automatically collected biomedical QA datasets have been introduced: emrQA (Pampari et al., 2018) is an extractive QA dataset for electronic medical records (EHR) built by re-purposing existing annotations on EHR corpora. BioRead (Pappas et al., 2018) and BMKC (Kim et al., 2018) both collect cloze-style QA instances by masking biomedical named entities in sentences of research articles and using other parts of the same article as context.

Yes/No QA: Datasets such as HotpotQA (Yang et al., 2018), Natural Questions (Kwiatkowski et al., 2019), ShARC (Saeidi et al., 2018) and BioASQ (Tsatsaronis et al., 2015) contain yes/no questions as well as other types of questions. BoolQ (Clark et al., 2019) specifically focuses on naturally occurring yes/no questions, and those questions are shown to be surprisingly difficult to answer. We add a "maybe" choice in PubMedQA to cover uncertain instances.

Typical neural approaches to answering yes/no questions involve encoding both the question and context, and decoding the encoding to a class output, which is similar to the well-studied natural language inference (NLI) task. Recent breakthroughs of pre-trained language models like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) show significant performance im-

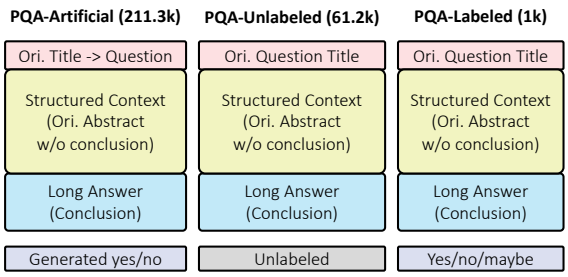

Figure 2: Architecture of PubMedQA dataset. PubMedQA is split into three subsets, PQA-A(rtificial), PQA-U(nlabeled) and PQA-L(abeled).

provements on NLI tasks. In this work, we use domain specific versions of them to set baseline performance on PubMedQA.

3 PubMedQA Dataset

3.1 Data Collection

PubMedQA is split into three subsets: labeled, unlabeled and artificially generated. They are denoted as PQA-L(abeled), PQA-U(nlabeled) and PQA-A(rtificial), respectively. We show the architecture of PubMedQA dataset in Fig. 2.

Statistic	PQA-L	PQA-U	PQA-A
Number of QA pairs	1.0k	61.2k	211.3k
Prop. of yes (%)	55.2	–	92.8
Prop. of no (%)	33.8	–	7.2
Prop. of maybe (%)	11.0	–	0.0
Avg. question length	14.4	15.0	16.3
Avg. context length	238.9	237.3	238.0
Avg. long answer length	43.2	45.9	41.0

Table 1: PubMedQA dataset statistics.

Collection of PQA-L and PQA-U: PubMed articles which have i) a question mark in the titles and ii) a structured abstract with conclusive part are collected and denoted as pre-PQA-U. Now each instance has 1) a question which is the original title 2) a context which is the structured abstract without the conclusive part and 3) a long answer which is the conclusive part of the abstract.

Two annotators[3] labeled 1k instances from pre-PQA-U with yes/no/maybe to build PQA-L using Algorithm 1. The annotator 1 doesn't need to do much reasoning to annotate since the long answer is available. We denote this reasoning-free setting. However, the annotator 2 cannot use the long answer, so reasoning over the context is required for annotation. We denote such setting as reasoning-required setting. Note that the annotation process might assign wrong labels when both annotator 1 and annotator 2 make a same mistake, but considering human performance in §5.1, such error rate could be as low as 1%[4]. 500 randomly sampled PQA-L instances are used for 10-fold cross validation and the rest 500 instances consist of PubMedQA test set.

Algorithm 1 PQA-L data collection procedure

Input: pre-PQA-U
ReasoningFreeAnnotation $\leftarrow \{\}$
ReasoningRequiredAnnotation $\leftarrow \{\}$
GroundTruthLabel $\leftarrow \{\}$
while not finished **do**
  Randomly sample an instance $inst$ from pre-PQA-U
  if $inst$ is not yes/no/maybe answerable **then**
    Remove $inst$ and continue to next iteration
  end if
  Annotator 1 annotates $inst$ with $l_1 \in \{\text{yes, no, maybe}\}$ using question, context and long answer
  Annotator 2 annotates $inst$ with $l_2 \in \{\text{yes, no, maybe}\}$ using question and context
  if $l_1 = l_2$ **then**
    $l_a \leftarrow l_1$
  else
    Annotator 1 and Annotator 2 discuss for an agreement annotation l_a
    if not $\exists l_a$ **then**
      Remove $inst$ and continue to next iteration
    end if
  end if
  ReasoningFreeAnnotation$[inst] \leftarrow l_1$
  ReasoningRequiredAnnotation$[inst] \leftarrow l_2$
  GroundTruthLabel$[inst] \leftarrow l_a$
end while

Further, we include the unlabeled instances in pre-PQA-U with yes/no/maybe answerable questions to build PQA-U. For this, we use a simple rule-based method which removes all questions started with interrogative words (i.e. wh-words) or involving selections from multiple entities. This results in over 93% agreement with annotator 1 in identifying the questions that can be answered by yes/no/maybe.

Collection of PQA-A: Motivated by the recent successes of large-scale pre-training from ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), we use a simple heuristic to collect many noisily-labeled instances to build PQA-A for pre-training. Towards this end, we use PubMed articles with 1) a statement title which has POS tagging structures of NP-(VBP/VBZ)[5] and 2) a structured abstract including a conclusive part. The

[3] Both are qualified M.D. candidates.

[4] Roughly half of the products of two annotator error rates.

[5] Using Stanford CoreNLP parser (Manning et al., 2014).

Original Statement Title	Converted Question	Label	%
Spontaneous electrocardiogram alterations ***predict*** ventricular fibrillation in Brugada syndrome.	***Do*** spontaneous electrocardiogram alterations ***predict*** ventricular fibrillation in Brugada syndrome?	***yes***	92.8
Liver grafts from selected older donors ***do not have*** significantly more ischaemia reperfusion injury.	***Do*** liver grafts from selected older donors ***have*** significantly more ischaemia reperfusion injury?	***no***	7.2

Table 2: Examples of automatically generated instances for PQA-A. Original statement titles are converted to questions and answers are automatically generated according to the negation status.

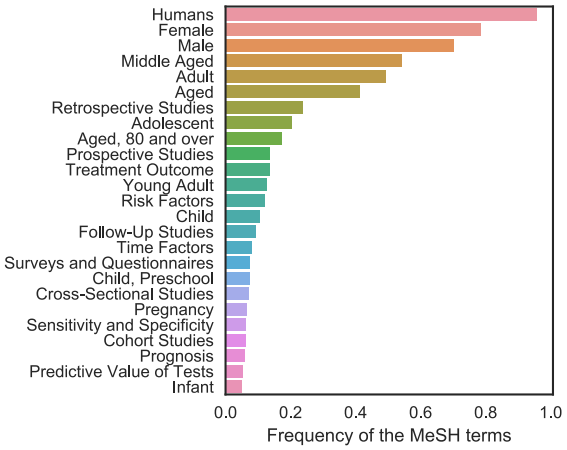

Figure 3: MeSH topic distribution of PubMedQA.

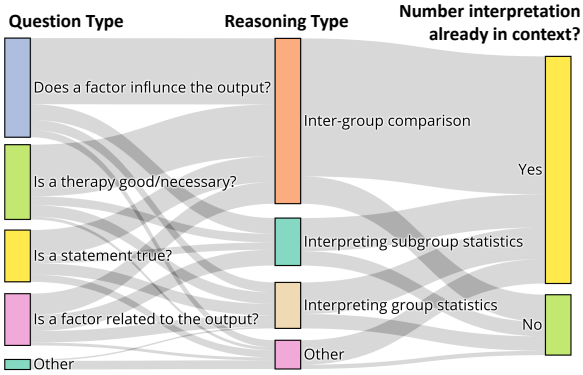

Figure 4: Proportional relationships between corresponded question types, reasoning types, and whether the text interpretations of numbers exist in contexts.

statement titles are converted to questions by simply moving or adding copulas ("is", "are") or auxiliary verbs ("does", "do") in the front and further revising for coherence (e.g.: adding a question mark). We generate the yes/no answer according to negation status of the VB. Several examples are shown in Table 2. We collected 211.3k instances for PQA-A, of which 200k randomly sampled instances are for training and the rest 11.3k instances are for validation.

3.2 Characteristics

We show the basic statistics of three PubMedQA subsets in Table 1.

Instance Topics: PubMed abstracts are manually annotated by medical librarians with Medical Subject Headings (MeSH)[6], which is a controlled vocabulary designed to describe the topics of biomedical texts. We use MeSH terms to represent abstract topics, and visualize their distribution in Fig. 3. Nearly all instances are human studies and they cover a wide variety of topics, including retrospective, prospective, and cohort studies, different age groups, and healthcare-related subjects like treatment outcome, prognosis and risk factors of diseases.

[6] https://www.nlm.nih.gov/mesh

Question and Reasoning Types: We sampled 200 examples from PQA-L and analyzed the types of questions and types of reasoning required to answer them, which is summarized in Table 3. Various types of questions have been asked, including causal effects, evaluations of therapies, relatedness, and whether a statement is true. Besides, PubMedQA also covers several different reasoning types: most (57.5%) involve comparing multiple groups (e.g.: experiment and control), and others require interpreting statistics of a single group or its subgroups. Reasoning over quantitative contents is required in nearly all (96.5%) of them, which is expected due to the nature of biomedical research. 75.5% of contexts have text descriptions of the statistics while 21.0% only have the numbers. We use a Sankey diagram to show the proportional relationships between corresponded question type and reasoning type, as well as corresponded reasoning type and whether there are text interpretations of numbers in Fig. 4.

3.3 Evaluation Settings

The main metrics of PubMedQA are accuracy and macro-F1 on PQA-L test set using question and context as input. We denote prediction using question and context as a **reasoning-required** setting, because under this setting answers are not directly

Question Type	%	Example Questions
Does a factor ***influence*** the output?	36.5	Does reducing spasticity ***translate into*** functional benefit? Does ibuprofen ***increase*** perioperative blood loss during hip arthroplasty?
Is a therapy ***good/necessary***?	26.0	***Should*** circumcision be performed in childhood? Is external palliative radiotherapy for gallbladder carcinoma ***effective***?
Is a ***statement*** true?	18.0	Sternal fracture in growing children: ***A rare and often overlooked fracture?*** Xanthogranulomatous cholecystitis: ***a premalignant condition***?
Is a factor ***related to*** the output?	18.0	Can PRISM ***predict*** length of PICU stay? Is trabecular bone ***related to*** primary stability of miniscrews?
Reasoning Type	**%**	**Example Snippet in Context**
Inter-group comparison	57.5	[...] Postoperative AF was significantly lower in the ***Statin group*** compared with the ***Non-statin group*** (16% versus 33%, p=0.005). [...]
Interpreting ***subgroup*** statistics	16.5	[...] 57% of patients were ***of lower socioeconomic status*** and they had more health problems, less functioning, and more symptoms [...]

Text Interpretations of Numbers	**%**	**Example Snippet in Context**
Existing ***interpretations*** of ***numbers***	75.5	[...] Postoperative AF was ***significantly lower*** in the Statin group compared with the Non-statin group (***16% versus 33%, p=0.005***). [...]
No interpretations (***numbers only***)	21.0	[...] 30-day mortality was ***12.4%*** in those aged<70 years and ***22%*** in those>70 years (***p<0.001***). [...]
No numbers (***texts only***)	3.5	[...] The halofantrine therapeutic dose group showed ***loss and distortion of inner hair cells and inner phalangeal cells*** [...]

Table 3: Summary of PubMedQA question types, reasoning types and whether there are text descriptions of the statistics in context. Colored texts are matched key phrases (sentences) between types and examples.

expressed in the input and reasoning over the contexts is required to answer the question. Additionally, long answers are available at training time, so generation or prediction of them can be used as an auxiliary task in this setting.

A parallel setting, where models can use question and long answer to predict yes/no/maybe answer, is denoted as **reasoning-free** setting since yes/no/maybe are usually explicitly expressed in the long answers (i.e.: conclusions of the abstracts). Obviously, it's a much easier setting which can be exploited for bootstrapping PQA-U.

4 Methods

4.1 Fine-tuning BioBERT

We fine-tune BioBERT (Lee et al., 2019) on PubMedQA as a baseline. BioBERT is initialized with BERT (Devlin et al., 2018) and further pre-trained on PubMed abstracts and PMC[7] articles. Expectedly, it vastly outperforms BERT in various biomedical NLP tasks. We denote the original transformer weights of BioBERT as θ_0.

While fine-tuning, we feed PubMedQA questions and contexts (or long answers), separated by the special `[SEP]` token, to BioBERT. The yes/no/maybe labels are predicted using the special `[CLS]` embedding using a softmax function. Cross-entropy loss of predicted and true label distribution is denoted as $\mathcal{L}_{\text{QA}}$.

4.2 Long Answer as Additional Supervision

Under reasoning-required setting, long answers are available in training but not inference phase. We use them as an additional signal for training: similar to Ma et al. (2018) regularizing neural machine translation models with binary bag-of-word (BoW) statistics, we fine-tune BioBERT with an auxiliary task of predicting the binary BoW statistics of the long answers, also using the special `[CLS]` embedding. We minimize binary cross-entropy loss of this auxiliary task:

$$\mathcal{L}_{\text{BoW}} = -\frac{1}{N}\sum_i b_i \log\hat{b}_i + (1-b_i)\log(1-\hat{b}_i)$$

where b_i and $\hat{b}_i$ are ground-truth and predicted probability of whether token i is in the long answers (i.e.: $b_i \in \{0,1\}$ and $\hat{b}_i \in [0,1]$), and N is the BoW vocabulary size. The total loss is:

$$\mathcal{L} = \mathcal{L}_{\text{QA}} + \beta\mathcal{L}_{\text{BoW}}$$

[7] https://www.ncbi.nlm.nih.gov/pmc/

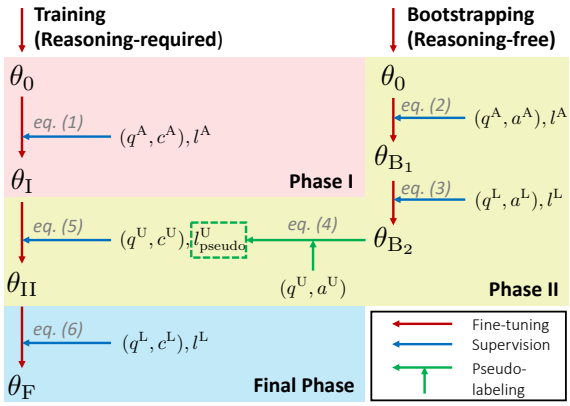

Figure 5: Multi-phase fine-tuning architecture. Notations and equations are described in §4.3.

In reasoning-free setting which we use for bootstrapping, the regularization coefficient β is set to 0 because long answers are directly used as input.

4.3 Multi-phase Fine-tuning Schedule

Since PQA-A and PQA-U have different properties from the ultimate test set of PQA-L, BioBERT is fine-tuned in a multi-phase style on different subsets. Fig. 5 shows the architecture of this training schedule. We use q, c, a, l to denote question, context, long answer and yes/no/maybe label of instances, respectively. Their source subsets are indexed by the superscripts of A for PQA-A, U for PQA-U and L for PQA-L.

Phase I Fine-tuning on PQA-A: PQA-A is automatically collected whose questions and labels are artificially generated. As a result, questions of PQA-A might differ a lot from those of PQA-U and PQA-L, and it only has yes/no labels with a very imbalanced distribution (92.8% yes v.s. 7.2% no). Despite these drawbacks, PQA-A has substantial training instances so models could still benefit from it as a pre-training step.

Thus, in Phase I of multi-phase fine-tuning, we initialize BioBERT with θ_0, and fine-tune it on PQA-A using question and context as input:

$$\theta_{\mathrm{I}} \leftarrow \mathrm{argmin}_\theta \, \mathcal{L}(\mathrm{BioBERT}_\theta(q^{\mathrm{A}}, c^{\mathrm{A}}), l^{\mathrm{A}}) \quad (1)$$

Phase II Fine-tuning on Bootstrapped PQA-U: To fully utilize the unlabeled instances in PQA-U, we exploit the easiness of reasoning-free setting to pseudo-label these instances with a bootstrapping strategy: first, we initialize BioBERT with θ_0, and fine-tune it on PQA-A using question and long answer (reasoning-free),

$$\theta_{\mathrm{B}_1} \leftarrow \mathrm{argmin}_\theta \, \mathcal{L}(\mathrm{BioBERT}_\theta(q^{\mathrm{A}}, a^{\mathrm{A}}), l^{\mathrm{A}}) \quad (2)$$

then we further fine-tune $\mathrm{BioBERT}_{\theta_{\mathrm{B}_1}}$ on PQA-L, also under the reasoning-free setting:

$$\theta_{\mathrm{B}_2} \leftarrow \mathrm{argmin}_\theta \, \mathcal{L}(\mathrm{BioBERT}_\theta(q^{\mathrm{L}}, a^{\mathrm{L}}), l^{\mathrm{L}}) \quad (3)$$

We pseudo-label PQA-U instances using the most confident predictions of $\mathrm{BioBERT}_{\theta_{\mathrm{B}_2}}$ for each class. Confidence is simply defined by the corresponding softmax probability and then we label a subset which has the same proportions of yes/no/maybe labels as those in the PQA-L:

$$l^{\mathrm{U}}_{\mathrm{pseudo}} \leftarrow \mathrm{BioBERT}_{\theta_{\mathrm{B}_2}}(q^{\mathrm{U}}, a^{\mathrm{U}}) \quad (4)$$

In phase II, we fine-tune $\mathrm{BioBERT}_{\theta_{\mathrm{I}}}$ on the bootstrapped PQA-U using question and context (under reasoning-required setting):

$$\theta_{\mathrm{II}} \leftarrow \mathrm{argmin}_\theta \, \mathcal{L}(\mathrm{BioBERT}_\theta(q^{\mathrm{U}}, c^{\mathrm{U}}), l^{\mathrm{U}}_{\mathrm{pseudo}}) \quad (5)$$

Final Phase Fine-tuning on PQA-L: In the final phase, we fine-tune $\mathrm{BioBERT}_{\theta_{\mathrm{II}}}$ on PQA-L:

$$\theta_{\mathrm{F}} \leftarrow \mathrm{argmin}_\theta \, \mathcal{L}(\mathrm{BioBERT}_\theta(q^{\mathrm{L}}, c^{\mathrm{L}}), l^{\mathrm{L}}) \quad (6)$$

Final predictions on instances of PQA-L validation and test sets are made using $\mathrm{BioBERT}_{\theta_{\mathrm{F}}}$:

$$l_{\mathrm{pred}} = \mathrm{BioBERT}_{\theta_{\mathrm{F}}}(q^{\mathrm{L}}, c^{\mathrm{L}})$$

4.4 Compared Models

Majority: The majority (about 55%) of the instances have the label "yes". We use a trivial baseline denoted as Majority where we simply predict "yes" for all instances, regardless of the question and context.

Shallow Features: For each instance, we include the following shallow features: 1) TF-IDF statistics of the question 2) TF-IDF statistics of the context/long answer and 3) sum of IDF of the overlapping non-stop words between the question and the context/long answer. To allow multi-phase fine-tuning, we apply a feed-forward neural network on the shallow features instead of using a logistic classifier.

BiLSTM: We simply concatenate the question and context/long answer with learnable segment embeddings appended to the biomedical word2vec embeddings (Pyysalo et al., 2013) of each token. The concatenated sentence is then fed to a biLSTM, and the final hidden states of the forward and backward network are used for classifying the yes/no/maybe label.

ESIM with BioELMo: Following the state-of-the-art recurrent architecture of NLI (Peters et al., 2018), we use pre-trained biomedical contextualized embeddings BioELMo (Jin et al., 2019) for word representations. Then we apply the ESIM model (Chen et al., 2016), where a biLSTM is used to encode the question and context/long answer, followed by an attentional local inference layer and a biLSTM inference composition layer. After pooling, a softmax output unit is applied for predicting the yes/no/maybe label.

4.5 Compared Training Schedules

Final Phase Only: Under this setting, we train models only on PQA-L. It's an extremely low resources setting where there are only 450 training instances in each fold of cross-validation.

Phase I + Final Phase: Under this setting, we skip the training on bootstrapped PQA-U. Models are first fine-tuned on PQA-A, and then fine-tuned on PQA-L.

Phase II + Final Phase: Under this setting, we skip the training on PQA-A. Models are first fine-tuned on bootstrapped PQA-U, and then fine-tuned on PQA-L.

Single-phase Training: Instead of training a model sequentially on different splits, under single-phase training setting we train the model on the combined training set of all PQA splits: PQA-A, bootstrapped PQA-U and PQA-L.

5 Experiments

5.1 Human Performance

Human performance is measured during the annotation: As shown in Algorithm 1, annotations of annotator 1 and annotator 2 are used to calculate reasoning-free and reasoning-required human performance, respectively, against the discussed ground truth labels. Human performance on the test set of PQA-L is shown in Table 4. We only test single-annotator performance due to limited resources. Kwiatkowski et al. (2019) show that an ensemble of annotators perform significantly better than single-annotator, so the results reported in Table 4 are the lower bounds of human performance. Under reasoning-free setting where the annotator can see the conclusions, a single human achieves 90.4% accuracy and 84.2% macro-F1. Under reasoning-required setting, the task becomes much harder, but it's still possible for humans to solve: a single annotator can get 78.0% accuracy and 72.2% macro-F1.

Setting	Accuracy (%)	Macro-F1 (%)
Reasoning-Free	90.40	84.18
Reasoning-Required	78.00	72.19

Table 4: Human performance (single-annotator).

5.2 Main Results

We report the test set performance of different models and training schedules in Table 5. In general, multi-phase fine-tuning of BioBERT with additional supervision outperforms other baselines by large margins, but the results are still much worse than just single-human performance.

Comparison of Models: A trend of BioBERT $>$ ESIM w/ BioELMo $>$ BiLSTM $>$ shallow features $>$ majority, conserves across different training schedules on both accuracy and macro-F1. Fine-tuned BioBERT is better than state-of-the-art recurrent model of ESIM w/ BioELMo, probably because BioELMo weights are fixed while all BioBERT parameters can be fine-tuned, which better benefit from the pre-training settings.

Comparison of Training Schedules: Multi-phase fine-tuning setting gets 5 out of 9 model-wise best accuracy/macro-F1. Due to lack of annotated data, training only on the PQA-L (final phase only) generates similar results as the majority baseline. In phase I + Final setting where models are pre-trained on PQA-A, we observe significant improvements on accuracy and macro-F1 and some models even achieve their best accuracy under this setting. This indicates that a hard task with limited training instances can be at least partially solved by pre-training on a large automatically collected dataset when the tasks are similarly formatted.

Improvements are also observed in phase II + Final setting, though less significant than those of phase I + Final. As expected, multi-phase fine-tuning schedule is better than single-phase, due to different properties of the subsets.

Additional Supervision: Despite its simplicity, the auxiliary task of long answer BoW prediction clearly improves the performance: most results (28/40) are better with such additional supervision than without.

5.3 Intermediate Results

In this section we show the intermediate results of multi-phase fine-tuning schedule.

Phase I: Results are shown in Table 6. Phase I is fine-tuning on PQA-A using question and context. Since PQA-A is imbalanced due to its collection process, a trivial majority baseline gets 92.76% accuracy. Other models have better accuracy and especially macro-F1 than majority baseline. Fine-tuned BioBERT performs best.

Model	w/o A.S.		w/ A.S.	
	Acc	F1	Acc	F1
Majority	55.10	23.68	–	–
Shallow Features	76.66	66.12	77.71	67.97
Majority	56.53	24.07	–	–
BiLSTM	85.33	81.32	85.68	81.87
Majority	55.10	23.68	–	–
ESIM w/ BioELMo	78.47	63.32	79.62	64.91
Majority	54.82	24.87	–	–
BioBERT	80.93	68.84	81.02	70.04

Table 8: Phase II results (eq. 5). Experiments are on pseudo-labeled PQA-U under reasoning-required setting. A.S.: additional supervision.

Bootstrapping: Results are shown in Table 7. Bootstrapping is a three-step process: fine-tuning on PQA-A, then on PQA-L and pseudo-labeling PQA-U. All three steps are using question and long answer as input. Expectedly, models perform better in this reasoning-free setting than they do in reasoning-required setting (for PQA-A, Eq. 2 results in Table 7 are better than the performance in Table 6; for PQA-L, Eq. 3 results in Table 7 are better than the performance in Table 5).

Phase II: Results are shown in Table 8. In Phase II, since each model is fine-tuned on its own pseudo-labeled PQA-U instances, results are not comparable between models. While the ablation study in Table 5 clearly shows that Phase II is helpful, performance in Phase II doesn't necessarily correlate with final performance on PQA-L.

6 Conclusion

We present PubMedQA, a novel dataset aimed at biomedical research question answering using yes/no/maybe, where complex quantitative reasoning is required to solve the task. PubMedQA has substantial automatically collected instances as well as the largest size of expert annotated yes/no/maybe questions in biomedical domain. We provide a strong baseline using multi-phase fine-tuning of BioBERT with long answer as additional supervision, but it's still much worse than just single human performance.

There are several interesting future directions to explore on PubMedQA, e.g.: (1) about 21% of PubMedQA contexts contain no natural language descriptions of numbers, so how to properly handle these numbers is worth studying; (2) we use binary BoW statistics prediction as a simple demonstration for additional supervision of long answers. Learning a harder but more informative auxiliary task of long answer generation might lead to further improvements.

Articles of PubMedQA are biased towards clinical study-related topics (described in Appendix B), so PubMedQA has the potential to assist evidence-based medicine, which seeks to make clinical decisions based on evidence of high quality clinical studies. Generally, PubMedQA can serve as a benchmark for testing scientific reasoning abilities of machine reading comprehension models.

A Yes/no/maybe Answerability

Not all naturally occuring question titles from PubMed are answerable by yes/no/maybe. The first step of annotating PQA-L (as shown in algorithm 1) from pre-PQA-U is to manually identify questions that can be answered using yes/no/maybe. We labeled 1091 (about 50.2%) of 2173 question titles as unanswerable. For example, those questions cannot be answered by yes/no/maybe:

- "Critical Overview of HER2 Assessement in Bladder Cancer: What Is Missing for a Better Therapeutic Approach?" (wh- question)
- "Otolaryngology externships and the match: Productive or futile?" (multiple choices)

B Over-represented Topics

Clinical study-related topics are over-represented in PubMedQA: we found proportions of MeSH terms like:

- "Pregnancy Outcome"
- "Socioeconomic Factors"
- "Risk Assessment"
- "Survival Analysis"
- "Prospective Studies"
- "Case-Control Studies"
- "Reference Values"

are significantly higher in the PubMedQA articles than those in 200k most recent general PubMed articles (significance is defined by $p < 0.05$ in two-proportion z-test).

C Annotation Criteria

Strictly speaking, most yes/no/maybe research questions can be answered by "maybe" since there will always be some conditions where one statement is true and vice versa. However, the task will be trivial in this case. Instead, we annotate a question using "yes" if the experiments and results in the paper indicate it, so the answer is not universal but context-dependent.

Given a question like "Do patients benefit from drug X?": certainly not all patients will benefit from it, but if there is a significant difference in an outcome between the experimental and control group, the answer will be "yes". If there is not, the answer will be "no".

"Maybe" is annotated when (1) the paper discusses conditions where the answer is True and conditions where the answer is False or (2) more than one intervention/observation/etc. is asked, and the answer is True for some but False for the others (e.g.: "Do Disease A, Disease B and/or Disease C benefit from drug X?"). To model uncertainty of the answer, we don't strictly follow the logic calculations where such questions can always be answered by either "yes" or "no".

Quick and (not so) Dirty: Unsupervised Selection of Justification Sentences for Multi-hop Question Answering

Vikas Yadav, Steven Bethard, Mihai Surdeanu
University of Arizona, Tucson, AZ, USA
{vikasy, bethard, msurdeanu}@email.arizona.edu

Abstract

We propose an unsupervised strategy for the selection of justification sentences for multi-hop question answering (QA) that (a) maximizes the relevance of the selected sentences, (b) minimizes the overlap between the selected facts, and (c) maximizes the coverage of both question and answer. This unsupervised sentence selection method can be coupled with any supervised QA approach. We show that the sentences selected by our method improve the performance of a state-of-the-art supervised QA model on two multi-hop QA datasets: AI2's Reasoning Challenge (ARC) and Multi-Sentence Reading Comprehension (MultiRC). We obtain new state-of-the-art performance on both datasets among approaches that do not use external resources for training the QA system: 56.82% F1 on ARC (41.24% on Challenge and 64.49% on Easy) and 26.1% EM0 on MultiRC. Our justification sentences have higher quality than the justifications selected by a strong information retrieval baseline, e.g., by 5.4% F1 in MultiRC. We also show that our unsupervised selection of justification sentences is more stable across domains than a state-of-the-art supervised sentence selection method.

1 Introduction

Interpretable machine learning (ML) models, where the end user can understand how a decision was reached, are a critical requirement for the wide adoption of ML solutions in many fields such as healthcare, finance, and law (Samek et al., 2017; Alvarez-Melis and Jaakkola, 2017; Arras et al., 2017; Gilpin et al., 2018; Biran and Cotton, 2017)

For complex natural language processing (NLP) such as question answering (QA), human readable explanations of the inference process have been proposed as a way to interpret QA models (Zhou et al., 2018).

To which organ system do the esophagus, liver, pancreas, small intestine, and colon belong?
(A) reproductive system (B) excretory system
(C) **digestive system** (D) endocrine system

ROCC-selected justification sentences:
1. vertebrate **digestive system** has oral cavity, teeth and pharynx, *esophagus* and stomach, *small intestine, pancreas, liver* and the large intestine
2. **digestive system** consists liver, stomach, large intestine, *small intestine, colon*, rectum and anus

BM25-selected justification sentences:
1. their **digestive system** consists of a stomach, *liver*, *pancreas*, *small intestine*, and a large intestine
2. the *liver pancreas* and gallbladder are the solid organ of the **digestive system**

Figure 1: A multiple-choice question from the ARC dataset with the correct answer in bold, followed by justification sentences selected by our approach (ROCC) vs. sentences selected by a strong IR baseline (BM25). ROCC justification sentences fully cover the five key terms in the question (shown in italic), whereas BM25 misses two: *esophagus* and *colon*. Further, the second BM25 sentence is largely redundant with the first, not covering other query terms.

Recently, multiple datasets have been proposed for *multi-hop* QA, in which questions can only be answered when considering information from multiple sentences and/or documents (Clark et al., 2018; Khashabi et al., 2018a; Yang et al., 2018; Welbl et al., 2018; Mihaylov et al., 2018; Bauer et al., 2018; Dunn et al., 2017; Dhingra et al., 2017; Lai et al., 2017; Rajpurkar et al., 2018; Sun et al., 2019). The task of selecting justification sentences is complex for multi-hop QA, because of the additional knowledge aggregation requirement (examples of such questions and answers are shown in Figures 1 and 2). Although various neural QA methods have achieved high performance on some of these datasets (Sun et al., 2018; Trivedi et al., 2019; Tymoshenko et al., 2017; Seo et al., 2016; Wang and Jiang, 2016; De Cao et al., 2018; Back et al., 2018), we argue that more effort must be dedicated to explaining their inference process.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2578–2589,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

In this work we propose an *unsupervised* algorithm for the selection of *multi-hop* justifications from *unstructured* knowledge bases (KB). Unlike other supervised selection methods (Dehghani et al., 2019; Bao et al., 2016; Lin et al., 2018; Wang et al., 2018b,a; Tran and Niedereée, 2018; Trivedi et al., 2019), our approach does not require any training data for justification selection. Unlike approaches that rely on structured KBs, which are expensive to create, (Khashabi et al., 2016; Khot et al., 2017; Zhang et al., 2018; Khashabi et al., 2018b; Cui et al., 2017; Bao et al., 2016), our method operates over KBs of only unstructured texts. We demonstrate that our approach has a bigger impact on downstream QA approaches that use these justification sentences as additional signal than a strong baseline that relies on information retrieval (IR). In particular, the contributions of this work are:

(1) We propose an unsupervised, non-parametric strategy for the selection of justification sentences for multi-hop question answering (QA) that (a) maximizes the ***R***elevance of the selected sentences; (b) minimizes the lexical ***O***verlap between the selected facts; and (c) maximizes the lexical ***C***overage of both question and answer. We call our approach ROCC. ROCC operates by first creating $\binom{n}{k}$ justification sets from the top n sentences selected by the BM25 information retrieval model (Robertson et al., 2009), where k ranges from 2 to n, and then ranking them all by a formula that combines the three criteria above. The set with the top score becomes the set of justifications output by ROCC for a given question and candidate answer. As shown in Figure 1, the justification sentences selected by ROCC perform more meaningful knowledge aggregation than a strong IR baseline (BM25), which does not account for overlap (or complementarity) and coverage.

(2) ROCC can be coupled with any supervised QA approach that can use the selected justification sentences as additional signal. To demonstrate its effectiveness, we combine ROCC with a state-of-the-art QA method that relies on BERT (Devlin et al., 2018) to classify correct answers, using the text of the question, the answer, and (now) the justification sentences as input. On the Multi-Sentence Reading Comprehension (MultiRC) dataset (Khashabi et al., 2018a), we achieved a gain of 8.3% EM0 with ROCC justifications when compared to the case where the complete comprehension passage was provided to the BERT classifier. On AI2's Reasoning Challenge (ARC) dataset (Clark et al., 2018), the QA approach enhanced with ROCC justifications outperforms the QA method without justifications by 9.15% accuracy, and the approach that uses top sentences provided by BM25 by 2.88%. Further, we show that the justification sentences selected by ROCC are considerably more correct on their own than justifications selected by BM25 (e.g., the justification score in MultiRC was increased by 11.58% when compared to the best performing BM25 justifications), which indicates that the interpretability of the overall QA system was also increased.

(3) Lastly, our analysis indicates that ROCC is more stable across the different domains in the MultiRC dataset than a supervised strategy for the selection of justification sentences that relies on a dedicated BERT-based classifier, with a difference of over 10% F1 score in some configurations.

The ROCC system and the codes for generating all the analysis are provided here - `https://github.com/vikas95/AutoROCC`.

2 Related Work

The body of QA work that addresses the selection of justification sentences can be classified into roughly four categories: (a) supervised approaches that require training data to learn how to select justification sentences (i.e., questions and answers coupled with correct justifications); (b) methods that treat justifications as latent variables and learn jointly how to answer questions and how to select justifications from questions and answers alone; (c) approaches that rely on information retrieval to select justification sentences; and, lastly, (d) methods that do not use justification sentences at all.

In the first category, previous works (e.g., (Trivedi et al., 2019)) have used entailment resources including labeled trained datasets such as SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017) to train components for selecting justification sentences for QA. Other works have explicitly focused on training sentence selection components for QA models (Min et al., 2018; Lin et al., 2018; Wang et al., 2019). In datasets where gold justification sentences are not provided, researchers have trained such components by retrieving justifications from structured KBs (Cui et al., 2017; Bao et al., 2016; Zhang et al., 2016; Hao et al., 2017) such as ConceptNet (Speer et al., 2017), or from IR systems coupled

with denoising components (Wang et al., 2019). While these works offer exciting directions, they all rely on training data for justifications, which is expensive to generate and may not be available in real-world use cases.

The second group of methods tend to rely on reinforcement learning (Choi et al., 2017; Lai et al., 2018; Geva and Berant, 2018) or PageRank (Surdeanu et al., 2008) to learn how to select justification sentences without explicit training data. Other works have used end-to-end (mostly RNNs with attention mechanisms) QA architectures for learning to pay more attention on better justification sentences (Min et al., 2018; Seo et al., 2016; Yu et al., 2014; Gravina et al., 2018). While these approaches do not require annotated justifications, they need large amounts of question/answer pairs during training so they can discover the latent justifications. In contrast to these two directions, our approach requires no training data at all for the justification selection process.

The third category of methods utilize IR techniques to retrieve justifications from both unstructured (Yadav et al., 2019) and structured (Khashabi et al., 2016) KBs. Our approach is closer in spirit to this direction, but it is adjusted to account for more intentional knowledge aggregation. As we show in Section 4, this is important for both the quality of the justification sentences and the performance of the downstream QA system.

The last group of QA approaches learn how to classify answers without any justification sentences (Mihaylov et al., 2018; Sun et al., 2018; Devlin et al., 2018). While this has been shown to obtain good performance for answer classification, we do not focus on it in this work because these methods cannot easily explain their inference.

Note that some of the works discussed here transfer knowledge from external datasets into the QA task they address (Chung et al., 2017; Sun et al., 2018; Pan et al., 2019; Min et al., 2017; Qiu et al., 2018; Chen et al., 2017). In this work, we focus solely on the resources provided in the task itself because such compatible external resources may not be available in real-world applications of QA.

3 Approach

ROCC, coupled with a QA system, operates in the following steps (illustrated in Figure 2):

(1) Retrieval of candidate justification sentences: For datasets that rely on huge supporting KBs (e.g., ARC), we retrieve the top n sentences[1] from this KB using an IR query that concatenates the question and the candidate answer, similar to Clark et al. (2018); Yadav et al. (2019). We implemented this using the BM25 IR model with the default parameters in Lucene[2]. For reading comprehension datasets where the question is associated with a text passage (e.g., MultiRC), all the sentences in this passage become candidates.

(2) Generation of candidate justification sets: Since its focus is on knowledge aggregation, ROCC ranks *sets* of justification sentences (see below) rather than individual sentences. In this step we create candidate justification sets by generating $\binom{n}{k}$ groups of sentences from the previous n sentences, using multiple values of k.

(3) Ranking of candidate justification sets: For every candidate justification set, we calculate its ROCC score (see Section 3.1), which estimates the likelihood that this group of justifications explains the given answer. We then rank the justification sets in descending order of ROCC score, and choose the top set as the group of justifications that is the output of ROCC for the given question and answer. In MultiRC, we rearrange the justification sentences according to their original indexes in the given passage to bring coherence in the selected sequence of sentences.

(4) Answer classification: ROCC can be coupled with any supervised QA component for answer classification. In this work, we feed in the question, answer, and justification texts into a state-of-the-art classifier that relies on BERT (see Section 3.2). Because the justification sentences in the reading comprehension use case (e.g., MultiRC) come from the same passage and their sequence is likely to be coherent, we concatenate them into a single passage, and use a single BERT instance for classification. This approach is shown on the left side of the answer classification component in Figure 2. On the other hand, the justification sentences retrieved from an external KB (e.g., ARC) may not form a coherent passage when aggregated. For this reason, in the ARC use case, we classify each justification sentence separately (together with the question and candidate answer), and then average all these scores to produce a single score for the candidate answer (right-hand side of the figure).

[1] In this work we used $n = 20$ as in Yadav et al. (2019)

[2] https://lucene.apache.org

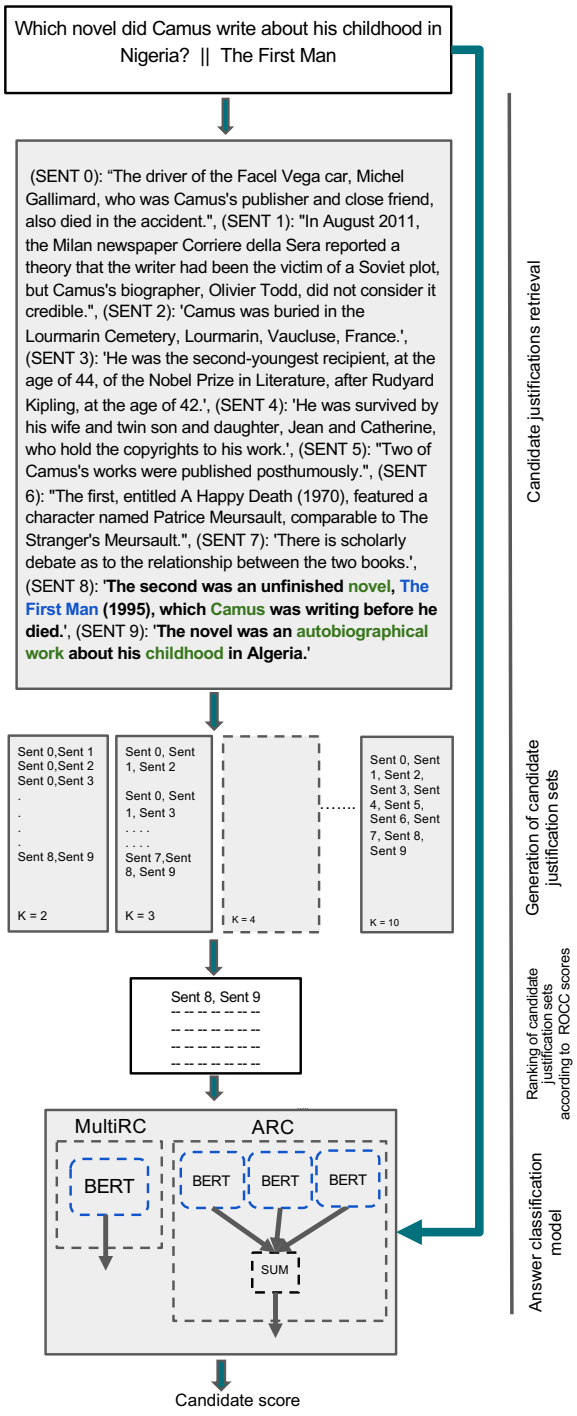

Figure 2: An example of the ROCC process for a question from the MultiRC dataset. Here, ROCC correctly extracts the two justification sentences necessary to explain the correct answer.

3.1 Ranking of Candidate Justification Sets

Each set of justifications is ranked based on its ROCC score, which: (a) maximizes the *R*elevance of the selected sentences; (b) minimizes the lexical *O*verlap between the selected facts; and (c) maximizes the lexical *C*overage of both question and answer (C_{ques}, C_{ans}). The overall score for a given justification set P_i is calculated as:

$$S(P_i) = \frac{R}{\epsilon + O(P_i)} \cdot (\epsilon + C(A)) \cdot (\epsilon + C(Q)) \quad (1)$$

To avoid zeros, we add a small constant ($\epsilon = 1$ here) to each component that can have a value of 0.[3] We detail the components of this formula below.

Relevance (R) We use the Lucene implementation[4] of the BM25 IR model (Robertson et al., 2009) to estimate the relevance of each justification sentence to a given question and candidate answer. In particular, we form a query that concatenates the question and candidate answer, and use as underlying document collection (necessary to compute document statistics such as inverse document frequencies (IDF)) either: sentences in the entire KB (for ARC), or all sentences in the corresponding passage in the case of reading comprehension (MultiRC). The arithmetic mean of BM25 scores over all sentences in a given justification set gives the value of R for the entire set.

Overlap (O) To ensure diversity and complementarity between justification sentences, we compute the overlap between all sentence pairs in a given group. Thus, minimizing this score reduces redundancy and encourages the aggregated sentences to address *different* parts of the question and answer:

$$O(S) = \frac{\sum_{s_i \in S} \sum_{s_j \in S - s_i} \frac{|t(s_i) \cap t(s_j)|}{\max(|t(s_i)|, |t(s_j)|)}}{\binom{|S|}{2}} \quad (2)$$

where S is the given set of justification sentences; s_i is the i^{th} sentence in S; and $t(s_i)$ denotes the set of unique terms in sentence s_i. Note that we divide by $\binom{|S|}{2}$ to normalize across different sizes of justification sets.

Coverage (C) Complementing the overlap score, this component measures the lexical coverage of the question and the answer texts by the given set of justifications S. This coverage is weighted by the IDF of question and answer terms. Thus, maximizing this value encourages the justifications to address more of the meaningful content mentioned

[3] Our R score relies on BM25, which is larger than 0 on the top n sentences.

[4] https://lucene.apache.org/core/7_0_1/core/org/apache/lucene/search/similarities/BM25Similarity.html

in the question ($X = Q$) and the answer ($X = A$):

$$C_t(X) = \bigcup_{s_i \in S} t(X) \cap t(s_i) \quad (3)$$

$$C(X) = \frac{\sum_{t=1}^{|C_t(X)|} IDF[C_t(X)[t]]}{|t(X)|} \quad (4)$$

where $t(X)$ denotes the unique terms in X, and $C_t(X)$ represents the set of all unique terms in X that are present in any of the sentences of the given justification set. $C(X)$ gives the IDF weighted average of $C_t(X)$ terms.

3.2 Answer Classification

As indicated earlier, we propose two flavors for the answer classification component: if the sentences in a justification group come from the same passage and, thus, are likely to be coherent, they are concatenated into a single text before classification, and handled by a single answer classifier. If the sentences come from different texts, they are handled by separate instances of the answer classifier. In the latter case, all scores are averaged to produce a single score for a candidate answer. In all situations we used BERT (Devlin et al., 2018) for answer classification. In particular, we employed BERT as a binary classifier operating over two texts. The first text consists of the concatenated question and answer, and the second text consists of the justification text. The classifier operates over the hidden states of the two texts, i.e., the state corresponding to the `[CLS]` token (Devlin et al., 2018).[5]

We observed empirically that pre-training the BERT classifier on *all* n sentences retrieved by BM25, and then fine tuning on the ROCC justifications improves performance on all datasets we experimented with. This resembles the transfer learning discussed by Howard and Ruder (2018), where the source domain would be the BM25 sentences, and the target domain the ROCC justifications. However, one important distinction is that, in our case, all this knowledge comes solely from the resources provided within each dataset, and is retrieved using unsupervised method (BM25). We conjecture that this helped mainly because the pre-training step exposed BERT to more data which, even if imperfect, is topically related to the corresponding question and answer.

[5]We used the following hyper parameters with BERT Large: learning rate of 1e-5, maximum sequence length of 128, batch size = 16, number of epochs = 6.

Question + answer text	Justification set
Animal cells obtain energy by || absorbing nutrients	1) obtain water and nutrient by absorbing them directly into plant cell 2) the animal obtain nourishment by absorbing nutrient released by symbiotic bacteria

Table 1: Example of a justification set in ARC which was scored by annotator with a precision of $\frac{1}{2}$ because the first justification sentence is not relevant, and a coverage of $\frac{1}{2}$ because the link between *nourishment* and *energy* is not covered.

4 Empirical Evaluation

We evaluated ROCC coupled with the proposed QA approach on two QA datasets. We use the standard train/development/test partitions for each dataset, as well as the standard evaluation measures: accuracy for ARC (Clark et al., 2018), and $F1_m$ (macro-F1 score), $F1_a$ (micro-F1 score), and EM0 (exact match) for MultiRC (Khashabi et al., 2018a).

Multi-sentence reading comprehension (MultiRC): this is a reading comprehension dataset implemented as multiple-choice QA (Khashabi et al., 2018a). Each question is accompanied by a supporting passage, which contains the correct answer. We use all sentences from such paragraphs as candidate justifications for the corresponding questions.

AI2's Reasoning Challenge (ARC): this is a multiple-choice question dataset, containing questions from science exams from grade 3 to grade 9 (Clark et al., 2018). The dataset is split in two partitions: Easy and Challenge, where the latter partition contains the more difficult questions that require reasoning. Most of the questions have 4 answer choices, with <1% of all the questions having either 3 or 5 answer choices. Importantly, ARC includes a supporting KB of 14.3M unstructured text passages. We use BM25 over this entire KB to retrieve candidate justification sentences for ROCC.

4.1 Justification Results

To demonstrate that ROCC has the capacity to select better justification sentences, we also report the quality of the extracted justification sentences. For MultiRC, we report precision/recall/F1 justification scores, computed against the gold justification sentences provided by the dataset.[6] For ARC, where gold justifications are not provided, we used an

[6]We use these gold justifications only for evaluation, *not* for training, since ROCC is an unsupervised algorithm.

Table 2: Performance on the MultiRC dataset, under various configurations. k indicates the size(s) of the sets of justification sentences. In parametric ROCC, k is a hyper parameter; in AutoROCC, k is selected automatically. The pre-trained ROCC configurations pre-train BERT on the entire passage corresponding to the question, before fine tuning it on the ROCC sentences. Bold values with * indicate state-of-the-art results that used external labeled resources or other supervised methods for the selection of justification sentences. Italicized bold values show state-of-the-art results from experiments that do not use any external labeled resources.

external annotator to annotate the justifications for a random stratified sample of 70 questions, with 10 questions selected from each grade (3 – 9).The annotator reported two scores: precision, and coverage. Precision was defined as the fraction of justification sentences that are relevant for the inference necessary to connect the corresponding question and candidate answer. Coverage was defined as 1 if the justification set completely covers the inference process for the given question and answer, $1/2$ if the set of justifications partially addresses the inference, and 0 if the justification set is completely irrelevant. Table 1 illustrates these scores with an actual output from ARC.

4.2 Question answering results

In addition to comparing ROCC with previously reported results, we include multiple baselines: (a) the BERT answer classifier trained on the entire passage of the given question (MultiRC), to demonstrate that ROCC has the capacity to filter out irrelevant content from these paragraphs; (b) BERT trained without any justification sentences (ARC), to show that ROCC has the capacity to aggregate useful information from large unstructured KBs, and (c) BERT trained on sentences retrieved using BM25, to demonstrate that ROCC performs better than other unsupervised approaches. Note that the

Table 3: Performance on the ARC dataset, under various configurations. Notations are the same as in Table 2.

BM25 baseline has an additional hyper parameter: the number of sentences to be considered (k).

Table 2 reports comprehensive results on MultiRC, including both overall QA performance, measured using $F1_m$, $F1_a$, and EM0, as well as justification quality, measured using standard precision (P), recall (R), and F1. Note that the bulk of the results are reported on the development partition. The last row in the table reports results on the test partition, computed using the official submission portal which can be accessed only once per model (including its variants). To understand ROCC's behavior, the table includes both the parametric form of ROCC, where the size of the justification sets (k) is manually tuned as well as the non-parametric ROCC, where k is automatically selected in the third step of the ROCC algorithm (see Figure 2) by sorting across all sizes of justification sets together, instead of sorting within each value of k. Table 3 lists equivalent results on ARC.

We draw several observations from these tables:

(1) Despite its simplicity, ROCC combined with the BERT classifier obtains new state-of-the-art performance on both MultiRC and ARC for the class of approaches that do not use external resources to either train the justification sentence selection or the answer classifier. For example, ROCC outperforms the previous best result in MultiRC by 2.5 EM0 points on the development partition (row 24 vs. row 6), and 1.6 EM0 points on test (row 30 vs. row 29). In ARC, ROCC outperforms the previous best approach by 5.8% accuracy on the Challenge partition, and 2.9% overall (row 23 vs. row 9).

(2) On both datasets, the non-parametric form of ROCC (AutoROCC) slightly outperforms the parametric variant. Importantly, it always achieves higher justification scores compared to the parametric ROCC. In MultiRC, AutoROCC outperforms our baseline of BERT + entire passage (row 10 vs 22) by 8.3% EM0, indicating that AutoROCC can filter out irrelevant content. In ARC, AutoROCC outperforms the baseline with no justification sentences by 9.1% (row 21 vs row 11), demonstrating that ROCC aggregates useful knowledge.

(3) The results of the parametric forms of ROCC (rows 16 – 19 in Table 2 and rows 17 – 20 in Table 3) indicate that performance continues to increase until $k = 4$ in MultiRC and $k = 3$ in ARC. This indicates that: (a) knowledge aggregation is beneficial for these tasks; (b) ROCC can robustly handle non-trivial cases of aggregation with larger values of k; and (c) similar to other QA methods (Chen and Durrett, 2019), performance

train/test	Science textbook	Fiction	News	Wiki articles	wikiMovie Summaries	Society, Law and Justice	All
AutoROCC	54.57	53.88	54.32	60.49	57.10	61.06	56.44

Table 4: Domain robustness of the non-parametric ROCC vs. a supervised sentence selection model, evaluated on the gold justification sentences from MultiRC. Each column represents a section of the MultiRC development set. Each row after AutoROCC represents a justification sentence selection component trained only on the specified section of MultiRC (these sections are listed in descending order of the number of passages in the training data).

decreases for large values of k, suggesting that knowledge aggregation remains an open research challenge.

(4) The justification scores in both datasets are considerably higher than the equivalent configuration that uses BM25 instead of ROCC (i.e., row 24 vs. row 23 in Table 2, and row 23 vs. row 22 in Table 3). This confirms that the *joint* scoring of sets of justifications that ROCC performs is better than the individual ranking of justification sentences performed by standard IR models such as BM25.

4.3 Domain Robustness Analysis

To understand ROCC's domain robustness, we compared it against a supervised BERT-based classifier for the selection of justification sentences, as well as against GPT-2 (Wang et al., 2019). For this experiment, we used MultiRC, where gold justifications are provided. We used this data to train a classifier for the selection of justification sentences on various domain-specific sections of MultiRC. The results of this experiment are shown in Table 4. Unsurprisingly, training and testing in the same domain (e.g., Fiction) leads to the best performance on sentence selection. However, ROCC is more stable across domains than the supervised sentence selection component, with a difference of over 10 F1 points in some configurations. This suggests that ROCC is a better solution for real-world use cases where the distribution of the test data may be very different from the training data.

Compared to BERT, the unsupervised AutoROCC achieves almost the same or better performance in the majority of the domains except Wiki articles and News. We conjecture this happens because the BERT language model was trained on a large text corpus that comes from these two domains. However, importantly, AutoROCC is more robust across domains that are different from these two, since it is an unsupervised approach that is not tuned for any specific domain.

#	Ablations	ARC	MultiRC EM0	MultiRC Justification F1
0	Full AutoROCC	**56.09**	**25.29**	**56.44**
1	– IDF	54.11	24.65	54.19
2	– $C(A)$	54.90	21.82	52.93
3	– $C(Q)$	54.66	23.61	52.09
4	– O	55.88	24.03	55.97
5	R*	53.90	23.40	44.81

Table 5: Ablation study, removing different components of ROCC. The scores are reported on the ARC test set and MultiRC dev set. R* denotes the best approach that relies just on the R score. The hyper parameter k in R*, was tuned on the development partition of the respective dataset.

The ARC dataset does not provide justification sentences, so we instead ask how well our question-answering models do on a related inference task, the SciTail entailment dataset (Khot et al., 2018). We trained three QA classifiers on the ARC dataset: BERT with no justification, BERT with BM25 ($k = 4$) justifications, and BERT with AutoROCC justifications. We tested these on SciTail, and achieved 64.49%, 69.70%, and 73.46% accuracy, respectively, indicating that AutoROCC's knowledge aggregation is a valid proxy for entailment.

4.4 Ablation Analysis

Table 5 shows an ablation of the different components of ROCC. Row 0 reports the score from the full AutoROCC model. In row 1, we remove IDF weights from coverage calculations (see eq. (4))

Question type	Precision	Recall	F-1 score
True/False/Yes/No	54.1	68.9	60.6
Verbatim	49.7	71.2	58.5
Non-verbatim	47.3	68.7	56.0

Table 6: Justification selection performance of AutoROCC on different types of questions, in the MultiRC development dataset.

of both question and answer text. In row 2, 3 and 4, we remove the coverage of answer, coverage of question, and overlap from the ROCC formula (see eq. (1)) respectively. In all the cases, we found small drops in both performance and justification scores across both the datasets, with the removal of either $C(A)$ or $C(Q)$ having the largest impact.

4.5 Error Analysis

We analyzed ROCC's justification selection performance on three different types of questions in MultiRC: True/False/Yes/No, Verbatim, and Non-verbatim (Khashabi et al., 2018b). As shown in Table 6, AutoROCC achieves higher recall scores on Verbatim questions, where the answer text is likely to appear within the given justification passage, and worse recall on question types where such overlap does not exist, e.g., Non-verbatim and True/False. This suggests that the $C(A)$ component of ROCC is important for the extraction of meaningful justifications.

4.6 Alignment ROCC

To understand the dependence between ROCC and exact lexical match, we compare the justification selection performance of ROCC when its score components are computed based on lexical match (the approach used throughout the paper up to this point) vs. the semantic alignment match of Yadav et al. (2018). The latter approach relaxes the requirement for lexical match, i.e., two tokens are considered to be matched when the cosine similarity of their embedding vectors is larger than 0.95.[7] As shown in Table 7, the alignment-based ROCC indeed performs better than the ROCC that relies on lexical match. However, the improvements are not large, e.g., the maximum improvement is 1.6% (when $k = 4$), which indicates that ROCC is robust to a certain extent to lexical variation.

[7]This threshold was tuned on the MultiRC development set. We used 100-dimensional GloVe embeddings for this experiment, which performed similarly to larger embedding vectors (300), but allowed for faster experiments.

ROCC (k sentences)	Lexical ROCC	Align. ROCC
ROCC ($k = 2$ sentences)	51.4	51.4
ROCC ($k = 3$ sentences)	54.7	55.5
ROCC ($k = 4$ sentences)	51.6	53.2
ROCC ($k = 5$ sentences)	48.1	49.2

Table 7: Justification selection performance of the ROCC configuration that uses lexical match (BM25) to retrieve candidate justifications (Lexical ROCC), compared against a ROCC variant that uses the semantic alignment approach of Yadav et al. (2018) to retrieve candidates (Align. ROCC). This experiment used the MultiRC development dataset.

5 Conclusion

We introduced ROCC, a simple unsupervised approach for selecting justification sentences for question answering, which balances relevance, overlap of selected sentences, and coverage of the question and answer. We coupled this method with a state-of-the-art BERT-based supervised question answering system, and achieved a new state-of-the-art on the MultiRC and ARC datasets among approaches that do not use external resources during training. We showed that ROCC-based QA approaches are more robust across domains, and generalize better to other related tasks like entailment. In the future, we envision that ROCC scores can be used as distant supervision signal to train supervised justification selection methods.

Abstract

It is challenging for current one-step retrieve-and-read question answering (QA) systems to answer questions like *"Which novel by the author of 'Armada' will be adapted as a feature film by Steven Spielberg?"* because the question seldom contains retrievable clues about the missing entity (here, the author). Answering such a question requires multi-hop reasoning where one must gather information about the missing entity (or facts) to proceed with further reasoning. We present GOLDEN (Gold Entity) Retriever, which iterates between reading context and retrieving more supporting documents to answer open-domain multi-hop questions. Instead of using opaque and computationally expensive neural retrieval models, GOLDEN Retriever generates natural language search queries given the question and available context, and leverages off-the-shelf information retrieval systems to query for missing entities. This allows GOLDEN Retriever to scale up efficiently for open-domain multi-hop reasoning while maintaining interpretability. We evaluate GOLDEN Retriever on the recently proposed open-domain multi-hop QA dataset, HOTPOTQA, and demonstrate that it outperforms the best previously published model despite not using pretrained language models such as BERT.

1 Introduction

Open-domain question answering (QA) is an important means for us to make use of knowledge in large text corpora and enables diverse queries without requiring a knowledge schema ahead of time. Enabling such systems to perform multi-step inference can further expand our capability to explore the knowledge in these corpora (*e.g.*, see Figure 1).

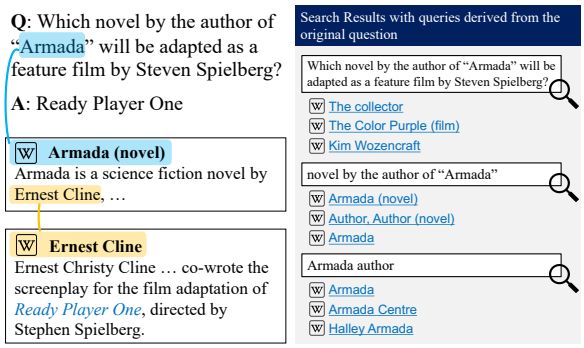

Figure 1: An example of an open-domain multi-hop question from the HOTPOTQA dev set, where "Ernest Cline" is the missing entity. Note from the search results that it cannot be easily retrieved based on merely the question. (Best viewed in color)

Fueled by the recently proposed large-scale QA datasets such as SQuAD (Rajpurkar et al., 2016, 2018) and TriviaQA (Joshi et al., 2017), much progress has been made in open-domain question answering. Chen et al. (2017) proposed a two-stage approach of retrieving relevant content with the question, then reading the paragraphs returned by the information retrieval (IR) component to arrive at the final answer. This "*retrieve and read*" approach has since been adopted and extended in various open-domain QA systems (Nishida et al., 2018; Kratzwald and Feuerriegel, 2018), but it is inherently limited to answering questions that do not require multi-hop/multi-step reasoning. This is because for many multi-hop questions, not all the relevant context can be obtained in a single retrieval step (*e.g.*, "Ernest Cline" in Figure 1).

More recently, the emergence of multi-hop question answering datasets such as QAngaroo (Welbl et al., 2018) and HOTPOTQA (Yang et al., 2018) has sparked interest in multi-hop QA in the research community. Designed to be more challenging than SQuAD-like datasets, they feature questions that require context of more than one

*Equal contribution, order decided by a random number generator.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2590–2602, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

document to answer, testing QA systems' abilities to infer the answer in the presence of multiple pieces of evidence and to efficiently find the evidence in a large pool of candidate documents. However, since these datasets are still relatively new, most of the existing research focuses on the few-document setting where a relatively small set of context documents is given, which is guaranteed to contain the "gold" context documents, all those from which the answer comes (De Cao et al., 2019; Zhong et al., 2019).

In this paper, we present GOLDEN (Gold Entity) Retriever. Rather than relying purely on the original question to retrieve passages, the central innovation is that at each step the model also uses IR results from previous hops of reasoning to generate a new natural language query and retrieve new evidence to answer the original question. For the example in Figure 1, GOLDEN would first generate a query to retrieve *Armada (novel)* based on the question, then query for *Ernest Cline* based on newly gained knowledge in that article. This allows GOLDEN to leverage off-the-shelf, general-purpose IR systems to scale open-domain multi-hop reasoning to millions of documents efficiently, and to do so in an interpretable manner. Combined with a QA module that extends BiDAF++ (Clark and Gardner, 2017), our final system outperforms the best previously published system on the open-domain (fullwiki) setting of HOTPOTQA without using powerful pretrained language models like BERT (Devlin et al., 2019).

The main contributions of this paper are: (a) a novel iterative retrieve-and-read framework capable of multi-hop reasoning in open-domain QA;[1] (b) a natural language query generation approach that guarantees interpretability in the multi-hop evidence gathering process; (c) an efficient training procedure to enable query generation with minimal supervision signal that significantly boosts recall of gold supporting documents in retrieval.

2 Related Work

Open-domain question answering (QA) Inspired by the series of TREC QA competitions,[2] Chen et al. (2017) were among the first to adapt neural QA models to the open-domain setting. They built a simple inverted index lookup with TF-IDF on the English Wikipedia, and used the question as the query to retrieve top 5 results for a reader model to produce answers with. Recent work on open-domain question answering largely follow this retrieve-and-read approach, and focus on improving the information retrieval component with question answering performance in consideration (Nishida et al., 2018; Kratzwald and Feuerriegel, 2018; Nogueira et al., 2019). However, these one-step retrieve-and-read approaches are fundamentally ill-equipped to address questions that require multi-hop reasoning, especially when necessary evidence is not readily retrievable with the question.

Multi-hop QA datasets QAngaroo (Welbl et al., 2018) and HOTPOTQA (Yang et al., 2018) are among the largest-scale multi-hop QA datasets to date. While the former is constructed around a knowledge base and the knowledge schema therein, the latter adopts a free-form question generation process in crowdsourcing and span-based evaluation. Both datasets feature a few-document setting where the gold supporting facts are provided along with a small set of distractors to ease the computational burden. However, researchers have shown that this sometimes results in gameable contexts, and thus does not always test the model's capability of multi-hop reasoning (Chen and Durrett, 2019; Min et al., 2019a). Therefore, in this work, we focus on the fullwiki setting of HOTPOTQA, which features a truly open-domain setting with more diverse questions.

Multi-hop QA systems At a broader level, the need for multi-step searches, query task decomposition, and subtask extraction has been clearly recognized in the IR community (Hassan Awadallah et al., 2014; Mehrotra et al., 2016; Mehrotra and Yilmaz, 2017), but multi-hop QA has only recently been studied closely with the release of large-scale datasets. Much research has focused on enabling multi-hop reasoning in question answering models in the few-document setting, *e.g.*, by modeling entity graphs (De Cao et al., 2019) or scoring answer candidates against the context (Zhong et al., 2019). These approaches, however, suffer from scalability issues when the number of supporting documents and/or answer candidates grow beyond a few dozen. Ding et al. (2019) apply entity graph modeling to HOTPOTQA, where

[1] Code and pretrained models available at https://github.com/qipeng/golden-retriever

[2] http://trec.nist.gov/data/qamain.html

they expand a small entity graph starting from the question to arrive at the context for the QA model. However, centered around entity names, this model risks missing purely descriptive clues in the question. Das et al. (2019) propose a neural retriever trained with distant supervision to bias towards paragraphs containing answers to the given questions, which is then used in a multi-step reader-reasoner framework. This does not fundamentally address the discoverability issue in open-domain multi-hop QA, however, because usually not all the evidence can be directly retrieved with the question. Besides, the neural retrieval model lacks explainability, which is crucial in real-world applications. Talmor and Berant (2018), instead, propose to answer multi-hop questions at scale by decomposing the question into sub-questions and perform iterative retrieval and question answering, which shares very similar motivations as our work. However, the questions studied in that work are based on logical forms of a fixed schema, which yields additional supervision for question decomposition but limits the diversity of questions. More recently, Min et al. (2019b) apply a similar idea to HotpotQA, but this approach similarly requires additional annotations for decomposition, and the authors did not apply it to iterative retrieval.

3 Model

In this section, we formally define the problem of open-domain multi-hop question answering, and motivate the architecture of the proposed GoldEn (Gold Entity) Retriever model. We then detail the query generation components as well as how to derive supervision signal for them, before concluding with the QA component.

3.1 Problem Statement

We define the problem of *open-domain multi-hop QA* as one involving a question q, and S relevant (gold) supporting context documents $d_1, \ldots, d_S$ which contain the desired answer a.[3] These supporting documents form a chain of reasoning necessary to arrive at the answer, and they come from a large corpus of documents $\mathcal{D}$ where $|\mathcal{D}| \gg S$. In this chain of reasoning, the supporting documents are usually connected via shared entities or textual similarities (*e.g.*, they describe similar entities or events), but these connections do not necessarily conform to any predefined knowledge schema.

We contrast this to what we call the *few-document setting* of multi-hop QA, where the QA system is presented with a small set of documents $\mathcal{D}_{\text{few-doc}} = \{d_1, \ldots, d_S, d'_1, \ldots, d'_D\}$, where $d'_1, \ldots, d'_D$ comprise a small set of "distractor" documents that test whether the system is able to pick out the correct set of supporting documents in the presence of noise. This setting is suitable for testing QA systems' ability to perform multi-hop reasoning given the gold supporting documents with bounded computational budget, but we argue that it is far from a realistic one. In practice, an open-domain QA system has to locate all gold supporting documents from $\mathcal{D}$ on its own, and as shown in Figure 1, this is often difficult for multi-hop questions based on the original question alone, as not all gold documents are easily retrievable given the question.

To address this gold context discoverability issue, we argue that it is necessary to move away from a single-hop retrieve-and-read approach where the original question serves as the search query. In the next section, we introduce GoldEn Retriever, which addresses this problem by iterating between retrieving more documents and reading the context for multiple rounds.

3.2 Model Overview

Essentially, the challenge of open-domain multi-hop QA lies in the fact that the information need of the user $(q \rightarrow a)$ cannot be readily satisfied by any information retrieval (IR) system that models merely the similarity between the question q and the documents. This is because the true information need will only unfold with progressive reasoning and discovery of supporting facts. Therefore, one cannot rely solely on a similarity-based IR system for such iterative reasoning, because the potential pool of relevant documents grows exponentially with the number of hops of reasoning.

To this end, we propose GoldEn (Gold Entity) Retriever, which makes use of the gold document[4] information available in the QA dataset at training time to iteratively query for more relevant supporting documents during each hop of reasoning. Instead of relying on the original question as the search query to retrieve all supporting facts,

[3] In this work, we only consider extractive, or span-based, QA tasks, but the problem statement and the proposed method apply to generative QA tasks as well.

[4] In HotpotQA, documents usually describe entities, thus we use "documents" and "entities" interchangeably.

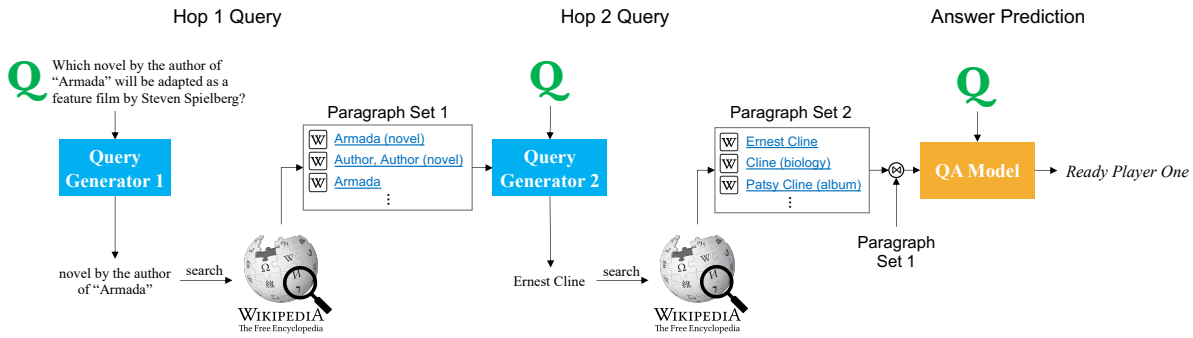

Figure 2: Model overview of GOLDEN Retriever. Given an open-domain multi-hop question, the model iteratively retrieves more context documents, and concatenates all retrieved context for a QA model to answer from.

or building computationally expensive search engines that are less interpretable to humans, we propose to leverage text-based IR engines for interpretability, and generate different search queries as each reasoning step unfolds. In the very first hop of reasoning, GOLDEN Retriever is presented the original question q, from which it generates a search query q_1 that retrieves supporting document d_1.[5] Then for each of the subsequent reasoning steps ($k = 2, \ldots, S$), GOLDEN Retriever generates a query q_k from the question and the available context, $(q, d_1, \ldots, d_{k-1})$. This formulation allows the model to generate queries based on information revealed in the supporting facts (see Figure 2, for example).

We note that GOLDEN Retriever is much more efficient, scalable, and interpretable at retrieving gold documents compared to its neural retrieval counterparts. This is because GOLDEN Retriever does not rely on a QA-specific IR engine tuned to a specific dataset, where adding new documents or question types into the index can be extremely inefficient. Further, GOLDEN Retriever generates queries in natural language, making it friendly to human interpretation and verification. One core challenge in GOLDEN Retriever, however, is to train query generation models in an efficient manner, because the search space for potential queries is enormous and off-the-shelf IR engines are not end-to-end differentiable. We outline our solution to this challenge in the following sections.

3.3 Query Generation

For each reasoning step, we need to generate the search query given the original question q and some context of documents we have already retrieved (initially empty). This query generation problem is conceptually similar to the QA task in that they both map a question and some context to a target, only instead of an answer, the target here is a search query that helps retrieve the desired supporting document for the next reasoning step. Therefore, we formulate the query generation process as a question answering task.

To reduce the potentially large space of possible queries, we favor a QA model that extracts text spans from the context over one that generates free-form text as search queries. We therefore employ DrQA's Document Reader model (Chen et al., 2017), which is a relatively light-weight recurrent neural network QA model that has demonstrated success in few-document QA. We adapt it to query generation as follows.

For each reasoning step $k = 1, \ldots, S$, given a question q and some *retrieval context* C_k which *ideally* contains the gold supporting documents $d_1, \ldots, d_{k-1}$, we aim to generate a search query q_k that helps us retrieve d_k for the next reasoning step. A Document Reader model is trained to select a span from C_k as the query

$$q_k = G_k(q, C_k),$$

where G_k is the query generator. This query is then used to search for supporting documents, which are concatenated with the current retrieval context to update it

$$C_{k+1} = C_k \bowtie \text{IR}_n(q_k)$$

where $\text{IR}_n(q_k)$ is the top n documents retrieved from the search engine using q_k, and $C_1 = q$.[6] At the end of the retrieval steps, we provide q as question along with C_S as context to the final few-

[5] For notational simplicity, d_k denotes the supporting document needed to complete the k-th step of reasoning. We also assume that the goal of each IR query is to retrieve one and only one gold supporting document in its top n results.

[6] In the query result, the title of each document is delimited with special tokens <t> and </t> before concatenation.

Question	Hop 1 Oracle	Hop 2 Oracle
What government position was held by the woman who portrayed Corliss Archer in the film Kiss and Tell?	Corliss Archer in the film Kiss and Tell	Shirley Temple
Scott Parkin has been a vocal critic of Exxonmobil and another corporation that has operations in how many countries?	Scott Parkin	Halliburton
Are Giuseppe Verdi and Ambroise Thomas both Opera composers?	Giuseppe Verdi	Ambroise Thomas

Table 1: Example oracle queries on the HOTPOTQA dev set.

document QA component detailed in Section 3.5 to obtain the final answer to the original question.

To train the query generators, we follow the steps above to construct the retrieval contexts, but during training time, when d_k is not part of the IR result, we replace the lowest ranking document with d_k before concatenating it with C_k to make sure the downstream models have access to necessary context.

3.4 Deriving Supervision Signal for Query Generation

When deriving supervision signal to train our query generators, the potential search space is enormous for each step of reasoning even if we constrain ourselves to predicting spans from the context. This is aggravated by multiple hops of reasoning required by the question. One solution to this issue is to train the query generators with reinforcement learning (RL) techniques (*e.g.*, REINFORCE (Sutton et al., 2000)), where (Nogueira and Cho, 2017) and (Buck et al., 2018) are examples of one-step query generation with RL. However, it is computationally inefficient, and has high variance especially for the second reasoning step and forward, because the context depends greatly on what queries have been chosen previously and their search results.

Instead, we propose to leverage the limited supervision we have about the gold supporting documents $d_1, \ldots, d_S$ to narrow down the search space. The key insight we base our approach on is that at any step of open-domain multi-hop reasoning, there is some *semantic overlap* between the retrieval context and the next document(s) we wish to retrieve. For instance, in our *Armada* example, when the retrieval context contains only the question, this overlap is the novel itself; after we have expanded the retrieval context, this overlap becomes the name of the author, *Ernest Cline*. Finding this semantic overlap between the retrieval context and the desired documents not only reveals the chain of reasoning naturally, but also allows us to use it as the search query for retrieval.

Because off-the-shelf IR systems generally optimize for shallow lexical similarity between query and candidate documents in favor of efficiency, a good proxy for this overlap is locating spans of text that have high lexical overlap with the intended supporting documents. To this end, we propose a simple yet effective solution, employing several heuristics to generate candidate queries: computing the longest common string/sequence between the current retrieval context and the title/text of the intended paragraph ignoring stop words, then taking the contiguous span of text that corresponds to this overlap in the retrieval context. This allows us to not only make use of entity names, but also textual descriptions that better lead to the gold entities. It is also more generally applicable than question decomposition approaches (Talmor and Berant, 2018; Min et al., 2019b), and does not require additional annotation for decomposition.

Applying various heuristics results in a handful of candidate queries for each document, and we use our IR engine (detailed next) to rank them based on recall of the intended supporting document to choose one as the final oracle query we train our query generators to predict. This allows us to train the query generators in a fully supervised manner efficiently. Some examples of oracle queries on the HOTPOTQA dev set can be found in Table 1. We refer the reader to Appendix B for more technical details about our heuristics and how the oracle queries are derived.

Oracle Query vs Single-hop Query We evaluate the oracle query against the single-hop query, i.e., querying with the original question, on the HOTPOTQA dev set. Specifically, we compare the recall of gold paragraphs, because the greater the recall, the fewer documents we need to pass into the expensive neural multi-hop QA component.

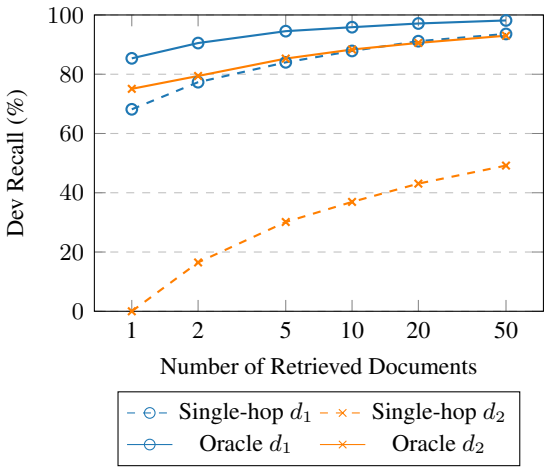

Figure 3: Recall comparison between single-hop queries and GOLDEN Retriever oracle queries for both supporting paragraphs on the HOTPOTQA dev set. Note that the oracle queries are much more effective than the original question (single-hop query) at retrieving target paragraphs in both hops.

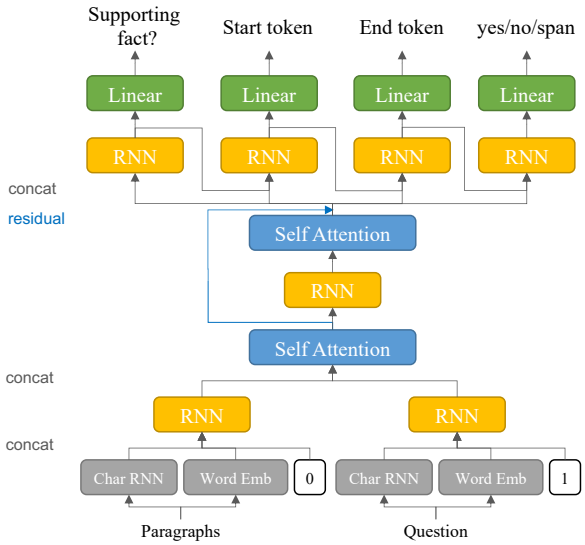

Figure 4: Question answering component in GOLDEN Retriever. (Best viewed in color)

We index the English Wikipedia dump with introductory paragraphs provided by the HOTPOTQA authors[7] with Elasticsearch 6.7 (Gormley and Tong, 2015), where we index the titles and document text in separate fields with bigram indexing enabled. This results in an index with 5,233,329 total documents. At retrieval time, we boost the scores of any search result whose title matches the search query better – this results in a better recall for entities with common names (*e.g.*, "*Armada*" the novel). For more details about how the IR engine is set up and the effect of score boosting, please refer to Appendix A.

In Figure 3, we compare the recall of the two gold paragraphs required for each question in HOTPOTQA at various number of documents retrieved (R@n) for the single-hop query and the multi-hop queries generated from the oracle. Note that the oracle queries are much more effective at retrieving the gold paragraphs than the original question in both hops. For instance, if we combine R@5 of both oracles (which effectively retrieves 10 documents from two queries) and compare that to R@10 for the single-hop query, the oracle queries improve recall for d_1 by 6.68%, and that for d_2 by a significant margin of 49.09%.[8] This means that the final QA model will need to consider far fewer documents to arrive at a decent set of supporting facts that lead to the answer.

3.5 Question Answering Component

The final QA component of GOLDEN Retriever is based on the baseline model presented in (Yang et al., 2018), which is in turn based on BiDAF++ (Clark and Gardner, 2017). We make two major changes to this model. Yang et al. (2018) concatenated all context paragraphs into one long string to predict span begin and end offsets for the answer, which is potentially sensitive to the order in which these paragraphs are presented to the model. We instead process them separately with shared encoder RNN parameters to obtain paragraph order-insensitive representations for each paragraph. Span offset scores are predicted from each paragraph independently before finally aggregated and normalized with a global softmax operation to produce probabilities over spans. The second change is that we replace all attention mechanism in the original model with self attention layers over the concatenated question and context. To differentiate context paragraph representations from question representations in this self-attention mechanism, we indicate question and context tokens by concatenating a 0/1 feature at the input layer. Figure 4 illustrates the QA model architecture.

[7] https://hotpotqa.github.io/wiki-readme.html

[8] Since HOTPOTQA does not provide the logical order its gold entities should be discovered, we simply call the document d_1 which is more easily retrievable with the queries, and the other as d_2.

System	Answer		Sup Fact		Joint	
	EM	F_1	EM	F_1	EM	F_1
Baseline (Yang et al., 2018)	25.23	34.40	5.07	40.69	2.63	17.85

Table 2: End-to-end QA performance of baselines and our GOLDEN Retriever model on the HOTPOTQA fullwiki test set. Among systems that were not published at the time of submission of this paper, "BERT pip." was submitted to the official HOTPOTQA leaderboard on May 15th (thus contemporaneous), while "Entity-centric BERT Pipeline" and "PR-Bert" were submitted after the paper submission deadline.

4 Experiments

4.1 Data and Setup

We evaluate our models in the fullwiki setting of HOTPOTQA (Yang et al., 2018). HOTPOTQA is a question answering dataset collected on the English Wikipedia, containing about 113k crowd-sourced questions that are constructed to require the introduction paragraphs of two Wikipedia articles to answer. Each question in the dataset comes with the two gold paragraphs, as well as a list of sentences in these paragraphs that crowdworkers identify as supporting facts necessary to answer the question. A diverse range of reasoning strategies are featured in HOTPOTQA, including questions involving missing entities in the question (our *Armada* example), intersection questions (*What satisfies property A and property B?*), and comparison questions, where two entities are compared by a common attribute, among others. In the few-document *distractor* setting, the QA models are given ten paragraphs in which the gold paragraphs are guaranteed to be found; in the open-domain *fullwiki* setting, which we focus on, the models are only given the question and the entire Wikipedia. Models are evaluated on their answer accuracy and explainability, where the former is measured as overlap between the predicted and gold answers with exact match (EM) and unigram F_1, and the latter concerns how well the predicted supporting fact sentences match human annotation (Supporting Fact EM/F_1). A joint metric is also reported on this dataset, which encourages systems to perform well on both tasks simultaneously.

We use the Stanford CoreNLP toolkit (Manning et al., 2014) to preprocess Wikipedia, as well as to generate POS/NER features for the query generators, following (Yang et al., 2018) and (Chen et al., 2017). We always detokenize a generated search query before sending it to Elasticsearch, which has its own preprocessing pipeline. Since all questions in HOTPOTQA require exactly two supporting documents, we fix the number of retrieval steps of GOLDEN Retriever to $S = 2$. To accommodate arbitrary steps of reasoning in GOLDEN Retriever, a stopping criterion is required to determine when to stop retrieving for more supporting documents and perform few-document question answering, which we leave to future work. During training and evaluation, we set the number of retrieved documents added to the retrieval context to 5 for each retrieval step, so that the total number of paragraphs our final QA model considers is 10, for a fair comparison to (Yang et al., 2018).

We include hyperparameters and training details in Appendix C for reproducibility.

4.2 End-to-end Question Answering

We compare the end-to-end performance of GOLDEN Retriever against several QA systems on the HOTPOTQA dataset: (1) the baseline presented in (Yang et al., 2018), (2) CogQA (Ding et al., 2019), the top-performing previously published system, and (3) other high-ranking systems on the leaderboard. As shown in Table 2, GOLDEN Retriever is much better at locating the correct supporting facts from Wikipedia compared

Setting	Ans F_1	Sup F_1	R@10*
GOLDEN Retriever	49.79	64.58	75.46
Single-hop query	38.19	54.82	62.38
HOTPOTQA IR	36.34	46.78	55.71

Table 3: Question answering and IR performance amongst different IR settings on the dev set. We observe that although improving the IR engine is helpful, most of the performance gain results from the iterative retrieve-and-read strategy of GOLDEN Retriever. (*: for GOLDEN Retriever, the 10 paragraphs are combined from both hops, 5 from each hop.)

System	Ans F_1	Sup F_1	Joint F_1
GOLDEN Retriever	49.79	64.58	40.21
w/ Hop 1 oracle	52.53	68.06	42.68
w/ Hop 1 & 2 oracles	62.32	77.00	52.18

Table 4: Pipeline ablative analysis of GOLDEN Retriever end-to-end QA performance by replacing each query generator with a query oracle.

to CogQA, as well as most of the top-ranking systems. However, the QA performance is handicapped because we do not make use of pretrained contextualization models (*e.g.*, BERT) that these systems use. We expect a boost in QA performance from adopting these more powerful question answering models, especially ones that are tailored to perform few-document multi-hop reasoning. We leave this to future work.

To understand the contribution of GOLDEN Retriever's iterative retrieval process compared to that of the IR engine, we compare the performance of GOLDEN Retriever against two baseline systems on the dev set: one that retrieves 10 supporting paragraphs from Elasticsearch with the original question, and one that uses the IR engine presented in HOTPOTQA.[9] In all cases, we use the QA component in GOLDEN Retriever for the final question answering step. As shown in Table 3, replacing the hand-engineered IR engine in (Yang et al., 2018) with Elasticsearch does result in some gain in recall of the gold documents, but that does not translate to a significant improvement in QA performance. Further inspection reveals that despite Elasticsearch improving overall recall of gold documents, it is only able to retrieve both gold documents for 36.91% of the dev set questions, in comparison to 28.21% from the IR engine in (Yang et al., 2018). In contrast, GOLDEN Retriever improves this percentage to 61.01%, almost doubling the recall over the single-hop baseline, providing the QA component a much better set of context documents to predict answers from.

Lastly, we perform an ablation study in which we replace our query generator models with our query oracles and observe the effect on end-to-end performance. As can be seen in Table 4, replacing G_1 with the oracle only slightly improves end-to-end performance, but further substituting G_2 with the oracle yields a significant improvement. This illustrates that the performance loss is largely attributed to G_2 rather than G_1, because G_2 solves a harder span selection problem from a longer retrieval context. In the next section, we examine the query generation models more closely by evaluating their performance without the QA component.

4.3 Analysis of Query Generation

To evaluate the query generators, we begin by determining how well they emulate the oracles. We evaluate them using Exact Match (EM) and F_1 on the span prediction task, as well as compare their queries' retrieval performance against the oracle queries. As can be seen in Table 6, the performance of G_2 is worse than that of G_1 in general, confirming our findings on the end-to-end pipeline. When we combine them into a pipeline, the generated queries perform only slightly better on d_1 when a total of 10 documents are retrieved (89.91% vs 87.85%), but are significantly more effective for d_2 (61.01% vs 36.91%). If we further zoom in on the retrieval performance on non-comparison questions for which finding the two entities involved is less trivial, we can see that the recall on d_2 improves from 27.88% to 53.23%, almost doubling the number of questions we have the complete gold context to answer. We note that the IR performance we report on the full pipeline is different to that when we evaluate the query generators separately. We attribute this difference to the fact that the generated queries sometimes retrieve both gold documents in one step.

To better understand model behavior, we also randomly sampled some examples from the dev set to compare the oracle queries and the predicted queries. Aside from exact matches, we find that the predicted queries are usually small variations of the oracle ones. In some cases, the model selects spans that are more natural and informative

[9] For the latter, we use the fullwiki test input file the authors released, which contains the top-10 IR output from that retrieval system with the question as the query.

	Question	Predicted q_1	Predicted q_2
(1)	What video game character did the voice actress in the animated film Alpha and Omega voice?	voice actress in the animated film Alpha and Omega *(animated film Alpha and Omega voice)*	Hayden Panettiere
(2)	What song was created by the group consisting of Jeffrey Jey, Maurizio Lobina and Gabry Ponte and released on 15 January 1999?	Jeffrey Jey *(group consisting of Jeffrey Jey, Maurizio Lobina and Gabry Ponte)*	Gabry Ponte and released on 15 January 1999 *("Blue (Da Ba Dee)")*
(3)	Yau Ma Tei North is a district of a city with how many citizens?	Yau Ma Tei North	Yau Tsim Mong District of Hong Kong *(Hong Kong)*
(4)	What company started the urban complex development that included the highrise building, The Harmon?	highrise building, The Harmon	CityCenter

Table 5: Examples of predicted queries from the query generators on the HOTPOTQA dev set. The oracle query is displayed in blue in parentheses if it differs from the predicted one.

Model	Span		R@5
	EM	F_1	
G_1	51.40	78.75	85.86
G_2	52.29	63.07	64.83

Table 6: Span prediction and IR performance of the query generator models for Hop 1 (G_1) and Hop 2 (G_2) evaluated separately on the HOTPOTQA dev set.

(Example (1) in Table 5). When they differ a bit more, the model is usually overly biased towards shorter entity spans and misses out on informative information (Example (2)). When there are multiple entities in the retrieval context, the model sometimes selects the wrong entity, which suggests that a more powerful query generator might be desirable (Example (3)). Despite these issues, we find that these natural language queries make the reasoning process more interpretable, and easier for a human to verify or intervene as needed.

Limitations Although we have demonstrated that generating search queries with span selection works in most cases, it also limits the kinds of queries we can generate, and in some cases leads to undesired behavior. One common issue is that the entity of interest has a name shared by too many Wikipedia pages (*e.g.*, "*House Rules*" the 2003 TV series). This sometimes results in the inclusion of extra terms in our oracle query to expand it (*e.g.*, Example (4) specifies that "*The Harmon*" is a highrise building). In other cases, our span oracle makes use of too much information from the gold entities (Example (2), where a human would likely query for "*Eiffel 65 song released 15 January 1999*" because "*Blue*" is not the only song mentioned in d_1). We argue, though, these are due to the simplifying choice of span selection for query generation and fixed number of query steps. We leave extensions to future work.

5 Conclusion

In this paper, we presented GOLDEN (Gold Entity) Retriever, an open-domain multi-hop question answering system for scalable multi-hop reasoning. Through iterative reasoning and retrieval, GOLDEN Retriever greatly improves the recall of gold supporting facts, thus providing the question answering model a much better set of context documents to produce an answer from, and demonstrates competitive performance to the state of the art. Generating natural languages queries for each step of reasoning, GOLDEN Retriever is also more interpretable to humans compared to previous neural retrieval approaches and affords better understanding and verification of model behavior.

A Elasticsearch Setup

A.1 Setting Up the Index

We start from the Wikipedia dump file containing the introductory paragraphs used in HOTPOTQA that Yang et al. (2018) provide,[10] and add the fields corresponding to Wikipedia page titles and the introductory paragraphs (text) into the index.

For the title, we use Elasticsearch's `simple` analyzer which performs basic tokenization and lowercasing of the content. For the text, we join all the sentences and use the `standard` analyzer which further allows for removal of punctuation and stop words. For both fields, we index an auxiliary field with bigrams using the `shingle` filter,[11] and perform basic `asciifolding` to map non ASCII characters to a similar ASCII character (*e.g.*, "é"→ "e").

At search time, we launch a `multi_match` query against all fields with the same query, which performs a full-text query employing the BM25 ranking function (Robertson et al., 1995) with all fields in the index, and returns the score of the best field for ranking by default. To promote documents whose title match the search query, we boost the search score of all title-related fields by 1.25 in this query.

A.2 Reranking Search Results

In Wikipedia, it is common that pages or entity names share rare words that are important to search engines, and a naive full-text search IR system will not be able to pick the one that matches the query the best. For instance, if one set up Elasticsearch according to the instructions above and searched for "*George W. Bush*", he/she would be surprised to see that the actual page is not even in the top-10 search results, which contains entities such as "*George W. Bush Childhood Home*" and "*Bibliography of George W. Bush*".

To this end, we propose to rerank these query results with a simple but effective heuristic that alleviates this issue. We would first retrieve at least 50 candidate documents for each query for consideration, and boost the query scores of documents whose title exactly matches the search query, or is a substring of the search query. Specifically, we multiply the document score by a heuristic constant between 1.05 and 1.5, depending on how well the document title matches the query, before reranking all search results. This results in a significant improvement in these cases. For the query "*George W. Bush*", the page for the former US president is ranked at the top after reranking. In Table 7, we also provide results from the single-hop query to show the improvement from title score boosting introduced from the previous section and reranking.

IR System	R@10 for d_1	R@10 for d_2
Final system	87.85	36.91
w/o Title Boosting	86.85	32.64
w/o Reranking	86.32	34.77
w/o Both	84.67	29.55

Table 7: IR performance (recall in percentages) of various Elasticsearch setups on the HOTPOTQA dev set using the original question.

B Oracle Query Generation

We mainly employ three heuristics to find the semantic overlap between the retrieval context and the desired documents: longest common subsequence (LCS), longest common substring (LCSubStr), and overlap merging which generalizes the two. Specifically, the overlap merging heuristic looks for contiguous spans in the retrieval context that have high rates of overlapping tokens with the desired document, determined by the total number of overlapping tokens divided by the total number of tokens considered in the span.

In all heuristics, we ignore stop words and lowercase the rest in computing the spans to capture more meaningful overlaps, and finally take the span in the retrieval context that all the overlapping words are contained in. For instance, if the retrieval context contains "*the* GOLDEN *Retriever model on* HOTPOTQA" and the desired document contains "GOLDEN *Retriever on the* HOTPOTQA *dataset*", we will identify the overlapping terms as "GOLDEN", "*Retriever*", and "HOTPOTQA", and return the span "GOLDEN *Retriever model on* HOTPOTQA" as the resulting candidate query.

To generate candidates for the oracle query, we apply the heuristics between combinations of {cleaned question, cleaned question without punctuation} × {cleaned document title, cleaned paragraph}, where cleaning means stop word removal and lowercasing. Once oracle queries are gener-

Hyperparameter	Values
Learning rate	$\underline{5 \times 10^{-4}}$, $\mathbf{1 \times 10^{-3}}$
Finetune embeddings	0, 200, **500**, *1000*
Epoch	**25**, *40*
Batch size	***32***, 64, 128
Hidden size	64, ***128***, 256, 512, 768
Max sequence length	15, *20*, 30, **50**, 100
Dropout rate	0.3, 0.35, ***0.4***, 0.45

Table 8: Hyperparameter settings for the query generators. The final hyperparameters for the Hop 1 query generator are shown in **bold**, and those for the Hop 2 query generator are shown in *underlined italic*.

ated, we launch these queries against Elasticsearch to determine the rank of the desired paragraph. If multiple candidate queries are able to place the desired paragraph in the top 5 results, we further rank the candidate queries by other metrics (*e.g.*, length of the query) to arrive at the final oracle query to train the query generators. We refer the reader to our released code for further details.

C Training Details

C.1 Query Generators

Once the oracle queries are generated, we train our query generators to emulate them on the training set, and choose the best model with F_1 in span selection on the dev set. We experiment with hyperparameters such as learning rate, training epochs, batch size, number of word embeddings to finetune, among others, and report the final hyperparameters for both query generators (G_1 and G_2) in Table 8.

C.2 Question Answering Model

Our final question answering component is trained with the paragraphs produced by the oracle queries (5 from each hop, 10 in total), with d_1 and d_2 inserted to replace the lowest ranking paragraph in each hop if they are not in the set already.

We develop our model based on the baseline model of Yang et al. (2018), and reuse the same default hyperparameters whenever possible. The main differences in the hyperparameters are: we optimize our QA model with Adam (with default hyperparameters) (Kingma and Ba, 2015) instead of stochastic gradient descent with a larger batch size of 64; we anneal the learning rate by 0.5 with a patience of 3 instead of 1, that is, we multiply the learning rate by 0.5 after three consecutive failures to improve dev F_1; we clip the gradient down to a maximum ℓ_2 norm of 5; we apply a 10% dropout to the model, for which we have increased the hidden size to 128; and use 10 as the coefficient by which we multiply the supporting facts loss, before mixing it with the span prediction loss. We configure the model to read 10 context paragraphs, and limit each paragraph to at most 400 tokens including the title.

NL2pSQL: Generating Pseudo-SQL Queries from Under-Specified Natural Language Questions

Abstract

Generating SQL codes from natural language questions (NL2SQL) is an emerging research area. Existing studies have mainly focused on clear scenarios where specified information is fully given to generate a SQL query. However, in developer forums such as Stack Overflow,[1] questions cover more diverse tasks including table manipulation or performance issues, where a table is not specified. The SQL query posted in Stack Overflow, Pseudo-SQL (pSQL), does not usually contain table schemas and is not necessarily executable, is sufficient to guide developers. Here we describe a new NL2pSQL task to generate pSQL codes from natural language questions on under-specified database issues, in short, NL2pSQL. In addition, we define two new metrics suitable for the proposed NL2pSQL task, Canonical-BLEU and SQL-BLEU, instead of the conventional BLEU. With a baseline model using sequence-to-sequence architecture integrated with denoising autoencoder, we confirm the validity of our task. Experiments show that the proposed NL2pSQL approach yields well-formed queries (up to 43% more than a standard Seq2Seq model). Our code and datasets are publicly available at http://github.com/clovaai/nl2psql.

1 Introduction

Converting natural-language questions to SQL codes (NL2pSQL) is an active area of research in natural language processing. However, earlier work (Hemphill et al., 1990; Brad et al., 2017; Zelle and Mooney, 1996; Tang and Mooney, 2000; Popescu et al., 2003; Lawrence and Riezler, 2016; Li and Jagadish, 2014; Roy et al., 2013; Yaghmazadeh et al., 2017; Zhong et al., 2017; Yu et al., 2018c; Finegan-Dollak et al., 2018) mainly focused on fully specified questions where the given question and the table can be uniquely answered by a generated SQL query. For example, a question such as "who is the manufacturer for the order year 1998?" can only be uniquely answered when the table that can answer the question is attached to the question. This requires the generated SQL query to be executable, in order to verify its correctness.

Meanwhile, real-life NL2pSQL questions from developer forums such as Stack Overflow (SO) (StackOverflow, 2018) are mostly under-specified to generate an executable answer. Actual questions deal with more diverse issues, including table creation, backup, or performance, and often present with a less detailed context (such as missing table name or schema). For example, a SO question[2] such as "How to reset AUTO_INCREMENT in MySQL?" can only be answered by a non-executable template "ALTER TABLE [tablename] AUTO_INCREMENT = 1", where human developers are expected to read and then feed the missing context. We call these questions *Under-specified NL2pSQL*, distinguished from the conventional NL2pSQL task on fully specified questions.

Our key contribution is to address 1) the novel problem of generating human-readable pseudo SQL code to diverse ranges of under-specified developer questions with our own curated dataset and to propose 2) a new approach as well as 3) evaluation metrics suitable for the proposed task. Our dataset contains crawled posts in SO between the year of 2008 and 2017. The proposed task addresses the following new opportunities and challenges.

First, our new dataset covers diverse scenarios with 362 distinct SQL keywords, such as *USING, UNIQUE, SELECT, UPDATE, TRUNCATE, etc*,

[1]https://www.stackoverflow.com

[2]https://stackoverflow.com/questions/8923114

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2603–2613, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

unlike specified scenarios such as data lookup using simple *SELECT* queries. Meanwhile, 19% of the answers in SO do not contain the *SELECT* keyword at all.

Second, we eliminate the requirement of a generated code to be executable, for which we propose new evaluation metrics without such a requirement. An existing metric is lexical comparisons with the human-generated templates using BLEU scores (Papineni et al., 2002). This metric based on counting matching n-gram may penalize mismatches in non-essential tokens such as variable names (Lin et al., 2018; Zhong et al., 2017), while mismatches of SQL keywords should not be tolerated.

Our contribution includes the following:

- **Dataset:** We publicly release the NL2pSQL dataset containing 1,244 pairs as well as the denoising dataset for NL2pSQL containing 406,384 pairs.[3]

- **NL2pSQL:** We propose an end-to-end natural NL2pSQL model without the restriction of an executable SQL query trained and evaluated for under-specifed questions. Existing sequence-to-sequence models are known to generate repetitive tokens, but our denoising autoencoder can effectively fix errors in SQL statements towards readable codes. Our model performs a two-step translation by cascading two sequence-to-sequence models, one for generating initial SQL statements from natural language input, and the other to fix ill-formed SQL statements.

- **Evaluation metric:** While existing NL2pSQL metrics penalize the mismatch of any terms, we propose novel metrics allowing the mismatches for non-essential terms, yet requiring matches for important SQL keyword: Specifically, Canonical-BLEU abstracts the identifier names of the SQL statements before calculating the BLEU scores while SQL-BLEU calculates the BLEU scores using only the SQL keywords. Different forms of SQL queries may exist for a given natural language, and we note that no single metric is capable to accurately discern one form from the other. Thus, two proposed metrics complement each other.

2 Related Work

Natural Language to SQL. Bridging the gap between natural language and SQL queries has been a long-studied area (Warren and Pereira, 1982; Popescu et al., 2003, 2004; Li et al., 2006; Giordani and Moschitti, 2012). With the emergence of deep learning, neural network-based approaches have gained popularity including models using sequence-to-sequence and reinforcement learning (Zhong et al., 2017; Xu et al., 2018; Iyer et al., 2017; Dong and Lapata, 2016; Yu et al., 2018a). These models assume fully-specified questions and require human-annotated executable SQL queries for training and evaluation. Thus, they are not applicable to under-specified questions, which are the majority of issues in real-world software developer forums.

An alternative approach is designing semantic parsers, to exploit rich prior knowledge in the form of features and grammars (Zettlemoyer and Collins, 2005). It aims at mapping natural language utterances to an executable logical form such as SQL. They require rich resources – in the form of either grammars or training data to extract such grammars. As existing semantic parsers on SQL build on pairs of SQL and their execution results, which cannot exist in our problem context (Xu et al., 2018; Zhong et al., 2017; Sun et al., 2018; Yu et al., 2018c,b) of under-specified questions, we adopt a generative approach in our model.

Program Synthesis Program synthesis or automatic code generation is a relatively new field and has gained much attention lately. In previous work (Ling et al., 2016; Rabinovich et al., 2017; Yin and Neubig, 2017; Balog et al., 2017; Murali et al., 2018), the generated code is targeted at programming languages such as Java and Python, or they used a reduced specification such as a domain-specific language (DSL). Meanwhile, Beltramelli utilized GUI screenshots to generate markup language codes (Beltramelli, 2017). Our work differs in the sense that we are not constrained to a reduced specification but deal with a new domain of SQL statements, instead of markup languages or fully-fledged programming languages such as Java and Python.

Denoising and Program Repair Denoising is a popular research area in computer vision (Buades et al., 2005; Elad and Aharon, 2006; Dabov et al., 2007; Zhang et al., 2017; Meiniel et al., 2018) and

natural language processing (Kouno et al., 2015; Napoles et al., 2017). In software engineering, denoising tasks focus on bug fixing in fully-fledged programming languages such as Java and C (Long and Rinard, 2015; Mechtaev et al., 2016; Gupta et al., 2017). Our work is different in that we are combining the denoising aspect into the auto-generated SQL queries to complement the limitation of neural generation, which has not been previously considered.

3 Proposed Approach

3.1 NL2pSQL Dataset

To obtain human-written pseudo SQL statements with their corresponding natural language description, we turn to Stack Overflow (SO). We use the public SO data from the Stack Exchange Data Dump website for convenience purposes as the data are already structured in an XML form, e.g., 'Posts.xml', for easy extraction. Our goal is to curate question and code pairs: For example, in the SO Question 6308594, [4] the natural language input is *"how can I copy data from one column to another in the same table"*, and the code is *"update table set columnB = columnA"*.

In particular, we collect all the answers where they have a single code block and their corresponding questions are labeled with an *SQL* tag from 'Posts.xml'. Note that this xml file contains all the SO questions and answers since its establishment from August 2008 to September 2017. We also used the data from 'Postlinks.xml' (described in the later paragraph).

A code block can contain multiple lines of codes. We observed that indentation for code readability made numerous SQL statements be represented with multiple lines. A SQL statement indented with a different style will have a trivial effect when being read and executed by a SQL parser. Thus, we transformed all the multi-line SQL statements into a single line by replacing the line break with a white space. In this study, we only consider the SQL statement with a maximum token (delimited by a white space) length of 100.

Among questions with SQL answers, we avoid error debugging questions but focus on implementation questions with code answers. To this end, we first collect all the QA pairs tagged with SQL. We then extract the title from the QA pairs for classifying the implementation questions, as the title description has been reported as sufficient (Iyer et al., 2016). We only keep QA pairs where their question titles start with "how",[5] and not containing the following keywords *bug, error, fix* within the title content to exclude questions on error debugging. We manually inspected these QA pairs to ensure all of them to be implementation-related questions. As a result, 1,225 QA pairs in total were found.

Another issue is redundancy: 'Postlinks.xml' may also contain recurring question pairs from SO, asking the same questions in lexically different forms (or paraphrased) (Chen and Kim, 2015). We found 19 such recurring questions, and we union them to the previously mentioned 1,225 QA pairs. A total of 1,244 implementation question QA pairs were collected.

We observed that the queries in our dataset mostly involve complex conditions such as the combination of multiple joined tables with ordering and grouping clauses that are not supported by existing NL2pSQL approaches. A majority of the natural text contains 11 to 40 tokens, with SQL queries containing 11 and 15 tokens. To gain more insights on the difficulty of SQL queries, we measured Halstead complexity metrics (Halstead et al., 1977) on the training, development, and test sets and found most queries fall under the complexity score of 0-5 and well-split with near-identical distributions across the three splits.

3.2 Model: NL2pSQL with Denoising

While semantic parsing approaches require the machine-executable code for training (as outlined in Section 2), we focus on a new generative model without executability requirements for our proposed scenario. Essentially, our model consists of two layers of autoencoder architecture (Figure 1). The first layer is for generating SQL code given a natural language as input (NL2pSQL) through an autoencoder. The input to the first autoencoder is the word embedding of the natural language.

However, this model suffers a well-known problem of low-quality generation, such as token repetitions (Holtzman et al., 2018), or "ill-formed". Though our approach does not require a code segment to be machine-executable, generated codes

[4] https://stackoverflow.com/questions/6308594

[5] We are aware that the same intention can be paraphrased, and we can use paraphrased patterns to increase recall (and the data size). However, we focus on maintaining a high-precision set to start with.

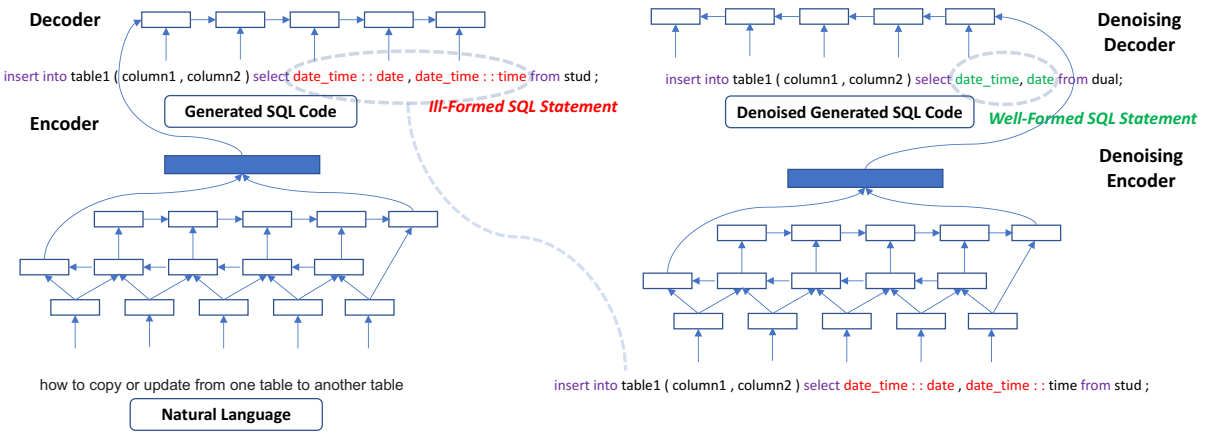

Figure 1: Overview of NL2pSQL with Denoising Autoencoder. Our model performs a two-step translation by cascading two sequence-to-sequence models. The input layers are the natural-language word embeddings in the 1st autoencoder and the SQL statement (generated by the first autoencoder) word embeddings in the 2nd autoencoder.

should be sufficiently "well-formed" to ensure human readablity. For example, a generated code with repetitive tokens will be considered ill-formed and transformed into its well-formed counterpart (or, denoising). Our contribution is thus to denoise the ill-formed queries by employing a subsequent autoencoder architecture. The input to the second autoencoder is the word embeddings of the generated SQL statements from the first autoencoder. This denoising functionality is included in the second layer with the goal of producing well-formed SQL statements.

For training the denoiser, we propose to synthesize a pair of ill- and well-formed SQL statements from the given dataset: <a *well-formed SQL statement*, an *ill-formed SQL statement*> as the input to the denoising autoencoder module. Formally, we define a well-formed SQL statement as a valid SQL statement recognized by an SQL parser whereas an ill-formed SQL statement is detected as an erroneous SQL statement construct.

We first collect well-formed SQL statements among SQL statements written by developers in SO using MySQL parser (GuduSoftware, 2018), as MySQL is the most popular SQL dialect among developers (StackOverflowSurvey, 2018). Next, we generate its ill-formed counterpart, by perturbing each of the collected well-formed SQL statements. Specifically, we randomly decide to inject into or remove from the well-formed SQL statement a token for k iterations to generate multiple ill-formed statements for a given well-formed SQL statement. In our model, we set k to be four.

To the best of our knowledge, this is the first NL2pSQL model that is not restricted to the executability from specified questions. This work is also the first in attempting to fix (denoise) ill-formed SQL statements through a neural network-based autoencoder architecture.

3.3 Evaluation Metrics

To evaluate the generated SQL statements, we first check if the generated SQL statements are well-formed (Section 3.3.1). In addition, we propose two new BLEU variants. Previous studies have reported that the BLEU score may be inappropriate in measuring the correctness of the generated code against the target code (Lin et al., 2018; Zhong et al., 2017). This is because a generated code may be written differently but still perform the intended function. The first example in Table 6 illustrates this problem. The generated SQL statement performs the semantics as required in the natural language but is structurally different as compared to the ground truth (GT). By using the vanilla BLEU, it produces a much heavily penalized score of 0.065. Thus, in our study, we use two modified versions of BLEU, namely Canonical-BLEU and SQL-BLEU, as will be described in Section 3.3.2.

3.3.1 Well-Formed SQL Statements

To evaluate the effectiveness of our denoising autoencoder, we compare the relative number of well-formed SQL statements between the generated SQL statements before and after denoising. Whether a particular SQL statement is well-formed is determined by using a SQL parser.

3.3.2 Canonical-BLEU and SQL-BLEU

Here, we first motivate the need for introducing two new BLEU variants, namely Canonical-BLEU and SQL-BLEU, before describing them in more detail. Canonical-BLEU first abstracts the identifiers of the SQL statement before calculating the BLEU score, while SQL-BLEU only considers the SQL keywords within the SQL statement when computing the BLEU score.

We note that two queries with the same semantics may have syntactically different forms. For example, a join statement (**S1**) such as "*select a.car from a,b where a.id=b.id*" can be equivalent to a nested select statement (**S2**) such as "*select a.car from a where a.id in (select b.id from b where b.name='Mary')*". When **S1** is generated and the ground truth is a similar join statement, it will have a correct and high SQL-BLEU score, yet having lower computing complexity. When the ground truth is similar to **S2**, SQL-BLEU and Vanilla BLEU would penalize more heavily than our Canonical-BLEU. In this respect, both SQL-BLEU and Canonical-BLEU complement each other and should be used together.

Canonical-BLEU Generated SQL statements may have different identifiers such as variable and table names, as compared to the original (ground truth) SO SQL statements. The difference in the identifiers' name between the generated SQL statements and the ground truth should not be heavily penalized if their SQL forms are semantically the same. To mitigate this issue, we first "canonicalize" all the identifier names (e.g., MY_COLUMN) into indexed placeholders (e.g., var_1). This transformation is performed both on the ground truth SQL statements and the generated SQL statements, and their BLEU scores are calculated. We call this Canonical-BLEU.

SQL-BLEU In a SQL statement, several words are considered keywords that serve as particular functions. For example, *SELECT* and *UPDATE* are both keywords in the SQL language. *SELECT* is used for retrieving a record from a relational database table whereas *UPDATE* is used to modify the content of a record. In SO, developers are free to adopt and use different column or table names. However, despite that, if the SQL code is about the retrieval of records, there should have a *SELECT* keyword within the SQL statement. Furthermore, we analyze the syntactically correct answers from SO between the period of 2008 and 2017 and found that 362 distinct SQL keywords (e.g., *YEAR, DATABASES, USING, UNIQUE, SELECT, UPDATE, TRUNCATE, etc*) are used, and 19% of the answers (that are well-formed) do not contain the *SELECT* keyword. We also found that multiple different variations of retrieval-type answers (i.e., 348 different keywords are used together with *SELECT*) use different combinations of keywords such as *WHEN, EXIST, INNER JOIN, IN, GROUP BY, etc*. Thus, we decided to use SQL keywords as another form of measure.

We first transform the generated SQL statements into their token types using a SQL parser. Each word will have its corresponding token type. For example, the word *SELECT* will be tagged as a *keyword* by the SQL parser. We remove all words that are non-keywords and only those words tagged as keywords are left in the SQL statements (we preserve their word ordering) to calculate the BLEU score. This transformation is performed both on the ground truth SQL code as well as the generated SQL statements and their BLEU scores are calculated. We call this SQL-BLEU.

4 Experiment Setup

4.1 Data Description

The used dataset is randomly split into train, dev and test sets in the ratio 60:20:20 to be mutual exclusive.

4.2 Baseline and Backbone Models

We stress that our work is focused on under-specified NL2pSQL and is designed for users to read/adjust the missing context for their specific usage. This is the first work on under-specified NL2pSQL and is mostly a resource and new problem/metric definition paper. Note that existing NL2pSQL work is all fully-specified and cannot be used for comparison as they involve semantic parsing and query execution on a valid database schema, which is absent in our context. In addition, making the system fully-specified is beyond the scope of this paper.

We conduct experiments for NL2pSQL generation with denoising on two neural machine translation models, Seq2Seq and CopyNet, which have shown competitive performance on natural-language-to-code translation (Lin et al., 2018). In addition, we carry out experiments in both token and character levels on both of these models, denoted as Seq2Seq(Token), Seq2Seq(Char), Copy-

Net(Token), CopyNet(Char). For each model, we perform a two-step translation by cascading two sequence-to-sequence models, for pSQL generation and denoising respectively. Each model is trained with the following hyperpameters: [6]

- Seq2Seq (Cho et al., 2014) encodes questions and decodes into queries using recurrent neural networks (RNNs). The encoder dimension is 200 by using a bi-directional RNN with concatenation. The dimension of the decoder RNN is set as 100. We optimized our objective function with Adam (Kingma and Ba, 2015), using the default momentum hyperparameters. We set the initial learning rate as 0.0001 and the mini-batch size as 32. We also used variational RNN dropout (Gal and Ghahramani, 2016) with a dropout rate of 0.4. During beam-search decoding (Hwang and Chang, 2007), we set the beam size as 100, and we ran for 100 epochs to train the model. For beam size, it has been reported that a larger beam size will lead to a higher translation quality at the expense of the decoder speed (Freitag and Al-Onaizan, 2017). We wanted to find a balance between translation quality and decoding speed. We tested different beam sizes and an entire decoding process to generate a SQL statement takes only a few seconds when the beam size is set to 100.

- CopyNet (Gu et al., 2016) extends the model above, to selectively "copy" some input sequence into output, using the same hyperparameters discussed above.

- The information retrieval (IR)-based baseline is a Lucene-based code retrieval tool, widely adopted for code search such as Sourcerer (Linstead et al., 2009). It retrieves top-3 matches, based on answer titles, matching the given question.

All the experiments were performed based on NAVER Smart Machine Learning (NSML) (Kim et al., 2018; Sung et al., 2017).

[6]Following description is for generation, and when the same model is used for denoising, we make a minor change: mini-batch size (set as 16 rather than 32), and the beam size (set as 10 instead of 100), due to a relatively large size of the dataset. Character-level encoding for denoising is unreported, as it is empirically inferior to that of token-level, as argued in prior work (Lin et al., 2018) as well.

5 Results

This section shows the quantitative (Sections 5.1 and 5.2) as well as qualitative analysis (Section 5.3) from our experiments.

5.1 Well-Formed SQL Statements

Table 1 shows the change in the number of SQL statements determined as well-formed by the SQL parser, after going through our denosing autoencoder module trained with a Seq2Seq and a CopyNet model.

Our module certainly increases the number of well-formed SQL statements. For example, when paired with a *Seq2Seq denoising autoencoder* for the top-1 prediction, the number of well-formed statements increases from 47 to 66 (19% increase). Such increase ranges from 12% to 19%, from 14% to 19%, from 30% to 43%, and from 0% to 7%, in Seq2Seq (Token), CopyNet (Token), Seq2Seq (Char), and CopyNet (Char), respectively. When paired with a *CopyNet Denoising autoencoder*, such increase is less significant. When comparing token- and character-level generation after denoising, we can see that token-level generation shows higher increase, as shown in **bold**.

5.2 Comparison of Canonical and SQL-BLEU

Here, we report the mean scores of both Canonical-BLEU and SQL-BLEU over all the generated SQL statements in the test set (including their denoised version) using the Seq2Seq and CopyNet autoencoder models in both the token and character levels.

5.2.1 Mean SQL-BLEU

Tables 2 and 3 show the changes in the mean SQL-BLEU scores on the first three generated SQL statements, after using denoising autoencoders trained with a Seq2Seq and a CopyNet model, respectively.

For example, when paired with a Seq2Seq denoising autoencoder for the top-1 prediction, the mean SQL-BLEU scores has a negligible decrease of 0.01 (from 0.28 to 0.27). Such decrease ranges from 0.01 to 0.01, from 0.01 to 0.01, from 0.02 to 0.03, and from 0.02 to 0.02, in Seq2Seq(Token), CopyNet (Token), Seq2Seq (Char), and CopyNet(Char), respectively. When paired with a *CopyNet Denoising autoencoder*, we observed similar negligible decrease in the

Table 1: % of well-formed, generated SQL queries using a Seq2Seq/CopyNet & after denoising autoencoder models. P1, P2, and P3 correspond to the first three predictions. Columns (2, 4, 6, 8) & (3, 5, 7, 9) show the increased in well-formed queries after going through a Seq2Seq & CopyNet denoising autoencoder respectively.

	P1		**P2**		**P3**		**Top 3 (%)**	
	Seq2Seq	CopyNet	Seq2Seq	CopyNet	Seq2Seq	CopyNet	Seq2Seq	CopyNet
Seq2Seq (Token)	47 → **66**	47 → 50	37 → **49**	37 → 40	33 → **52**	33 → 35	59 → **80**	59 → 64

Seq2Seq (C)	0.23 (+0.01)	0.26 (0.00)	0.29 (-0.01)
CopyNet (C)	0.29 (-0.01)	0.30 (0.00)	0.30 (-0.01)
IR	0.23	0.23	0.24

mean SQL-BLEU after denoising. Compared to IR approach, token level approaches mostly yield higher SQL-BLEU scores.

5.2.2 Mean Canonical-BLEU

Table 4 and 5 show the change in the mean Canonical-BLEU scores on the first three generated SQL statements, after using denoising autoencoders trained with a Seq2Seq and a CopyNet model respectively.

For example, when paired with a Seq2Seq denoising autoencoder for the top-1 prediction, the mean Canonical-BLEU scores has a negligible decrease in Seq2Seq (Token), from 0.00 to 0.01, or 0.01 decrease. Such decrease ranges from 0.00 to 0.02, from 0.00 to 0.01, from 0.01 to 0.02, and from 0.02 to 0.03, in Seq2Seq(Token), CopyNet (Token), Seq2Seq (Char), and CopyNet(Char), respectively. When paired with a *CopyNet Denoising autoencoder*, we observed similar negligible decrease in the mean SQL-BLEU after denoising. Compared to the IR approach, we observed that most of the generative approaches yield higher Canonical-BLEU scores.

In Section 5.1, we previously reported up to 43% more well-formed SQL statements in the denoised version than the non-denoised version. This suggests that the two metrics (*Well-Formed SQL Statements and the two variants of BLEU – Canonical BLEU and SQL BLEU*) we proposed are complementary, in that Canonical-BLEU and SQL-BLEU alone cannot distinguish well-formed SQL statements. We also note that for denoising, while enhancing one metric, it does not hurt another.

5.3 Qualitative Analysis

Table 6 shows the output examples generated by our models in the unseen data (the test set), including the denoised version. We only show the generated outputs from the Seq2Seq model as they yield the best results in our experiments. Each example consists of the natural language input, the ground truth, the top prediction of the generated output from the Seq2Seq model, and its denoised version.

The first example is about copying or updating from one table to another. In the generated SQL statement, it performs the intended copying function but is syntactically incorrect in the use of

date_time. The denoised version fixes it by replacing *date_time : : date* and *date_time : : time* with proper column names. Furthermore, the ground truth is coupled with comments, and its SQL statement is much longer than the generated version. The retrieved statement by the IR baseline has similar semantics on observing the same type of an insertion query with our approach. Although both of them are similar, the IR baseline appears more complicated as it contains more columns for insertion and a nested table structure. We believe that the generated SQL statement is a much better choice in this case.

The second example is about counting the number of rows. The generated SQL statement shows the counting-related code. Interestingly, the IR approach produces the exact query. In the last example, it is about inserting a record from another table. Similar to the IR approach, the generated SQL statement is able to churn out a query performing an insertion operation from another table. Both generated SQL statements from the last two examples do not contain any syntax errors, and the denoised autocoders did not change the SQL statements. In the last example, it is difficult to include "*top500*" which requires verbal explanation of defining one's own function in the "*order by*" clause. This part was omitted, but all the other semantics are fully preserved.

6 Conclusions

This paper addressed the problem of generating human-readable pseudo SQL queries from natural-languge questions without code-executability restriction, and propose a new dataset. Despite excluding executability, our task covers much more diverse issues including table manipulation and performance-related problems beyond simple table lookup. This coverage allows our task to help software engineers to deal with various practical implementation and operation issues. In addition, we describe a new NL2pSQL model and two evaluation metrics suitable for dealing with our task. Our result shows that adding a denoising autoencoder module enables our model to generate a more number of well-formed queries, to complement a known weakness of neural code generation.

Table 6: Generated examples

NL	how to copy or update from one table to another table
GT	- - 1) insert new record insert into old_table (id , column) select n . id , n . column from new_table n left join old_table o on n . id = o . id where o . id is null - - 2) update existed record update o set column = n . column from old_table o join new_table n on n . id = o . id

Leveraging Frequent Query Substructures to Generate Formal Queries for Complex Question Answering

Abstract

Formal query generation aims to generate correct executable queries for question answering over knowledge bases (KBs), given entity and relation linking results. Current approaches build universal paraphrasing or ranking models for the whole questions, which are likely to fail in generating queries for complex, long-tail questions. In this paper, we propose SubQG, a new query generation approach based on frequent query substructures, which helps rank the existing (but nonsignificant) query structures or build new query structures. Our experiments on two benchmark datasets show that our approach significantly outperforms the existing ones, especially for complex questions. Also, it achieves promising performance with limited training data and noisy entity/relation linking results.

1 Introduction

Knowledge-based question answering (KBQA) aims to answer natural language questions over knowledge bases (KBs) such as DBpedia and Freebase. Formal query generation is an important component in many KBQA systems (Bao et al., 2016; Cui et al., 2017; Luo et al., 2018), especially for answering complex questions. Given entity and relation linking results, formal query generation aims to generate correct executable queries, e.g., SPARQL queries, for the input natural language questions. An example question and its formal query are shown in Figure 1. Generally speaking, formal query generation is expected to include but not be limited to have the capabilities of (i) recognizing and paraphrasing different kinds of constraints, including triple-level constraints (e.g., *"movies"* corresponds to a typing constraint for the target variable) and higher level constraints (e.g., subgraphs). For instance, *"the same ... as"*

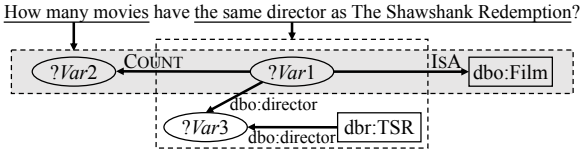

Figure 1: An example for complex question and query

represents a complex structure shown in the middle of Figure 1; (ii) recognizing and paraphrasing aggregations (e.g., "how many" corresponds to COUNT); and (iii) organizing all the above to generate an executable query (Singh et al., 2018; Zafar et al., 2018).

There are mainly two kinds of query generation approaches for complex questions. (i) Template-based approaches choose a pre-collected template for query generation (Cui et al., 2017; Abujabal et al., 2017). Such approaches highly rely on the coverage of templates, and perform unstably when some complex templates have very few natural language questions as training data. (ii) Approaches based on semantic parsing and neural networks learn entire representations for questions with different query structures, by using a neural network following the encode-and-compare framework (Luo et al., 2018; Zafar et al., 2018). They may suffer from the lack of training data, especially for long-tail questions with rarely appeared structures. Furthermore, both above approaches cannot handle questions with unseen query structures, since they cannot generate new query structures.

To cope with the above limitations, we propose a new query generation approach based on the following observation: the query structure for a complex question may rarely appear, but it usually contains some substructures that frequently appeared in other questions. For example, the query structure for the question in Figure 1 appears rarely, however, both *"how many movies"* and *"the same ... as"* are common expressions,

which correspond to the two query substructures in dashed boxes. To collect such frequently appeared substructures, we automatically decompose query structures in the training data. Instead of directly modeling the query structure for the given question as a whole, we employ multiple neural networks to predict query substructures contained in the question, each of which delivers a part of the query intention. Then, we select an existing query structure for the input question by using a combinational ranking function. Also, in some cases, no existing query structure is appropriate for the input question. To cope with this issue, we merge query substructures to build new query structures. The contributions of this paper are summarized below:

- We formalize the notion of query structures and define the substructure relationship between query structures.
- We propose a novel approach for formal query generation, which firstly leverages multiple neural networks to predict query substructures contained in the given question, and then ranks existing query structures by using a combinational function.
- We merge query substructures to build new query structures, which handles questions with unseen query structures.
- We perform extensive experiments on two KBQA datasets, and show that SubQG significantly outperforms the existing approaches. Furthermore, SubQG achieves a promising performance with limited training data and noisy entity/relation linking results.

2 Preliminaries

An entity is typically denoted by a URI and described with a set of properties and values. A fact is an $\langle entity, property, value\rangle$ triple, where the value can be either a literal or another entity. A KB is a pair $\mathcal{K} = (\mathcal{E}, \mathcal{F})$, where $\mathcal{E}$ denotes the set of entities and $\mathcal{F}$ denotes the set of facts.

A *formal query* (or simply called *query*) is the structured representation of a natural language question executable on a given KB. Formally, a query is a pair $\mathcal{Q} = (\mathcal{V}, \mathcal{T})$, where $\mathcal{V}$ denotes the set of vertices, and $\mathcal{T}$ denotes the set of labeled edges. A vertex can be either a variable, an entity or a literal, and the label of an edge can be either

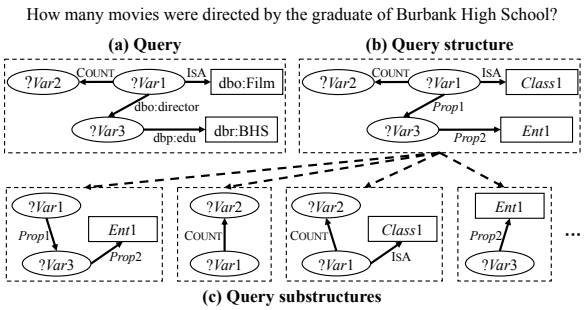

Figure 2: Illustration of a query, a query structure and query substructures

a built-in property or a user-defined one. For simplicity, the set of all edge labels are denoted by $\mathcal{L}_e(\mathcal{Q})$. In this paper, the built-in properties include COUNT, AVG, MAX, MIN, MAXATN, MINATN and ISA (RDF:TYPE), where the former four are used to connect two variables. For example, $\langle ?Var1, \text{COUNT}, ?Var2\rangle$ represents that $?Var2$ is the counting result of $?Var1$. MAXATN and MINATN take the meaning of ORDER BY in SPARQL (Bao et al., 2016). For instance, $\langle ?Var1, \text{MAXATN}, 2\rangle$ means ORDER BY DESC($?Var1$) LIMIT 1 OFFSET 1.

To classify various queries with similar query intentions and narrow the search space for query generation, we introduce the notion of *query structures*. A query structure is a set of structurally-equivalent queries. Let $\mathcal{Q}_a = (\mathcal{V}_a, \mathcal{T}_a)$ and $\mathcal{Q}_b = (\mathcal{V}_b, \mathcal{T}_b)$ denote two queries. $\mathcal{Q}_a$ is structurally-equivalent to $\mathcal{Q}_b$, denoted by $\mathcal{Q}_a \cong \mathcal{Q}_b$, if and only if there exist two bijections $f : \mathcal{V}_a \to \mathcal{V}_b$ and $g : \mathcal{L}_e(\mathcal{Q}_a) \to \mathcal{L}_e(\mathcal{Q}_b)$ such that:

(i) $\forall v \in \mathcal{V}_a$, v is a variable $\Leftrightarrow f(v)$ is a variable;

(ii) $\forall r \in \mathcal{L}_e(\mathcal{Q}_a)$, r is a user-defined property $\Leftrightarrow g(r)$ is a user-defined property; if r is a built-in property, $g(r) = r$;

(iii) $\forall v \forall r \forall v' \langle v, r, v'\rangle \in \mathcal{T}_a \Leftrightarrow \langle f(v), g(r), f(v')\rangle \in \mathcal{T}_b$.

The query structure for $\mathcal{Q}_a$ is denoted by $\mathcal{S}_a = [\mathcal{Q}_a]$, which contains all the queries structurally-equivalent to $\mathcal{Q}_a$. For graphical illustration, we represent a query structure by a representative query among the structurally-equivalent ones and replace entities and literals with different kinds of placeholders. An example of query and query structure is shown in the upper half of Figure 2.

For many simple questions, two query structures, i.e., $(\{?Var1, Ent1\}, \{\langle ?Var1, Prop1, Ent1\rangle\})$ and $(\{?Var1, Ent1\}, \{\langle Ent1, Prop1, ?Var1\rangle\})$, are sufficient. However, for complex

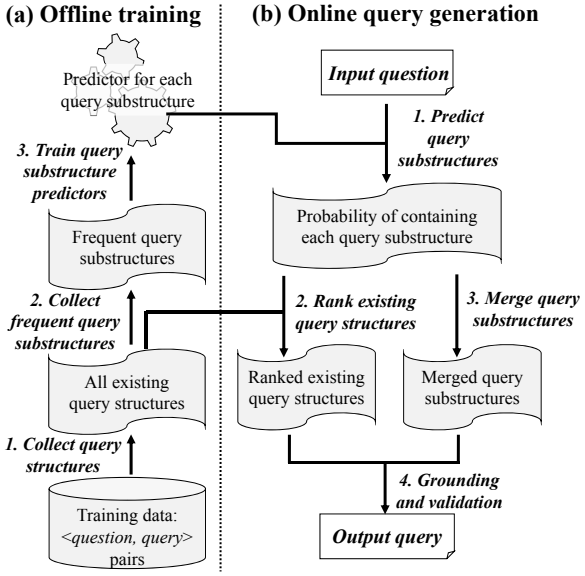

Figure 3: Framework of the proposed approach

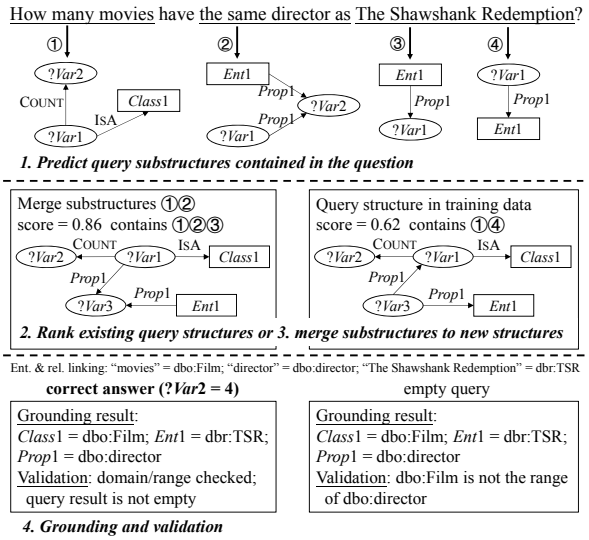

Figure 4: An example for online query generation

questions, a diversity of query structures exist and some of them share a set of frequently-appeared substructures, each of which delivers a part of the query intention. We give the definition of *query substructures* as follows.

Let $\mathcal{S}_a = [\mathcal{Q}_a]$ and $\mathcal{S}_b = [\mathcal{Q}_b]$ denote two query structures. $\mathcal{S}_a$ is a query substructure of $\mathcal{S}_b$, denoted by $\mathcal{S}_a \preceq \mathcal{S}_b$, if and only if $\mathcal{Q}_b$ has a subgraph $\mathcal{Q}_c$ such that $\mathcal{Q}_a \cong \mathcal{Q}_c$. Furthermore, if $\mathcal{S}_a = [\mathcal{Q}_a] \preceq \mathcal{S}_b = [\mathcal{Q}_b]$, we say that $\mathcal{Q}_b$ has $\mathcal{S}_a$, and $\mathcal{S}_a$ is contained in $\mathcal{Q}_b$.

For example, although the query structures for the two questions in Figures 1 and 2 are different, they share the same query substructure $(\{?Var1, ?Var2, Class1\}, \{\langle ?Var1, \text{COUNT}, ?Var2\rangle, \langle ?Var1, \text{ISA}, Class1\rangle\})$, which corresponds to the phrase "how many movies". Note that, a query substructure can be the query structure of another question.

The goal of this paper is to leverage a set of frequent query (sub-)structures to generate formal queries for answering complex questions.

3 The Proposed Approach

In this section, we present our approach, SubQG, for query generation. We first introduce the framework and general steps with a running example (Section 3.1), and then describe some important steps in detail in the following subsections.

3.1 Framework

Figure 3 depicts the framework of SubQG, which contains an offline training process and an online query generation process.

Offline. The offline process takes as input a set of training data in form of $\langle question, query\rangle$ pairs, and mainly contains three steps:

1. Collect query structures. For questions in the training data, we first discover the structurally-equivalent queries, and then extract the set of all query structures, denoted by $\mathbf{TS}$.

2. Collect frequent query substructures. We decompose each query structure $\mathcal{S}_i = (\mathcal{V}_i, \mathcal{T}_i) \in \mathbf{TS}$ to get the set for all query substructures. Let $\mathcal{T}_j$ be a non-empty subset of $\mathcal{T}_i$, and $\mathcal{V}_{\mathcal{T}_j}$ be the set of vertices used in $\mathcal{T}_j$. $\mathcal{S}_j = (\mathcal{V}_{\mathcal{T}_j}, \mathcal{T}_j)$ should be a query substructure of $\mathcal{S}_i$ according to the definition. So, we can generate all query substructures of $\mathcal{S}_i$ from each subset of $\mathcal{T}_i$. Disconnected query substructures would be ignored since they express discontinuous meanings and should be split into smaller query substructures. If more than γ queries in training data have substructure $\mathcal{S}_j$, we consider $\mathcal{S}_j$ as a frequent query substructure. The set for all frequent query substructures is denoted by $\mathbf{FS}^*$.

3. Train query substructure predictors. We train a neural network for each query substructure $\mathcal{S}_i^* \in \mathbf{FS}^*$, to predict the probability that $\mathcal{Q}^y$ has $\mathcal{S}_i^*$ (i.e., $\mathcal{S}_i^* \preceq [\mathcal{Q}^y]$) for input question y, where $\mathcal{Q}^y$ denotes the formal query for y. Details for this step are described in Section 3.2.

Online. The online query generation process takes as input a natural language question y, and mainly contains four steps:

1. Predict query substructures. We first predict the probability that $\mathcal{S}_i^* \preceq [\mathcal{Q}^y]$ for each $\mathcal{S}_i^* \in \mathbf{FS}^*$, using the query substructure predictors trained in the offline step. An example question and four query substructures with highest prediction prob-

abilities are shown in the top of Figure 4.

2. Rank existing query structures. To find an appropriate query structure for the input question, we rank existing query structures ($\mathcal{S}_i \in \mathbf{TS}$) by using a scoring function, see Section 3.3.

3. Merge query substructures. Consider the fact that the target query structure $[\mathcal{Q}^y]$ may not appear in $\mathbf{TS}$ (i.e., there is no query in the training data that is structurally-equivalent to $\mathcal{Q}^y$), we design a method (described in Section 3.4) to merge question-contained query substructures for building new query structures. The merged results are ranked using the same function as existing query structures. Several query structures (including the merged results and the existing query structures) for the example question are shown in the middle of Figure 4.

4. Grounding and validation. We leverage the query structure ranking result, alongside with the entity/relation linking result from some existing black box systems (Dubey et al., 2018) to generate executable formal query for the input question. For each query structure, we try all possible combinations of the linking results according to the descending order of the overall linking score, and perform validation including grammar check, domain/range check and empty query check. The first non-empty query passing all validations is considered as the output for SubQG. The grounding and validation results for the example question are shown in the bottom of Figure 4.

3.2 Query Substructure Prediction

In this step, we employ an attention based BiLSTM network (Raffel and Ellis, 2015) to predict $\Pr[\mathcal{S}_i^* \mid y]$ for each frequent query substructure $\mathcal{S}_i^* \in \mathbf{FS}^*$, where $\Pr[\mathcal{S}_i^* \mid y]$ represents the probability of $\mathcal{S}_i^* \preceq [\mathcal{Q}^y]$. There are mainly three reasons that we use a predictor for each query substructure instead of a multi-tag predictor for all query substructures: (i) a query substructure usually expresses part of the meaning of input question. Different query substructures may focus on different words or phrases, thus, each predictor should have its own attention matrix; (ii) multi-tag predictor may have a lower accuracy since each tag has unbalanced training data; (iii) single pre-trained query substructure predictor from one dataset can be directly reused on another without adjusting the network structure, however, the multi-tag predictor need to adjust the size of the output layer and retrain when the set of frequent query substructures changes.

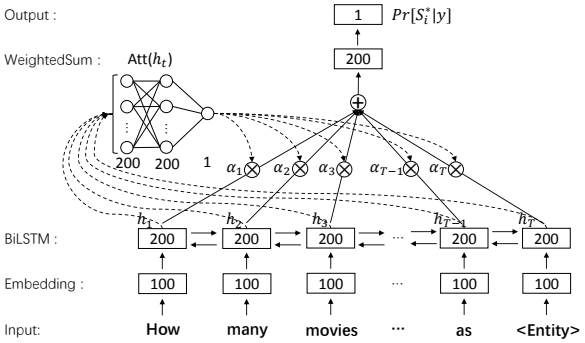

Figure 5: Attention-based BiLSTM network

The structure of the network is shown in Figure 5. Before the input question is fed into the network, we replace all entity mentions with $\langle \textit{Entity} \rangle$ using EARL (Dubey et al., 2018), to enhance the generalization ability. Given the question word sequence $\{w_1, ..., w_T\}$, we first use a word embedding matrix to convert the original sequence into word vectors $\{\mathbf{e}_1, ..., \mathbf{e}_T\}$, followed by a BiLSTM network to generate the context-sensitive representation $\{\mathbf{h}_1, ..., \mathbf{h}_T\}$ for each word, where

$$\mathbf{h}_t = [\textsc{Lstm}(\mathbf{e}_t, \overrightarrow{\mathbf{h}}_{t-1}); \textsc{Lstm}(\mathbf{e}_t, \overleftarrow{\mathbf{h}}_{t+1})]. \quad (1)$$

Then, the attention mechanism takes each $\mathbf{h}_t$ as input, and calculates a weight α_t for each $\mathbf{h}_t$, which is formulated as follows:

$$\alpha_t = \frac{e^{\text{Att}(\mathbf{h}_t)}}{\sum_{k=1}^{T} e^{\text{Att}(\mathbf{h}_k)}}, \quad (2)$$

$$\text{Att}(\mathbf{h}_t) = \mathbf{v}_{att}^T \tanh(\mathbf{W}_{att}\mathbf{h}_t + \mathbf{b}_{att}), \quad (3)$$

where $\mathbf{W}_{att} \in \mathbb{R}^{|\mathbf{h}_t| \times |\mathbf{h}_t|}$, $\mathbf{b}_{att} \in \mathbb{R}^{|\mathbf{h}_t|}$ and $\mathbf{v}_{att} \in \mathbb{R}^{|\mathbf{h}_t|}$. Next, we get the representation for the whole question $\mathbf{q}^c$ as the weighted sum of $\mathbf{h}_t$:

$$\mathbf{q}^c = \sum_{t=1}^{T} \alpha_t \mathbf{h}_t. \quad (4)$$

The output of the network is a probability

$$\Pr[\mathcal{S}_i^* \mid y] = \sigma(\mathbf{v}_{out}^T \mathbf{q}^c + b_{out}), \quad (5)$$

where $\mathbf{v}_{out} \in \mathbb{R}^{|\mathbf{q}^c|}$ and $b_{out} \in \mathbb{R}$.

The loss function minimized during training is the binary cross-entropy:

$$\begin{aligned} \text{Loss}(\mathcal{S}_i^*) = &- \sum_{\substack{(y,\mathcal{Q}^y)\in\mathbf{Train} \\ \text{s.t. } \mathcal{S}_i^* \preceq [\mathcal{Q}^y]}} \log(\Pr[\mathcal{S}_i^* \mid y]) \\ &- \sum_{\substack{(y,\mathcal{Q}^y)\in\mathbf{Train} \\ \text{s.t. } \mathcal{S}_i^* \not\preceq [\mathcal{Q}^y]}} \log(1 - \Pr[\mathcal{S}_i^* \mid y]), \end{aligned} \quad (6)$$

where $\mathbf{Train}$ denotes the set of training data.

Algorithm 1: Query substructure merging

Input: Question y, freq. query substructures $\mathbf{FS}^*$

$\mathbf{FS}^+ := \{\mathcal{S}_i^* \in \mathbf{FS}^* \mid \Pr[\mathcal{S}_i^* \mid y] > 0.5\}$;
$\mathbf{M}^{(0)} := \{\mathcal{S}_i^* \in \mathbf{FS}^* \mid \text{Score}[\mathcal{S}_i^* \mid y] > \theta\}$;
for $i = 1$ *to* K **do** *// K is maximum iterations*
  $\mathbf{M}^{(i)} := \emptyset$;
  forall $\mathcal{S}_i^* \in \mathbf{FS}^+, \mathcal{S}_j \in \mathbf{M}^{(i-1)}$ **do**
    $\mathbf{M}^{(i)} := \mathbf{M}^{(i)} \cup \text{Merge}(\mathcal{S}_i^*, \mathcal{S}_j)$;
  $\mathbf{M}^{(i)} := \{\mathcal{S}_l \in \mathbf{M}^{(i)} \mid \text{Score}[\mathcal{S}_l \mid y] > \theta\}$;
return $\bigcup_{i=0}^{K} \mathbf{M}^{(i)}$;

3.3 Query Structure Ranking

In this step, we use a combinational function to score each query structure in the training data for the input question. Since the prediction result for each query substructure is independent, the score for query structure $\mathcal{S}_i$ is measured by joint probability, which is

$$\text{Score}(\mathcal{S}_i \mid y) = \prod_{\substack{\mathcal{S}_j^* \in \mathbf{FS}^* \\ \text{s.t. } \mathcal{S}_j^* \preceq \mathcal{S}_i}} \Pr[\mathcal{S}_j^* \mid y] \times \prod_{\substack{\mathcal{S}_j^* \in \mathbf{FS}^* \\ \text{s.t. } \mathcal{S}_j^* \not\preceq \mathcal{S}_i}} (1 - \Pr[\mathcal{S}_j^* \mid y]). \quad (7)$$

Assume that $\mathcal{Q}^y \in \mathcal{S}_i, \forall \mathcal{S}_j^* \preceq \mathcal{S}_i$, we have $\mathcal{S}_j^* \preceq [\mathcal{Q}^y]$. Thus, $\Pr[\mathcal{S}_j^* \mid y]$ should be 1 in the ideal condition. On the other hand, $\forall \mathcal{S}_j^* \not\preceq \mathcal{S}_i$, $\Pr[\mathcal{S}_j^* \mid y]$ should be 0. Thus, we have $\text{Score}(\mathcal{S}_i \mid y) = 1$, and $\forall \mathcal{S}_k \neq \mathcal{S}_i$, we have $\text{Score}(\mathcal{S}_k \mid y) = 0$.

3.4 Query Substructure Merging

We proposed a method, shown in Algorithm 1, to merge question-contained query substructures to build new query structures. In the initialization step, it selects some query substructures of high scores as candidates, since the query substructure may directly be the appropriate query structure for the input question. In each iteration, the method merges each question-contained substructures with existing candidates, and the merged results of high scores are used as candidates in the next iteration. The final output is the union of all the results from at most K iterations.

When merging different query substructures, we allow them to share some vertices of the same kind (variable, entity, etc.) or edge labels, except the variables which represent aggregation results. Thus, the merged result of two query substructures is a set of query structures instead of one. Also, the following restrictions are used to filter the merged results:

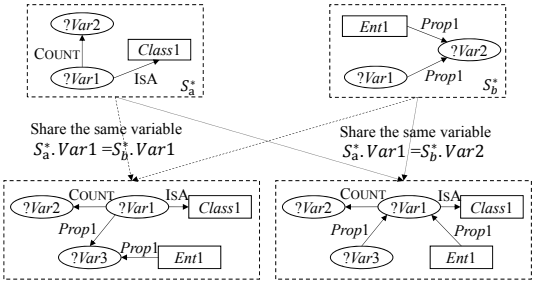

Figure 6: Merge results for two query substructures

(i) The merged results should be connected;

(ii) The merged results have $\leq \tau$ triples;

(iii) The merged results have $\leq \delta$ aggregations;

An example for merging two query substructures is shown in Figure 6.

4 Experiments and Results

In this section, we introduce the query generation datasets and state-of-the-art systems that we compare. We first show the end-to-end results of the query generation task, and then perform detailed analysis to show the effectiveness of each module. Question sets, source code and experimental results are available online.[1]

4.1 Experimental Setup

Datasets We employed the same datasets as Singh et al.(2018) and Zafar et al.(2018): (i) the large-scale complex question answering dataset (**LC-QuAD**) (Trivedi et al., 2017), containing 3,253 questions with non-empty results on DBpedia (2016-04), and (ii) the fifth edition of question answering over linked data (**QALD-5**) dataset (Unger et al., 2015), containing 311 questions with non-empty results on DBpedia (2015-10). Both datasets are widely used in KBQA studies (Zou et al., 2014; Dubey et al., 2018), and have become benchmarks for some annual KBQA competitions[2][3]. We did not employ the WebQuestions (Berant et al., 2013) dataset, since approximately 85% of its questions are simple. Also, we did not employ the ComplexQuestions (Bao et al., 2016) and ComplexWebQuestions (Talmor and Berant, 2018) dataset, since the existing works on these datasets have not reported the formal query generation result, and it is difficult to separate the formal query generation component from the end-to-end KBQA systems in these works.

[3] http://qald.aksw.org/index.php?q=5

Table 1: Datasets and implementation details

	LC-QuAD	QALD-5
No. of questions (complex)	3,253 (2,249)	311 (192)
No. of query structures	35	52
No. of freq. substructures	37	10
Avg. training time	1,102s	272s
Avg. prediction time	0.291s	0.122s
Avg. query generation time	0.356s	0.197s

Implementation details All the experiments were carried out on a machine with an Intel Xeon E3-1225 3.2GHz processor, 32 GB of RAM, and an NVIDIA GTX1080Ti GPU. For the embedding layer, we used random embedding. For each dataset, we performed 5-fold cross-validation with the train set (70%), development set (10%), and test set (20%). The threshold γ for frequent query substructures is set to 30, the maximum iteration number K for merging is set to 2, θ in Algorithm 1 is set to 0.3, the maximum triple number τ for merged results is set to 5, and the maximum aggregation number δ is set to 2. Other detailed statistics are shown in Table 1.

4.2 End-to-End Results

We compared SubQG with several existing approaches. SINA (Shekarpour et al., 2015) and NLIWOD conduct query generation by predefined rules and existing templates. SQG (Zafar et al., 2018) firstly generates candidate queries by finding valid walks containing all of entities and properties mentioned in questions, and then ranks them based on Tree-LSTM similarity. CompQA (Luo et al., 2018) is a KBQA system which achieved state-of-the-art performance on WebQuesions and ComplexQuestions over Freebase. We re-implemented its query generation component for DBpedia, which generates candidate queries by staged query generation, and ranks them using an encode-and-compare network.

The average F1-scores for the end-to-end query generation task are reported in Table 2. All these results are based on the gold standard entity/relation linking result as input. Our approach SubQG outperformed all the comparative approaches on both datasets. Furthermore, as the results shown in Table 3, it gained a more significant improvement on complex questions compared with CompQA.

Both SINA and NLIWOD did not employ a query ranking mechanism, i.e., their accuracy and coverage are limited by the rules and templates. Although both CompQA and SQG have a strong ability of generating candidate queries, they perform not quite well in query ranking. According to our observation, the main reason is that these approaches tried to learn entire representations for questions with different query structures (from simple to complex) using a single network, thus, they may suffer from the lack of training data, especially for the questions with rarely appeared structures. As a contrast, our approach leveraged multiple networks to learn predictors for different query substructures, and ranked query structures using combinational function, which gained a better performance.

The results on QALD-5 dataset is not as high as the result on LC-QuAD. This is because QALD-5 contains 11% of very difficult questions, requiring complex filtering conditions such as REGEX and numerical comparison. These questions are currently beyond our approach's ability. Also, the size of training data is significant smaller.

4.3 Detailed Analysis

4.3.1 Ablation Study

We compared the following settings of SubQG:

Rank w/o substructures. We replaced the query substructure prediction and query structure ranking module, by choosing an existing query structure in the training data for the input question, using a BiLSTM multiple classification network.

Rank w/ substructures We removed the merging module described in Section 3.4. This setting assumes that the appropriate query structure for an input question exists in the training data.

Merge query substructures This setting ignored existing query structures in the training data, and only considered the merged results of query substructures.

As the results shown in Table 4, the full ver-

Table 4: Average F1-scores for different settings

	LC-QuAD	QALD-5
SubQG	$\mathbf{0.846}_{\pm 0.016}$	$\mathbf{0.624}_{\pm 0.030}$
Rank w/o substructures	$0.756_{\pm 0.012}$	$0.383_{\pm 0.024}$
Rank w/ substructures	$0.841_{\pm 0.014}$	$0.614_{\pm 0.036}$
Merge query substructures	$0.679_{\pm 0.020}$	$0.454_{\pm 0.055}$

Table 5: Accuracy of query substructure prediction

	LC-QuAD	QALD-5
BiLSTM w/ attention	$\mathbf{0.929}_{\pm 0.002}$	$0.816_{\pm 0.010}$
BiLSTM w/o attention	$0.898_{\pm 0.004}$	$0.781_{\pm 0.009}$
BiLSTM w/ attention + POS	$0.925_{\pm 0.004}$	$\mathbf{0.818}_{\pm 0.007}$
CNN in (Yih et al., 2015)	$0.856_{\pm 0.006}$	$0.740_{\pm 0.010}$

sion of SubQG achieved the best results on both datasets. *Rank w/o substructures* gained a comparatively low performance, especially when there is inadequate training data (on QALD-5). Compared with *Rank w/ substructures*, SubQG gained a further improvement, which indicates that the merging method successfully handled questions with unseen query structures.

Table 5 shows the accuracy of some alternative networks for query substructure prediction (Section 3.2). By removing the attention mechanism (replaced by unweighted average), the accuracy declined approximately 3%. Adding additional part of speech tag sequence of the input question gained no significant improvement. We also tried to replace the attention based BiLSTM with the network in (Yih et al., 2015), which encodes questions with a convolutional layer followed by a max pooling layer. This approach did not perform well since it cannot capture long-term dependencies.

4.3.2 Results with Noisy Linking

We simulated the real KBQA environment by considering noisy entity/relation linking results. We firstly mixed the correct linking result for each mention with the top-5 candidates generated from EARL (Dubey et al., 2018), which is a joint entity/relation linking system with state-of-the-art performance on LC-QuAD. The result is shown in the second row of Table 6. Although the precision for first output declined 11.4%, in 85% cases we still can generate correct answer in top-5. This is because SubQG ranked query structures first and considered linking results in the last step. Many error linking results can be filtered out by the empty query check or domain/range check.

We also test the performance of our approach only using the EARL linking results. The performance dropped dramatically in comparison to the first two rows. The main reason is that, for

Table 6: Average Precision@k scores of query generation on LC-QuAD with noisy linking

	Precision@1	Precision@5
Gold standard	$0.842_{\pm 0.017}$	$0.886_{\pm 0.014}$
Top-5 EARL + gold standard	$0.728_{\pm 0.011}$	$0.850_{\pm 0.009}$
Top-5 EARL	$0.126_{\pm 0.012}$	$0.146_{\pm 0.010}$

82.8% of the questions, EARL provided partially correct results. If we consider the remaining questions, our system again have 73.2% and 84.8% of correctly-generated queries in top-1 and top-5 output, respectively.

4.3.3 Results on Varied Sizes of Training Data

We tested the performance of SubQG with different sizes of training data. The results on LC-QuAD dataset are shown in Figure 7. With more training data, our query substructure based approaches obtained stable improvements on both precision and recall. Although the merging module impaired the overall precision a little bit, it shows a bigger improvement on recall, especially when there is very few training data. Generally speaking, equipped with the merging module, our substructure based query generation approach showed the best performance.

4.3.4 Error Analysis

We analyzed 100 randomly sampled questions that SubQG did not return correct answers. The major causes of errors are summarized as follows:

Query structure errors (71%) occurred due to multiple reasons. Firstly, 21% of error cases have entity mentions that are not correctly detected before query substructure prediction, which highly influenced the prediction result. Secondly, in 39% of the cases a part of substructure predictors provided wrong prediction, which led to wrong structure ranking results. Finally, in the remaining 11% of the cases the correct query structure did not appear in the training data, and they cannot be generated by merging substructures.

Grounding errors (29%) occurred when SubQG generated wrong queries with correct query structures. For example, for the question *"Was Kevin Rudd the prime minister of Julia Gillard"*, SubQG cannot distinguish $\langle JG, primeMinister, KR\rangle$ from $\langle KR, primeMinister, JG\rangle$, since both triples exist in DBpedia. We believe that extra training data are required for fixing this problem.

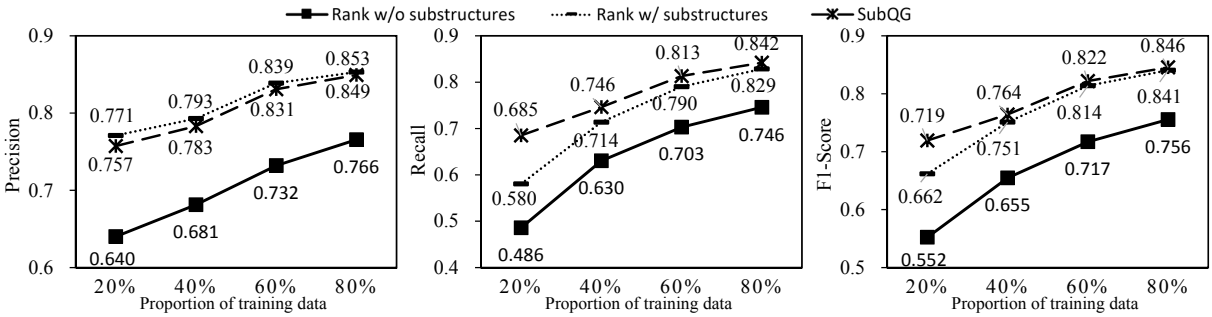

Figure 7: Precision, recall and F1-score with varied proportions of training data

5 Related Work

Alongside with entity and relation linking, existing KBQA systems often leverage formal query generation for complex question answering (Bao et al., 2016; Trivedi et al., 2017). Based on our investigation, the query generation approaches can be roughly divided into two kinds: *template*-based and *semantic parsing*-based.

Template-based approaches transform the input question into a formal query by employing pre-collected query templates. Cui et al.(2017) collect different natural language expressions for the same query intention from question-answer pairs. Singh et al.(2018) re-implement and evaluate the query generation module in NLIWOD, which selects an existing template by some simple features such as the number of entities and relations in the input question. Recently, several query decomposition methods are studied to enlarge the coverage of the templates. Abujabal et al.(2017) present a KBQA system named QUINT, which collects query templates for specific dependency structures from question-answer pairs. Furthermore, it rewrites the dependency parsing results for questions with conjunctions, and then performs sub-question answering and answer stitching. Zheng et al.(2018) decompose questions by using a huge number of triple-level templates extracted by distant supervision. Compared with these approaches, our approach predicts all kinds of query substructures (usually 1 to 4 triples) contained in the question, making full use of the training data. Also, our merging method can handle questions with unseen query structures, having a larger coverage and a more stable performance.

Semantic parsing-based approaches translate questions into formal queries using bottom up parsing (Berant et al., 2013) or staged query graph generation (Yih et al., 2015). gAnswer (Zou et al., 2014; Hu et al., 2018) builds up semantic query graph for question analysis and utilize subgraph matching for disambiguation. Recent studies combine parsing based approaches with neural networks, to enhance the ability for structure disambiguation. Bao et al.(2016), Luo et al.(2018) and Zafar et al.(2018) build query graphs by staged query generation, and follow an encode-and-compare framework to rank candidate queries with neural networks. These approaches try to learn entire representations for questions with different query structures by using a single network. Thus, they may suffer from the lack of training data, especially for questions with rarely appeared structures. By contrast, our approach utilizes multiple networks to learn predictors for different query substructures, which can gain a stable performance with limited training data. Also, our approach does not require manually-written rules, and performs stably with noisy linking results.

6 Conclusion

In this paper, we introduced SubQG, a formal query generation approach based on frequent query substructures. SubQG firstly utilizes multiple neural networks to predict query substructures contained in the question, and then ranks existing query structures using a combinational function. Moreover, SubQG merges query substructures to build new query structures for questions without appropriate query structures in the training data. Our experiments showed that SubQG achieved superior results than the existing approaches, especially for complex questions.

In future work, we plan to add support for other complex questions whose queries require UNION, GROUP BY, or numerical comparison. Also, we are interested in mining natural language expressions for each query substructures, which may help current parsing approaches.

Abstract

Knowledge Graph (KG) reasoning aims at finding reasoning paths for relations, in order to solve the problem of incompleteness in KG. Many previous path-based methods like PRA and DeepPath suffer from lacking memory components, or stuck in training. Therefore, their performances always rely on well-pretraining. In this paper, we present a deep reinforcement learning based model named by **AttnPath**, which incorporates LSTM and Graph Attention Mechanism as the memory components. We define two metrics, Mean Selection Rate (**MSR**) and Mean Replacement Rate (**MRR**), to quantitatively measure how difficult it is to learn the query relations, and take advantages of them to fine-tune the model under the framework of reinforcement learning. Meanwhile, a novel mechanism of reinforcement learning is proposed by forcing an agent to walk forward every step to avoid the agent stalling at the same entity node constantly. Based on this operation, the proposed model not only can get rid of the pretraining process, but also achieves state-of-the-art performance comparing with the other models. We test our model on FB15K-237 and NELL-995 datasets with different tasks. Extensive experiments show that our model is effective and competitive with many current state-of-the-art methods, and also performs well in practice.

1 Introduction

Knowledge Graphs (KGs), such as NELL (Carlson et al., 2010), Freebase (Bollacker et al., 2008) and WordNet (Miller, 1995) play an increasingly critical role in many downstream NLP applications, e.g., question answering (Dubey et al., 2018), information retrieval (Liu et al., 2018), personalized recommendations (Wang et al., 2019), etc. However, KGs are always incomplete, which would affect many downstream tasks. Many links could miss among the entities in a KG. Thus, it is an important and challenge task on how to complete the KG by predicting the missing links between the entities through the method based on reasoning. For instance, if $athletePlaysForTeam(X, Y)$ and $teamPlaysInLeague(Y, Z)$ both exist in the KG, then we can infer that $athletePlaysInLeague(X, Z)$, i.e, filling the missing edge $athletePlaysInLeague$ between X and Z.

There are mainly three ways to accomplish this task, such as Rule-Based (Wang and Cohen, 2016; Yang et al., 2017), Embedding-Based (Bordes et al., 2013; Lin et al., 2015) and Path-Based (Lao et al., 2011). Meanwhile, it provides a new perspective to bring Deep Reinforcement Learning (DRL) into the task of predicting the missing links, such as DeepPath (Xiong et al., 2017), a type of path-based method. DeepPath is the first work which incorporates DRL into KG reasoning. It achieves significant improvements compared with PRA, but still has several drawbacks. First, it lacks memory components, resulting in requiring **pretraining**. The operation of pretraining is demanded to provide many known (or existed) paths to the model training. This brute-force operation may make the model prone to overfit on the given paths from pretraining. Second, it's inappropriate to set the same hyperparameter for different relations in a KG when training, which ignores the diversity of connections among the entities. Last, when the agent selects an invalid path, it will stop and reselect, which leads to select this invalid path constantly and finally stuck in one node.

Thus, in this paper, we present a novel deep reinforcement learning model and an algorithm, which aims at tackling the drawbacks mentioned above. The proposed model also belongs to the path-based framework. Our contributions can be summarized as follows:

- We propose **AttnPath**, a model which incor-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2623–2631, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

porates **LSTM** and **graph attention** as memory components, and is no longer subject to pretraining.

- Two metrics are defined (**MSR** and **MRR**), to quantitatively measure the difficulty to learn a relation's replaceable paths, which are used to fine-tune the model.

- A novel mechanism of reinforcement learning is proposed by forcing an agent to walk forward every step to avoid the agent stalling at the same entity node constantly.

We test **AttnPath** on FB15K-237 and NELL-995 datasets with two downstream tasks: fact prediction and link prediction. We also test on the success rate in finding paths and show the effectiveness of the Graph Attention Mechanism in the experiments.

2 Related Works

To date, there are many works proposed to solve the problem of KG incompleteness. Rule-Based methods, like ProPPR (Wang and Cohen, 2016) and Neural LP (Yang et al., 2017), generate reasoning rules manually or by mathematical logic rules, and then apply them to fill missing links based on existing triples. Although this type of methods has a solid mathematical background, they are hard to scale to large KGs, since they directly operate on symbols, while the number of possible reasoning paths is exponential to the number of the entities. Embedding-Based methods, like TransE (Bordes et al., 2013) and TransR (Lin et al., 2015), map entities and relations into a low-dimensional and continuous vector space, which captures the feature of distance between entities and relations. Then, they judge whether the query relation exists by comparing the distance between the two trained entities' embeddings and the query relation's embedding. This type of methods requires all triples in the KG to participate in training, and are only suitable for single-hop reasoning.

Path-Based, like PRA (Lao et al., 2011) and DeepPath (Xiong et al., 2017), train an agent to navigate on a KG, find replaceable paths for a certain relation, and then, use them as features to the downstream tasks. Path Ranking Algorithm (PRA) is the first path-based reasoning method. Neelakantan et al. develop a compositional model based on RNN, which composes the implications of a path and reasons about conjunctions of multi-hop relations non-atomically (Neelakantan et al., 2015). Guu et al. propose a soft edge traversal operator, which can be recursively applied to predict paths and reduce cascaded propagation errors faced by single-hop KG completion methods like TransE and TransR (Guu et al., 2015). Toutanova et al. propose a dynamic programming algorithm which incorporates all relations' paths of bounded length in a KG, and models both relations and intermediate nodes in the compositional path representations (Toutanova et al., 2016). Such representations can aid in generating more high-quality reasoning paths.

Das et al. improve DeepPath (Xiong et al., 2017) to MINERVA (Das et al., 2018), which views KG from QA's perspective. It gets rid of pretraining, introduces LSTM to memorize paths traversed before, and trains an agent to circulate on a certain entity if it believes this entity is the right answer. Lin et al. improve these two methods by introducing reward shaping and action dropout (Lin et al., 2018). Reward shaping replaces fixed penalty for useless selection with a dynamic penalty, which can either base on margin-based pretrained embeddings like TransE, or probability-based embeddings like ConvE (Dettmers et al., 2018). While action dropout randomly masks a certain proportion of valid actions, in order to reduce irrelevant paths to the query relation. DIVA (Chen et al., 2018) regards paths as latent variables, and relations as observed variables, so as to build a variational inference model to accomplish the KG reasoning task. It also uses beam search to broaden the search horizon. M-Walk (Shen et al., 2018) utilizes another RL algorithm called Monte Carlo Tree Search (MCTS), to tackle the problem of sparse rewards. The attention mechanism is first introduced into multi-hop KG reasoning by (Wang et al., 2018). However, it only computes the attention weights of the query's embedding and all found paths' embeddings. They are used to help to judge whether the answer found by the vanilla model is true.

3 AttnPath: Incorporating Memory Components

In this section, we will introduce the details of the proposed AttnPath. We will also show the definition of mean selection rate (MSR) and mean replacement rate (MRR), and also how they are used to fine-tune the model for different query relations.

3.1 RL framework for KG reasoning

Since we use Reinforcement Learning (RL) as the training algorithm of a sequential decision model, we first introduce basic elements of the RL framework in the KG reasoning, including environment, state, action, and reward.

Environment: In this task, the environment refers to the whole KG, excluding the query relation and its inverse. The environment retains consistent in the whole training process.

State: The state of an agent is concatenated with three parts: the embedding part, the LSTM part, and the graph attention part. We will show the computation of the LSTM part and the graph attention part in the next section, and introduce the embedding part first.

Following (Xiong et al., 2017), the embedding part $\mathbf{m}_t$ is concatenated with two subparts. The first one is $\mathbf{e}_t$, which is the embedding of the current entity node. The other one is $\mathbf{e}_{target} - \mathbf{e}_t$, denoting the distance between the tail entity node and the current node. Different from DeepPath which uses TransE (Bordes et al., 2013) as pretrained embeddings, we take advantage of TransD (Ji et al., 2015), which is an improvement of TransE and also a common-used benchmark. Under TransD, for a query relation, we project all the entities onto the vector space of this query relation. Then, an entity's projected embedding $\mathbf{e}_\perp$ becomes

$$\mathbf{e}_\perp = (\mathbf{r_p}\mathbf{e_p}^\top + \mathbf{I})\mathbf{e}, \tag{1}$$

where $\mathbf{p}$ indicates the projection vectors. So $\mathbf{m}_t$ should be $[\mathbf{e}_{t\perp}; \mathbf{e}_{target\perp} - \mathbf{e}_{t\perp}]$.

Action: For the KG reasoning task, an action refers to an agent choosing a relation path to step forward. Based on the framework of DRL, it chooses the relation according to the probabilities obtained by the model. Actions are either valid or invalid. Valid action means that there is an output relation connected with the current entity, while invalid action denotes that there is no relation.

Reward: Reward is a feedback to the agent according to whether the action is valid, and whether a series of actions can lead to ground truth tail entities in a specified number of times. We adopt reward shaping trick proposed by (Lin et al., 2018). For the invalid actions, the reward is -1. For the actions which don't lead to ground truth, we choose the output of ConvE (Dettmers et al., 2018) as the reward. Since ConvE outputs probabilities, which are in the range of $(0, 1)$, we resort a logarithm operator to enlarge the range of this reward and improve discrimination. For the actions which lead to ground truth, i.e, a successful episode, the reward is the weighted sum of the global accuracy, the path efficiency, and the path diversity. The global accuracy is set to 1 by convention, and the path efficiency is the reciprocal of the path length, because we encourage the agent to step as fewer times as possible. The path diversity is defined as

$$r_{\text{DIVERSITY}} = -\frac{1}{|F|}\sum_{i=1}^{|F|}\cos(\mathbf{p}, \mathbf{p}_i), \tag{2}$$

where $|F|$ is the number of found paths, and $\mathbf{p}$ is the path embedding, simply the sum of all relations' embeddings in the path. The above definition guarantees that the reward of the valid actions are always larger than the invalid actions, and the reward of the successful episodes are always larger than the unsuccessful ones.

3.2 LSTM and Graph Attention as Memory Components

In our model, we utilize a three-layer LSTM, enabling the agent to memorize and learn from the actions taken before. Denote the hidden state of LSTM at step t by $\mathbf{h}_t$, and the initial hidden state $\mathbf{h}_0$ by $\mathbf{0}$. Then we obtain

$$\mathbf{h}_t = \text{LSTM}(\mathbf{h}_{t-1}, \mathbf{m}_t), \tag{3}$$

where $\mathbf{m}_t$ is defined in Eq. (1). This is the LSTM part of the state described above.

Typically, an entity has several different aspects, for example, a football player may be connected with professional relations like $playsForTeam$ or $playsInLeague$, and also family relations like $spouse$ or $father$. For different query relations, it's better for the agent to focus more on relations and neighbors which are highly related to the query relations. So we introduce Graph Attention mechanism (GAT) into our model, which is proposed by (Velickovic et al., 2018).

GAT is indeed self-attention on the entity nodes. We use a single-layer feedforward neural network to calculate attention weights, with a linear transformation matrix $\mathbf{W}$ and a weight vector $\vec{\mathbf{a}}$ shared across all entities. LeakyReLU with negative input slope $\alpha = 0.2$ is chosen as nonlinearity. So the attention weight from entity i to entity j is calculated as

$$a_{ij} = \text{LeakyReLU}(\vec{\mathbf{a}}^\top[\mathbf{W}\mathbf{e}_{i\perp}; \mathbf{W}\mathbf{e}_{j\perp}]). \tag{4}$$

For entity i, we only compute attention weights to all its direct-connected neighbors, and normalize them with SoftMax. So the normalized attention weight is

$$\alpha_{ij} = \frac{\exp(a_{ij})}{\sum_{k \in \mathcal{N}_i} \exp(a_{ik})}. \quad (5)$$

Now we can compute the graph attention part for the state, which is simply the weighted sum of all neighbors' embedding on the attention space with

$$\mathbf{a}_i = \sum_{k \in \mathcal{N}_i} \alpha_{ik} \mathbf{W} \mathbf{e}_k. \quad (6)$$

Thus, the state vector $\mathbf{s}_{i,t}$ of entity i in time t is

$$\mathbf{s}_{i,t} = [\mathbf{m}_{i,t}; \mathbf{h}_t; \mathbf{a}_i], \quad (7)$$

which in turn inputs a three-layer feedforward neural network, whose final output is a Softmax probability with length equal to the number of all relations in KG. The agent selects an action and obtains a reward. After it successfully reaches the tail entity or doesn't reach in a specified number of times, the rewards of the whole episode are used to update all parameters. The optimization is done using the REINFORCE (Williams, 1992) algorithm and updates θ with the following stochastic gradient:

$$\nabla_\theta J(\theta) \approx \nabla_\theta \sum_{t=1}^{T} R(\mathbf{s}_T | e_s, r) \log \pi_\theta(a_t | s_t), \quad (8)$$

where e_s is head entity, r the query relation, and $\pi_\theta(a_t|s_t)$ the probability of all relations. Figure 1 shows our **AttnPath** model.

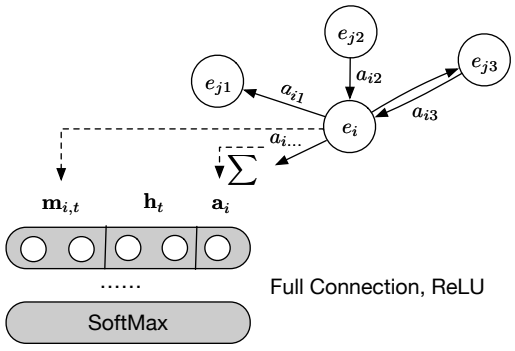

Figure 1: AttnPath: an RL framework composed with LSTM and graph attention for KG reasoning.

  end if
end for

3.3 Mean Selection / Replacement Rate

For different query relations, it is required to train different models for each of them. While, in practice, the difficulty values of each relation are quite different. Some relation may have more replacement relations, indicating that an agent can easily choose a replacement path walking from head entity to tail. So we invent two metrics, **Mean Selection Rate (MSR)** and **Mean Replacement Rate (MRR)** here, to quantitatively measure the difficulty value of each relation.

Denote all triples related to relation r by a set

of $\mathcal{T}_r = \{(h, r_o, t)|r_o = r\}$. The selection rate for relation r with regard to triple (h, r, t) is defined as

$$SR((h, r, t)) = \frac{|\{(h_o, r_o, t_o)|h_o = h, r_o = r\}|}{|\{(h_o, r_o, t_o)|h_o = h\}|}, \quad (9)$$

i.e, the proportion of relation r occupying h's outgoing paths.

Thus, MSR is the average of SR on $\mathcal{T}_r$:

$$MSR(r) = \sum_{(h_o,r,t_o)\in\mathcal{T}_r} SR(h_o, r, t_o)/|\mathcal{T}_r|. \quad (10)$$

Lower MSR denotes that it's more difficult to learn r, because the entities connected with relation r may have more aspects.

The replacement rate for relation r with regard to triple (h, r, t) is defined as

$$RR((h, r, t)) = \frac{|\{(h_o,r_o,t_o)|h_o=h,r_o\neq r,t_o=t\}|}{|\{(h_o,r_o,t_o)|h_o=h,t_o=t\}|}, \quad (11)$$

i.e, the proportion of relations that directly connects h and t, except relation r.

Similarly, MRR is the average of RR on $\mathcal{T}_r$:

$$MRR(r) = \sum_{(h_o,r,t_o)\in\mathcal{T}_r} RR(h_o, r, t_o)/|\mathcal{T}_r|. \quad (12)$$

Higher MRR denotes a relation may have more replacement relations, so it's easier to learn since an agent can directly choose an alternative relation to reach the destination.

In our model, we have three ways to prevent overfitting: L2 regularization, dropout, and action dropout. However, for the relations which are easier to learn (high MSR and MRR), we wish to impose more regularization to encourage the agent to find more diverse paths, without overfitting on the immediate success. Otherwise, for the relations which are more difficult to learn (low MSR and MRR), we'd better focus on the success rate of finding a path, so we should impose less regularization.

For simplicity, we use exponential to compute the difficulty coefficient of relation r. It is defined as $\exp(MSR(r) + MRR(r))$ and multiplied with the base rate of three regularization methods, respectively. The base rate of regularization methods is KG-based, shared across all relations in the same KG.

Table 1: Statistics of the datasets. #Rel. and #Tri. doesn't include the inverse triples.

Dataset	#Ent.	#Rel.	#Tri.	#Task
FB15K-237	14,505	237	310,116	20
NELL-995	75,492	200	154,213	12

3.4 Overall Training Algorithm

Based on the proposed model, we present a novel training algorithm shown in Algorithm 1.

One of our contributions in our algorithm is, when the agent selects an invalid path, our model not only penalizes it, but also forces it to select a valid relation to step forward. The probabilities from the neural network are normalized across all valid relations, which in turn act the probabilities of the forced action.

After the initializations, Line 6 samples an action according to the output of the network. When the agent selects an invalid action, Line 7 $\sim$ 10 is executed, and Line 9 $\sim$ 10 forces the agent to step forward. When the agent selects a valid action, Line 12 is executed. Lines 19, 22 and 25 update parameters for the invalid actions, the valid actions in a successful episode, and the valid actions in an unsuccessful episode, respectively, with reward -1, R_{total} and $R_{shaping}$.

4 Experiments

In this section, we will perform extensive experiments to validate the effectiveness of our proposed AttnPath. For each task, we will mainly focus on three quantitative metrics: success rate (**SR**) in finding paths, MAP of fact prediction (**FP**), and MAP of link prediction (**LP**). We will also demonstrate some reasoning paths and triples to show that graph attention is effective in finding more high-quality paths and mining which aspect of the entity is important in a specific task.

4.1 Datasets and Settings

Two datasets, FB15K-237 (Toutanova et al., 2015) and NELL-995 (Xiong et al., 2017), are used in our experiments. Statistics of these two datasets are displayed in Table 1. Following the previous works, for each triple (h, r, t), we add its inverse triple (t, r^{-1}, h), to allow the agent to step backward.

We summary the hyperparameters involved in our experiments here. The pretrained embedding dimension is set to 100. The LSTM hidden dimension is set to 200. The attention dimension

is set to 100. Thus, $\mathbf{s}$ is a 500-dimension vector by concatenating the above three vectors with two times of the pretrained embedding dimension. λ_1 is 0.1, λ_2 is 0.8, λ_3 is 0.1. For FB15K-237 dataset, we set base L2 regularization, Dropout rate and action dropout rate to 0.005, 0.15, and 0.15, respectively. Also, for NELL-995, we set them to 0.005, 0.1 and 0.1, respectively. We choose Adam (Kingma and Ba, 2015) as the optimizer with different learning rates of 0.001, β_1 0.9 and β_2 0.999. For each task, we train 500 episodes, and for each episode, max_steps is set to 50.

We verify the learned paths for each triple in FP and LP tasks when training, by the BFS-based method (Xiong et al., 2017).

4.2 Success Rate in Finding Paths

Our model is ignorant of the environment and triples at first, since it doesn't rely on pretraining. Thus, we record total SR, and SR in the recent 10 episodes to validate the agent's ability to learn the paths. For the tasks with less than 500 training samples, the samples are iterated first, then randomly sampled to reach 500 episodes. For the tasks with more than 500 training samples, we randomly select 500 out for training.

We select two relations, $athletePlaysInLeague$ and $organizationHeadquarteredInCity$ from NELL-995, to investigate its total SR and SR in recent 10 episodes. The former has relatively lower MSR and MRR, and the latter has higher. Figure 2 shows the results. It can be discovered that DeepPath outperforms our method at first, however, after 50 $\sim$ 150 epochs, our models surpass it. From SR-10 of AttnPath Force, we find that the initial SR is approximate to MRR, because the model knows nothing at all at first, so it selects a path randomly. As the training proceeds, the performance gains steady improvement. Similar results can also be found in other relations on FB15K-237.

4.3 Fact Prediction

Fact prediction (**FP**) aims at predicting whether an unknown fact is true or false. The proportion of positive triples and negative triples is about 1 : 10. For each relation, we use all found paths and reciprocal of length as weight, to accumulate the score of each triple based on whether the path is valid between h and t. Scores are ranked across all test set and Mean Average Precision (MAP) is used as the evaluation metric. The results are shown in Table 2. It can be seen that AttnPath outperforms TransE / R and DeepPath significantly. AttnPath MS / RR, which uses MSR and MRR to fine-tune the hyperparameters, also gains performance improvement. AttnPath Force is also effective. By forcing the agent to walk forward every step, it improves the SR of finding a path, which in turn enriches the feature of the downstream tasks. This is especially important for the relations, which lack direct-connected replacement paths and require path with long-term dependency. In fact, our methods achieve **SOTA** results on both the two datasets.

Table 2: Fact prediction MAP (%). Results of TransE / H / R / D are cited from (Xiong et al., 2017). DeepPath is retrained with TransD for a fair comparison, which performs slightly better than (Xiong et al., 2017) based on TransE.

Method	FB15K-237	NELL-995
TransE	27.7	38.3
TransH	30.9	38.9
TransR	30.2	40.6
TransD	30.3	41.3
DeepPath TransD	31.3	53.5
AttnPath	31.5	59.8
AttnPath MS / RR	34.6	65.4
AttnPath Force	**37.9**	**69.3**

4.4 Link Prediction

Link prediction (**LP**) aims at predicting the target entities. For each (h, r) pair, there is a ground truth t and about 10 generated false t. It is divided into a training set and a test set. We use the found paths as binary features, and train a classification model on the training set, applying it on the test set. LP also uses MAP as the evaluation metric, and the detailed results are shown in Table 3 [1]. Alike FP, our model also attains better results in LP, and the **SOTA** results on FB15K-237 dataset[2].

However, we also notice that AttnPath doesn't attain the best result under a small part of query relations, even lower than TransE / R. By analyzing triples related to these relations, we found that: 1) they have more outgoing edges of the other relations pointing to the entities which are not the

[1] We omit to show detailed result of TransH / D here, while (Xiong et al., 2017) also doesn't give detailed result of it, and it is mentioned in this paper that vanilla DeepPath already outperforms main embedding-based methods, including TransE / H / R / D.

[2] DIVA (Chen et al., 2018) claims that it attains 88.6% MAP on NELL-995 dataset.

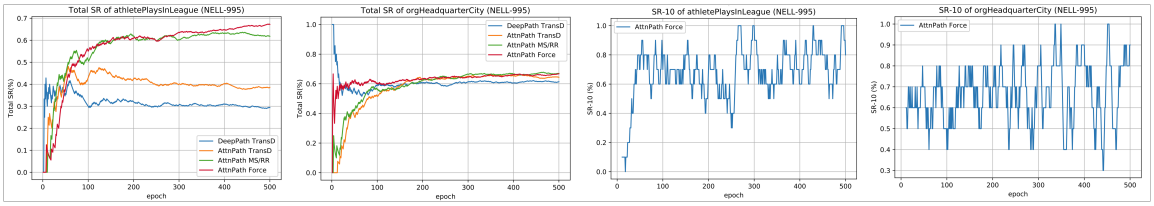

Figure 2: Total SR and SR-10 for two relations of NELL-995. DeepPath / AttnPath TransD means using TransD as the pretrained embeddings. AttnPath MS/RR is adding MSR and MRR to fine-tune hyperparameters. AttnPath Force is forcing the agent to move forward every step. These abbreviations are used throughout this section.

Table 3: Link Prediction MAP. Top half is **FB15K-237**, bottom half is **NELL-995**. TE, TR, DP, AP, APM and APF are abbreviations of TransE, TransR, DeepPath, AttnPath, AttnPath MS/RR, AttnPath Force, respectively. The result of TransE / R is cited from (Xiong et al., 2017). All the numbers are percentage (%).

true tails, so MSR of these query relations are low. 2) Tail entities are only connected with edges of query relations and their inverse, while these edges are removed during training, so tail entities become isolated, without any possible replaceable paths. It will also lower MRR of these query relations. Take $birthPlace$ and $bornLocation$ as examples. If a person was born in a remote place, this place is difficult to be connected with the other entities, so it is prone to be isolated. However, such one-to-one relations are the strength of TransX methods.

4.5 Qualitative Analysis

4.5.1 Paths Found By DeepPath and AttnPath

We take $capitalOf$ from FB15K-237, and $athletePlaysInLeague$ from NELL-995, as examples, to analyze these paths found by DeepPath and AttnPath. Table 4 shows the top 5 frequent paths and their frequencies for all the methods. It shows that AttnPath is more capable of capturing long-term dependencies between relations, which is useful for relations lack of direct-connected replaceable paths. AttnPath can also find more important and concentrated paths, so the distribution of paths doesn't have a heavy long tail. In the training process, we also find that AttnPath is better at stepping backward when it enters a dead end.

4.5.2 Effectiveness of Graph Attention Mechanism

We sample several pairs of entity and relation, compute the entity's attention weights to its neighbors under this relation, and investigate neighbors with top 5 attention weights. Table 5 displays the examples. It shows that GAT is capable of pay-

Table 4: Top 5 frequent paths found for $capitalOf$ (FB15K-237) and $athletePlaysInLeague$ (NELL-995) using two methods. "_inv" indicates inverse relation.

ing more attention to the neighbors, which is related to the query relation, especially for Anthony Minghella and Brandon Marshall, which pay different attention to neighbors with different query relations.

5 Conclusion and Future Work

In this paper, we propose **AttnPath**, a DRL based model for KG reasoning task which incorporates LSTM and Graph Attention Mechanism as memory components, to alleviate the model from pre-training. We also invent two metrics, MSR and MRR, to measure the learning difficulty of relations, and use it to better fine-tune training hyperparameters. We improve the training process to avoid the agent stalling in a meaningless state. Qualitative experiments and quantitative analysis show that our method outperforms DeepPath and embedding-based method significantly, proving its effectiveness.

In the future, we are interested in utilizing multi-task learning, to enable the model to learn reasoning paths for several query relations simultaneously. We would also like to research how to utilize GAT, MSR and MRR into other KG related tasks, such as KG representation, relation clustering and KB-QA.

Abstract

News streams contain rich up-to-date information which can be used to update knowledge graphs (KGs). Most current text-based KG updating methods rely on elaborately designed information extraction systems and carefully crafted rules, which are often domain-specific and hard to maintain or generalize. However, such methods may not pay enough attention to the implicit information that lies underneath texts, thus often suffer from coverage issues. In this paper, we propose a novel graph based neural network method, GUpdater, to tackle these problems[1]. GUpdater is built upon graph neural networks (GNNs) with a text-based attention mechanism to guide the updating message passing through the KG structures. Experiments on a real-world KG updating dataset show that our model can effectively broadcast the news information to the KG structures and perform necessary link-adding or link-deleting operations to ensure the KG up-to-date according to news snippets.

1 Introduction

Knowledge graphs have been widely used in different areas, where keeping the knowledge triples up-to-date is a crucial step to guarantee the KG quality.

Existing works attempt to synchronize KGs with encyclopedia sources (Morsey et al., 2012; Liang et al., 2017), which basically leverage structured data, while directly updating KGs using plain texts, such as news snippets, is not an easy task and still remains untouched. For example, given a KG recording the rosters of all NBA teams, we need to update this KG according to a news article which describes a trade between different teams. Given the following news snippet that reports a trade between Minnesota Timberwolves and Philadelphia 76ers, one has to add and delete many links in the KG, as illustrated in Figure 1.

> The Minnesota Timberwolves has acquired forward Robert Covington, forward Dario Šarić, guard Jerryd Bayless and a 2022 second-round draft pick from the Philadelphia 76ers in exchange for forward Jimmy Butler and center Justin Patton.

Current approaches either rely on manual updating, or often solve it in a two-step manner: first, using an off-the-shelf information extraction (IE) tool to extract triples from the text, and then modifying the KG according to certain rules predefined by domain experts. However, we should notice that besides what we can explicitly extract from the text, the implicit information, i.e., information that is not mentioned in the text but can be inferred from the text, should also be taken into consideration. This requires far more complicated updating rules. In the above example, if Robert Covington (RC) is traded from Philadelphia 76ers to Minnesota Timberwolves, his teammates should all be changed accordingly, which is not mentioned in the news at all. This is what we referred as implicit information in this scenario.

We should point out that both explicit and implicit information are just different aspects of the same event, which is different from another stream of research that focuses on the evolution of graphs (Pareja et al., 2019; Jin et al., 2019). For example, changing the head coach may trigger a possible trade for his/her favorite players in the future, but these are actually two events, thus beyond the scope of our work.

Intuitively, the implicit information behind the news is related to the KG structures. Many recent works focus on embedding a KG into a continuous vector space, which can be used to fill in miss-

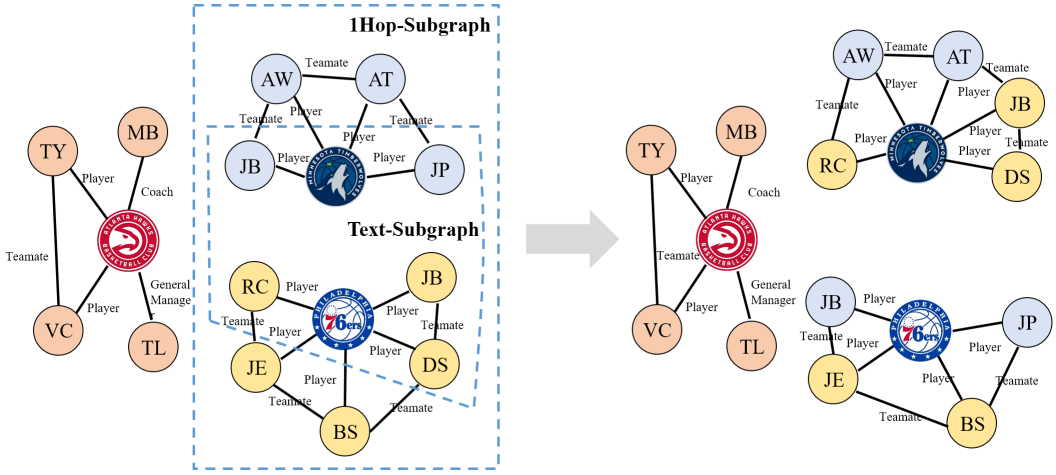

Figure 1: An example illustrating a trade in the KG of NBA teams. Note that all changes described by the news happen in the text-subgraph, the implicit changes, e.g., the teammate changes of player Robert Covington (RC), locate outside the text-subgraph but inside the 1hop-subgraph. The outside of the 1hop-subgraph, e.g, the Atlanta Hawks part, will not be affected by this trade.

ing links in KGs (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Yang et al., 2014; Trouillon et al., 2016; Schlichtkrull et al., 2018). However, most of them learn from static KGs, thus unable to help with our task, since they can not dynamically add new links or delete obsolete links according to extra text information.

In this paper, we propose a novel neural model, GUpdater, to tackle this problem, which features a graph based encoder to learn latent KG representations with the guidance from the news text, and a decoder to score candidate triples with reconstructing the KG as the objective. Our encoder is built upon the combination of recently proposed R-GCN (Schlichtkrull et al., 2018) and GAT (Velickovic et al., 2017) with two new key factors designed specifically for our task. The main idea is to control the updating message from the text passing through the KG. First, we use the given text to generate all the graph attention weights in order to selectively control message passing. Second, we link all entities mentioned in the news text together as shortcuts in order to let the message pass to each other even if they are topologically far from each other in the KG. For the decoder, we simply use DistMult (Yang et al., 2014) to score related triples to be updated. To evaluate our method, we construct a new real-world dataset, NBAtransactions, for this task. Experimental results show that our model can effectively use the news text to dynamically add new links and remove obsolete links accordingly.

Our contributions are in two-fold:

1. we propose a new text-based KG updating task and release a new real-world dataset to the community for further research.

2. we design a novel neural methodl, GUpdater, to read text snippets, which features an attention mechanism to selectively control the message passing over KG structures. This novel architecture enables us to perform both link-adding and link-deleting to ensure the KG up-to-date.

2 Task Formulation

We first formally define the task. Given a knowledge graph $\mathcal{G} = (\mathbf{E}, \mathbf{R}, \mathbf{T})$, where $\mathbf{E}$, $\mathbf{R}$ and $\mathbf{T}$ are the entity set, relation set and KG triple set, respectively, and a news text snippet $S = \{w_1, w_2, \cdots, w_{|S|}\}$, for which entity linking has been performed to build the mentioned entity set $\mathbf{L} \subset \mathbf{E}$, the text-based knowledge graph updating task is to read the news snippet S and update $\mathbf{T}$ accordingly to get the final triple set $\mathbf{T}'$ and the updated graph $\mathcal{G}' = (\mathbf{E}, \mathbf{R}, \mathbf{T}')$. In this paper, we focus on the scenarios where the entity set remains unchanged.

As a single event can only affect the KG in a limited range, for each event that is described by a news snippet, we consider two kinds of subgraphs that are defined by their entity sets, as illustrated in Figure 1:

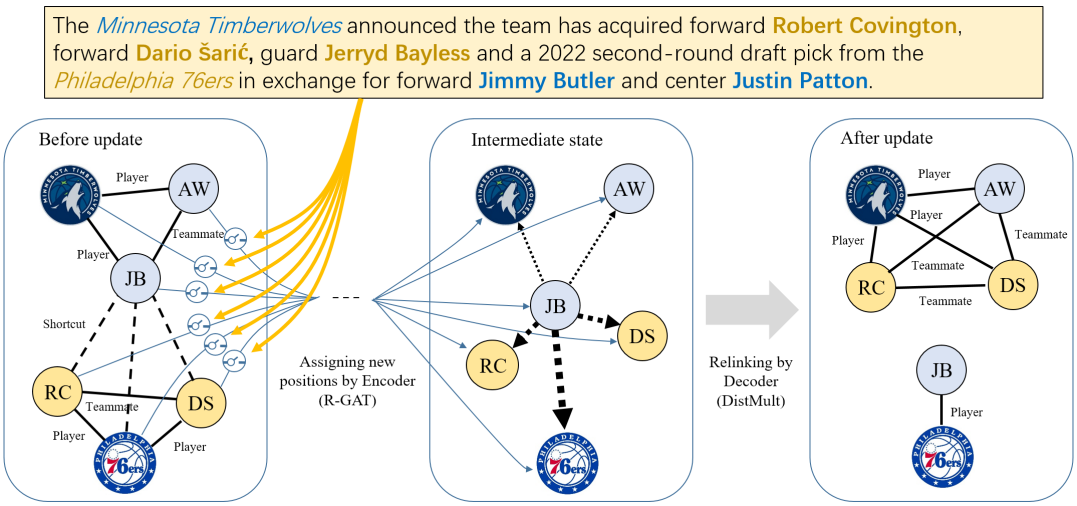

Figure 2: Overview of our GUpdater. By adding shortcuts in the R-GAT encoder, we enable Jimmy Butler (JB) to directly receive information from Philadelphia 76ers. Then with the guidance of text-based attention, Jimmy Butler selectively gathers neighbors' messages and moves closer to Philadelphia 76ers in the latent space. Dashed lines with arrow in the intermediate state indicate the moving directions, and the width of the dash line illustrates how possible Jimmy Butler will move to that direction. Finally, new links are generated by the DistMult decoder.

Text-Subgraph Subgraphs with entity set $\mathbf{E}_{text} = \mathbf{L}$, i.e., all the entities are mentioned in news snippet S. Explicit information in the texts can lead to changes in these graphs only.

1Hop-Subgraph If we expand text-subgraphs by one hop, we get 1hop-subgraphs. For each entity in 1hop-subgraphs, either itself or one of its neighbors is mentioned in the news. The one-hop entity set is formally defined as $\mathbf{E}_{1hop} = \{e|e \in \mathbf{L} \vee (((e,r,t) \in \mathbf{T} \vee (t,r,e) \in \mathbf{T}) \wedge t \in \mathbf{L})\}$.

We argue that updating in 1hop-subgraphs only is a good balance of effectiveness and efficiency. On the one hand, implicit changes always occur around explicit changes usually within a short distance. In fact, most of the implicit changes can be captured in the one-hop range. Here we give an extreme example: given the news snippet "*Barack Obama was elected president.*", the explicit change is to add (Barack Obama, Position, President) to the KG, while one of the implicit changes is to add (Michelle Obama, Position, First Lady) to the KG. Note that in this case, both "Michelle Obama" and "First Lady" are not mentioned in the news, but, because they are neighbors of "Barack Obama" and "President", respectively, this implicit change can be found in the 1hop-subgraph. On the other hand, updating in small subgraphs can avoid a huge amount of meaningless computation, and meanwhile can reduce mis-prediction. For these two reasons, we select the one-hop range, i.e., the 1hop-subgraph as the main testbed for this task. Also note that this one-hop setting can be easily extended to two-hop or larger scopes if necessary.

3 Our Method

The overview of our model is illustrated in Figure 2. As mentioned before, our GUpdater follows an encoder-decoder framework with the objective to reconstruct the modified KGs.

3.1 Relational Graph Attention Layer

In order to better capture the KG structures, we propose a new graph encoding layer, the relational graph attention layer (R-GAT), as the basic building block of GUpdater's encoder. R-GAT can be regarded as a combination of R-GCN (Schlichtkrull et al., 2018) and GAT (Velickovic et al., 2017), which benefits from both the ability of modeling relational data and the flexibility of attention mechanism. Recall that the layer-wise propagation rule of R-GCN can be written as follows:

$$\mathbf{H}^{l+1} = \sigma\left(\sum_{r \in \mathbf{R}} \hat{\mathbf{A}}_r^l \mathbf{H}^l \mathbf{W}_r^l\right), \quad (1)$$

where $\hat{\mathbf{A}}_r^l$ is the normalized adjacent matrix for relation r, W_r^l is a layer-specific trainable weight matrix for relation r, and $\sigma(\cdot)$ denotes an activa-

tion function, here we use ReLU. H^l is the latent entity representations in the l^{th} layer.

Upon R-GCN, we can easily introduce attention mechanisms by computing $\hat{\mathbf{A}}_r$ using an attention function:

$$a_{ij}^{lr} = \begin{cases} \dfrac{\exp(att^{lr}(\mathbf{h}_i^l, \mathbf{h}_j^l))}{\sum_{k \in \mathcal{N}_i^r} \exp(att^{lr}(\mathbf{h}_i^l, \mathbf{h}_k^l))} & , j \in \mathcal{N}_i^r \\ 0 & , \text{otherwise} \end{cases} \tag{2}$$

where a_{ij}^{lr} is the i^{th} row and j^{th} column element of $\hat{\mathbf{A}}_r^l$, and $\mathcal{N}_i^r$ denotes the set of neighbor indices of node i under relation r. $att^{lr}(\cdot,\cdot)$ is the attention function. $\mathbf{h}_i^l$ and $\mathbf{h}_j^l$ are the i^{th} and the j^{th} entity representations of layer l, respectively.

A known issue for R-GCN (Eq.(1)) is that the number of model parameters grows rapidly with the increasing number of relation types. We thus use *basis-decomposition* (Schlichtkrull et al., 2018) for regularization. In a standard R-GCN layer, if there are R relations involved, there will be R weight matrices for each layer. Basis-decomposition regularizes these matrices by defining each weight matrix as a linear combination of $B(B < R)$ basis matrices, which significantly decreases the parameter number.

3.2 Text-based Attention

The core idea of GNNs is to gather neighbors' information. In our case, we propose a text-based attention mechanism to utilize the news snippet to guide the message passing along the KG structure within the R-GAT layer.

We first use bi-GRU (Cho et al., 2014) to encode the given news text S into a sequence of representations $\{\mathbf{u}_1, \mathbf{u}_2, \cdots, \mathbf{u}_{|S|}\}$, then we leverage the sequence attention mechanism (Luong et al., 2015) to compute the context vector:

$$\mathbf{c}^{lr} = \sum_{t=1}^{|S|} b_t^{lr} \mathbf{u}_t \tag{3}$$

where b_t^{lr} is the text attention weight, and is computed as follow:

$$b_t^{lr} = \frac{\exp(\mathbf{u}_t^T \mathbf{g}_{text}^{lr})}{\sum_{k=1}^{|S|} \exp(\mathbf{u}_k^T \mathbf{g}_{text}^{lr})} \tag{4}$$

where $\mathbf{g}_{text}^{lr}$ is a trainable guidance vector to guide the extraction of relation-dependent context.

Recall that in GAT, the way to compute the attention weights is similar to the formula below:

$$att^{lr}(\mathbf{h}_i^l, \mathbf{h}_j^l) = {\mathbf{g}_{graph}^{lr}}^T [\mathbf{h}_i^l || \mathbf{h}_j^l] \tag{5}$$

where $||$ denotes concatenation operation, and $\mathbf{g}_{graph}^{lr}$ is a relation-specific trainable vector that serves as a graph guidance vector to decide which edge to pay attention to.

Here, we generate the final guidance vector $\mathbf{g}_{fin}^{lr}$ that combines textual information to the graph guidance vector by simply using linear interpolation, and we replace $\mathbf{g}_{graph}^{lr}$ in Eq.(5) by $\mathbf{g}_{fin}^{lr}$ to get our final attention function:

$$\mathbf{g}_{fin}^{lr} = \alpha^{lr} \mathbf{g}_{graph}^{lr} + (1 - \alpha^{lr}) \mathbf{U}^{lr} \mathbf{c}^{lr}, \tag{6}$$

$$att^{lr}(\mathbf{h}_i^l, \mathbf{h}_j^l) = {\mathbf{g}_{fin}^{lr}}^T [\mathbf{h}_i^l || \mathbf{h}_j^l] \tag{7}$$

where $\mathbf{U}^{lr}$ is a trainable transformation matrix, and $\alpha^{lr} \in [0, 1]$ can either be trainable or fixed. If we set $\alpha^{lr} = 1$, then Eq.(7) degenerates to Eq.(5) and our encoder degenerates to R-GAT. It makes it easy to pre-train the model to get good embeddings for all entities and relations when news snippets are not provided.

3.3 Shortcuts

Shortcuts In practice, entities in $\mathbf{L}$ can be far from each other in the KG, even unreachable sometimes, while a single- or two-layer R-GAT can only gather information from a near neighborhood. In order to encourage more direct interactions through the graph structure, before running the model, we simply link all entities in $\mathbf{L}$ to each other and assign these links with a new relation label, *SHORTCUT*.

Shortcuts with labels Actually, relations between entities in $\mathbf{L}$ can be different. For example, if a player is traded from one team to another, the relations between this player and that two teams must be opposite. Thus a unified shortcut label may make it difficult to correctly pass opposite messages, even with the help of the attention mechanism. So we further extend the shortcuts' label to 3 types: *ADD*, *DEL* and *OTHER*. *ADD* (*DEL*) denotes that these triples are explicitly mentioned in the text to be added to (deleted from) the KG. The rest are labeled with *OTHER*. Off-the-shelf IE tools can be used to generate these labeled shortcuts.

	Data type distribution		Edge number distribution (average number of edges in one instance)					
Type	**Count**	**Percentage**	**Added**	**Deleted**	**Unchanged**	**T-added**	**T-deleted**	**T-unchanged**
Trade	1245	30.4%	37.48	37.19	330.51	2.08	2.09	0.50
Head coach	77	1.9%	1.0	1.0	217.0	1.0	1.0	0.14
Free agency	1078	26.3%	19.19	0.0	179.89	1.0	0.0	0.0
Draft	137	3.3%	18.84	0.0	173.42	1.0	0.0	0.0
Released	1382	33.7%	0.0	18.65	170.26	0.0	1.0	0.0
Overseas	85	2.1%	0.0	17.62	150.05	0.0	1.0	0.0
Retirement	57	1.4%	0.0	16.51	132.07	0.0	1.0	0.0
D-league	39	1.0%	0.0	19.13	178.0	0.0	1.0	0.0
Overall	4100	100%	17.07	18.37	221.56	0.95	1.03	0.15

Table 1: The Statistics of NBAtransactions. Added, Deleted and Unchanged represent the average number of edges that should be added to, deleted from and remain unchanged in the KG, respectively. T-added represents the average edge addition in the text-subgraphs, similar for T-deleted and T-unchanged.

Here, we easily build a simple extraction model using our GUpdater encoder. We get the entity representations from GUpdater's encoder (with unified shortcuts), then for each entity pair (e_i, e_j), where $e_i, e_j \in \mathbf{L}, i \neq j$, we use an MLP classifier to get the probability of each label:

$$P(z) = \text{softmax}\left(\text{MLP}([\mathbf{h}_i||\mathbf{h}_j])\right) \quad (8)$$

where shortcut label $z \in \{\textit{ADD}, \textit{DEL}, \textit{OTHER}\}$, $\mathbf{h}_i$ and $\mathbf{h}_j$ are entity representations for entity e_i, e_j, respectively.

In our experiments, we train the shortcut-labeling module separately, as we find that the results are good enough while saving training time. One can surely perform the extraction step in a joint training fashion.

3.4 Decoder

We use DistMult (Yang et al., 2014), which is known to have good performance on standard KG completion tasks, followed by sigmoid function, as the decoder, i.e., for each possible triple (e_i, r_k, e_j) where $e_i, e_j \in \mathbf{E}_{1hop}, r_k \in \mathbf{R}$, the probability of this triple to appear in the final KG is computed as follow:

$$P(y) = \text{sigmoid}\left(\mathbf{h}_i^T(\mathbf{r}_k \circ \mathbf{h}_j)\right) \quad (9)$$

where $\circ$ denotes element-wise multiplication.

Since we formulate KG updating as a binary classification task, we use the cross-entropy loss to train the model.

4 Experiments

4.1 Dataset

We construct a new dataset, NBAtransactions, to evaluate our method. NBAtransactions contains 4,100 transaction-news pairs in NBA from 2010 to 2019, 3,261 for training, 417 for validation and 422 for testing. We consider 8 different kinds of transactions, which can be divided into 3 categories according to the updating patterns: 1) *Adding edges only*: free agency and draft. 2) *Deleting edges only*: released, overseas, retirement and d-league. 3) *Both adding and deleting edges*: trade and head coach.

For each transaction, a news snippet S with mentioned entity set $\mathbf{L}$ and two undirected KG fragments, $\mathcal{G}_{1hop}$ and $\mathcal{G}'_{1hop}$, representing the corresponding 1hop-subgraphes before and after the transaction, respectively, are given. Averagely, one subgraph contains 27.86 entities, 4 types of relations, and 239.28 triples, and one news snippet contains 29.10 words and 2.66 KG entities. Each transaction averagely causes adding of 17.07 edges and deleting of 18.37 edges; among them, only 0.95 (for adding) and 1.03 edges (for deleting) are in the text-subgraph, i.e., only 5.6% of the edge changes are explicitly mentioned in the news texts. Detailed statistics are shown in Table 1.

Our dataset is collected from several NBA related webistes. The KGs we used in the dataset are constructed using the roster of each NBA team in each season collected from Basketball-Reference[2]. For each NBA season, we build a large KG that records all teams, players, head coaches, general managers and their relations at the beginning of that season. So there are 9 large KGs in total, one KG for one NBA season. Wikipedia[3] records all NBA transactions from 1946 to 2019 in a structured form and provides URLs of news sources for most of the transactions after 2010. We crawled all the available

[2] https://www.basketball-reference.com

[3] https://en.wikipedia.org/wiki/Category:NBA_transactions

news and corresponding transactions. For each transaction, $\mathcal{G}_{1hop}$ can be easily extracted from the corresponding large KG. However, we cannot get $\mathcal{G}'_{1hop}$ directly, as our KGs only record the rosters at the beginning of each season. To generate the $\mathcal{G}'_{1hop}$, we manually create a large set of complicated conversion rules for each transaction type to modify $\mathcal{G}_{1hop}$ and obtain the 1hop-subgraph after the transaction. We use string matching algorithms to perform entity linking, and meanwhile generate the mentioned entity set $\mathbf{L}$.

4.2 Setup

The dimensions of all embeddings (words, entities, and relations) are all set to 128, and the hidden dimension is 256. We use a single layer encoder, as we find that more layers do not bring any benefit. The basis number of basis-decomposition is 2. We replace the word embeddings of entity mentions in the text by the entity embeddings for better alignment of word embedding space and entity embedding space. The entity embeddings and relation embeddings are pre-trained using R-GAT, and the word embeddings are randomly initialized. We set dropout (Srivastava et al., 2014) rate to 0.5. The batch size in our experiments is 1. We use Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 for training.

We consider updating in two different scopes: 1) Text-Subgraphs: changes in these subgraphs correspond to the explicit information mentioned in the texts. 2) 1Hop-Subgraphs: all explicit and implicit changes happen in these subgraphs, thus this setting is treated as the overall/real-world updating evaluation.

4.3 Metrics

As our model aims to reconstruct the KG using binary classification, i.e., deciding whether a possible triple should be in the modified KG, we use accuracy, precision, recall and F1 score as the evaluation metrics. Further, to evaluate the ability of link-adding, link-deleting and link-preserving, respectively, we collect all added edges, deleted edges, and unchanged edges and compute the prediction accuracies separately, which we denote as Added Acc, Deleted Acc and Unchanged Acc, respectively.

4.4 Baseline Models

Because most current text-based KG updating methods are in two steps: first extract information from texts, then add and remove links in KGs, we select non-rule-based models that perform well on these two steps and also their combination as our baseline models.

PCNN (Zeng et al., 2015) is a strong baseline for relation extraction, which divides the sentence into three pieces and applies max-pooling in a piecewise manner after the convolution layer.

IE-gold is a simulation of an ideal IE model that can perfectly extract explicit information from given texts. This is an upper bound for the information extraction step.

DistMult (Yang et al., 2014) is a widely-used multiplication-based triple scoring function for KG completion, which computes the three-way inner-product of the triples. Its symmetric nature is suitable for NBAtransactions as the KGs are undirected.

R-GCN (Schlichtkrull et al., 2018) is one of the strongest baselines for KG completion, which first encodes entities by gathering neighbors' information, then decodes them by DistMult. Note that compared to traditional KG completion tasks, here the target KGs are the modified KGs and usually different from the input KGs. Because of the lack of network structure, single DistMult is unable to train like this.

IE-gold + R-GCN is the combination of IE-gold and R-GCN. We first use IE-gold to generate a perfectly updated text-subgraph, then use R-GCN to predict other changes outside the text-subgraph.

4.5 Main Results

We summarize the main results in Table 2. As we can see, PCNN performs pretty well in extracting explicit information from the news (over 0.96 in Added Acc, Deleted Acc and Unchanged Acc in Text-Subgraphs). However, the explicit changes only take up 5.8% in the testing set, while the majority of changes are implicit. Therefore, even a perfect IE model, IE-gold, which never makes any wrong predictions, can only correctly predict about 6% of the changes in the 1hop-subgraphs.

The implicit changes are highly related to KG structures. Compared to DistMult, which just preserves the original structures and scores 0.0656 in Added Acc, 0.1220 in Deleted Acc in the 1Hop-Subgraphs, R-GCN can use the modified KGs for training and learns to predict changes without reading the news. R-GCN beats DistMult by

	Accuracy	Precision	Recall	F1	Added Acc	Deleted Acc	Unchanged Acc
Text-Subgraphs							
PCNN	0.9664	0.9573	0.9676	0.9624	0.9674	0.9638	0.9686
IE-gold	1.0	1.0	1.0	1.0	1.0	1.0	1.0
DistMult	0.8372	0.1640	0.1670	0.1655	0.0679	0.0652	0.7093
R-GCN	0.8601	0.3249	0.4147	0.3644	0.4055	0.2077	0.4651
IE-gold + R-GCN	1.0	1.0	1.0	1.0	1.0	1.0	1.0
GUpdater	0.9783	0.8871	0.8887	0.8879	0.8684	0.9185	0.9651
1Hop-Subgraphs							
PCNN	0.9799	0.9245	0.9270	0.9257	0.0586	0.0541	0.9995
IE-gold	0.9805	0.9248	0.9274	0.9261	0.0606	0.0561	1.0
DistMult	0.9644	0.8277	0.9225	0.8725	0.0656	0.1220	0.9944
R-GCN	0.9837	0.9243	0.9547	0.9393	0.4348	0.2005	0.9984
IE-gold + R-GCN	0.9847	0.9285	0.9577	0.9429	0.4681	0.2448	0.9989
GUpdater	0.9964	0.9819	0.9913	0.9866	0.8926	0.8988	0.9991

Table 2: Model performance on NBAtransactions. Here, PCNN performs multi-class classification while others are binary classification models.

0.37 in Added Acc and 0.08 in Deleted Acc in the 1Hop-Subgraphs. Such a huge improvement suggests that the blind prediction is not completely arbitrary, and R-GCN indeed learns certain updating patterns through the KG structures. Besides, R-GCN scores 0.9393 in F1 in the 1hop-subgraphs, outperforms IE-gold by 1%, once again underlines the importance of implicit changes.

IE-gold + R-GCN combines the advantages of IE-gold and R-GCN, and performs best among the baselines. However, in the 1hop-subgraphs, the Added Acc and Deleted Acc are only 0.4681 and 0.2448, which are still quite low. Although IE-gold + R-GCN can perfectly extract explicit information from the news, there is no mechanism for the IE model to pass the extracted information to the R-GCN module, thus this two-step method still performs poorly in finding out the implicit changes.

For overall performance, GUpdater significantly outperforms all baseline models, which coincides to our intuition. Particularly, in the 1hop-subgraphs, GUpdater beats IE-gold + R-GCN by 0.42 in Added Acc, 0.65 in Deleted Acc, indicating that GUpdater can well capture both explicit and implicit information in the news snippets.

4.6 Ablation Analysis

We also perform ablation test to figure out the effect of each component of GUpdater. As shown in Table 3, compared to R-GAT, both GUpdater-shortcut (GUpdater without shortcut) and GUpdater-text (GUpdater without text-based attention) improve the overall performance with different levels, showing that both the text-based attention and the shortcuts are helpful for this task.

Generally, we can see that adding shortcuts is key to this task, as it brings a giant leap to nearly all indicators. Actually, updating KGs using news can be regarded as information injection from one semantic space to another, the text mentioned entities can be seen as junctions of these two spaces and serve as entrances for information injection. So, in the KG, the text mentioned entities are information sources, and send messages to the explicitly and implicitly related target entities. However, the targets may be very far and hard to reach, it is the shortcuts that make the successful information delivery possible.

However, if there are too many shortcuts, the messages are easy to get to wrong targets. The text-based attention mechanism can be regarded as gates that selectively open several shortcuts that are easy for message passing, and this helps the model get 2%-3% steady improvements in both Added Acc and Deleted Acc.

When adding explicit labels to shortcuts, we get much better performance than the basic GUpdater (7% improvement in Added Acc, 8% improvement in Deleted Acc in 1hop-subgraphs), which indicates that splitting the shortcuts into different channels for different kinds of messages is crucial for better information delivery, and that makes it easier to dig out implicit information. The result also indicates that our model is well extensible and can easily incorporate off-the-shelf IE tools.

4.7 Visualization of Attention on Shortcuts

In order to explore how the information actually passes along shortcuts, we select 5 different types of trades, as shown in Table 4, and we get the corresponding attention weight on each shortcut in

	Accuracy	Precision	Recall	F1	Added Acc	Deleted Acc	Unchanged Acc
Text-Subgraphs							
GUpdater	0.9783	0.8871	0.8887	0.8879	0.8684	0.9185	0.9651
-shortcut-text (R-GAT)	0.8623	0.3343	0.4273	0.3751	0.4225	0.2179	0.4535
-shortcut	0.8656	0.3551	0.4776	0.4074	0.2059	0.5112	0.3372
-text	0.9705	0.8550	0.8366	0.8457	0.8323	0.8982	0.8605
GUpdater+label	0.9936	0.9779	0.9551	0.9664	0.9584	0.9603	0.9862
1Hop-Subgraphs							
GUpdater	0.9964	0.9819	0.9913	0.9866	0.8926	0.8988	0.9991
-shortcut-text (R-GAT)	0.9833	0.9216	0.9547	0.9378	0.4290	0.2073	0.9990
-shortcut	0.9843	0.9267	0.9563	0.9413	0.4726	0.2044	0.9989
-text	0.9957	0.9793	0.9885	0.9839	0.8668	0.8619	0.9987
GUpdater+label	0.9981	0.9889	0.9969	0.9929	0.9668	0.9792	0.9991

Table 3: Results of the ablation test, where -text indicates removing the text-based attention mechanism from GUpdater.

GUpdater. We find that most shortcuts are closed by the attention mechanism, i.e., their corresponding attention weights are very close to 0, and only a small portion of shortcuts are open for message passing.

For each trade type, the remaining shortcuts are organized in a similar pattern: there is a central team selected by the model that sends messages to all other entities and receives the message from another team. For symmetric trades, i.e., each team plays the same role in the trade (T2, T3 in Table 4), the selection of the central team seems to be arbitrary, while for asymmetric trades (T4, T5), the central teams are the teams that involved in more transactions.

It seems that GUpdater learns a 2-team trade rule from that pattern: if two teams send messages mutually through shortcuts, they will exchange all their players in text-subgraphs. T1 and T2 are most simple 2-team trades, thus our model updates the graphs perfectly with this message passing pattern. T4 and T5 look difficult and complicated, but they are actually direct combinations of two simple 2-team trades, e.g., T4 can be decomposed into two trades: the Grizzlies trades JS to the Celtics for FM, and the Thunder trades RG to the Celtics. So for these trades, GUpdater also performs quite well, as only two not-that-important triples are missing in T5. However, in T3, three teams exchange players in a rotation, and it cannot be decomposed into several 2-team trades, thus leads to a severe mis-prediction: (TS, player, Jazz), as placing a player in a wrong team may cause more teammate-errors in the 1hop-subgraph. The inability of perfectly performing rotational three-team trades may due to the lack of training instance, as in the past 10 years, such kind of trade happened nearly once a year.

5 Related Work

KG Representation Learning aims to embed a KG into a continuous vector space, which preserves the KG structures. There are mainly two streams of researches. The first is addition-based models (also called translation-based models), which based on the principle that for every valid triple (h, r, t), their embeddings holds: $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. **TransE**(Bordes et al., 2013) is the first such model. **TransH**(Wang et al., 2014) projects entity embeddings into relation-specific hyperplanes. **TransR**(Lin et al., 2015) generalize TransH by extending projection to linear transformation. **TransD** (Ji et al., 2015) simplifies TransR by decomposing the transformation matrix into the product of two vectors. Another is multiplication-based models, which comes from the idea of tensor decomposition. **RESCAL**(Nickel et al., 2011) is one of the earlist studies, which using a bilinear scoring function. **DistMult**(Yang et al., 2014) simplifies RESCAL by using a diagonal matrix. **ComplEx**(Trouillon et al., 2016) extend DistMult into the complex space to handle asymmetric relations. **SimplE** (Kazemi and Poole, 2018) learns two embeddings for each entity dependently. A direct application is KG completion.

Graph Neural Networks allow passing information horizontally among nodes (Gilmer et al., 2017). Recently, many tecniques has been incorporated to GNN model, and lots of attempt has bean made to promote GNNs to more application scenarios. **GCN**(Kipf and Welling, 2016) leverages graph spectrums for semi-supervised node classification. **GAT**(Velickovic et al., 2017) extends GCN by bringing attention mechanism

	$\mathcal{G}_{text}$	$\mathcal{G}'_{text}$	Selected Shortcuts	Results in Text-Subgraph
T1				✓
T2				✓
T3				wrong predictions: (TS, player, Jazz) (TS, teammate, Pacers)
T4				✓
T5				missing triples: (VK, teammate, BM) (TE, teammate, BM)

Table 4: Examples of visualization for the attention on shortcuts. Each row shows an example of one type of trade. $\mathcal{G}_{text}$ and $\mathcal{G}'_{text}$ represent the actual text-subgraphs before and after the trade, respectively. *Selected Shortcuts* represents the shortcuts selected by the attention mechanism, and the arrows indicate the directions of message passing. *Results in Text-Subgraph* lists the prediction errors of GUpdater.

into GNN. To better capture KG information, **R-GCN**(Schlichtkrull et al., 2018) was proposed to incorporates relation embeddings into GNN.

Relation Extraction task aims to extract relations from texts. Current relation extraction models are mainly under distant supervision (Mintz et al., 2009), and are trained in bag level. **PCNN** (Zeng et al., 2015) divides the sentence into three pieces and applies max-pooling in a piecewise manner after the convolution layer. **APCNN** (Ji et al., 2017) uses sentence-level attention to select multiple valid sentences with different weights in a bag. (Luo et al., 2017) uses a transition matrix to model the noise and use curriculum for training.

6 Conclusion

In this paper, we propose a new text-based KG updating task and construct a dataset, NBAtransactions, for evaluation. We design a novel GNN-based model, GUpdater, which uses text information to guide the message passing through the KG structure. Experiments show that our model can effectively handle both explicit and implicit information, and perform necessary link-adding and link-deleting operations accordingly. In the future, we will try to investigate how to update KGs when entities are involved in several successive events.

{liruiping,chengxiang}@bupt.edu.cn

Abstract

Knowledge graphs (KGs) often suffer from sparseness and incompleteness. Knowledge graph reasoning provides a feasible way to address such problems. Recent studies on knowledge graph reasoning have shown that reinforcement learning (RL) based methods can provide state-of-the-art performance. However, existing RL-based methods require numerous trials for path-finding and rely heavily on meticulous reward engineering to fit specific dataset, which is inefficient and laborious to apply to fast-evolving KGs. In this paper, we present DIVINE, a novel plug-and-play framework based on generative adversarial imitation learning for enhancing existing RL-based methods. DIVINE guides the path-finding process, and learns reasoning policies and reward functions self-adaptively through imitating the demonstrations automatically sampled from KGs. Experimental results on two benchmark datasets show that our framework improves the performance of existing RL-based methods without extra reward engineering.

1 Introduction

Knowledge graphs (Suchanek et al., 2007; Auer et al., 2007; Bollacker et al., 2008; Carlson et al., 2010; Vrandečić and Krötzsch, 2014), typically composed of massive relational triples, are useful resources for many downstream natural language processing applications such as information extraction and question answering. Although existing KGs have an extraordinarily large scale, they are still highly incomplete (Min et al., 2013), leading extensive research efforts on automated inference of missing information from observed evidence. In this paper, we focus on the problem of multi-hop reasoning in KGs, which learns explicit inference formulas from existing triples to complete missing ones.

*Corresponding author

To tackle multi-hop reasoning, various path-based methods (Lao et al., 2011; Gardner et al., 2013, 2014; Guu et al., 2015; Neelakantan et al., 2015; Toutanova et al., 2016; Das et al., 2017) have been proposed, which leverage the elaborately selected relational paths in KGs as the reasoning evidence. However, such evidential paths are obtained by random walks, which inevitably introduces inferior or even noisy paths. To address this problem, the RL-based methods, such as DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018), strive for more reliable evidential paths by policy-conditioned walking and achieve state-of-the-art performance. They formulate the path-finding problem as a Markov decision process where their policy-based agents continuously choose the most promising relation for state transition based on the current state and reasoning policy. Once a relational path found, the reasoning policy is updated by a reward function according to the path quality. Finally, through such a trial-and-error process, the well-trained policy-based agent can be used to find evidential paths for predictions.

However, these RL-based methods still suffer from the following pain points. Firstly, they tend to require numerous trials from scratch to find a reliable evidential path since the action space can be very large due to the complexity of KGs, which leads to poor convergence properties. Secondly, and most importantly, an efficient trial-and-error optimization in RL requires designing a reward function manually to fit the specific dataset. However, such reward engineering depends on meticulous artificial design with domain expertise, which can be significantly challenging in practice (Ng et al., 2000). In particular, these RL-based methods are extremely sensitive to their reward functions, where a little variation may lead to a significant fluctuation of the reasoning performance.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2642–2651, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Therefore, for different datasets, the reward functions in the RL-based methods need manual adjustments to achieve a good performance, which will not only be inefficient and laborious but also difficult to adapt to the rapid evolutions of real-world KGs (Shi and Weninger, 2018).

In this paper, we present a novel plug-and-play framework based on generative adversarial imitation learning (GAIL) (Ho and Ermon, 2016) for enhancing existing RL-based methods, which is referred to as DIVINE for "Deep Inference via Imitating Non-human Experts". DIVINE trains a reasoner, consisting of a generator and a discriminator, from demonstrations by employing generative adversarial training, where the generator can be any of the policy-based agents in existing RL-based methods and the discriminator can be considered as a self-adaptive reward function. In this way, for different datasets, the reward functions can be automatically tuned to approximate the optimal performance, eliminating extra reward engineering and manual interventions. In particular, to enable the policy-based agent to find more diverse evidential paths for predictions, we propose a path-based GAIL method, which can learn the reasoning policy by imitating the path-level semantic features of the demonstrations. In addition, to acquire demonstrations without extra manual labor, we design an automated sampler for our framework to dynamically sample relational paths from KGs as the demonstrations according to the specific environment of each entity.

In summary, our contributions are threefold:

- We present a plug-and-play framework based on GAIL to enhance existing RL-based reasoning in KGs by learning reasoning policies and reward functions through imitating demonstrations. To the best of our knowledge, we are the first to introduce GAIL into the field of knowledge graph reasoning.
- We propose a path-based GAIL method to encourage the diversity of evidential paths and design an automated sampler for our framework to sample demonstrations without extra manual labor.
- We conduct extensive experiments on two benchmark datasets. The experimental results illustrate that our framework improves the performance of the current state-of-the-art RL-based methods while eliminating extra reward engineering.

2 Related Work

Automated reasoning on KGs has been a long-standing task for natural language processing. In recent years, various embedding-based methods using tensor factorization (Nickel et al., 2011; Bordes et al., 2013; Riedel et al., 2013; Yang et al., 2014; Trouillon et al., 2017) or neural network models (Socher et al., 2013) have been developed, where they learn a projection which maps the triples into a continuous vector space for further tensor operations. Despite the impressive results they achieved, most of them lack the ability to capture chains of multi-hop reasoning patterns contained in paths.

To address the limitation of the embedding-based methods, a series of path-based methods have been proposed, which consider the selected relational paths as reasoning evidence. Lao et al. (2011) propose the Path-Ranking Algorithm (PRA) which uses random walks for path-finding. Gardner et al. (2013, 2014) propose a variation on PRA which computes feature similarity in the vector space. To combine the embedding-based methods, several neural multi-hop models (Neelakantan et al., 2015; Guu et al., 2015; Toutanova et al., 2015, 2016; Das et al., 2017) are proposed which perform a hybrid reasoning. Nevertheless, the evidential paths they used are gathered by random walks, which might be inferior and noisy.

Recently, DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018) were proposed to address the problem above by using reinforcement learning, where they are committed to learn a policy which guides the agent to find more superior evidential paths to maximize the expected reward. Specifically, DeepPath parameterizes its policy with a fully-connected neural network and uses manual reward criteria, including global accuracy, efficiency and diversity, to evaluate the path quality. In the training phase, DeepPath applies the linear combination of these criteria as the positive reward while using a hand-craft constant as the negative penalty. As for MINERVA, it parameterizes its policy with a long short-term memory network (LSTM) and considers the path validity as the only reward criterion. In the training phase, MINERVA uses boolean value as a terminal signal to evaluate whether the current path reaches the target entity and manually tunes a moving average of cumulative discounted reward on different datasets for variance reduction.

3 Preliminaries

3.1 Knowledge Graph Reasoning

Given an incomplete knowledge graph $\mathcal{G} = \{(h, r, t)|h \in \mathcal{E}, t \in \mathcal{E}, r \in \mathcal{R}\}$, where $\mathcal{E}$ and $\mathcal{R}$ denote the entity set and relation set, respectively. There are two main tasks in knowledge graph reasoning, namely link prediction and fact prediction. Link prediction involves inferring the tail entity t given the head entity h and the query relation r_q, while fact prediction seeks to predict whether an unknown fact (h, r_q, t) holds or not. Recently, RL-based reasoning has become a popular approach for knowledge graph reasoning, which achieves state-of-the-art performance. In general, RL-based reasoning methods strive to find relational paths to tune their reasoning policies for predictions and formulate the path-finding problem as a Markov decision process (MDP). In such a process, the policy-based agent decides to take an action $a \in \mathcal{A}$ from the current state (i.e., the current entity and its context information) $s \in \mathcal{S}$ to reach the next one according to its reasoning policy π, where the action space is defined as all the relations in $\mathcal{G}$. In particular, each relational chain in the relational paths can be considered as a reasoning chain.

3.2 Imitation Learning

Imitation learning focuses on learning policies from demonstrations, which has achieved great success in solving reward engineering. The classical approach is to find the optimal reward function by inverse reinforcement learning (IRL) (Russell, 1998; Ng et al., 2000) to explain expert behaviors. However, IRL requires solving RL inside a learning loop, which can be expensive to run in large environments. Therefore, generative adversarial imitation learning (GAIL) (Ho and Ermon, 2016) has recently been proposed, which learns the expert policy with generative adversarial network (GAN) (Goodfellow et al., 2014), eliminating any intermediate IRL steps.

In GAIL, a generator G_θ is trained to generate trajectories matching the distribution of expert trajectories (i.e., demonstrations). Each trajectory τ is represented as a state-action sequence $[(s_t, a_t)]_{t=0}^{\infty}$ $(s_t \in \mathcal{S}, a_t \in \mathcal{A})$. In addition, a discriminator D_ω is learned to distinguish between the generated policy π_θ and expert policy π_E. For each training epoch, the discriminator is updated first with the gradient as:

$$\mathbb{E}_\tau[\nabla_\omega log(D(s,a))] + \mathbb{E}_{\tau_E}[\nabla_\omega log(1 - D(s,a))], \quad (1)$$

where τ_E denotes the expert trajectories generated by π_E and the trajectory expectation can be calculated in the γ-discounted infinite horizon as:

$$\mathbb{E}_\tau[D(s,a)] = \sum_{t=0}^{\infty} \mathbb{E}[\gamma^t D(s_t, a_t)], \quad (2)$$

where the discriminator here can be interpreted as a local reward function to provide feedback for the policy learning process. Then, the generator is updated with the cost function $\log(D(s,a))$ using the trust region policy optimization (TRPO) (Schulman et al., 2015). After sufficient adversarial training, the optimal policy $\hat{\pi}$ can be found by GAIL to rationalize the expert policy π_E.

4 Methodology

4.1 Framework Overview

As shown in Figure 1, our framework DIVINE consists of two modules, namely a generative adversarial reasoner and a demonstration sampler. In particular, the reasoner is composed of a generator and a discriminator. The generator can be any of the policy-based agents in existing RL-based methods and the discriminator can be interpreted as a self-adaptive reward function. For each query relation, the sampler and the generator are adopted respectively to automatically extract demonstrations and generate relational paths from the given KG. The discriminator is then used to evaluate the semantic similarity between the generated paths and demonstrations to update the generator.

After sufficient adversarial training between the generator and the discriminator alternatively, the well-trained policy-based agent (i.e., generator) can be used to find evidential paths matching the distribution of the demonstrations and make predictions by synthesizing these evidential paths.

4.2 Generative Adversarial Reasoner

In our framework, the reasoner is learned from the demonstrations through generative adversarial training. A straightforward approach is to directly apply GAIL to train the reasoner. In particular, the policy-based agent in the reasoner is trained to find evidential paths by imitating the state-action pairs in each expert trajectory (i.e., demonstration). However, such an approach may lead to

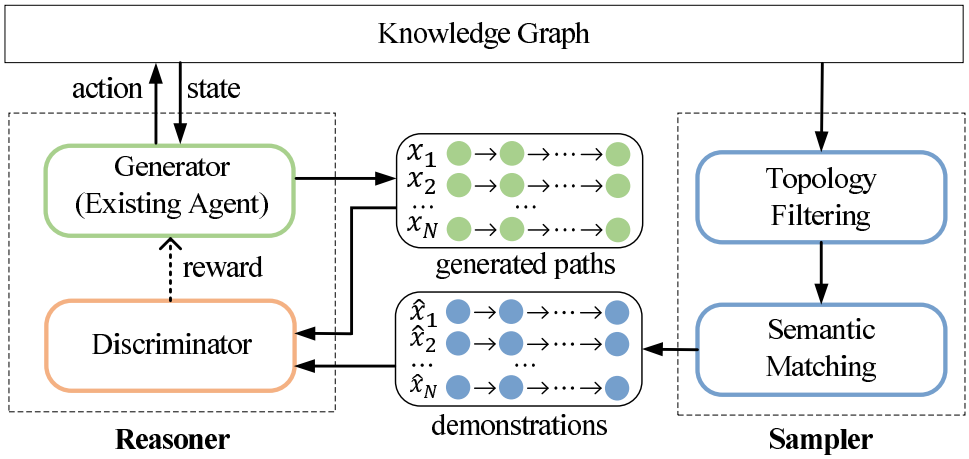

Figure 1: Overview of our framework DIVINE, where the generator can be any of the existing policy-based agent for knowledge graph reasoning and the discriminator can be considered as a self-adaptive reward function.

poor performance. The main reason lies in that the agent will tend to choose the same actions as in the expert trajectories under certain states, while ignoring many valuable evidential paths which are semantically similar to the expert trajectories but contain different reasoning chains.

Therefore, to encourage the agent to find more diverse evidential paths, it is desirable to train the agent by imitating each trajectory instead of each of its state-action pairs. In addition, in the scenario of knowledge graph reasoning, since the reasoning chains consist of only relations, the demonstrations do not necessarily contain the state information. In other words, the demonstrations can be composed of only relational paths.

Based on the above analysis, we propose a path-based GAIL method, where the reasoning policy is learned by imitating the path-level semantic features of the demonstrations which are composed of only relational paths.

In what follows, we first describe the two components of the reasoner, i.e., the generator and the discriminator. Then, we show how to extract the path-level semantic features.

Generator

The generator can be any of the policy-based agent in existing RL-based methods. We strive to enable the generator to find more diverse evidential paths matching the distribution of the demonstrations in the semantic space.

Discriminator

To better semantically distinguish between generated paths and demonstrations, we choose the convolutional neural networks (CNNs) to construct our discriminator D, as CNNs have shown high performance in semantic feature extraction from natural languages (Kim, 2014).

Semantic Feature Extraction

For each positive entity pair, we respectively pack the current generated paths and corresponding demonstrations in the same package form. For each package $\mathcal{P} = \{x_1, x_2, ..., x_N\}$ containing N relational paths, we encode the package to a real-valued matrix as:

$$\boldsymbol{p} = \boldsymbol{x}_1 \oplus \boldsymbol{x}_2 \oplus ... \oplus \boldsymbol{x}_N, \tag{3}$$

where $\boldsymbol{x}_n \in \mathbb{R}^k$ is the k-dimensional path embedding and $\oplus$ denotes the concatenation operator for the package representation $\boldsymbol{p} \in \mathbb{R}^{N \times k}$. In particular, given a relational path $x = \{r_1, r_2, ...r_t, ...\}$, the path embedding $\boldsymbol{x}$ is encoded as:

$$\boldsymbol{x} = \sum_{r_t \in x} \boldsymbol{r}_t, \tag{4}$$

where each relation r_t is mapped into a real-valued embedding $\boldsymbol{r}_t \in \mathbb{R}^k$ pre-trained by TransE (Bordes et al., 2013).

After packing, we feed the package representation $\boldsymbol{p}$ into our discriminator D to parameterize its semantic features $D(\boldsymbol{p})$. Specifically, a convolutional layer activated by ReLU nonlinearity is first used to extract local features by sliding a kernel $\boldsymbol{\omega} \in \mathbb{R}^{h \times l}$ for a new feature map:

$$\boldsymbol{c} = ReLU(Conv(\boldsymbol{p}, \boldsymbol{\omega}) + \boldsymbol{b}_c), \tag{5}$$

where $\boldsymbol{b}_c$ denotes the bias term. Then, a fully-connected hidden layer and an output layer are used for further semantic feature extraction:

$$D(\boldsymbol{p}) = \sigma(\boldsymbol{W}_2 ReLU(\boldsymbol{W}_1 \boldsymbol{c})), \tag{6}$$

where the corresponding biases are not shown above for brevity and the output layer is normalized by a sigmoid function while other layers are activated by ReLU nonlinearity.

4.3 Demonstration Sampler

For imitation learning, the first prerequisite is to have high-quality demonstrations. However, due to the large scale and complexity of KGs, manually constructing a large number of reasoning demonstrations requires considerable time and expert efforts. Therefore, we design an automated sampler to sample reliable reasoning demonstrations from KGs without supervision and extra manual labor.

Static Demo Sampling

For each query relation, we use all positive entity pairs to sample demonstration candidates from the given KG. Specifically, for each positive entity pair, we use bi-directional breadth-first search to explore the shortest path between two entities. In particular, since the shorter paths incline to characterize more direct correlations between two entities, we prefer to use them for initialization to ensure the quality of demonstration candidates. As for the longer paths, despite their potential utility values, they are more likely to contain worthless or even noisy inference steps, thus we learn them only in the training phase. In doing so, we can get a demonstration set Ω_E which contains all the candidates we sampled. Finally, to accommodate the fixed input dimension of the discriminator D, we can simply select a subset $P_e \subseteq \Omega_E$ with the top N occurrence frequency, where N is normally much smaller than $|\Omega_E|$.

Dynamic Demo Sampling

Despite the simplicity of the static demo sampling method, the obtained demonstrations by this method are fixed and ignore the specific environment of each entity in the given KG. Therefore, we propose an improving method to dynamically sample demonstrations by taking the topological correlations of entities into consideration.

Given a positive entity pair $\langle e_{head}, e_{tail} \rangle$, we introduce a relational set $\mathcal{R}_h$ which contains all relations directly connected to e_{head}. For each reasoning attempt, $\mathcal{R}_h$ can be considered as the region of interest (ROI) of the agent to start reasoning, where the ROI related paths tend to be more relevant to the current entity pair. Thus, we refine the demonstration set by filtering out the demonstrations which begin from $\mathcal{R}_h$:

$$\Omega'_E = \{x \mid r_1(x) \in \mathcal{R}_h, x \in \Omega_E\} \ (\mathcal{R}_h \neq \varnothing), \quad (7)$$

where Ω_E is generated by the static demo sampling method and $r_1(x)$ denotes the first relation in relational path $x = \{r_1, r_2, ...r_t, ...\}$.

In most cases, we can obtain enough demonstrations in Ω'_E to select a subset $P_e \subseteq \Omega'_E$ in the same way as the static demo sampling method. However, due to the sparsity of data in KG, we may get insufficient demonstrations on long-tail entities. To solve this problem, we perform semantic matching to explore more demonstrations from the remaining candidates $\mathcal{C}_E = \Omega_E \setminus \Omega'_E$. Since the reasoning policy is updated based on the semantic similarities between the generated paths and demonstrations, candidates which are semantically similar to the current demonstrations are also instructive for the imitation process.

Inspired by the neighborhood attention for one-shot imitation learning (Duan et al., 2017), we use each demonstration in Ω'_E to query other candidates in correlation to itself. We adopt the dot product to measure the semantic matching similarity between two path embeddings:

$$\alpha_i = \sum_{x_j \in \Omega'_E} \bar{\boldsymbol{x}}_i \cdot \boldsymbol{x}_j \quad i = 1, 2, ..., |\mathcal{C}_E|, \quad (8)$$

where α_i represents the sum of matching scores between the current candidate $\bar{x}_i$ and existing demonstrations in Ω'_E. Finally, we iteratively select the candidate with the highest α to pad the refined demonstration set Ω'_E until accommodating the required input dimension N.

4.4 Training

In the training phase, all the positive entity pairs are used to generate demonstration candidates Ω_E for the imitation learning process. Specifically, for each positive entity pair, the demonstration sampler is required first to choose the corresponding demonstrations, while the generator is conducted to generate some relational paths. Then, the demonstrations are packed into package $\mathcal{P}_e$ and the generated paths are packed into different packages $\{\mathcal{P}_g \mid \mathcal{P}_g \subseteq \Omega_G\}$ according to their validity, i.e., whether the agent can reach the target entity along the current path, where Ω_G is the collection of all generated paths.

For each package pair $\langle \mathcal{P}_g, \mathcal{P}_e \rangle$, we train the discriminator D by minimizing its loss and expect it to be expert in distinguishing between $\mathcal{P}_e$ and $\mathcal{P}_g$. In addition, to make the adversarial training process more stable and effective, we adopt the loss function proposed in WGAN-GP (Gulrajani et al., 2017) to update the discriminator:

$$\begin{aligned} \mathcal{L}_C &= \mathbb{E}[D(\boldsymbol{p}_g)] - \mathbb{E}[D(\boldsymbol{p}_e)]; \\ \mathcal{L}_P &= \lambda \mathbb{E}[(\parallel \nabla_{\tilde{\boldsymbol{p}}} D(\tilde{\boldsymbol{p}}) \parallel_2 -1)^2]; \\ \mathcal{L}_D &= \mathcal{L}_C + \mathcal{L}_P, \end{aligned} \tag{9}$$

where $\mathcal{L}_C$, $\mathcal{L}_P$ and $\mathcal{L}_D$ respectively denote the original critic loss, gradient penalty and the loss of discriminator, λ is the gradient penalty coefficient and $\tilde{\boldsymbol{p}}$ is sampled uniformly along straight lines between $\boldsymbol{p}_g$ and $\boldsymbol{p}_e$. According to the feedback of the discriminator, we calculate the reward $\mathcal{R}_G$ as:

$$\mathcal{R}_G = \delta_g \max\{\mathbb{E}[D(\boldsymbol{p}_g)] - \mathbb{E}[D(\boldsymbol{p}_n)], 0\}, \tag{10}$$

$$\delta_g = \begin{cases} 1, & \mathcal{P}_g \subseteq \Omega_G^+ \\ 0, & otherwise \end{cases}, \tag{11}$$

where $\boldsymbol{p}_n$ denotes a noise embedding composed of random noise with continuous uniform distribution, δ_g is a characteristic function which characterizes the validity of package $\mathcal{P}_g$, Ω_G^+ is the collection of all valid generated paths. We only give positive rewards for partial valid paths that at least have higher expectations than noise embedding $\boldsymbol{p}_n$, which filters out the paths of inferior quality to improve the convergence efficiency of the training process. Once the reward obtained, we updated the generator G by maximizing the expected cumulative reward with Monte-Carlo Policy Gradient (i.e., REINFORCE) (Williams, 1992).

We use mini-batch stochastic gradient descent (SGD) to optimize the loss function of discriminator, while the generator is updated with the Adam algorithm (Kingma and Ba, 2014).

5 Experiments

5.1 Datasets and Evaluation Metrics

Dataset	# Ent.	# Rel.	# Facts	# Tasks
NELL-995	75,492	200	154,213	12
FB15K-237	14,505	237	310,116	20

Table 1: Statistics of the datasets. # Ent. denotes the number of unique entities and # Rel. denotes the number of relations.

The experiments are conducted on two benchmark datasets: NELL-995 (Xiong et al., 2017) and FB15K-237 (Toutanova et al., 2015). The details of the two datasets are described in Table 1. In particular, NELL-995, which is known to be a simple dataset for reasoning tasks, is generated from the 995th iteration of the NELL system (Carlson et al., 2010) by selecting the triples with Top-200 frequently occurring relations. Compared to NELL-995, FB15K-237 is more challenging and closer to real-world scenarios, where its facts are created from FB15K (Bordes et al., 2013) with redundant relations removed. For each triple (h, r, t), both datasets contain the inverse triple (h, r^{-1}, t) such that the agent can step backward in KGs, which makes it possible to recover from a potentially wrong decision that has been taken before. For each reasoning task with a query relation r_q, all the triples with r_q or r_q^{-1} are removed from the KG and split into train and test samples.

Similar to recent works (Das et al., 2018; Xiong et al., 2017), we use mean average precision (MAP), mean reciprocal rank (MRR) and Hits@k to evaluate the reasoning performance, where Hits@k is the fraction of positive instances ranked in the top k positions.

5.2 Baselines and Implementation Details

In our experiments, we consider two state-of-the-art RL-based methods as baselines: DeepPath (Xiong et al., 2017) and MINERVA (Das et al., 2018). Deep path feeds the gathered evidential paths to PRA (Lao et al., 2011) for both link prediction and fact prediction tasks, while MINERVA directly applies the well-trained agent to the link prediction task for question answering. For DeepPath, we use the code released by Xiong et al. (2017). For MINERVA, we use the code released by Das et al. (2018). The experiment settings for the baselines are set according to the suggestions in the original papers.

In the implementation of our framework, we set the path number N to 5 for each path package $\mathcal{P}$, while the path dimension k is set to 200 which is the same as the relation dimension in baselines. For the discriminator, we set the convolution kernel size to 3×5, the hidden layer size to 1024, and the output layer size to the path dimension k, while the gradient penalty coefficient λ is set to 5 and L2 regularization is also used to avoid over-fitting.

During testing, we also rank the answer triples

Data	Metric	Link Prediction				Fact Prediction	
		DeepPath	**Div(DeepPath)**	**MINERVA**	**Div(MINERVA)**	**DeepPath**	**Div(DeepPath)**
NELL-995	Hits@1	0.718	0.749	0.799/0.663†	0.840/0.668†	0.687	0.701
	Hits@3	0.847	0.878	0.936/0.773†	0.936/0.778†	0.839	0.841
	MRR	0.784	0.811	0.852/0.725†	0.874/0.731†	0.764	0.774
	MAP	0.796	0.821	0.885	0.893	0.774/0.493‡	0.785/0.494‡
FB15K-237	Hits@1	0.417	0.520	0.427/0.217†	0.444/0.223†	0.394	0.421
	Hits@3	0.646	0.740	0.582/0.329†	0.590/0.331†	0.565	0.599
	MRR	0.560	0.639	0.546/0.293†	0.556/0.296†	0.522	0.545
	MAP	0.572	0.658	0.553	0.568	0.536/0.311‡	0.558/0.339‡

Table 2: Overall results on NELL-995 and FB15K-237. "†" denotes the results with settings for question answering and "‡" denotes the results of directly ranking all the positive and negative triples given a query relation.

against the negative triples used in DeepPath and MINERVA. In particular, there are approximately 10 corresponding negative triples for each positive ones. Each negative triple is generated by replacing the answer entity t with a faked one t' given a positive triple (h, r, t).

5.3 Results

The main results on the two datasets are shown in Table 2. We use "Div(*)" to denote the RL-based method "*" which adopts our framework DIVINE. For a fair comparison, we follow MINERVA to report the Hits@k and MRR scores (denoted with "†") to evaluate the link prediction performance for question answering, which ranks entities according to the probability that the agent can reach the entity along evidential paths. Moreover, we also follow DeepPath to report the MAP scores (denoted with "‡") on the fact prediction task, which directly ranks all the positive and negative triples for a given query relation.

From the results shown in Table 2, we can observe that our framework produces consistent improvements for the two RL-based methods under varying degrees on both link prediction and fact prediction tasks. On the one hand, for existing RL-based methods, their results on FB15K-237 are generally lower than those on NELL-995 since FB15K-237 is more complex and arguably more difficult to design proper reward functions manually. However, our framework reliefs this problem to some extent by dynamically learning superior reward functions, thus we make greater improvements on challenging FB15K-237. On the other hand, for different datasets, the improvements our framework makes for DeepPath vary a lot while MINERVA not. This is because MINERVA manually adjusts its hyper-parameters accordingly when calculating cumulative discounted reward, while DeepPath keeps the same. Obviously, it validates the necessity for existing RL-based methods to adjust their reward functions accordingly to fit different datasets. Enhanced by our framework, these RL-based methods no longer require additional manual adjustments for different datasets, which reveals great robustness.

Similar to existing RL-based methods, we also report the decomposed results of link prediction and use MAP to evaluate the performance for each query relation on NELL-995 in Table 3. From the results, we can observe that the results on different relations are of high variance and the enhanced RL-based methods achieve better or comparable performance for all query relations.

5.4 Effectiveness of the Path-Based GAIL Method

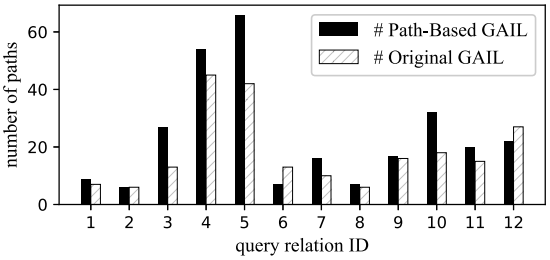

Figure 2: Statistics of path-finding on NELL-995.

	Path Avg.	MAP

(11) TeampPlaysSport	0.739	**0.816**	0.846	**0.874**
(12) WorksFor	0.711	**0.741**	**0.825**	0.822
Overall	0.796	**0.821**	0.885	**0.893**

Table 3: Results of link prediction decomposed over different query relations on NELL-995.

gent by the original GAIL method, the demonstrations are composed of state-action trajectories. For each state-action pair (s_t, a_t), the state representation $\boldsymbol{s}_t$ is calculated by $(\boldsymbol{e}_t, \boldsymbol{e}_{tail} - \boldsymbol{e}_t)$, where $\boldsymbol{e}_t$ and $\boldsymbol{e}_{tail}$ denote the embeddings of the current entity and the tail entity, respectively. In Figure 2, we show the statistics of the evidential path set P_{new} which are found by the agent and different from the demonstrations. In Table 4, we compare the average path number of P_{new} and the reasoning performance on the two prediction tasks.

As shown in Figure 2 and Table 4, we can observe that our path-based GAIL method obtains more evidential paths for most query relations and achieves better performance on both link and fact predictions, which validates the effectiveness of our path-based GAIL method and the rationality of encouraging the agent to find more diverse evidential paths.

5.5 Ablation Studies

We conduct ablation studies by embedding DeepPath into our framework to quantify the role of components. Specifically, we re-train our framework by ablating certain components:

- W/O Semantic Matching, where no semantic matching is performed on long-tail entities. Instead, we directly extract some paths from the remaining demonstration candidates $\mathcal{C}_E$ according to their occurrence frequency.
- W/O Dynamic Sampling, where no dynamic demo sampling is performed to incorporate the local environment of entities. In other words, we only adopt the static demo sampling method to obtain demonstrations.
- W/O Demo Sampling, where no demonstration is used for imitation learning, which degenerates to DeepPath.

	MAP	
Configuration	NELL-995	FB15K-237
Div(DeepPath)	0.821	0.658
W/O Semantic Matching	0.818	0.651
W/O Dynamic Sampling	0.806	0.640
W/O Demo Sampling	0.796	0.572

Table 5: Ablation on different components.

We use MAP to evaluate the link prediction performance on both NELL-995 and FB15K-237 in Table 5. From the results, we can observe that: (1) Based on imitation learning, our framework can effectively improve the reasoning performance, even if we use the static demo sampling method to obtain demonstrations; (2) High-quality demonstrations are crucial for imitation learning, which indicates both topology filtering and semantic matching play important roles in the demonstration sampler of our framework.

6 Conclusion

In this paper, we proposed a novel plug-and-play framework DIVINE for knowledge graph reasoning based on generative adversarial imitation learning, which enables existing RL-based methods to learn reasoning policies and reward functions self-adaptively to adapt the fast evolutions of real-world KGs. The experimental results show that our framework improves the performance of existing RL-based methods while eliminating extra reward engineering.

Original Semantics-Oriented Attention and Deep Fusion Network for Sentence Matching

Mingtong Liu, Yujie Zhang, Jinan Xu, Yufeng Chen

Abstract

Sentence matching is a key issue in natural language inference and paraphrase identification. Despite the recent progress on multi-layered neural network with cross sentence attention, one sentence learns attention to the intermediate representations of another sentence, which are propagated from preceding layers and therefore are uncertain and unstable for matching, particularly at the risk of error propagation. In this paper, we present an original semantics-oriented attention and deep fusion network (OSOA-DFN) for sentence matching. Unlike existing models, each attention layer of OSOA-DFN is oriented to the original semantic representation of another sentence, which captures the relevant information from a fixed matching target. The multiple attention layers allow one sentence to repeatedly read the important information of another sentence for better matching. We then additionally design deep fusion to propagate the attention information at each matching layer. At last, we introduce a self-attention mechanism to capture global context to enhance attention-aware representation within each sentence. Experiment results on three sentence matching benchmark datasets SNLI, SciTail and Quora show that OSOA-DFN has the ability to model sentence matching more precisely.

1 Introduction

Natural language sentence matching is a key technique of comparing two sentences and identifying the semantic relationship between them, which is usually viewed as a classification problem (Wang et al., 2017). The technique has applications in natural language inference to judge whether a hypothesis sentence can be inferred from a premise sentence (Bowman et al., 2015) and in paraphrase identification to determine whether two sentences express the equivalent meaning or not (Yin et al., 2015). The core issue for sentence matching is to model the relatedness between two sentences (Rocktäschel et al., 2015; Parikh et al., 2016; Wang et al., 2017; Duan et al., 2018).

Recently, neural network-based models for sentence matching have attracted more attention for their powerful ability to learn sentence representation (Bowman et al., 2015; Wang et al., 2017; Duan et al., 2018). There are mainly two types of frameworks: sentence encoding based framework and attention-based framework. For the first type of framework, a simple and effective model is proposed by using two sentence vectors (Bowman et al., 2015), but the interaction between two sentences is neglected. For the second type of framework, attention mechanism is introduced to model word-level interaction between two sentences and a higher accuracy is achieved (Rocktäschel et al., 2015; Parikh et al., 2016; Wang et al., 2017). Particularly, multi-layered deep matching network with attention shows that deeper models outperform shallower models (Duan et al., 2018).

However, the existing attention mechanism still has some limitations. When one sentence learns attention to another sentence, the attention is performed between two parallel layers and oriented to the intermediate representations from the preceding layer of another one. As a result, semantics to be paid attention are uncertain and unstable for matching because semantics are changed at different layers. On the other hand, the intermediate representations tend to be affected by error propagation in multi-layered attentions, in which if the first attention aligns the wrong position, the second attention will now have the incorrect information as input for alignment.

In order to address these problems, we propose an original semantics-oriented attention and deep fusion network (OSOA-DFN) for sentence matching. OSOA-DFN mainly consists of three sub-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2652–2661, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

components: (1) original semantics-oriented cross sentence attention; (2) deep fusion; and (3) self-attention mechanism. The cross sentence attention is oriented to the original semantic representations of another sentence, so as to be able to capture inherent semantics by relying on the fixed matching target. The multiple cross attention operations allow one sentence to repeatedly read the important information of another sentence for better interaction. We then design a deep fusion in addition to usual fusion to augment the propagation of attention information at each matching layer. The self-attention mechanism is also introduced at the last to capture global context to enhance attention-aware representation within each sentence. Experiment results demonstrate that OSOA-DFN has the ability to model sentence matching more precisely on the SNLI, the SciTail, and the Quora datasets.

Our contributions can be summarized as follows:

- We pay attention to the original semantic representations for cross sentence interaction and the matching target of attention for a certain sentence is therefore ensured to be fixed in spite of multiple layers. The multiple cross attention operations allow one sentence to repeatedly read the important information of another sentence for better interaction.
- We design a deep fusion in addition to usual fusion to augment the propagation of attention information for matching, and introduce a self-attention mechanism at the last to capture global context to enhance attention-aware representation within each sentence.
- We evaluate our model on three challenging datasets and show that the proposed model has the ability to model sentence matching more precisely and significantly improves the performance.

2 General Neural Attention-Based Model for Sentence Matching

Formally, we can define the sentence matching as follows. Given two sentences $P = [p_1, \cdots, p_i, \cdots, p_m]$ and $Q = [q_1, \cdots, q_j, \cdots, q_n]$, the goal is to predict a label $y^* \in \mathcal{Y}$, where $\mathcal{Y}$ = {entailment, contradiction, neutral} in natural language inference and $\mathcal{Y}$ = {0,1} in paraphrase identification, indicating the logic semantic relationship between two sentences P and Q (Wang et al., 2017).

$$y^* = \arg\max_{y \in \mathcal{Y}} P_{\mathrm{r}}(\mathrm{y}|P, Q) \quad (1)$$

Generally, the architecture of neural attention-based models for sentence matching includes three components (Wang et al., 2017; Duan et al., 2018): (1) **input encoding layer** encodes each sentence into semantic representation; (2) **attention-based matching layer** models word-level alignment between two sentences and produces attention-aware representation for each sentence; and (3) **prediction layer** predicts the semantic relation between two sentences. Figure 1(a) illustrates the general model.

2.1 Input Encoding Layer

For the given sentence pairs $P = [p_1, \cdots, p_i, \cdots, p_m]$ and $Q = [q_1, \cdots, q_j, \cdots, q_n]$, where p_i and q_j indicate the i-th and j-th word in P and Q respectively, the input encoding layer first converts words of P and Q into vectors $[\mathbf{e}_{p_1}, \cdots, \mathbf{e}_{p_i}, \cdots, \mathbf{e}_{p_m}]$ and $[\mathbf{e}_{q_1}, \cdots, \mathbf{e}_{q_j}, \cdots, \mathbf{e}_{q_n}]$ by looking up M respectively, where $M \in \mathbf{R}^{d \times |V|}$ is the embedding table. d is the dimension of embeddings and $|V|$ is the size of the vocabulary.

In order to encode contextual information into word representations, we use a BiLSTM neural network (Hochreiter and Schmidhuber, 1997) to encode two sentences P and Q. The sequential BiLSTM calculates a new hidden state conditioned on the previous states to incorporate contextual information, and several previous works have shown its effectiveness for sentence matching (Rocktäschel et al., 2015; Wang et al., 2017; Duan et al., 2018).

$$\mathbf{h}^0_{p_i} = \mathrm{BiLSTM}(\mathbf{e}_{p_i}, \overrightarrow{\mathbf{h}}^0_{p_{i-1}}, \overleftarrow{\mathbf{h}}^0_{p_{i+1}}) \quad (2)$$

$$\mathbf{h}^0_{q_j} = \mathrm{BiLSTM}(\mathbf{e}_{q_j}, \overrightarrow{\mathbf{h}}^0_{q_{j-1}}, \overleftarrow{\mathbf{h}}^0_{q_{j+1}}) \quad (3)$$

Then the two sentences are converted to $\mathbf{H}^0_P = [\mathbf{h}^0_{p_1}, \cdots, \mathbf{h}^0_{p_i}, \cdots, \mathbf{h}^0_{p_m}]$ and $\mathbf{H}^0_Q = [\mathbf{h}^0_{q_1}, \cdots, \mathbf{h}^0_{q_j}, \cdots, \mathbf{h}^0_{q_n}]$. Hereafter, we call $\mathbf{H}^0_P$ and $\mathbf{H}^0_Q$ as original semantic representations of sentences P and Q respectively. In this paper, we will use them as the targets of cross sentence attention.

2.2 Attention-Based Matching Layer

Generally, this layer employs the attention mechanism to model the interaction information between

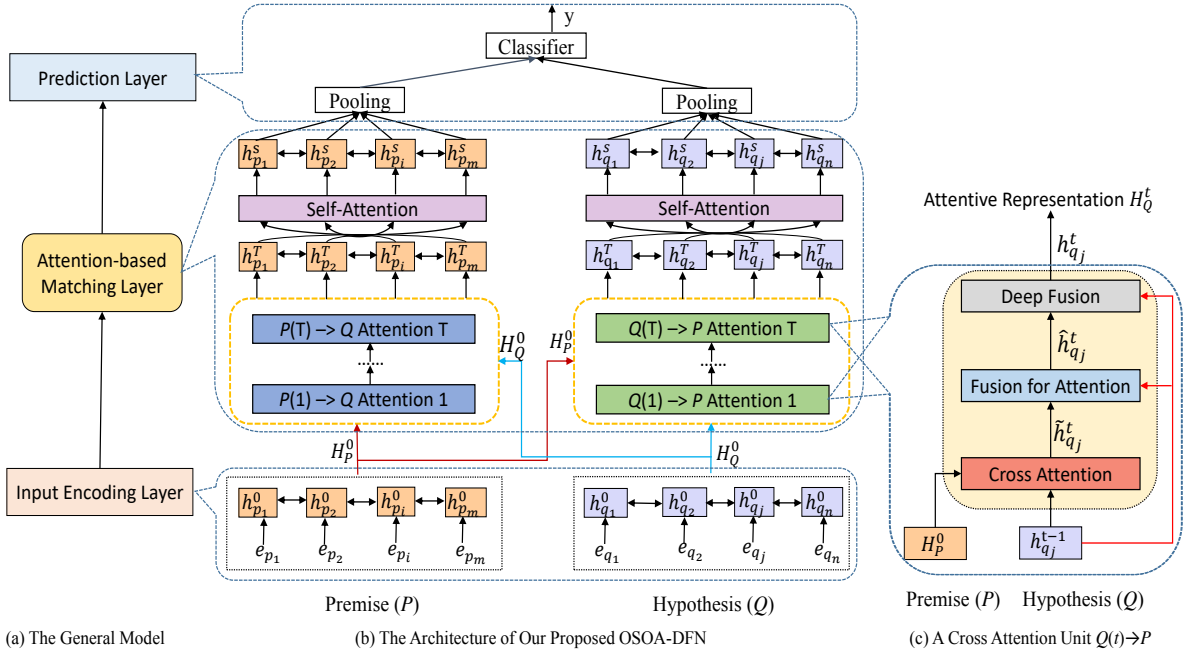

Figure 1: (a) is the general model for sentence matching. (b) is an overview architecture of our proposed OSOA-DFN. (c) is an original semantics-oriented cross attention unit that learns the interaction information from the original semantic representation of another sentence.

two sentences. It can be formulated as:

$$\mathbf{V}_P = \text{Match}(\mathbf{H}_P^0, \mathbf{H}_Q^0), \mathbf{V}_Q = \text{Match}(\mathbf{H}_Q^0, \mathbf{H}_P^0) \quad (4)$$

where Match$(\cdot)$ is a neural attention-based matching function, $\mathbf{V}_P = [\mathbf{v}_{p_1}, \cdots, \mathbf{v}_{p_i}, \cdots, \mathbf{v}_{p_m}]$ and $\mathbf{V}_Q = [\mathbf{v}_{q_1}, \cdots, \mathbf{v}_{q_j}, \cdots, \mathbf{v}_{q_n}]$ are new attention-aware representations for P and Q, respectively. This layer is the core layer for sentence matching. Match$(\cdot)$ is mainly focused by researches and some effective frameworks are proposed (Rocktäschel et al., 2015; Wang et al., 2017; Duan et al., 2018). In this paper, we also focus on this layer, and propose an original semantics-oriented attention and deep fusion network. The details will be described in Section 3.

2.3 Prediction Layer

A pooling layer is used to convert the resulting representations of all position in P and Q into a fixed-length vector and feed it into a classifier to determine the semantic relationship between the two sentences.

A mean pooling is usually adopted on each sentence for capturing all of the information and also a max pooling for highlighting the significant properties. In this paper, we get a fixed dimensional representation $\mathbf{V}$ by concatenating them together as (Chen et al., 2017; Duan et al., 2018).

$$\mathbf{V}_{P_{mean}} = \frac{1}{m}\sum_{i=1}^{m}\mathbf{v}_{p_i}, \mathbf{V}_{P_{max}} = \max_{i=1}^{m}\mathbf{v}_{p_i} \quad (5)$$

$$\mathbf{V}_{Q_{mean}} = \frac{1}{n}\sum_{j=1}^{n}\mathbf{v}_{q_j}, \mathbf{V}_{Q_{max}} = \max_{j=1}^{n}\mathbf{v}_{q_j} \quad (6)$$

$$\mathbf{V} = [\mathbf{V}_{P_{mean}}; \mathbf{V}_{P_{max}}; \mathbf{V}_{Q_{mean}}; \mathbf{V}_{Q_{max}}] \quad (7)$$

Finally, we pass representation $\mathbf{V}$ into a multilayer perceptron (MLP) classifier to calculate the probability $P_r(\cdot)$ of each label.

$$P_r(\cdot|P,Q) = \text{softmax}(\mathbf{W}_2\text{ReLU}(\mathbf{W}_1\mathbf{V}+\mathbf{b}_1)+\mathbf{b}_2) \quad (8)$$

where, $\mathbf{W}_1$, $\mathbf{W}_2$, $\mathbf{b}_1$, $\mathbf{b}_2$ are learnable parameters.

3 Original Semantics-Oriented Attention and Deep Fusion Network

In this paper, we mainly focus on the structure of attention-based matching layer. Inspired by the recent successful deep models (He et al., 2016; Duan et al., 2018), we propose an original semantics-oriented attention and deep fusion network (OSOA-DFN) for sentence matching, as shown in Figure 1(b). OSOA-DFN is mainly composed of: (1) original semantics-oriented cross sentence attention; (2) deep fusion; and (3) self-attention mechanism. (1) and (2) are combined to

form one unit of cross attention, as shown in Figure 1(c), and there are T units in attention-based matching layer. Finally, one layer of self-attention is introduced after the T units of cross attention.

3.1 Original Semantics-Oriented Cross Sentence Attention

Cross sentence attention is utilized to model the relevance between two sentences. In the t-th attention layer, we use $P(t)\rightarrow Q$ to annotate that the sentence P learns attention to the sentence Q to extract the relevant information from Q.

Given the representations of P and Q: $\mathbf{H}_P^{t-1} = [\mathbf{h}_{p_1}^{t-1}, \cdots, \mathbf{h}_{p_i}^{t-1}, \cdots, \mathbf{h}_{p_m}^{t-1}]$ and $\mathbf{H}_Q^0 = [\mathbf{h}_{q_1}^0, \cdots, \mathbf{h}_{q_j}^0, \cdots, \mathbf{h}_{q_n}^0]$, each cross attention $P(t)\rightarrow Q$ will use the original semantics $\mathbf{H}_Q^0$ of Q for interaction, where $t = \{1, \cdots, T\}$ and $t = 1$ represents P using the original representation $\mathbf{H}_P^0$. We first compute the unnormalized attention weights as the similarity of $P(t)$ and Q, the alignment matrix $\mathbf{A}^t \in \mathbf{R}^{m\times n}$ is defined as follows:

$$\mathbf{A}_{ij}^t = \mathbf{h}_{p_i}^{t-1^T}\mathbf{W}^t\mathbf{h}_{q_j}^0 + \langle \mathbf{U}_p^t, \mathbf{h}_{p_i}^{t-1}\rangle + \langle \mathbf{U}_q^t, \mathbf{h}_{q_j}^0\rangle \quad (9)$$

where $\mathbf{W}^t \in \mathbf{R}^{h\times h}$, $\mathbf{U}_p^t$, $\mathbf{U}_q^t \in \mathbf{R}^h$ are learnable parameters, and $\langle\cdot,\cdot\rangle$ denotes the inner production operation. p_i and p_j are the the i-th and j-th word in the P and Q respectively. Next, the semantics of sentence Q related to $\mathbf{h}_{p_i}^{t-1}$ is extracted to compute $\widetilde{\mathbf{h}}_{p_i}^t$ according to $\mathbf{A}^t$, as shown in Equation (10).

$$\widetilde{\mathbf{h}}_{p_i}^t = \sum_{j=1}^{n} \frac{exp(\mathbf{A}_{ij}^t)}{\sum_{k=1}^{n} exp(\mathbf{A}_{ik}^t)}\mathbf{h}_{q_j}^0 \quad (10)$$

Intuitively, $\widetilde{\mathbf{h}}_{p_i}^t$ is a representation by using attentive information in $\mathbf{H}_Q^0$ that is softly aligned to $\mathbf{h}_{p_i}^{t-1}$, and the semantics of $\mathbf{H}_Q^0$ is more probably selected if it is more related to $\mathbf{h}_{p_i}^{t-1}$.

3.2 Deep Fusion

To further enrich the interaction, we first perform an usual fusion and then design a deep fusion for each cross attention to augment the propagation of attention information.

The usual fusion (Wang and Jiang, 2016a; Duan et al., 2018) can be formulated as the Equations (11) - (13).

$$\overline{\mathbf{h}}_{p_i}^t = [\mathbf{h}_{p_i}^{t-1}; \widetilde{\mathbf{h}}_{p_i}^t; |\, \mathbf{h}_{p_i}^{t-1} - \widetilde{\mathbf{h}}_{p_i}^t \,|; \mathbf{h}_{p_i}^{t-1} \odot \widetilde{\mathbf{h}}_{p_i}^t] \quad (11)$$

$$\widetilde{\mathbf{h}}_{p_i}^t = \mathrm{ReLU}(\mathbf{W}_{\mathrm{h}}^{\mathrm{t}}\overline{\mathbf{h}}_{\mathrm{p_i}}^{\mathrm{t}} + \mathbf{b}_{\mathrm{h}}^{\mathrm{t}}) \quad (12)$$

$$\widehat{\mathbf{h}}_{p_i}^t = \mathrm{BiLSTM}(\widetilde{\mathbf{h}}_{p_i}^t, \overrightarrow{\mathbf{h}}_{p_{i-1}}^t, \overleftarrow{\mathbf{h}}_{p_{i+1}}^t) \quad (13)$$

where $[\cdot;\cdot;\cdot;\cdot]$ refers to the concatenation operation. In matching operation, the concatenation can retain all the information (Wang and Jiang, 2016a; Chen et al., 2017). We use a neural nonlinear transformation ReLU (Glorot et al., 2011) as local comparison function. This operation helps the model to better fuse the attention information and also reduce the complexity of vector representation. Since the understanding of some word-level alignments may rely on the contextual matching information, we then apply a BiLSTM to incorporate the sequential matching information, which further gathers interactive features between two sentences.

We design the deep fusion layer as follows. A gated connection layer is used to learn adaptively controlling how much information to be stored and carried to the next attention layer. It can be formulated as Equations (14) - (17):

$$\mathbf{r}_{p_i}^t = \sigma(\mathbf{W}_r^t[\mathbf{h}_{p_i}^{t-1}; \widehat{\mathbf{h}}_{p_i}^t; \mathbf{h}_{p_i}^{t-1} \odot \widehat{\mathbf{h}}_{p_i}^t] + \mathbf{b}_r^t) \quad (14)$$

$$\mathbf{z}_{p_i}^t = \sigma(\mathbf{W}_z^t[\mathbf{h}_{p_i}^{t-1}; \widehat{\mathbf{h}}_{p_i}^t; \mathbf{h}_{p_i}^{t-1} \odot \widehat{\mathbf{h}}_{p_i}^t] + \mathbf{b}_z^t) \quad (15)$$

$$\widetilde{\mathbf{c}}_{p_i}^t = \tanh(\mathbf{W}_c^t[\mathbf{r}_{p_i}^t \odot \mathbf{h}_{p_i}^{t-1}; \widehat{\mathbf{h}}_{p_i}^t] + \mathbf{b}_c^t) \quad (16)$$

$$\mathbf{h}_{p_i}^t = \mathbf{z}_{p_i}^t \odot \mathbf{h}_{p_i}^{t-1} + (1 - \mathbf{z}_{p_i}^t) \odot \widetilde{\mathbf{c}}_{p_i}^t \quad (17)$$

where $\mathbf{W}_*^t$ and $\mathbf{b}_*^t$ are the learnable parameters, $\mathbf{h}_{p_i}^t$ is the result of current layer, $\mathbf{h}_{p_i}^{t-1}$ is the result from preceding layer, σ is a sigmoid function, the value of $\mathbf{r}_{p_i}^t$ and $\mathbf{z}_{p_i}^t$ is between 0 and 1. Intuitively, the model can learn to set the $\mathbf{r}_{p_i}^t$ and $\mathbf{z}_{p_i}^t$ close to 1, thus the more attention information from the preceding layers will be propagated to the following attention layers for matching, and close to 0 implying that the information of preceding layers is less propagated.

After the t-th layer of the original semantics-oriented cross attention, each word p_i in sentence P is newly represented by $\mathbf{h}_{p_i}^t$. Similarly, we conduct cross attention for $Q(t)\rightarrow P$, implying that the sentence Q learns attention to the sentence P, which will be oriented to the original semantic representation $\mathbf{H}_P^0$ of P to derive the attention-aware representation $\mathbf{h}_{q_j}^t$ for each word q_j of Q.

3.3 Self-Attention Mechanism

We additionally introduce a self-attention mechanism after cross sentence attention. It captures long-distance context information to learn word representation within each sentence and further enhances the attention-aware representation.

For sentence P, its attentive representation $\mathbf{H}_p^T = [\mathbf{h}_{p_1}^T, \cdots, \mathbf{h}_{p_i}^T, \cdots, \mathbf{h}_{p_m}^T]$ is computed after T layers of original semantics-oriented cross sentence attention. We first compute a self-attention matrix $\mathbf{S}^s \in \mathbf{R}^{m \times m}$ as Equation (9).

$$\mathbf{S}_{ij}^s = \langle \mathbf{h}_{p_i}^T, \mathbf{h}_{p_j}^T \rangle \tag{18}$$

where, $\mathbf{S}_{ij}^s$ indicates the relevance between the i-th word and j-th word in P. Then, the self-attention vector for each word in P is computed as follows:

$$\widetilde{\mathbf{h}}_{p_i}^s = \sum_{j=1}^{m} \frac{exp(\mathbf{S}_{ij}^s)}{\sum_{k=1}^{m} exp(\mathbf{S}_{ik}^s)} \mathbf{h}_{p_j}^T \tag{19}$$

Intuitively, $\widetilde{\mathbf{h}}_{p_i}^s$ augments each word representation with global context of the sentence P.

After that, an usual fusion augmented by deep fusion, as described in Section 3.2, is also introduced to further enhance the self-attention information within each sentence as follows:

$$\overline{\mathbf{h}}_{p_i}^s = [\mathbf{h}_{p_i}^T; \widetilde{\mathbf{h}}_{p_i}^s; | \mathbf{h}_{p_i}^T - \widetilde{\mathbf{h}}_{p_i}^s |; \mathbf{h}_{p_i}^T \odot \widetilde{\mathbf{h}}_{p_i}^s] \tag{20}$$

$$\widetilde{\mathbf{h}}_{p_i}^s = \mathrm{ReLU}(\mathbf{W}_{\mathrm{h}}^{\mathrm{s}} \overline{\mathbf{h}}_{\mathrm{p_i}}^{\mathrm{s}} + \mathbf{b}_{\mathrm{h}}^{\mathrm{s}}) \tag{21}$$

$$\widehat{\mathbf{h}}_{p_i}^s = \mathrm{BiLSTM}(\widetilde{\mathbf{h}}_{p_i}^s, \overrightarrow{\mathbf{h}}_{p_{i-1}}^s, \overleftarrow{\mathbf{h}}_{p_{i+1}}^s) \tag{22}$$

The deep fusion after the self-attention layer is computed as Equations (14) and (17), which fuses the $\mathbf{h}_{p_i}^T$ from original semantics-oriented cross attention and the $\widehat{\mathbf{h}}_{p_i}^s$ from self-attention to get the final attention-ware representation.

Similarly, we conduct self-attention and deep fusion operations to the sentence Q to derive the attention-aware representation $\mathbf{h}_{q_j}^s$ for each word q_j of Q. Then, two sentences are converted to $\mathbf{H}_P^s = [\mathbf{h}_{p_1}^s, \cdots, \mathbf{h}_{p_i}^s, \cdots, \mathbf{h}_{p_m}^s]$ and $\mathbf{H}_Q^s = [\mathbf{h}_{q_1}^s, \cdots, \mathbf{h}_{q_j}^s, \cdots, \mathbf{h}_{q_n}^s]$. Finally, $\mathbf{H}_P^s$ and $\mathbf{H}_Q^s$ are passed into the prediction layer as input $\mathbf{V}_P$ and $\mathbf{V}_Q$ for deciding their semantic relationship.

4 Training

For model training, we employ cross-entropy as the loss function since the goal is the make the correct classification. Considering the model complexity, we also add l_2-norm of all learnable parameters to the final loss function. Finally, the object is to minimize the following objective function $\mathcal{J}(\theta)$, which can be formulated as:

$$\mathcal{J}(\theta) = -\frac{1}{N} \sum_{i=1}^{N} \log P(y^{(i)} | P^{(i)}, Q^{(i)}; \theta) + \frac{1}{2} \lambda \|\theta\|_2^2 \tag{23}$$

Dataset	Train	Dev	Test	Avg.L		Vocab
SNLI	549K	9.8K	9.8K	14	8	36K
SciTail	23K	1.3K	2.1K	17	12	24K
Quora	384K	10K	10K	12	12	107K

Table 1: Statistics of datasets: SNLI, SciTail and Quora. Avg.L refers to average length of a pair of sentences.

where θ denotes all the learnable parameters of our model, N is the number of instances in the training set, $(P^{(i)}, Q^{(i)})$ are the sentence pairs, and $y^{(i)}$ denotes the corresponding annotated label for the i-th instance.

Word Embedding Following (Tay et al., 2017), to represent each input word, we concatenate three types of vectors: a pre-trained vector, a learnable vector for each word type, and a learnable vector for the POS tag of the word. We use NLTK [1] to acquire POS tags. Finally, we apply a nonlinear transformation ReLU to the concatenated vector to get the final word embedding.

5 Experiments

5.1 Dataset

We evaluate our model on natural language inference and paraphrase identification tasks with three datasets: the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), the SciTail dataset (Khot et al., 2018), and the Quora Questions Pairs dataset (Quora).

SNLI is a natural language inference dataset (Bowman et al., 2015). The original data set contains 570,152 sentence pairs, each labeled with one of the following relationships: $\mathcal{Y}$ = {entailment, contradiction, neutral}. We follow the same data split as in (Bowman et al., 2015).

SciTail is a binary entailment classification task and $\mathcal{Y}$ = {entailment, neutral}. We have the same data split as in (Khot et al., 2018). Notably, the premise and the corresponding hypothesis have high lexical similarity both for entailed and non-entailed pairs, which makes the task particularly difficult.

Quora consists of over 400,000 question pairs and $\mathcal{Y}$ = {0, 1} indicating whether two questions are paraphrases of each other. We have the same data split as in (Wang et al., 2017).

Table 2: Comparative results with previous models on SNLI dataset.

The detailed statistical information of the three datasets is shown in Table 1.

5.2 Implementation Details

We set word embeddings and all of the hidden states of BiLSTMs and MLPs to 300 dimensions. Pre-trained word vectors are 300-dimensional $Glove\ 840B$ (Pennington et al., 2014) and without updating during training. The learnable word vectors and POS vectors have 30 dimensions. For all datasets, there are 3 cross sentence attention layers and 1 self-attention layer. The batch size is set to 64 for SNLI and Quora, 32 for SciTail. We use the Adam method (Kingma and Ba, 2014) for model training. We set the initial learning rate to 5e-4 with a decay ratio of 0.95 for each epoch, and l_2 regularizer strength to 6e-5. To prevent overfitting, we use dropout regularization (Srivastava et al., 2014) with a drop rate of 0.2 for all MLPs.

5.3 Ensemble

The ensemble strategy has been proved to effectively improve model accuracy. Following (Duan et al., 2018), our ensemble model averages the probability distributions from three individual single OSOA-DFNs, and each of them has the same architecture but different parameter initialization.

5.4 Comparison on Natural Language Inference

SNLI We compare our model with the following previous models on SNLI dataset, and show the results in Table 2. LstmAtt (Rocktäschel et al., 2015) extend the general LSTM model with attention mechanism. mLSTM (Wang and Jiang, 2016b) exploit LSTM with memory. DecompAtt (Parikh et al., 2016) propose a decomposable word-by-word matching model with attention, and use pre-trained word vector without relying on any word-order information. SAN (Im and Cho, 2017) is a distance-based self-attention network. BiMPM (Wang et al., 2017) design a bilateral multi-perspective matching model from both directions. ESIM (Chen et al., 2017) incorporate the chain LSTM and tree LSTM. Recently, AF-DMN (Duan et al., 2018) adopt attention-fused deep matching network by using multiple stacked cross attention and self-attention layers.

In Table 2, our single OSOA-DFN achieves 88.8% test accuracy. Moreover, we also report the ensemble result, and the test accuracy is 89.3%. Comparative results show that our model outperforms the previous models on single and ensemble scenarios on SNLI dataset. ELMO (Peters et al., 2018) and BERT (Devlin et al., 2018) have been well known as pre-trained language model for acquiring contextual word vectors. However, our model has less computing complexity (340M parameters in BERT while 10M in our model), but obtained competitive performance. We will conduct the comparison with them in the future. In this paper, we evaluated the contribution of original semantics-oriented cross attention and deep fusion to our model.

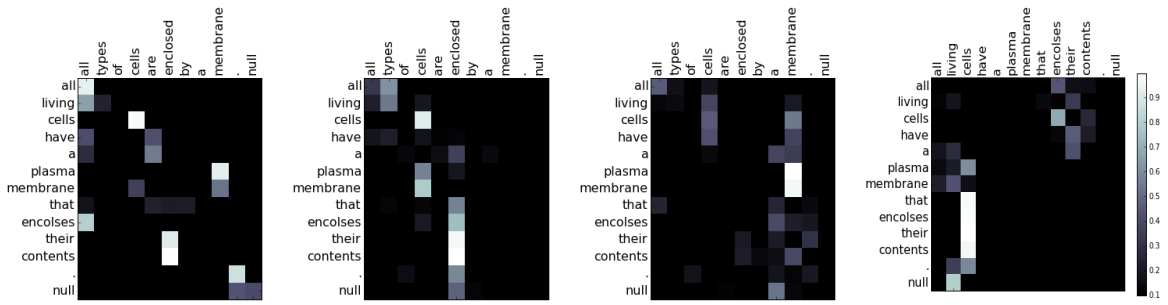
tures. DEISTE (Yin et al., 2018) propose deep explorations of inter-sentence interaction. AF-DMN (re-imp) is our re-implementation of the multi-layered attention model in (Duan et al., 2018) that have not reported the results on this dataset.

On this dataset, our single OSOA-DFN significantly outperforms these strong baselines, achieving the state-of-the-art performance with 86.8% accuracy on the test set. It demonstrates that our model has the ability to improve semantic matching on the challenging SciTail dataset.

5.5 Comparison on Paraphrase Identification

Quora We compare our model with the following previous models on Quora dataset, and show the results in Table 4. The Siamese-CNN model and Siamese-LSTM model encode sentences with CNN and LSTM respectively, and then predict the relationship between them based on the cosine similarity (Wang et al., 2017). Multi-Perspective-CNN and Multi-Perspective-LSTM adopt multiple perspective cosine matching function (Wang et al., 2017). L.D.C (Wang et al., 2016) and BiMPM (Wang et al., 2017) adopt attention-based framework that performs word-level matching.

As we can see, our single OSOA-DFN outperforms the baselines and achieves 89.03% accuracy on the test set. The results prove that our model is very effective for paraphrase identification task.



5.6 Effect of Original Semantics-Oriented Cross Sentence Attention

To verify the effect of original semantics-oriented cross sentence attention, we first implement a variant of our model, namely OSOA-DFN (inter-attention), as shown in Table 5. As in the model of (Duan et al., 2018), we make the cross sentence attention oriented to the intermediate representations from the preceding layer of another sentence, where cross attention is performed on parallel layers between two sentences. The results show that our method achieves higher accuracy on the test set of SciTail dataset, which proves the effect of original semantics-oriented cross attention on extracting expressive features from another sentence for semantic matching.

We further verify the effect of the depth of cross sentence attention on performance, as shown in Table 6. As the number of stacked attention layers increases from 1 to 5, we can see that the performance increases both on the development set and the test set of SciTail dataset. But from 3 to 5, the increased accuracy is slower. We can conclude that the multiple original semantics-oriented attentions are effective in improving matching performance. However, the parameters will grow rapidly with the increasing of the number of stacked attention layer, and a large of number of parameters will increase model complexity. Because of computational cost, we just set the number of cross attention layers to 3 in our experiment.

5.7 Effect of Deep Fusion and Self-Attention Mechanism

We verify the effect of deep fusion and self-attention for better understanding of the performance improvement of OSOA-DFN, as shown in Table 7. Only using BiLSTM fusion without deep fusion, the accuracy drops by 2.1% on the test set of SciTail dataset. This indicates the augmented deep fusion at different layers is important in prop-

(a) 1st cross attention. (b) 2nd cross attention. (c) 3rd cross attention. (d) self-attention.

Figure 2: The visualization of alignment matrices in the three cross sentence attention layers and the self-attention layer.

agating attention information through the network for deep interaction. Without the self-attention, the accuracy is degraded to 84.8%. This indicates that the self-attention mechanism is effective in capturing global context information for augmenting attention-aware semantic representation.

We also verify the effect of BiLSTM fusion, without the BiLSTM fusion, the accuracy is degraded to 83.2%. This shows contextual information gathered by BiLSTM fusion is important for interaction between two sentences.

5.8 What is Learned by Attention ?

We further investigate the results of the multi-layered cross sentence attention and the self-attention and then visualize the results in Figure 2. This is an instance from the test set of the SciTail dataset: {P: *all living cells have a plasma membrane that encloses their contents. Q: all types of cells are enclosed by a membrane.* The label y: *entailment.*}. The results are produced by OSOA-DFN with 3 original semantics-oriented cross sentence attentions $P(t) \rightarrow Q$ and 1 self-attention. We visualize the attention matrices for each layer to show the dynamic attention changes.

From the results, we observe that the first attention layer may have erroneous alignments. We can find that the premise word "*encloses*" is incorrectly aligned with hypothesis word "*all*". In the second attention layer, the alignment quality is improved dramatically, where the "*encloses*" is correctly aligned to "*enclosed*". It shows that the second attention layer effectively revises the errors from the first attention layer. In the second and third attention layers, the attention gradually tends to capture phrase-level alignments, such as "*that encloses their contents*" and "*enclosed*", and "*cells have a plasma membrane*" and "*membrane*". Meanwhile, with the increment of interaction, the high attention layers also tend to capture new alignment information from another sentence that is not captured in low attention layers.

In the self-attention layer, we observe that the phrase "*plasma membrane that encloses their contents*" is strongly aligned to the phrase "*living cells*". This layer captures long-distance semantic dependency within the sentence. The visualization of attention further shows that our proposed model is capable of capturing alignment information from two sentences for better semantic matching.

6 Related Works

Recently, deep neural network models have achieved promising results in modeling sentence matching. A standard practice is to encode each sentence as a vector with a neural network (Bowman et al., 2015; Mou et al., 2015; Tan et al., 2015), and then the relation is decided based on the two sentence vectors. This kind of framework ignores the interaction between two sentences.

Most recent works (Wang and Jiang, 2016a; Chen et al., 2017; Duan et al., 2018) employ attention mechanism to model interaction between two sentences. The attention-based framework matches two sentences at the word level. (Wang and Jiang, 2016b) design a specific LSTM called matching-LSTM that performs word-by-word matching of the hypothesis with the premise. Furthermore, (Wang et al., 2017) and (Chen et al., 2017) propose a new framework to model the relationship between two sentences, which performs the matching from two directions. To improve the attention-based framework, (Duan et al., 2018) propose an attention-fused deep matching

network (AD-DMN), which is based on multi-layered attention mechanism and shows that multiple stacked attention layers can improve matching performance. Besides cross sentence attention, the self-attention mechanism is proposed to solve the limitations of RNN model on the long-term dependency problem, which aims to align the sentence with itself and has been used in a variety of tasks (Lin et al., 2017; Duan et al., 2018).

Our proposed OSOA-DFN conducts original semantics-oriented cross sentence attention to model the matching. We design deep fusion to augment the propagation of attention information. At last, we introduce a self-attention mechanism to capture global context to enhance semantic representation. Compared to AF-DMN (Duan et al., 2018), we just use one self-attention layer instead of multiple layers, which reduces model complexity but achieves outperformed accuracy.

7 Conclusions and Future Work

In this paper, we propose an original semantics-oriented attention and deep fusion network (OSOA-DFN) for sentence matching. It leverages original semantics-oriented cross sentence attention, deep fusion and self-attention mechanism jointly. We compare our model with the previous models on two sentence matching tasks: natural language inference and paraphrase identification. Experiment results show that OSOA-DFN has the ability to model sentence matching more precisely and significantly improves the performance.

In the future, we will further investigate the effect of the network depth on sentence matching and explore introducing external knowledge, such as pre-trained language model BERT (Devlin et al., 2018) and paraphrase database (Ganitkevitch et al., 2013), to help learning more accurate and robust sentence representation.

Abstract

Incompleteness is a common problem for existing knowledge graphs (KGs), and the completion of KG which aims to predict links between entities is challenging. Most existing KG completion methods only consider the direct relation between nodes and ignore the relation paths which contain useful information for link prediction. Recently, a few methods take relation paths into consideration but pay less attention to the order of relations in paths which is important for reasoning. In addition, these path-based models always ignore nonlinear contributions of path features for link prediction. To solve these problems, we propose a novel KG completion method named OPTransE. Instead of embedding both entities of a relation into the same latent space as in previous methods, we project the head entity and the tail entity of each relation into different spaces to guarantee the order of relations in the path. Meanwhile, we adopt a pooling strategy to extract nonlinear and complex features of different paths to further improve the performance of link prediction. Experimental results on two benchmark datasets show that the proposed model OPTransE performs better than state-of-the-art methods.

1 Introduction

Knowledge graphs (KGs) are built to store structured facts which are encoded as triples, e.g., (**Beijing**, *CapitalOf*, **China**) (Lehmann et al., 2015). Each triple (h, r, t) consists of two entities h, t and a relation r, indicating there is a relation r between h and t. Large-scale KGs such as YAGO (Suchanek et al., 2007), Freebase (Bollacker et al., 2008) and WordNet (Miller, 1995) contain billions of triples and have been widely applied in various fields (Riedel et al., 2013; Dong et al., 2015). However, a common problem with these KGs is that they are far from complete, which has limited the development of KG's applications. Thus, KG completion with the goal of filling in missing parts of the KG has become an urgent issue. Specifically, KG completion aims to predict whether a relationship between two entities is likely to be true, which is defined as the link prediction in KGs.

Most existing KG completion methods are based on representation learning, which embed both entities and relations into continuous low-dimension spaces. TransE (Bordes et al., 2013) is one of the most classical KG completion models, which embeds entities and relations into the same latent space. To better deal with complex relations like 1-to-N, N-to-1 and N-to-N, TransH (Wang et al., 2014) and TransR (Lin et al., 2015b) employ relation-specific hyperplanes and relation-specific spaces respectively to separate triples according their corresponding relation. Unfortunately, these models ignore the relation paths between entities which are helpful for reasoning. For example, if we know A is B's brother, and B is C's parent, then we can infer that A is C's uncle.

Recently, a few researchers take relation paths in KGs as additional information for representation learning and attempt to project paths into latent spaces, which get better performance compared with conventional methods. PTransE-ADD (Lin et al., 2015a) considers relation paths as translations between entities and represents each path as the vector sum of all the relations in the path. Moreover, RPE (Lin et al., 2018) extends the TransR model by incorporating the path-specific projection. However, these methods pay less attention to the order of relations in paths which is important for link prediction. Figure 1 shows an example of the meaning change when the order of relations is altered. In addition, these path-based models assume information from different paths between an entity pair only contributes to the re-

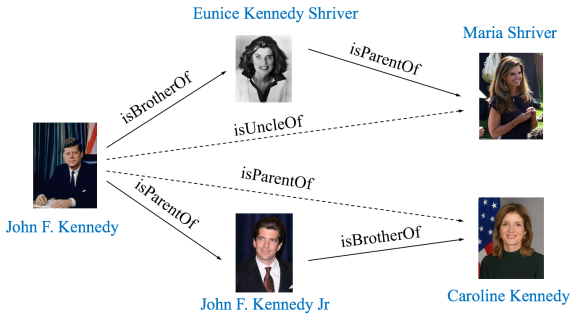

Figure 1: Example of the meaning change when the order of relations is altered.

lation inference linearly and ignore other complex interactions between them.

To address these issues, we propose a novel KG completion model named OPTransE. In the model, we project the head entity and the tail entity of each relation into different spaces and introduce sequence matrices to keep the order of relations in the path. Moreover, a pooling strategy is adopted to extract nonlinear features of different paths for relation inferences. Experimental results on two benchmark datasets WN18 and FB15K show that OPTransE significantly outperforms state-of-the-art methods.

The remainder of this paper is organized as follows. Section 2 discusses related work. Section 3 presents the proposed model and algorithm in detail. Empirical evaluation of the proposed algorithm and comparison with other state-of-the-art algorithms are presented in Section 4. Finally, Section 5 summarises the whole paper and points out some future work.

2 Related Work

2.1 Translation-based Models

In recent years, there has been a great deal of work on representation learning for KG completion, and most studies concentrate on translation-based models. This kind of models propose to embed both entities and relations into a continuous low-dimensional vector space according to some distance-based scoring functions.

TransE (Bordes et al., 2013) is one of the most fundamental and representative translation-based models. For the entities and relations in KGs, TransE encodes them as vectors in the same space. For each fact (h, r, t), TransE believes that $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ when (h, r, t) holds. Thus, the scoring function is defined as

$$f_r(h,t) = \| \mathbf{h} + \mathbf{r} - \mathbf{t} \|_{1/2} . \quad (1)$$

where $\mathbf{h}$, $\mathbf{r}$ and $\mathbf{t}$ represent the vectors of head entity h, relation r and tail entity t, respectively. If the fact (h, r, t) is true, its score $f_r(h, t)$ tends to be close to zero.

TransE is a simple and efficient method for KG completion. However, its simple structure has flaws in dealing with complicated relations like 1-to-N, N-to-1 and N-to-N. In order to address this problem, TransH (Wang et al., 2014) introduces relation-specific hyperplanes and projects entities as vectors onto the given hyperplanes. Similar to TransH, TransR (Lin et al., 2015b) also aims to cope with complicated relations. Instead of employing the hyperplane like TransH, TransR proposes a matrix $\mathbf{W_r} \in \mathbb{R}^{m \times n}$ to project entity vectors into a relation-specific space. Moreover, STransE (Nguyen et al., 2016) extends TransR by introducing two projection matrices for the head entity and the tail entity, respectively. Therefore, the head and tail entities in a triple will be projected differently into the corresponding relation space.

2.2 Incorporating Relation Paths

The models introduced so far only exploit facts observed in KGs to conduct representation learning. In fact, there is a large amount of useful information in relation paths that can be incorporated into translation-based models to improve the performance of link prediction.

Lin et al. (2015a) proposes a path-based translation model named PTransE for KG completion. It regards relation paths as translations between entities for representation learning and utilizes a path-constraint resource allocation algorithm to evaluate the reliability of relation paths. RTransE (García-Durán et al., 2015) and TransE-COMP (Guu et al., 2015) take the sum of the vectors of all relations in a path as the representation for a relation path. For the Bilinear-COMP model (Guu et al., 2015), and the PRUNED-PATHS model (Toutanova et al., 2016), they represent each relation as a diagonal matrix, and evaluate the relation path by matrix multiplication. Most recently, PaSKoGE model (Jia et al., 2018) is proposed for KG embedding by minimizing a path-specific margin-based loss function. Moreover, RPE (Lin et al., 2018), inspired by PTransE, ex-

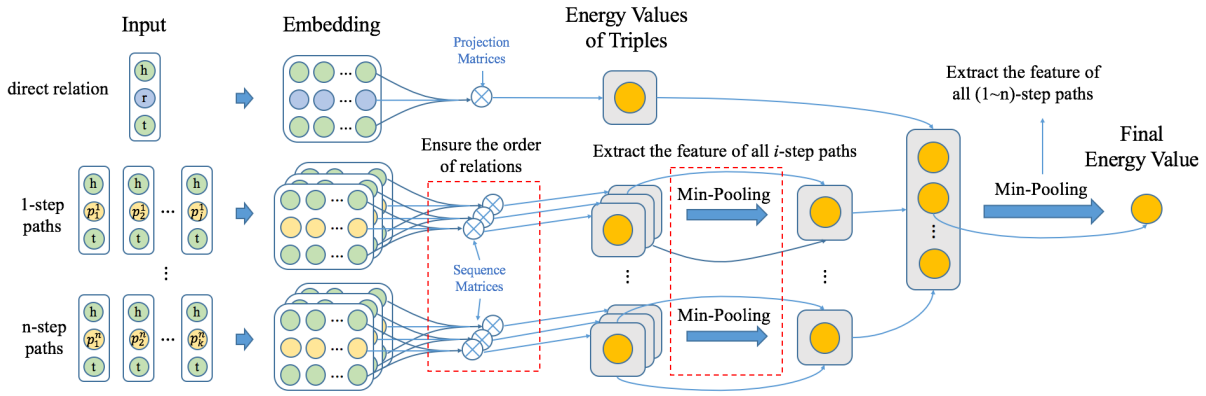

Figure 2: Architecture of OPTransE.

tends the TransR model by incorporating the path-specific projection for paths between entity pairs.

These methods try to incorporate information of relation paths to get better performance. However, they pay less attention to the order of relations in a path when learning representations of the path. In fact, changes in the relation order of paths will alter the meanings of paths to a great extent (as shown in Figure 1). Moreover, the methods stated above assume information from different paths between an entity pair only contributes to the relation inference linearly. Unfortunately, they ignore the complex nonlinear features of different paths. In order to solve these problems, we propose OPTransE, a novel KG completion model, which learns representations of ordered relation paths and designs a pooling method to better extract nonlinear features from various relation paths.

3 Our Model

To infer the missing parts of KGs, we propose a KG completion model called OPTransE, whose architecture is shown in Figure 2. We first embed the entities and relations of KG into latent spaces with the consideration of the order of relations in paths. Then, we try to infer the missing relations using these latent representations. Different from previous methods which embed the head and tail of a relation into the same latent space, we project them into different spaces. Therefore, we can distinguish the order of relations in the path. To extract the complex and nonlinear path information for relation reasoning, we design a two layer pooling strategy to fuse the information from different paths.

In this section, we will first introduce the embedding representations of ordered relation paths. After that, we utilize a two layer pooling strategy to construct the total energy function of triples and then the objective function is presented. Finally, we will describe the detail of model implementation and analyze the complexity of the model.

3.1 Ordered Relation Paths Representation

For each triple (h, r, t) in KG, we employ vectors to represent the entity pair and the relation. Specifically, $\mathbf{h}\in\mathbb{R}^d$ denotes the head entity h, $\mathbf{t}\in\mathbb{R}^d$ denotes the tail entity t and $\mathbf{r}\in\mathbb{R}^d$ indicates the relation r.

We assume the paths connecting two entities contain indicative information for the direct relation between these two entities. To measure these kinds of indicative effects while guarantee the order of relations in a path, we define an energy function in Equation (2). Let $p^{s=n}$ denote one of the n-step path from h to t, i.e., $h \xrightarrow{r_1} \cdots \xrightarrow{r_n} t$. If the relation path is reasonable from h to t, it will obtain a lower energy value.

$$E\left(h, p^{s=n}, t\right) = \| \mathbf{h_p} + \sum_{i=1}^{n} \mathbf{S}_{\mathbf{p}}^{i}\mathbf{r}_i - \mathbf{t_p} \|_{1/2}, \quad (2)$$

where

$$\mathbf{h_p} = f(p, \mathbf{h}), \quad \mathbf{t_p} = g(p, \mathbf{t}), \quad (3)$$

$$\mathbf{S}_{\mathbf{p}}^{i} = \mathbf{W}(p, i). \quad (4)$$

$\mathbf{h_p}$ and $\mathbf{t_p}$ denote the representations of the head entity h and the tail entity t in the ordered relation path p, respectively. $\mathbf{S}_{\mathbf{p}}^{i}\in\mathbb{R}^{d\times d}$ denotes the sequence matrix with respect to the i-th relation in the given path p.

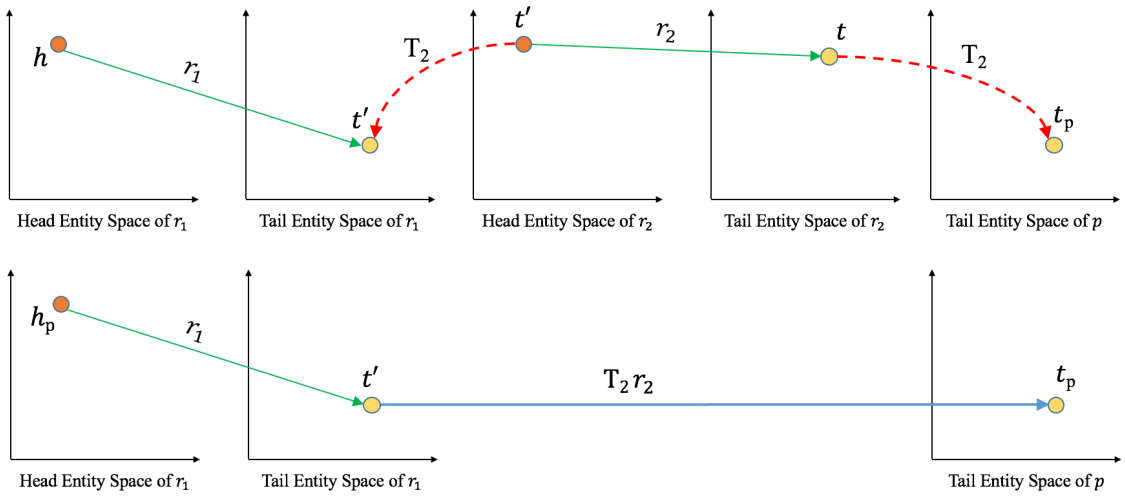

Figure 3: The representation of path p ($h \xrightarrow{r_1} t' \xrightarrow{r_2} t$). The top part of the figure depicts the process of space transition of t' and t, while the bottom part illustrates the generated continuous path from h_p to t_p after the transition.

Note that a triple (h, r, t) in the KG can be seen as a one-step path between h and t. Thus, the value of $E(h, r, t)$ is able to be obtained by substituting direct relation r as $p^{s=1}$ into Equation (2).

From Equation (2) we could observe that the sequence matrix $\mathbf{S}_\mathbf{p}^i$ before each relation $\mathbf{r}_i$ is different. If the order of several relations in a path is altered, the value of energy function will also change at the same time. Therefore, paths with the same relation set but different relation order will infer out distinct direct relations in our model. The specific representation of the ordered relation path will be demonstrated in the following contents.

To keep the order information of relations in paths, we project the head and tail entities of a relation into different spaces by introducing two matrices for each relation. Let $\mathbf{W}_{\mathbf{r},\mathbf{1}} \in \mathbb{R}^{d\times d}$ and $\mathbf{W}_{\mathbf{r},\mathbf{2}} \in \mathbb{R}^{d\times d}$ denote the projection matrices of the head entity and the tail entity for relation r, respectively. With these two matrices, we will project the head and tail entities into distinct spaces with respect to the same relation. Suppose there is a path $r_1, r_2, \ldots, r_\mathrm{n}$ from h to t, ideally, we define the following equations

$$\begin{cases} \mathbf{W}_{\mathbf{r_1},\mathbf{1}}\mathbf{h} + \mathbf{r_1} = \mathbf{W}_{\mathbf{r_1},\mathbf{2}}\mathbf{t}^{(1)} \\ \mathbf{W}_{\mathbf{r_2},\mathbf{1}}\mathbf{t}^{(1)} + \mathbf{r_2} = \mathbf{W}_{\mathbf{r_2},\mathbf{2}}\mathbf{t}^{(2)} \\ \vdots \\ \mathbf{W}_{\mathbf{r_n},\mathbf{1}}\mathbf{t}^{(n-1)} + \mathbf{r_n} = \mathbf{W}_{\mathbf{r_n},\mathbf{2}}\mathbf{t} \end{cases}, \tag{5}$$

where $\mathbf{t}^{(i)}$ indicates the i-th passing node on the path.

For the entity pair with a relation path, we get their representations after eliminating the passing nodes from Equation (5). Thus, the concrete forms of the variables in Equation (2) are shown as follows,

$$\mathbf{h_p} = \mathbf{W}_{\mathbf{r_1},\mathbf{1}}\mathbf{h}, \quad \mathbf{t_p} = \mathbf{W}_{\mathbf{p^{s=n}}}\mathbf{t}, \tag{6}$$

$$\mathbf{S}_\mathbf{p}^i = \prod_{k=1}^{i} \mathbf{T}_k, \tag{7}$$

where

$$\mathbf{W}_{\mathbf{p^{s=n}}} = \mathbf{S}_\mathbf{p}^n \mathbf{W}_{\mathbf{r_n},\mathbf{2}}, \tag{8}$$

$$\mathbf{T}_k = \begin{cases} I & k = 1 \\ \mathbf{M}\left(r_k, r_{k-1}\right) & k > 1 \end{cases}. \tag{9}$$

$\mathbf{W}_{\mathbf{p^{s=n}}} \in \mathbb{R}^{d\times d}$ indicates the projection matrix for path $p^{s=n}$, which aims to project the tail entity in a path to the space of $p^{s=n}$. Moreover, I in Equation (9) denotes the identity matrix and $\mathbf{M}\left(r_k, r_{k-1}\right) \in \mathbb{R}^{d\times d}$ means the space transition matrix from the head entity space of r_k to the tail entity space of r_{k-1}, i.e., $\mathbf{M}\left(r_k, r_{k-1}\right)\mathbf{W}_{\mathbf{r_k},\mathbf{1}} = \mathbf{W}_{\mathbf{r_{k-1}},\mathbf{2}}$.

Figure 3 illustrates the representation of the relation path in our model. Suppose there is a 2-step path from h to t passing t', i.e., $h \xrightarrow{r_1} t' \xrightarrow{r_2} t$. It is obvious that t' acts as the tail entity of relation r_1 and as the head entity of relation r_2 at the same time, which is shown on the top part of Figure 3. To connect relations in different spaces, we try to

unify the passing node in the path into the same space. As defined in Equation (9), T_2 is utilized to transfer the passing node t' from the head entity space of r_2 to the tail entity space of r_1. Moreover, T_2 is also assigned to the relation r_2 and the tail entity t. Note that the tail entity t will be projected into the space of path p which is defined in Equation (6). Finally, the path from h_p to t_p will pass through r_1 and $T_2 r_2$ as shown on the bottom part of Figure 3.

3.2 Pooling Strategy

We design a two layer pooling strategy to fuse the information from different paths. First, we utilize a minimum pooling method to extract feature information from paths with i steps and define an energy function as follows,

$$E\left(h, P_r^{s=i}, t\right) = \text{Min}[\, E\left(h, p^{s=i}, t\right) \mid p^{s=i} \in P_r^{s=i}], \tag{10}$$

where $P_r^{s=i}$ indicates the set of all *i*-step paths which are relevant to the relation r from the head entity h to the tail entity t. To obtain $P_r^{s=i}$, we introduce a conditional probability $\Pr(r|p^{s=i})$ to represent the reliability of a path $p^{s=i}$ associated with the given relation r,

$$\begin{aligned} \Pr\left(r\middle|p^{s=i}\right) &= \Pr(r, p^{s=i}) / \Pr(p^{s=i}) \\ &= \frac{N(r, p^{s=i})/N(p)}{N(p^{s=i})/N(p)} \\ &= \frac{N(r, p^{s=i})}{N(p^{s=i})}, \end{aligned} \tag{11}$$

where $\Pr(r, p^{s=i})$ denotes the joint probability of r and $p^{s=i}$, $\Pr(p^{s=i})$ denotes the marginal probability of $p^{s=i}$. In addition, $N(r, p^{s=i})$ denotes the number of cases where r and $p^{s=i}$ link the same entity pair in the KG, $N(p^{s=i})$ denotes the number of the path $p^{s=i}$ in the KG and $N(p)$ denotes the total number of paths in the KG. Since $N(p)$ can be removed from both the numerator and denominator of the fractional expression, we finally convert the probability into frequency for computation.

We filter the paths by choosing all $p^{s=i}$ from h to t whose $\Pr\left(r\middle|p^{s=i}\right) > 0$. Thus, $P_r^{s=i}$ is the set of all filtered $p^{s=i}$. Sometimes we could infer the fact not from the direct relation r but from the path, which means the value of $E\left(h, P_r^{s=i}, t\right)$ could possibly be less than that of $E\left(h, r, t\right)$.

Furthermore, we utilize a minimum pooling method to fuse information from paths with different lengths and define an energy function as follows,

$$\begin{aligned} E_{final}\left(h, r, t\right) = \text{Min}[\, & E\left(h, r, t\right),\ E\left(h, P_r^{s=1}, t\right), \\ & E\left(h, P_r^{s=2}, t\right), \ldots,\ E\left(h, P_r^{s=n}, t\right)], \end{aligned} \tag{12}$$

where $E\left(h, r, t\right)$ indicates the energy value of direct relation r and it is calculated by substituting r as $p^{s=1}$ into Equation (2). $E\left(h, P_r^{s=i}, t\right)$ is initialized as **infinite**, thus it will not influence the outcome of final energy function if there is no *i*-step path between h and t.

In summary, we adopt the min-pooling strategy twice in our model. For $E\left(h, P_r^{s=i}, t\right)$, min-pooling aims to choose the most matched path with r among all *i*-step paths. And for the final energy function, min-pooling tries to extract nonlinear features from paths of various lengths. In addition, the min-pooling method addresses the problem that there may be no relation paths between h and t.

3.3 Objective Function

The objective function for the proposed model OPTransE is formalized as

$$\begin{aligned} L\left(S\right) = \sum_{(h,r,t)\in S} \Bigg\{ & L\left(h, r, t\right) + \lambda \cdot \sum_i \Bigg[\frac{1}{Z_i} \\ & \cdot \sum_{p^{s=i} \in P_r^{s=i}} \Pr\left(p^{s=i}\middle|h, t\right) \cdot \Pr\left(r\middle|p^{s=i}\right) \cdot L\left(h, p^{s=i}, t\right) \Bigg] \Bigg\}, \end{aligned} \tag{13}$$

where $L\left(h, r, t\right)$ indicates the loss function for the triple (h, r, t), and $L\left(h, p^{s=i}, t\right)$ represents the loss value with respect to the relation path $p^{s=i}$. The probability $\Pr\left(p^{s=i}\middle|h, t\right)$ indicates the reliability of the relation path $p^{s=i}$ given the entity pair (h, t), and $\Pr(r|p^{s=i})$ denotes the reliability of a path $p^{s=i}$ associated with the given relation r. The details of $\Pr\left(p^{s=i}\middle|h, t\right)$ are shown in (Lin et al., 2015a), which is computed by a path-constraint resource allocation algorithm. $Z_i = \sum_{p^{s=i}\in P_r^{s=i}} \Pr\left(p^{s=i}\middle|h, t\right) \Pr\left(r\middle|p^{s=i}\right)$ is a normalization factor, and λ is utilized to balance the triple loss and paths losses.

We adopt the margin-based loss in our model, i.e.,

$$L\left(h, r, t\right) = \sum_{(h', r, t')\in S'} \left[\gamma + E\left(h, r, t\right) - E(h', r, t')\right]_+, \tag{14}$$

$$L\left(h, p^{s=i}, t\right) = \sum_{(h',r,t')\in S'} [\gamma_i + E\left(h, p, t\right) - E(h', p, t')]_+, \tag{15}$$

where p is the simple form of $p^{s=i}$. $[x]_+ = max(x, 0)$ returns the higher one between x and 0. γ_i is the margin to separating positive and negative samples. It is noteworthy that we employ different margin γ_i for paths with different step number because the noise of energy function will be magnified as the number of steps increases. The corrupted triple set S' for (h, r, t) is denoted as follows:

$$S' = \{(h', r, t) \cup (h, r, t')\}. \tag{16}$$

We replace the head entity or the tail entity in the triple randomly and guarantee that the new triple is not an existing valid triple.

Our goal is to minimize the total loss. Valid relation paths will obtain lower energy value after the optimization, so that paths can sometimes replace directed relations when performing the prediction.

3.4 Parameter Learning

We utilize stochastic gradient descent (SGD) to optimize the objective function in Equation (13) and learn parameters of the model. To ensure the convergence of the model, we impose limitations to the norm of vectors, i.e., $||\mathbf{h}||_2 \leq 1$, $||\mathbf{r}||_2 \leq 1, ||\mathbf{t}||_2 \leq 1, ||\mathbf{W_{r,1}h}||_2 \leq 1, ||\mathbf{W_{r,2}t}||_2 \leq 1$. Moreover, we note that the objective function defined in Equation (13) has two parts. The first part is for the basic triple and the second part is for the relation paths. To focus on the representation of ordered relation paths in the second part, we only update the parameters of relation vectors in the path when conducting the optimization of the model.

In addition, we follow PTransE (Lin et al., 2015a) to generate reverse relation r^{-1} to enlarge the training set, and the inference in KGs can be through the reverse paths. For instance, for the fact (**Honolulu**, *CapitalOf*, **Hawaii**), we will also add a fact with the reverse relation to the KG, i.e., (**Hawaii**, *CapitalOf*$^{-1}$, **Honolulu**).

3.5 Complexity Analysis

Let d denote the dimension of entities and relations, N_e and N_r denote the number of entities and relations, respectively. The number of model parameters for OPTransE is ($N_e d$ + $N_r d$ + $2N_r d^2$), which is the same as that of STransE.

Moreover, let N_p denote the expected number of relation paths between the entity pair, N_t denote the number of triples for training, k denote the maximum length of relation paths. According to the objective function shown in Equation (13) and details of parameter learning stated in Section 3.4, the time complexity of OPTransE for optimization is $O(k^2 d^3 N_p N_t)$, which is on the same magnitude as that of RPE(MCOM) (Lin et al., 2018).

4 Experiments

4.1 Datasets

To evaluate the proposed model OPTransE, we use two benchmark datasets: WN18 and FB15K as experimental data. They are subsets of the knowledge graph WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008), respectively (Bordes et al., 2013). These two datasets have been widely employed by researchers for KG completion (Jia et al., 2018; Lin et al., 2018). The statistic details of the two datasets are shown in Table 1. In our experiments, as we add triples of reverse relations to the datasets, the number of relations and training triples are doubled.

Table 1: Statistics of datasets

Dataset	#Rel	#Ent	#Train	#Valid	#Test
WN18	18	40,943	141,442	5,000	5,000
FB15K	1345	14,951	483,142	50,000	59,071

4.2 Experimental Settings

We adopt the idea from TransR (Lin et al., 2015b) and initialize the vectors and matrices of OPTransE by an existing method STransE (Nguyen et al., 2016). Following TransH (Wang et al., 2014), *Bernoulli* method is applied for generating head or tail entities when sampling corrupted triples.

As the length of paths increases, the reliability of the path will decline accordingly. To better determine the maximum length of paths for experiment, before the test on FB15K, we had evaluated OPTransE with 3-step paths on WN18. However, OPTransE (3-step) performs comparably as OPTransE (2-step) with a higher computational cost. This indicates that longer paths hardly contain more useful information and it is unnecessary

Table 2: Evaluation results on link prediction

Model	WN18				FB15K			
	Mean Rank		Hits@10(%)		Mean Rank		Hits@10(%)	
	Raw	Filtered	Raw	Filtered	Raw	Filtered	Raw	Filtered

to enumerate longer paths. Therefore, considering the computational efficiency, we limit the maximum length of relation paths as 2 steps.

In our experiments, we utilize the grid search to choose the best parameters for the two datasets, respectively. The best configurations for OPTransE are as follows: the dimension of entity and relation vectors $d = 50$, the learning rate $\alpha = 0.0001$, the margin $\gamma = 5.0$, $\gamma_1 = 5.0, \gamma_2 = 5.5$, the balance factor $\lambda = 0.01$ on WN18; and $d = 100$, $\alpha = 0.0005$, $\gamma = 4.0$, $\gamma_1 = 4.5, \gamma_2 = 5.0$, $\lambda = 0.01$ on FB15K. In addition, L1 norm is employed for scoring and we run SGD for 2000 epochs in the training procedure.

4.3 Evaluation Metrics and Baselines

The same as in previous work (Bordes et al., 2013; Nguyen et al., 2016), we evaluate the proposed model OPTransE on the link prediction task. This task aims to predict the missing entity in a triple (h, r, t), i.e., predicting h when r and t are given, or predicting t given h and r. When testing a fact (h, r, t), we replace either head or tail entity with all entities in the dataset and calculate scores of generated triples according to Equation (12). And then we sort the entities with their scores in ascending order to locate the rank of the target entity.

For specific evaluation metrics, we employ the widely used mean rank (MR) and Hits@10 in the experiments. Mean rank indicates the average rank of correct entities and Hits@10 means the proportion of correct entities ranked in top 10. Higher Hits@10 or lower value of mean rank implies the better performance of the model on the link prediction task. Moreover, it is noted that the generated triple for test may exist in the dataset as a fact, thus such triples will affect the final rank of the target entity to some extent. Hence, we could filter out these generated triples which are facts in the dataset before ranking. If we have performed filtering, the result will be denoted as "Filtered", otherwise it will be denoted as "Raw".

Moreover, Bordes et al. (2013) defined four categories of relations in KGs by mapping their properties such as 1-to-1, 1-to-N, N-to-1 and N-to-N. Thus, experimental results of distinguishing the four different relation types have also been

Table 3: Filtered evaluation results on FB15K by mapping properties of relations(%)

Tasks	Predicting Head Entities (Hits@10)				Predicting Tail Entities (Hits@10)			
Relation Category	1-to-1	1-to-N	N-to-1	N-to-N	1-to-1	1-to-N	N-to-1	N-to-N
SE	35.6	62.6	17.2	37.5	34.9	14.6	68.3	41.3
SME (linear)	35.1	53.7	19.0	40.3	32.7	14.9	61.6	43.3
SME (bilinear)	30.9	69.6	19.9	38.6	28.2	13.1	76.0	41.8

PTransE(ADD, 2-step)	91.0	92.8	60.9	83.8	91.2	74.0	88.9	86.4
PTransE(MUL, 2-step)	89.0	86.8	57.6	79.8	87.8	71.4	72.2	80.4
PTransE(ADD, 3-step)	90.1	92.0	58.7	86.1	90.7	70.7	87.5	88.7
PaSKoGE	89.7	94.8	62.3	86.7	89.3	72.9	93.4	88.9
RPE (ACOM)	92.5	96.6	63.7	87.9	92.5	79.1	95.1	90.8
RPE (MCOM)	91.2	95.8	55.4	87.2	91.2	66.3	94.2	89.9
RotatE	92.2	96.7	60.2	89.3	92.3	71.3	96.1	92.2
OPTransE	**93.1**	**97.4**	**69.0**	**89.8**	**92.8**	**87.4**	**96.7**	**92.3**

recorded for comparison.

In the link prediction task, several competitive KG completion methods are utilized as baselines, including SE (Bordes et al., 2011), SME (Bordes et al., 2014), TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransR (Lin et al., 2015b), TranSparse (Ji et al., 2016), STransE (Nguyen et al., 2016), ITransF (Xie et al., 2017), HolE (Nickel et al., 2016), ComplEx (Trouillon et al., 2016), ANALOGY (Liu et al., 2017), ProjE (Shi and Weninger, 2017), RTransE (García-Durán et al., 2015), PTransE (Lin et al., 2015a), PaSKoGE (Jia et al., 2018), RPE (Lin et al., 2018) and RotatE (Sun et al., 2019). Among them, RTransE, PTransE, PaSKoGE and RPE exploit the information of paths between entity pairs.

4.4 Results

Table 2 shows the performances of different methods on the link prediction task according to various metrics. Numbers in **bold** mean the best results among all methods and the underlined ones mean the second best. The evaluation results of baselines are from their original work, and "-" in the table means there is no reported results in prior work. Note that we implement ProjE and PTransE on WN18 using the public codes.

From Table 2 we could observe that: (1) PTransE performs better than its basic model TransE, and RPE outperforms its original method TransR. This indicates that additional information from relation paths between entity pairs is helpful for link prediction. Note that OPTransE outperforms baselines which do not take relation paths into consideration in most cases. These results demonstrate the effectiveness of OPTransE to take advantage of the path features in the KG. (2) OPTransE performs better than previous path-based models like RTransE, PTransE, PaSKoGE and RPE on all metrics. This implies that the order of relations in paths is of great importance for reasoning, and learning representations of ordered relation paths can significantly improve the accuracy of link prediction. Moreover, the proposed pooling strategy which aims to extract nonlinear features from different relation paths also contributes to the improvements of performance.

Specific evaluation results on FB15K by mapping properties of relations (1-to-1, 1-to-N, N-to-1, and N-to-N) are shown in Table 3. Several methods which have reported these results are listed as baselines. OPTransE achieves the highest scores in all sub-tasks. We note that it is more difficult to predict head entities of N-to-1 relations and tail entities of 1-to-N relations, since the prediction accuracy on these two sub-tasks is generally lower than those of other sub-tasks. Surprisingly, OPTransE has achieved significant improvements on these two sub-tasks. Especially when predicting tail entities of 1-to-N relations, OPTransE promotes Hits@10 to 87.4% which is 8.3% higher than the best performance among

baselines. Meanwhile, since the average prediction accuracy for N-to-N relations of OPTransE on the two datasets has reached 91.1%, we can also infer that our model has strong ability to deal with N-to-N relations. OPTransE projects the head and tail entities of a triple into different relation-specific spaces, thus, it is able to better discriminate the relevant entities. Furthermore, these results also confirm that ordered relation paths between entity pairs which are exploited by OPTransE contain useful information and can help to perform more accurate inference when facing complex relations.

5 Conclusion and Future Work

In this paper, we propose a novel KG completion model named OPTransE, which aims to address the issue of relation orders in paths. In our model, we project the head entity and the tail entity of each relation into different spaces to guarantee the order of the path. In addition, a pooling method is applied to extract complex and nonlinear features from numerous relation paths. Finally, we evaluate our proposed model on two benchmark datasets and experimental results demonstrate the effectiveness of OPTransE.

In the future, we will explore the following research directions: (1) we will study the applications of the proposed models in various domains, like personalized recommendation (Liu et al., 2018); (2) we will explore other techniques to fuse the ordered relation information from different paths (Liu et al., 2019).

Abstract

In recent years, there has been a surge of interests in interpretable graph reasoning methods. However, these models often suffer from limited performance when working on sparse and incomplete graphs, due to the lack of evidential paths that can reach target entities. Here we study *open knowledge graph reasoning*—a task that aims to reason for missing facts over a graph augmented by a background text corpus. A key challenge of the task is to filter out "*irrelevant*" facts extracted from corpus, in order to maintain an effective search space during path inference. We propose a novel reinforcement learning framework to train two collaborative agents jointly, i.e., a *multi-hop graph reasoner* and a *fact extractor*. The fact extraction agent generates fact triples from corpora to enrich the graph on the fly; while the reasoning agent provides feedback to the fact extractor and guides it towards promoting facts that are helpful for the interpretable reasoning. Experiments on two public datasets demonstrate the effectiveness of the proposed approach. Source code and datasets used in this paper can be downloaded at https://github.com/shanzhenren/CPL.

1 Introduction

Knowledge graph completion or reasoning—i.e., the task of inferring the missing facts (entity relationships) for a given graph—is an important problem in natural language processing and has a wide range of applications (Bordes et al., 2011; Socher et al., 2013; Trouillon et al., 2016). Recent neural graph reasoning methods, such as MINERVA (Das et al., 2017), DeepPath (Xiong et al., 2017) and Multi-Hop (Lin et al., 2018), have achieved impressive results on the task, offering both good *prediction accuracy* (compared to embedding-based methods (Trouillon et al., 2016; Dettmers et al., 2018)) and *interpretability* of the model predictions. These reasoning methods frame the link inference task as a path finding problem over the graph (see Fig. 1 for example).

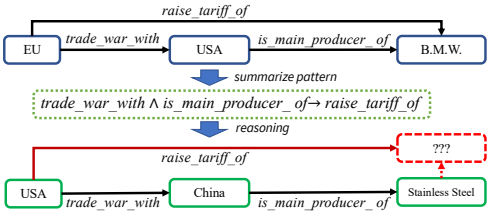

Figure 1: **Illustration of the Knowledge Graph Reasoning Task.** Given an entity (e.g., *Miami*) and a query relation (e.g., *located in*), we learn to infer reasoning paths over the existing graph structure to help predict the answer entity (i.e., *USA*).

However, current neural graph reasoning methods encounter two main challenges as follows: (1) their performance are often sensitive to the sparsity and completeness of the graph—missing edges (i.e., potential false positives) make it harder to find evidential paths reaching target entities. (2) existing models assume the graph is static, and cannot adapt to dynamically enriched graphs where emerging new facts are constantly added.

In this paper, we study the new task of Open Knowledge Graph Reasoning (OKGR), where the new facts extracted from the text corpora will be used to augment the graph dynamically while performing reasoning (as illustrated in Figure 2). All the recent joint graph and text embedding methods focus on learning better knowledge graph embeddings for reasoning (Xu et al., 2014; Han et al., 2018), but we consider adding more facts to the graph from the text to improve the reasoning performance and further provide interpretability. A straightforward solution for the OKGR problem is to directly add extracted facts (by a pre-trained relation extraction model) to the graph. However, most facts so extracted may be noisy or irrelevant

[*] Work done while the authors interned at USC.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2672–2681, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

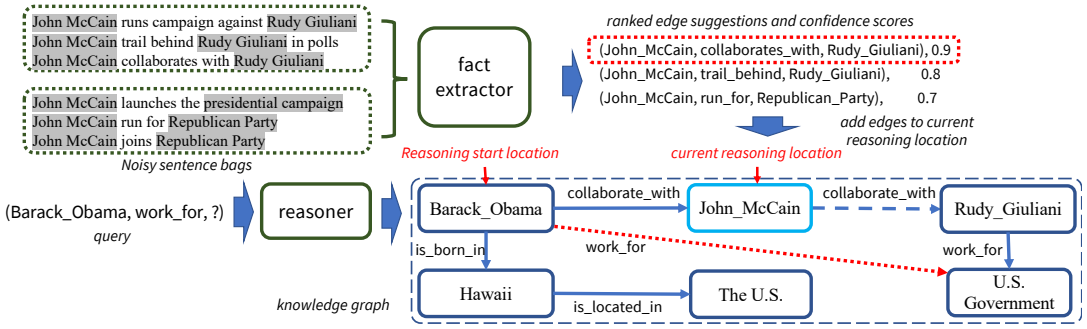

Figure 2: **Overview of our CPL framework for the OKGR problem.** To augment the reasoning with the information from a background corpus, CPL extracts relevant facts (e.g., the triple linked by the blue dotted arrow) to augment the KG dynamically. CPL involves two agents: one learns fact extraction policy to suggest relevant facts; the other learns to reason on dynamically augmented graphs to make predictions (e.g., the red dotted arrow).

to the path inference process. Moreover, adding a large number of edges to the graph will create an ineffective search space and cause scalability issues to the path finding models. Therefore, it is desirable to design a method that can filter out irrelevant facts for augmenting the reasoning model.

To address the above challenges for OKGR, we propose a novel *collaborative policy learning* (CPL) framework to jointly train two RL agents in a mutually enhancing manner. In CPL, besides training a *reasoning* agent for path finding, we further introduce a *fact extraction* agent, which learns the policy to select relevant facts extracted from the corpus, based on the context of the reasoning process and the corpus (see Fig. 2). At inference time, the fact extraction agent dynamically augments the graph with only the most informative edges, and thus enables the reasoning agent to identify positive paths effectively and efficiently.

Specifically, during policy learning, the reasoning agent will be rewarded when reaching the targets, while this positive feedback will also be transferred back to the fact extracting agent if its edge suggestions are adopted by the reasoning agent, i.e. making up correct reasoning paths. This ensures that the fact extraction policy can be learned in a way that edges which are beneficial to path inference will be preferred. By doing so, the fact extraction agent can learn to augment knowledge graphs dynamically to facilitate the reasoning agent, while the reasoning agent performs effective path-inference and provides reward signals to the fact extraction agent. Please refer to Sec. 3 and Fig. 3 for more implementation details.

The major contributions of our work are as follows: (1) We study knowledge graph reasoning in an "open-world" setting, where new facts extracted from background corpora can be used to facilitate path finding; (2) We propose a novel collaborative policy learning framework which models the interactions between fact extraction and graph reasoning; (3) Extensive experiments and analysis are conducted to demonstrate the effectiveness and strengths of our proposed method.

2 Background and Problem

This section introduces basic concepts and notations related to the knowledge graph reasoning task and provides a formal problem definition.

A *knowledge graph* (KG) can be represented by a set of triples (facts) $G = \{(e_s, r, e_o)|e_s, e_o \in E, r \in R\}$, where E is the set of entities and R is the set of relations. e_s, r, and e_o are the subject entity, relation, and object entity respectively.

The task of *knowledge graph reasoning* (KGR) is defined as follows. Given the KG G, a query triple (e_s, r_q, e_q) where e_q is unknown, KGR is to infer e_q through finding a path starting from e_s to e_q on G, namely $\{(e_s, r_1, e_1), ..., (e_n, r_n, e_q)\}$. Usually, KGR methods produce multiple candidate answers by ranking the found paths, while traditional KG completion methods rank all possible answer triples by exhaustively enumerating.

A *background corpus* is a set of sentences labeled with respective entity pairs, namely $C = \{(s_i : (e_k, e_j))|s_i \in S, e_k, e_j \in E\}$, where S is the set of sentences, and the corpus shares the same entity set with G. In our problem setting, we assume the entities have already been extracted; thus, extracting facts from the corpus is equivalent to the relation extraction task. We process the corpus by labeling the sentences with subject and object entity pairs through Distant Supervision (Mintz et al., 2009). There may be many sen-

tences labeled with the same entity pair. Following the formulation of previous work (Lin et al., 2016), we organize the sentences into *sentence bags*, i.e., A sentence bag contains the sentences which are labeled with the same entity pair.

Problem. Formally, *Open Knowledge Graph Reasoning* (**OKGR**) aims to perform KGR based on both G and C, where G is dynamically enriched by the facts extracted from C. This paper focuses on OKGR, i.e., empowering KGR with the corpus information and enriching the graph with relevant facts dynamically. Thus, the evaluation of the relation extraction performance are out of the scope of this paper. We leave this as future work.

3 Proposed Framework

Overview. To resolve the challenges in OKGR, we propose a novel collaborative policy learning (CPL) framework (see Fig. 2), which jointly train two RL agents, i.e., a path reasoning agent and a fact extraction agent. Given a query (e_s, r_q, e_q), the reasoning agent tries to infer e_q via finding a reasoning path on the (augmented) G, while the fact extraction agent aims to select the most informative facts from C to enrich G dynamically. With such an extractor, the framework can effectively overcome the edge sparsity problem while remaining reasonably efficient (compared to the naive solution that adds all possible facts to G). We train the extraction agent by rewarding it according to the the reasoning agent's performance. Hence the fact extractor can learn how to extract the most informative facts to benefit the reasoning.

3.1 Graph Reasoning Agent

The goal of the reasoner is learning to reason via paths finding on KGs. Specifically, given e_s, r_q, the reasoner aims at inferring a path from e_s to some entity e_o regarding r_q, and specifying how likely the relationship r_q holds between e_s and e_o. The inference path acts as the evidence of the prediction, and thus offers interpretation (see Fig. 1). At each time step, the reasoner tries to select an edge based on the observed information. The Markov Decision Process (MDP) of the reasoner is defined as follows:

State. In path-based reasoning, each succeeding edge is closely related to the preceding edge on the path and the query in semantics. Similar to MINERVA(Das et al., 2017), we want the state to encode all observed information, i.e., we define $s_R^t = (e_s, r_q, h^t) \in \mathcal{S}_R$, where h^t encodes the path history, and (e_s, r_q) is the context shared among all states. Specifically, we use a LSTM module to encode the history, $h^t = \text{LSTM}(h^{t-1}, [r^t, e^t])$ (see Fig. 3). e^t is the current reasoning location and r^t is the previous relation connecting e^t.

Action. At time t, the reasoner will select an edge among e^t's out-edges. The reasoner's action space is a union of the edges in the current KG and edges extracted from the corpus. See Sec. 3.3 for details.

Transition. The transition function $f : \mathcal{S}_R \times \mathcal{A}_R \rightarrow \mathcal{S}_R$ is defined as $f(s_R^t, a_R^t) = (e^s, r^q, h^{t+1})$ naturally.

Reward. The reasoner is expected to learn effective reasoning path patterns. We let it explore for a fixed number of steps, which is a hyper-parameter. Only when it reaches the correct target entity, it receives a terminal reward 1, and 0 otherwise. All intermediate states always receive reward 0.

3.2 Fact Extraction Agent

The fact extractor learns to suggest the most relevant facts w.r.t. the current inference step of the reasoner. Suppose the reasoner arrives at entity e^t on the graph at time t, the fact extractor will extract facts in the form of $(e^t, r', e') \notin G$ from the corpus and add them to the graph temporarily. Consequently, the reasoner is offered more choices to expand the reasoning path.

State. When the reasoner is at e^t, the fact extractor tries to extract information from the corpus (sentences) and suggests promising out-edges of entity e^t. Let b_{e^t} denote the sentence bags labeled with $(e^t, e'), e' \in E$. We define the state of the fact extractor to encode the current observed information, i.e., $s_E^t = (b_{e^t}, e^t) \in \mathcal{S}_E$, where $\mathcal{S}_E$ is the whole state space, containing all possible combinations of entities and corresponding sentence bags.

Action. The goal of the fact extractor is to select a reasoning-relevant fact contained in the corpus semantically. At step t, the reasoner will move to a new entity from e^t, and hence only the out-edges of e^t should be considered, e.g., (e^t, r', e') (see Fig. 3). Therefore, for each fact (e^t, r', e') which can be extracted from the sentence bag b_{e^t}, we can derive an action $a_E^t = (r', e')$, and the action space at step t can be denoted as $A_E^t = \{(r', e')\}_{(e^t, r', e') \in b_{e^t}} \subset \mathcal{A}_E$. $\mathcal{A}_E$ is the whole action space containing all facts in the corpus.

Transition. The transition function $f : \mathcal{S}_E \times \mathcal{A}_E \rightarrow \mathcal{S}_E$ is defined as $f(s_E^t, a_E^t) = (r', e')$.

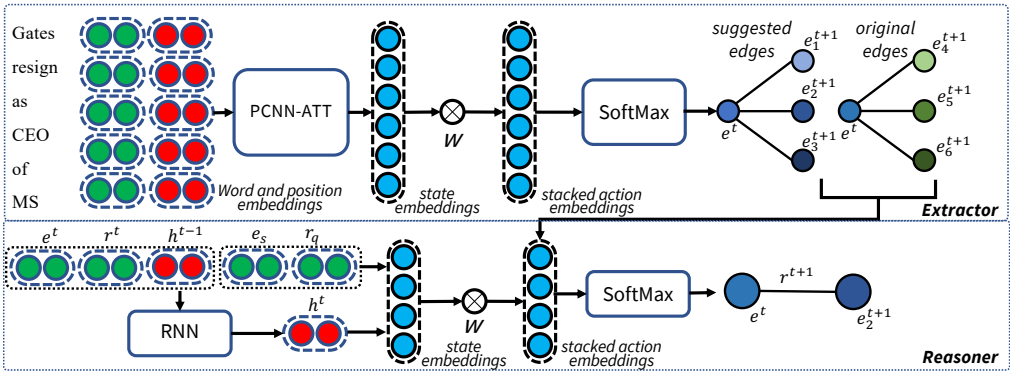

Figure 3: **Detailed Model Design of Collaborative Policy Learning (CPL).** Take PCNN-ATT as an example of the sentence encoder. The figure shows how it works at a certain inference time step t, the reasoner is at entity e^t and will select one edge from the *joint action space*, which consists of new edges extracted by the extractor and the edges in the original graph.

Reward. The fact extractor receives a step-wise delayed reward from the reasoner according to how it improves the reasoners performance. The extractor will be positively rewarded when its suggestion benefits the reasoning process. Please see Sec. 3.3 for details.

3.3 Collaborative Policy Learning

In this section, we will introduce the detailed training process and the collaboration mechanism between the two agents. At the high level, we adopt an *alternative training procedure* to update the two agents jointly: training one of the agents for a few iterations while freezing the other; and vice versa. The policies of both agents are updated via REINFORCE algorithm (Williams, 1992) (details are in later of this section). Specifically, we introduce the details on agent collaboration as follows.

Augmented Action Space for Reasoning. At time t, the fact extractor helps the reasoner via expanding its action space with new edges extracted from the corpus (see Fig. 3). Due to the sparsity and incompleteness of the KG, there may be missing edges preventing the reasoner from inferring the correct reasoning path (Fig. 2). Therefore, we add high-confidence edges extracted by the extractor to the action space of the reasoner. Formally, at time t, the reasoner is at location e^t (Fig. 3) and tries to select an edge out of all out-edges of e^t. Let A_K^t denote the edge set in the current KG, $A_K^t = \{(r, e)|(e^t, r, e) \in G\}$. Let A_C^t denote the edge set suggested by the extractor, $A_C^t = \{(r', e')|(e^t, r', e') \in C\}$. The action space at time t of the reasoner is defined as $A_R^t = A_K^t \cup A_C^t$, $A_R^t \subset \mathcal{A}_R$, where $\mathcal{A}_R$ denotes the whole action space of the reasoner, i.e., all possible edges in the KG and the corpus. The reasoner learns a policy to select the best edges out of the joint action space for reasoning.

Reasoning Feedback for Fact Extraction. The reasoner helps the extractor to learn the extracting policy through providing feedbacks regarding how much the extractor contributes to the reasoning. Therefore we define that the fact extractor receives a step-wise delayed reward from the reasoner. Specifically, when the reasoner finishes exploration (at time T) and arrives at the correct target, we consider the path is effective and positive for reasoning. If the fact extractor contributes to this positive path, it can be rewarded positively, i.e., if an edge on the positive path is suggested by the extractor at time $t, 0 \leq t \leq T$, the extractor will be rewarded 1 at time t, and 0 otherwise. Extracted edges triggering positive rewards will be kept in the graph, while the others will be removed when both agents move to the next state.

Policy Update. The MDPs of both agents are explicitly defined above now, and we can use the typical REINFORCE algorithm (Williams, 1992) to train the two agents. Specifically, their goals are maximizing the reward expectation, defined as

$$J(\theta) = \mathbb{E}_{\pi_\theta(a|s)}[R(s, a)], \tag{1}$$

where $R(s, a)$ is the reward of selecting a given s, and $\pi_\theta(a|s)$ is the policy learned by the agents and will be defined formally in Section. 4.

Given a training sequence sampled from π_θ: $\{(s^1, a^1, r^1), ..., (s^T, a^T, r^T)\}, r^t = R(s^t, a^t)$, at time step t, the parameters are updated according to the REINFORCE algorithm:

$$\theta \leftarrow \theta + \alpha \nabla_\theta \log \pi_\theta(a^t|s^t) G^t$$
$$G^t = \sum_{k=t}^{T} \gamma^{k-t} R(s^k, a^k), \quad (2)$$

where G^t is the discounted accumulated reward.

According to Eq. (2), we can see that REINFORCE will update the parameters only when G^t is non-zero. In other words, the value of γ determines how the parameters are updated and to what extent the the internal states will be influenced by the future. If $\gamma > 0$, for positive training sequences, it is easy to verify that the G^t of all states will be non-zero. Thus, the internal states will be positively rewarded, and the model parameters will be updated by the gradients of the internal states. For different task, we should carefully select the value of γ. For the extractor, we set $\gamma = 0$ for the extractor to avoid policy updating on zero-rewarded state-action experiences. This is because zero-rewarded experiences are mostly negative examples. Specifically, if a state of the extractor is zero-rewarded, we can infer that either the suggested edge is not selected by the reasoner, or the selected edge does not contribute to reaching the target. We can not allow the model to be updated on such experiences, so we set $\gamma = 0$ to avoid the influence of future. In contrast, we set $\gamma = 1$ for the reasoner because all the intermediate selected edges are meaningful as long as it leads to the target finally.

4 Model Implementation

In this section, we introduce the policy network architectures (cf. Fig. 3) of the two agents and provide details on model training and inference.

4.1 Policy Network Architectures

Reasoning Agent. We construct the state embedding by concatenating all related embeddings, $s_R^t = [e_s, r_q, h^t]$, where $h^t = \text{LSTM}(h^{t-1}, [r^t, e^t])$. We construct the action embedding by concatenating the relation-entity embedding pair, i.e., $a_R^t = [r, e], (e^t, r, e) \in G \cup C$. We stack all action embeddings in $\mathbf{A}_R^t$. The policy network is defined as:

$$\pi_\theta(a_R^t|s_R^t) = \sigma(\mathbf{A}_R^t W_2(Relu(W_1[e_s, r_q, h^t]))),$$

σ is softmax, and W_1, W_2 are learnable weights.

Fact extraction Agent. We use a PCNN-ATT as the sentence encoder in our experiments to construct the distributed representations for the sentences. Let b_{e^t} denote all the sentence bags labeled by $(e^t, e'), e' \in E$. At time t, we input b_{e^t} into the PCNN-ATT to obtain the sentence-bag-level embeddings E_b^t, which is regarded as the latent state embeddings. As mentioned in Sec. 2, the object entity has been labeled beforehand. We need to select the best relation first, then select the best entity under this relation. Thus, we stack the relation embeddings in A_E^t as $\mathbf{A}_E^t \in \mathbb{R}^{|A_E^t| \times d}$, where d is the dimension of relation embedding. The policy network is defined formally as:

$$\pi_\theta(a_E^t|s_E^t) = \sigma(\mathbf{A}_E^t W E_b^t),$$

where W is a learnable weight.

The extractor will predict the scores for each sentence bag regarding the relation. We will select the sentence bag with the highest score, more formally, the corresponding relation-entity pair in that sentence bag will be chosen as the next action. We train the agents as introduced in Sec. 3.3.

4.2 Model Training and Inference

Training. We use *model pre-training* and *adaptive sampling* to increase training efficiency. In particular, we first train the reasoner on the original KG to get a better initialization. Similarly, we train the extractor on the corpus labeled by distant supervision. Next, we use adaptive sampling to adaptively increase the selecting-priority of corpus-extracted-edges when generating training experiences for the two agents. Adaptive sampling is designed to encourage the reasoner to explore more on new edges and facilitate the collaboration during the joint training. Replay memories (Mnih et al., 2013) are also used to increase training efficiency. We develop several model variants such as removing adaptive sampling or replay memory, or freezing the extractor all the time to conduct ablation studies. Please see Supplementary Material for more details.

Inference. At inference (reasoning) time, we use the trained model to predict missing facts via path finding. The process is similar to the training experience generation step in the training stage, i.e. using the reasoner for path-inference while the extractor suggests edges from the corpus constantly. The only differences are that we do not request rewards, and we use beam search to generate multiple reasoning paths over the graph, and rank them by the scores from the reasoner.

Dataset	#triples(C)	#triple(G)	#entities(C)	#entities(G)	#rel(C)	#rel(G)	S(train)	S(test)	CT/CE	CR/KR
FB60K-NYT10	172,448	268,280	63,696	69,514	57	1,327	570k	172k	2.71	0.04
UMLS-PubMed	910,320	2,030,841	6,575	59,226	271	443	4,73M	910k	138.45	0.61

Table 1: **The dataset information.** #triples(C) & #triples(G) denote the number of triples in the corpus and the KG respectively, and so on. S(train) denotes the number of sentences in the training corpus, while S(test) denotes the number of sentences in the testing corpus. CT/CE denotes triple-entity ratio. Lower triple-entity ratio indicates less triples per entity in average can be extracted from the corpus. CR/KR denotes corpus-relation-quantity/KG-relation-quantity ratio. Lower CR/KR indicates less information overlap between the corpus and the KG.

5 Experiment

5.1 Datasets and Compared Methods

Dataset	Relations
UP	*'gene_associated_with_disease'* *'disease_has_associated_gene'* *'gene_mapped_to_disease'* *'disease_mapped_to_gene'* *'may_be_treated_by'* *'may_treat'* *'may_be_prevented_by'* *'may_prevent'*
FN	*'people/person/nationality'* *'location/location/contains'* *'people/person/place_lived'* *'people/person/place_of_birth'* *'people/deceased_person/place_of_death'* *'people/person/ethnicity'* *'people/ethnicity/people'* *'business/person/company'* *'people/person/religion'* *'location/neighborhood/neighborhood_of'* *'business/company/founders'* *'people/person/children'* *'location/administrative_division/country'* *'location/country/administrative_divisions'* *'business/company/place_founded'* *'location/us_county/county_seat'*

Table 2: **The concerned relations in two datasets.** UP means the UMLS-PubMed dataset, while FB means the FB60K-NYT10 dataset.

Datasets. We construct two datasets for evaluation: *FB60K-NYT10*[1] and *UMLS-PubMed*[2]. FB60K-NYT10 dataset includes the FB-60K KG and the NYT10 corpus; The UMLS dataset contains the UMLS KG and the PubMed corpus. Statistics of both datasets are summarized in Table 1. We study the datasets and find that the relation distributions of the two datasets are very imbalanced. There are not enough reasoning paths for some relation types. Moreover, some relations are meaningless and of no reasoning value. Thus, we select a few meaningful and valuable relations (suggested by domain experts, in Table 2) with enough reasoning paths and construct two subgraphs accordingly. To show the impact of graph size, we sub-sample the KG into different subgraph. Specifically, for the two datasets, we first partition the whole KG into three parts according to the proportion 8:1:1 (The training set, validation set, and testing set). Next we create sub-train-sets with different ratio via random sampling.

Analysis of corpus-KG alignment. We analyze the information overlap (i.e., alignment) between the corpus and the KG in Table 1. The CT/CE (the ratio of triple quantity against entity quantity) of PubMed is far higher than NYT10. Higher CT/CE indicates adding corpus-edges to the KG increases the average degree more significantly, leading to more reduction in sparsity. The low CR/KR ratio of FB60K-NYT10 indicates the overlap between FB60K and NYT10 is lower than that between UMLS and PubMed. We can conclude that the alignment level of FB60K-NYT10 is lower than UMLS-PubMed. Intuitively, FB60K-NYT10 is a more difficult dataset than UMLS-PubMed.

Compared Algorithms. We compare our algorithm with (1) SOTA methods for KG embedding ; (2) methods for joint text and graph embedding; and (3) neural graph reasoning methods.

For triple-ranking-based KG embedding methods, we evaluate **DistMult** (Yang et al., 2014), **ComplEx** (Trouillon et al., 2016), and **ConvE** (Dettmers et al., 2018). For joint text and graph embedding methods, we evaluate **RC-Net** (Xu et al., 2014) and **Joint-NRE** (Han et al., 2018). We also construct a baseline, **TransE+LINE**, by constructing a word-entity co-occurrence network as RC-Net does. We use LINE (Tang et al., 2015) and TransE (Bordes et al., 2011) to jointly learn the entity and relation embeddings to preserve the structure information within the co-occurrence network and the KG. For neural graph reasoning method, we use **MINERVA** (Das et al., 2017), a reinforcement learning based path reasoning method[4].

Table 3: **Performance comparison on the KG reasoning on the UMLS-PubMed dataset.**[3] We test on different graph sizes (i.e., 20-100% of the original graph) using Hits@K (in %). CPL is the best performing graph reasoning method, and gradually outperforms the others when the graphs are denser.

To validate the effectiveness of fact extraction policy in CPL, we design a two-step baseline (i.e., **Two-Step**). It first uses PCNN-ATT to extract relational triples from the corpora, and augments KG with the triples whose prediction confidences are greater than a threshold. PCNN-ATT (Lin et al., 2016) is a fact extraction model, which completes the fact extraction part. We tune the threshold on the dev-set. Then, a MINERVA model is trained on the augmented KG for reasoning.

CPL is our full-fledged model as introduced in Sec. 3. For all the methods, we upload the source codes and list hyper-parameters we used in the supplemental materials.

5.2 Evaluation and Experimental Setup

Following previous work on KG completion (Bordes et al., 2011), we use Hits@K and mean reciprocal rank (MRR) to evaluate the effectiveness of the KGR and OKGR. Given a query $(e_s, r, ?)$ (for each triple in the test set, we pretend not to know the object entity), we rank the correct entity e_q among a list of candidates entities. Suppose $rank_i$ is the rank of the correct answer entity for the i^{th} query. We define $Hit@K = \sum_i \mathbf{1}(rank_i < K)/N$ and $MRR = \frac{1}{N}\sum_i \frac{1}{rank_i}$.

In our experiments, we use a held-out validation set for all compared methods to search for the best hyper-parameters and the best model for testing (via logging checkpoints). For all methods, we train models using three fixed random seeds (55, 83, 5583), and report the metrics in average. More details on model training can be found in the Supplementary Material.

fers from out-of-memory problems on large-scale datasets.

5.3 Performance Comparison

Performances of the KG reasoning of all the algorithms are given in Table 3, 4 and Figure 6. We can draw conclusions as follows:

1. Triple ranking vs. path inference. CPL and MINERVA perform worse than triple-ranking methods when the size of KGs is small, while outperforms them significantly when adding more triples to the KGs (Figure 6). This is because the general and evidential paths for reasoning on sparse KGs are not enough, and path-based models cannot capture the underlying patterns.

2. CPL vs. joint embedding methods. CPL is inferior to RC-net, TransE+Line, and JointNRE on small KG partitions because they are not path-based models and the connections on small KGs are too sparse. CPL outperforms them significantly on larger datasets. The reasons are two-fold : 1) the graphs are denser to provide enough reasoning paths for training; 2) other algorithms do not filter noisy text information in joint-training.

3. CPL vs. other graph reasoning methods. CPL outperforms MINERVA significantly because CPL makes use of relevant text information for prediction. MINERVA is better than CPL on full FB60K-NYT10 because the alignment between FB60K and NYT10 is very limited (Sec. 5.1). The graph is dense at 100%, and the benefits from the corpus information are indiscernible.

5.4 Performance Analysis

1. Ablation Study on Model Components. In CPL, we apply multiple learning techniques to improve the performance, including collaboration, replay memory, and adaptive sampling as introduced in Sec. 4. To show the effects of differ-

Table 4: **Performance comparison on the KG reasoning on the FB60K-NYT10 dataset.** We can observe similar performance trends as those on the UMLS-PubMed dataset.

ent components, we remove them one by one and train the respective model variants. In addition, to shown the effect of collaboration, we train a model variation with the parameters of the extractor frozen. The result is shown in Fig. 5.

From the result, we find that 1) replay memory is only effective when adaptive sampling is also enabled. This is because adaptive sampling solves the sparse positive sample problem to some extent. There are enough positive experiences for replay. 2) Collaboration improves performance significantly. CPL with a trainable extractor performs better than with a frozen extractor, which means the suggestions of the extractor can be improved by the reasoner's feedbacks. 3) The improvement of CPL over MINERVA reduces as we increase the KG size. This is because with more data for training, the graph becomes denser, and hence the contribution from texts will be diluted.

2. Effectiveness of Fact Selection. As mentioned above, Two-Step is the naive solution to OKGR. The best performing Two-Step model adds tens times more edges into the KG than CPL, whereas the Two-Step model's performance is inferior to CPL and MINERVA on all the datasets (Table 3, 4). The reasons are 1) most of the extracted edges used in the Two-Step model are noisy; 2) adding so many edges significantly enlarges the exploration space for reasoning.

2. We perform a case study on the FB60K-NYT10 dataset to show the effectiveness of dynamically fact-filtering. We check the reasoning performance of the MINERVA and CPL periodically during the training. The results show that the extractor's contribution increases along with the training progress and the adaptive sampling can generate sufficient positive training experiences at the very beginning.

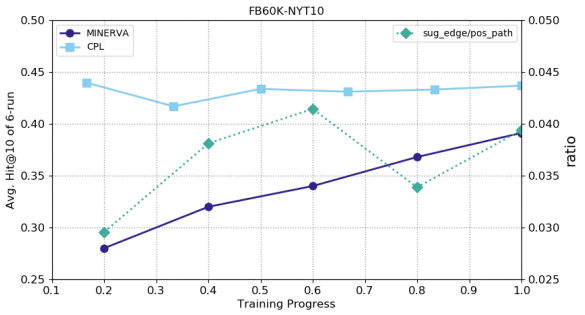

Figure 4: **KG reasoning performance change w.r.t. time.** sug_edge/pos_path means the ratio of positive edges suggested by the extractor w.r.t. the positive paths found by the reasoner.

The result is shown in Figure 4. We find a few interesting points as follows: **1)** the sug_edge/pos_path ratio curve in Figure 4 suggests that the extractor's contribution increases along with the training progress; **2)** CPL has a high initial performance because the adaptive sampling generates sufficient positive training experiences quickly. **3)** The valley shape in the performance curve is because the agent has not learned a stable exploring policy when the adaptive sampling stops, and the adaptive sampling somehow twisted the true pattern distribution in the dataset. But with a good start, the agent can explore on its own to approach the true distribution.

5.5 Case Study of Reasoning Paths

We randomly sample some reasoning paths from the inference results of CPL as examples. Due to the space limit, please refer to the supplemental materials for these examples. These examples show 1) how the reasoner finds the path patterns for the respective relations; 2) how the reasoner finds the inference paths according to the patterns; 3) how the extractor suggests rel-

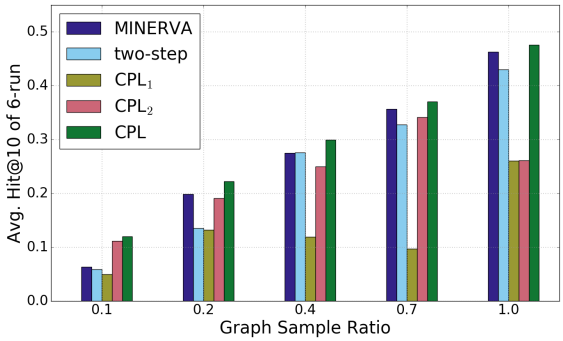

Figure 5: **Ablation Study on UMLS-PubMed dataset.** CPL_1 denotes CPL without adaptive sampling, and the extractor is frozen during training. CPL_2 denotes CPL without adaptive sampling. CPL denotes our proposed final model (with all the components).

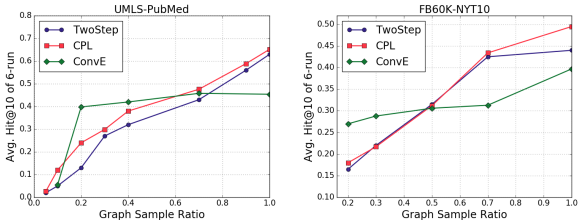

Figure 6: **KG reasoning performance change w.r.t. the size of the graph.** Triple-ranking based methods perform pretty well on smaller partitions, but are soon surpassed by path-based KG reasoning methods with the increase of graph size.

evant edges for each positive paths; 4) how the extractor extracts the relevant facts from related sentences. In summary, these cases show how CPL performs interpretable knowledge graph reasoning (infer the query entity through semantics-related path searching) and how CPL performs interpretable fact-filtering (suggest edges w.r.t the learned reasoning path patterns).

6 Related Work

Knowledge Graph Reasoning. Diverse approaches of embedding-based KG reasoning are presented, including linear models (Bordes et al., 2011), latent factor models (Trouillon et al., 2016), matrix factorization models (Yang et al., 2014) and convolutional neural networks (Dettmers et al., 2018). Performances of these methods are promising, but their predictions are barely interpretable. RL plays a crucial role in interpretable KG reasoning. MINERVA (Das et al., 2017) and DeepPath (Xiong et al., 2017) employ policy networks; (Xiong et al., 2017) uses extra rule-based supervision. Multi-hop (Lin et al., 2018) improves MINERVA via reward shaping and action drop-out.

Joint Embedding of Text and KG. Joint embedding methods aim to unite text corpus and KG. Contrary to our focus, they mainly utilize KGs for better performances of other tasks. (Toutanova et al., 2015) focuses on fact-extraction on the corpus labeled via dependency parsing with the aids of KG and word embeddings, while (Han et al., 2016) conducts the same task with the raw corpus text. As a newer joint model developed from (Han et al., 2016), (Han et al., 2018) deals with fact extraction by employing the mutual attention.

Open-World KG Completion. There are works focusing on similar topics as ours. (Shi and Weninger, 2018) defines an Open World KG Completion problem, in which they complete the KG with unseen entities. (Friedman and Broeck, 2019) introduces the Open-World Probabilistic Databases, an analogy to KGs. Unlike our setting, they try to complete the KG with logical inferences without extra information. (Sun et al., 2018) proposes an open, incomplete KB environment (or KG) with text corpora, but they focus on extracting answers from question-specific subgraphs.

7 Conclusion

In this paper, we focus on a new task named as Open Knowledge Graph Reasoning, which aims at boosting the knowledge graph reasoning with new knowledge extracted from the background corpus. We propose a novel and general framework, namely Collaborative Policy Learning, for this task. CPL trains two collaborative agents, the reasoner and fact extractor, which learns the path-reasoning policy and relevant-fact-extraction policy respectively. CPL can perform efficient interpretable reasoning on the KG and filtering of noisy facts. Experiments on two large real-world datasets demonstrate the strengths of CPL. Our work can cope with different path-finding modules such as MultHop with reward shaping by ConvE or RotatE and thus can improve its performance as the module improves.

Abstract

Understanding event and event-centered commonsense reasoning are crucial for natural language processing (NLP). Given an observed event, it is trivial for human to infer its intents and effects, while this type of If-Then reasoning still remains challenging for NLP systems. To facilitate this, a If-Then commonsense reasoning dataset Atomic is proposed, together with an RNN-based Seq2Seq model to conduct such reasoning. However, two fundamental problems still need to be addressed: first, the intents of an event may be multiple, while the generations of RNN-based Seq2Seq models are always semantically close; second, external knowledge of the event background may be necessary for understanding events and conducting the If-Then reasoning. To address these issues, we propose a novel context-aware variational autoencoder effectively learning event background information to guide the If-Then reasoning. Experimental results show that our approach improves the accuracy and diversity of inferences compared with state-of-the-art baseline methods.

1 Introduction

Recently, event-centered commonsense knowledge has attracted much attention (Chambers and Jurafsky, 2008; Segers et al., 2016; Wang et al., 2017; Li et al., 2018), because of understanding events is an important component of NLP. Given a daily-life event, human can easily understand it and reason about its causes, effects, and so on. However, it still remains a challenging task for NLP systems. This is partly due to most of them are trained for task-specific datasets or objectives, which results in models that are adapt at finding task-specific underlying correlation patterns but have limited capability in simple and explainable commonsense reasoning (Sap et al., 2018).

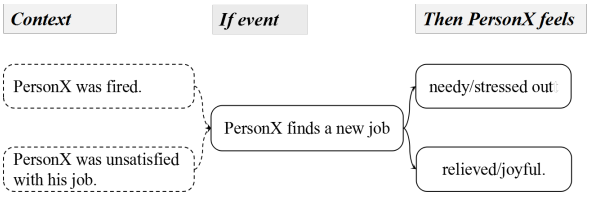

Figure 1: A illustration of two challenging problems in If-Then reasoning. (a) Given an observed event, the feelings about this event could be multiple. (b) Background knowledge is need for generating reasonable inferences, which is absent in the dataset (marked by dashed lines).

To facilitate this, Rashkin et al. (2018) build the Event2Mind dataset and Sap et al. (2018) present the Atomic dataset, mainly focus on nine If-Then reasoning types to describe causes, effects, intents and participant characteristic about events. Together with these datasets, a simple RNN-based encoder-decoder framework is proposed to conduct the If-Then reasoning.

However, there still remains two challenging problems. First, as illustrated in Figure 1, given an event "PersonX finds a new job", the plausible feeling of PersonX about that event could be multiple (such as *"needy/stressed out"* and *"relieved/joyful"*). Previous work showed that for the one-to-many problem, conventional RNN-based encoder-decoder models tend to generate generic responses, rather than meaningful and specific answers (Li et al., 2016; Serban et al., 2016).

Second, as a commonsense reasoning problem, rich background knowledge is necessary for generating reasonable inferences. For example, as shown in Figure 1, the feeling of PersonX upon the event "PersonX finds a new job" could be multiple. However, after given a context "*PersonX was fired*", the plausible inferences would be narrowed down to "*needy*" or "*stressed out*".

To better solve these problems, we propose a context-aware variational autoencoder (CWVAE) together with a two-stage training procedure. Vari-

ational Autoencoder (VAE) based models have shown great potential in modeling the one-to-many problem and generate diversified inferences (Bowman et al., 2015; Zhao et al., 2017).

In addition to the traditional VAE structure, we introduces an extra context-aware latent variable in CWVAE to learn the event background knowledge. In the pretrain stage, CWVAE is trained on an auxiliary dataset (consists of three narrative story corpora and contains rich event background knowledge), to learn the event background information by using the context-aware latent variable. Subsequently, in the finetune stage, CWVAE is trained on the task-specific dataset to adapt the event background information to each specific aspect of If-Then inferential target (e.g., intents, reactions, etc.).

Experiments on the Event2Mind and Atomic dataset show that our proposed approach outperforms baseline methods in both the accuracy and diversity of inferences. The code is released at https://github.com/sjcfr/CWVAE.

2 Background

Before specifically describing two dataset —- Event2Mind and Atomic used in this paper as well as the If-Then reasoning task, for clarity, we define the following terminologies:

Base event: the prerequisite event in If-Then reasoning, organized as a verb phrase with a predicate and its arguments, such as the event "PersonX finds a new job" shown in Figure 1.

Inference dimension: a particular If-Then reasoning type, e.g., intents, effects of the base event. Details are shown in Table 1 and Table 2.

Target: the inferential results. For example, as shown in Figure 1, given a base event "PersonX finds a new job" and one inference dimension "xReact", the targets could be "*relieved*" or "*needy*". Notice that each inference dimension can have multiple targets.

Event2Mind Dataset contains 25K base events and 300K targets, annotated through crowdsourcing. Event2Mind is organized in a hierarchical form: each base event has three types of inference dimensions, and given a base event, under one of inference dimensions, several targets may simultaneously exist. Table 1 shows the (base event-inference dimension-target) hierarchical structure through an example from Event2Mind.

Atomic Dataset Inspired by Event2Mind, the Atomic dataset shares the same hierarchical structure as Event2Mind, while scales up the size of dataset and expands the scope to nine types of inference dimensions. Table 2 shows the (base event-inference dimension-target) hierarchical structure through an example from Atomic. Though Atomic covers the inference dimensions of Event2Mind, the base event collection of Event2Mind is nonidentical to that of Atomic.

Base event	Inference Dim.	Target
PersonX writes PersonY a letter	xIntent	to send a message, express themself
	xReact	nervous, thoughtful
	oReact	indifferent, receptive

Table 1: Hierarchical structure of Event2Mind dataset. For specific inference dimensions, "x" and "o" refers to PersonX and others respectively.

Base event	Inference Dim.	Target
PersonX adopts a child	xIntent	to help another person, to have a child
	xNeed	to visit adoption agency, to be approved for adoption
	xAttr	compassionate, generous
	xEffect	becomes a parent, gains love and companionship
	xWant	take child home, buy child clothes
	xReact	happy, caring
	oReact	has a parent, receives love and affection
	oWant	try on new clothes, to have a family
	oEffect	has a parent, Receives love and affection

Table 2: Hierarchical structure of Atomic dataset. For specific inference dimensions, "x" and "o" refers to PersonX and others respectively.

Problem Definition The If-Then reasoning task could be formally defined as a conditional one-to-many generation problem: given a base event x and one inference dimension d, the model is required to generate targets $y = f(x, d)$ as close to the ground truths as possible. Both x and y consist of sequence of words: $x = \{x_1, \ldots, x_m\}$, and $y = \{y_1, \ldots, y_n\}$, where m and n denotes the length of x and y, respectively.

Conditional Variational Autoencoder The variational autoencoder (VAE) defines a generative framework suited for one-to-many generation problem (Kingma and Welling, 2014). While con-

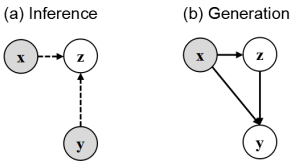

Figure 2: Illustration of inference and generation process of CVAE in a directed graph. Dashed lines represent the inference of z. Solid lines represent the generation process.

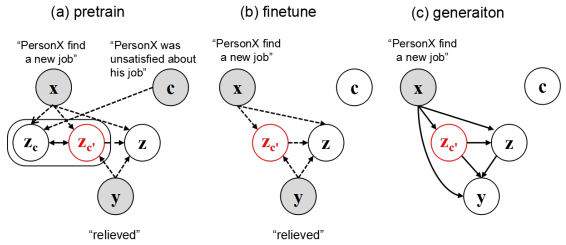

Figure 3: Illustration of pretrain, finetune and generation process of CWVAE in a directed graph. Dashed lines represent the inference of z, z_c and $z_{c'}$. Solid lines represent the generation process. Red circle denotes the context-aware latent variable.

ditional variational autoencoder (CVAE) (Sohn et al., 2015) is an extension of VAE on the conditional generation problem. As shown in Figure 2 (a), CVAE characterizes the conditional one-to-many generation problem using three random variables: event x, target y and a latent variable z, which is used for modeling the latent distribution of semantic over targets given an event. Hence, under a certain inference dimension, with regard to the latent semantic variable z, the conditional generation problem could be expressed as $p(y|x) = \int p(y|x,z)p(z|x)dz$. CVAE models $p(y|x,z)$ and $p(z|x)$ using deep neural networks (parameterized by θ) $p_\theta(y|x,z)$ and $p_\theta(z|x)$. Then as illustrated in Figure 2 (b), y could be generated from x and z.

CVAE is trained to maximize the conditional likelihood $p(y|x)$, which involves an intractable marginalization over the latent variable z. Instead, following Kingma and Welling (2014), a practical way is to introduce another deep network (parameterized by ϕ) $q_\phi(z|x,y)$ to approximate the true posterior distribution $p(z|x,y)$ and maximize the evidence lower bound (ELBO) of the log-likelihood function:

$$\begin{aligned} L^{ELBO}(\theta,\phi) =& \mathbb{E}_{q_\phi(z|x,y)}\log(p_\theta(y|x,z)) - \\ & \mathrm{KL}(q_\phi(z|x,y)||p_\theta(z|x)) \\ & \leq \log p(y|x) \end{aligned} \quad (1)$$

Therefore, CVAE is composed of three neural networks in general. We refer to $p_\theta(z|x)$ as a prior network, $q_\phi(z|x,y)$ as a recognition network, and $p_\theta(y|x,z)$ as a neural decoder.

3 Context-aware Variational Autoencoder

Traditional CVAE can model the `event-target` relation. In other words, given an observed event, CVAE can generate its corresponding targets. While in this paper we model the If-Then reasoning as a `[(background), event]-target` process. It means that in addition to the observed event, we also want to involve the event background knowledge (which can be learned from event contexts) to generate the reasonable targets.

To this end, we propose a context-aware variational autoencoder (CWVAE), with two additional latent variables: a context-acquiring latent variable z_c to directly acquire context information, and a context-aware latent variable $z_{c'}$ to learn background knowledge from z_c, as shown in Figure 3 (a). However, the event context information is absent in the Event2Mind and Atomic dataset. To learn from the external event context information, we design the following two-stage training procedure for CWVAE.

Pretrain: Learning Event Background Knowledge from Auxiliary Dataset In the pretrain stage, CWVAE is trained on three narrative story corpora with rich event context information. As shown in Figure 3 (a), context-acquiring latent variable z_c is directly conditioned on the context c. Hence, z_c could be employed for acquiring background knowledge from event contexts. Then, we minimize the distance between z_c and the context-aware latent variable $z_{c'}$, by which the event background knowledge is transferred from z_c to $z_{c'}$.

Finetune: Adapt Event Background Knowledge to Each Inference Dimension In the finetune stage, as shown in Figure 3 (b), CWVAE is trained on the Event2Mind and Atomic dataset without the event context information. Pretrained CWVAE is finetuned to learn the specific inferential knowledge of each inference dimension. After the training procedure, as shown in Figure 3 (c), samples of z is generated based on x and samples of $z_{c'}$, where $z_{c'}$ contains rich event background knowledge helpful for If-Then reasoning.

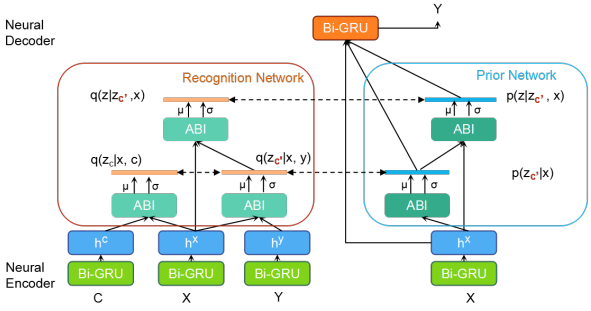

Figure 4: Architecture of CWVAE. We mark Neural encoder in green, prior network in blue, recognition network in brown and neural decoder in orange, respectively.

3.1 Architecture of CWVAE

As shown in Figure 4, CWVAE is mainly composed of four parts: a neural encoder that provides distributed representations of base events/targets, a recognition network for inferring $q_\phi(z|x,y)$, $q_\phi(z_c|x,c)$ and $q_\phi(z|z_{c'},x)$, a prior network for modeling $p_\theta(z_{c'}|x)$ and $p_\theta(z|x,z_{c'})$, and a neural decoder that integrates the information from z and $z_{c'}$ to generate targets.

Neural Encoder We employ a bidirectional GRU as neural encoder, which encodes context c, event x and target y into distributed representations $h^c = \{h^c_1, \ldots, h^c_{l_c}\}$, $h^x = \{h^x_1, \ldots, h^x_{l_x}\}$ and $h^y = \{h^y_1, \ldots, h^y_{l_y}\}$, where l_c, l_x and l_y is the length of c, x and y, respectively.

Recognition Network The recognition network models $q_\phi(z|x,y)$, $q_\phi(z_c|x,c)$, $q_\phi(z|z_{c'},x)$ based on h^x, h^y and h^c.

Following traditional VAE, the above-mentioned three distributions are assumed to be multivariate Gaussian distribution with a diagonal covariance structure:

$$\begin{aligned} q_\phi(z_c|x,c) &\sim N(\mu_{z_c}(x,c), \sigma_{z_c}(x,c)I) \\ q_\phi(z_{c'}|x,y) &\sim N(\mu_{z_{c'}}(x,y), \sigma_{z_{c'}}(x,y)I) \\ q_\phi(z|x,y) &\sim N(\mu_z(x,y), \sigma_z(x,y)I) \end{aligned} \quad (2)$$

where μ denotes the mean of the distribution, σ denotes the standard deviation of the distribution, and I denotes the identity matrix.

Given h^x, h^y and h^c, we propose a novel attention-based inferer (ABI) module to estimate the mean and standard deviation of $q_\phi(z_c|x,c)$, $q_\phi(z_{c'}|x,y)$ and $q_\phi(z|x,y)$:

$$\begin{aligned} \mu_{z_c}, \sigma_z &= \mathrm{ABI}_c(h^c, h^x) \\ \mu_{z_{c'}}, \sigma_z &= \mathrm{ABI}_{c'}(h^y, h^x) \\ \mu_z, \sigma_z &= \mathrm{ABI}_z(z_{c'}, h^x) \end{aligned} \quad (3)$$

Briefly, through the attention mechanism, ABI can capture the semantic interaction between input sequences, and estimate the parameters of distributions based on it. We will introduce the specific structure of ABI in below.

Prior Network Prior Network models $p_\theta(z_{c'}|x)$ and $p_\theta(z|x,z_{c'})$ based on h^x. The distribution of $p_\theta(z_{c'}|x)$ and $p_\theta(z|x,z_{c'})$ are still assumed to be multivariate Gaussian, whereas the parameters are different:

$$\begin{aligned} p_\theta(z|x) &\sim N(\mu'_z(x), \sigma'_z(x)I) \\ p_\theta(z_{c'}|x) &\sim N(\mu'_{z_{c'}}(x), \sigma'_{z_{c'}}(x)I) \end{aligned} \quad (4)$$

where μ' denotes the mean of the distribution, σ' denotes the standard deviation of the distribution and I denotes the identity matrix.

Then the attention-based inferer module is still employed to estimate parameters of distributions:

$$\begin{aligned} \mu'_{z_{c'}}, \sigma'_z &= \mathrm{ABI}'_{c'}(h^y, h^x) \\ \mu'_z, \sigma'_z &= \mathrm{ABI}'_z(z_{c'}, h^x) \end{aligned} \quad (5)$$

Neural Decoder Given the base event x, the semantic latent variable z, and the context-aware latent variable $z_{c'}$, the neural decoder defines the generation probability of y as following:

$$p(y|x,z,z_{c'}) = \prod_{j=1}^{n} p(y_j|y<j, z, z_{c'}, x) \quad (6)$$

where $p(y_j|y<j,z,z_{c'},x) = g(y_{j-1}, s_{j-1}, e_j)$, $g(\cdot)$ is an attention-based feed forward model, $e_j = \sum_i \alpha_{ji} h^x_i$ is the context vector and s_{j-1} is the hidden state of the decoder. We obtain $g(\cdot)$ and e_j the same way as Bahdanau et al. (2014). Whereas our decoder differs from Bahdanau et al. (2014) in that our model integrates the context-aware latent variable $z_{c'}$ and semantic latent variable z in the computation of $s_j = \mathrm{GRU}([E_{yj}; s_{j-1}, z, z_{j-1}])$, where E_{yj} is the word embeddings of target words.

Note that through concatenating z and $z_{c'}$ with E_{yj} and s_{j-1}, s_j could be affected by context-aware latent variable $z_{c'}$ and semantic latent variable z. This allows model to directly access to the event background knowledge from $z_{c'}$. In addition, the randomness of z and $z_{c'}$ would increase the diversity of model generation.

Attention-based Inferer Attention mechanism has shown strong ability in capturing semantic interactions (Gong et al., 2017). Inspired by the co-attention mechanism (Parikh et al., 2016), we propose an attention-based inferer (ABI) to estimate

the mean and standard deviation of a distribution belongs to $p_\theta(\cdot)$ or $q_\phi(\cdot)$ by capturing semantic interactions of input sequences.

Specifically, given two input sequences (e.g., representations of contexts and events) $a = \{a_1, \ldots, a_{l_a}\}$ and $b = \{b_1, \ldots, b_{l_b}\}$ with length l_a and l_b, we first obtain the attention scores from each side through:

$$\begin{aligned}\gamma_t^a &= \frac{\exp[(W_a h_t^a)^T (W_b h_i^b)]}{\sum_i \exp[(W_a h_t^a)^T (W_b h_i^b)]} \\ \gamma_t^b &= \frac{\exp[(W_a h_i^a)^T (W_b h_t^b)]}{\sum_i \exp[(W_a h_i^a)^T (W_b h_t^b)]}\end{aligned} \tag{7}$$

where $W_a \in \mathbb{R}^{d \times d_a}$ and $W_b \in \mathbb{R}^{d \times d_b}$ are parameter weights.

With these attention scores, the context vectors of both sequences are given by:

$$\begin{aligned}c_t^a &= a\gamma_t^a \\ c_t^b &= b\gamma_t^b\end{aligned} \tag{8}$$

Then we perform a mean pooling operation on context vectors of both sequences:

$$\begin{aligned}\bar{c^a} &= \frac{1}{l_a}\sum_{t=1}^{l_a} c_t^a \\ \bar{c^b} &= \frac{1}{l_b}\sum_{t=1}^{l_b} c_t^b\end{aligned} \tag{9}$$

To obtain the mean and standard deviation, the pooled context vectors $\bar{c^a}$ and $\bar{c^b}$ which carry semantic interaction between two sequences, are concatenated and projected into a latent semantic space through a nonlinear transformation:

$$h_z = \tanh(W[\bar{c}^a; \bar{c}^b] + b_z) \tag{10}$$

Finally the mean and standard deviation are generated through a nonlinear transformation over h_z:

$$\begin{aligned}\mu &= W_\mu h_z + b_\mu \\ \sigma &= \text{softplus}(W_\sigma h_z + b_\sigma)\end{aligned} \tag{11}$$

3.2 Optimizing

With the incorporation of $z_{c'}$, the original loglikelihood could be decomposed as:

$$\log p(y|x) = \iint p(y|z, z_{c'}, x) dz dz_{c'} \tag{12}$$

Then following traditional CVAE, the ELBO of CWVAE is defined as follows:

$$\begin{aligned}L^{ELBO}(\theta, \phi) = & \\ & \underbrace{\mathbb{E}_{q_\phi(z|x,z_{c'})q_\phi(z_{c'}|x,y)} \log p_\theta(y|x, z, z_{c'})}_{\text{Reconstruction Loss}} \\ & - \underbrace{\int q_\phi(z|x,y)\text{KL}(q_\phi(z_{c'}|x,y)||p_\theta(z_{c'}|x))dz}_{\text{KL term}} \\ & - \underbrace{\int q_\phi(z_{c'}|x,y)\text{KL}(q_\phi(z|x,z_{c'})||p_\theta(z|x,z_{c'}))dz_{c'}}_{\text{KL term}}\end{aligned} \tag{13}$$

which is the objective function at the finetune stage.

While in the pretrain stage, as we aim to learn background knowledge through minimizing the distance between z_c and $z_{c'}$, in addition to L^{ELBO}, a context-aware regulation term is introduced:

$$\begin{aligned}L^{PT}(\theta, \phi) = & L^{ELBO}(\theta, \phi) \\ & \underbrace{- \lambda \int \text{KL}(q_\phi(z_c|x,c)||q_\phi(z_{c'}|x,y))dz_{c'}}_{\text{context-aware regulation}}\end{aligned} \tag{14}$$

where the context aware regularization term is the KL distance between z and $z_{c'}$. Through minimizing the context aware regularization term, we aim to pass event context knowledge from z_c to the context aware latent variable $z_{c'}$.

3.3 Training Details

To test the performance of CWVAE, we split the Event2Mind and Atomic dataset into training, development and test sets (80%, 10%, 10%) in the same way as Rashkin et al. (2018) and Sap et al. (2018), respectively.

We initialize the embedding layer from 300d GloVe word embeddings. The neural encoder is chosen to be biGRU with 300 hidden units. For the ABI module, size of W_a and W_b is set to be $100 \times d_a$ and $100 \times d_b$ respectively. The dimension of z_c, $z_{c'}$ and z is all set as 40. The neural decoder is set to be GRU with 300d hidden state. Regulation coefficient λ of context-aware regulation term is set to be 0.1. Models are trained using an Adam optimizer (Kinga and Adam, 2015) with a learning rate of 0.001.

4 Experiments

4.1 Auxiliary Dataset

The auxiliary dataset is built upon three human-written story corpora: ROCStories (Mostafazadeh

Context	Event	Inference Target
① jason had been really stressed out at work. ② he decided he needed a different kind of job. ③ jason applied for a job in a different field.	④ he got the job .	⑤ jason was much happier at his new job .

Table 3: An example for the construction of auxiliary dataset. For a five-sentence-paragraph, the first three sentences are taken as event context, while the fourth and fifth sentence is taken as base event and target respectively.

et al., 2016), VIST (Huang et al., 2016) and WritingPrompts (Fan et al., 2018). ROCStories and VIST are composed of short stories with five sentences. We filter out stories of more than 1,000 words in WritingPrompts, and cut the remaining stories into five-sentence-paragraphs.

For each five-sentence-paragraph, we define the first three sentences as contexts of the base event, the fourth sentence as the base event, and the fifth sentence as the inference target. For example, as shown in Table 3, the first three sentences describe a context that Jason was unsatisfied about his job and applied for a new job. Hence, after happening the event "he got the job", a plausible react about the event could be "jason was much happier at his new job". In total, the auxiliary dataset contains 192,316 $(context, event, target)$ triples.

4.2 Baselines

We compared our proposed model with the following four baseline methods:

- **RNN-based Seq2Seq** proposed by Sap et al. (2018) for the If-Then reasoning on Atomic.
- **Variational Seq2Seq** combines a latent variable with the encoder-decoder structure through converting the last hidden state of RNN encoder into a Gaussian distributed latent variable (Bowman et al., 2015).
- **VRNMT** Propose by Su et al. (2018), VRNMT combines CVAE with attention-based encoder-decoder framework through introduces a latent variable to model the semantic distribution of targets.
- **CWVAE-Unpretrained** refers to the CWVAE model without the pretrain stage.

Note that, for each baseline method, we train distinct models for each distinct inference dimension, respectively.

4.3 Evaluation Metrics

Automatic Evaluation We first compare the perplexity of CWVAE with baseline methods. Perplexity measures the probability of model to regenerate the exact targets, which is particular suitable for evaluating the model performance on one-to-many problem (Serban et al., 2017). Further, we employ BLEU score to evaluate the accuracy of generations (Papineni et al., 2002), and the number of distinct n-gram to evaluate the diversity of generations (Li et al., 2016). The distinct is normalized to $[0, 1]$ by dividing the total number of generated tokens.

Metric	Methods	xIntent	xReact	oReact
PPL	RNN-based Seq2Seq	44.12	29.18	14.08
	Variational Seq2Seq	42.06	28.22	12.62
	VRNMT	33.45	25.54	11.93
	CWVAE-Unpretrained	31.32	24.07	11.37

Table 5: Distinct-1 and distinct-2 scores for the top 10 generations under each inference dimension of Event2Mind. The the best result for each dimension is emboldened.

Human Evaluation Since automatic evaluation of generations is still a challenging task (Liu et al., 2016), we also conduct human evaluations on the model performance. Five human experts are employed to evaluate the *coherence*, *diversity* and *fluency* of generated targets. Experts are asked to vote for if a generation is fluent or coherent for each generated target, and give a 1-5 score for the diversity of generations. For both Event2Mind and Atomic datasets, 100 events are randomly selected from the test set. For each method, top 10 generated targets of each base event are used for eval-

uation. Finally we report three overall averaged scores of *coherence*, *diversity* and *fluency* on both datasets, respectively.

4.4 Overall Results

We list the perplexity and BLEU score of CWVAE and baseline methods on Event2Mind and Atomic in Table 4 and Table 6, respectively, and show the distinct-1 and distinct-2 score on Event2Mind and Atomic in Table 5 and Table 7, respectively. We find that:

(1) As shown in Table 5 and Table 7, comparison between RNN-based Seq2Seq and variational-based methods, including Variational Seq2Seq, VRNMT, CWVAE-unpretrained and CWVAE shows that, variational-based methods could increase the diversity of generations. This confirms one of our motivations that variational-based methods could capture the latent semantic distribution within targets and increase the diversity of If-Then reasoning.

(2) Comparing CWVAE-unpretrained with other baseline methods shows that, in general CWVAE improves the accuracy and diversity on both dataset. These results indicate the efficiency of CWVAE in capturing the latent semantic distribution of targets, and generate more reasonable inferential results.

(3) Comparison between CWVAE and CWVAE-unpretrained shows that the pre-train stage could enhance the performance of CWVAE in both the accuracy and diversity. This is mainly because event knowledge could offer the guidance for If-Then reasoning. In the pretrain stage, CWVAE could capture the event background knowledge through context-aware latent variable, and such knowledge could be be adapted to our task through the fintune stage.

Methods	Coherence	Diversity	Fluency
RNN-based Seq2Seq	0.28	2.03	0.73
Variational Seq2Seq	0.33	1.67	0.92
VRNMT	0.32	2.60	0.83
CWVAE-Unpretrained	0.36	2.10	0.92
CWVAE	**0.43**	**2.85**	**0.96**

Table 8: Human evaluation results on Event2Mind.

Methods	Coherence	Diversity	Fluency
RNN-based Seq2Seq	0.21	2.66	0.78
Variational Seq2Seq	0.22	2.70	0.90
VRNMT	0.24	2.61	0.78
CWVAE-Unpretrained	0.25	2.72	0.83
CWVAE	**0.32**	**3.03**	**0.90**

Table 9: Human evaluation results on Atomic.

To further evaluate the effectiveness of our proposed approach, we also conduct human evaluations, the results of which are shown in Table 8 and Table 9. On both datasets, CWVAE-based methods achieve consistent better coherence, diversity and fluency performances. While comparing with CWVAE-Unpretrained, the pretrain procedure could improves the performance

Base event	Inference dim.	Generations		Ground truth
		CWVAE	RNN-based Seq2Seq	
PersonX works tirelessly	xIntent	be productive and hardworking finish his work soon earn more money and accomplish goal finish his work and make money finish his work and accomplish goal be productive and successful	get the job done get the job done on time get the job done in the way get the job done for his life make money for his own future make money for his own money	be productive finish the project as soon as possible reach goal

Table 10: An example of inferences made by CWVAE and RNN-based Seq2Seq model under inference dimension "xIntent".

on coherence and fluency. The main reasons are twofold: first, the CWVAE has advantage in capturing the semantic distribution of targets; second, event background learned from the pretrain stage is helpful for the If-Then reasoning.

4.5 Case Study

Table 10 provides an example of model generations given the base event "PersonX works tirelessly" and the inference dimension "xIntent". The generations under CWVAE mainly contain four kinds of semantics: (1) be productive, (2) finish his work soon, (3) accomplish goal, (4) earn more money. While the semantics of generations using baseline RNN-based Seq2Seq model is relatively limited. Furthermore, the first three kinds of semantic overlap the three ground truth targets, and the fourth kind of semantic is in accordance with daily-life commonsense. Compared to RNN-based Seq2Seq model, our approach can increase the diversity and rationality of generations, meanwhile keep the accuracy.

5 Related Work

5.1 Event-Centered Commonsense Reasoning

Understanding events and constructing event-centered commonsense knowledge are crucial to many NLP applications, such as intention recognition (Goldwasser and Zhang, 2016) and dialog generation (Wen et al., 2017). Recently a growing number of studies focus on event-centered commonsense reasoning, which mainly concentrates on two areas, script event prediction and story ending generation/choosing.

Script event prediction concerns with the temporal relationships between script events (Granroth-Wilding and Clark, 2016), which requires models to choose a correct subsequent triple-organized event among the candidates (Wang et al., 2017). Prior work mainly focused on modeling event pairs (Granroth-Wilding and Clark, 2016), event chains (Wang et al., 2017) and event graph (Li et al., 2018) to predict the subsequent event. Story ending generation focuses on generating plausible story endings (Mostafazadeh et al., 2016), which requires models to understand the story context, and keep generated endings logically consistent with it (Peng et al., 2017; Guan et al., 2019). The above tasks mainly investigate the logical orders of events, whereas the If-Then reasoning task focuses on inferring the mental state of event participants.

5.2 Variational AutoEncoder-Decoder Based Natural Language Generation

VAE (Kingma and Welling, 2014) has been widely applied in various of text generation tasks, such as dialogue and machine translation.

In dialogue generation, Zhao et al. (2017) adapts VAE with encoder-decoder framework to model the latent semantic distribution of answers, which can increase the diversity of generations. For the task of machine translation, Su et al. (2018) and Zhang et al. (2016) employ a latent variable to capture the semantic interaction between the source and target sentence, and regard the latent variable as a supplementation of attention mechanism. While Wang et al. (2019) use the latent variable to model topic distributions in text generation. In this paper, we introduce an additional context-aware latent variable to effectively learn background knowledge and conduct If-Then reasoning on the guidance of it.

6 Conclusion

In this paper, we propose a novel context-aware VAE (CWVAE) framework with two training stages for If-Then commonsense reasoning. By introducing an additional context-aware latent variable, CWVAE is able to learn external background knowledge, and conduct If-Then reasoning under its guidance. In the pretrain stage, CWVAE learns event background knowledge, then in the finetune stage CWVAE adapts such knowledge to each inference dimension. Experimental results demonstrate that CWVAE outperforms baseline methods in both the accuracy and diversity of generations.

Abstract

Natural language inference aims to predict whether a premise sentence can infer another hypothesis sentence. Existing methods typically have framed the reasoning problem as a semantic matching task. The both sentences are encoded and interacted symmetrically and in parallel. However, in the process of reasoning, the role of the two sentences is obviously different, and the sentence pairs for NLI are asymmetrical corpora. In this paper, we propose an **asynchronous deep interaction network (ADIN)** to complete the task. ADIN is a neural network structure stacked with multiple inference sub-layers, and each sub-layer consists of two local inference modules in an asymmetrical manner. Different from previous methods, this model deconstructs the reasoning process and implements the asynchronous and multi-step reasoning. Experiment results show that ADIN achieves competitive performance and outperforms strong baselines on three popular benchmarks: SNLI, MultiNLI, and SciTail.

1 Introduction

Natural language inference (NLI) is a pivotal and fundamental task in natural language understanding and artificial intelligence. The goal of NLI is to predict whether a premise sentence can infer another hypothesis sentence. As illustrated in Table 1, logical relationships between the two sentences include *entailment* (if the premise is true, then the hypothesis must be true), *contradiction* (if the premise is true, then the hypothesis must be false), and *neutral* (neither entailment nor contradiction).

As a core task, conventional approaches have studied various aspects of the inference problem (MacCartney and Manning, 2008; Heilman and Smith, 2010). Thanks to the release of the largest publicly available corpus - the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015), neural network-based models have also been successfully used for this task (Parikh et al., 2016; Chen et al., 2016; Tay et al., 2018; Duan et al., 2018). These methods typically treat the premise sentence and the hypothesis sentence equally, learn an alignment of sub-phrases in both sentences symmetrically and in parallel, and fuse local information for making a global decision at the sentence level. They all frame the inference problem as a semantic matching task and ignore the reasoning process.

Premise: A dog is jumping for a Frisbee in the snow. **Hypothesis:** An animal is playing with a plastic toy. **Label:** Entailment
Premise: He was crying like his mother had just walloped him. **Hypothesis:** He was crying like his mother hit him with a spoon. **Label:** Neutral
Premise: Several men in front of a white building. **Hypothesis:**Several people in front of a gray building. **Label:** contradiction

Table 1: Examples of natural language inference.

However, different from a simple semantic matching task, reasoning should be asynchronous and fully interpretable (Yi et al., 2018). Moreover, the sentence pairs for NLI are asymmetrical corpora, i.e., $I(a, b) \neq I(b, a)$. Considering the first

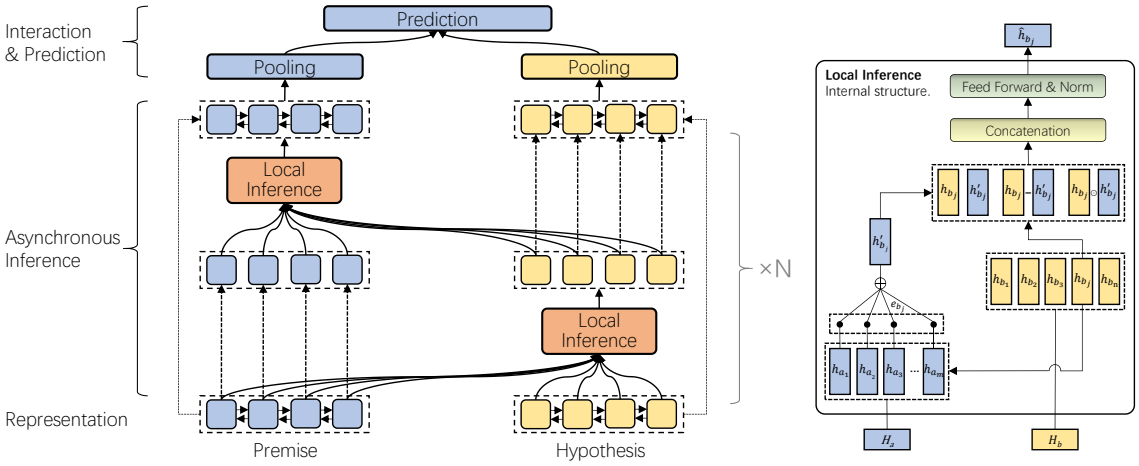

Figure 1: The overall view of our model. The left part is the main framework of this work. The dashed lines refer to the copy operation. The asynchronous inference layer is stacked with N inference sub-layers. In the first sub-layer of the asynchronous inference layer, the input is from the representation layer. Subsequently, the input of sub-layers come from the previous sub-layers. The right part is the detailed structure of the local inference module, taking $\hat{\mathbf{h}}_{b_j}$ as an example.

example in Table 1, the premise sentence can infer the hypothesis sentence, however, the hypothesis sentence can't infer the premise sentence. The inference process intuitively needs to consider the relationship between two sentences in sequential order. According to the actual inference process, we argue that the model should first get the inferential information to model the hypothesis sentence, based on the premise sentence, and then model premise sentence, based on the new representation for hypothesis sentence.

In this paper, we propose an asynchronous deep interaction network (ADIN) to achieve the reasoning. This model is stacked with multiple inference sub-layers to implement the multi-step reasoning, and each sub-layer consists of two local inference modules in an asymmetrical manner to simulate the asynchronous and interpretable reasoning process. In a local inference module, we update the sentence representation by using the local inference information, based on the attention of the other sentence. Lastly, we combine the inference information between the two sentences to make a global decision.

To demonstrate the effectiveness of our model, we evaluate it on three popular benchmarks: SNLI, MultiNLI, and SciTail. The experimental results on these three data sets reveal that our method achieves competitive performance.

The main contributions of this work can be summarized as follows:

- We break the matching architecture that interacts with the information between two sentences for alignment, and propose an asynchronous deep interaction network to achieve the asynchronous and multi-step reasoning.
- We deconstruct the reasoning process between the two sentences, and the process can be analyzed step-by-step.
- The experimental results on three highly competitive benchmark datasets demonstrate that our model can achieve better performance than other strong baselines.

2 Approach

We define the natural language inference as a classification task that predicts the relation $y \in Y$ for a given pair of sentences, where $Y = \{entailment, contradiction, neutral\}$. In this work, we propose an asynchronous deep interaction network (ADIN) to complete this task. The overall architecture of the model is illustrated on the left part of Figure 1.

Our sentence inference architecture, ADIN , is composed of the following three components: (1) *information representation layer* converts the two sentences into semantic representations; (2) *asynchronous inference layer* produces new representations for the two sentences, based on the inference information; and (3) *interaction and prediction layer* determines the overall inference relationship between a premise and hypothesis.

2.1 Local Inference Module

Given two natural sentences a and b, $\mathbf{H}_a = \{\mathbf{h}_{a_i}|\mathbf{h}_{a_i} \in \mathbb{R}^k, i = 1, 2, ..., m\}$ and $\mathbf{H}_b = \{\mathbf{h}_{b_j}|\mathbf{h}_{b_j} \in \mathbb{R}^k, j = 1, 2, ..., n\}$ denote their k-dimensional representations respectively , where m, n denote the length of two sentences. Here, we implement a general reasoning process where the module captures the relevance between the two sentences, then incorporates the inferential information to the new representation for sentence b, based on the sentence a. First, we compute a co-attention matrix $E \in \mathbb{R}^{m \times n}$ to capture the relevance between the two sentences, each element $\mathbf{E}_{i,j} \in R$ indicates the relevance between the i-th word of sentence a and the j-th word of b. Formally, the co-attention matrix could be computed as:

$$\mathbf{E}_{i,j} = \mathbf{P}^T tanh(\mathbf{W}(\mathbf{h}_{a_i} \odot \mathbf{h}_{b_j})), \quad (1)$$

where $\mathbf{W} \in \mathbb{R}^{s \times k}$, $\mathbf{P} \in \mathbb{R}^s$, and $\odot$ denotes the element-wise production operation. Then, we get a-guided attentive vectors for sentence b:

$$\mathbf{e}_{b_j} = softmax(\mathbf{E}_{:,j}), \quad (2)$$

$$\mathbf{h}'_{b_j} = \mathbf{H}_a \cdot \mathbf{e}_{b_j}, \quad (3)$$

In order to enhance the interaction further, we combine the original vector and a-guided attentive vector for sentence b. More formally:

$$\mathbf{h}''_{b_j} = [\mathbf{h}_{b_j}; \mathbf{h}'_{b_j}; \mathbf{h}_{b_j} - \mathbf{h}'_{b_j}; \mathbf{h}_{b_j} \odot \mathbf{h}'_{b_j}], \quad (4)$$

$$\tilde{\mathbf{h}}_{b_j} = ReLU(\mathbf{W}_{b_j}\mathbf{h}''_{b_j} + \mathbf{b}_{b_j}), \quad (5)$$

where $[\cdot;\cdot;\cdot;\cdot]$ refers to the concatenation operation. In Equation 4, we first calculate the difference and the element-wise product for $(\mathbf{h}_{b_j}, \mathbf{h}'_{b_j})$. We get the new representation containing a-guided inferential information for sentence b:

$$\tilde{\mathbf{H}}_b = (\tilde{\mathbf{h}}_{b_1}, \tilde{\mathbf{h}}_{b_2}, ..., \tilde{\mathbf{h}}_{b_n}), \quad (6)$$

$$\hat{\mathbf{H}}_b = LayerNorm(\tilde{\mathbf{H}}_b), \quad (7)$$

Where $LayerNorm(.)$ is layer normalization (Ba et al., 2016). The result $\hat{\mathbf{H}}_b$ is a 2D-tensor that has the same shape as $\mathbf{H}_b$, and we refer to the whole inferential module as:

$$\textbf{InferentialModule}(\mathbf{H}_a, \mathbf{H}_b), \quad (8)$$

As described, the inferential module can capture the relevance between the two sentences, incorporate the inferential information to the new representation for sentence b, based on the sentence a.

2.2 Information Representation Layer

The information representation layer converts each word or phrase in the sentences into a vector representation and constructs the representation matrix for the sentences. We combine the multi-level features as the sentence representation. Each token is represented as a vector by using the pre-trained word embedding such as GloVe (Pennington et al., 2014), word2Vec (Mikolov et al., 2013), and fasttext (Joulin et al., 2016). It can also incorporate more syntactical and lexical information into the feature vector.

For ADIN, we use a concatenation of word embedding, character embedding, and syntactical features as the sentence representation. The word embedding is obtained by mapping token to high dimensional vector space by pre-trained word vector (300D Glove 840B), and the word embedding is updated during training. Character-level embedding could alleviate out-of-vocabulary (OOV) problems and capture helpful morphological information. As in (Kim et al., 2016; Lee et al., 2016), we filter the character embedding with 1D convolution kernel. The character convolutional feature maps are then max pooled over the time dimension for each token to obtain a vector.

As in (Chen et al., 2018), the syntactical features consist of one-hot part-of-speech (POS) tagging feature and binary exact match (EM) feature. For one sentence, the EM value is activated if the same word is found in the other sentence.

Next, ADIN adopts bidirectional Long Short-Term Memory network (Bi-LSTM) (Graves and Schmidhuber, 2005) to model the internal temporal interaction on both directions of the sentences. Consider a premise sentence p and a hypothesis sentence q, we have got their multi-level features representation. Suppose the length of p and q are m and n respectively. These multi-level features representation are then passed to a Bi-LSTM encoder to obtain the context-dependent hidden state matrix, i.e, $\mathbf{H}_p = \{\mathbf{h}_{p_i}|\mathbf{h}_{p_i} \in \mathbb{R}^d, i = 1, 2, ..., m\}$, and $\mathbf{H}_q = \{\mathbf{h}_{q_j}|\mathbf{h}_{q_j} \in \mathbb{R}^d, j = 1, 2, ..., n\}$, where d is the dimension of Bi-LSTM's hidden state.

2.3 Asynchronous Inference Layer

Recently, along with the development of deep learning methods, some neural attention-based models have also been successfully used for NLI (Rocktäschel et al., 2015; Parikh et al., 2016; Duan et al., 2018). However, these methods typically

frame the inference problem as a semantic matching task and ignore the reasoning process, where the premise sentence and the hypothesis sentence are encoded and interacted symmetrically and in parallel.

In this paper, we utilize the local inference module to deconstruct the reasoning process and achieve the asynchronous and multi-step reasoning for NLI. To model the multi-step reasoning habit, this model is stacked with N inference sub-layers to capture step-by-step the logic relationship between the two sentences. In the each inference sub-layer , two inferential modules perform two asynchronous inference processes respectively.

Concretely, in the t-th inference sub-layer, given the representations of two sentences computed in the previous sub-layer : $\mathbf{V}_p^{t-1} = (\mathbf{v}_{p_1}^{t-1}, \mathbf{v}_{p_2}^{t-1}, ..., \mathbf{v}_{p_m}^{t-1})$ and $\mathbf{V}_q^{t-1} = (\mathbf{v}_{q_1}^{t-1}, \mathbf{v}_{q_2}^{t-1}, ..., \mathbf{v}_{q_n}^{t-1})$, we get the deeper-level representations:

$$\hat{\mathbf{V}}_q^t = \textbf{InferentialModule}(\mathbf{V}_p^{t-1}, \mathbf{V}_q^{t-1}), \quad (9)$$

$$\hat{\mathbf{V}}_p^t = \textbf{InferentialModule}(\mathbf{V}_q^t, \mathbf{V}_p^{t-1}), \quad (10)$$

$$\tilde{\mathbf{v}}_{q_i}^t = [\hat{\mathbf{v}}_{q_i}^t; \mathbf{v}_{q_i}^{t-1}], \quad \tilde{\mathbf{v}}_{p_j}^t = [\hat{\mathbf{v}}_{p_j}^t; \mathbf{v}_{p_j}^{t-1}], \quad (11)$$

$$\mathbf{v}_{q_i}^t = \text{Bi-LSTM}(\tilde{\mathbf{v}}_{q_{i-1}}^t, \tilde{\mathbf{v}}_{q_i}^t, \tilde{\mathbf{v}}_{q_{i+1}}^t), \quad (12)$$

$$\mathbf{v}_{p_j}^t = \text{Bi-LSTM}(\tilde{\mathbf{v}}_{p_{j-1}}^t, \tilde{\mathbf{v}}_{p_j}^t, \tilde{\mathbf{v}}_{p_{j+1}}^t), \quad (13)$$

where $\mathbf{V}_p^0 = \mathbf{H}_p$, $\mathbf{V}_q^0 = \mathbf{H}_q$, $\hat{\mathbf{V}}_p^t = (\hat{\mathbf{v}}_{p_1}^t, \hat{\mathbf{v}}_{p_2}^t, ..., \hat{\mathbf{v}}_{p_m}^t)$, and $\hat{\mathbf{V}}_q^t = (\hat{\mathbf{v}}_{q_1}^t, \hat{\mathbf{v}}_{q_2}^t, ..., \hat{\mathbf{v}}_{q_n}^t)$. In an inference sub-layer, we first get the inferential information to update the representation for hypothesis sentence, based on the premise sentence. Next, the model incorporates the inferential information to the premise sentence, based on the new representation for hypothesis sentence.

2.4 Interaction and Prediction Layer

To extract a proper representation for each sentence, we apply a mean pooling and a max pooling on each of them. Formally:

$$\mathbf{V}_p^{mean} = \sum_{i=1}^{m} \frac{\mathbf{v}_{p_i}^N}{m}, \quad \mathbf{V}_p^{max} = \max_{i=1}^{m} \mathbf{v}_{p_i}^N, \quad (14)$$

$$\mathbf{V}_q^{mean} = \sum_{j=1}^{n} \frac{\mathbf{v}_{q_j}^N}{n}, \quad \mathbf{V}_q^{max} = \max_{j=1}^{n} \mathbf{v}_{q_j}^N, \quad (15)$$

$$\mathbf{V}_p^{new} = [\mathbf{V}_p^{mean}; \mathbf{V}_p^{max}], \quad \mathbf{V}_q^{new} = [\mathbf{V}_q^{mean}; \mathbf{V}_q^{max}], \quad (16)$$

	Train	Dev	Test	L(P)	L(H)	Vocab
SNLI	549K	9.8K	9.8K	14	8	36K
MultiNLI[1]	392K	9.8K	9.8K	22	11	85K
MultiNLI[2]		9.8K	9.8K	22	11	85K
SciTail	23.6K	1.3K	2.1K	10	7	-

Table 2: Statistics of datasets: SNLI, MultiNLI, SciTail. L(P) and L(H) refer to the average length of two sentences. MultiNLI[1] and MultiNLI[2] indicate the in-domain and cross-domain datasets.

Then, we aggregate these representations $\mathbf{V}_p^{new}$ and $\mathbf{V}_q^{new}$ for the two sentences p and q in various ways in the interaction layer and the final feature vector $\mathbf{r}$ for the inference is obtained as follows:

$$\mathbf{r} = [\mathbf{V}_p^{new}; \mathbf{V}_q^{new}; \mathbf{V}_p^{new} - \mathbf{V}_q^{new}; \mathbf{V}_p^{new} \odot \mathbf{V}_q^{new}], \quad (17)$$

Finally, based on the aggregated feature $\mathbf{r}$, we use a multi-layer perceptron (MLP) classifier to predict the label:

$$\boldsymbol{v} = ReLU(\mathbf{W}_r \mathbf{r} + \mathbf{b}_r), \quad (18)$$

$$\hat{\boldsymbol{y}} = softmax(\mathbf{W}_v \boldsymbol{v} + \mathbf{b}_v). \quad (19)$$

where $\mathbf{W}_r, \mathbf{b}_r, \mathbf{W}_v$, and $\mathbf{b}_v$ are trainable parameters. The entire model is trained end-to-end, optimizing the standard multi-class cross-entropy loss function.

3 Experiments

In this section, we present the evaluation of our model. We first perform quantitative evaluation, comparing our model with other strong baselines. We then conduct some qualitative analyses to understand how ADIN achieve the asynchronous and multi-step inference between the premise sentence and the hypothesis sentence.

3.1 Dataset

We evaluate our model on three popular benchmarks: the Stanford Natural Language Inference (SNLI), the MultiGenre NLI Corpus (MultiNLI) and SciTail. Detailed statistical information of these datasets is shown in Table 2.

SNLI is a collection of 570k human written sentence pairs based on image captioning, supporting the task of natural language inference (Bowman et al., 2015). The labels are composed of entailment, neutral and contradiction. The data splits are provided in (Bowman et al., 2015).

MultiNLI The corpus (Williams et al., 2017) is a new dataset for NLI, which contains 433k sentences pairs. Similar to SNLI, each pair is labeled with one of the following relationships: entailment, contradiction, or neutral. We compare on two test sets (matched and mismatched) which represent in-domain and out-domain performance. We use the same data split as provided by (Williams et al., 2017).

SciTail We also include the newly released SciTail dataset (Khot et al., 2018) which is a binary entailment classification task constructed from science questions. This is the first entailment set that is created solely from natural sentences that already exist independently "in the wild" rather than sentences authored specifically for the entailment task. We use the same data split as in (Khot et al., 2018).

3.2 Models for Comparing

To analyze the effectiveness of our model, we evaluate some traditional and state-of-the-art methods as baselines as follows on the above three data sets:

- **DecompAtt** (Parikh et al., 2016) is a simple model that decomposes the problem into parallelizable attention computations.
- **ESIM** (Chen et al., 2016) is a previous state-of-the-art model for the natural language inference (NLI) task. It is a sequential model that incorporates the chain LSTM and the tree LSTM to infer local information between two sentences.
- **BiMPM** is proposed in (Wang et al., 2017). The model combines two sentence encoders and employs a multi-perspective matching mechanism in sentence pair modeling tasks.
- **DIIN** (Gong et al., 2017) is a novel class of neural network architectures that is able to achieve high-level understanding of the sentence pair by hierarchically extracting semantic features from the interaction space. The model uses word-by-word dimension-wise alignment tensors to encode the high-order alignment relationship between sentence pairs.
- **DGEM** (Khot et al., 2018) is a entailment model that exploits structure from the hypothesis only. This model shows the value of structured representation on just the hypothesis for NLI.
- **MwAN** (Tan et al., 2018) is a multiway attention network that applies multiple attention functions to model the matching between a pair of sentences.
- **CAFE** (Tay et al., 2018) compares and compresses alignment pairs using factorization layers which leverages the rich history of standard machine learning literature to achieve this task.
- **AF-DMN** (Duan et al., 2018) stacks multiple computational blocks in its matching layer to learn the interaction of the sentence pair better.
- **KIM** (Chen et al., 2018) is neural network-based NLI model that can benefit from external knowledge. The model is capable of leveraging external knowledge in co-attention, local inference collection, and inference composition components.

3.3 Experiment Configurations

Hyper-parameters may influence the performance of a neural network-based model. For all the three datasets, there are 3 inference sub-layers in the asynchronous inference Layer. An Adam (Kingma and Ba, 2014) optimizer with β_1 as 0.9 and β_2 as 0.999 is used to optimize all trainable parameters. The initial learning rate is set to 0.001 and is halved when the accuracy on the dev set decreases. We also apply dropout (Srivastava et al., 2014) on the all MLPs to avoid over-fitting, and the dropout rate is set to 0.2. For preprocessing, we just tokenize the sentences and lowercase the tokens.

For initialization, we initialize the word embeddings with a 300D Glove 840B (Pennington et al., 2014), and the out-of- vocabulary (OOV) words are randomly initialized. All word embeddings are updated during training. Parameters, including neural network parameters and OOV word embeddings, are initialized with a uniform distribution between $[-0.01, 0.01]$. The character embeddings are randomly initialized with 100D. We crop or pad each token to have 16 characters. And the 1D convolution kernel size for character embedding is 5.

Table 4: Comparison with previous models on the MultiNLI dataset.

3.4 Ensemble

The ensemble strategy is an effective method to improve model accuracy. Following (Wang et al., 2017), our ensemble model averages the probability distributions from five individual single ADINs, who have exactly identical architectures but distinguished initializations on parameters.

3.5 Quantitative Results

We use the accuracy to evaluate the performance of ADIN and other models on datasets SNLI, MultiNLI, and SciTail.

Table 3 shows the results of different models on the training and test sets of SNLI. In Table 3, the first category of methods are single models and the second category of methods are ensemble models. We show our model, ADIN, achieves state-of-the-art performance on the competitive leaderboard. In this table, KIM is neural network-based NLI model that can benefit from external knowledge, and other strong baselines encode and interact the both sentences symmetrically and in parallel.

Table 4 reports our results on the MultiNLI dataset. Similar to Table 3, the first category of methods are single models and the second category of methods are ensemble models. On MultiNLI, we compare on two test sets (matched and mismatched) which represent in-domain and out-domain performance. ADIN significantly outperforms ESIM, a strong baseline on the both test sets. An ensemble of ADIN models also achieve competitive result on the MultiNLI dataset.

As illustrated in Table 5, our model outperforms the baselines and achieves an accuracy of 84.6% in the test set of the SciTail dataset. As such, empirical results demonstrate the effectiveness of our proposed ADIN model on the challenging SciTail dataset.

For the results on all three datasets, we conduct the students paired t-test. For SNLI and MultiNLI, the p-value of the significance test between the results of our model and AF-DMN is less than 0.01 and 0.05, respectively. For SciTail, the p-value of the significance test between the results of our model and CAFE is also less than 0.01. These results further prove the effectiveness of our model.

Model	Accuracy
ESIM (Chen et al., 2016)	70.6
DecompAtt (Parikh et al., 2016)	72.3
DGEM (Khot et al., 2018)	77.3

1	88.6	88.4
2	88.9	88.6
3	89.0	88.8

Table 6: Effect of number of asynchronous inference layers on the SNLI.

3.6 Model Analysis

To better understand the performance of ADIN, we analyze the effect of each key component of the proposed model on the SNLI dateset.

Table 6 shows the performance with a different number of asynchronous inference sub-layers. As we can see, with the number of sub-layers increases from 1 to 3, the performance increases both on the development set and the test set. As the level of reasoning deepens, the model captures more inferential information. Because of computational cost, we just set the number of sub-layers as 3 on SNLI and other two datesets.

In Table 7, we show the results of ablation study on our base model. After removing the Bi-LSTM in the asynchronous inference Layer, the model performance decrease by 0.3 percentage points on the test set. Furthermore, we study the effect of two inferential modules in one asynchronous inference sub-layer. Without the first inferential module, that is, without the reasoning process from premise to hypothesis, the model performance sharply decreases by 0.8 percentage points. However, remove the second module and the test accuracy decreases by 0.5 percentage points. (exchanged inference order) indicates that we get the inferential information to first model the premise sentence, and then model hypothesis sentence. The performance of the model is reduced to 88.3% after exchanging inference order between two sentences. The above three experiments reflect that the both modules are not equally important for the inference and the sentence pair for NLI is asymmetrical corpora. In the last comparative experiment, we explore the role of multi-level features. We remove character embedding and syntactical features and just keep word embedding as the representation. The test accuracy is reduced to 88.2%.

Models	Dev	Test
(-Bi-LSTM)	88.7	88.5
(-first inferential module)	88.4	88.0
(-second inferential module)	88.5	88.3
(exchanged inference order)	88.6	88.3
(-char-emb - syntactical fea)	88.5	88.2
ADIN (ours)	89.0	**88.8**

Table 7: Effect of components on the SNLI.

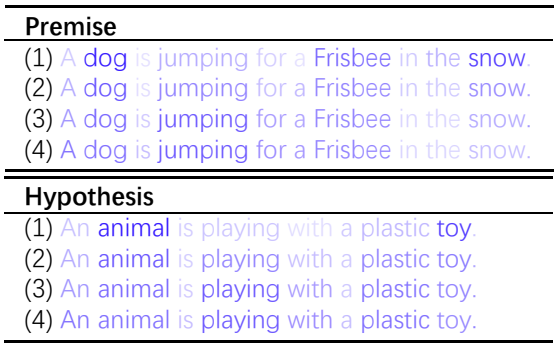

Figure 2: Gradient visualization of premise and hypothesis. (1) Gradient scale of $\mathbf{H}_p, \mathbf{H}_q$ on representation layer. (2) Gradient scale of $\mathbf{V}_p^1, \mathbf{V}_q^1$ on the first asynchronous inference sub-layer. (3) Gradient scale of $\mathbf{V}_p^2, \mathbf{V}_q^2$ on the second asynchronous inference sub-layer. (4) Gradient scale of $\mathbf{V}_p^3, \mathbf{V}_q^3$ on the third asynchronous inference sub-layer. Darker color corresponds to a higher scale of gradient, and implies a higher contribution to the final prediction.

3.7 Case study

To visually demonstrate the validity of the model, we do a qualitative study using the first example in Table 1.

$\mathbf{H}_p, \mathbf{H}_q$ are the hidden states at the representation layer of premise sentence and hypothesis sentence, and $\mathbf{V}_p^t, \mathbf{V}_q^t$ are the hidden states at the t-th asynchronous inference sub-layer. For a hidden state $\mathbf{h}_{p_i}$ of word p_i, we can calculate the gradient scale $\left\| \frac{\partial \mathcal{J}}{\partial \mathbf{h}_{p_i}} \right\|^2$ to show its contribution to the final prediction, where $\mathcal{J}$ is the cross-entropy loss. Figure 2 gives a visualization of the contribution to the final prediction of every word. As we can see, some phrases (like *jumping for a Frisbee* and *play-*

ing with a plastic toy) instead of isolated words (like *Frisbee* and *toy*) become more focused after an asynchronous inference layer. The results imply that ADIN could capture some higher-level patterns. As the level of reasoning deepens, the model captures more inferential information.

4 Related Work

As a long standing problem in NLP research, natural language inference (or textual entailment recognition) has been widely investigated for many years. Conventional works on NLI relies on handcrafted features such as syntactic information, n-gram overlapping and so on (Bowman et al., 2015; Heilman and Smith, 2010).

Benefiting from the development of deep learning and the availability of large-scale annotated datasets (Bowman et al., 2015), neural network-based models have also been successfully used for this task. And two categories of neural network-based models have been developed for this problem. The first set of models is sentence encoding-based and aims to find vector representation for each sentence and classifies the relation by using the concatenation of two vector representation (Bowman et al., 2016; Nangia et al., 2017; Mou et al., 2015). However, this kind of framework ignores the interaction between two sentences.

The other set of models uses the cross-sentence feature or inter-sentence attention from one sentence to another, and is hence referred to as a matching-aggregation framework. Parikh et al. (2016) use attention to decompose the problem into subproblems that can be solved separately, thus making it trivially parallelizable. Chen et al. (2016) propose a state-of-the-art model for the natural language inference (NLI) task. It is a sequential model that incorporates the chain LSTM and the tree LSTM to infer local information between two sentences. A novel class of neural network architectures is proposed in (Gong et al., 2017) that is able to achieve high-level understanding of the sentence pair by hierarchically extracting semantic features from interaction space. Tan et al. (2018) propose a multiway attention network that designs four attention functions to match words in corresponding sentences, aggregates the matching information from each function, and combines the information from all functions to obtain the final representation. Tay et al. (2018) compare and compress alignment pairs using factorization layers which leverages the rich history of standard machine learning literature to achieve this task. AF-DMN (Duan et al., 2018) stacks multiple computational blocks in its matching layer to learn the interaction of the sentence pair better. KIM (Chen et al., 2018) is capable of leveraging external knowledge in co-attention, local inference collection, and inference composition components to improve the performance. These methods all frame the inference problem as a semantic matching task and ignore the reasoning process.

Different from the above methods, ADIN is a neural network structure stacked with multiple asynchronous inference sub-layers, and each sub-layer consists of two local inference modules in an asymmetrical manner. This model deconstructs the reasoning process and implements the asynchronous and multi-step reasoning.

5 Conclusions

In this paper, we propose an asynchronous deep interaction network (ADIN) for natural language inference. To simulate human reasoning process, ADIN is stacked with multiple asynchronous inference sub-layers, and each sub-layer consists of two inferential modules in an asymmetrical manner. The model deconstructs the reasoning process and implements the asynchronous and multi-step reasoning. We evaluate our model on three popular benchmarks: SNLI, MultiNLI, and SciTail. The experiment results show that ADIN achieves competitive performance and outperforms strong baselines.

Abstract

In this paper, we present a novel method for measurably adjusting the semantics of text while preserving its sentiment and fluency, a task we call *semantic text exchange*. This is useful for text data augmentation and the semantic correction of text generated by chatbots and virtual assistants. We introduce a pipeline called *SMERTI* that combines entity replacement, similarity masking, and text infilling. We measure our pipeline's success by its *Semantic Text Exchange Score (STES)*: the ability to preserve the original text's sentiment and fluency while adjusting semantic content. We propose to use *masking (replacement) rate threshold* as an adjustable parameter to control the amount of semantic change in the text. Our experiments demonstrate that SMERTI can outperform baseline models on Yelp reviews, Amazon reviews, and news headlines.

1 Introduction

There has been significant research on style transfer, with the goal of changing the style of text while preserving its semantic content. The alternative where semantics are adjusted while keeping style intact, which we call *semantic text exchange (STE)*, has not been investigated to the best of our knowledge. Consider the following example, where the replacement entity defines the new semantic context:

Original Text: *It is **sunny** outside! Ugh, that means I must **wear sunscreen**. I hate being **sweaty** and **sticky all over.***
Replacement Entity: weather = ***rainy***
Desired Text: *It is **rainy** outside! Ugh, that means I must **bring an umbrella**. I hate being **wet** and **having to carry it around.***

The weather within the original text is sunny, whereas the actual weather may be rainy. Not only is the word *sunny* replaced with *rainy*, but the rest of the text's content is changed while preserving its negative sentiment and fluency.

With the rise of natural language processing (NLP) has come an increased demand for massive amounts of text data. Manually collecting and scraping data requires a significant amount of time and effort, and data augmentation techniques for NLP are limited compared to fields such as computer vision. STE can be used for text data augmentation by producing various modifications of a piece of text that differ in semantic content.

Another use of STE is in building emotionally aligned chatbots and virtual assistants. This is useful for reasons such as marketing, overall enjoyment of interaction, and mental health therapy. However, due to limited data with emotional content in specific semantic contexts, the generated text may contain incorrect semantic content. STE can adjust text semantics (e.g. to align with reality or a specific task) while preserving emotions.

One specific example is the development of virtual assistants with adjustable socio-emotional personalities in the effort to construct assistive technologies for persons with cognitive disabilities. Adjusting the emotional delivery of text in subtle ways can have a strong effect on the adoption of the technologies (Robillard et al., 2018). It is challenging to transfer style this subtly due to lack of datasets on specific topics with consistent emotions. Instead, large datasets of emotionally consistent interactions not confined to specific topics exist. Hence, it is effective to generate text with a particular emotion and then adjust its semantics.

We propose a pipeline called SMERTI (pronounced '*smarty*') for STE.[1] Combining entity replacement (ER), similarity masking (SM), and text

infilling (TI), SMERTI can modify the semantic content of text. We define a metric called the *Semantic Text Exchange Score (STES)* that evaluates the overall ability of a model to perform STE, and an adjustable parameter *masking (replacement) rate threshold (MRT/RRT)* that can be used to control the amount of semantic change.

We evaluate on three datasets: Yelp and Amazon reviews (He and McAuley, 2016), and Kaggle news headlines (Misra, 2018). We implement three baseline models for comparison: Noun WordNet Semantic Text Exchange Model (NWN-STEM), General WordNet Semantic Text Exchange Model (GWN-STEM), and Word2Vec Semantic Text Exchange Model (W2V-STEM).

We illustrate the STE performance of two SMERTI variations on the datasets, demonstrating outperformance of the baselines and pipeline stability. We also run a human evaluation supporting our results. We analyze the results in detail and investigate relationships between the semantic change, fluency, sentiment, and MRT/RRT. Our major contributions can be summarized as:

- We define a new task called *semantic text exchange (STE)* with increasing importance in NLP applications that modifies text semantics while preserving other aspects such as sentiment.
- We propose a pipeline *SMERTI* capable of multi-word entity replacement and text infilling, and demonstrate its outperformance of baselines.
- We define an evaluation metric for overall performance on semantic text exchange called the *Semantic Text Exchange Score (STES)*.

2 Related Work

2.1 Word and Sentence-level Embeddings

Word2Vec (Mikolov et al., 2013a,b) allows for analogy representation through vector arithmetic. We implement a baseline (W2V-STEM) using this technique. The Universal Sentence Encoder (USE) (Cer et al., 2018) encodes sentences and is trained on a variety of web sources and the Stanford Natural Language Inference corpus (Bowman et al., 2015). Flair embeddings (Akbik et al., 2018) are based on architectures such as BERT (Devlin et al., 2019). We use USE for SMERTI as it is designed for transfer learning and shows higher performance on textual similarity tasks compared to other models (Perone et al., 2018).

2.2 Text Infilling

Text infilling is the task of filling in missing parts of sentences called masks. MaskGAN (Fedus et al., 2018) is restricted to a single word per mask token, while SMERTI is capable of variable length infilling for more flexible output. Zhu et al. (2019) uses a transformer-based architecture. They fill in random masks, while SMERTI fills in masks guided by semantic similarity, resulting in more natural infilling and fulfillment of the STE task.

2.3 Style and Sentiment Transfer

Notable works in style/sentiment transfer include (Shen et al., 2017; Fu et al., 2018; Li et al., 2018; Xu et al., 2018). They attempt to learn latent representations of various text aspects such as its context and attributes, or separate style from content and encode them into hidden representations. They then use an RNN decoder to generate a new sentence given a targeted sentiment attribute.

2.4 Review Generation

Hovy (2016) generates fake reviews from scratch using language models. (Lipton et al., 2015; Dong et al., 2017; Juuti et al., 2018) generate reviews from scratch given auxiliary information (e.g. the item category and star rating). Yao et al. (2017) generates reviews using RNNs with two components: generation from scratch and review customization (Algorithm 2 in Yao et al. (2017)). They define review customization as modifying the generated review to fit a new topic or context, such as from a Japanese restaurant to an Italian one. They condition on a keyword identifying the desired context, and replace similar nouns with others using WordNet (Miller, 1995). They require a *"reference dataset"* (required to be *"on topic"*; easy enough for restaurant reviews, but less so for arbitrary conversational agents). As noted by Juuti et al. (2018), the method of Yao et al. (2017) may also replace words independently of context. We implement their review customization algorithm (NWN-STEM) and a modified version (GWN-STEM) as baseline models.

3 SMERTI

3.1 Overview

The task is to transform a corpus C of lines of text S_i and associated replacement entities RE_i : $C = \{(S_1, RE_1), (S_2, RE_2), \ldots, (S_n, RE_n)\}$ to a modified corpus $\hat{C} = \{\hat{S}_1, \hat{S}_2, \ldots, \hat{S}_n\}$, where

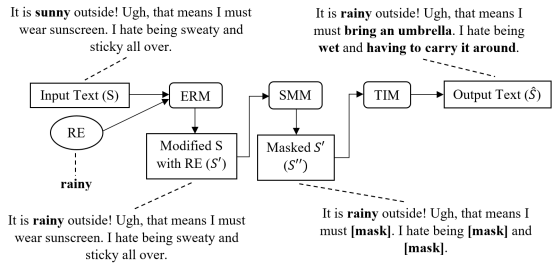

Figure 1: Overall architecture and example, showing the three modules: Entity Replacement (ERM), Similarity Masking (SMM), and Text Infilling (TIM)

$\hat{S}_i$ are the original text lines S_i replaced with RE_i and overall semantics adjusted. SMERTI consists of the following modules, shown in Figure 1:

1. Entity Replacement Module (ERM): Identify which word(s) within the original text are best replaced with the RE, which we call the Original Entity (OE). We replace OE in S with RE. We call this modified text S'.
2. Similarity Masking Module (SMM): Identify words/phrases in S' similar to OE and replace them with a *[mask]*. Group adjacent *[mask]*s into a single one so we can fill a variable length of text into each. We call this masked text S''.
3. Text Infilling Module (TIM): Fill in *[mask]* tokens with text that better suits the RE. This will modify semantics in the rest of the text. This final output text is called $\hat{S}$.

3.2 Entity Replacement Module (ERM)

For entity replacement, we use a combination of the Universal Sentence Encoder (Cer et al., 2018) and Stanford Parser (Chen and Manning, 2014).

Stanford Parser

The Stanford Parser is a constituency parser that determines the grammatical structure of sentences, including phrases and part-of-speech (POS) labelling. By feeding our RE through the parser, we are able to determine its parse-tree. Iterating through the parse-tree and its sub-trees, we can obtain a list of constituent tags for the RE. We then feed our input text S through the parser, and through a similar process, we can obtain a list of leaves (where leaves under a single label are concatenated) that are equal or similar to any of the RE constituent tags. This generates a list of entities having the same (or similar) grammatical structure as the RE, and are likely candidates for the OE. We then feed these entities along with the RE into the Universal Sentence Encoder (USE).

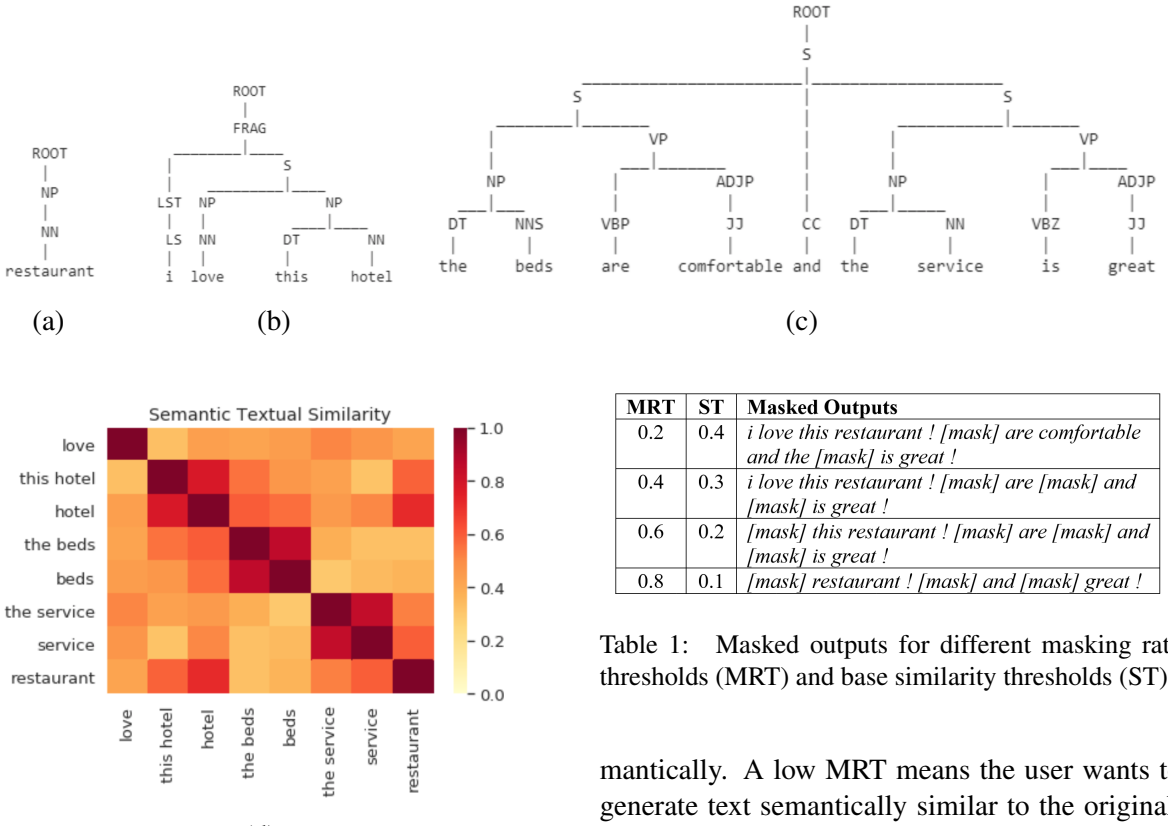
Universal Sentence Encoder (USE)

The USE is a sentence-level embedding model that comes with a deep averaging network (DAN) and transformer model (Cer et al., 2018). We choose the transformer model as these embeddings take context into account, and the exact same word/phrase will have a different embedding depending on its context and surrounding words.

We compute the semantic similarity between two embeddings u and v: $sim(u, v)$, using the angular (cosine) distance, defined as: $\cos(\theta_{u,v}) = (u \cdot v)/(||u||||v||)$, such that $sim(u, v) = 1 - \frac{1}{\pi} arccos(\cos(\theta_{u,v}))$. Results are in $[0, 1]$, with higher values representing greater similarity.

Using USE and the above equation, we can identify words/phrases within the input text S which are most similar to RE. To assist with this, we use the Stanford Parser as described above to obtain a list of candidate entities. In the rare case that this list is empty, we feed in each word of S into USE, and identify which word is the most similar to RE. We then replace the most similar entity or word (OE) with the RE and generate S'.

An example of this entity replacement process is in Figure 2. Two parse-trees are shown: for RE (a) and S (b) and (c). Figure 2(d) is a semantic similarity heat-map generated from the USE embeddings of the candidate OEs and RE, where values are similarity scores in the range $[0, 1]$.



As seen in Figure 2(d), we calculate semantic similarities between RE and entities within S which have *noun* constituency tags. Looking at the row for our RE *restaurant*, the most similar entity (excluding itself) is *hotel*. We can then generate:

S' = i love this restaurant ! the beds are comfortable and the service is great !

3.3 Similarity Masking Module (SMM)

Next, we mask words similar to OE to generate S'' using USE. We look at semantic similarities between every word in S and OE, along with semantic similarities between OE and the candidate entities determined in the previous ERM step to broaden the range of phrases our module can mask. We ignore RE, OE, and any entities or phrases containing OE (for example, *'this hotel'*).

After determining words similar to the OE (discussed below), we replace each of them with a

(a) (b) (c)

(d)

Figure 2: ERM example with S = *i love this hotel ! the beds are comfortable and the service is great !* and RE = *restaurant* showing (a) Parse tree for RE; (b) and (c) Parse tree for S; (d) Semantic similarity heat map

[mask] token. Next, we replace *[mask]* tokens adjacent to each other with a single *[mask]*.

We set a base similarity threshold (ST) that selects a subset of words to mask. We compare the actual fraction of masked words to the masking rate threshold (MRT), as defined by the user, and increase ST in intervals of 0.05 until the actual masking rate falls below the MRT.[2] Some sample masked outputs (S'') using various MRT-ST combinations for the previous example are shown in Table 1 (more examples in Appendix A).

The MRT is similar to the temperature parameter used to control the "novelty" of generated text in works such as Yao et al. (2017). A high MRT means the user wants to generate text very semantically dissimilar to the original, and may be desired in cases such as creating a lively chatbot or correcting text that is heavily incorrect semantically. A low MRT means the user wants to generate text semantically similar to the original, and may be desired in cases such as text recovery, grammar correction, or correcting a minor semantic error in text. By varying the MRT, various pieces of text that differ semantically in subtle ways can be generated, assisting greatly with text data augmentation. The MRT also affects sentiment and fluency, as we show in Section 6.5.

[2]There are certain cases where two or more outputs for different MRT may be equal. This occurs when a valid ST cannot be found that masks a larger portion of the sentence without going over MRT.

MRT	ST	Masked Outputs
0.2	0.4	*i love this restaurant ! [mask] are comfortable and the [mask] is great !*
0.4	0.3	*i love this restaurant ! [mask] are [mask] and [mask] is great !*
0.6	0.2	*[mask] this restaurant ! [mask] are [mask] and [mask] is great !*
0.8	0.1	*[mask] restaurant ! [mask] and [mask] great !*

Table 1: Masked outputs for different masking rate thresholds (MRT) and base similarity thresholds (ST)

3.4 Text Infilling Module (TIM)

We use two seq2seq models for our TIM: an RNN (recurrent neural network) model (Sutskever et al., 2014) (called SMERTI-RNN), and a transformer model (called SMERTI-Transformer).

Bidirectional RNN with Attention

We use a bidirectional variant of the GRU (Cho et al., 2014), and hence two RNNs for the encoder: one reads the input sequence in standard sequential order, and the other is fed this sequence in reverse. The outputs are summed at each time step, giving us the ability to encode information from both past and future context.

The decoder generates the output in a sequential token-by-token manner. To combat information loss, we implement the attention mechanism (Bahdanau et al., 2015). We use a Luong attention layer (Luong et al., 2015) which uses global attention, where all the encoder's hidden states are considered, and use the decoder's current time-step

hidden state to calculate attention weights. We use the dot score function for attention, where h_t is the current target decoder state and $\bar{h}_s$ is all encoder states: $score(h_t, \bar{h}_s) = h_t^T \bar{h}_s$.

Transformer

Our second model makes use of the transformer architecture, and our implementation replicates Vaswani et al. (2017). We use an encoder-decoder structure with a multi-head self-attention token decoder to condition on information from both past and future context. It maps a query and set of key-value pairs to an output. The queries and keys are of dimension d_k, and values of dimension d_v. To compute the attention, we pack a set of queries, keys, and values into matrices Q, K, and V, respectively. The matrix of outputs is computed as:

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (1)$$

Multi-head attention allows the model to jointly attend to information from different positions. The decoder can make use of both local and global semantic information while filling in each *[mask]*.

4 Experiment

4.1 Datasets

We train our two TIMs on the three datasets. The Amazon dataset (He and McAuley, 2016) contains over 83 million user reviews on products, with duplicate reviews removed. The Yelp dataset includes over six million user reviews on businesses. The news headlines dataset from Kaggle contains approximately $200,000$ news headlines from 2012 to 2018 obtained from HuffPost (Misra, 2018).

We filter the text to obtain reviews and headlines which are English, do not contain hyperlinks and other obvious noise, and are less than 20 words long. We found that many longer than twenty words ramble on and are too verbose for our purposes. Rather than filtering by individual sentences we keep each text in its entirety so SMERTI can learn to generate multiple sentences at once. We preprocess the text by lowercasing and removing rare/duplicate punctuation and space.

For Amazon and Yelp, we treat reviews greater than three stars as containing positive sentiment, equal to three stars as neutral, and less than three stars as negative. For each training and testing set, we include an equal number of randomly selected positive and negative reviews, and half as many neutral reviews. This is because neutral reviews only occupy one out of five stars compared to positive and negative which occupy two each. Our dataset statistics can be found in Appendix B.

4.2 Experiment Details

To set up our training and testing data for text infilling, we mask the text. We use a tiered masking approach: for each dataset, we randomly mask 15% of the words in one-third of the lines, 30% of the words in another one-third, and 45% in the remaining one-third. These masked texts serve as the inputs, while the original texts serve as the ground-truth. This allows our TIM models to learn relationships between masked words and relationships between masked and unmasked words.

The bidirectional RNN decoder fills in blanks one by one, with the objective of minimizing the cross entropy loss between its output and the ground-truth. We use a hidden size of 500, two layers for the encoder and decoder, teacher-forcing ratio of 1.0, learning rate of 0.0001, dropout of 0.1, batch size of 64, and train for up to 40 epochs.

For the transformer, we use scaled dot-product attention and the same hyperparameters as Vaswani et al. (2017). We use the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.98$, and $\epsilon = 10^{-9}$. As in Vaswani et al. (2017), we increase the $learning_rate$ linearly for the first $warmup_steps$ training steps, and then decrease the $learning_rate$ proportionally to the inverse square root of the step number. We set $factor = 1$ and use $warmup_steps = 2000$. We use a batch size of 4096, and we train for up to 40 epochs.

4.3 Baseline Models

We implement three models to benchmark against.[3] First is NWN-STEM (Algorithm 2 from Yao et al. (2017)). We use the training sets as the "reference review sets" to extract similar nouns to the RE (using MIN_{sim} = 0.1). We then replace nouns in the text similar to the RE with nouns extracted from the associated reference review set.

Secondly, we modify NWN-STEM to work for verbs and adjectives[4], and call this GWN-STEM. From the reference review sets, we extract similar nouns, verbs, and adjectives to the RE (using

[3] See Appendix C for more implementation details

[4] WordNet can only work for single words (and not phrases). Also, it turns out that it cannot work for most adjective REs, as discussed in Appendix C

MIN$_{sim}$ = 0.1), where the RE is now not restricted to being a noun. We replace nouns, verbs, and adjectives in the text similar to the RE with those extracted from the associated reference review set.

Lastly, we implement W2V-STEM using Gensim (Řehůřek and Sojka, 2010). We train uni-gram Word2Vec models for single word REs, and four-gram models for phrases. Models are trained on the training sets. We use cosine similarity to determine the most similar word/phrase in the input text to RE, which is the replaced OE. For all other words/phrases, we calculate $w_i' = w_i - w_{OE} + w_{RE}$, where w_i is the original word/phrase's embedding vector, w_{OE} is the OE's, w_{RE} is the RE's, and w_i' is the resulting embedding vector. The replacement word/phrase is w_i''s nearest neighbour. We use similarity thresholds to adjust replacement rates (RR) and produce text under various replacement rate thresholds (RRT).

5 Evaluation

5.1 Evaluation Setup

We manually select 10 nouns, 10 verbs, 10 adjectives, and 5 phrases from the top 10% most frequent words/phrases in each test set as our evaluation REs. We filter the verbs and adjectives through a list of sentiment words (Hu and Liu, 2004) to ensure we do not choose REs that would obviously significantly alter the text's sentiment.[5]

For each evaluation RE, we choose one-hundred lines from the corresponding test set that does not already contain RE. We choose lines with at least five words, as many with less carry little semantic meaning (e.g. *'Great!', 'It is okay'*). For Amazon and Yelp, we choose 50 positive and 50 negative lines per RE.[6] We repeat this process three times, resulting in three sets of 1000 lines per dataset per POS (excluding phrases), and three sets of 500 lines per dataset for phrases. Our final results are averaged metrics over these three sets.

For SMERTI-Transformer, SMERTI-RNN, and W2V-STEM, we generate four outputs per text for MRT/RRT of 20%, 40%, 60%, and 80%, which represent upper-bounds on the percentage of the input that can be masked and/or replaced. Note that NWN-STEM and GWN-STEM can only evaluate on limited POS and their maximum replacement rates are limited.[7] We select *MIN$_{sim}$* values of 0.075 and 0 for nouns and 0.1 and 0 for verbs, as these result in replacement rates approximately equal to the actual MR/RR of the other models' outputs for 20% and 40% MRT/RRT, respectively.

5.2 Key Evaluation Metrics

Fluency (SLOR) We use syntactic log-odds ratio (SLOR) (Kann et al., 2018) for sentence level fluency and modify from their word-level formula to character-level ($SLOR_c$). We use Flair perplexity values from a language model trained on the One Billion Words corpus (Chelba et al., 2013):

$$SLOR_c(S) = \frac{1}{|S|}(ln(p_M(S)) - \frac{ln(\prod_{w \in S} p_M(w))}{\sum_{w \in S} |w|} \quad (2)$$

$$= -ln(PPL_s) + \frac{\sum_{w \in S} |w| ln(PPL_W)}{\sum_{w \in S} |w|} \quad (3)$$

where $|S|$ and $|w|$ are the character lengths of the input text S and the word w, respectively, $p_M(S)$ and $p_M(w)$ are the probabilities of S and w under the language model M, respectively, and PPL_S and PPL_w are the character-level perplexities of S and w, respectively. SLOR (from hereon we refer to character-level SLOR as simply SLOR) measures aspects of text fluency such as grammaticality. Higher values represent higher fluency.

We rescale resulting SLOR values to the interval [0,1] by first fitting and normalizing a Gaussian distribution. We then truncate normalized data points outside [-3,3], which shifts approximately 0.69% of total data. Finally, we divide each data point by six and add 0.5 to each result.

Sentiment Preservation Accuracy (SPA) is defined as the percentage of outputs that carry the same sentiment as the input. We use VADER (Hutto and Gilbert, 2014) to evaluate sentiment as positive, negative, or neutral. It handles typos, emojis, and other aspects of online text.

Content Similarity Score (CSS) ranges from 0 to 1 and indicates the semantic similarity between generated text and the RE. A value closer to 1 indicates stronger semantic exchange, as the output is closer in semantic content to the RE. We also use the USE for this due to its design and strong performance as previously mentioned.

5.3 Semantic Text Exchange Score (STES)

We come up with a single score to evaluate overall performance of a model on STE that combines

[5] A list of the chosen REs along with more detailed explanation of how they were selected is in Appendix D

[6] We don't test on neutral reviews as evaluation of accuracy in sentiment is less well defined (i.e. most "neutral" reviews actually carry more positive or negative sentiment)

[7] See Appendix C for explanations

Model	SPA	SLOR	CSS	STES
Input	---	0.5962	0.1166	---
SMERTI-Transformer	0.6606	**0.5255 (-11.86%)**	0.2857 (+145.03%)	0.4337
SMERTI-RNN	0.6574	0.5122 (-14.09%)	**0.2927 (+151.03%)**	**0.4354**
W2V-STEM	0.6667	0.4672 (-21.64%)	0.2851 (+144.51%)	0.4197

Table 2: Overall average results by model (with % changes from the input)

the key evaluation metrics. It uses the harmonic mean, similar to the F_1 score (or F-score) (Chinchor, 1992; Rijsbergen, 1979), and we call it the *Semantic Text Exchange Score (STES)*:

$$STES = \frac{3 * A * B * C}{A * B + A * C + B * C} \quad (4)$$

where A is SPA, B is SLOR, and C is CSS. STES ranges between 0 and 1, with scores closer to 1 representing higher overall performance. Like the F_1 score, STES penalizes models which perform very poorly in one or more metrics, and favors balanced models achieving strong results in all three.

5.4 Automatic Evaluation Results

Table 2 shows overall average results by model.[8] Table 3 shows outputs for a Yelp example.[9]

As observed from Table 3 (see also Appendix F), SMERTI is able to generate high quality output text similar to the RE while flowing better than other models' outputs. It can replace entire phrases and sentences due to its variable length infilling. Note that for nouns, the outputs from GWN-STEM and NWN-STEM are equivalent.[10]

5.5 Human Evaluation Setup

We conduct a human evaluation with eight participants, 6 males and 2 females, that are affiliated project researchers aged 20-39 at the University of Waterloo.[11] We randomly choose one evaluation line for a randomly selected word or phrase for each POS per dataset. The input text and each model's output (for 40% MRT/RRT - chosen as a good middle ground) for each line is presented to participants, resulting in a total of 54 pieces of text, and rated on the following criteria from 1-5:

- *RE Match*: *"How related is the entire text to the concept of [X]", where [X] is a word or phrase (1 - not at all related, 3 - somewhat related, 5 - very related)*. Note here that [X] is a given RE.
- *Fluency*: *"Does the text make sense and flow well?" (1 - not at all, 3 - somewhat, 5 - very)*
- *Sentiment*: *"How do you think the author of the text was feeling?" (1 - very negative, 3 - neutral, 5 - very positive)*

Each participant evaluates every piece of text. They are presented with a single piece of text at a time, with the order of models, POS, and datasets completely randomized.

5.6 Human Evaluation Results

Average human evaluation scores are displayed in Table 4. *Sentiment Preservation* (between 0 and 1) is calculated by comparing the average *Sentiment* rating for each model's output text to the *Sentiment* rating of the input text, and if both are less than 2.5 (negative), between 2.5 and 3.5 inclusive (neutral), or greater than 3.5 (positive), this is counted as a valid case of *Sentiment Preservation*. We repeat this for every evaluation line to calculate the final values per model. Harmonic means of all three metrics (using rescaled 0-1 values of *RE Match* and *Fluency*) are also displayed.

6 Analysis

6.1 Performance by Model

As seen in Table 2, both SMERTI variations achieve higher STES and outperform the other models overall, with the WordNet models performing the worst. SMERTI excels especially on fluency and content similarity. The transformer variation achieves slightly higher SLOR, while the RNN variation achieves slightly higher CSS.

The WordNet models perform strongest in sentiment preservation (SPA), likely because they modify little of the text and only verbs and nouns. They achieve by far the lowest CSS, likely in part due to this limited text replacement. They also do not account for context, and many words (e.g. proper nouns) do not exist in WordNet. Overall, the WordNet models are not very effective at STE.

W2V-STEM achieves the lowest SLOR, especially for higher RRT, as supported by the example in Table 3 (see also Appendix F). W2V-STEM and WordNet models output grammatically incorrect text that flows poorly. In many cases, words are

Table 5: Average TTR values by model

repeated multiple times. We analyze the average Type Token Ratio (TTR) values of each model's outputs, which is the ratio of unique divided by total words. As shown in Table 5, the SMERTI variations achieve the highest TTR, while W2V-STEM and NWN-STEM the lowest.

Note that while W2V-STEM achieves lower CSS than SMERTI, it performs comparably in this aspect. This is likely due to its vector arithmetic operations algorithm, which replaces each word with one more similar to the RE. This is also supported by the lower TTR, as W2V-STEM frequently outputs the same words multiple times.

6.2 Performance By Model - Human Results

As seen in Table 4, the SMERTI variations outperform all baseline models overall, particularly in *RE Match*. SMERTI-Transformer performs the best, with SMERTI-RNN second. The WordNet models achieve high *Sentiment Preservation*, but much lower on *RE Match*. W2V-STEM achieves comparably high *RE Match*, but lowest *Fluency*.

These results correspond well with our automatic evaluation results in Table 2. We look at the Pearson correlation values between *RE Match*, *Fluency*, and *Sentiment Preservation* with CSS, SLOR, and SPA, respectively. These are 0.9952, 0.9327, and 0.8768, respectively, demonstrating that our automatic metrics are highly effective and correspond well with human ratings.

POS	Nouns	Verbs	Adjectives	Phrases
Input SLOR	0.5971	0.5960	0.5977	0.5939
Input CSS	0.1175	0.1287	0.0935	0.1267

SMERTI STES	0.4464	0.4073	0.3876	0.4895

Table 6: Input text's avg. SLOR, CSS, and SMERTI's avg. SPA, SLOR, CSS, and STES by POS

6.3 SMERTI's Performance By POS

As seen from Table 6[12] , SMERTI's SPA values are highest for nouns, likely because they typically carry little sentiment, and lowest for adjectives, likely because they typically carry the most.

SLOR is lowest for adjectives and highest for phrases and nouns. Adjectives typically carry less semantic meaning and SMERTI likely has more trouble figuring out how best to infill the text. In contrast, nouns typically carry more, and phrases the most (since they consist of multiple words).

SMERTI's CSS is highest for phrases then nouns, likely due to phrases and nouns carrying

[12]Note that the SMERTI values in Tables 6 to 8 refer to the average between SMERTI-Transformer and SMERTI-RNN

Dataset	Amazon	Yelp	News Headlines
Input SLOR	0.6230	0.5532	0.6123
Input CSS	0.1113	0.1429	0.0955
SMERTI SPA	0.6738	0.7238	0.5793
SMERTI SLOR	0.5406	0.4765	0.5394
SMERTI CSS	0.2778	0.2835	0.3062
SMERTI STES	0.4326	0.4281	0.4381

Table 7: Input text's avg. SLOR, CSS, and SMERTI's avg. SPA, SLOR, CSS, and STES by dataset

MRT / RRT	20%	40%	60%	80%
SMERTI SPA	0.7994	0.7124	0.6202	0.5040
SMERTI SLOR	0.5489	0.5375	0.5197	0.4694
SMERTI CSS	0.2461	0.2557	0.2828	0.3722
SMERTI STES	0.4204	0.4181	0.4240	0.4410
SMERTI BLEU	0.5490	0.3527	0.1752	0.0448

Table 8: SMERTI's avg. SPA, SLOR, CSS, STES, and BLEU by MRT/RRT

more semantic meaning, making it easier to generate semantically similar text. Both SMERTI's and the input text's CSS are lowest for adjectives, likely because they carry little semantic meaning.

Overall, SMERTI appears to be more effective on nouns and phrases than verbs and adjectives.

6.4 SMERTI's Performance By Dataset

As seen in Table 7, SMERTI's SPA is lowest for news headlines. Amazon and Yelp reviews naturally carry stronger sentiment, likely making it easier to generate text with similar sentiment.

Both SMERTI's and the input text's SLOR appear to be lower for Yelp reviews. This may be due to many reasons, such as more typos and emojis within the original reviews, and so forth.

SMERTI's CSS values are slightly higher for news headlines. This may be due to them typically being shorter and carrying more semantic meaning as they are designed to be attention grabbers.

Overall, it seems that using datasets which inherently carry more sentiment will lead to better sentiment preservation. Further, the quality of the dataset's original text, unsurprisingly, influences the ability of SMERTI to generate fluent text.

6.5 SMERTI's Performance By MRT/RRT

From Table 8, it can be seen that as MRT/RRT increases, SMERTI's SPA and SLOR decrease while CSS increases. These relationships are very strong as supported by the Pearson correlation values of -0.9972, -0.9183, and 0.9078, respectively. When SMERTI can alter more text, it has the opportunity to replace more related to sentiment while producing more of semantic similarity to the RE.

Further, SMERTI generates more of the text itself, becoming less similar to the human-written input, resulting in lower fluency. To further demonstrate this, we look at average SMERTI BLEU (Papineni et al., 2002) scores against MRT/RRT, shown in Table 8. BLEU generally indicates how close two pieces of text are in content and structure, with higher values indicating greater similarity. We report our final BLEU scores as the average scores of 1 to 4-grams. As expected, BLEU decreases as MRT/RRT increases, and this relationship is very strong as supported by the Pearson correlation value of -0.9960.

It is clear that MRT/RRT represents a trade-off between CSS against SPA and SLOR. It is thus an adjustable parameter that can be used to control the generated text, and balance semantic exchange against fluency and sentiment preservation.

7 Conclusion and Future Work

We introduced the task of semantic text exchange (STE), demonstrated that our pipeline SMERTI performs well on STE, and proposed an STES metric for evaluating overall STE performance. SMERTI outperformed other models and was the most balanced overall. We also showed a trade-off between semantic exchange against fluency and sentiment preservation, which can be controlled by the masking (replacement) rate threshold.

Potential directions for future work include adding specific methods to control sentiment, and fine-tuning SMERTI for preservation of persona or personality. Experimenting with other text infilling models (e.g. fine-tuning BERT (Devlin et al., 2019)) is also an area of exploration. Lastly, our human evaluation is limited in size and a larger and more diverse participant pool is needed.

We conclude by addressing potential ethical misuses of STE, including assisting in the generation of spam and fake-reviews/news. These risks come with any intelligent chatbot work, but we feel that the benefits, including usage in the detection of misuse such as fake-news, greatly outweigh the risks and help progress NLP and AI research.

Query-Focused Scenario Construction

Abstract

The news coverage of events often contains not one but multiple incompatible accounts of what happened. We develop a query-based system that extracts compatible sets of events (scenarios) from such data, formulated as one-class clustering. Our system incrementally evaluates each event's compatibility with already selected events, taking order into account. We use synthetic data consisting of article mixtures for scalable training and evaluate our model on a new human-curated dataset of scenarios about real-world news topics. Stronger neural network models and harder synthetic training settings are both important to achieve high performance, and our final scenario construction system substantially outperforms baselines based on prior work.

1 Introduction

While a situation is developing, news reports often contain multiple contradictory stories (scenarios) of what happened, and it is hard to piece together the individual scenarios. For example, surrounding the disappearance of the Saudi journalist Jamal Khashoggi, there were initially multiple conflicting accounts of what happened. One states that he was the victim of a murder scheme; an alternative suggests that he walked out of the consulate alive. The task of identifying these individual scenarios is also being considered in the Active Interpretation of Disparate Alternatives (AIDA) program,[1] and in a recent Text Analysis Conference (TAC).[2]

We frame the task as query-based scenario discovery: given a *topic* (e.g., the disappearance of Jamal Khashoggi) and a *query* (e.g. *Jamal Khashoggi was murdered*), we want to retrieve a *scenario*, a set of compatible events, from the given reports. We formulate query-based scenario discovery as one-class clustering (Bekkerman and Crammer, 2008). We specifically focus on discovering a scenario of *compatible events* (Barzilay and Lapata, 2008; Chambers and Jurafsky, 2008, 2009; Mostafazadeh et al., 2017) in a collection of related and unrelated event-denoting sentences, which may contain conflicting and irrelevant information. We start with a query (see Figure 1) and then iteratively insert sentences into the "scenario-in-construction". Sentences are chosen based on overall compatibility as well as the ease with which scenario sentences can be arranged into an order. We additionally use an adapted relation network (Santoro et al., 2017) to assess connections between words.

Query: Jamal Khashoggi was murdered.

Jamal Khashoggi entered the consulate of Saudi Arabia consulate in Istambul. He exited the Saudi consulate after a few minutes. The team wanted to arrest Khashoggi but botched it. He never exited the Saudi consulate but died there. Khashoggi, according to the reporter, was seen on a flight leaving Turkey for Estonia. A team flew from Saudi Arabia to Turkey prior to Khashoggi's appointment at the consulate specifically to intercept him. The team was sent by the Saudi crown prince with the order to murder Khashoggi. Jamal A. Khashoggi works for The Washington Post, and is the editor-in-chief of Al-Arab News.

Figure 1: An example for query-based scenario construction. Given the **query**, we want to select event-denoting sentences from a document mixture to build a target scenario with a sequence of compatible events. The mixture also contains sentences which may be irrelevant or part of an alternative scenario.

For our evaluation, we collect a human-curated set of competing scenarios for real-world news topics. As collecting such data is costly, we follow past work in training our model on synthetic data consisting of document mixtures (Wang et al., 2018) and compare our models directly to theirs. We show that training on such synthetic data yields a model that can substantially outper-

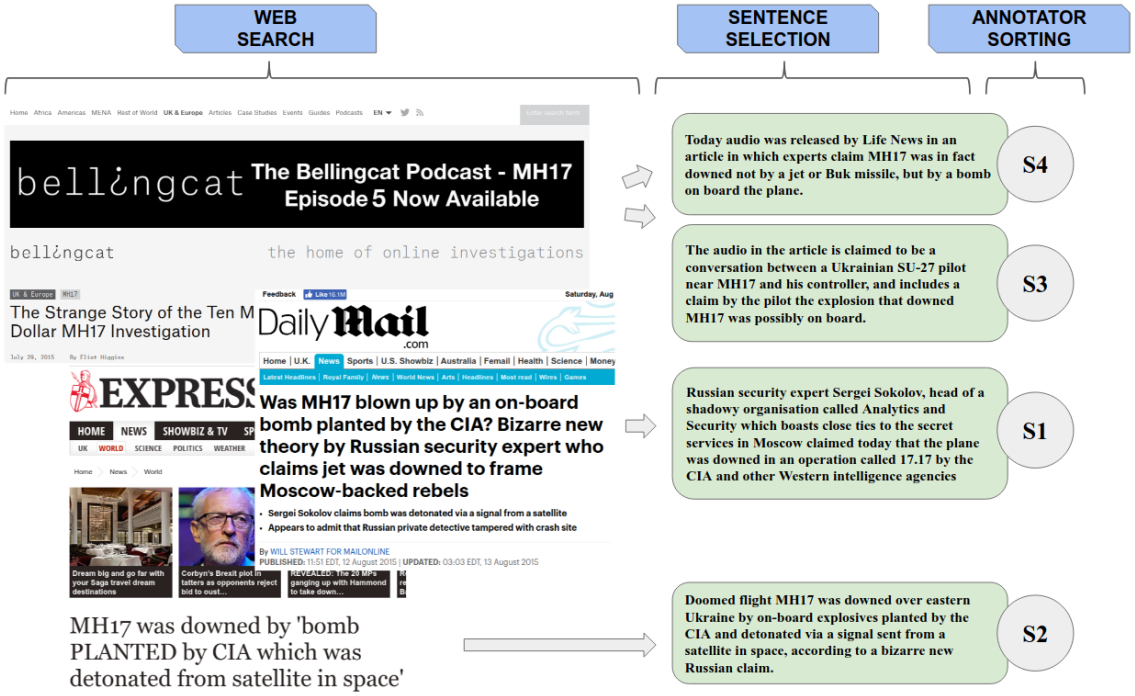

Figure 2: Phase 2 (cf. Table 1) of generating human evaluation data Human100: given the topic *Why did MH-17 crash?* and the scenario *MH-17 had a bomb on board*. The annotator searches the web and finds the webpages above. From these pages, she first selects 4 sentences which are relevant, then sorts them so that they make a consistent scenario that could be read from start to finish.

form lexical baselines and the strong neural model proposed in Wang et al.'s seminal work.

Our contribution is three-fold: (1) A query-based scenario construction task, for which we introduce a model to iteratively build a scenario with compatible events, exploiting ordering. (2) A human-curated evaluation set consisting of multiple accounts of real-world new events, along with a collection of scalably-built synthetic simulation datasets, which we show serve as an effective source of training data. (3) Comprehensive experiments and analysis that cast light on the properties of the task and data, as well as on the challenges.

2 Background

Our work traces its roots to research in *script* (Schank and Abelson, 1977; Mooney and DeJong, 1985) and *narrative schema* learning (Chambers and Jurafsky, 2008; Pichotta and Mooney, 2016). Early work explored tasks such as script modeling (Mooney and DeJong, 1985). Recent work built on the idea that compatibility of events can be learned from corpus data, evaluated on narrative cloze (Chambers and Jurafsky, 2009) and predicting-next-events (Pichotta and Mooney, 2016; Mostafazadeh et al., 2017).

We introduce a task with a more practical objective in mind: given a query or an information cue, extract the rest of the pieces to build a compatible scenario. The task is related to conversation disentanglement of multiple entangled conversations in a dialogue transcript (Elsner and Charniak, 2008, 2011; Jiang et al., 2018; Kummerfeld et al., 2019), and more closely to narrative clustering (Wang et al., 2018), i.e. identifying all the scenarios in an information source by grouping relevant sentences/events. Unlike Wang et al. (2018), we do not attempt to identify all the scenarios in the source, but are guided by one particular user's information need (e.g. the scenario about Khashoggi's murder, as opposed to all the theories regarding his disappearance, like in Wang et al. (2018)). Further, we do not assume the number of scenarios is known a priori (as Wang et al. (2018) do).

We phrase query-based scenario construction as one-class clustering. One-class models assume the availability of data for only one (positive) class, rather than positive and negative data. In particular, one-class clustering assumes that the data consists of few positive cases among a large group of outliers (Bekkerman and Crammer, 2008; Banu

Topic question: ***Why did MH-17 crash?***
scenario 1. ***MH-17 had a bomb on board***
(1) Doomed flight MH17 was downed over eastern Ukraine by on-board explosives planted by the CIA and detonated via a signal sent from a satellite in space, according to a bizarre new Russian claim. (2) Russian security expert Sergei Sokolov head of a shadowy organisation called Analytics and Security which boasts close ties to the secret services in Moscow claimed today that the plane was downed in an operation called 17.17 by the CIA and other Western intelligence agencies. (3) Today audio was released by Life News in an article in which experts claim MH17 was in fact downed not by a jet or Buk missile, but by a bomb on board the plane. (4) The audio in the article is claimed to be a conversation between a Ukrainian SU-27 pilot near MH17 and his controller, and includes a claim by the pilot the explosion that downed MH17 was possibly on board.
scenario 2. ***MH-17 was shot down by missiles.***
(1) The shoot-down occurred in the War in Donbass, during the Battle of Shakhtarsk, in an area controlled by pro-Russian rebels. (2) The responsibility for investigation was delegated to the Dutch Safety Board (DSB) and the Dutch-led joint investigation team (JIT), who concluded that the airliner was downed by a Buk surface-to-air missile launched from pro-Russian separatist-controlled territory in Ukraine. (3) According to the JIT, the Buk that was used originated from the 53rd Anti-Aircraft Missile Brigade of the Russian Federation, and had been transported from Russia on the day of the crash, fired from a field in a rebel-controlled area, and the launcher returned to Russia after it was used to shoot down MH17. (4) Previously, the investigative website Bellingcat has pointed to involvement of the same brigade using open-source information.

Table 1: An example from the crowdsourced Human100 dataset. Phase 1 (in bold): an MTurk worker writes (by web searching and editing) a topic question and two scenarios that answers the question. Phase 2: an annotator elaborates on the two scenarios (also through search-and-edit) with a compatible scenario.

and Karthikeyan, 2014). Finally, our task is superficially similar to query-based summarization (Otterbacher et al., 2005; Baumel et al., 2018) but has a different goal: we want to distinguish potentially conflicting narrative scenarios rather than conduct single-topic information compression. We also distinguish our work from multi-document summarization (McKeown et al., 2002; Radev et al., 2005), as we are explicitly drawing distinctions among conflictive scenarios rather than summarizing the entire (single) topic.

3 Data

This section first introduces our human-curated, realistic evaluation data for our objective. Then we describe how we synthesized various types of training data for our model.

3.1 Human-curated Data

Realistic data on this task is hard to obtain, as after a time, a single scenario tends to dominate in the news. The Linguistics Data Consortium (LDC) has data for the AIDA project, and the 2018 Text Analysis Conference (TAC) had a hypothesis generation task, but both use a single topic only (the Russia-Ukraine conflict of 2014), with no hypotheses available (TAC) or no hypotheses at sentence level (LDC). As a step in the direction of realistic data for the task, we had human annotators collect news items that have multiple scenarios of what happened around the same topic (Table 1).

We collected data in two phases: in phase 1, we asked workers on Amazon Mechanical Turk (MTurk) to provide (1) a topic in the form of an English wh-question; (2) two scenarios that answer the topic question mutually exclusively. See the bold text in Table 1 for an example. In phase 2 (Figure 2), a group of non-Turk annotators[3] pieced together English sentences from the web to elaborate on the scenarios from phase 1 (Table 1, non-bold). Annotators were instructed to build scenarios which can be read fluently. Sentences that could be copy-and-pasted directly from web search results were prioritized. When such sentences were unattainable, annotators were allowed to edit the style of the text to fit the scenario in the tone of a news report. We allowed this relaxation because, as mentioned above, often one scenario is dominant in web search results. For instance, in the Jamal Khashoggi story, English media almost unanimously report that he was a victim of murder, whereas the alternative scenario – he "disappeared and is still alive" is harder to find. A set of 100 mixtures were collected this way. We refer to the dataset as **Human100** (stats in Table 2).[4]

Wang et al. (2018) gauge the difficulty of a mixture by measuring the *topic similarity* between the target and the distractor(s) using the cosine distance between the average word embeddings. A mixture of documents (or scenarios) will typically be more difficult to separate if the scenarios/documents are more topically similar, since lexical cues are less reliable in this case. Specif-

[3] In our pilots for phase 2, the data Turkers created were not ideal, therefore we opted for hiring local annotators which produced higher quality results.

[4] Available before main conference: http://www.katrinerk.com/home/software-and-data/query-focused-scenario-construction

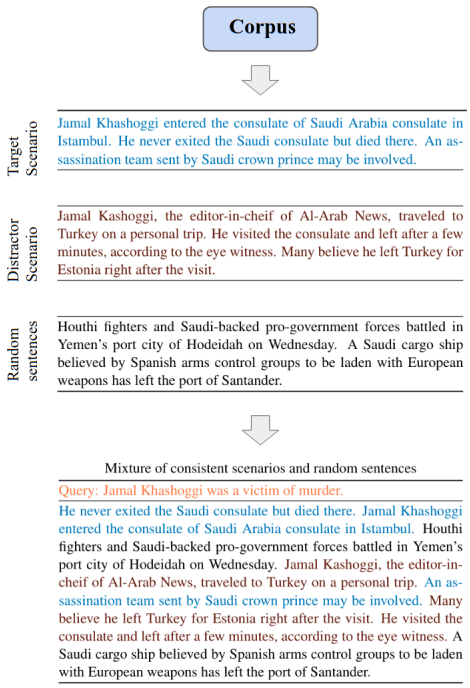

Figure 3: Synthetic data generation illustrated with our running example. First randomly sample news paragraphs (one is randomly assigned as the target scenario, the rest are distractors) and random sentences, then mix the target scenario with (a) other complete distractor scenarios (red) and (b) random sentences.

ically, Wang et al. found that their models struggled to separate scenarios even at 0.6 topical similarity, with accuracy on a binary clustering task dropping from 85% (all) to 68% (the hard ones). By this criterion Human100, at 0.8 average topic similarity cosine, is a hard dataset that challenges NLP models for their abilities to perform beyond shallow textual inference. Human-level performance is nonetheless fairly strong: 0.81 with distractor scenarios, and 0.97 with randomly sampled sentences (both are F1 scores, more details in Section 5).

3.2 Training with Proxy Synthetic Data

The idea we follow for synthetic data creation is the same as in Wang et al. (2018): we can use different articles as proxies for different scenarios, even though articles in the synthetic setting do not necessarily belong to the same topic. *Our hypothesis is that a model trained to predict which sentences came from the same news article will also do better at predicting which sentences come from the same scenario in the human-curated data.*

We synthesize data from two source corpora: the New York Times portion of English Gigaword (Graff et al., 2003) (**NYT**), which Wang et al. (2018) used to construct their document mixtures, and ROCStories (Mostafazadeh et al., 2017) (**ROC**). NYT is chosen for having the same domain as the human-constructed news data.[5] With ROC we want to gauge the generality of our approach out-of-domain: on news-only data a model could "cheat" by memorizing common named entities. We want to see to what extent models go beyond that to learn general event compatibility.

Corpus	#scenarios	Vocab	Words/scenario	Sents/scenario
Human100	200 (2/topic)	-	127.9	4
NYT	1.14m	50,000	189.5	9.5
ROC	113k	39,954	46.5	5.0

Table 2: Corpora statistics. Top: human-curated data; Bottom: synthetic data. For NYT, we truncated the vocabulary to the most frequent 50k (the full vocabulary is over 100k). For NYT and ROC we apply a 85%/5%/10% split to construct train/dev/test sets. The two datasets share 27,795 words in vocabulary.

The synthesis method is summarized in Figure 3, with corpus statistics in Table 2. In the first condition we mix a randomly sampled target scenario with a distractor scenario (also randomly sampled), following Wang et al. (2018). The mixtures are denoted **NYT/ROC-w18**. For the second condition, we replace the distractor scenario with unconnected randomly sampled sentences (corpus-wide), hence **NYT/ROC-rand**. We also combine both conditions, giving a mixture with both types of distractors. We also vary the number of distractor scenarios in a mixture (2, 3, or, 4, including the target scenario). To equalize the number of sentences in mixtures, we pad them all to a fixed number of sentences. We call these **NYT/ROC-2/3/4**.

4 Models

Given a query q and a mixture of sentences, we want to select sentences that form a compatible scenario with the query. Our models select the sentences iteratively: the process begins with a *target set* $\mathcal{T}^{(1)} = \{q\}$ (i.e. initialized with only the query in the set) and a *candidate set* $\mathcal{C}^{(1)}$ (i.e.

[5] The Human100 dataset is created based on search results, which could conceivably be from a variety of domains, but annotators are largely selecting news articles about given topics. The topics themselves are general news with a skew towards politics, which is reflected in the NYT dataset as well. So both datasets consist mostly of political newswire writing, which we view as similar domain.

the mixture), and terminates at some time step i with a predicted scenario $\mathcal{T}^{(i)}$.

We experiment with two termination conditions: (1) **fixed #sentences**: a pre-specified number of sentences are extracted; (2) **dynamic #sentences**: a special end-of-scenario token <end> is predicted as the next candidate. (1) simulates the case where the user desires to specify the amount of information to be extracted (i.e. a consistent yet not necessarily all-inclusive scenario), and (2) the case where the model finds a complete scenario.[6]

Notation We describe one step of candidate selection without loss of generality, thus whenever no confusion arises, we drop the timestep superscripts to use $\mathcal{T}, \mathcal{C}$ for simplification. $t \in \mathcal{T}$ denotes a sentence in the target scenario, and $c \in \mathcal{C}$ a candidate. We use bold lower case letters for embeddings. The acronyms for the models are introduced at the beginning of model description (e.g. COMP for compatibility-attention).

4.1 Architectures

Compatibility-Attention (COMP) In scenario building, intuitively we select a candidate c_j that fits best with $\mathcal{T}$ such that the updated target scenario is $\mathcal{T} \cup \{c_j\}$, the most compatible scenario-in-construction possible. The prediction $\hat{c}_j$ is then:

$$\hat{c}_j = \underset{c_j \in \mathcal{C}}{\text{argmax}}\ \text{COMP}(\mathcal{T}, c_j) \quad (1)$$

For example, take the example in Figure 1, *He never exited the consulate but died there* is a good candidate, as it clearly relates to the scenario that Khashoggi was murdered, compatible with the current scenario-in-construction $\mathcal{T}^{(1)} = \{$*Jamal Khashoggi was murdered*$\}$.

Now note for $\mathcal{T}^{(i)}$, where $i > 1$ (i.e. multiple sentences in the scenario-in-construction), its member sentences do not contribute equally to the decision on a $\hat{c}_j$. For example, say $\mathcal{T}^{(2)} = \{$*Jamal Khashoggi was murdered*; *A team flew from Saudi Arabia ... to intercept him*$\}$, the first sentence is more informative for us to pick out *He never exited the consulate but died there* as a good candidate. We implement this with a bi-linear attention

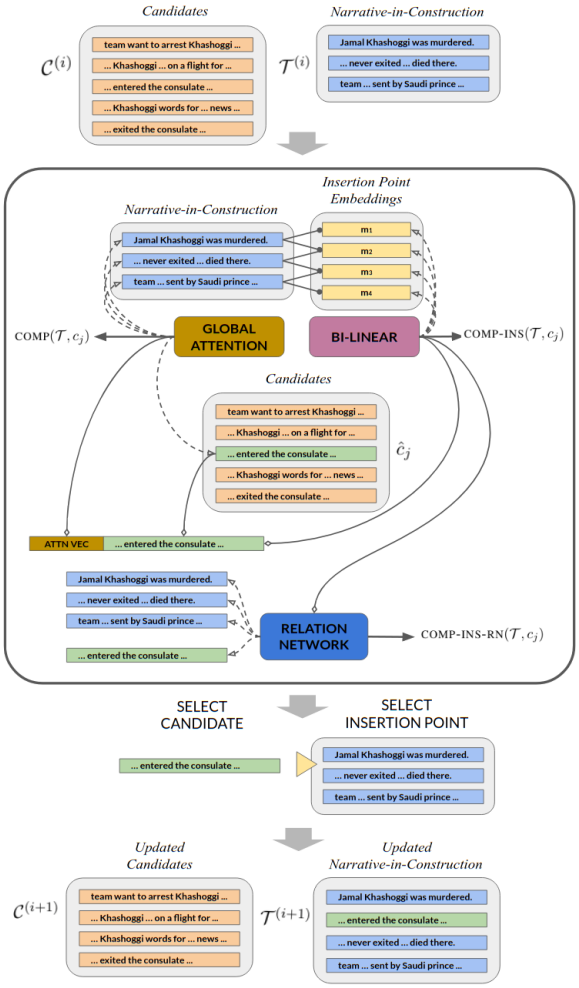

Figure 4: Iterative models for one step of candidate selection. Embeddings of scenario sentences in $\mathcal{T}$ are shown in light blue, candidate embeddings in $\mathcal{C}$ in orange, and the sentence embedding being processed and selected is in light green. COMP-ATT: only runs GLOBAL ATTENTION to produce $\text{COMP}(\mathcal{T}, c_j)$, which selects a candidate *but not an insertion point*. COMP-INS runs GLOBAL ATTENTION and BI-LINEAR to get $\text{COMP-INS}(\mathcal{T}, c_j)$, which selects a candidate as well as an insertion point. COMP-INS-RN additionally employs a RELATION NETWORK on top of COMP-INS.

layer with parameters U:

$$\alpha_{j,k} = \text{softmax}_k(\boldsymbol{c}_j^\intercal U \boldsymbol{t}_k)$$

$$\text{COMP}(\mathcal{T}, c_j) = \text{softmax}_j\left(\text{linear}\left(\sum_k \alpha_{j,k}\boldsymbol{t}_k\right)\right)$$

i.e. c_j attends to the sentences $\{t_k\}$ in the current scenario, which computes a vector that is scored to compute the weight score of c_j under COMP.

Insertion-sort based selection (COMP-INS) If $\mathcal{T}$ is an ordered scenario, it is possible to further

[6] We select the same number of sentences as in the target scenario for the fixed #sents condition. This is extra supervision compared to the dynamic #sents condition. Changing this number changes the precision/recall tradeoff, but it would not lead to significant gains in the F1 values we report.

improve the quality of the candidate selection by selecting a c_j that is *easy-to-insert* into $\mathcal{T}$. For instance, for the example in Figure 1, the most readable update can be made by inserting *He never exited the consulate but died there* to the right of *Jamal Khashoggi was murdered*. Essentially, we imagine an insertion-sort based candidate selection technique: we iteratively pick out the easiest candidate to insert and maintain $\mathcal{T}$ as ordered. Crucially, note that we want to use ordering to aid clustering, rather than aiming for ordered scenarios: the model performance is only evaluated on clustering the correct set of sentences.

Let m_k be the insertion point to the left of the sentence t_k. For $\mathcal{T}$ we have insertion points $\{m_1, \cdots, m_{|\mathcal{T}|+1}\}$. For each ⟨insertion point, candidate⟩ tuple $\langle m_k, c_j \rangle$, we want to compute a weight $z_{k \leftarrow j}$ to indicate the "easy-to-insert-ness" of c_j to insertion point m_k. First we embed m_k and c_j: $\boldsymbol{c}_j$ is embedded with a BiLSTM, and $\boldsymbol{m}_k$ is computed from the embedded sentences in $\mathcal{T}$:

$$\boldsymbol{m}_k = \begin{cases} \boldsymbol{t}_1 & \text{if } k = 1 \\ \boldsymbol{t}_{|\mathcal{T}|} & \text{if } k = |\mathcal{T}| + 1 \\ \text{average}(\boldsymbol{t}_{k-1}, \boldsymbol{t}_k) & \text{otherwise} \end{cases} \quad (2)$$

Finally, applying a bilinear function:

$$z_{k \leftarrow j} = \boldsymbol{m}_k^\intercal W [\boldsymbol{a}_j; \boldsymbol{c}_j] \quad (3)$$

where $[;]$ is concatenation. This results in a model $\text{COMP-INS}(\mathcal{T}, c_j)$ s.t.

$$\hat{c}_j = \underset{c_j \in \mathcal{C}}{\text{argmax}}\ \text{COMP-INS}(\mathcal{T}, c_j) \quad (4)$$

$$\text{COMP-INS}(\mathcal{T}, c_j) = \max_k (z_{k \leftarrow j}) \quad (5)$$

i.e. the easy-to-insert-ness of c_j is indicated with its highest z score over all the available insertion points: the larger the largest $z_{k \leftarrow j}$ is, the clearer the model is about where to insert c_j.

Relation Networks (COMP-INS-RN) Oftentimes word tokens in $\mathcal{T}$ and $\mathcal{C}$ are also indicative of which candidate is the best. E.g. in Figure 1, the candidate *He never exited the consulate but died there* has the event *died* which relates to the *murder* in the query. Similarly the entity *he* is likely anaphoric to *Jamal Khashoggi*. The relations make the sentence an ideal candidate.[7]

Adapting the *Relation Network* as per Santoro et al. (2017),[8] we summarize the relation between the word tokens in c_j and $\mathcal{T}$ with a summary score r_j, i.e. how strongly the candidate is connected to the scenario-in-construction, based on the relations between its tokens and that of the scenario-in-construction. The process breaks down to three steps: first, we pair c_j with each of the sentences $t_k \in \mathcal{T}$ and compute a sentence-sentence relational vector $\boldsymbol{v}_{j,k}$ which is the sum over all the word-word bi-linear contraction (the bi-linear contraction of two word embeddings $\boldsymbol{w}_a, \boldsymbol{w}_b$ is $\boldsymbol{w}_a^\intercal V \boldsymbol{w}_b$, where $\boldsymbol{w} \in \mathbb{R}^d, V \in \mathbb{R}^{d \times l \times d}$). Then, we average over the sentence-sentence relation vectors to obtain a summary vector $\boldsymbol{p}_j = \underset{k}{\text{average}}(\boldsymbol{v}_{j,k})$. Finally we compute $r_j = \text{linear}(\boldsymbol{p}_j)$. We incorporate the relation network with COMP-INS by adding r_j to all the $z_{k \leftarrow j}$ over k. Patterning after the model descriptions above, we get a model $\text{COMP-INS-RN}(\mathcal{T}, c_j)$:

$$\hat{c}_j = \underset{c_j \in \mathcal{C}}{\text{argmax}}\ \text{COMP-INS-RN}(\mathcal{T}, c_j) \quad (6)$$

$$\text{COMP-INS-RN}(\mathcal{T}, c_j) = \max_k (z_{k \leftarrow j} + r_j) \quad (7)$$

4.2 Optimization

Since our models' supervision comes in the form of whole scenarios, supervising our iterative insertion clustering model is not completely straightforward. In particular, there may be multiple correct sentences that can be added to the current scenario. For example, in Figure 1, all the sentences labeled with (B) are possible candidates. We thus optimize the marginal log-likelihood of making any correct decision.[9]

Specifically, we minimize: $\mathcal{L} = -\log \sum_j p(c_j)$, which maximizes the sum of the probabilities of the correct candidates. For Eq. (5, 7), we optimize for

$$\mathcal{L} = -\log \sum_{(k,j)} p(\langle m_k, c_j \rangle) \quad (8)$$

i.e. maximizing the probability sum over all correct (insertion point, candidate) pairs.[10]

[7] Note that Wang et al. (2018) apply a mutual attention mechanism (Hermann et al., 2015) for the similar modeling purpose, but with many more parameters than our relation net. For practicality we believe the latter is a better option.

[8] Santoro et al. (2017) abstract word tokens as *objects* to summarize the relation between two sentences (or, in general, sequences) with a compound function $f(\sum_{i,j} g(o_{1,i}, o_{2,j}))$, where $o_{1,i}$ is the i-th token in sentence 1 (similar for $o_{2,j}$), and f, g can be any model (e.g. a feedforward net).

[9] E.g. Durrett and Klein (2013) employ the same technique to optimize for multiple viable coreference candidates.

[10] Maximizing marginal likelihood has the attractive property that it allows our model to learn the "easiest" way to build the desired gold scenarios, rather than forcing one analysis.

At train time, we treat each timestep of scenario construction as a training example. We use a form of teacher forcing where we assume that a correct partial scenario has been built and we want to make some correct decision from there. The partial scenarios are built by adding *random* correct sentences, so the model learns to make correct decisions in a range of settings.

5 Experiments

We use scalably synthesized data for training and reserve the realistic data, which is expensive to produce, for evaluation. To better understand which techniques work, we also conduct evaluation on the synthetic data.

Data Preparation The statistics of our source corpora are summarized in Table 2. For all the synthetic datasets, we make 100k mixtures for training, 5k for validation and 10k for test, mixed from a 0.85/0.05/0.10 split of the total 113k scenarios. For NYT/ROC-w18, to properly compare with Wang et al. (2018), all mixtures have 2 scenarios. For NYT/ROC-2/3/4, we first mix 2/3/4 randomly sampled scenarios, then pad the resulting mixtures to a fixed lengths. For NYT/ROC-rand, we sample equal #sentences as for NYT/ROC-2/3/4.

Baselines We apply three baselines: (1) **UNIF**, which randomly selects $n-1$ candidates ($n-1$: #sentences in the target scenario minus the query). (2) **AVG**, an iterative model that always selects the candidate the embedding of which is the closest (in cosine) to the average embedding of the sentences in the scenario-in-construction. A sentence embedding is the average over each of its word embeddings. (3) **PAIRWISE**, which adapts Wang et al. (2018)'s best model. It predicts a probability for a pair of sentences to indicate how likely they are from the same scenario. PAIRWISE replaces the cosine in AVG with the pairwise model.

Implementation All the models are constructed with PyTorch 0.4.1 (Paszke et al., 2017). We use pretrained 1024-dim ELMo embeddings (Peters et al., 2018). The hidden size for the BiLSTM and the relation network are 200. We run 10 epochs with an initial learning rate of 1e-4 (with Adam (Kingma and Ba, 2014)).

Evaluation For clustering performance, we use macro-averaged F1, comparing our recovered cluster for each query to the gold cluster. For sorting-clustering correlation, Spearman's Rho (ρ); and for sorting per se, Kendall's Tau (τ).[11]

Condition	Model	NYT-w18	NYT-rand	NYT-4
Fixed#sent	UNIF	0.45	0.18	0.18
	AVG	0.51	0.46	0.29
	PAIRWISE	0.68	0.64	0.53
	COMP	0.86	0.84	0.76
	COMP-INS	0.87	0.84	0.81
	COMP-INS-RN	**0.93**	**0.92**	**0.84**
Dyn. #sent	COMP	0.70	0.66	0.58
	COMP-INS	0.75	0.70	0.61
	COMP-INS-RN	**0.78**	**0.73**	**0.65**

Table 3: Intrinsic evaluation: F1 scores (testing) for models trained on different NYT mixtures in fixed and dynamic #sentences conditions. In the dynamic #sentences condition, the baselines no longer apply because they do not model a stopping condition.

5.1 Constructing Effective Training Mixtures

Which method for synthetic mixture creation leads to the best results on Human100? We first run our models in the three mixing conditions – scenario distractor only, random sentence distractor only, and both distractors (see Section 3.2), then evaluate both intrinsically and on the human-curated Human100. Here we only use our domain-proxy NYT-* datasets.

COMP-INS-RN	NYT-w18	NYT-rand	NYT-4
Fixed #sent	0.65	0.60	0.70
Dyn. #sent	0.60	0.56	0.62
Human benchmark		0.82	

Table 4: Which scenario mixture method is the best? F1 scores on the Human100 data of the COMP-INS-RN model trained in different mixing conditions. The most complex condition (NYT-4) gives the best results.

Examining the results in Table 3,[12] we observe the hybrid mixtures with both types of distractors are the most difficult, with substantially lower performance. But how does this translate into human evaluation? In Table 4, we evaluate the best-performing model (COMP-INS-RN, trained on NYT-* sets) on Human100. We find that harder training conditions (i.e., the hybrid mixing) give stronger results on Human100. Our initial conclusion is: the more challenging hybrid mixing serves

[11] More discussion on the ρ-τ mix is at the end of sec 5.2.

[12] As we test on examples with more mixtures (i.e., going from NYT/ROC-2 to NYT/ROC-4), test accuracy steadily decreases (0.93/0.86/0.84 for NYT-2/3/4, 0.92/0.91/0.90 for ROC), as is to be expected. To avoid cluttering we only report scores on *-4 data.

better as a training proxy to the realistic data. We also see in both Tables 3 and 4 that the dynamic #sent setting, where the model needs to decide when to stop adding events, is considerably more difficult throughout.

5.2 Do Our Modules All Contribute?

We additionally evaluate our proposed modules – insertion-sort based selection and relation nets – to see which contributes substantially in the intrinsic evaluation (Table 3). The COMP-INS module achieves a gain of 3 points of F1 on average over COMP, and COMP-INS-RN improves 4.5 F1 on average over COMP-INS. In addition we see a clear and large margin of the models over the baselines. To evaluate the modules on Human100, we use the models trained on the best hybrid mixtures (Section 5.1). The results are summarized in Table 5.

	COMP	COMP-INS	COMP-INS-RN
Fixed #sent	0.62	0.68	0.70
Dyn. #sent	0.53	0.61	0.62
Human benchmark		0.82	

Table 5: How do modeling modules contribute? F1 scores on Human 100 of different models with the best hybrid training mixtures (NYT-4).

Similar to the intrinsic evaluation, both modules improve performance across fixed and dynamic conditions. While in intrinsic evaluation, relation nets are the stronger contributor, insertion-sort based selection leads to a higher performance gain on Human100.

COMP-INS	sorting	corr. clustering
Fixed #sent	0.31	0.38
Dyn. #sent	0.30	0.40

Table 6: Sorting performance (τ) and its correlation with clustering accuracy (ρ)

While sorting performance in itself is not very high, it has a reasonable correlation with clustering performance (Table 6): following Cui et al. (2018), we use Kendall's τ to compute sorting performance (as correlation of predicted and gold ordering). We then calculate the correlation between sorting performance and model performance, using Spearman's ρ as the most widely used correlation measure in NLP.[13]

[13]Sorting and clustering performance are calculated one pair per instance. In computing τ we drop incorrectly extracted candidates as they do not have gold ordering with target sentences.

5.3 Do We Learn Compatibility that Generalizes?

As argued previously (Section 3.1), NYT contains plenty of shallow textual cues, meaning an expressive model can do well at the task doing bag-of-words clustering of the data rather than more sophisticated event compatibility inference.

COMP-INS-RN	ROC-w18	ROC-rand	ROC-4
Train-on-ROC (in-domain)	0.95	0.95	0.90
Train-on-NYT (out-domain)	0.85	0.87	0.81

Table 7: Generalization out-of-domain text: train on NYT-*/ROC-* and evaluate on ROC-* (fixed #sents).

The first question is: do the models generalize out-of-domain, particularly when textual cues are much fewer? We train our strongest COMP-INS-RN on NYT-* and evaluate on the corresponding ROC-* datasets (Table 7): in in-domain evaluation (i.e., train and test on ROC) our model produces excellent performance, and in out-of-domain evaluation (i.e., train on NYT test on ROC) it manages to keep up with fairly strong results. This indicates our model captures information beyond surface cues.

5.4 Final Model

From the domain-generalization test in Table 7, we see there is likely NYT-* sets do not subsume all the information in ROC-* sets. Exploiting all the data we have available, we combine ROC and NYT in a domain-joint training. The results in Table 8 show that in both fixed and dynamic #sent conditions, the model improves on the performance with single-domain training (Table 4, 5).

6 Analyzing Human-curated Data

To set up a human-level performance benchmark, we asked two additional annotators (they did not participate in the collection of Human100) to manually perform the same task as the models in fixed #sentences condition on a sample of 30 with randomly chosen query and target scenario. On average the F1 is 0.82 (one worker 0.81, the other 0.83). While even our best model (COMP-INS-RN) is inferior to the human-level performance, it draws quite close.

This however does not tell the whole story: qualitatively comparing the scenarios built by COMP-INS-RN vs. annotators, we observe human annotators tend to construct much more reasonable scenarios even when they include sentences

COMP-INS-RN	R&N-w18	R&N-rand	R&N-4	rand-scenario
Fixed #sents	0.70	0.61	0.74	0.90
Dynamic #sents	0.65	0.59	0.67	0.79
UNIF	0.50	0.50	0.50	0.42
AVG	0.49	0.50	0.51	0.50
PAIRWISE	0.56	0.60	0.56	0.64
Human benchmark		0.82		0.97

Table 8: **Left table**: F1 scores for Human100 evaluation with the best model (COMP-INS-RN) in fixed and dynamic #sentences conditions. The model is trained with three domain-joint training datasets. The model clears a sizable margin over the baselines, but falls short from human-level. **Right table**: F1 for COMP-INS-RN with *modified Human100*, i.e. the distractor scenario is now a random sample from NYT rather than one collected by an annotator. Human100 has a topic similarity of over 0.8 but the modified version only 0.45. This demonstrates *high* topic similarity is a strong contributor to the difficulty of Human100, which is true for both models and humans.

Target scenario: *Trump says Russia is the sole party to be blamed.*
(1) Trump says that Russia is the sole party to be blamed. (2) White House issued a statement which says Moscow is violating the Reagan-era agreement. (3) Secretary of State Mike Pompeo announced the decision to suspend the accord, declaring that countries must be held scenarioable when they break the rules. (4) "We can no longer be restricted by the treaty while Russia shamelessly violates it," Mr. Pompeo said.
Distractor scenario: *Russians accused the wrong doing on the part of the Trump administration*
(1) Russians accuse the wrong doing on the part of the Trump administration. (2) This is the latest step in the Trump administrations pattern of abandoning the diplomatic tools that have prevented nuclear war for 70 years. (3) Russia has also complained about the alleged lack of U.S. diplomacy. (4) Russian foreign minister Sergei Lavrov accused the U.S. of being obstinate. U.S. representatives arrived with a prepared position that was based on an ultimatum and centered on a demand for us to destroy this rocket, its launchers and all related equipment under US supervision.

Table 9: Humans make more reasonable mistakes (the query is underscored): the annotator selected sentence (2) as a part of the target scenario, which, while not part of the gold, does make a comperent scenario. The model however chose sentence (1), which is in direct contradiction with the target scenario.

are not from the gold scenario (Table 9). This indicates that models for the task could benefit from textual inference capabilities (Cases et al., 2017), or from deeper meaning representations.

Discussion The results on Human100 are largely in line with those on synthetic datasets, which indicates that results on synthetic data gives a reasonable estimate of results on more realistic data. While the performance on Human100 is lower overall, the findings are encouraging. Further, realistic cases of scenario discovery have the property that different scenarios for the same topic have a high vocabulary overlap. This can be seen in Human100. This property of the data penalizes shallow processing based models while encouraging learning deeper semantics.

One caveat about Human100 is that the dataset is still relatively small; a larger dataset would be useful to strengthen quantitative analysis. Also, variable-size scenarios would be more realistic for evaluating the more general case. Finally, we would like to improve the crowdsourcing technique in future work: in phase 1, some collected scenarios are not entirely in conflict with each other, for example two talking points Trump made in his State of the Union Address. An extra step where additional crowdworkers rate the compatibility of scenarios could be useful. In phase 2, we would like to have scenarios which exhibit more nuanced conflicting points that capture a wider range of cues that distinguish different scenarios.

7 Conclusion

Identifying an individual scenario in a blend of contradictory stories is a task that is targeted by the Active Interpretation of Disparate Alternatives (AIDA) program as well in a recent Text Analysis Conference (TAC). We address this task through query-based scenario construction, and find sizable performance improvements both from taking sentence order into account (INS) and from encoding connections between words (RN). Evaluating on a new human-curated dataset, we find that the synthetic training data serves as a reasonable proxy for the human-curated data.

Our current model sometimes gets misled by superficially similar sentences, and it will be an important future direction to move towards deeper reasoning for the task. In addition, we plan to create larger human-curated datasets with variable size scenarios.

Abstract

Entity alignment aims at integrating complementary knowledge graphs (KGs) from different sources or languages, which may benefit many knowledge-driven applications. It is challenging due to the heterogeneity of KGs and limited seed alignments. In this paper, we propose a semi-supervised entity alignment method by joint **K**nowledge **E**mbedding model and **C**ross-**G**raph model (**KECG**). It can make better use of seed alignments to propagate over the entire graphs with KG-based constraints. Specifically, as for the knowledge embedding model, we utilize TransE to implicitly complete two KGs towards consistency and learn relational constraints between entities. As for the cross-graph model, we extend Graph Attention Network (GAT) with projection constraint to robustly encode graphs, and two KGs share the same GAT to transfer structural knowledge as well as to ignore unimportant neighbors for alignment via attention mechanism. Results on publicly available datasets as well as further analysis demonstrate the effectiveness of KECG. Our codes can be found in https://github.com/THU-KEG/KECG.

1 Introduction

Recently, many Knowledge Graphs (KGs) (e.g., DBpedia (Lehmann et al., 2015), YAGO (Rebele et al., 2016) and BabelNet (Navigli and Ponzetto, 2012)) have emerged to provide structural knowledge for different applications. These separately constructed KGs contain heterogeneous but complementary contents; thus integrating KGs from different sources or languages into a unified KG becomes essential to better benefit knowledge-driven applications, ranging from information extraction (Han et al., 2018; Cao et al., 2018) to question answering (Cui et al., 2017).

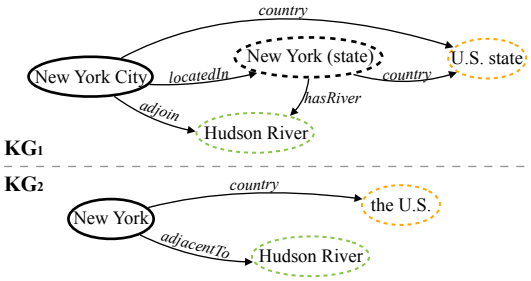

Figure 1: Example of the *New York City* entity and its neighbors in two heterogeneous KGs (Dashed circles in the same color means prior alignments).

Some efforts have been made to integrate KGs by aligning entities with their semantically same counterparts, namely entity alignment. Early entity alignment approaches either rely on human efforts (Mahdisoltani et al., 2013) or extra resources (Hu et al., 2011; Wang et al., 2013) to discover new equivalent entity pairs. Recent embedding approaches show significant improvement on entity alignment. We roughly classify these embedding models into two groups: KG-based models and graph-based models. KG-based models (Hao et al., 2016; Chen et al., 2017; Sun et al., 2017; Zhu et al., 2017; Sun et al., 2018; Chen et al., 2018) utilize existing KG representation learning methods to learn embeddings of entities and relations in different KGs, and then align them into a unified vector space. This type of method can not only preserve KG structures, but also implicitly complete KG with the missing links from existing knowledge. However, KG-based methods require a sufficient number of seed alignments, which is usually expensive to obtain.

To alleviate the burden of seed alignments, graph-based methods (Wang et al., 2018) utilize Graph Convolutional Network (GCN) (Kipf and Welling, 2017) to enhance entity embeddings with their neighbors' information, thus can make better use of seed alignments to propagate them over

the entire graph. However, GCN-based models are sensitive to structural differences of KGs (Vaswani et al., 2017) and may not perform well for entity alignment, since different KGs are very heterogeneous. Another issue of this type of method is that they fail to consider relation types, which actually play an important role in entity alignment. As shown in Figure 1, the *New York City* entity has different surface forms in the two KGs (i.e., *New York City* in KG_1 and *New York* in KG_2). There are two possible mappings from the *New York City* and *New York (state)* in KG_1 to the *New York* in KG_2, and the *New York* in KG_2 shares the same neighbors *Hudson River* and *U.S. state* with *New York City* and *New York (state)* in KG_1. In this case, we need to further consider the relation types: *adjoin* and *hasRiver* to distinguish the two candidate alignments; otherwise, a graph-based method may be misled here.

In this paper, we propose a semi-supervised entity alignment method by joint **K**nowledge **E**mbedding model and **C**ross-**G**raph model (**KECG**), which combines the above two types of methods. The basic idea of KECG is to utilize a cross-graph model to embed entities into a unified vector space by using inner-graph structure and inter-graph alignments information; meanwhile the knowledge embedding model learns KG representations to implicitly complete different KGs towards consistency and model relational constraints among entities. There are two key points for high-quality jointly training. First, the completion from KG learning may exacerbate the heterogeneity between two KGs, because two KGs may contain different rich parts, which shall become richer during training. Second, different from conventional KG representation learning, entity alignment requires one-to-one mapping, which implies that the similar entities sharing common neighbors cannot be embeded closely, otherwise they shall be aligned incorrectly as shown in Figure 1.

Therefore, as for cross-graph model, we propose to utilize an extended Graph Attention Network (GAT) (Vaswani et al., 2017) as our cross-graph model that allows robustly encoding of KGs. To alleviate the negative impacts of heterogeneity, we encode different KGs with the same GAT, so that it not only highlights the entities that are important for alignment in the graph, but also transfers structural knowledge via shared parameters. We also extend it with constraints on weight matrices, making our model more efficient and effective. Moreover, we employ the nearest neighbor sampling strategy to differentiate the entities that are embeded closely but not the same to further boost the performance. We summarize the main contributions as follows:

1. We propose a novel semi-supervised KECG model for entity alignment by joint knowledge embedding model and cross-graph model.

2. We utilize an extended GAT to alleviate the negative impacts of heterogeneous KGs, and employ the nearest neighbor sampling strategy for KG representation learning towards one-to-one mapping, making the combination more suitable for entity alignment.

3. We evaluate KECG on five publicly available datasets including three cross-lingual datasets and two large-scale datasets from different sources. Compared with four state-of-the-art baselines, experimental results and further analysis demonstrate the outperformance of KECG.

2 Background

2.1 Problem Formulation

Formally, we represent two heterogeneous KGs as $G_1 = (E_1, R_1, T_1)$ and $G_2 = (E_2, R_2, T_2)$, where E_i, R_i, T_i represent the sets of entity, relation and triplet in $G_i, i \in \{1, 2\}$, respectively. $N_e = \{e'|(e, r, e') \in T\} \cup \{e'|(e', r, e) \in T\}$ is the set of neighbors of the entity e in G. $S = \{(e_1, e_2) \in E_1 \times E_2 | e_1 \leftrightarrow e_2\}$ is a set of labeled entity pairs that are same in semantics, where an equivalence relation $\leftrightarrow$ holds between e_1 and e_2, e.g., e_1 in G_1 describes the same real-world entity with e_2 in G_2. Entity alignment aims to find the remaining semantically same entity pairs in $E_1 \times E_2$. For convenience, we put G_1 and G_2 together into one large graph $G = G_1 + G_2$, $R = R_1 \cup R_2$, $T = T_1 \cup T_2$, and $n = |E_1| + |E_2|$ is the total number of entities. We use bold-face letters to denote the vector representations of the corresponding terms throughout the paper.

2.2 Graph Neural Networks (GNNs)

GNNs are a type of neural network model that directly deals with structured data (Bruna et al.,

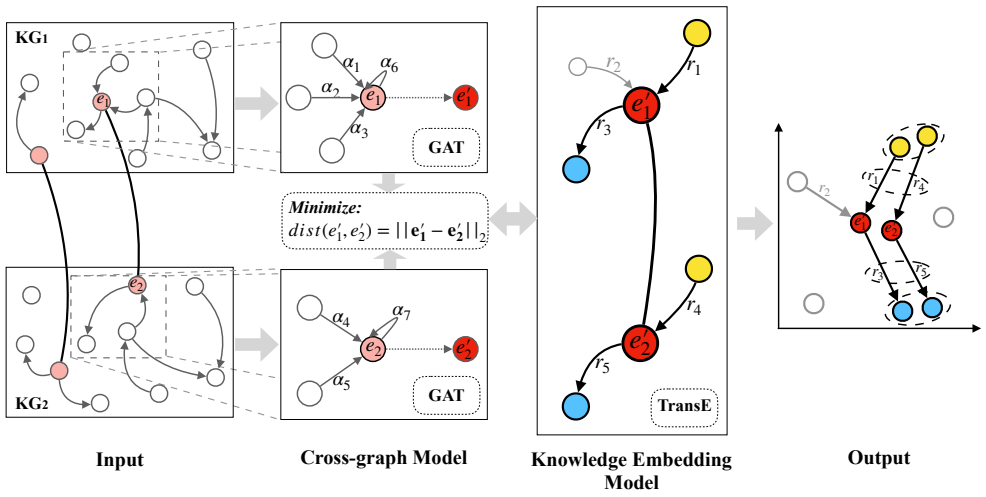

Figure 2: The overview framework of KECG. Solid lines (in Input) connect pre-aligned entities in two KGs. Nodes in different sizes (in Knowledge Embedding Model) show the attention of the center nodes over their neighbors. Circled nodes in the output are the potentially equivalent entities that we want to find out (in Output).

2014; Defferrard et al., 2016; Hamilton et al., 2017). They take a graph as an input, output labels for each node, and are similar to a propagation model: to enhance the features of a node according to its neighbor nodes. Among them, GCN (Kipf and Welling, 2017) is a simplification of spectral graph convolutions, whose formulation is as follows:

$$\mathbf{H}^{(l+1)} = \sigma(\mathbf{A}\mathbf{H}^{(l)}\mathbf{W}^{(l)})$$

where $\mathbf{A}$ is a normalized adjacent matrix of the input graph with self-connection, $\mathbf{H}^{(l)}$ and $\mathbf{W}^{(l)}$ are the hidden states and weights in the l_{th} layer, and $\sigma(\cdot)$ is a non-linear activation, such as $ReLu$. Subsequently, Vaswani et al. (2017) introduce attention mechanism into GCN by dynamically calculating $\mathbf{A}$ according to the attention values between each entity pairs, which is capable of mining structural knowledge better.

3 Method

To combine KG-based methods and graph-based methods with consideration of seed limit and KG heterogeneity, we propose a novel semi-supervised method KECG for entity alignment. As shown in Figure 2, KECG consists of two parts: cross-graph model and knowledge embedding model. The input of KECG includes a composition G of two KGs and their prior alignment set S.

3.1 Cross-graph Model

The goal of our cross-graph model is to utilize structural information, including inner-graph structure and inter-graph alignments, to embed entities into a unified vector space. Due to the incompleteness of KGs, there may be some entities and relations existing in one KG but missing in another KG. We utilize an extended GAT with projection constraint as an encoder to embed the KGs while paying different attention over their neighbors, therefore it is able to alleviate the negative impact of heterogeneity by ignoring some unimportant neighbors for alignment. Besides, the graph convolution operation allows us to leverage both the labeled entities and the abundant unlabeled entity information for alignment, making our method naturally semi-supervised.

The input of the encoder includes an entity embedding matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$ and neighbor sets of all entities as KG structure, where d is the dimension of entities. The KG encoder is built by stacking multiple GAT layers:

$$\mathbf{H}^{(l+1)} = \sigma(\mathbf{A}^{(l)}\mathbf{H}^{(l)}\mathbf{W}^{(l)}) \quad (1)$$

where $\mathbf{H}^{(l)} \in \mathbb{R}^{n \times d^{(l)}}$ and $\mathbf{W}^{(l)} \in \mathbb{R}^{d^{(l)} \times d^{(l+1)}}$ are the hidden states and weights in the l_{th} layer, $\mathbf{H}^{(0)} = \mathbf{X}$, $\sigma(\cdot)$ is a non-linear activation chosen as $ReLU(\cdot) = max(0, \cdot)$, and $\mathbf{A}^{(l)} \in \mathbb{R}^{n \times n}$ is a connectivity matrix computed by self-attention over the input graph. Considering a single element $a_{ij}^{(l)}$ of $\mathbf{A}^{(l)}$, the weight from entity e_i to entity e_j, we compute it using self-attention mechanism:

$$a_{ij}^{(l)} = softmax(c_{ij}^{(l)}) = \frac{exp(c_{ij}^{(l)})}{\sum_{e_k \in N_{e_i} \cup \{e_i\}} exp(c_{ik}^{(l)})} \quad (2)$$

, where $N_{e_i} \cup \{e_i\}$ is the neighbor set of e_i with self-loop, $c_{ij}^{(l)}$ is the attention coefficient of entity e_i to entity e_j. Following Velickovic et al. (2018), the attention coefficient $c_{ij}^{(l)}$ is computed as follows:

$$c_{ij}^{(l)} = LeakyReLU(\mathbf{q}^T[\mathbf{W}^{(l)}\mathbf{h}_i^{(l)} \oplus \mathbf{W}^{(l)}\mathbf{h}_j^{(l)}]) \quad (3)$$

where $\mathbf{h}_i^{(l)}, \mathbf{h}_j^{(l)} \in \mathbf{H}^{(l)}$ are the hidden states of e_i and e_j, respectively, $LeakyReLU$ (Maas et al., 2013) is a nonlinear function, $\mathbf{q} \in \mathbb{R}^{2d^{(l)}}$ is a learnable parameter, $\cdot^T$ represents transposition and $\oplus$ indicates vector concatenation. Let L be the number of layers. After L iterations of convolution, the hidden state $\mathbf{H}^{(L)}$ integrates both features of entities and their neighbors, the i_{th} row of which represents the **attention enhanced embedding** of entity e_i.

Projection Constraint. Note that in every forward propagation, we use $\mathbf{W}^{(l)}$ to transform from $d^{(l)}$ dimension vector space to $d^{(l+1)}$ dimension. Motivated by (Yang et al., 2015), we keep the dimensions of the layers and embeddings to be the same, and restrict the projection matrix $\mathbf{W}$ to be a diagonal matrix. Such constraint can reduce the number of parameters and computations, increase the generalizability of the model. That's why we claim that we extend the normal GAT.

Objective O_C. For semi-supervised entity alignment, we then minimize the representation distance of equivalent entities over all labeled alignments similar to (Wang et al., 2018):

$$O_C = \sum_{(e_i,e_j)\in S} \sum_{(e_i^{'},e_j^{'})\in S'} [dist(e_i, e_j) + \gamma_1 - dist(e_i^{'}, e_j^{'})]_+ \quad (4)$$

where $dist(e_i, e_j) = ||\mathbf{e}_i - \mathbf{e}_j||_2$ is the L_2 distance between the aligned entity pair (e_i, e_j), representations of e_i and e_j are from the attention enhanced embedding matrix $\mathbf{H}^{(L)}$, S' represents the negative pair set of S generated by nearest neighbor sampling (Kotnis and Nastase, 2017), and $\gamma_1 > 0$ is a margin hyper-parameter. Because an entity can only have one corresponding entity in another KG, the entity closest to the corresponding entity in the same KG should be the best choice as a negative example to accurately discriminate the target entity. More formally, given a pre-aligned entity pair $(e_i, e_j) \in S$, where $e_i \in E_1$, $e_j \in E_2$, K_2 is the number of negative samples, we choose K_2 entities that are nearest to e_j in E_2 as the negative samples of e_i, and vice versa for e_j. After that, each pre-aligned entity pair will have $2*K_2$ negative samples. We utilize the L_2 distance as the measure to search for the nearest negative samples due to its superior performance in experiments.

3.2 Knowledge Embedding Model

The goal of our knowledge embedding model is to model inner-graph relationships, making entities more distinguishable. Here, we use TransE (Bordes et al., 2013), which is one of the most representative translation-based methods, as our knowledge embedding model. It is worth mentioning that other advanced KG learning methods can also be applied to our knowledge embedding model such as TransD (Ji et al., 2015), which is left for future work as our main idea is to joint cross-graph embeddings and knowledge embeddings for entity alignment.

Objective O_K. Formally, given a relational triplet (e_h, r, e_t), TransE wants $\mathbf{e_h} + \mathbf{r} \simeq \mathbf{e_t}$. So it defines the score function $f(e_h, r, e_t) = ||\mathbf{e_h} + \mathbf{r} - \mathbf{e_t}||_2$ to measure the plausibility of (e_h, r, e_t), where $||\cdot||_2$ means 2-norm. Following TransE, we utilize a margin-based ranking loss function as the training objective of the knowledge embedding model, defined as:

$$O_K = \sum_{(e_h,r,e_t)\in T} \sum_{(e_h^{'},r',e_t^{'})\in T'} [f(e_h, r, e_t) + \gamma_2 - f(e_h^{'}, r', e_t^{'})]_+ \quad (5)$$

where $[\cdot]_+ = max\{0, \cdot\}$ represents the maximum between 0 and the input, embeddings of entities e_h and e_t are from the attention enhanced embedding matrix $\mathbf{H}^{(L)}$, relation r is from the relation matrix $\mathbf{R} \in \mathbb{R}^{|R|\times d}$ which needs to be learned, T' stands for the negative sample triplet set of T, and $\gamma_2 > 0$ is a margin hyper-parameter separating positive and negative triplets. T' is generated by corrupting T. For a triplet $(e_h, r, e_t) \in T$, we replace e_h to generate a negative triplet (e_h', r, e_t), where e_h' also has the same relation type r connect to other entities, and so does e_t. K_1 is the number of negative samples for each positive triplet. For example, we think *Beijing City* can be a replacer for *New York City* in (*New York City*, *country*, *United States*), since *Beijing City* also has the relation *country* but connected with a different tail entity *China*. If the number of replacers is less than K_1, we randomly sample replacers from all entities as what the uniform negative sampling method does.

3.3 Optimization and Inference

Overall Objective O. Here, we define the objective function of KECG corresponding to the above two parts:

$$O = O_C + O_K \tag{6}$$

where O_C and O_K denote the objective function of the cross-graph model and the knowledge embedding model, respectively. It is worth noting that we can set different weights for O_C and O_K. But in order to treat both kinds of models equally, here, we set the same weight for them in experiments. We use AdaGrad (Duchi et al., 2011) to optimize the overall objective O.

Inference. When inferring, new equivalent entities are discovered based on the L_2 distances between entities in the joint embeddings. Equivalent entities should become close with each other, so do equivalent relation types, e.g., circled nodes, r_1 and r_4 in the output of Figure 2.

4 Experiments

We evaluate KECG on entity alignment with five publicly available datasets including three cross-lingual datasets and two large-scale datasets from different sources. We compare KECG with four state-of-the-art baselines and conduct further analysis of essential components of KECG.

4.1 Datasets

Following (Sun et al., 2017, 2018; Wang et al., 2018), we use the DBP15K and the DWY100K datasets for evaluation. **DBP15K** contains three cross-lingual datasets built from DBpedia, denoted by $\text{DBP15K}_{\text{ZH-EN}}$(Chinese to English), $\text{DBP15K}_{\text{JA-EN}}$(Japanese to English) and $\text{DBP15K}_{\text{FR-EN}}$(French to English). Each dataset contains 15,000 reference entity alignments. To test the adaptability of KECG to large-scale data, we evaluate on **DWY100K**. **DWY100K** contains two large-scale datasets extracted from DBpedia, Wikidata and YAGO3, denoted by $\text{DWY100K}_{\text{WD}}$(DBpedia to Wikidata) and $\text{DWY100K}_{\text{YG}}$(DBpedia to YAGO3). Each dataset has 100,000 reference entity alignments. The detailed information of each dataset is listed in Table 1.

Datasets		Entities	Relations	Rel. triplets
$\text{DBP15K}_{\text{ZH-EN}}$	Chinese	66,469	2,830	153,929
	English	98,125	2,317	237,674
$\text{DBP15K}_{\text{JA-EN}}$	Japanese	65,744	2,043	164,373
	English	95,680	2,096	233,319
$\text{DBP15K}_{\text{FR-EN}}$	French	66,858	1,379	192,191
	English	105,889	2,209	278,590
$\text{DWY100K}_{\text{WD}}$	DBpedia	100,000	330	463,294
	Wikidata	100,000	220	448,774
$\text{DWY100K}_{\text{YG}}$	DBpedia	100,000	302	428,952
	YAGO3	100,000	31	502,563

Table 1: Statistics of DBP15K and DWY100K.

4.2 Experiment Settings

To investigate the ability of KECG, we compare it with the following state-of-the-art entity alignment methods including three KG-based models and one graph-based model.

- KG-based models: **MTransE** (Chen et al., 2017) is the basic KG-based method. **JAPE** (Sun et al., 2018) combines relation and attribute embeddings for entity alignment. **AlignEA** is the non-iterative version of BootEA (Sun et al., 2018) for entity alignment, which gets the best results.

- Graph-based model: **GCN-Align** (Wang et al., 2018) aligns cross-lingual entity via GCN.

More specifically, we use a 3-layer extended GAT as the encoder to process the composite KG G to generate embeddings of its entities. We set the dimension of all layers to be the same d. The entity embedding matrix $\mathbf{X}$ and the relation matrix $\mathbf{R}$ are initialized randomly and updated during training. Besides, we separated two variants from KECG for ablation study, called KECG(w/o NNS) and KECG(w/o K).

- KECG(w/o NNS) replaces the nearest neighbor sampling (NNS) strategy with normal uniform negative sampling.

- KECG(w/o K) simply removes the knowledge embedding model, only considering the equivalent relation as what GCN-Align does.

For all the compared approaches, we randomly split 30% of the reference entity alignments as prior alignments (i.e., training data) and leave the remaining as testing data. We use two evaluation metrics in this task: (1) the mean reciprocal rank of all correct entities (MRR) and (2) the proportion of correct entities that rank no larger than N

Table 2: Results comparison on entity alignment(Results of Hits@1 and Hits@10 are percentage values).

(Hits@N). Higher values of MRR and Hits@N indicate a better entity alignment model.

For parameter settings, the dimension of the hidden units in each GAT layer is set to be the same $d = 128$ as the entity and relation embeddings. Learning rate λ for AdaGrad is chosen among $\{0.001, 0.005, 0.01, 0.05, 0.1\}$. Margin γ_1 and γ_2 are chosen among $\{1.0, 2.0, 3.0\}$. The number of negative samples for cross-graph model and knowledge model are $K_1 = 25$ and $K_2 = 2$, respectively, and the negative samples will be updated every 10 epochs. The total number of training rounds is 1000. The optimal configuration of our models for the entity alignment task is: $\lambda = 0.005$, $\gamma_1 = 3.0$, $\gamma_2 = 3.0$.

4.3 Results

Table 2 lists the results of entity alignment on DBP15K and DWY100K. In general, KECG is significantly more effective than MTransE, JAPE, and GCN-Align on all datasets, and slightly outperform AlignEA on small-scale datasets but greatly on large-scale datasets. Among all the baselines, AlignEA is the strongest one, which results from it using two margins to control the scores of triplets, making the KG structure modeling based on triplets more accurate than others. We conclude the detailed results in three aspects:

- **For different model groups.** Compared with the KG-based models, KECG performs much better than MTransE and JAPE. On $\text{DBP15K}_{\text{ZH-EN}}$, KECG and AlignEA get very close results regarding Hits@1 with a gap of 0.59%, but as for Hits@10 and MRR, the differences become 4.31% and 0.017, respectively. The reason is that, though some entities are not accurately aligned, their neighbors, or neighbors of neighbors, may already be aligned. And KECG propagates these features to unaligned entities, making the positions of the unaligned entities in the vector space very close to the corresponding entities. It reflects the importance of the global structural information of KGs. Compared with the graph-based model, KECG significantly outperforms GCN-Align regarding all metrics. It shows that involving the local relationships between entities can make entities more distinguishable, making the alignment more accurate.

- **For different data scales.** It can be seen that KECG has good adaptability on different data scales. The average gains of KECG regarding Hits@1 are 8%-41.3% on large-scale datasets and 1.7%-20.7% on small-scale datasets. With large-scale KGs providing richer relational and structural information, KECG can encode entities with more semantics. However, we found that, on $\text{DWY100K}_{\text{YG}}$, KECG's variant KECG(w/o K) works better than itself. This will be further discussed in Section 4.4.

- **For different language pairs.** KECG performs best on all language pairs. It improves the MRR score to 0.61 on $\text{DBP15K}_{\text{JA-EN}}$, which is a nearly 8% improvement compared with the best baseline. To the best of our knowledge, the imbalanced resources of non-English KGs with English KG result in the heterogeneity of cross-lingual KGs, making it challenging to align them. KG-based models, such as MTransE, cannot learn good representations to model the structures of non-English KGs, as restraints for entities are relatively insufficient. Methods based on GCNs, such as GCN-Align, are sensitive to structural differences, and find it hard to narrow the differences for alignment. KECG makes use of the extended GAT to alleviate the neg-

ative impacts of heterogeneous KGs, which successfully highlights the entities that are important for alignment in the graph. Because English and French share many similarities, both KECG and baselines get satisfactory results on $\text{DBP15K}_{\text{FR-EN}}$.

4.4 Analysis

4.4.1 Effectiveness of Knowledge Embedding Model

For better comparison, we draw two detailed Hits@N bar plots of GCN-Align, AlignEA, KECG(w/o K) and KECG on $\text{DBP15K}_{\text{ZH-EN}}$ and $\text{DWY100K}_{\text{YG}}$, as shown in Figure 3. In Figure 3(a), KECG(w/o K) gets better results than GCN-Align, which reflects the power of the graph attention mechanism. However, KECG(w/o K) cannot exceed AlignEA, showing that only considering structural information is not enough for entity alignment. After adding the knowledge embedding model, KECG achieves the highest Hits@{1,10,50}. The effectiveness of knowledge embedding model lies in two parts. Firstly, it applies constraints to entities by involving representation of relation types. Entity alignment leads to some relationship alignment, and entities having similar relations become close. Secondly, the knowledge embedding model is beneficial for the graph attention mechanism to learn better attention values.

In Figure 3(b), KECG still outperforms GCN-Align and AlignEA, but KECG(w/o K) exceeds KECG regarding three metrics, which reflects the weakness of the current knowledge embedding model. According to our statistics, the 1-to-N, N-to-1, and N-to-N relations account for 79.58% of the total in $\text{DWY100K}_{\text{YG}}$, while 60.05% in $\text{DBP15K}_{\text{ZH-EN}}$. The introduced knowledge embedding model is based on TransE, lacking the ability of modeling complex relationships (e.g., 1-to-N, N-to-1, and N-to-N relations). When there are too many complex relationships in the datasets, it brings more decrement rather than improvement to the results. To ease this situation, we can use a stronger representation model for complex relationships, such as TransR (Lin et al., 2015). We leave this for future work.

4.4.2 Effectiveness of Nearest Neighbor Sampling

In Table 2, it can be seen that KECG(w/o NNS) outperforms many baselines and its Hits@1 on

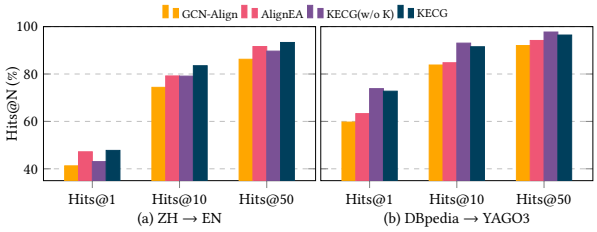

Figure 3: Detailed Hits@N for investigating the effectiveness of Knowledge Embedding Model.

$\text{DBP15K}_{\text{FR-EN}}$ reaches 39.30%, which is higher than another graph-based method GCN-Align by 2.01%. But the Hits@1 of KECG(w/o NNS) is lower than GCN-Align's by approximately 3% on DWY100K. It is because DWY100K has a larger number of triplets, while the number of relations is relatively small. Involving the representation of complex relationships will introduce noise and affect the performance of the cross-graph model. After employing the nearest neighbor sampling strategy in cross-graph model, KECG considerably improves the results of KECG(w/o NNS), e.g., Hits@1 on $\text{DWY100K}_{\text{WD}}$ is raised from 46.95% to 63.23%. The excellent performance of nearest neighbor sampling owing to its accurately discriminating the target entity from other close entities, especially on large-scale datasets.

4.4.3 Sensitivity to Proportion of Prior Alignment

To investigate whether KECG is sensitive to the proportion of pre-aligned entities, we vary the proportion from 10% to 50% with step 10% for training, and use the rest of pre-aligned entities for testing. Intuitively, more pre-aligned entities should provide more information to discover the potential pairs of equivalent entities.

Figure 4 illustrates the changes in Hits@1 and Hits@10 of KECG, AlignEA and GCN-Align on all datasets. As expected, the results of all methods become better with the increase in proportion. Given half of the prior alignment like 50%, all three methods get close and satisfactory Hits@1. When given a very small proportion of prior alignment like 10%, the results of AlignEA and GCN-Align decrease enormously, but our KECG still achieves outstanding results. Therefore, KECG works well on entity alignment even with a limited number of prior alignment.

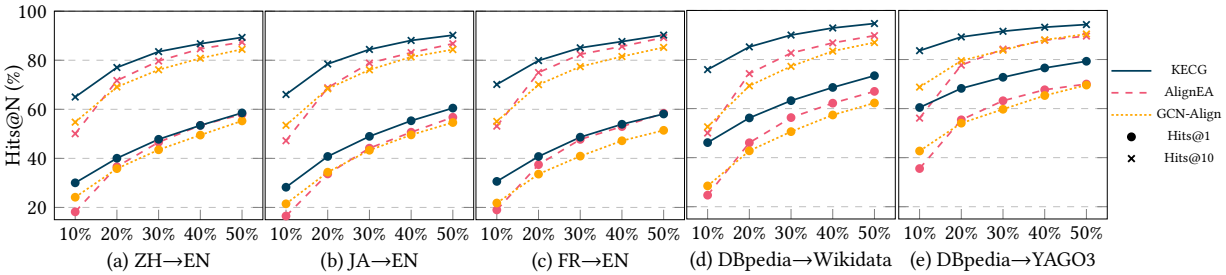

Figure 4: Hits@N of KECG, AlignEA and GCN-Align on entity alignment w.r.t. proportion of prior alignment.(The x-axis represents the proportion of prior alignment.)

5 Related Work

5.1 KG Embedding

Various KG embedding methods have shown effectiveness in modeling the semantic information of KGs. TransE (Bordes et al., 2013) is a milestone in learning embeddings for KGs, which interprets a relation as the translation from its head entity to its tail entity. Then it motivated several enhanced methods like TransR (Lin et al., 2015). In addition to them, non-translational methods also achieve satisfactory performances, such as RESCAL (Nickel et al., 2011), ConvE (Dettmers et al., 2018) and RotatE (Sun et al., 2019). Meanwhile, external information in KGs is fused to improve embedding (Wang and Li, 2016). More detailed KG embedding methods are summarized in (Wang et al., 2017).

5.2 Entity Alignment

Early human efforts, such as crowdsourcing and hand-crafted features (Lehmann et al., 2015; Mahdisoltani et al., 2013), are utilized to address the entity alignment problem. Though reaching high precisions, they are usually time-consuming and costly. Many automated approaches leverage the extra resources, such as OWL properties and Wikipedia links (Hu et al., 2011; Wang et al., 2013) to align entities, but such extra information is not generally available for all KGs.

Recently, KG embedding-based approaches become the most popular solution for entity alignment. JE (Hao et al., 2016) is an early work to jointly embed different KGs into a uniform vector space to align entities in KGs. MTransE (Chen et al., 2017) learns transitions to translate each entity embedding vector to its counterparts in another space. JAPE (Sun et al., 2017) jointly trains the attribute embedding and structure embedding by a skip-gram model and a translational model, respectively, to align entities. GCN-Align (Wang et al., 2018) is a new graph-based model aligning KGs via GCN. It takes advantage of GCN to propagate information from neighbors, and align entity embeddings enhanced by structural knowledge. However, GCN-Align only considers the equivalent relations between entities in model training, neglecting the use of abundant relationships in KGs to precisely distinguish entities with similar neighbors. At the same time, iterative alignment becomes a new fashion to improve the results of entity alignment. IPTransE (Zhu et al., 2017) and BootEA (Sun et al., 2018) integrate knowledge among different KGs by enlarging the training data (prior alignments) in a bootstrapping way. KDCoE (Chen et al., 2018) iteratively co-trains multilingual KG embeddings and fuses them with entity description information for alignment. The aforementioned iterative methods improve the results mainly by increasing the number of pre-align entity pairs while training, and such a strategy can be a general enhancement for most alignment approaches (Sun et al., 2018). A better non-iterative method should achieve better results through bootstrap. Therefore, we are more concerned with the best result that a non-iterative method can achieve.

6 Conclusions

In this paper, we propose a semi-supervised entity alignment method KECG that combines the knowledge embedding model and graph-based model. We utilize an extended GAT to encode heterogeneous KGs and perform entity alignment by propagating alignment information over the entire graphs. Meanwhile, the KG learning is involved to model different relation types, making entities more distinguishable. Experimental results show that KECG significantly outperforms four state-of-the-art baselines.

For future work, we will extend the knowledge

embedding model of KECG to other KG representation learning methods, such as TransD (Ji et al., 2015), to gain a stronger ability of modeling relationships. Besides, iteratively discovering new entity alignments based on the framework of KECG is another interesting direction.

Designing and Interpreting Probes with Control Tasks

Abstract

Probes, supervised models trained to predict properties (like parts-of-speech) from representations (like ELMo), have achieved high accuracy on a range of linguistic tasks. But does this mean that the representations encode linguistic structure or just that the probe has learned the linguistic task? In this paper, we propose *control tasks*, which associate word types with random outputs, to complement linguistic tasks. By construction, these tasks can only be learned by the probe itself. So a good probe, (one that reflects the representation), should be *selective*, achieving high linguistic task accuracy and low control task accuracy. The selectivity of a probe puts linguistic task accuracy in context with the probe's capacity to memorize from word types. We construct control tasks for English part-of-speech tagging and dependency edge prediction, and show that popular probes on ELMo representations are not selective. We also find that dropout, commonly used to control probe complexity, is ineffective for improving selectivity of MLPs, but that other forms of regularization are effective. Finally, we find that while probes on the first layer of ELMo yield slightly better part-of-speech tagging accuracy than the second, probes on the second layer are substantially more selective, which raises the question of which layer better represents parts-of-speech.

1 Introduction

As large-scale unsupervised representations such as BERT and ELMo improve downstream performance on a wide range of natural language tasks (Devlin et al., 2019; Peters et al., 2018a; Radford et al., 2019), what these models learn about language remains an open scientific question. An emerging body of work investigates this question through *probes*, supervised models trained to predict a property (like parts-of-speech) from a constrained view of the representation. Probes trained on various representations have obtained high accuracy on tasks requiring part-of-speech and morphological information (Belinkov et al., 2017), syntactic and semantic information (Peters et al., 2018b; Tenney et al., 2019), among other properties (Conneau et al., 2018), providing evidence that deep representations trained on large datasets are predictive of a broad range of linguistic properties.

Sentence 1	The	cat	ran	quickly	.
Part-of-speech	DT	NN	VBD	RB	.
Control task	10	37	10	15	3
Sentence 2	The	dog	ran	after	!
Part-of-speech	DT	NN	VBD	IN	.
Control task	10	15	10	42	42

Figure 1: Our control tasks define random behavior (like a random output, top) for each word type in the vocabulary. Each word token is assigned its type's output, regardless of context (middle, bottom.) Control tasks have the same input and output space as a linguistic task (e.g., parts-of-speech) but can only be learned if the probe memorizes the mapping.

But when a probe achieves high accuracy on a linguistic task using a representation, can we conclude that the representation encodes linguistic structure, or has the probe just learned the task? Probing papers tend to acknowledge this uncertainty, putting accuracies in context using random representation baselines (Zhang and Bowman, 2018) and careful task design (Hupkes et al., 2018). Even so, as long as a representation is a lossless encoding, a sufficiently expressive probe with enough training data can learn *any* task on top of it.

In this paper, we propose *control tasks*, which associate word types with random outputs, to give intuition for the expressivity of probe families and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2733–2743,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

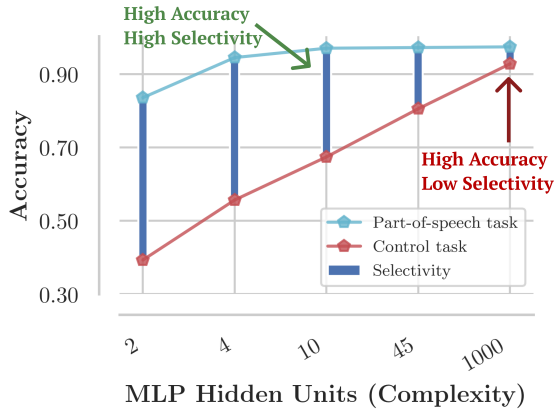

Figure 2: Selectivity is defined as the difference between linguistic task accuracy and control task accuracy, and can vary widely, as shown, across probes which achieve similar linguistic task accuracies. These results taken from § 3.5.

provide insight into how representation and probe interact to achieve high task accuracy.

Control tasks are based on the intuition that the more a probe is able to make task output decisions independently of the linguistic properties of a representation, the less its accuracy on a linguistic task necessarily reflects the properties of the representation. Thus, a good probe (one that provides insights into the linguistic properties of a representation) should be what we call *selective*, achieving high linguistic task accuracy and low control task accuracy (see Figure 2).

We show that selectivity can be a guide in designing probes and interpreting probing results, complementary to random representation baselines; as of now, there is little consensus on how to design probes. Early probing papers used linear functions (Shi et al., 2016; Ettinger et al., 2016; Alain and Bengio, 2016), which are still used (Bisazza and Tump, 2018; Liu et al., 2019), but multi-layer perceptron (MLP) probes are at least as popular (Belinkov et al., 2017; Conneau et al., 2018; Adi et al., 2017; Tenney et al., 2019; Ettinger et al., 2018). Arguments have been made for "simple" probes, e.g., that we want to find easily accessible information in a representation (Liu et al., 2019; Alain and Bengio, 2016). As a counterpoint though, "complex" MLP probes have also been suggested since useful properties might be encoded non-linearly (Conneau et al., 2018), and they tend to report similar trends to simpler probes anyway (Belinkov et al., 2017; Qian et al., 2016).

We define control tasks corresponding to English part-of-speech tagging and dependency edge prediction, and use ELMo representations to conduct a broad study of probe families, hyperparameters, and regularization methods, evaluating both linguistic task accuracy and selectivity. We propose that selectivity be used for building intuition about the expressivity of probes and the properties of models, putting probing accuracies into richer context. We find that:

1. With popular hyperparameter settings, MLP probes achieve very low selectivity, suggesting caution in interpreting how their results reflect properties of representations. For example, on part-of-speech tagging, 97.3 accuracy is achieved, compared to 92.8 control task accuracy, resulting in 4.5 selectivity.

2. Linear and bilinear probes achieve relatively high selectivity across a range of hyperparameters. For example, a linear probe on part-of-speech tagging achieves a similar 97.2 accuracy, and 71.2 control task accuracy, for 26.0 selectivity. This suggests that the small accuracy gain of the MLP may be explained by increased probe expressivity.

3. The most popular method for controlling probe complexity, dropout, does not consistently lead to selective MLP probes. However, control of MLP complexity through unintuitively small (10-dimensional) hidden states, as well as small training sample sizes and weight decay, lead to higher selectivity and similar linguistic task accuracy.

Finally, we ask, *can we meaningfully compare the linguistic properties of layers of a model using only linguistic task accuracy*? We raise a potential problem with this approach: it fails to take into account differences in ease of memorization across layers. In particular, we find that while linear and MLP probes on the first layer of ELMo (ELMo1) achieve slightly higher part-of-speech accuracy than those on the second layer (ELMo2), (97.2 compared to 96.6, for a loss of 0.6), the same probes achieve much greater selectivity on ELMo2 (31.4 compared to 26.0, for a gain of 5.4). Thus, the difference in selectivity in favor of ELMo2 is much greater than the commonly known (Peters et al., 2018a; Liu et al., 2019) difference in linguistic task accuracy in favor of ELMo1; the difference in accuracy may be explained by probes more easily accessing word identity features in ELMo1.

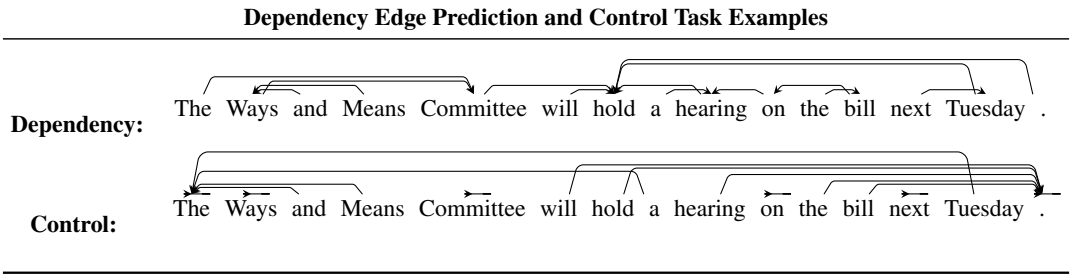

Figure 3: Example dependency tree from the development set of the Penn Treebank with dependents pointing at heads, and the structure resulting from our dependency edge prediction control task on the same sentence.

2 Control Tasks

In this section, we describe how to construct control tasks. At a high level, control tasks have:

structure: The output for a word token is a deterministic function of the word type[1].

randomness: The output for each word type is sampled independently at random.

We start with some notation; denote as $1:T$ the sequence of integers $\{1, ..., T\}$. Let V be the vocabulary containing all word types in a corpus. A sentence of length T is $\mathbf{x}_{1:T}$, where each $x_i \in V$, and the word representations of the model being probed are $\mathbf{h}_{1:T}$, where $h_i \in \mathbb{R}^d$. A *task* is a function that maps a sentence to a single output per word, $f(\mathbf{x}_{1:T}) = \mathbf{y}_{1:T}$, where each output is from a finite set of outputs: $y_i \in \mathcal{Y}$. Each *control task* is defined in reference to a *linguistic task*, and the two share $\mathcal{Y}$. We'll now use part-of-speech tagging and dependency edge prediction as examples to describe the construction of control tasks.

2.1 Part-of-speech tagging control task

In part-of-speech tagging, the set $\mathcal{Y}$ is the tagset, $1:45$ (corresponding to NN, NNS, VB,...). To construct a control task, we independently sample a *control behavior* $C(v)$ for each $v \in V$. The control behavior specifies how to define $y_i \in \mathcal{Y}$ for a word token x_i with word type v. For part-of-speech tagging, each control behavior directly specifies the output y_i for x_i as an integer from $1:45$, so we sample from 45 behaviors[2]. The part-of-speech control task is the function that maps each token x_i to the label specified by the behavior $C(x_i)$:

$$f_{\text{control}}(\mathbf{x}_{1:T}) = f(C(x_1), C(x_2), ...C(x_T)). \quad (1)$$

This task is visualized in Figure 1.

[1]Equivalently, word identity.

[2]The exact distribution from which we sample isn't crucial, but for part-of-speech tagging, we sample from the empirical token distribution of part-of-speech tagging, so the marginal probability of each label is similar.

2.2 Dependency edge prediction control task

The dependency edge prediction task is the function $f_{\text{DEP}}(\mathbf{x}_{1:T}) = \mathbf{y}_{1:T}$ where y_i is the index of the parent of x_i in the dependency tree on the sentence $\mathbf{x}_{1:T}$. Thus, the output space $\mathcal{Y} = 1:T$ depends on the length of the sentence, T. To accommodate this in our control task, we define the control behaviors $C(v)$ in a length-independent way that still fully specifies y_i. The possible behaviors $C(v)$ are as follows:

attach to self: Always attach tokens of this type to themselves. That is, $y_i = i$.

attach to first: Always attach tokens of this type to the first token. That is, $y_i = 1$.

attach to last: Always attach tokens of this type to the last word in the sentence. That is, $y_i = T$.

We sample uniformly from the three. Given these behaviors, the control task is defined as before by Eqn 1. This task is visualized in Figure 3.

While very similar to dependency parsing, dependency edge prediction differs in two ways. The output is not constrained to be a tree for evaluation; each prediction is evaluated independently. So, while our control tasks do not define trees, the two tasks' output spaces are still the same. Second, in dependency edge prediction, the root of the sentence is omitted from evaluation; no sentence-external `ROOT` token is posited for evaluation.

2.3 Properties of control tasks

To summarize, a control task is defined for a single linguistic task, and shares the linguistic task's output space $\mathcal{Y}$. To construct a control task, a control behavior $C(v)$ is sampled independently at random for each word type $v \in V$. The control task is a function mapping $\mathbf{x}_{1:T}$ to a sequence of outputs $\mathbf{y}_{1:T}$ which is fully specified by the sequence of behaviors, $[C(x_1), ..., C(x_T)]$.

From this construction, we note that the ceiling on performance is the fraction of tokens in the evaluation set whose types occur in the training set (plus chance accuracy on all other tokens.) Further, $C(v)$ must be memorized independently for each word type, and a probe taking vectors $h_{1:T}$ as input must identify for each h_i its corresponding x_i, and output the element of $\mathcal{Y}$ specified by $C(x_i)$.

3 Experiments on Probe Selectivity

In this section, we conduct a broad study of probe families (e.g, linear, MLP) and hyperparameter choices (weight matrix rank/hidden state size, amount of regularization) on a single representation (ELMo1) to determine (1) what probe choices exhibit high linguistic task accuracy *and* high selectivity (and whether this holds for a range of hyperparameters), and (2) whether each probe family can be made selective through hyperparameter choices without substantially sacrificing linguistic task accuracy.

3.1 Probe families

We experiment with three types of probes per task.

For part-of-speech tagging, we experiment with linear, MLP-1, and MLP-2 probes. The linear probe is a multiclass model mapping h_i to $y_i \sim \text{softmax}(Ah_i + b)$. The MLP-1 probe is a multilayer perceptron with one hidden layer and ReLU nonlinearity defined as:

$$y_i \sim \text{softmax}(W_2\ g(W_1 h_i)). \quad (2)$$

And the MLP-2 probe is defined as:

$$y_i \sim \text{softmax}(W_3\ g(W_2\ g(W_1 h_i))). \quad (3)$$

where g is the ReLU function, and bias terms are omitted from all affine transformations for brevity.

For dependency edge prediction, we experiment with bilinear, MLP-1, and MLP-2 probes. These probes take as input the entire sequence $\mathbf{h}_{1:T}$ as well as the vector h_i of a given state to produce y_i; the softmax operates over the sequence to construct a distribution over the T classes. Formally, the bilinear model is defined as $y_i \sim \text{softmax}(\mathbf{h}_{1:T}^\top A h_i + b)$. The MLP-1 probe is defined as follows:

$$y_i \sim \text{softmax}(W_2\ g(W_1[\mathbf{h}_{1:T}; h_i])). \quad (4)$$

Note here that h_i broadcasts to $\mathbb{R}^{T\times d}$,while $W_1 \in \mathbb{R}^{\ell\times d}$, and $W_2 \in \mathbb{R}^{1\times \ell}$ broadcast as well. That is, each $[h_j; h_i]$ pair is mapped to a single scalar independently of all others, leading to T logits used as input to the softmax. Similarly, the MLP-2 model is defined as follows:

$$y_i \sim \text{softmax}(W_3\ g(W_2\ g(W_1[\mathbf{h}_{1:T}; h_i]))). \quad (5)$$

3.2 Complexity control

It is well-known that probes should not be too complex (Liu et al., 2019; Alain and Bengio, 2016); this is the motivation behind constraining the input to the probe to be a single vector or pair of vectors. However, there has been no systematic investigation of probe complexity. We study what complexity control is necessary to achieve selectivity. As we will see, the typical practice of regularizing to reduce the generalization gap (difference between training and test task accuracy) is insufficient if one is interested in selectivity.

Rank/hidden dimensionality constraint. For our linear and bilinear probes, we constrain the rank of weight matrices through an LR decomposition. We let $A \in \mathbb{R}^{k\times d}$, where k is the output space (45 for part-of-speech tagging; 1 for dependency head prediction). To constrain A to rank ℓ, we factor $A = LR$, where $L \in \mathbb{R}^{k\times\ell}$ and $R \in \mathbb{R}^{\ell\times|V|}$, and optimize over L and R. For MLP models, we let the hidden state size be equal to ℓ.[3]

From the default value of rank-1000 and 1000-dimensional hidden states, we let ℓ take on the values $\{2, 4, 10, 45\}$ for part-of-speech, and $\{5, 10, 50, 100\}$ for dependency edge prediction.[4]

Dropout. We apply dropout (Srivastava et al., 2014) with probability p to the input for linear and bilinear probes, and to the input and the output of each hidden layer for MLP probes. From the default value of 0, we let p range over $\{0.2, 0.4, 0.6, 0.8\}$.

Number of training examples. We artificially constrain the number of sentences the probe is trained on, with the intuition that general rules can be learned more sample-efficiently than memorization. Zhang and Bowman (2018) showed this to be an effective distinguishing factor between trained representations and random representation controls. From the default of 39832 (the number of training

[3] One could constrain the matrices of the MLP to be rank ℓ without making the hidden state smaller, but one must choose a hidden state size anyway, so we believed a study changing the hidden state size would be most informative.

[4] Note that for linear models, the rank is constrained by k regardless, since $A \in \mathbb{R}^{k\times d}$.

Probe	PoS	Ctl	Select.	Dep	Ctl	Select.
Probes with Default Hyperparameters						
Linear	97.2	71.2	26.0	-	-	-
Bilinear	-	-	-	89.0	82.4	6.6
MLP-1	97.3	92.8	4.5	92.3	93.0	-0.7
MLP-2	97.3	93.2	4.2	93.9	92.0	1.9
Probes with 0.4 Dropout						
Linear	97.1	67.3	29.8	-	-	-
Bilinear	-	-	-	90.4	73.7	16.7
MLP-1	97.5	93.4	4.1	93.8	93.1	0.7
MLP-2	97.4	94.1	3.4	94.7	93.5	1.3
Probes Designed with Control Tasks						
Linear	97.0	64.0	33.0	-	-	-
Bilinear	-	-	-	91.0	83.1	7.9
MLP-1	97.2	80.6	16.6	90.5	84.3	6.2
MLP-2	97.2	81.7	15.4	92.8	89.8	3.0

Table 1: Probe accuracies on linguistic tasks and control tasks. Default hyperparameters correspond to a hidden state of dimensionality 1000 and no dropout. Under Probes Designed with Control Tasks, we used selectivity to hand-pick a hyperparameter setting for each probe. In particular, part-of-speech probes designed with control tasks all use rank-10 weight matrices (10-dimensional hidden state) and no other changes. Dependency edge prediction probes designed with control tasks had, for the bilinear model, weight decay of 0.01, for MLP-1, weight decay of 0.1, for MLP-2, a rank-50 weight matrix.

examples in the dataset), we train on $\{4000, 400\}$ examples, corresponding to roughly 100%, 10%, and 1% of the total data, as suggested by Zhang and Bowman (2018).

L_2 regularization. We apply weight decay to the probe parameters. From the default of 0, we let the weight decay constant take on the values $\{0.01, 0.1, 1.0, 10.0\}$, unnormalized by batch size.

Early stopping. All of our probing models are trained with Adam (Kingma and Ba, 2014). By default, we anneal the learning rate by a factor of 0.5 each time an epoch does not lead to a new minimum loss on the development set, and stop training when 4 such epochs occur in a row. However, in early stopping, we explicitly halt training at a fixed number of gradient steps. From the default of 100000 (approximately 40 epochs), we let this maximum take on the values $\{50000, 25000, 12500, 6000, 3000, 1500\}$.

3.3 Dataset

We use the Penn Treebank (PTB) dataset (Marcus et al., 1993) with the traditional parsing training/development/testing splits[5] without preprocessing. We report accuracies on the development set. We convert the PTB constituency trees to the Stanford Dependencies formalism (de Marneffe et al., 2006) for our dependency edge prediction task.

[5]As given by the code of Qi and Manning (2017) at https://github.com/qipeng/arc-swift.

3.4 Representation

We use the 5.5 billion-word pre-trained ELMo representations (Peters et al., 2018a). Since the output of the first BiLSTM layer was recently shown to be the most transferrable on a wide variety of tasks, including part-of-speech and syntax (Liu et al., 2019), we focus on analyzing that layer, which we denote ELMo1.

3.5 Results

Selectivity of default hyperparameters. Our results with linear, bilinear, and MLP probes with "default" hyperparameters, as specified in § 3.2, are found in Table 1 (top). We find that linear probes achieve similar part-of-speech accuracies to MLPs (97.2 compared to 97.3) with substantially higher selectivity (26.0 vs 4.50). In dependency edge prediction, we find a definite gap between bilinear probe accuracy (89.0) and MLP-1 accuracy (92.3). However, the bilinear probe achieves 16.7 selectivity, compared to -0.7 by MLP-1 and 1.3 by MLP-2. Thus, with no regularization, modest gains in linguistic task accuracy through MLP probes over linear/bilinear probes are tempered by losses in selectivity. Bilinear and linear probes themselves show a significant capacity for memorization.

Does adding moderate regularization through dropout (e.g., $p = 0.4$) consistently lead to selectivity? Surprisingly, as shown in Table 1 (middle), the opposite is true for some MLP probes, where selectivity actually decreases (e.g., $4.2 \rightarrow 3.4$ for MLP-2). In one case, the MLP-1 probe on dependency edge prediction, dropout increases selectivity ($-0.7 \rightarrow 0.7$) but for no others.

How hard is it to find selective probes? We tried 6 methods for controlling probe complexity, and all worked except dropout and early stopping, though never for a broad range of hyperparameters. For each complexity control method except dropout and early stopping, we find hyperparameters that lead to high linguistic task accuracy and high selectivity. Our results are summarized in Figure 4.

We find that constraining the **hidden state dimensionality** of MLPs is an effective way to encourage selectivity at little cost to linguistic task

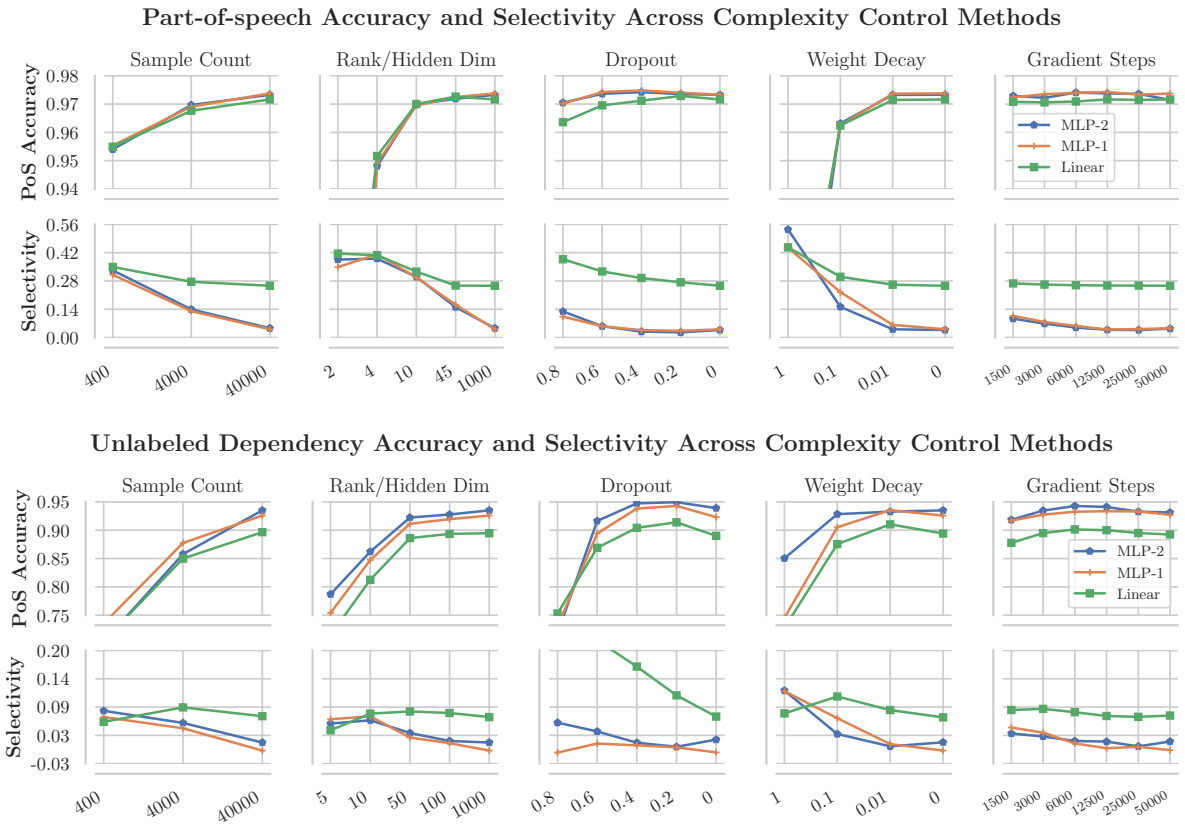

Figure 4: Linguistic task accuracies and selectivities for the 5 complexity control methods. All methods except dropout and early stopping are shown to improve selectivity without a large impact on linguistic task accuracy. All methods for the same task share a common y-axis, and use their own categorical x-axis. All x-axes are ordered from most severe constraints on complexity (left) to most laissez-faire (right).

accuracy. MLP hidden state sizes of 10 and 50, for part-of-speech tagging and dependency head prediction respectively, lead to increased selectivity while maintaining high linguistic task accuracy. As such, MLP probes with hundreds or 1000 hidden units, as is common, are overparameterized.

Constraining the **number of training examples** is effective for part-of-speech, suggesting that learning each linguistic task requires fewer samples than our control task. However, for dependency edge prediction, this leads to significantly reduced linguistic task accuracy. Finally, we find that the right **weight decay** constant can also lead to high-accuracy, high-selectivity probes, especially for dependency edge prediction. As shown, however, it is unclear what hyperparameters to use (e.g., weight decay 0.1) to achieve both high accuracy and high selectivity; that is, finding selective MLP probes is non-trivial.

Applying **dropout**, the most popular probing regularization method (Adi et al., 2017; Belinkov and Glass, 2019; Şahin et al., 2019; Kim et al., 2019; Elloumi et al., 2018; Belinkov and Glass, 2017; Belinkov et al., 2018) does not consistently lead to high-accuracy, high-selectivity MLP probes across a broad range of dropout probabilities ($p = 0.2$ to $p = 0.8$) on part-of-speech tagging. For dependency edge prediction, dropout of $p = 0.6$ improves the selectivity of MLP-2 but not MLP-1, and considerably increases the already relatively large selectivity of the bilinear probe. **Early stopping** in the ranges tested also has little impact on part-of-speech tagging, selectivity, but does improve selectivity of MLP dependency edge prediction probes.

From our study, we pick a set of hyperparameters for linear, bilinear, MLP-1 and MLP-2 probes to encourage selectivity and linguistic task accuracy together, to compare to default parameters and dropout. We chose rank constraints of 10 and 45, respectively (with no other changes,) for linear and MLP part-of-speech tagging probes, weight decay of 0.01 for the bilinear dependency probe, and weight decay of 0.1 for MLP dependency probes. We report the results of these probes in Table 1 (bottom). In all cases, we see that the right choice of probe leads to considerably higher selectivity than dropout or no regularization. In particular, for part-of-speech tagging, our chosen MLP-1

probe achieves 16.6 selectivity, up from 4.5, and on dependency head prediction, 6.2 selectivity, up from -0.7.

3.6 Discussion

Our most consistent result seems to be that all probes, whether linear, bilinear, or multi-layer perceptron, are over-parameterized and needlessly high-capacity if using defaults like full-rank weight matrices, hidden states with a few hundred dimensions, and moderate dropout. We can tell this is the case because we're able to heavily constrain the probes (e.g., to rank or 10-dimensional hidden states with little loss in accuracy.

We find that the most selective probes of those tested, even after careful complexity control, are linear or bilinear models. They also have the advantage that they exhibit high selectivity without the need to search over complexity control methods.

However, the most accurate probes on the more complex task of dependency edge prediction are MLPs, even with hyperparameters tuned for selectivity. This suggests that while much of the part-of-speech information of ELMo is extractable linearly, some information about syntactic trees is not available to a bilinear function. In some cases, therefore, one might opt for an MLP probe to extract non-linear features, while optimizing for selectivity through hyperparameter choices.

Errors in Selective and Non-Selective Probes Do selective and non-selective probes make different types of errors? We ran a qualitative study on this, training ten MLP-1 probes and ten linear probes, each with default parameters, on part-of-speech tagging. We then manually inspected their aggregate confusion matrices for trends in differences between the models' errors.

While the MLP performed marginally better at recognizing many categories, the plurality of improvement over the linear probe by far was in correctly identifying the difference between nouns and adjectives in phrases. For example,

> Kan.-based/JJ National/NNP Pizza/NNP
> rental/JJ equipment/NN

were correctly labeled by the MLP but not the linear probe, which incorrectly labeled the adjectives as nouns. As can be seen with the second example, the distinction between a *JJ NN* modified noun and a *NN NN* noun compound is quite subtle, and the MLP picks up on the distinction considerably better.

The linear probe, however, was substantially more accurate at predicting the NNP tag, which the MLP probe frequently mislabeled as NNPS. Manual inspection showed a general trend:

> Environmental/NNP Systems/NNP Co./NNP
> Cara/NNP Operations/NNP Co./NNP
> 7.8/CD %/NN stake/NN in/IN Dataproducts/NNP

In each case, the MLP probe mislabeled the word with the suffix *-s* as NNPS. The linear probe was considerably less prone to this error. We hypothesize that this is because the MLP probe is expressive enough to pick up on (spurious) markers of plurality as well as status as a proper noun independently and combine them, whereas the linear probe is less able to do so. If this hypothesis is true, then this serves as an example of how less selective probes may be less faithful in representing the linguistic information of the model being probed, since features may be combined to make fine-grained distinctions.

4 Selectivity Differences Confound Layer Comparisons

In this section, we use selectivity to shed light on confounding factors when comparing the linguistic capabilities of different representations. Multiple studies have found probes on ELMo1 to perform better at part-of-speech tagging than probes on ELMo2 (Peters et al., 2018a; Tenney et al., 2019; Liu et al., 2019). As we note, these results depend on the probe as well as the representation; given what we know about probes' capacity for memorizing at the type level, we explore an alternative to the hypothesis that ELMo1 has higher-quality part-of-speech representations than ELMo2. In particular, word identities are strong features in part-of-speech tagging when used in combination with other indicators; since ELMo1 is closer to the word representations than ELMo2, it may be easier to identify word identities from it, meaning the probe may utilize word identities more readily, as opposed to picking up on a representation of part-of-speech.

4.1 Experiments

We run experiments on the first and second contextual layers of ELMo, denoted ELMo1 and ELMo2.

We also examine the representations of an untrained BiLSTM run on the non-contextual character CNN word embeddings of ELMo, shown to be a strong baseline contextualization method, but without any linguistic knowledge learned from context (Zhang and Bowman, 2018; Hewitt and Manning, 2019). We denote this model Proj0.

We train linear and MLP-1 probes for part-of-speech tagging, and bilinear and MLP-1 probes for dependency edge prediction, all with default hyperparameters (§ 3.2). We examine both the linguistic task accuracy and selectivity achieved by each probe on each representation.

4.2 Results & Discussion

We find probes on ELMo2 to be strikingly more selective than those on ELMo1, consistent across all probes, both for part-of-speech tagging and dependency head prediction. In particular, the linear probe on ELMo2 achieves selectivity of 31.4, compared to selectivity of 26.0 for ELMo1, for a gain of 5.4. The same probe achieves 96.6 linguistic task accuracy on ELMo2 and 97.2 on ELMo1, for a loss of 0.6. The MLP probe shows roughly the same result. So, does ELMo1 have a better grasp of part-of-speech than ELMo2? Our results, summarized in Table 2, offer the alternative hypothesis that probes use word identity as a feature to predict part-of-speech, and that feature is less easily available in ELMo2 than ELMo1.

Probes on Proj0 and ELMo2 achieve similar part-of-speech tagging accuracy, echoing findings of (Zhang and Bowman, 2018), but we find that Proj0 is far less selective, suggesting that probes on ELMo2 rely far less on word identities than those on Proj0. Without considering selectivity, it might be thought that ELMo2 encodes nothing about part-of-speech, since it doesn't beat the Proj0 random representation baseline. Taking selectivity into account, we see that probes on ELMo2 are unable to rely on word identity features like those on Proj0, so to achieve high accuracy, they must rely on emergent properties of the representation.

Part-of-speech Tagging				
	Linear		MLP-1	
Model	Accuracy	Selectivity	Accuracy	Selectivity
Proj0	96.3	20.6	97.1	1.6
ELMo1	97.2	26.0	97.3	4.5
ELMo2	96.6	31.4	97.0	8.8
Dependency Edge Prediction				
	Bilinear		MLP-1	
Model	Accuracy	Selectivity	Accuracy	Selectivity
Proj0	79.9	-4.3	86.5	-9.0
ELMo1	89.7	6.7	92.5	-1.0
ELMo2	84.5	6.2	89.5	1.4

Table 2: Part-of-speech and dependency edge prediction probe accuracies and selectivities across three representations. ELMo1 and ELMo2 are the two contextual layers of ELMo, while Proj0 refers to an untrained BiLSTM contextualization of ELMo's non-contextual character CNN representations.

5 Related Work

Early work in probing, (also known as diagnostic classification (Hupkes et al., 2018),) extracted properties like parts-of-speech, gender, tense, and number from distributional word vector spaces like word2vec and GloVe (Mikolov et al., 2013; Pennington et al., 2014) using linear classifiers (Köhn, 2015; Gupta et al., 2015). Soon after, the investigation of intermediate layers of deep models using linear probes was introduced independently by Ettinger et al. (2016) and Shi et al. (2016) in NLP and Alain and Bengio (2016) in computer vision.

Since then, probing methods have varied as to whether they investigate whole-sentence properties like sentence length and word content using a sentence vector (Shi et al., 2016; Adi et al., 2017; Conneau et al., 2018), word properties like verb tense or part-of-speech using word vectors (Shi et al., 2016; Belinkov et al., 2017; Liu et al., 2019), or word-pair properties like syntactic relationships using pairs of vectors (Tenney et al., 2019; Hewitt and Manning, 2019). Probes have been used to make relative claims between models or components (Adi et al., 2017; Liu et al., 2019; Belinkov et al., 2017) or absolute claims about models above baselines. Probes have also been used to test hypotheses about the mechanisms by which models perform tasks (Hupkes et al., 2018; Giulianelli et al., 2018).

Previous work has made extensive use of control representations like non-contextual word embeddings or models with random weights (Belinkov et al., 2017; Tenney et al., 2019; Saphra and Lopez, 2019; Hewitt and Manning, 2019); our control tasks provide a complementary perspective, measuring a probe's ability to decode a random function from the representation of interest.

The most related work to ours is that of Zhang and Bowman (2018), who presented experiments for understanding the roles probe training sample size and memorization have on linguistic

task accuracy. They observed that untrained BiLSTM contextualizers achieved almost the same part-of-speech tagging accuracies as trained contextualizers, and found that by reducing the probe training set, the trained models could be shown to significantly outperform the untrained model. They evaluated which representations were easiest to memorize from by probing to predict nearby words, finding as we do that word identities are most easily available in untrained contextualizers' representations. They take this as evidence that gains in part-of-speech probing accuracy on the trained representations over the untrained representations are due to linguistic properties, not memorization. Our experiments with selectivity complement their results, finding among other things that even though untrained BiLSTMs are better for memorization than ELMo, there is still a striking capacity for memorization using ELMo when using high-capacity probes.

5.1 Random tasks

Zhang et al. (2017) defined completely random tasks related to Rademacher complexity (Bartlett and Mendelson, 2001) to understand the capacity of neural networks to overfit, showing that they are expressive enough to fit random noise, but still function as effective models. In our random control tasks, randomness is applied at the type-level rather than at the example-level, and are designed to have strong non-linguistic structure as opposed to absolutely no structure. While the tasks of Zhang et al. (2017) aid in understanding the expressivity of neural nets, our control tasks aid in understanding the expressivity of a probe model with respect to a specific linguistic task.

6 Conclusion

Through probing methods, it has been shown that a broad range of supervised learning tasks can be turned into tools for understanding the properties of contextual word representations (Conneau et al., 2018; Tenney et al., 2019). Alain and Bengio (2016) suggested we may think of probes as "thermometers used to measure the temperature simultaneously at many different locations". We instead emphasize the joint roles of representations and probes together in achieving high accuracy on a task; we suggest that probes be thought of as *craftspeople*; their performance depends not only on the materials they're given, but also on their expressivity.

To explore the relationship between representations, probes, and task accuracies, we defined control tasks, which by construction can only be learned by the probe itself. We've suggested that a probe which provides insights into the properties of the representation should be *selective*, achieving high linguistic task accuracy and low control task accuracy. Selectivity measures the probe's ability to make numerous output decisions independently of linguistic properties of the representation.

We've found that linear and bilinear models achieve higher selectivity at similar accuracy to MLP probes on part-of-speech tagging. MLP probes, achieving higher accuracy on the more complex task of dependency edge prediction, can be re-designed to achieve higher selectivity at a relatively small cost to dependency edge accuracy, but often not through dropout, the most popular MLP probe regularization method.

Finally, we showed how selectivity can be used to provide added context to probing results, demonstrating that marginal differences in part-of-speech tagging accuracy between ELMo1 and ELMo2 correspond to large differences in selectivity, and similarly, the even though ELMo2 achieves similar part-of-speech tagging accuracy to a random representation baseline, ELMo2 achieves it with much higher selectivity.

As probes are used increasingly to study representations, we hope that control tasks and selectivity, as diagnostic tools, can help us better interpret the results of these probes, ultimately leading us to better understand what is learned by these remarkably effective representations.

Reproducibility. All code, data, and experiments are available at `https://worksheets.codalab.org/worksheets/0xb0c351d6f1ac4c51b54f1023786bf6b2`.

Specializing Word Embeddings (for Parsing) by Information Bottleneck

Abstract

Pre-trained word embeddings like ELMo and BERT contain rich syntactic and semantic information, resulting in state-of-the-art performance on various tasks. We propose a very fast variational information bottleneck (VIB) method to nonlinearly compress these embeddings, keeping only the information that helps a discriminative parser. We compress each word embedding to either a discrete tag or a continuous vector. In the *discrete* version, our automatically compressed tags form an alternative tag set: we show experimentally that our tags capture most of the information in traditional POS tag annotations, but our tag sequences can be parsed more accurately at the same level of tag granularity. In the *continuous* version, we show experimentally that moderately compressing the word embeddings by our method yields a more accurate parser in 8 of 9 languages, unlike simple dimensionality reduction.

1 Introduction

Word embedding systems like BERT and ELMo use spelling and context to obtain contextual embeddings of word tokens. These systems are trained on large corpora in a task-independent way. The resulting embeddings have proved to then be useful for both syntactic and semantic tasks, with different layers of ELMo or BERT being somewhat specialized to different kinds of tasks (Peters et al., 2018b; Goldberg, 2019). State-of-the-art performance on many NLP tasks can be obtained by fine-tuning, i.e., back-propagating task loss all the way back into the embedding function (Peters et al., 2018a; Devlin et al., 2018).

In this paper, we explore what task-specific information appears in the embeddings *before* fine-tuning takes place. We focus on the task of dependency parsing, but our method can be easily extended to other syntactic or semantic tasks. Our method compresses the embeddings by extracting just their syntactic properties—specifically, the information needed to reconstruct parse trees (because that is our task). Our nonlinear, stochastic compression function is explicitly trained by variational information bottleneck (VIB) to forget task-irrelevant information. This is reminiscent of canonical correspondence analysis (Anderson, 2003), a method for reducing the dimensionality of an input vector so that it remains predictive of an output vector, although we are predicting an output tree instead. However, VIB goes beyond mere dimensionality reduction to a fixed lower dimensionality, since it also avoids unnecessary *use* of the dimensions that are available in the compressed representation, blurring unneeded capacity via randomness. The effective number of dimensions may therefore vary from token to token. For example, a parser may be content to know about an adjective token only that it is adjectival, whereas to find the dependents of a verb token, it may need to know

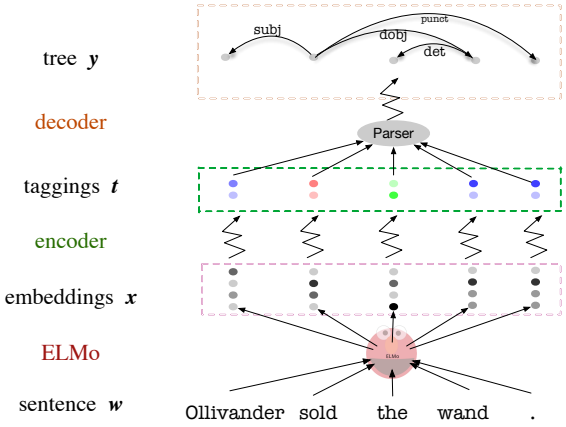

Figure 1: Our instantiation of the information bottleneck, with bottleneck variable T. A jagged arrow indicates a stochastic mapping, i.e. the jagged arrow points from the parameters of a distribution to a sample drawn from that distribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2744–2754, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the verb's number and transitivity, and to attach a preposition token, it may need to know the identity of the preposition.

We try compressing to both discrete and continuous task-specific representations. Discrete representations yield an interpretable clustering of words. We also extend information bottleneck to allow us to control the contextual specificity of the token embeddings, making them more like type embeddings.

This specialization method is complementary to the previous fine-tuning approach. Fine-tuning introduces *new* information into word embeddings by backpropagating the loss, whereas the VIB method learns to exploit the *existing* information found by the ELMo or BERT language model. VIB also has less capacity and less danger of overfitting, since it fits fewer parameters than fine-tuning (which in the case of BERT has the freedom to adjust the embeddings of all words and word pieces, even those that are rare in the supervised fine-tuning data). VIB is also very fast to train on a single GPU.

We discover that our syntactically specialized embeddings are predictive of the gold POS tags in the setting of few-shot-learning, validating the intuition that a POS tag summarizes a word token's *syntactic* properties. However, our representations are tuned explicitly for discriminative parsing, so they prove to be even more useful for this task than POS tags, even at the same level of granularity. They are also more useful than the uncompressed ELMo representations, when it comes to generalizing to test data. (The first comparison uses discrete tags, and the second uses continuous tags.)

2 Background: Information Bottleneck

The information bottleneck (IB) method originated in information theory and has been adopted by the machine learning community as a training objective (Tishby et al., 2000) and a theoretical framework for analyzing deep neural networks (Tishby and Zaslavsky, 2015).

Let X represent an "input" random variable such as a sentence, and Y represent a correlated "output" random variable such as a parse. Suppose we know the joint distribution $p(X, Y)$. (In practice, we will use the empirical distribution over a sample of (x, y) pairs.) Our goal is to learn a stochastic map $p_\theta(t \mid x)$ from X to some compressed representation T, which in our setting will be something like a tag sequence. IB seeks to minimize

$$\mathcal{L}_{IB} = -\,\mathrm{I}(Y;T) + \beta \cdot \mathrm{I}(X;T) \qquad (1)$$

where $\mathrm{I}(\cdot;\cdot)$ is the mutual information.[1] A low loss means that T does not retain very much information about X (the second term), while still retaining enough information to predict Y.[2] The balance between the two MI terms is controlled by a Lagrange multiplier β. By increasing β, we increase the pressure to keep $\mathrm{I}(X;T)$ small, which "narrows the bottleneck" by favoring compression over predictive accuracy $\mathrm{I}(Y;T)$. Regarding β as a Lagrange multiplier, we see that the goal of IB is to maximize the predictive power of T subject to some constraint on the amount of information about X that T carries. If the map from X to T were deterministic, then it could lose information only by being non-injective: the traditional example is dimensionality reduction, as in the encoder of an encoder-decoder neural net. But IB works even if T can take values throughout a high-dimensional space, because the randomness in $p_\theta(t \mid x)$ means that T is noisy in a way that wipes out information about X. Using a high-dimensional space is desirable because it permits the amount of effective dimensionality reduction to vary, with T perhaps retaining much more information about some x values than others, as long as the *average* retained information $\mathrm{I}(X;T)$ is small.

3 Formal Model

In this paper, we extend the original IB objective (1) and add terms $\mathrm{I}(T_i; X|\hat{X}_i)$ to control the context-sensitivity of the extracted tags. Here T_i is the tag associated with the ith word, X_i is the ELMo token embedding of the ith word, and $\hat{X}_i$ is the same word's ELMo type embedding (before context is incorporated).

$$\mathcal{L}_{IB} = -\,\mathrm{I}(Y;T) + \beta\,\mathrm{I}(X;T) + \gamma \sum_{i=1}^{n} \mathrm{I}(T_i; X|\hat{X}_i) \quad (2)$$

In this section, we will explain the motivation for the additional term and how to efficiently estimate variational bounds on all terms (lower bound for $\mathrm{I}(Y;T)$ and upper bound for the rest).[3]

[1] In our IB notation, larger β means more compression. Note that there is another version of IB that puts β as the coefficient in front of $\mathrm{I}(Y;T)$: $\mathcal{L}_{IB} = -\beta \cdot \mathrm{I}(Y;T) + \mathrm{I}(X;T)$ The two versions are equivalent.

[2] Since T is a stochastic function of X with no access to Y, it obviously cannot convey more information about Y than the uncompressed input X does. As a result, Y is independent of T given X, as in the graphical model $T \to X \to Y$.

[3] Traditional Shannon entropy $\mathrm{H}(\cdot)$ is defined on discrete variables. In the case of continuous variables, we interpret H

We instantiate the variational IB (VIB) estimation method (Alemi et al., 2016) on our dependency parsing task, as illustrated in Figure 1. We compress a sentence's word embeddings X_i into continuous vector-valued tags or discrete tags T_i ("encoding") such that the tag sequence T retains maximum ability to predict the dependency parse Y ("decoding"). Our chosen architecture compresses each X_i independently using the same stochastic, information-losing transformation.

The IB method introduces the new random variable T, the tag sequence that compresses X, by defining the conditional distribution $p_\theta(t \mid x)$. In our setting, p_θ is a stochastic tagger, for which we will adopt a parametric form (§3.1 below). Its parameters θ are chosen to minimize the IB objective (2). By IB's independence assumption,[2] the joint probability can be factored as $p_\theta(x, y, t) = p(x) \cdot p(y \mid x) \cdot p_\theta(t \mid x)$.

3.1 $\mathrm{I}(X;T)$ — the Token Encoder $p_\theta(t \mid x)$

Under this distribution, $\mathrm{I}(X;T) \stackrel{\text{def}}{=} \mathbb{E}_{x,t}\left[\log \frac{p_\theta(t|x)}{p_\theta(t)}\right] = \mathbb{E}_x\left[\mathbb{E}_{t\sim p_\theta(t|x)}\left[\log \frac{p_\theta(t|x)}{p_\theta(t)}\right]\right]$. Making this term small yields a representation T that, on average, retains little information about X. The outer expectation is over the true distribution of sentences x; we use an empirical estimate, averaging over the unparsed sentences in a dependency treebank. To estimate the inner expectation, we could sample, drawing taggings t from $p_\theta(t \mid x)$.

We must also compute the quantities within the inner brackets. The $p_\theta(t \mid x)$ term is defined by our parametric form. The troublesome term is $p_\theta(t) = \mathbb{E}_{x'}\left[p_\theta(t \mid x')\right]$, since even estimating it from a treebank requires an inner loop over treebank sentences x'. To avoid this, variational IB replaces $p_\theta(t)$ with some variational distribution $r_\psi(t)$. This can only increase our objective function, since the difference between the variational and original versions of this term is a KL divergence and hence non-negative:

$$\overbrace{\mathop{\mathbb{E}}_{x}\Big[\mathop{\mathbb{E}}_{t\sim p_\theta(t|x)}\Big[\log \frac{p_\theta(t|x)}{r_\psi(t)}\Big]\Big]}^{\text{upper bound}} - \overbrace{\mathop{\mathbb{E}}_{x}\Big[\mathop{\mathbb{E}}_{t\sim p_\theta(t|x)}\Big[\log \frac{p_\theta(t \mid x)}{p_\theta(t)}\Big]\Big]}^{\mathrm{I}(X;T)}$$
$$= \mathop{\mathbb{E}}_{x}\left[\mathrm{KL}(p_\theta(t) \mid\mid r_\psi(t))\right] \geq 0$$

Thus, the variational version (the first term above) is indeed an upper bound for $\mathrm{I}(X;T)$ (the second term above). We will minimize this upper bound by adjusting not only θ but also ψ, thus making the bound as tight as possible given θ. Also we will no longer need to sample t for the inner expectation of the upper bound, $\mathbb{E}_{t\sim p_\theta(t|x)}\left[\log \frac{p_\theta(t|x)}{r_\psi(t)}\right]$, because this expectation equals $\mathrm{KL}[p_\theta(t \mid x) \mid\mid r_\psi(t)]$, and we will define the parametric p_θ and r_ψ so that this KL divergence can be computed exactly: see §4.

3.2 Two Token Encoder Architectures

We choose to define $p_\theta(t \mid x) = \prod_{i=1}^{n} p_\theta(t_i \mid x_i)$. That is, our stochastic encoder will compress each word x_i individually (although x_i is itself a representation that depends on context): see Figure 1. We make this choice not for computational reasons—our method would remain tractable even without this—but because our goal in this paper is to find the syntactic information in each individual ELMo token embedding (a goal we will further pursue in §3.3 below).

To obtain continuous tags, define $p_\theta(t_i \mid x_i)$ such that $t_i \in \mathbb{R}^d$ is Gaussian-distributed with mean vector and diagonal covariance matrix computed from the ELMo word vector x_i via a feedforward neural network with $2d$ outputs and no transfer function at the output layer. To ensure positive semidefiniteness of the diagonal covariance matrix, we squared the latter d outputs to obtain the diagonal entries.[4]

Alternatively, to obtain discrete tags, define $p_\theta(t_i \mid x_i)$ such that $t_i \in \{1, \ldots, k\}$ follows a softmax distribution, where the k softmax parameters are similarly computed by a feedforward network with k outputs and no transfer function at the output layer.

We similarly define $r_\psi(t) = \prod_{i=1}^{n} r_\psi(t_i)$, where ψ directly specifies the $2d$ or k values corresponding to the output layer above (since there is no input x_i to condition on).

3.3 $\mathrm{I}(T_i; X|\hat{X}_i)$ — the Type Encoder $s_\xi(t_i|\hat{x}_i)$

While the IB objective (1) asks each tag t_i to be informative about the parse Y, we were concerned that it might not be interpretable as a tag of word i specifically. Given ELMo or any other black-box conversion of a length-n sentence to a sequence of contextual vectors $x_1, \ldots, x_n$, it is possible that x_i

to instead denote differential entropy (which would be $-\infty$ for discrete variables). Scaling a continuous random variable affects its differential entropy—but not its mutual information with another random variable, which is what we use here.

[4] Our restriction to diagonal covariance matrices follows Alemi et al. (2016). In pilot experiments that dropped this restriction, we found learning to be numerically unstable, although that generalization is reasonable in principle.

contains not only information about word i but also information describing word $i+1$, say, or the syntactic constructions in the vicinity of word i. Thus, while $p_\theta(t_i \mid x_i)$ might extract some information from x_i that is very useful for parsing, there is no guarantee that this information came from word i and not its neighbors. Although we *do* want tag t_i to consider context—e.g., to distinguish between noun and verb uses of word i—we want "most" of t_i's information to come from word i itself. Specifically, it should come from ELMo's level-0 embedding of word i, denoted by $\hat{x}_i$—a word *type* embedding that does *not* depend on context.

To penalize T_i for capturing "too much" contextual information, our modified objective (2) adds a penalty term $\gamma \cdot \mathrm{I}(T_i; X|\hat{X}_i)$, which measures the amount of information about T_i given by the sentence X as a whole, beyond what is given by $\hat{X}_i$: $\mathrm{I}(T_i; X \mid \hat{X}_i) \stackrel{\text{def}}{=} \mathbb{E}_x\left[\mathbb{E}_{t_i \sim p_\theta(t_i|x)}\left[\log \frac{p_\theta(t_i|x)}{p_\theta(t_i|\hat{x}_i)}\right]\right]$. Setting $\gamma > 0$ will reduce this contextual information.

In practice, we found that $\mathrm{I}(T_i; X \mid \hat{X}_i)$ was small even when $\gamma = 0$, on the order of 3.5 nats whereas $\mathrm{I}(T_i; X)$ was 50 nats. In other words, the tags extracted by the classical method were already fairly local, so increasing γ above 0 had little qualitative effect. Still, γ might be important when applying our method to ELMo's competitors such as BERT.

We can derive an upper bound on $\mathrm{I}(T_i; X|\hat{X}_i)$ by approximating the conditional distribution $p_\theta(t_i \mid \hat{x}_i)$ with a variational distribution $s_\xi(t_i \mid \hat{x}_i)$, similar to §3.1.

$$\overbrace{\mathop{\mathbb{E}}_{x}\Big[\mathop{\mathbb{E}}_{t_i \sim p_\theta(t_i|x)}\Big[\log \frac{p_\theta(t_i|x)}{s_\xi(t_i|\hat{x}_i)}\Big]\Big]}^{\text{upper bound}} - \overbrace{\mathop{\mathbb{E}}_{x}\Big[\mathop{\mathbb{E}}_{t_i \sim p_\theta(t_i|x)}\Big[\log \frac{p_\theta(t_i|x)}{p_\theta(t_i|\hat{x}_i)}\Big]\Big]}^{\mathrm{I}(T_i;X|\hat{X}_i)}$$
$$= \mathop{\mathbb{E}}_{x}\left[\mathrm{KL}(p_\theta(t_i \mid \hat{x}_i) \mid\mid s_\xi(t_i \mid \hat{x}_i))\right] \geq 0$$

We replace it in (2) with this upper bound, which is equal to $\mathbb{E}_x\left[\sum_{i=1}^n \mathrm{KL}[p_\theta(t_i|x) \mid\mid s_\xi(t_i \mid \hat{x}_i)]\right]$.

The formal presentation above does not assume the specific factored model that we adopted in §3.2. When we adopt that model, $p_\theta(t_i \mid x)$ above reduces to $p_\theta(t_i \mid x_i)$—but our method in this section still has an effect, because x_i still reflects the context of the full sentence whereas $\hat{x}_i$ does not.

Type Encoder Architectures Notice that $s_\xi(t_i \mid \hat{x}_i)$ may be regarded as a type encoder, with parameters ξ that are distinct from the parameters θ of our token encoder $p_\theta(t_i \mid x_i)$. Given a choice of neural architecture for $p_\theta(t_i \mid x_i)$ (see §3.2), we always use the same architecture for $s_\xi(t_i \mid \hat{x}_i)$, except that p_θ takes a token vector as input whereas s_ξ takes a context-independent type vector. s_ξ is not used at test time, but only as part of our training objective.

3.4 $\mathrm{I}(Y;T)$ — the Decoder $q_\phi(y \mid t)$

Finally, $\mathrm{I}(Y;T) \stackrel{\text{def}}{=} \mathbb{E}_{y,t\sim p_\theta}\left[\log \frac{p_\theta(y|t)}{p(y)}\right]$. The $p(y)$ can be omitted during optimization as it does not depend on θ. Thus, making $\mathrm{I}(Y;T)$ large tries to obtain a high log-probability $p_\theta(y \mid t)$ for the true parse y when reconstructing it from t alone.

But how do we compute $p_\theta(y \mid t)$? This quantity effectively marginalizes over possible sentences x that *could have* explained t. Recall that p_θ is a joint distribution over x, y, t: see just above §3.1. So $p_\theta(y \mid t) \stackrel{\text{def}}{=} \frac{\sum_x p_\theta(x,y,t)}{\sum_{x,y'} p_\theta(x,y',t)}$. To estimate these sums accurately, we would have to identify the sentences x that are most consistent with the tagging t (that is, $p(x) \cdot p_\theta(t|x)$ is large): these contribute the largest summands, but might not appear in any corpus.

To avoid this, we replace $p_\theta(y \mid t)$ with a variational approximation $q_\phi(y \mid t)$ in our formula for $\mathrm{I}(Y;T)$. Here $q_\phi(\cdot \mid \cdot)$ is a tractable conditional distribution, and may be regarded as a stochastic parser that runs on a compressed tag sequence t instead of a word embedding sequence x. This modified version of $\mathrm{I}(Y;T)$ forms a lower bound on $\mathrm{I}(Y;T)$, for any value of the variational parameters ϕ, since the difference between them is a KL divergence and hence positive:

$$\overbrace{\mathop{\mathbb{E}}_{y,t\sim p_\theta}\left[\log \frac{p_\theta(y|t)}{p(y)}\right]}^{\mathrm{I}(Y;T)} - \overbrace{\mathop{\mathbb{E}}_{y,t\sim p_\theta}\left[\log \frac{q_\phi(y|t)}{p(y)}\right]}^{\text{lower bound}}$$
$$= \mathop{\mathbb{E}}_{t\sim p_\theta}\left[\mathrm{KL}(p_\theta(y \mid t) \mid\mid q_\phi(y \mid t))\right] \geq 0$$

We will maximize this lower bound of $\mathrm{I}(Y;T)$ with respect to both θ and ϕ. For any given θ, the optimal ϕ minimizes the expected KL divergence, meaning that q_ϕ approximates p_θ well.

More precisely, we again drop $p(y)$ as constant and then maximize a *sampling-based estimate* of $\mathbb{E}_{y,t\sim p_\theta}\left[\log q_\phi(y|t)\right]$. To sample y, t from the joint $p_\theta(x, y, t)$ we must first sample x, so we rewrite as $\mathbb{E}_{x,y}\left[\mathbb{E}_{t\sim p_\theta(t|x)}\left[\log q_\phi(y|t)\right]\right]$. The outer expectation $\mathbb{E}_{x,y}$ is estimated as usual over a training treebank. The expectation $\mathbb{E}_{t\sim p_\theta(t|x)}$ recognizes that t is stochastic, and again we estimate it by sampling. In short, when t is a stochastic compression of a treebank sentence x, we would like our variational parser *on average* to assign high log-probability $q_\phi(y \mid t)$ to its treebank parse y.

Decoder Architecture We use the deep biaffine dependency parser (Dozat and Manning, 2016) as our variational distribution $q_\phi(y \mid t)$, which functions as the decoder. This parser uses a Bi-LSTM to extract features from compressed tags or vectors and assign scores to each tree edge, setting $q_\phi(y \mid t)$ proportional to the exp of the total score of all edges in y. During IB training, the code[5] computes only an approximation to $q_\phi(y|t)$ for the gold tree y (although in principle, it could have computed the exact normalizing constant in polytime with Tutte's matrix-tree theorem (Smith and Smith, 2007; Koo et al., 2007; McDonald and Satta, 2007)). When we test the parser, the code does exactly find $\text{argmax}_y\, q_\phi(y \mid t)$ via the directed spanning tree algorithm of Edmonds (1966).

4 Training and Inference

With the approximations in §3, our final minimization objective is this upper bound on (2):

$$\mathop{\mathbb{E}}_{x,y}\Big[\mathop{\mathbb{E}}_{t\sim p_\theta(t|x)}[-\log q_\phi(y|t)] + \beta\,\mathrm{KL}(p_\theta(t|x)||r_\psi(t)) + \gamma\sum_{i=1}^{n}\mathrm{KL}(p_\theta(t_i \mid x)\;||\;s_\xi(t_i \mid \hat{x}_i))\Big] \quad (3)$$

We apply stochastic gradient descent to optimize this objective. To get a stochastic estimate of the objective, we first sample some (x, y) from the treebank. We then have many expectations over $t \sim p_\theta(t \mid x)$, including the KL terms. We could estimate these by sampling t from the token encoder $p_\theta(t \mid x)$ and then evaluating all q_ϕ, p_θ, r_ψ, and s_ξ probabilities. However, in fact we use the sampled t only to estimate the first expectation (by computing the decoder probability $q_\phi(y \mid t)$ of the gold tree y); we can compute the KL terms exactly by exploiting the structure of our distributions. The structure of p_θ and r_ψ means that the first KL term decomposes into $\sum_{i=1}^{n}\mathrm{KL}(p_\theta(t_i|x_i)||r_\psi(t_i))$. All KL terms are now between either two Gaussian distributions over a continuous tagset[6] or two categorical distributions over a small discrete tagset.[7]

To compute the stochastic gradient, we run backpropagation on this computation. We must apply the reparametrization trick to backpropagate through the step that sampled t. This finds the gradient of parameters that derive t from a random variate z, while holding z itself fixed. For continuous t, we use the reparametrization trick for multivariate Gaussians (Rezende et al., 2014). For discrete t, we use the Gumbel-softmax variant (Jang et al., 2016; Maddison et al., 2017).

To evaluate our trained model's ability to parse a sentence x from compressed tags, we obtain a parse as $\text{argmax}_y\, q_\phi(y \mid t)$, where $t \sim p_\theta(\cdot \mid x)$ is a single sample. A better parser would instead estimate $\text{argmax}_y\, \mathbb{E}_t\,[q_\phi(y \mid t)]$ where $\mathbb{E}_t$ averages over many samples t, but this is computationally hard.

Language	Treebank	#Tokens	$\mathrm{H}(A \mid \hat{X})$	$\mathrm{H}(A)$
Arabic	PADT	282k	0.059	2.059

Table 1: Statistics of the datasets used in this paper. "Treebank" is the treebank identifier in UD, "#Token" is the number of tokens in the treebank, "$\mathrm{H}(A)$" is the entropy of a gold POS tag (in nats), and "$\mathrm{H}(A \mid \hat{X})$" is the conditional entropy of a gold POS tag conditioned on a word type (in nats).

5 Experimental Setup

Data Throughout §§6–7, we will examine our compressed tags on a subset of Universal Dependencies (Nivre et al., 2018), or UD, a collection of dependency treebanks across 76 languages using the same POS tags and dependency labels. We experiment on Arabic, Hindi, English, French, Spanish, Portuguese, Russian, Italian, and Chinese (Table 1)—languages with different syntactic properties like word order. We use only the sentences with length ≤ 30. For each sentence, x is obtained by running the standard pre-trained ELMo on the UD token sequence (although UD's tokenization may not perfectly match that of ELMo's training data), and y is the labeled UD dependency parse *without* any part-of-speech (POS) tags. Thus, our tags t are tuned to predict only the dependency relations in UD, and not the gold POS tags a also in UD.

Pretrained Word Embeddings For English, we used the pre-trained English ELMo model from the AllenNLP library (Gardner et al., 2017). For the

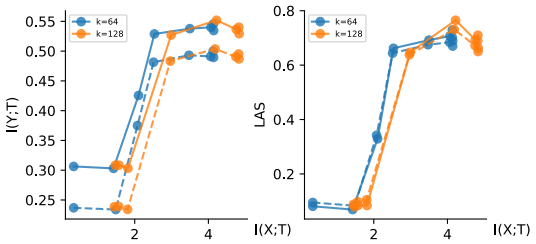
[5] We use the implementation from AllenNLP library (Gardner et al., 2017).

[6] $\mathrm{KL}(\mathcal{N}_0 \,||\, \mathcal{N}_1) = \frac{1}{2}(\mathrm{tr}(\Sigma_1^{-1}\Sigma_0) + (\mu_1-\mu_0)^T\Sigma_1^{-1}(\mu_1-\mu_0) - d + \log(\frac{\det(\Sigma_1)}{\det(\Sigma_0)})$

[7] $\mathrm{KL}(p_\theta(t_i|x_i)||r_\psi(t_i)) = \sum_{t_i=1}^{k} p_\theta(t_i \mid x_i)\log\frac{p_\theta(t_i|x_i)}{r_\psi(t_i)}$

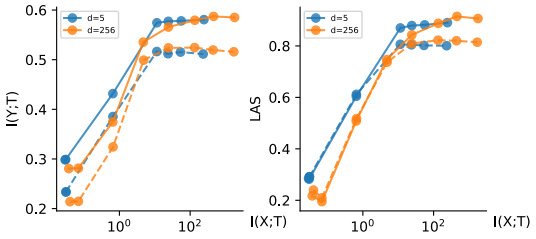
other 8 languages, we used the pre-trained models from Che et al. (2018). Recall that ELMo has two layers of bidirectional LSTM (layer 1 and 2) built upon a context-independent character CNN (layer 0). We use either layer 1 or 2 as the input (x_i) to our token encoder p_θ. Layer 0 is the input ($\hat{x}_i$) to our type encoder s_ξ. Each encoder network (§§3.2–3.3) has a single hidden layer with a tanh transfer function, which has $2d$ hidden units (typically 128 or 512) for continuous encodings and 512 hidden units for discrete encodings.

Optimization We optimize with Adam (Kingma and Ba, 2014), a variant of stochastic gradient descent. We alternate between improving the model $p_\theta(t|x)$ on even epochs and the variational distributions $q_\phi(y|t)$, $r_\psi(t)$, $s_\xi(t_i \mid \hat{x}_i)$ on odd epochs.



We train for 50 epochs with minibatches of size 20 and L_2 regularization. The learning rate and the regularization coefficients are tuned on dev data for each language separately. For each training sentence, we average over 5 i.i.d. samples of T to reduce the variance of the stochastic gradient. The initial parameters θ, ϕ, ψ, ξ are all drawn from $\mathcal{N}(0, I)$. We experiment with different dimensionalities $d \in \{5, 32, 256, 512\}$ for the continuous tags, and different cardinalities $k \in \{32, 64, 128\}$ for the discrete tag set. We also tried different values $\beta, \gamma \in \{10^{-6}, 10^{-5}, \cdots, 10^{1}\}$ of the compression tradeoff parameter. We use temperature annealing when sampling from the Gumbel-softmax distribution (§4). At training epoch i, we use temperature τ_i, where $\tau_1 = 5$ and $\tau_{i+1} = \max(0.5, e^{-\gamma}\tau_i)$. We set the annealing rate $\gamma = 0.1$. During testing, we use $\tau = 0$, which gives exact softmax sampling.

6 Scientific Evaluation



In this section, we study what information about words is retained by our automatically constructed tagging schemes. First, we show the relationship between $I(Y;T)$ and $I(X;T)$ on English as we reduce β to capture more information in our tags.[8]

Second, across 9 languages, we study how our automatic tags correlate with gold part-of-speech tags (and in English, with other syntactic properties), while suppressing information about semantic properties. We also show how decreasing β gradually refines the automatic discrete tag set, giving intuitive fine-grained clusters of English words.

[8]We always set $\gamma = \beta$ to simplify the experimental design.

(a) Discrete Version

(b) Continuous Version

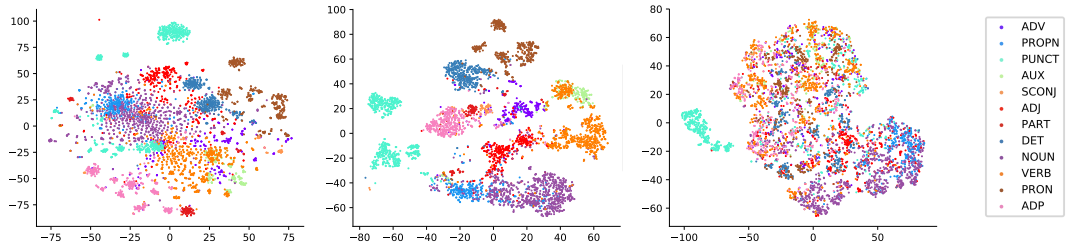


Figure 2: Compression-prediction tradeoff curves of VIB in our dependency parsing setting. The upper figures use discrete tags, while the lower figures use continuous tags. The dashed lines are for test data, and the solid lines for training data. The "dim" in the legends means the dimensionality of the continuous tag vector or the cardinality of the discrete tag set. On the left, we plot predictiveness $I(Y;T)$ versus $I(X;T)$ as we lower β multiplicatively from 10^1 to 10^{-6} on a log-scale. On the right, we alter the y-axis to show the labeled attachment score (LAS) of 1-best dependency parsing. All mutual information and entropy values in this paper are reported in nats per token. Furthermore, the mutual information values that we report are actually our variational upper bounds, as described in §3. The reason that $I(X;T)$ is so large for continuous tags is that it is *differential* mutual information (see footnote 3). Additional tradeoff curves w.r.t. $I(T_i; X \mid \hat{X}_i)$ are in Appendix B.

6.1 Tradeoff Curves

As we lower β to retain more information about X, both $I(X;T)$ and $I(Y;T)$ rise, as shown in Figure 2. There are diminishing returns: after some point, the additional information retained in T does not contribute much to predicting Y. Also noteworthy is that at each level of $I(X,T)$, very low-dimensional tags ($d = 5$) perform on par with high-dimensional ones ($d = 256$). (Note that the high-dimensional stochastic tags will be noisier to keep the same $I(X,T)$.) The low-dimensional tags allow far faster CPU parsing. This indicates that VIB can achieve strong practical task-specific compression.

6.2 Learned Tags vs. Gold POS Tags

We investigate how our automatic tag T_i correlates with the gold POS tag A_i provided by UD.

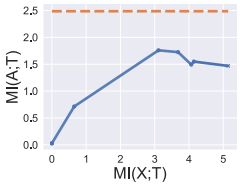
(a) ELMo, $I(X;T) = H(X) \approx 400.6$ (b) $I(X;T) \approx 24.3$ (c) $I(X;T) \approx 0.069$

Figure 3: t-SNE visualization of VIB model ($d = 256$) on the projected space of the continuous tags. Each marker in the figure represents a word token, colored by its gold POS tag. This series of figures (from left to right) shows a progression from no compression to moderate compression and to too-much compression.

Continuous Version We use t-SNE (van der Maaten and Hinton, 2008) to visualize our compressed continuous tags on held-out test data, coloring each token in Figure 3 according to its gold POS tag. (Similar plots for the discrete tags are in Figure 6 in the appendix.)

In Figure 3, the first figure shows the original uncompressed level-1 ELMo embeddings of the tokens in test data. In the two-dimensional visualization, the POS tags are vaguely clustered but the boundaries merge together and some tags are diffuse. The second figure is when $\beta = 10^{-3}$ (moderate compression): our compressed embeddings show clear clusters that correspond well to gold POS tags. Note that the gold POS tags were not used in training either ELMo or our method. The third figure is when $\beta = 1$ (too much compression), when POS information is largely lost. An interesting observation is that the purple NOUN and blue PROPN distributions overlap in the middle distribution, meaning that it was unnecessary to distinguish common nouns from proper nouns for purposes of our parsing task.[9]

Discrete Version We also quantify how well our specialized discrete tags capture the traditional POS categories, by investigating $I(A;T)$. This can be written as $H(A) - H(A \mid T)$. Similarly to §3.4, our probability distribution has the form $p_\theta(x, a, t) = p(x, a) \cdot p_\theta(t \mid x)$, leading us to write $H(A \mid T) \leq \mathbb{E}_{x,a}\left[\mathbb{E}_{t \sim p_\theta(t|x)}\left[-\log q(a \mid t)\right]\right]$ where $q(a \mid t) = \prod_i q(a_i \mid t_i)$ is a variational distribution that we train to minimize this upper bound. This is equivalent to training $q(a \mid t)$ by maximum conditional likelihood. In effect, we are doing transfer learning, fixing our trained IB encoder (p_θ) and now using it to predict A instead of Y, but otherwise following §3.4. We similarly upper-bound $H(A)$ by assuming a model $q'(a) = \prod_i q'(a_i)$ and estimating q' as the empirical distribution over training tags. Having trained q and q' on training data, we estimate $H(A \mid T)$ and $H(A)$ using the same upper-bound formulas on our test data.



We experiment on all 9 languages, taking T_i at the moderate compression level $\beta = 0.001$, $k = 64$. As Figure 4 shows, averaging over the 9 languages, the reconstruction retains 71% of POS information (and as high as 80% on Spanish and French). We can conclude that the information encoded in the specialized tags correlates with the gold POS tags, but does not perfectly predict the POS.

The graph in Figure 4 shows a "U-shaped" curve, with the best overall error rate at $\beta = 0.01$. That is, moderate compression of ELMo embeddings helps for predicting POS tags. Too much compression squeezes out POS-related information, while too little compression allows the tagger to overfit the training data, harming generalization to test data. We will see the same pattern for parsing in §7.

Syntactic Features As a quick check, we determine that our tags also make syntactic distinctions beyond those that are recognized by the UD POS tag set, such as tense, number, and transitivity. See Appendix D for graphs. For example, even with moderate compression, we achieve 0.87 classification accuracy in distinguishing between transitive and intransitive English verbs, given only tag t_i.

Stem When we compress ELMo embeddings to k discrete tags, the semantic information must be squeezed out because k is small. But what about the continuous case? In order to verify that semantic information is excluded, we train a classifier that predicts the stem of word token i from its mean tag vector $\mathbb{E}[T_i]$. We expect "player" and "buyer" to have similar compressed vectors, because they share syntactic roles, but we should *fail*

[9] Both can serve as arguments of verbs and prepositions. Both can be modified by determiners and adjectives, giving rise to proper NPs like "The Daily Tribune."

embeddings	Arabic	English	Spanish	French	Hindi	Italian	Portuguese	Russian	Chinese
H(A)	2.016	2.486	2.345	2.206	2.247	2.291	2.306	2.131	2.195
ELMo0	67.2%	74.2%	75.7%	79.6%	70.1%	77.9%	76.5%	73.2%	57.3%
ELMo1	67.2%	76.1%	71.7%	78.0%	70.5%	78.1%	72.3%	73.8%	59.8%
ELMo2	63.8%	71.0%	79.7%	78.7%	67.2%	74.5%	75.3%	72.2%	59.4%

Figure 4: Graph at left: I($A;T$) vs. I($X;T$) in English (in units of nats per token). Table at right: how well the discrete specialized tags predict gold POS tags for 9 languages. The H(A) row is the entropy (in nats per token) of the gold POS tags in the test data corpus, which is an upper bound for I($A;T$). The remaining rows report the percentage I($A;T$)/H(A).

to predict that they have different stems "play" and "buy." The classifier is a feedforward neural network with *tanh* activation function, and the last layer is a softmax over the stem vocabulary. In the English treebank, we take the word lemma in UD treebank and use the NLTK library (Bird et al., 2009) to stem each lemma token. Our result (Appendix E in the appendix) suggests that more compression destroys stem information, as hoped. With light compression, the error rate on stem prediction can be below 15%. With moderate compression $\beta = 0.01$, the error rate is 89% for ELMo layer 2 and 66% for ELMo layer 1. Other languages show the same pattern, as shown in Appendix E in the appendix. Thus, moderate and heavy compression indeed squeeze out semantic information.

6.3 Annealing of Discrete Tags

Deterministic annealing (Rose, 1998; Friedman et al., 2001) is a method that gradually decreases β during training of IB. Each token i has a stochastic distribution over the possible tags $\{1, \ldots, k\}$. This can be regarded as a soft clustering where each token is fractionally associated with each of the k clusters. With high β, the optimal solution turns out to assign to all tokens an identical distribution over clusters, for a mutual information of 0. Since all clusters then have the same membership, this is equivalent to having a single cluster. As we gradually reduce β, the cluster eventually splits. Further reduction of β leads to recursive splitting, yielding a hierarchical clustering of tokens (Appendix A).

We apply deterministic annealing to the English dataset, and the resulting hierarchical structure reflects properties of English syntax. At the top of the hierarchy, the model places nouns, adjectives, adverbs, and verbs in different clusters. At lower levels, the anaphors ("yourself," "herself" ...), possessive pronouns ("his," "my," "their" ...), accusative-case pronouns ("them," "me," "him," "myself" ...), and nominative-case pronouns ("I," "they," "we" ...) each form a cluster, as do the *wh*-words ("why," "how," "which," "who," "what," ...).

7 Engineering Evaluation

As we noted in §1, learning how to compress ELMo's tags for a given task is a fast alternative to fine-tuning all the ELMo parameters. We find that indeed, training a compression method to keep only the relevant information does improve our generalization performance on the parsing task.

We compare 6 different token representations according to the test accuracy of a dependency parser trained to use them. The same training data is used to jointly train the parser and the token encoder that produces the parser's input representations.

Continuous tags:

`Iden` is an baseline model that leaves the ELMo embeddings uncompressed, so $d = 1024$.

`PCA` is a baseline that simply uses Principal Components Analysis to reduce the dimensionality to $d = 256$. Again, this is not task-specific.

`MLP` is another deterministic baseline that uses a multi-layer perceptron (as in Dozat and Manning (2016)) to reduce the dimensionality to $d = 256$ in a task-specific and nonlinear way. This is identical to our continuous VIB method except that the variance of the output Gaussians is fixed to 0, so that the d dimensions are fully informative.

`VIBc` uses our stochastic encoder, still with $d = 256$. The average amount of stochastic noise is controlled by β, which is tuned per-language on dev data.

Discrete tags:

`POS` is a baseline that uses the $k \leq 17$ gold POS tags from the UD dataset.

`VIBd` is our stochastic method with $k = 64$ tags. To compare fairly with **`POS`**, we pick a β value for each language such that $\mathrm{H}(T_i \mid X_i) \approx \mathrm{H}(A_i \mid X_i)$.

Runtime. Our VIB approach is quite fast. With minibatching on a single GPU, it is able to train on 10,000 sentences in 100 seconds, per epoch.

Models	Arabic	Hindi	English	French	Spanish	Portuguese	Russian	Chinese	Italian
Iden	0.751	**0.870**	0.824	0.784	0.808	0.813	0.783	0.709	**0.863**
PCA	0.743	**0.866**	0.823	0.749	0.802	0.808	0.777	0.697	0.857
MLP	0.759	**0.871**	0.839	0.816	**0.835**	0.821	0.800	0.734	**0.867**
VIBc	**0.779**	**0.866**	**0.851**	**0.828**	**0.837**	**0.836**	**0.814**	**0.754**	**0.867**
POS	0.652	0.713	0.712	0.718	**0.739**	**0.743**	**0.662**	0.510	0.779
VIBd	**0.672**	**0.736**	**0.742**	**0.723**	**0.725**	0.710	**0.651**	**0.591**	**0.781**

Table 2: Parsing accuracy of 9 languages (LAS). Black rows use continuous tags; gray rows use discrete tags (which does worse). In each column, the best score for each color is boldfaced, along with all results of that color that are not significantly worse (paired permutation test, $p < 0.05$). These results use only ELMo layer 1; results from all layers are shown in Table 3 in the appendix, for both LAS and UAS metrics.

Analysis. Table 2 shows the test accuracies of these parsers, using the standard training/development/test split for each UD language.

In the continuous case, the VIB representation outperforms all three baselines in 8 of 9 languages, and is not significantly worse in the 9th language (Hindi). In short, our VIB joint training generalizes better to test data. This is because the training objective (2) includes terms that focus on the parsing task and also regularize the representations.

In the discrete case, the VIB representation outperforms gold POS tags (at the same level of granularity) in 6 of 9 languages, and of the other 3, it is not significantly worse in 2. This suggests that our learned discrete tag set could be an improved alternative to gold POS tags (cf. Klein and Manning, 2003) when a discrete tag set is needed for speed.

8 Related Work

Much recent NLP literature examines syntactic information encoded by deep models (Linzen et al., 2016) and more specifically, by powerful unsupervised word embeddings. Hewitt and Manning (2019) learn a linear projection from the embedding space to predict the distance between two words in a parse tree. Peters et al. (2018b) and Goldberg (2019) assess the ability of BERT and ELMo directly on syntactic NLP tasks. Tenney et al. (2019) extract information from the contextual embeddings by self-attention pooling within a span of word embeddings.

The IB framework was first used in NLP to cluster distributionally similar words (Pereira et al., 1993). In cognitive science, it has been used to argue that color-naming systems across languages are nearly optimal (Zaslavsky et al., 2018). In machine learning, IB provides an information-theoretic perspective to explain the performance of deep neural networks (Tishby and Zaslavsky, 2015).

The VIB method makes use of variational upper and lower bounds on mutual information. An alternative lower bound was proposed by Poole et al. (2019), who found it to work better empirically.

9 Conclusion and Future Work

In this paper, we have proposed two ways to syntactically compress ELMo word token embeddings, using variational information bottleneck. We automatically induce stochastic discrete tags that correlate with gold POS tags but are as good or better for parsing. We also induce stochastic continuous token embeddings (each is a Gaussian distribution over $\mathbb{R}^d$) that forget non-syntactic information captured by ELMo. These stochastic vectors yield improved parsing results, in a way that simpler dimensionality reduction methods do not. They also transfer to the problem of predicting gold POS tags, which were not used in training.

One could apply the same training method to compress the ELMo or BERT token sequence x for other tasks. All that is required is a model-specific decoder $q_\phi(y \mid t)$. For example, in the case of sentiment analysis, the approach should preserve only sentiment information, discarding most of the syntax. One possibility that does not require supervised data is to create artificial tasks, such as reproducing the input sentence or predicting missing parts of the input (such as affixes and function words). In this case, the latent representations would be essentially generative, as in the variational autoencoder (Kingma and Welling, 2013).

Deep Contextualized Word Embeddings in Transition-Based and Graph-Based Dependency Parsing – A Tale of Two Parsers Revisited*

Abstract

Transition-based and graph-based dependency parsers have previously been shown to have complementary strengths and weaknesses: transition-based parsers exploit rich structural features but suffer from error propagation, while graph-based parsers benefit from global optimization but have restricted feature scope. In this paper, we show that, even though some details of the picture have changed after the switch to neural networks and continuous representations, the basic trade-off between rich features and global optimization remains essentially the same. Moreover, we show that deep contextualized word embeddings, which allow parsers to pack information about global sentence structure into local feature representations, benefit transition-based parsers more than graph-based parsers, making the two approaches virtually equivalent in terms of both accuracy and error profile. We argue that the reason is that these representations help prevent search errors and thereby allow transition-based parsers to better exploit their inherent strength of making accurate local decisions. We support this explanation by an error analysis of parsing experiments on 13 languages.

1 Introduction

For more than a decade, research on data-driven dependency parsing has been dominated by two approaches: transition-based parsing and graph-based parsing (McDonald and Nivre, 2007, 2011). Transition-based parsing reduces the parsing task to scoring single parse actions and is often combined with local optimization and greedy search algorithms. Graph-based parsing decomposes parse trees into subgraphs and relies on global optimization and exhaustive (or at least non-greedy) search to find the best tree. These radically different approaches often lead to comparable parsing accuracy, but with distinct error profiles indicative of their respective strengths and weaknesses, as shown by McDonald and Nivre (2007, 2011).

In recent years, dependency parsing, like most of NLP, has shifted from linear models and discrete features to neural networks and continuous representations. This has led to substantial accuracy improvements for both transition-based and graph-based parsers and raises the question whether their complementary strengths and weaknesses are still relevant. In this paper, we replicate the analysis of McDonald and Nivre (2007, 2011) for neural parsers. In addition, we investigate the impact of deep contextualized word representations (Peters et al., 2018; Devlin et al., 2019) for both types of parsers.

Based on what we know about the strengths and weaknesses of the two approaches, we hypothesize that deep contextualized word representations will benefit transition-based parsing more than graph-based parsing. The reason is that these representations make information about global sentence structure available locally, thereby helping to prevent search errors in greedy transition-based parsing. The hypothesis is corroborated in experiments on 13 languages, and the error analysis supports our suggested explanation. We also find that deep contextualized word representations improve parsing accuracy for longer sentences, both for transition-based and graph-based parsers.

2 Two Models of Dependency Parsing

After playing a marginal role in NLP for many years, dependency-based approaches to syntactic parsing have become mainstream during the last fifteen years. This is especially true if we consider languages other than English, ever since the influ-

ential CoNLL shared tasks on dependency parsing in 2006 (Buchholz and Marsi, 2006) and 2007 (Nivre et al., 2007) with data from 19 languages.

The transition-based approach to dependency parsing was pioneered by Yamada and Matsumoto (2003) and Nivre (2003), with inspiration from history-based parsing (Black et al., 1992) and data-driven shift-reduce parsing (Veenstra and Daelemans, 2000). The idea is to reduce the complex parsing task to the simpler task of predicting the next parsing action and to implement parsing as greedy search for the optimal sequence of actions, guided by a simple classifier trained on local parser configurations. This produces parsers that are very efficient, often with linear time complexity, and which can benefit from rich non-local features defined over parser configurations but which may suffer from compounding search errors.

The graph-based approach to dependency parsing was developed by McDonald et al. (2005a,b), building on earlier work by Eisner (1996). The idea is to score dependency trees by a linear combination of scores of local subgraphs, often single arcs, and to implement parsing as exact search for the highest scoring tree under a globally optimized model. These parsers do not suffer from search errors but parsing algorithms are more complex and restrict the scope of features to local subgraphs.

The terms *transition-based* and *graph-based* were coined by McDonald and Nivre (2007, 2011), who performed a contrastive error analysis of the two top-performing systems in the CoNLL 2006 shared task on multilingual dependency parsing: MaltParser (Nivre et al., 2006) and MSTParser (McDonald et al., 2006), which represented the state of the art in transition-based and graph-based parsing, respectively, at the time. Their analysis shows that, despite having almost exactly the same parsing accuracy when averaged over 13 languages, the two parsers have very distinctive error profiles. MaltParser is more accurate on short sentences, on short dependencies, on dependencies near the leaves of the tree, on nouns and prounouns, and on subject and object relations. MSTParser is more accurate on long sentences, on long dependencies, on dependencies near the root of the tree, on verbs, and on coordination relations and sentence roots.

McDonald and Nivre (2007, 2011) argue that these patterns can be explained by the complementary strengths and weaknesses of the systems. The

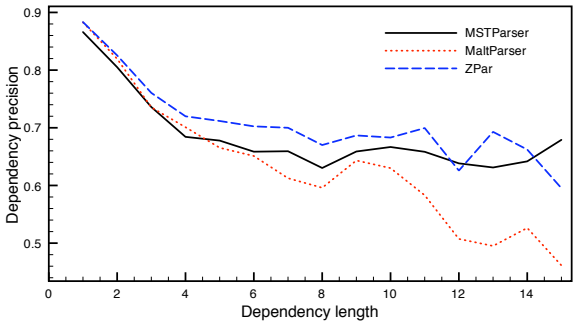

Figure 1: Labeled precision by dependency length for MST (global–exhaustive–graph), Malt (local–greedy–transition) and ZPar (global–beam–transition). From Zhang and Nivre (2012).

transition-based MaltParser prioritizes rich structural features, which enable accurate disambiguation in local contexts, but is limited by a locally optimized model and greedy algorithm, resulting in search errors for structures that require longer transition sequences. The graph-based MSTParser benefits from a globally optimized model and exact inference, which gives a better analysis of global sentence structure, but is more restricted in the features it can use, which limits its capacity to score local structures accurately.

Many of the developments in dependency parsing during the last decade can be understood in this light as attempts to mitigate the weaknesses of traditional transition-based and graph-based parsers without sacrificing their strengths. This may mean evolving the model structure through new transition systems (Nivre, 2008, 2009; Kuhlmann et al., 2011) or higher-order models for graph-based parsing (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010); it may mean exploring alternative learning strategies, in particular for transition-based parsing, where improvements have been achieved thanks to global structure learning (Zhang and Clark, 2008; Zhang and Nivre, 2011; Andor et al., 2016) and dynamic oracles (Goldberg and Nivre, 2012, 2013); it may mean using alternative search strategies, such as transition-based parsing with beam search (Johansson and Nugues, 2007; Titov and Henderson, 2007; Zhang and Clark, 2008) or exact search (Huang and Sagae, 2010; Kuhlmann et al., 2011) or graph-based parsing with heuristic search to cope with the complexity of higher-order models, especially for non-projective parsing (McDonald and Pereira, 2006; Koo et al., 2010; Zhang and McDonald, 2012); or it may mean hybrid or en-

semble systems (Sagae and Lavie, 2006; Nivre and McDonald, 2008; Zhang and Clark, 2008; Bohnet and Kuhn, 2012). A nice illustration of the impact of new techniques can be found in Zhang and Nivre (2012), where an error analysis along the lines of McDonald and Nivre (2007, 2011) shows that a transition-based parser using global learning and beam search (instead of local learning and greedy search) performs on par with graph-based parsers for long dependencies, while retaining the advantage of the original transition-based parsers on short dependencies (see Figure 1).

Neural networks for dependency parsing, first explored by Titov and Henderson (2007) and Attardi et al. (2009), have come to dominate the field during the last five years. While this has dramatically changed learning architectures and feature representations, most parsing models are still either transition-based (Chen and Manning, 2014; Dyer et al., 2015; Weiss et al., 2015; Andor et al., 2016; Kiperwasser and Goldberg, 2016) or graph-based (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017). However, more accurate feature learning using continuous representations and nonlinear models has allowed parsing architectures to be simplified. Thus, most recent transition-based parsers have moved back to local learning and greedy inference, seemingly without losing accurracy (Chen and Manning, 2014; Dyer et al., 2015; Kiperwasser and Goldberg, 2016). Similarly, graph-based parsers again rely on first-order models and obtain no improvements from using higher-order models (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017).

The increasing use of neural networks has also led to a convergence in feature representations and learning algorithms for transition-based and graph-based parsers. In particular, most recent systems rely on an encoder, typically in the form of a BiLSTM, that provides contextualized representations of the input words as input to the scoring of transitions – in transition-based parsers – or of dependency arcs – in graph-based parsers. By making information about the *global* sentence context available in *local* word representations, this encoder can be assumed to mitigate error propagation for transition-based parsers and to widen the feature scope beyond individual word pairs for graph-based parsers. For both types of parsers, this also obviates the need for complex structural feature templates, as recently shown by Falenska and Kuhn (2019). We should therefore expect neural transition-based and graph-based parsers to be not only more accurate than their non-neural counterparts but also more similar to each other in their error profiles.

3 Deep Contextualized Word Representations

Neural parsers rely on vector representations of words as their primary input, often in the form of pretrained word embeddings such as word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), or fastText (Bojanowski et al., 2016), which are sometimes extended with character-based representations produced by recurrent neural networks (Ballesteros et al., 2015). These techniques assign a single static representation to each word type and therefore cannot capture context-dependent variation in meaning and syntactic behavior.

By contrast, deep contextualized word representations encode words with respect to the sentential context in which they appear. Like word embeddings, such models are typically trained with a language-modeling objective, but yield sentence-level tensors as representations, instead of single vectors. These representations are typically produced by transferring a model's entire feature encoder – be it a BiLSTM (Hochreiter and Schmidhuber, 1997) or Transformer (Vaswani et al., 2017) – to a target task, where the dimensionality of the tensor $\mathbf{S}$ is typically $\mathbf{S} \in \mathbb{R}^{N \times L \times D}$ for a sentence of length N, an encoder with L layers, and word-level vectors of dimensionality D. The advantage of such models, compared to the parser-internal encoders discussed in the previous section, is that they not only produce contextualized representations but do so over several layers of abstraction, as captured by the model's different layers, and are pre-trained on corpora much larger than typical treebanks.

Deep contextualized embedding models have proven to be adept at a wide array of NLP tasks, achieving state-of-the-art performance in standard Natural Language Understanding (NLU) benchmarks, such as GLUE (Wang et al., 2019). Though many such models have been proposed, we adopt the two arguably most popular ones for our experiments: ELMo and BERT. Both models have previously been used for dependency parsing (Che et al., 2018; Jawahar et al., 2018; Lim et al., 2018;

Kondratyuk, 2019; Schuster et al., 2019), but there has been no systematic analysis of their impact on transition-based and graph-based parsers.

3.1 ELMo

ELMo is a deep contextualized embedding model proposed by Peters et al. (2018), which produces sentence-level representations yielded by a multi-layer BiLSTM language model. ELMo is trained with a standard language-modeling objective, in which a BiLSTM reads a sequence of N learned context-independent embeddings $\mathbf{w}_1, \ldots, \mathbf{w}_N$ (obtained via a character-level CNN) and produces a context-dependent representation $\mathbf{h}_{j,k} = \mathbf{BiLSTM}(\mathbf{w}_{1:N}, k)$, where j $(1 \leq j \leq L)$ is the BiLSTM layer and k is the index of the word in the sequence. The output of the last layer $\mathbf{h}_{L,k}$ is then employed in conjunction with a softmax layer to predict the next token at $k+1$.

The simplest way of transferring ELMo to a downstream task is to encode the input sentence $S = w_1, \ldots, w_N$ by extracting the representations from the BiLSTM at layer L for each token $w_k \in S$: $\mathbf{h}_{L,1}, \ldots, \mathbf{h}_{L,N},$. However, Peters et al. (2018) posit that the best way to take advantage of ELMo's representational power is to compute a linear combination of BiLSTM layers:

$$\mathbf{ELMo}_k = \gamma \sum_{j=0}^{L} s_j \mathbf{h}_{j,k} \quad (1)$$

where s_j is a softmax-normalized task-specific parameter and γ is a task-specific scalar. Peters et al. (2018) demonstrate that this scales the layers of linguistic abstraction encoded by the BiLSTM for the task at hand.

3.2 BERT

BERT (Devlin et al., 2019) is similar to ELMo in that it employs a language-modeling objective over unannotated text in order to produce deep contextualized embeddings. However, BERT differs from ELMo in that, in place of a BiLSTM, it employs a bidirectional Transformer (Vaswani et al., 2017), which, among other factors, carries the benefit of learning potential dependencies between words directly. This lies in contrast to recurrent models, which may struggle to learn correspondences between constituent signals when the time-lag between them is long (Hochreiter et al., 2001). For a token w_k in sentence S, BERT's input representation is composed by summing a word embedding $\mathbf{x}_k$, a position embedding $\mathbf{i}_k$, and a WordPiece embedding $\mathbf{s}_k$ (Wu et al., 2016): $\mathbf{w}_k = \mathbf{x}_k + \mathbf{i}_k + \mathbf{s}_k$.

Each $\mathbf{w}_k \in S$ is passed to an L-layered Bi-Transformer, which is trained with a masked language modeling objective (i.e., randomly masking a percentage of input tokens and only predicting said tokens). For use in downstream tasks, Devlin et al. (2019) propose to extract the Transformer's encoding of each token $w_k \in S$ at layer L, which effectively produces $\mathbf{BERT}_k$.

4 Hypotheses

Based on our discussion in Section 2, we assume that transition-based and graph-based parsers still have distinctive error profiles due to the basic trade-off between rich structural features, which allow transition-based parsers to make accurate local decisions, and global learning and exact search, which give graph-based parsers an advantage with respect to global sentence structure. At the same time, we expect the differences to be less pronounced than they were ten years ago because of the convergence in neural architectures and feature representations. But how will the addition of deep contextualized word representations affect the behavior of the two parsers?

Given recent recent work showing that deep contextualized word representations incorporate rich information about syntactic structure (Goldberg, 2019; Liu et al., 2019; Tenney et al., 2019; Hewitt and Manning, 2019), we hypothesize that transition-based parsers have most to gain from these representations because it will improve their capacity to make decisions informed by global sentence structure and therefore reduce the number of search errors. Our main hypothesis can be stated as follows:

> Deep contextualized word representations are more effective at reducing errors in transition-based parsing than in graph-based parsing.

If this holds true, then the analysis of McDonald and Nivre (2007, 2011) suggests that the differential error reduction should be especially visible on phenomena such as:

1. longer dependencies,
2. dependencies closer to the root,
3. certain parts of speech,
4. certain dependency relations,
5. longer sentences.

The error analysis will consider all these factors as well as non-projective dependencies.

5 Experimental Setup

5.1 Parsing Architecture

To be able to compare transition-based and graph-based parsers under equivalent conditions, we use and extend UUParser[1] (de Lhoneux et al., 2017a; Smith et al., 2018a), an evolution of bist-parser (Kiperwasser and Goldberg, 2016), which supports transition-based and graph-based parsing with a common infrastructure but different scoring models and parsing algorithms.

For an input sentence $S = w_1, \ldots, w_N$, the parser creates a sequence of vectors $\mathbf{w}_{1:N}$, where the vector $\mathbf{w}_k = \mathbf{x}_k \circ \textsc{BiLstm}(c_{1:M})$ representing input word w_k is the concatenation of a pretrained word embedding $\mathbf{x}_k$ and a character-based embedding $\textsc{BiLstm}(c_{1:M})$ obtained by running a BiLSTM over the character sequence $c_{1:M}$ of w_k. Finally, each input element is represented by a BiLSTM vector, $\mathbf{h}_k = \textsc{BiLstm}(\mathbf{w}_{1:N}, k)$.

In transition-based parsing, the BiLSTM vectors are input to a multi-layer perceptron (MLP) for scoring transitions, using the arc-hybrid transition system from Kuhlmann et al. (2011) extended with a SWAP transition to allow the construction of non-projective dependency trees (Nivre, 2009; de Lhoneux et al., 2017b). The scoring is based on the top three words on the stack and the first word of the buffer, and the input to the MLP includes the BiLSTM vectors for these words as well as their leftmost and rightmost dependents (up to 12 words in total).

In graph-based parsing, the BiLSTM vectors are input to an MLP for scoring all possible dependency relations under an arc-factored model, meaning that only the vectors corresponding to the head and dependent are part of the input (2 words in total). The parser then extracts a maximum spanning tree over the score matrix using the Chu-Liu-Edmonds (CLE) algorithm[2] (Edmonds, 1967) which allows us to construct non-projective trees.

It is important to note that, while we acknowledge the existence of graph-based parsers that outperform the implementation of Kiperwasser and Goldberg (2016), such models do not meet our criteria for systematic comparison. The parser by Dozat et al. (2017) is very similar, but employs the MLP as a further step in the featurization process prior to scoring via a biaffine classifier. To keep the comparison as exact as possible, we forego comparing our transition-based systems to the Dozat et al. (2017) parser (and its numerous modifications). In addition, preliminary experiments showed that our chosen graph-based parser outperforms its transition-based counterpart, which was itself competitive in the CoNLL 2018 shared task (Zeman et al., 2018).

5.2 Input Representations

In our experiments, we evaluate three pairs of systems – differing only in their input representations. The first is a baseline that represents tokens by $\mathbf{w}_k = \mathbf{x}_k \circ \textsc{BiLstm}(c_{1:M})$, as described in Section 5.1. The word embeddings $\mathbf{x}_k$ are initialized via pretrained fastText vectors ($\mathbf{x}_k \in \mathbb{R}^{300}$) (Grave et al., 2018), which are updated for the parsing task. We term these transition-based and graph-based baselines TR and GR.

For the ELMo experiments, we make use of pretrained models provided by Che et al. (2018), who train ELMo on 20 million words randomly sampled from raw WikiDump and Common Crawl datasets for 44 languages. We encode each gold-segmented sentence in our treebank via the ELMo model for that language, which yields a tensor $\mathbf{S}_{\text{ELMo}} = \mathbb{R}^{N \times L \times D}$, where N is the number of words in the sentence, $L = 3$ is the number of ELMo layers, and $D = 1024$ is the ELMo vector dimensionality. Following Peters et al. (2018) (see Eq. 1), we learn a linear combination and a task-specific γ of each token's ELMo representation, which yields a vector $\mathbf{ELMo}_k \in \mathbb{R}^{1024}$. We then concatenate this vector with $\mathbf{w}_k$ and pass it to the BiLSTM. We call the transition-based and graph-based systems enhanced with ELMo TR+E and GR+E.

For the BERT experiments, we employ the pretrained multilingual cased model provided by Google,[3][4] which is trained on the concatenation of WikiDumps for the top 104 languages with the largest Wikipedias.[5] The model's parameters feature a 12-layer transformer trained with 768 hid-

[4] Except for Chinese, for which we make use of a separate, pretrained model.

[5] See sorted list here: https://meta.wikimedia.org/wiki/List_of_Wikipedias

den units and 12 self-attention heads. In order to obtain a word-level vector for each token in a sentence, we experimented with a variety of representations: namely, concatenating each transformer layer's word representation into a single vector $\mathbf{w}_{concat} \in \mathbb{R}^{768*12}$, employing the last layer's representation, or learning a linear combination over a range of layers, as we do with ELMo (e.g., via Eq. 1). In a preliminary set of experiments, we found that the latter approach over layers 4–8 consistently yielded the best results, and thus chose to adopt this method going forward. Regarding tokenization, we select the vector for the first subword token, as produced by the native BERT tokenizer. Surprisingly, this gave us better results than averaging subword token vectors in a preliminary round of experiments. Like with the ELMo representations, we concatenate each BERT vector $\mathbf{BERT}_k \in \mathbb{R}^{768}$ with $\mathbf{w}_k$ and pass it to the respective TR+B and GR+B parsers.

It is important to note that while the ELMo models we work with are *monolingual*, the BERT model is *multilingual*. In other words, while the standalone ELMo models were trained on the tokenized WikiDump and CommonCrawl for each language respectively, the BERT model was trained only on the former, albeit simultaneously for 104 languages. This means that the models are not strictly comparable, and it is an interesting question whether either of the models has an advantage in terms of training regime. However, since our purpose is not to compare the two models but to study their impact on parsing, we leave this question for future work.

5.3 Language and Treebank Selection

For treebank selection, we rely on the criteria proposed by de Lhoneux et al. (2017c) and adapted by Smith et al. (2018b) to have languages from different language families, with different morphological complexity, different scripts and character set sizes, different training sizes and domains, and with good annotation quality. This gives us 13 treebanks from UD v2.3 (Nivre et al., 2018), information about which is shown in Table 1.

5.4 Parser Training and Evaluation

In all experiments, we train parsers with default settings[6] for 30 epochs and select the model with the best labeled attachment score on the dev set. For each combination of model and training set, we repeat this procedure three times with different random seeds, apply the three selected models to the test set, and report the average result.

Language	Treebank	Family	Order	Train
Arabic	PADT	non-IE	VSO	6.1k
Basque	BDT	non-IE	SOV	5.4k
Chinese	GSD	non-IE	SVO	4.0k
English	EWT	IE	SVO	12.5k

Hindi	HDTB	IE	SOV	13.3k
Italian	ISDT	IE	SVO	13.1k
Japanese	GSD	non-IE	SOV	7.1k
Korean	GSD	non-IE	SOV	4.4k
Russian	SynTagRus	IE	SVO	48.8k
Swedish	Talbanken	IE	SVO	4.3k
Turkish	IMST	non-IE	SOV	3.7k

Table 1: Languages and treebanks used in experiments. Family = Indo-European (IE) or not. Order = dominant word order according to WALS (Haspelmath et al., 2005). Train = number of training sentences.

5.5 Error Analysis

In order to conduct an error analysis along the lines of McDonald and Nivre (2007, 2011), we extract all sentences from the smallest development set in our treebank sample (Hebrew HTB, 484 sentences) and sample the same number of sentences from each of the other development sets (6,292 sentences in total). For each system, we then extract parses of these sentences for the three training runs with different random seeds (18,876 predictions in total). Although it could be interesting to look at each language separately, we follow McDonald and Nivre (2007, 2011) and base our main analysis on all languages together to prevent data sparsity for longer dependencies, longer sentences, etc.[7]

6 Results and Discussion

Table 2 shows labeled attachment scores for the six parsers on all languages, averaged over three training runs with random seeds. The results clearly corroborate our main hypothesis. While ELMo and BERT provide significant improvements for both transition-based and graph-based

[6] All hyperparameters are specified in the supplementary material (Part A).

[7] The supplementary material contains tables for the error analysis (Part B) and graphs for each language (Part C).

Table 2: Labeled attachment score on 13 languages for parsing models with and without deep contextualized word representations.

parsers, the magnitude of the improvement is greater in the transition-based case: 3.99 vs. 2.85 for ELMo and 4.47 vs. 3.13 for BERT. In terms of error reduction, this corresponds to 21.1% vs. 16.5% for ELMo and 22.5% vs. 17.4% for BERT. The differences in error reduction are statistically significant at $\alpha = 0.01$ (Wilcoxon).

Although both parsing accuracy and absolute improvements vary across languages, the overall trend is remarkably consistent and the transition-based parser improves more with both ELMo and BERT for every single language. Furthermore, a linear mixed effect model analysis reveals that, when accounting for language as a random effect, there are no significant interactions between the improvement of each model (over its respective baseline) and factors such as language family (IE vs. non-IE), dominant word order, or number of training sentences. In other words, the improvements for both parsers seem to be largely independent of treebank-specific factors. Let us now see to what extent they can be explained by the error analysis.

6.1 Dependency Length

Figure 2 shows labeled F-score for dependencies of different lengths, where the length of a dependency between words w_i and w_j is equal to $|i - j|$ (and with root tokens in a special bin on the far left). For the baseline parsers, we see that the curves diverge with increasing length, clearly indicating that the transition-based parser still suffers

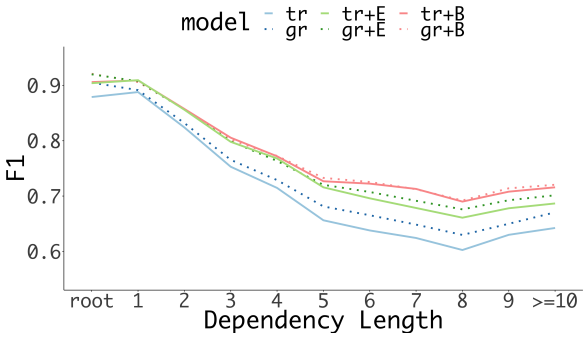

Figure 2: Labeled F-score by dependency length.

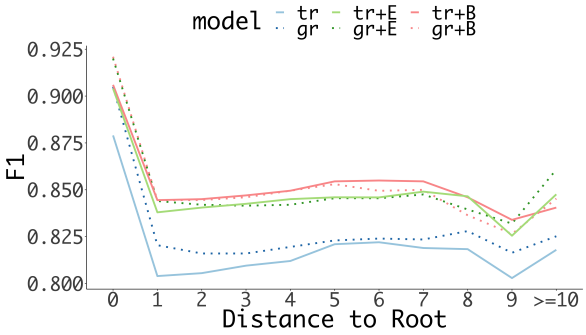

Figure 3: Labeled F-score by distance to root.

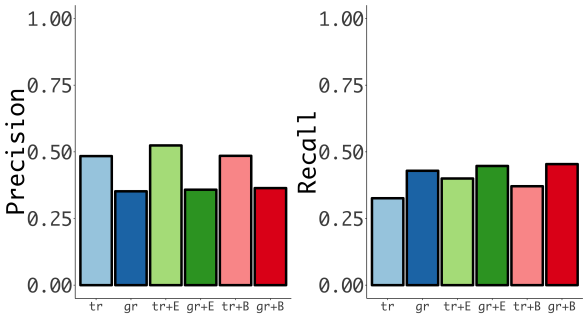

Figure 4: Labeled precision (left) and recall (right) for non-projective dependencies.

from search errors on long dependencies, which require longer transition sequences for their construction. However, the differences are much smaller than in McDonald and Nivre (2007, 2011) and the transition-based parser no longer has an advantage for short dependencies, which is consistent with the BiLSTM architecture providing the parsers with more similar features that help the graph-based parser overcome the limited scope of the first-order model.

Adding deep contextualized word representations clearly helps the transition-based parser to perform better on longer dependencies. For ELMo there is still a discernible difference for dependencies longer than 5, but for BERT the two curves

are almost indistinguishable throughout the whole range. This could be related to the aforementioned intuition that a Transformer captures long dependencies more effectively than a BiLSTM (see Tran et al. (2018) for contrary observations, albeit for different tasks). The overall trends for both baseline and enhanced models are quite consistent across languages, although with large variations in accuracy levels.

6.2 Distance to Root

Figure 3 reports labeled F-score for dependencies at different distances from the root of the tree, where distance is measured by the number of arcs in the path from the root. There is a fairly strong (inverse) correlation between dependency length and distance to the root, so it is not surprising that the plots in Figure 3 largely show the mirror image of the plots in Figure 2. For the baseline parsers, the graph-based parser has a clear advantage for dependencies near the root (including the root itself), but the transition-based parser closes the gap with increasing distance.[8] For ELMo and BERT, the curves are much more similar, with only a slight advantage for the graph-based parser near the root and with the transition-based BERT parser being superior from distance 5 upwards. The main trends are again similar across all languages.

6.3 Non-Projective Dependencies

Figure 4 shows precision and recall specifically for non-projective dependencies. We see that there is a clear tendency for the transition-based parser to have better precision and the graph-based parser better recall.[9] In other words, non-projective dependencies are more likely to be correct when they are predicted by the transition-based parser using the swap transition, but real non-projective dependencies are more likely to be found by the graph-based parser using a spanning tree algorithm. Interestingly, adding deep contextualized word representations has almost no effect on the graph-based parser,[10] while especially the ELMo embeddings improve both precision and recall for the transition-based parser.

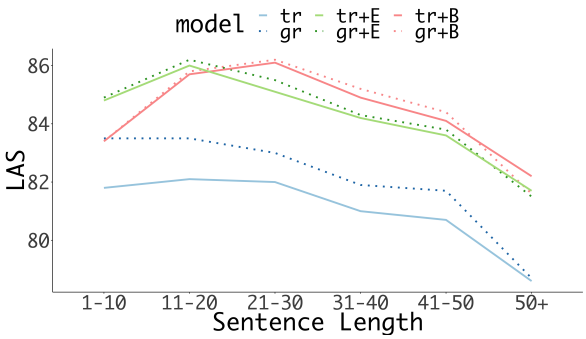

Figure 5: Labeled attachment score by sentence length.

6.4 Parts of Speech and Dependency Types

Thanks to the cross-linguistically consistent UD annotations, we can relate errors to linguistic categories more systematically than in the old study. The main impression, however, is that there are very few clear differences, which is again indicative of the convergence between the two parsing approaches. We highlight the most notable differences and refer to the supplementary material (Part B) for the full results.

Looking first at parts of speech, the baseline graph-based parser is slightly more accurate on verbs and nouns than its transition-based counterpart, which is consistent with the old study for verbs but not for nouns. After adding the deep contextualized word representations, both differences are essentially eliminated.

With regard to dependency relations, the baseline graph-based parser has better precision and recall than the baseline transition-based parser for the relations of coordination (conj), which is consistent with the old study, as well as clausal subjects (csubj) and clausal complements (ccomp), which are relations that involve verbs in clausal structures. Again, the differences are greatly reduced in the enhanced parsing models, especially for clausal complements, where the transition-based parser with ELMo representations is even slightly more accurate than the graph-based parser.

6.5 Sentence Length

Figure 5 plots labeled attachment score for sentences of different lengths, measured by number of words in bins of 1–10, 11–20, etc. Here we

[8] At the very end, the curves appear to diverge again, but the data is very sparse in this part of the plot.

[9] Incidentally, the same pattern is reported by McDonald and Nivre (2007, 2011), even though the techniques for processing non-projective dependencies are different in that study: pseudo-projective parsing (Nivre and Nilsson, 2005) for the transition-based parser and approximate second-order non-projective parsing (McDonald and Pereira, 2006) for the graph-based parser.

[10] The breakdown per language shows marginal improvements for the enhanced graph-based models on a few languages, canceled out by equally marginal degradations on others.

find the most unexpected results of the study. First of all, although the baseline parsers exhibit the familiar pattern of accuracy decreasing with sentence length, it is not the transition-based but the graph-based parser that is more accurate on short sentences and degrades faster. In other words, although the transition-based parser still seems to suffer from search errors, as shown by the results on dependency length and distance to the root, it no longer seems to suffer from error propagation in the sense that earlier errors make later errors more probable. The most likely explanation for this is the improved training for transition-based parsers using dynamic oracles and aggressive exploration to learn how to behave optimally also in non-optimal configurations (Goldberg and Nivre, 2012, 2013; Kiperwasser and Goldberg, 2016).

Turning to the models with deep contextualized word representations, we find that transition-based and graph-based parsers behave more similarly, which is in line with our hypotheses. However, the most noteworthy result is that accuracy *improves* with increasing sentence length. For ELMo this holds only from 1–10 to 11–20, but for BERT it holds up to 21–30, and even sentences of length 31–40 are parsed with higher accuracy than sentences of length 1–10. A closer look at the breakdown per language reveals that this picture is slightly distorted by different sentence length distributions in different languages. More precisely, high-accuracy languages seem to have a higher proportion of sentences of mid-range length, causing a slight boost in the accuracy scores of these bins, and no single language exhibits exactly the patterns shown in Figure 5. Nevertheless, several languages exhibit an increase in accuracy from the first to the second bin or from the second to the third bin for one or more of the enhanced models (especially the BERT models). And almost all languages show a less steep degradation for the enhanced models, clearly indicating that deep contextualized word representations improve the capacity to parse longer sentences.

7 Conclusion

In this paper, we have essentially replicated the study of McDonald and Nivre (2007, 2011) for neural parsers. In the baseline setting, where parsers use pre-trained word embeddings and character representations fed through a BiLSTM, we can still discern the basic trade-off identified in the old study, with the transition-based parser suffering from search errors leading to lower accuracy on long dependencies and dependencies near the root of the tree. However, important details of the picture have changed. The graph-based parser is now as accurate as the transition-based parser on shorter dependencies and dependencies near the leaves of the tree, thanks to improved representation learning that overcomes the limited feature scope of the first order model. And with respect to sentence length, the pattern has actually been reversed, with the graph-based parser being more accurate on short sentences and the transition-based parser gradually catching up thanks to new training methods that prevent error propagation.

When adding deep contextualized word representations, the behavior of the two parsers converge even more, and the transition-based parser in particular improves with respect to longer dependencies and dependencies near the root, as a result of fewer search errors thanks to enhanced information about the global sentence structure. One of the most striking results, however, is that both parsers improve their accuracy on longer sentences, with some models for some languages in fact being more accurate on medium-length sentences than on shorter sentences. This is a milestone in parsing research, and more research is needed to explain it.

In a broader perspective, we hope that future studies on dependency parsing will take the results obtained here into account and extend them by investigating other parsing approaches and neural network architectures. Indeed, given the rapid development of new representations and architectures, future work should include analyses of how all components in neural parsing architectures (embeddings, encoders, decoders) contribute to distinct error profiles (or lack thereof).

Abstract

Semantic parses are directed acyclic graphs (DAGs), so semantic parsing should be modeled as graph prediction. But predicting graphs presents difficult technical challenges, so it is simpler and more common to predict the *linearized* graphs found in semantic parsing datasets using well-understood sequence models. The cost of this simplicity is that the predicted strings may not be well-formed graphs. We present recurrent neural network DAG grammars, a graph-aware sequence model that ensures only well-formed graphs while sidestepping many difficulties in graph prediction. We test our model on the Parallel Meaning Bank—a multilingual semantic graphbank. Our approach yields competitive results in English and establishes the first results for German, Italian and Dutch.

1 Introduction

Semantic parsing is the task of mapping natural language to machine interpretable meaning representations, which in turn can be expressed in many different formalisms, including lambda calculus (Montague, 1973), dependency-based compositional semantics (Liang et al., 2011), frame semantics (Baker et al., 1998), abstract meaning representations (AMR; Banarescu et al. 2013), minimal recursion semantics (MRS; Copestake et al. 2005), and discourse representation theory (DRT; Kamp 1981).

Explicitly or implicitly, a representation in any of these formalisms can be expressed as a directed acyclic graph (DAG). Consider the sentence "*Every ship in the dock needs a big anchor*". Its meaning representation, expressed as a Discourse Representation Structure (DRS, Kamp 1981), is shown in Figure 1.[1] A DRS is drawn as a box with

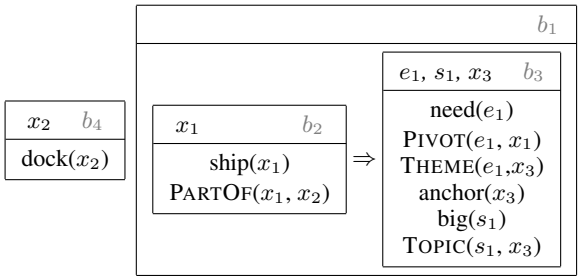

Figure 1: The discourse representation structure for "*Every ship in the dock needs a big anchor*". For ease of reference in later figures, each box includes a variable corresponding to the box itself, at top right in gray.

two parts: the top part lists variables for discourse referents (e.g. x_1, e_1) and the bottom part can contain unary predicates expressing the type of a variable (e.g. ship, need), binary predicates specifying relationships between variables (e.g. PARTOF, TOPIC), logical operators expressing relationships between nested boxes (e.g. $\Rightarrow$, $\neg$), or binary discourse relations (e.g., RESULT, CONTRAST). To express a DRS as a graph, we represent each box as a node labeled $\square$; each variable as a node labeled by its associated unary predicate; and each binary predicate, logical operator, or discourse relation as an edge from the first argument to the second (Figure 2). To fully realize the representation as a DAG, additional transformations are sometimes necessary: in DRS, when a box represents a *presupposition*, as box b_4 does, the label of the node corresponding to the presupposed variable is marked (e.g. x_2/dock^P); and edges can be reversed (e.g. TOPIC(s_1, x_3) becomes TOPICOF(s_1, x_3)).

Since meaning representations are graphs, semantic parsing should be modeled as graph prediction. But how do we predict graphs? A popular approach is to predict the *linearized* graph—that is, the *string* representation of the graph found in most semantic graphbanks. Figure 3 illus-

[1]For simplicity, our examples do not show time representations, though these are consistently present in our data.

    :DRS(x1/ship
      :PARTOF(x2/dock^p)))
  :IMP2(b3/□
    :DRS(e1/ need
      :PIVOT x1
      :THEME(x3/ anchor
        :TOPICOF(s1/ big)))))
```

Figure 3: The DAG of Figure 2 expressed as a string.

trates one style of linearization using PENMAN notation, in which graphs are written as well-bracketed strings which can also be interpreted as trees—note the correspondence between the tree-like structure of Figure 2 and the string in Figure 3.[2] Each subtree is a bracketed string starting with a node variable and its label (e.g. b_2/□), followed by a list of *relations* corresponding to the outgoing edges of the node. A relation consists of the edge label prefixed with a colon (:), followed by either the subtree rooted at the target node (e.g. :DRS (x_1/ship :PARTOF(x_2/dock^p))), or a *reference* to the target node (e.g. :PIVOT x_1). By convention, if a node is the target of multiple edges, then the leftmost one is written as a subtree, and the remainder are written as references. Hence, every node is written as a subtree exactly once.

The advantage of predicting linearized graphs is twofold. The first advantage is that graphbank datasets usually already contain linearizations, which can be used without additional work. These linearizations are provided by annotators or algorithms and are thus likely to be very consistent in ways that are beneficial to a learning algorithm. The second advantage is that we can use simple, well-understood sequence models (Gu et al., 2016; Jia and Liang, 2016; van Noord et al., 2018) to model them. But this simplicity comes with a cost: sequence models can predict strings that don't correspond to graphs—for example, strings with ill-formed bracketings or unbound variable names. While it is often possible to fix these strings with pre- or post-processing, we would prefer to model the problem in a way that does not require this.

Models that predict graphs are complex and far less well-understood than models that predict sequences. Fundamentally, this is because predicting graphs is difficult: every graph has many possible linearizations, so from a probabilistic perspective, the linearization is a latent variable that must be marginalized out (Li et al., 2018). Groschwitz et al. (2018) model graphs as trees, interpreted as the (latent) derivation trees of a graph grammar; Lyu and Titov (2018) model graphs with a conditional variant of the classic Erdös and Rényi (1959) model, first predicting an alignment for each node of the output graph, and then predicting, for each pair of nodes, whether there is an edge between them. Buys and Blunsom (2017), Chen et al. (2018), and Damonte et al. (2017) all model graph generation as a sequence of actions, each aligned to a word in the conditioning sentence. Each of these models has a latent variable—a derivation tree or alignment—which must be accounted for via preprocessing or complex inference techniques.

Can we combine the simplicity of sequence prediction with the fidelity of graph prediction? We show that this is possible by developing a new model that predicts sequences through a simple string rewriting process, in which each rewrite corresponds to a well-defined graph fragment. Importantly, any well-formed string produced by our model has exactly one derivation, and thus no latent variables. We evaluate our model on the Parallel Meaning Bank (PMB, Abzianidze et al. 2017), a multilingual corpus of sentences paired with DRS representations. Our model performs competitively on English, and better than sequence models in German, Italian, and Dutch.

2 Graph-aware string rewriting

We use a grammar to model the process of rewriting. Formally, our grammar is a *graph grammar*, specifically a *restricted DAG grammar* (Björklund

[2] Although PENMAN notation is now closely associated with AMR, it can represent quite arbitrary graphs as strings. Our actual implementation does not use PENMAN notation, but we use it here for expository purposes since it is relatively familiar; the underlying ideas are unchanged.

et al., 2016), a type of context-free graph grammar designed to model linearized DAGs. Since linearized DAGs are strings, we present it as a string-rewriting system, which can be described more compactly than a graph grammar while making the connection to sequences more explicit. The correspondence between string rewriting and graph grammars is given in the Appendix.

A grammar in our model is defined by a set Σ of **terminal symbols** consisting of all symbols that can appear in the final string—brackets, variable types, node labels, and edge labels; a set N of $n+1$ **nonterminal symbols** denoted by $\{L, T_0, \ldots, T_n\}$, for some maximum value n; an unbounded set V of **variable references** $\{\$1, \$2, \ldots\}$; and a set of productions, which are defined below.

We say that T_0 is the **start symbol**, and for each symbol $T_i \in N$, we say that i is its **rank**, and we say that L has a rank of 0. A nonterminal of rank i can be written as a **function** of i variable references—for example, we can write $T_2(\$1, \$2)$. By convention, we write the rank-0 nonterminals L and T_0 without brackets. Productions in our grammar take the form $\alpha \rightarrow \beta$, where α is a function of rank i over $\$1, \ldots, \$i$; and β is a linearized graph in PENMAN format, with each of its subtrees replaced by either a function or a variable reference. Optionally, the variable name in β may replace one of the variable references in α. All variable references in a production must appear at least twice. Hence every variable reference in α must appear at least once in β, and variables that do not appear in α must appear at least twice in β.

To illustrate, we will use the following grammar, which can generate the string in Figure 3, assuming L can also rewrite as any node label.

$$T_0 \rightarrow (b/\square \text{ :IMP}_1\ T_1(\$1)\ \text{:IMP}_2\ T_1(\$1)) \quad (r_1)$$
$$T_0 \rightarrow (x/L) \quad (r_2)$$
$$T_0 \rightarrow (s/L) \quad (r_3)$$
$$T_0 \rightarrow (x/L\ \text{:TOPICOF}\ T_0) \quad (r_4)$$
$$T_1(\$1) \rightarrow (b/\square\ \text{:DRS}\ T_1(\$1)) \quad (r_5)$$
$$T_1(\$1) \rightarrow (e/L\ \text{:PIVOT}\ \$1\ \text{:THEME}\ T_0) \quad (r_6)$$
$$T_1(x) \rightarrow (x/L\ \text{:PARTOF}\ T_0) \quad (r_7)$$

Our grammar derives strings by first rewriting the start symbol T_0, and at each subsequent step rewriting the leftmost function in the partially derived string, with special handling for variable references described below. A derivation is complete when no functions remain.

We illustrate the rewriting process in Figure 4. The start symbol T_0 at step 1 is rewritten by production r_1 in step 2, and the new b variable introduced at this step is deterministically renamed to the unique name b_1. In step 3, the leftmost $T_1(\$1)$ is rewritten by production r_5, and the new b variable is likewise renamed to the unique b_2. All productions apply in this way, simply replacing a left-hand-side function with a right-hand side expression. These rewrites are coupled with a mechanism to correctly handle multiple references to shared variables, as illustrated in Step 4 when production r_7 is applied. In this production, the left-hand-side function applies to the x variable naming the right-hand-side node. When this production applies, x is renamed to the unique x_1 as in previous steps, but because it appears in the left-hand-side, the reference $\$1$ is bound to this new variable name throughout the partially-derived string. In this way, the reference to x_1 is passed through the subsequent rewrites, becoming the target of a PIVOT edge at step 10. Derivations of a DAG grammar are context-free (Figure 5).[3]

Our model requires an explicit grammar like the one in $r_1 \ldots r_7$, which we obtain by converting each DAG in the training data into a sequence of productions. The conversion yields a single, unique sequence of productions via a simple linear-time algorithm that recursively decomposes a DAG into subgraphs (Björklund et al., 2016). Each subgraph consists of single node and its outgoing edges, as exemplified by the PENMAN-formatted right-hand-sides of r_1 through r_7. Each outgoing edge points to a nonterminal symbol representing a subgraph. If a subgraph does not share any nodes with its siblings, it is represented by T_0. But if any subgraphs share a node, then a variable reference must refer for this node in the production associated with the lowest common ancestor of all its incoming edges. For example, in Figure 3, the common ancestor of the two edges targeting x_1 is the node b_1, so production r_1 must contain two copies of variable reference $\$1$ to account for this. A more mathematical account can be found along with a proof of correctness in Björklund et al. (2016) Our implementation follows their description unchanged.

[3] However, the language of derived strings may not be context-free due to variable references.

Step	Action	Production	Result
1	START	start	$\underline{T_0}$
2	GEN-FRAG	r_1	$(b_1/\square$:IMP$_1$ $\underline{T_1(\$1)}$:IMP$_2$ $T_1(\$1))$

Figure 4: A partial derivation of the string in Figure 3. The stack operations follow closely each step in the derivation, where GEN-FRAG and GEN-LABEL are invoked when rewriting a non-terminal T and a terminal L respectively. In the result of each step, the leftmost function is underlined, and is rewritten in the fragment in blue in the next step. On the other hand, a REDUCE operation is invoked when a generated fragment does not contain non-terminals T to expand further (in this partial derivation, this is the case of the result of production r_2).

3 Neural Network Realizer

We model graph parsing with an encoder-decoder architecture that takes as input a sentence w and outputs a directed acyclic graph G derived using the rewriting system of Section 2. Specifically, we model its derivation tree in top-down, left-to-right order as a sequence of actions $a = a_1 \dots a_{|a|}$, inspired by Recurrent Neural Network Grammars (RNNG, Dyer et al., 2016). As in RNNG, we use a stack to store partial derivations.

We model two types of actions: **GEN-FRAG** rewrites T_i nonterminals, while **GEN-LABEL** rewrites L nonterminals, always resulting in a leaf of the derivation tree. A third **REDUCE** action is applied whenever a subtree of the derivation tree is complete, and since the number of subtrees is known in advance, it is applied deterministically. For example, when we predict r_1, this determines that we must rewrite an L and then recursively rewrite two copies of $T_1(\$1)$ and then apply **REDUCE**. Hence graph generation reduces to predicting rewrites only.

We define the probability of generating graph G conditioned of input sentence w as follows:

$$p(G|w) = p(a|w) = \prod_{i=1}^{|a|} p(a_i|a_{<i}, w) \quad (1)$$

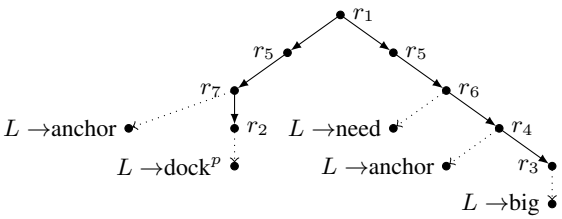

Figure 5: A derivation tree corresponding to Figure 4. Solid edges rewrite T_n nonterminals, while dotted rewrite L nonterminals.

Input Encoder We represent the ith word w_i of input sentence $w = w_1 \dots w_{|w|}$ using both learned and pre-trained word embeddings ($\mathbf{w}_i$ and $\mathbf{w}_i^p$ respectively), lemma embedding ($\mathbf{l}_i$), part-of-speech embedding ($\mathbf{p}_i$), universal semantic tag (Abzianidze and Bos, 2017) embedding ($\mathbf{u}_i$), and dependency label embedding ($\mathbf{d}_i$).[4] An input $\mathbf{x}_i$ is computed as the weighted concatenation of these features followed by a non-linear projection (with vectors and matrices in **bold**):

$$\mathbf{x}_i = \tanh(\mathbf{W^{(1)}}[\mathbf{w}_i; \mathbf{w}_i^p; \mathbf{l}_i; \mathbf{p}_i; \mathbf{u}_i; \mathbf{d}_i]) \quad (2)$$

Input $\mathbf{x}_i$ is then encoded with a bidirectional LSTM, yielding contextual representation $\mathbf{h}_i^e$.

[4] Universal semantic tags are language neutral tags intended to characterize lexical semantics.

Graph decoder Since we know in advance whether the next action is **GEN-FRAG** or **GEN-LABEL**, we use different models for them.

GEN-FRAG. If step t rewrites a T nonterminal, we predict the production y_t that rewrites it using context vector $\mathbf{c}_t$ and incoming edge embedding $\mathbf{e}_t$. To obtain $\mathbf{c}_t$ we use *soft attention* (Luong et al., 2015) and weight each input hidden representation $\mathbf{h}_i^e$ to decoding hidden state $\mathbf{h}_t^d$:

$$\begin{aligned} \text{score}(\mathbf{h}_i^e, \mathbf{h}_t^d) &= \mathbf{h}_i^e \mathbf{W}^{(2)} \mathbf{h}_t^d \\ \alpha_{ti} &= \frac{\exp(\text{score}(\mathbf{h}_i^e, \mathbf{h}_t^d))}{\sum_{i'} \exp(\text{score}(\mathbf{h}_{i'}^e, \mathbf{h}_t^d))} \\ \mathbf{c}_t &= \sum_{i=1}^{n} \alpha_{ti} \mathbf{h}_i^e \\ \mathbf{y}_t &= \mathbf{W}^{(3)} \mathbf{c}_t + \mathbf{W}^{(4)} \mathbf{e} \end{aligned} \tag{3}$$

The contribution of $\mathbf{c}$ and $\mathbf{e}$ is weighted by matrices $\mathbf{W}^{(3)}$ and $\mathbf{W}^{(4)}$, respectively.

We then update the stackLSTM representation using the embedding of the non-terminal fragment $\mathbf{y}_t$ (denoted as $\mathbf{y}_t^e$), as follows:

$$\mathbf{h}_{t+1}^d = \text{LSTM}(\mathbf{y}_t^e, \mathbf{h}_t^d) \tag{4}$$

GEN-LABEL. Labels L can be rewritten to either semantic constants (e.g., 'speaker', 'now', 'hearer') or unary predicates that often corresponds to the lemmas of the input words (e.g., 'love') or. We predict the former using a model identical to the one for GEN-FRAG. For the latter, we use a *selection mechanism* to choose an input lemma to copy to output. We model selection following Liu et al. (2018), assigning each input lemma a score o_{ji} that we then pass through a softmax layer to obtain a distibution:

$$\begin{aligned} o_{ji} &= \mathbf{h}_j^{dT} \mathbf{W}^{(5)} \mathbf{h}_i^e \\ p_i^{copy} &= \textsc{SoftMax}(o_{ji}) \end{aligned} \tag{5}$$

where $\mathbf{h}_i$ is the encoder hidden state for word w_i.

We allow the model to learn whether to use soft-attention or the selection mechanism through a binary classifier, conditioned on the decoder hidden state at time t, $\mathbf{h}_t^d$. Similar to Equation (4), we update the stackLSTM with the embedding of terminal predicted.[5]

[5]In the PMB, each terminal is annotated for sense (e.g. 'n.01', 's.01') and presupposition (e.g. for 'dock^p' in Figure 3) as well. We predict both the sense tag and whether a terminal is presupposed or not independently conditioned on the current stackLSTM state and the embedding of the main terminal labels but are **not** used to update the state of the stackLSTM.

REDUCE. When a reduce action is applied, we use an LSTM to compose the fragments on top of the stack. Using the derivation tree in Figure 5 as reference, let $[\mathbf{c}_1, ..., \mathbf{c}_n]$ denote the embeddings of one or more sister nodes r_i and p_u the embedding of their parent node, which we refer to as *children* and *parent fragments* respectively. A reduce operation runs an LSTM over the children fragments and the parent fragment in order and then uses the final state u to update the stack LSTM as follows:

$$\begin{aligned} \mathbf{i} &= [\mathbf{c}_1 ... \mathbf{c}_n, \mathbf{p}_u] \\ \overrightarrow{\mathbf{u}} &= LSTM(\mathbf{i}_t, \mathbf{h}_t^c) \\ \mathbf{h}_{t+1}^d &= LSTM(\mathbf{u}, \mathbf{h}_t^d) \end{aligned}$$

The models are trained to minimize a cross-entropy loss objective J over the sequence of gold actions a_i in the derivation:

$$J = -\sum_{i=1}^{|a|} log\ p(a_i) \tag{6}$$

4 Experimental Setup

We evaluated our model on the Parallel Meaning Bank (PMB; Abzianidze et al. 2017), a semantic bank where sentences in English, Italian, German, and Dutch have been annotated following Discourse Representation Theory (Kamp and Reyle, 2013). Lexical predicates in PMB are in English, even for non-English languages. Since this is not compatible with our copy mechanism, we revert predicates to their orignal language by substituting them with the lemmas of the tokens they are aligned to. In our experiments we used both PMB v.2.1.0 and v.2.2.0[6]; we included the former release in order to compare against the state-of-the-art seq2seq system of van Noord et al. (2018). Statistics on the data and the grammar extracted from v.2.2.0 are reported in Table 1.

4.1 Converting DRSs to Graphs

In this section we discuss how DRSs are converted to *acyclic*, *single-rooted*, and *fully-instantiated* graphs (i.e., how to translate Figure 1 to Figure 2). In general, box structures are converted to acyclic graphs by rendering boxes and lexical predicates

[6]English data is available for both releases at https://github.com/RikVN/DRS_parsing; for the other languages, we used the officially released data available at http://pmb.let.rug.nl/data.php

as nodes, while conditions, operators, and discourse relations become edge labels between these nodes.

We consider *main* boxes (see b_2, b_3, and b_4 in Figure 1 separately from *presuppositional* boxes (see b_1), which represent instances that are presupposed in the wider discourse context (e.g., definite expressions). Using Figure 2 as an example, b_2, b_3 and b_4 become nodes in the graph and material implication (IMP stands for $\Rightarrow$) becomes an edge label. If an operator or a relation is binary, as in this case, we number the edge label so as to preserve the order of the operands.

For each node in a *main* box, we expand the graph by adding all relations and variables belonging to it. We identify the head of the first relation or the first referent mentioned as the *head variable*. These are 'ship (x_1)' for b_2, and 'need(e_1)' for b_3. We attach the head variable as a child of the box-node and follow the relations recursively to expand the subgraph. If while expanding a graph a variable in a condition is part of a presuppositional box, we introduce it as a new node and add to its label the superscript ^{p}. When expanding the DAG along the edge PartOf, since x_2 is also in the presuppositional box in Figure 1, we attach the node 'dock^p'. Graphs extracted this way are mostly acyclic except for adjectival phrases and relative clauses where state variables can be themselves root (e.g., big "a.01" s_1). We get rid of these extra roots by reversing the direction of the edge involved and adding an '-of' to the edge label to flag this change (see TOPIC-OF).

4.2 System Comparison

We compared the performance of our graph parser (seq2graph below) with a sequence-to-sequence model (enchanced with a copy mechanism) which decodes to a string linearization of the graph similar to the one shown in Figure 3 (seq2seq + copy below). We also compare against the recently proposed model of van Noord et al. (2018); they introduce a seq2seq model that generates a DRS as a concatenation of *clauses*, essentially a flat version of the standard box notation. The decoded string is made aware of the overall graph structure during preprocessing where variables are replaced by indices indicating when they were first introduced and their recency. In contrast, we model the graph structure explicitly. van Noord et al. (2018) experimented with both word and character-based models, as well as with an ensemble of both, using word embedding features. Since all our models are word-based, we compare our results with their best word model, using word embedding features only (trained using 10-fold cross validation).

4.3 Model Configurations

In addition to word embeddings[7], we also report on experiments which make use of additional features. Specifically, for each word we add information about its universal PoS tag, lemma, universal semantic tag, and dependency label.[8]

In Section 2, we mentioned that given a production $\alpha \rightarrow \beta$, variable references in α should appear at least once in β (i.e., they should have the same rank). In all experiments so far, we did not model this constraint explicitly to investigate whether the model is able by default to predict rank correctly. However, in exploring model configurations we also report on whether adding this constrant leads to better performance .

4.4 Cross-lingual Experiments

We conducted two sets of experiments: one monolingual (mono below) where we train and test on the same language and one cross-lingual (cross below), where we train a model on English and test it on one of the other three languages. The goal of our cross-lingual experiments is to examine whether we need data in a target language at all since the semantic representation itself is language agnostic and lexical predicates are dealt with via

[7]We used word embeddings pre-trained with Glove and available at https://nlp.stanford.edu/projects/glove/.

[8]Universal PoS tags, lemmas and dependency labels for all languages were obtained using pretrained UDPipe models available at http://ufal.mff.cuni.cz/udpipe#download; gold-standard universal semantic tags were extracted from the PMB release.

the copy mechanism. Most of the features mentioned above are cross-linguistic and therefore fit both mono and cross-lingual settings, with the exception of lemma and word embeddings, where we exclude the former and replaced the latter with multilingual word embeddings.[9]

4.5 System settings

For training, we used the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001 and a decay rate of 0.1 every 10 epochs. Randomly initialized and pre-trained word embeddings have a dimensionality of 128 and 100 respectively, and all other features a dimensionality of 50. In all cross-lingual experiments, the pre-trained word embeddings have a dimensionality of 300. The LSTMs in the encoder and the decoder have a dimensionality of 150 and non-terminal and terminal embeddings during decoding have a dimensionality of 50. The system is trained for 30 epochs, with the best system chosen based on dev set performance.

4.6 Evaluation Metric

We evaluated our system by scoring the similarity between predicted and gold graphs. We used Counter (van Noord et al., 2018), an adaptation of Smatch (Cai and Knight, 2013) to Discourse Representation Structures where graphs are first transformed into a set of 'source node – edge label – target node' triples and the best mapping between the variables is found through an iterative hill-climbing strategy. Furthermore, Counter checks whether DRSs are well-formed in that all boxes should be connected, acyclic, with fully instantiated variables, and correctly assigned sense tags.

It is worth mentioning that there can be cases where our parser generates ill-formed graphs according to Counter; this is however not due to the model itself but to the way the graph is converted back in a format accepted by Counter.

All results shown are an averages over 5 runs.

[9]We experimented with embeddings obtained with iterative procrustes (available at https://github.com/facebookresearch/MUSE) and with Guo et al. (2016)'s 'robust projection' method where the embedding of non-English words is computed as the weighted average of English ones. We found the first method to perform better on cross-lingual word similarity tasks and used it in our experiments.

5 Results

System comparison Table 2 summarizes our results on the PMB gold data (v.2.1.0, test set). We compare our graph decoder against the system of van Noord et al. (2018) and our implementation of a seq2seq model, enhanced with a copy mechanism. Overall, we see that our graph decoder outperforms both models. Moreover, it reduces the number of illformed representations without any specific constraints or post-processing in order to ensure the well-formedness of the semantics of the output.

The PMB (v.2.1.0) contains a large number of silver standard annotations which have been only partially manually corrected (see Table 1). Following van Noord et al. (2018), we also trained our parser on both silver and gold standard data combined. As shown in Table 3, increasing the training data improves performance but the difference is not as dramatic as in van Noord et al. (2018). We found that this is because our parser requires graphs that are fully instantiated – all unary predicates (e.g. *ship(x)*) need to be present for the graph to be fully connected, which is often not the case for silver graphs. Our model is at a disadvantage since it could exploit less training data; during grammar extraction we could not process around 20K sentences and in some cases could not reconstruct the whole graph, as shown by the *conversion score*.[10]

[10]The conversion score is computed using Counter where we consider the converted graph representation as a 'predicted' DRS and the original DRS structure as gold data. As a comparison, converting the *gold* DRS sturctures yields a conversion score of 99.8%.

Table 5: Model performance across languages (Precision, Recall, F_1). Results are reported on the PMB test set (v.2.2.0) for each language.

Model configurations Table 4 reports on various ablation experiments investigating which features and combinations thereof perform best. The experiments were conducted on the development set (PMB v2.2.0). We show a basic version of our seq2graph model with word embeddings, to which we add information about rank (+restrict). We also experimented with the full gamut of additional features (+feats) as well as with ablations of individual feature classes. For comparsion, we also show the performance of a graph-to-string model (seq2seq+copy).

As can be seen, all linguistic features seem to improve performance. Restricting fragment selection by rank does not seem to improve the overall result showing that our baseline model is already able to predict fragments with the correct rank throughout the derivation. Subsequent experiments report results with this model using all linguistic features, unless otherwise specified.

Cross-lingual experiments Results on DRT parsing for languages other than English are reported in Table 5. There is no gold standard training data for non-English languages in the PMB (v.2.2.0). We therefore trained our parser on silver standard data but did use the provided gold standard data for development and testing (see Table 1). We present two versions of our parser, one where we train and test on the same language (s2g mono-silver) and another one where a model is trained on English but tested on the other languages (s2g cross-silver). We also show the results of a sequence-to-sequence model enhanced with a copy mechanism.

In the monolingual setting, our graph parser outperforms the seq2seq baseline by a large margin; we hypothesize this is due to the large percentage of ill-formed semantics, mostly due to training on silver data. The difference in performance between our cross-lingual parser and the monolingual parser for all languages is small, and in Dutch the two parsers perform on par, suggesting that English data and language independent features can be leveraged to build parsers in other languages when data is scarse or event absent. We also conducted various ablation studies to examine the contribution of individual features to cross-linguistic semantic parsing. Our experiments revealed that universal semantic tags are most useful, while the multilingual word embeddings that we have tested with are not. We refer the interested reader to the supplementary material for more detail on these experiments.

Error Analysis We further analyzed the output of our parser to gain insight as to what parts of meaning representation are still challenging. Table 6 shows a more detailed break-down of system output as computed by Counter, where *operators* (e.g., negation, implication), roles (i.e., binary relations, such as 'Theme'), concepts (i.e., unary predicates like 'ship'), and *synsets* (i.e., sense tags like 'n.01') are scored separately. Synsets are further broken down into into 'Nouns', 'Verbs', 'Adverbs', and 'Adjectives'. We compare our best seq2graph models (+*feats*) trained on the PMB v.2.2.0, gold and gold+silver data respectively.

Adding silver data helps with semantic elements (operators, roles and concepts), but does not in the case of sense prediction where the only category that benefits from additional data are is nouns. We also found that ignoring the prediction of sense tags altogether helps with the performance of both models.

		seq2graph(gold)	seq2graph(silver)
all clauses		74.42	**76.36**
DRS operators		88.05	**89.36**
Roles		72.95	**74.03**
Concepts		71.13	**74.42**
Synsets	– Nouns	77.13	**81.80**
	– Verbs	**55.63**	55.49
	– Adverbs	**44.44**	42.11
	– Adjectives	**61.67**	58.48
-sense		76.91	**78.93**

Table 6: F_1-scores of fine-grained evaluation on the PMB (v.2.2.0) development set; the seq2graph models trained on *gold* (left) and with *gold* and *silver* data combined (right) are compared.

6 Conclusions

In this paper we have introduced a novel graph parser that can leverage the power and flexibility of sequential neural models while still operating on graph structures. Heavy preprocessing tailored to a specific formalism is replaced by a flexible grammar extraction method that relies solely on the graph while yielding performance that is on par or better than string-based approaches. Future work should focus on extending our parser to other formalisms (AMR, MRS, etc.). We also plan to explore modelling alternatives, such as taking different graph generation oders into account (bottom-up vs. top-down) as well as predicting the components of a fragment (type, number of edges, edge labels) separately.

dankondratyuk@gmail.com, straka@ufal.mff.cuni.cz

Abstract

We present UDify, a multilingual multi-task model capable of accurately predicting universal part-of-speech, morphological features, lemmas, and dependency trees simultaneously for all 124 Universal Dependencies treebanks across 75 languages. By leveraging a multilingual BERT self-attention model pretrained on 104 languages, we found that fine-tuning it on all datasets concatenated together with simple softmax classifiers for each UD task can meet or exceed state-of-the-art UPOS, UFeats, Lemmas, (and especially) UAS, and LAS scores, without requiring any recurrent or language-specific components. We evaluate UDify for multilingual learning, showing that low-resource languages benefit the most from cross-linguistic annotations. We also evaluate for zero-shot learning, with results suggesting that multilingual training provides strong UD predictions even for languages that neither UDify nor BERT have ever been trained on. Code for UDify is available at https://github.com/hyperparticle/udify.

1 Introduction

In the absence of annotated data for a given language, it can be considerably difficult to create models that can parse the language's text accurately. Multilingual modeling presents an attractive way to circumvent this low-resource limitation. In a similar way learning a new language can enhance the proficiency of a speaker's previous languages (Abu-Rabia and Sanitsky, 2010), a model which has access to multilingual information can begin to learn generalizations across languages that would not have been possible through monolingual data alone. Works such as McDonald et al. (2011); Naseem et al. (2012); Duong et al. (2015); Ammar et al. (2016); de Lhoneux et al. (2018); Kitaev and Klein (2018); Mulcaire et al. (2019) consistently demonstrate how pairing the training data of similar languages can boost evaluation scores of models predicting syntactic information like part-of-speech and dependency trees. Multilinguality not only can improve a model's evaluation performance, but can also reduce the cost of training multiple models for a collection of languages (Johnson et al., 2017; Smith et al., 2018).

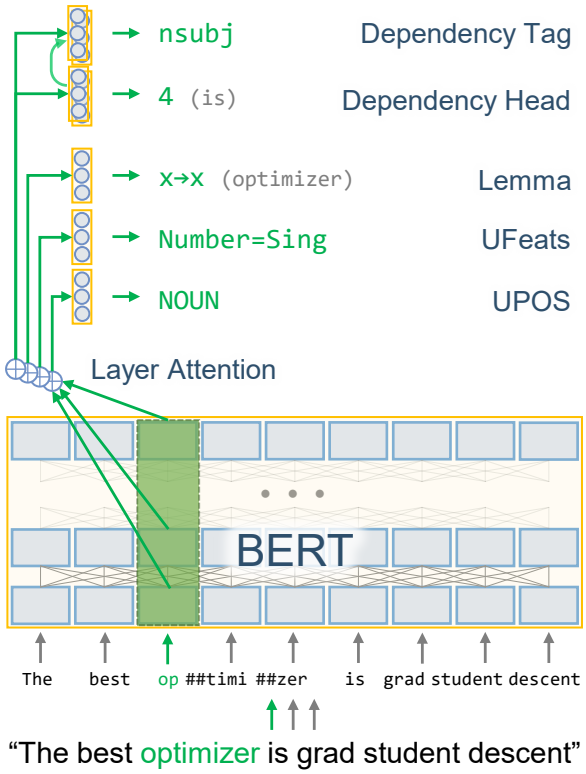

Figure 1: An illustration of the UDify network architecture with task-specific layer attention, inputting word tokens and outputting UD annotations for each token.

However, scaling to a higher number of languages can often be problematic. Without an ample supply of training data for the considered languages, it can be difficult to form appropriate generalizations and especially difficult if those

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2779–2795,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

languages are distant from each other. But recent techniques in language model pretraining can profit from a drastically larger supply of unsupervised text, demonstrating the capability of transferring contextual sentence-level knowledge to boost the parsing accuracy of existing NLP models (Howard and Ruder, 2018; Peters et al., 2018; Devlin et al., 2018).

One such model, BERT (Devlin et al., 2018), introduces a self-attention (Transformer) network that results in state-of-the-art parsing performance when fine-tuning its contextual embeddings. And with the release of a multilingual version pretrained on the entirety of the top 104 resourced languages of Wikipedia, BERT is remarkably capable of capturing an enormous collection of cross-lingual syntactic information. Conveniently, these languages nearly completely overlap with languages supported by the Universal Dependencies treebanks, which we will use to demonstrate the ability to scale syntactic parsing up to 75 languages and beyond.

The Universal Dependencies (UD) framework provides syntactic annotations consistent across a large collection of languages (Nivre et al., 2018; Zeman et al., 2018). This makes it an excellent candidate for analyzing syntactic knowledge transfer across multiple languages. UD offers tokenized sentences with annotations ideal for multi-task learning, including lemmas (LEMMAS), treebank-specific part-of-speech tags (XPOS), universal part-of-speech tags (UPOS), morphological features (UFEATS), and dependency edges and labels (DEPS) for each sentence.

We propose UDify, a semi-supervised multi-task self-attention model automatically producing UD annotations in any of the supported UD languages. To accomplish this, we perform the following:

1. We input all sentences into a pretrained multilingual BERT network to produce contextual embeddings, introduce task-specific layer-wise attention similar to ELMo (Peters et al., 2018), and decode each UD task simultaneously using softmax classifiers.

2. We apply a heavy amount of regularization to BERT, including input masking, increased dropout, weight freezing, discriminative fine-tuning, and layer dropout.

3. We train and fine-tune the model on the entirety of UD by concatenating *all* available training sets together.

We evaluate our model with respect to UDPipe Future, one of the winners of the CoNLL 2018 Shared Task on Multilingual Parsing from Raw Text to Universal Dependencies (Straka, 2018; Zeman et al., 2018). In addition, we analyze languages that multilingual training benefits prediction the most, and evaluate the model for zero-shot learning, i.e., treebanks which do not have a training set. Finally, we provide evidence from our experiments and other related work to help explain why pretrained self-attention networks excel in multilingual dependency parsing.

Our work uses the AllenNLP library built for the PyTorch framework. Code for UDify and a release of the fine-tuned BERT weights are available at https://github.com/hyperparticle/udify.

2 Multilingual Multi-Task Learning

In this section, we detail the multilingual training setup and the UDify multi-task model architecture. See Figure 1 for an architecture diagram.

2.1 Multilingual Pretraining with BERT

We leverage the provided BERT base multilingual cased pretrained model[1], with a self-attention network of 12 layers, 12 attention heads per layer, and hidden dimensions of 768 (Devlin et al., 2018). The model was trained by predicting randomly masked input words on the entirety of the top 104 languages with the largest Wikipedias. BERT uses a wordpiece tokenizer (Wu et al., 2016), which segments all text into (unnormalized) sub-word units.

2.2 Cross-Linguistic Training Issues

Table 1 displays a list of vocabulary sizes, indicating that UD treebanks possess nearly 1.6M unique tokens combined. To sidestep the problem of a ballooning vocabulary, we use BERT's wordpiece tokenizer directly for all inputs. UD expects predictions to be along word boundaries, so we take the simple approach of applying the tokenizer to each word using UD's provided segmentation. For prediction, we use the outputs of BERT corresponding to the first wordpiece per word, ignoring

[1] https://github.com/google-research/bert/blob/master/multilingual.md

Token	Vocab Size
Word Form	1,588,655
BERT Wordpieces	119,547
UPOS	17
XPOS	19,126
UFeats	23,974
Lemmas (tags)	109,639
Deps	251

Table 1: Vocabulary sizes of words and tags over all of UD v2.3, with a total of 12,032,309 word tokens and 668,939 sentences.

the rest[2].

In addition, the XPOS annotations are not universal across languages, or even across treebanks. Because each treebank can possess a different annotation scheme for XPOS which can slow down inference, we omit training and evaluation of XPOS from our experiments.

2.3 Multi-Task Learning with UD

For predicting UD annotations, we employ a multi-task network based on UDPipe Future (Straka, 2018), but with all embedding, encoder, and projection layers replaced with BERT. The remaining components include the prediction layers for each task detailed below, and layer attention (see Section 3.1). Then we compute softmax cross entropy loss on the output logits to train the network. For more details on reasons behind architecture choices, see Appendix A.

UPOS As is standard for neural sequence tagging, we apply a softmax layer along each word input, computing a probability distribution over the tag vocabulary to predict the annotation string.

UFeats Identical to UPOS prediction, we treat each UFeats string as a separate token in the vocabulary. We found this to produce higher evaluation accuracy than predicting each morphological feature separately. Only a small subset of the full Cartesian product of morphological features is valid, eliminating invalid combinations.

Lemmas Similar to Chrupała (2006); Müller et al. (2015), we reduce the problem of lemmatization to a sequence tagging problem by predicting a class representing an edit script, i.e., the sequence of character operations to transform the word form to the lemma. To precompute the tags, we first find the longest common substring between the form and the lemma, and then compute the shortest edit script converting the prefix and suffix of the form into the prefix and suffix of the lemma using the Wagner–Fischer algorithm (Wagner and Fischer, 1974). Upon predicting a lemma edit script, we apply the edit operations to the word form to produce the final lemma. See also Straka (2018) for more details. We chose this approach over a sequence-to-sequence architecture like Bergmanis and Goldwater (2018) or Kondratyuk et al. (2018), as this significantly reduces training efficiency.

Deps We use the graph-based biaffine attention parser developed by Dozat and Manning (2016); Dozat et al. (2017), replacing the bidirectional LSTM layers with BERT. The final embeddings are projected through arc-head and arc-dep feed-forward layers, which are combined using biaffine attention to produce a probability distribution of arc heads for each word. We then decode each tree with the Chu-Liu/Edmonds algorithm (Chu, 1965; Edmonds, 1967).

3 Fine-Tuning BERT on UD Annotations

We employ several strategies for fine-tuning BERT for UD prediction, finding that regularization is absolutely crucial for producing a high-scoring network.

3.1 Layer Attention

Empirical results suggest that when fine-tuning BERT, combining the output of the last several layers is more beneficial for the downstream tasks than just using the last layer (Devlin et al., 2018). Instead of restricting the model to any subset of layers, we devise a simple layer-wise dot-product attention where the network computes a weighted sum of all intermediate outputs of the 12 BERT layers using the same weights for each token. This is similar to how ELMo mixes the output of multiple recurrent layers (Peters et al., 2018).

More formally, let $\boldsymbol{w}_i$ be a trainable scalar for BERT embeddings $\mathbf{BERT}_{ij}$ at layer i with a token at position j, and let c be a trainable scalar. We compute contextual embeddings $\boldsymbol{e}^{(\text{task})}$ such that

$$\boldsymbol{e}_j^{(\text{task})} = c \sum_i \mathbf{BERT}_{ij} \cdot \text{softmax}(\boldsymbol{w})_i \quad (1)$$

To prevent the UD classifiers from overfitting to the information in any single layer, we devise

[2]We found last, max, or average pooling of the wordpieces were not any better or worse for evaluation. Kitaev and Klein (2018) report similar results.

layer dropout, where at each training step, we set each parameter $\boldsymbol{w}_i$ to $-\infty$ with probability 0.1. This effectively redistributes probability mass to all other layers, forcing the network to incorporate the information content of all BERT layers. We compute layer attention per task, using one set of $c, \boldsymbol{w}$ parameters for each of UPOS, UFeats, Lemmas, and Deps.

3.2 Transfer Learning with ULMFiT

The ULMFiT strategy defines several useful methods for fine-tuning a network on a pretrained language model (Howard and Ruder, 2018). We apply the same methods, with a few minor modifications.

We split the network into two parameter groups, i.e., the parameters of BERT and all other parameters. We apply discriminative fine-tuning, setting the base learning rate of BERT to be $5e^{-5}$ and $1e^{-3}$ everywhere else. We also freeze the BERT parameters for the first epoch to increase training stability.

While ULMFiT recommends decaying the learning rate linearly after a linear warmup, we found that this is prone to training divergence in self-attention networks, introducing vanishing gradients and underfitting. Instead, we apply an inverse square root learning rate decay with linear warmup (Noam) seen in training Transformer networks for machine translation (Vaswani et al., 2017).

3.3 Input Masking

The authors of BERT recommend not to mask words randomly with `[MASK]` when fine-tuning the network. However, we discovered that masking often reduces the tendency of the classifiers to overfit to BERT by forcing the network to rely on the context of surrounding words. This *word dropout* strategy has been observed in other works showing improved test performance on a variety of NLP tasks (Iyyer et al., 2015; Bowman et al., 2016; Clark et al., 2018; Straka, 2018).

4 Experiments

We evaluate UDify with respect to every test set in each treebank. As there are too many results to fit within one page, we display a salient subset of scores and compare them with UDPipe Future. The full results are listed in Appendix A.

We do not directly reference metrics from other models in the CoNLL 2018 Shared Task, as the tables of results do not assume gold word segmentation and may not provide a fair comparison. Instead, we retrained the open source UDPipe Future model using gold segmentation and report results here due to its architectural similarity to UDify and its strong performance.

Note that the UDPipe Future baseline does not itself use BERT. Evaluation of BERT utilization in UDPipe Future can be found in Straka et al. (2019).

4.1 Datasets

For all experiments, we use the full Universal Dependencies v2.3 corpus available on LINDAT (Nivre et al., 2018). We omit the evaluation of datasets that do not have their training annotations freely available, i.e., Arabic NYUAD (ar_nyuad), English ESL (en_esl), French FTB (fr_ftb), Hindi English HEINCS (qhe_heincs), and Japanese BCCWJ (ja_bccwj).

To train the multilingual model, we concatenate all available training sets together, similar to McDonald et al. (2011). Before each epoch, we shuffle all sentences and feed mixed batches of sentences to the network, where each batch may contain sentences from any language or treebank, for a total of 80 epochs[3].

4.2 Hyperparameters

A summary of hyperparameters can be found in Table 6 in Appendix A.1.

4.3 Probing for Syntax

Hewitt and Manning (2019) introduce a structural probe for identifying dependency structures in contextualized word embeddings. This probe evaluates whether syntax trees (i.e., unlabeled undirected dependency trees) can be easily extracted as a global property of the embedding space using a linear transformation of the network's contextual word embeddings. The probe trains a weighted adjacency matrix on the layers of contextual embeddings produced by BERT, identifying a linear transformation where squared L2 distance between embedding vectors encodes the distance between words in the parse tree. Edges are decoded by computing the minimum spanning tree on the weight matrix (the lowest sum of edge distances).

[3] We train on a GTX 1080 Ti for approximately 25 days. See Appendix A.1 for more details

5 Results

We show scores of UPOS, UFeats (Feats), and Lemma (Lem) accuracies, along with unlabeled and labeled attachment scores (UAS, LAS) evaluated using the offical CoNLL 2018 Shared Task evaluation script.[4] Results for a salient subset of high-resource and low-resource languages are shown in Table 2, with a comparison between UDPipe Future and UDify fine-tuning on all languages. In addition, the table compares UDify with fine-tuning on either a single language or both languages (fine-tuning multilingually, then fine-tuning on the language with the saved multilingual weights) to provide a reference point for multilingual influences on UDify. We provide

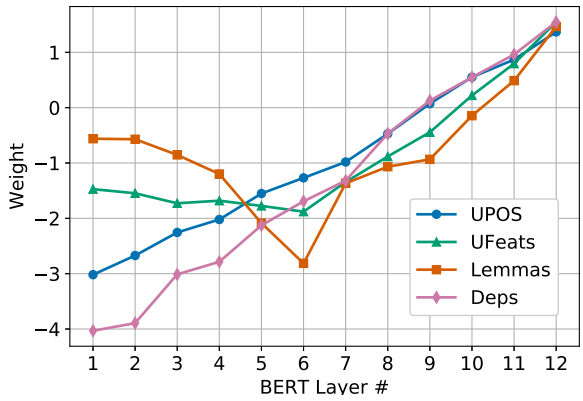

Figure 2: The unnormalized BERT layer attention weights $\boldsymbol{w}_i$ contributing to layer i for each task after training. A linear change in weight scales each BERT layer exponentially due to the softmax in Equation 1

a full table of scores for all treebanks in Appendix A.4.

A more comprehensive overview is shown in Table 3, comparing different attention strategies applied to UDify. We display an average of scores over all (89) treebanks with a training set. For zero-shot learning evaluation, Table 4 displays a subset of test set evaluations of treebanks that do not have a training set, i.e., Breton, Tagalog, Faroese, Naija, and Sanskrit. We plot the layer attention weights $\boldsymbol{w}$ after fine-tuning BERT in Figure 2, showing a set of weights per task. And Table 5 compares the unlabeled undirected attachment scores (UUAS) of dependency trees produced using a structural probe on both the unmodified multilingual cased BERT model and the extracted BERT model fine-tuned on the English EWT treebank.

6 Discussion

In this section, we discuss the most notable features of the results.

6.1 Model Performance

On average, UDify reveals a strong set of results that are comparable in performance with the state-of-the-art in parsing UD annotations. UDify excels in dependency parsing, exceeding UDPipe Future by a large margin especially for low-resource languages. UDify slightly underperforms with respect to Lemmas and Universal Features, likely due to UDPipe Future additionally using character-level embeddings (Santos and Zadrozny, 2014; Ling et al., 2015; Ballesteros et al., 2015; Kim et al., 2016), while (for simplicity) UDify does not. Additionally, UDify severely underperforms the baseline on a few low-resource languages, e.g., cop_scriptorum. We surmise that this is due to using mixed batches on an unbalanced training set, which skews the model towards predicting larger treebanks more accurately. However, we find that fine-tuning on the treebank individually with BERT weights saved from UDify eliminates most of these gaps in performance.

Echoing results seen in Smith et al. (2018), UDify also shows strong improvement leveraging multilingual data from other UD treebanks. In low-resource cases, fine-tuning BERT on all treebanks can be far superior to fine-tuning monolingually. A second round of fine-tuning on an individual treebank using UDify's BERT weights can improve this further, especially for treebanks that underperform the baseline. However, for languages that are already display strong results, we typically notice worse evaluation performance across all the evaluation metrics. This indicates that multilingual fine-tuning really is superior to single language fine-tuning with respect to these high-performing languages, showing improvements of up to 20% reduction in error.

Interestingly, Slavic languages tend to perform the best with multilingual training. While languages like Czech and Russian possess the largest UD treebanks and do not differ as much in performance from monolingual fine-tuning, evidenced by the improvements over single-language fine-tuning, we can see a large degree of morphological and syntactic structure has transferred to low-resource Slavic languages like Upper Sorbian, whose treebank contains only 646 sentences. But this is not only true of Slavic languages, as the Turkic language Kazakh (with less than 1,000 training sentences) has also improved significantly.

The zero-shot results indicate that fine-tuning on BERT can result in reasonably high scores on languages that do not have a training set. It can be seen that a combination of BERT pretraining and multilingual learning can improve predictions for Breton and Tagalog, which implies that the network has learned representations of syntax that cross lingual boundaries. Furthermore, despite the fact that neither BERT nor UDify have directly observed Faroese, Naija, or Sanskrit, we see unusually high performance in these languages. This can be partially attributed to each language closely resembling another: Faroese is very close to Ice-

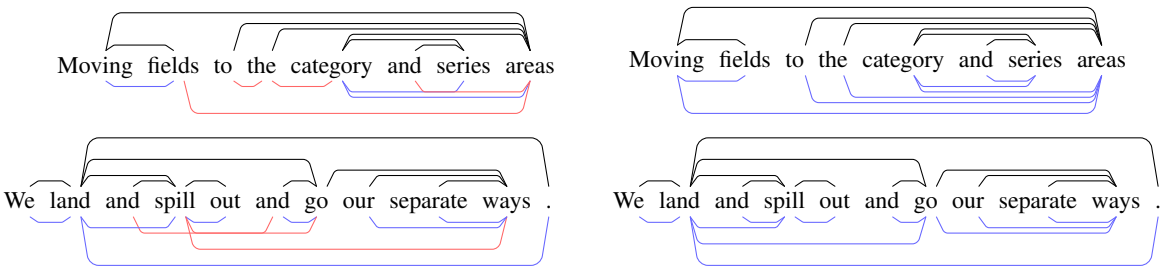

Figure 3: Examples of minimum spanning trees produced by the syntactic probe are shown below each sentence, evaluated on BERT (left) and on UDify (right). Gold dependency trees are shown above each sentence in black. Matched and unmatched spanning tree edges are shown in blue and red respectively.

landic, Naija (Nigerian Pidgin) is a variant of English, and Sanskrit is an ancient Indian language related to Greek, Latin, and Hindi.

Table 3 shows that layer attention on BERT for each task is beneficial for test performance, much more than using a global weighted average. In fact, Figure 2 shows that each task prefers the layers of BERT differently, uniquely extracting the optimal information for a task. All tasks favor the information content in the last 3 layers, with a tendency to disprefer layers closer to the input. However, an interesting observation is that for Lemmas and UFeats, the classifier prefers to also incorporate the information of the first 3 layers. This meshes well with the linguistic intuition that morphological features are more closely related to the surface form of a word and rely less on context than other syntactic tasks. Curiously enough, the middle layers are highly dispreferred, meaning that the most useful processing for multilingual syntax (tagging, dependency parsing) occurs in the last 3-4 layers. The results released by Tenney et al. (2019) also agree with the intuition behind the weight distribution above, showing how the different layers of BERT generate hierarchical information like a traditional NLP pipeline, starting with low-level syntax (e.g., POS tagging) and building up to high-level syntactic and semantic dependency parsing.

6.2 Effect of Syntactic Fine-Tuning on BERT

Even without any supervised training, BERT encodes its syntax in the embedding's distance close to human-annotated dependencies. But more notably, the results in Table 5 show that fine-tuning BERT on Universal Dependencies significantly boosts UUAS scores when compared to the gold dependency trees, an error reduction of 41%. This indicates that the self-attention weights have learned a linearly-transformable representation of its vectors more closely resembling annotated dependency trees defined by linguists. Even with just unsupervised pretraining, a global structural property of the vector space of the BERT weights already produces a decent representation of the dependency tree in the squared L2 distance. Following this, it should be no surprise that training with a non-linear graph-based dependency decoder would produce even higher quality dependency trees.

6.3 Attention Visualization

We performed a high-level visual analysis of the BERT attention weights to see if they have changed on any discernible level. Our observations reveal something notable: the attention weights tend to be more sparse, and are more often sensitive to constituent boundaries like clauses and prepositions. Figure 4 illustrates this point, showing the attention weights of a particular attention head on an example sentence. We find similar behavior in 13 additional attention heads for the provided example sentence.

We see that some of the attention structure remains after fine-tuning. Previously, the attention head was mostly sensitive to previous words and punctuation. But after fine-tuning, it demonstrates more fine-grained attention towards immediate wordpieces, prepositions, articles, and adjectives. We found similar evidence in other attention heads, which implies that fine-tuning on UD produces attention that more closely resembles localized dependencies within constituents. We also find that BERT base heavily preferred to attend to punctuation, while UDify BERT does to a much lesser degree.

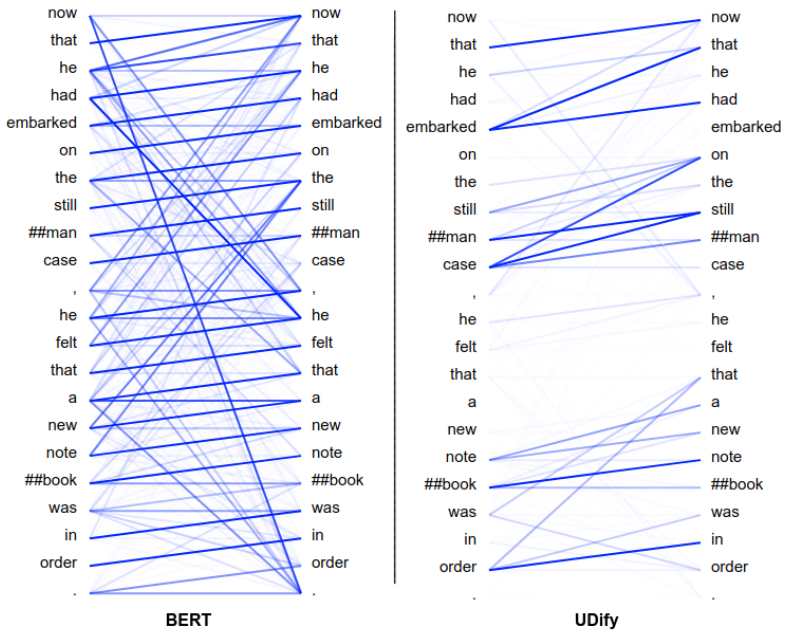

Figure 4: Visualization of BERT attention head 4 at layer 11, comparing the attended words on an English sentence between BERT base and UDify BERT after fine-tuning. The right column indicates the attended words (keys) with respect to the words in the left column (queries). Darker lines indicate stronger attention weights.

6.4 Factors that Enable BERT to Excel at Dependency Parsing and Multilinguality

Goldberg (2019) assesses the syntactic capabilities of BERT and concludes that BERT is remarkably capable of processing syntactic tasks despite not being trained on any supervised data. Conducting similar experiments, Vig (2019) and Sileo (2019) visualize the attention heads within each BERT layer, showing a number of distinct attention patterns, including attending to previous/next words, related words, punctuation, verbs/nouns, and coreference dependencies.

This neat delegation of certain low-level information processing tasks to the attention heads hints at why BERT might excel at processing syntax. We see that from the analysis on BERT fine-tuned with syntax using the syntactic probe and attention visualization, BERT produces a representation that keeps constituents close in its vector space, and improves this representation to more closely resemble human annotated dependency trees when fine-tuned on UD as seen in Figure 3. Furthermore, Ahmad et al. (2018) provide results consistent with their claim that self-attention networks can be more robust than recurrent networks to the change of word order, observing that self-attention networks capture less word order information in their architecture, which is what allows them to generally perform better at cross-lingual parsing. Wu and Dredze (2019) also analyze multilingual BERT and report that the model retains both language-independent as well as language-specific information related to each input sentence, and that the shared embedding space with the input wordpieces correlates strongly with cross-lingual generalization.

From the evidence above, we can see that the combination of strong regularization paired with the ability to capture long-range dependencies with self-attention and contextual pretraining on an enormous corpus of raw text are large contributors that enable robust multilingual modeling with respect to dependency parsing. Pretraining self-attention networks introduces a strong syntactic bias that is capable of generalizing across languages. The dependencies seen in the output dependency trees are highly correlated with the implicit dependencies learned by the self-attention, showing that self-attention is remarkably capable of modeling syntax by picking up on common syntactic patterns in text. The introduction of multilingual data also shows that these attention heads provide a surprising amount of capacity that do not degrade the performance considerably when compared to monolingual training. E.g., Devlin et al. (2018) report that the fine-tuning on the multilingual BERT model results in a small degradation in English fine-tune performance with 104

pretrained languages compared to an equivalent model pretrained only on English. This also hints that the BERT model can be compressed significantly without compromising heavily on evaluation performance.

7 Related Work

This work's main contribution in combining treebanks for multilingual UD parsing is most similar to the Uppsala system for the CoNLL 2018 Shared Task (Smith et al., 2018). Uppsala combines treebanks of one language or closely related languages together over 82 treebanks and parses all UD annotations in a multi-task pipeline architecture for a total of 34 models. This approach reduces the number of models required to parse each language while also showing results that are no worse than training on each treebank individually, and in especially low-resource cases, significantly improved. Combining UD treebanks in a language-agnostic way was first introduced in Vilares et al. (2016), which train bilingual parsers on pairs of UD treebanks, showing similar improvements.

Other efforts in training multilingual models include Johnson et al. (2017), which demonstrate a machine translation model capable of supporting translation between 12 languages. Recurrent models have also shown to be capable of scaling to a larger number of languages as seen in Artetxe and Schwenk (2018), which define a scalable approach to train massively multilingual embeddings using recurrent networks on an auxiliary task, e.g., natural language inference. Schuster et al. (2019) produce context-independent multilingual embeddings using a novel embedding alignment strategy to allow models to improve the use of cross-lingual information, showing improved results in dependency parsing.

8 Conclusion

We have proposed and evaluated UDify, a multilingual multi-task self-attention network fine-tuned on BERT pretrained embeddings, capable of producing annotations for any UD treebank, and exceeding the state-of-the-art in UD dependency parsing in a large subset of languages while being comparable in tagging and lemmatization accuracy. Strong regularization and task-specific layer attention are highly beneficial for fine-tuning, and coupled with training multilingually, also reduce the number of required models to train down to one. Multilingual learning is most beneficial for low-resource languages, even ones that do not possess a training set, and can be further improved by fine-tuning monolingually using BERT weights saved from UDify's multilingual training. All these results indicate that self-attention networks are remarkably capable of capturing syntactic patterns, and coupled with unsupervised pretraining are able to scale to a large number of languages without degrading performance.

A Appendix

In this section, we detail and explain hyperparameter choices and miscellaneous details related to model training and display the full tables of evaluation results of UDify across all UD languages.

A.1 Hyperparameters

Upon concatenating all training sets, we shuffle all the sentences, bundle them into batches of 32 sentences each, and train UDify for a total of 80 epochs before stopping. We hold the learning rate constant until we unfreeze BERT in the second epoch, where we and linearly warm up the learning rate for the next 8,000 batches and then apply inverse square root learning rate decay for the remaining epochs. For the dependency parser, we use feedforward tag and arc dimensions of 300

HYPERPARAMETER	VALUE
Dependency tag dimension	256
Dependency arc dimension	768
Optimizer	Adam
β_1, β_2	0.9, 0.99
Weight decay	0.01
Label Smoothing	0.03
Dropout	0.5
BERT dropout	0.2
Mask probability	0.2
Layer dropout	0.1
Batch size	32
Epochs	80
Base learning rate	$1e^{-3}$
BERT learning rate	$5e^{-5}$
Learning rate warmup steps	8000
Gradient clipping	5.0

Table 6: A summary of model hyperparameters.

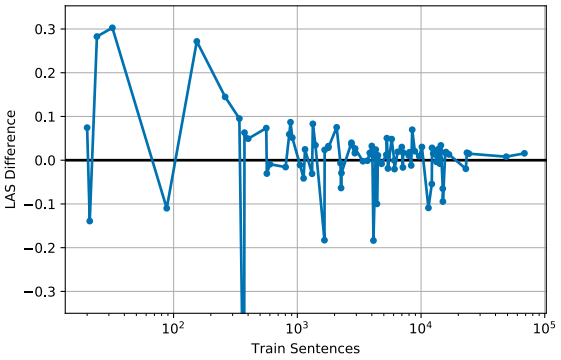

Figure 5: A plot of the difference in LAS between UDify and UDPipe Future with respect to the number of training sentences in each treebank.

and 800 respectively. We apply a small weight decay penalty of 0.01 to ensure that the weights remain small after each update. For optimization we use the Adam optimizer and we compute softmax cross entropy loss to train the network. We use a default β_1 value of 0.9 and lower the β_2 value from the typical 0.999 to 0.99. The reasoning is to increase the decay rate of the second moment in the Adam optimizer to reduce the chance of the optimizer being too optimistic with respect to the gradient history. We clip the gradient updates to a maximum L2 magnitude of 5.0. A summary of hyperparameters can be found in Table 6.

To speed up training, we employ bucketed batching, sorting all sentences by their length and grouping similar length sentences into each batch. However, to ensure that most sentences do not get grouped within the same batch, we fuzz the lengths of each sentence by a maximum of 10% of its true length when grouping sentences together.

Despite using all the regularization strategies shown previously, we still observe overfitting and must apply more aggressive techniques. To further regularize the network, we also increase the attention and hidden dropout rates of BERT from 0.1 to 0.2, and we also apply a dropout rate of 0.5 to all BERT layers before computing layer attention for each of the four tasks and applying a layer dropout with probability 0.1. We increase the masking probability of each wordpiece from 0.15 to 0.2.

With all these regularization strategies and hyperparameter choices combined, we are able to fine-tune BERT for far more epochs before the network starts to overfit, i.e., 80 as opposed to around 10. Even so, we believe even more regularization can improve test performance.

The final multilingual UDify model was trained over approximately 25 days on an NVIDIA GTX 1080 Ti taking an average of 8 hours per epoch. We use half-precision (fp16) training to be able to keep the BERT model in memory. One notable aspect of training is that while we observed the model start to level out in validation performance at around epoch 30, the model continually made small, incremental improvements over each subsequent epoch, resulting in far higher scores than if the model training was terminated early. This can be partially attributed to the decaying inverse square root learning rate.

Due to the high training times, we are only able to report on a small number of training experiments for the most relevant and useful results. Prior to developing the final model, we conducted fine-tuning experiments on pairs of languages to find a set of hyperparameters that worked best for multilingual learning. After this, we gradually scaled up training to 3 languages, 5 languages, 15 languages, and then finally the model presented above. We had high doubts, and wanted to see where the limit was in multilingual training. We were pleasantly surprised to find that this simple training scheme was able to scale up so well to all UD treebanks.

A.2 Training Size Effect on Performance

To gain a better understanding of where the largest score improvements in UDify occur, we plot the LAS improvement UDify provides over UDPipe Future for each treebank, ordered by the size (number of sentences) of the training set, see Fig-

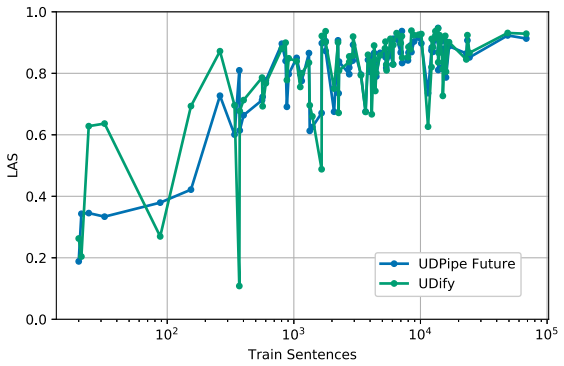

Figure 6: A plot of LAS between with respect to the number of training sentences in each treebank.

ure 5. The results show that the largest improvements tend to occur on small treebanks with less than 3,000 training examples. For absolute LAS values, see Figure 6, which indicates that more training resources tend to improve evaluation performance overall.

A.3 Miscellaneous Details

Our results show that modeling language-specific properties is not strictly necessary to achieve high-performing cross-lingual representations for dependency parsing, though we caution that the model can also likely be improved by these techniques.

Fine-tuning BERT on UD introduces a syntactic bias in the network, and we are interested in observing any differences in transfer learning by fine-tuning this new "UD-BERT" on other tasks. We leave a comprehensive evaluation of injecting syntactic bias into language models with respect to knowledge transfer for future work.

We note that saving the weights of BERT and fine-tuning a second round can improve performance as demonstrated in Stickland et al. (2019). The improvements of UDify+Lang over just UDify can be partially attributed to this, but we can see that even these improvements can be inferior to fine-tuning on all UD treebanks.

BERT limits its positional encoding to 512 wordpieces, causing some sentences in UD to be too long to fit into the model. We use a sliding window approach to break up long sentences into windows of 512 wordpieces, overlapping each window by 256 wordpieces. After feeding the windows into BERT, we select the first 256 wordpieces of each window and any remaining wordpieces in the last window to represent the contextual embeddings of each word in the original sentence.

A.4 Full Results of UD Scores

We show in Tables 7, 8, 9, and 10 UDify scores evaluated on all 124 treebanks with the official CoNLL 2018 Shared Task evaluation script. For comparison, we also include the full test evaluation of UDPipe Future on the subset of 89 treebanks with a training set. We also add a column indicating the size of each treebank, i.e., the number of sentences in the training set.

Abstract

Humans observe and interact with the world to acquire knowledge. However, most existing machine reading comprehension (MRC) tasks miss the interactive, information-seeking component of comprehension. Such tasks present models with static documents that contain all necessary information, usually concentrated in a single short substring. Thus, models can achieve strong performance through simple word- and phrase-based pattern matching. We address this problem by formulating a novel text-based question answering task: Question Answering with Interactive Text (QAit)[1]. In QAit, an agent must interact with a partially observable text-based environment to gather information required to answer questions. QAit poses questions about the existence, location, and attributes of objects found in the environment. The data is built using a text-based game generator that defines the underlying dynamics of interaction with the environment. We propose and evaluate a set of baseline models for the QAit task that includes deep reinforcement learning agents. Experiments show that the task presents a major challenge for machine reading systems, while humans solve it with relative ease.

1 Introduction

The research community has defined the task of machine reading comprehension (MRC) to teach machines to read and understand text. In most MRC tasks, given a knowledge source (usually a text document) and a question on its content, a model is required to answer the question either by pointing to words in the source or by generating a text string. Recent years have seen a flourishing of MRC works, including the release of numerous datasets (Rajpurkar et al., 2016; Trischler et al., 2016; Nguyen et al., 2016; Reddy et al., 2018; Yang et al., 2018) and a host of neural models that address them (Wang and Jiang, 2016; Wang et al., 2017; Chen et al., 2017).

Game	You find yourself in a backyard. You make out a patio table. You see a patio chair. It's stylish. In a corner you can see a BBQ. There's an open screen door leading south.
Quest	Is ghargh edible?
Agent	> **Qapla'**
Game	That's not a verb I recognize.
Agent	> **eat ghargh**
Game	You can't see any such thing.
Agent	> **go south**
Game	You've just entered a kitchen. You can see an open fridge here. It is empty! You see a closed oven. Look over there, it's a counter. On the counter you can see a diced potato, a red ghargh and a knife. A an open door is leading north.
Agent	> **eat ghargh**
Game	You need to take the red ghargh first.
Agent	> **take red ghargh**
Game	You take the red ghargh from the counter.
Agent	> **eat ghargh**
Game	You eat the red ghargh. Not bad.
Agent	> **wait**
Agent	> **answer: yes**

Table 1: Example of a player interacting with an environment to gather knowledge and answer a question.

Most existing MRC datasets, as a consequence of their construction, encourage models to do fairly shallow phrase and word matching between the question and the knowledge source. There are three reasons for this. First, questions tend to paraphrase or permute the text that expresses the answer, making pattern matching an effective strategy. On the SQuAD development set, for example, the average precision, recall, and F_1 score between questions and the sentences containing answer spans are 0.409, 0.271, 0.301, respectively. Exploiting this overlap, Trischler et al.

[*] Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2796–2813, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(2016) show that a simple Information Retrieval method can achieve high sentence-level accuracy on SQuAD.

Second, the information that supports predicting the answer from the source is often *fully observed*: the source is static, sufficient, and presented in its entirety. This does not match the information-seeking procedure that arises in answering many natural questions (Kwiatkowski et al., 2019), nor can it model the way humans observe and interact with the world to acquire knowledge.

Third, most existing MRC studies focus on *declarative* knowledge — the knowledge of facts or events that can be stated explicitly (i.e., declared) in short text snippets. Given a static description of an entity, declarative knowledge can often be extracted straightforwardly through pattern matching. For example, given the EMNLP website text, the conference deadline can be extracted by matching against a date mention. This focus overlooks another essential category of knowledge — *procedural* knowledge. Procedural knowledge entails executable sequences of actions. These might comprise the procedure for tying ones shoes, cooking a meal, or gathering new declarative knowledge. The latter will be our focus in this work. As an example, a more general way to determine EMNLP's deadline is to open a browser, head to the website, and then match against the deadline mention; this involves executing several mouse and keyboard interactions.

In order to teach MRC systems *procedures* for question answering, we propose a novel task: Question Answering with Interactive Text (QAit). Given a question $q \in Q$, rather than presenting a model with a static document $d \in D$ to read, QAit requires the model to interact with a partially observable environment $e \in E$ over a sequence of turns. The model must collect and aggregate evidence as it interacts, then produce an answer a to q based on its experience.

In our case, the environment e is a text-based game with no explicit objective. The game places an agent in a simple modern house populated by various everyday objects. The agent may explore and manipulate the environment by issuing text commands. An example is shown in Table 1. We build a corpus of related text-based games using a generator from Côté et al. (2018), which enables us to draw games from a controlled distribution. This means there are random variations across the environment set E, in map layouts and in the existence, location, and names of objects, etc. Consequently, an agent cannot answer questions merely by memorizing games it has seen before. Because environments are partially observable (i.e., not all necessary information is available at a single turn), an agent must take a sequence of decisions – analogous to following a search and reasoning procedure – to gather the required information. The learning target in QAit is thus not the declarative knowledge a itself, but the *procedure* for arriving at a by collecting evidence.

The main contributions of this work are as follows:

1. We introduce a novel MRC dataset, QAit, which focuses on *procedural* knowledge. In it, an agent interacts with an environment to discover the answer to a given question.

2. We introduce to the MRC domain the practice of generating training data on the fly. We sample training examples from a distribution; hence, an agent is highly unlikely to encounter the same training example more than once. This helps to prevent overfitting and rote memorization.

3. We evaluate a collection of baseline agents on QAit, including state-of-the-art deep reinforcement learning agents and humans, and discuss limitations of existing approaches.

2 The QAit Dataset

2.1 Overview

We make the question answering problem interactive by building text-based games along with relevant question-answer pairs. We use TextWorld (Côté et al., 2018) to generate these games. Each interactive environment is composed of multiple locations with paths connecting them in a randomly drawn graph. Several interactable objects are scattered across the locations. A player sends text commands to interact with the world, while the game's interpreter only recognizes a small subset of all possible command strings (we call these the valid commands). The environment changes state in response to a valid command and returns a string of text feedback describing the change.

The underlying game dynamics arise from a set of objects (e.g., doors) that possess attributes (e.g.,

	edible	drinkable	portable	openable	cuttable	sharp	heat_source	cookable	holder
Butter knife			1			1			
Oven				1			1		1
Raw chicken			1		1			1	
Fried chicken	1		1		1			1	

Table 2: Supported attributes along with examples.

doors are openable), and a set of rules (e.g., opening a closed door makes the connected room accessible). The supported attributes are shown in Table 2, while the rules can be inferred from the list of supported commands (see Appendix C). Note that player interactions might affect an object's attributes. For instance, cooking a piece of *raw chicken* on the stove with a frying pan makes it edible, transforming it into *fried chicken*.

In each game, the existence of objects, the location of objects, and their names are randomly sampled. Depending on the task, a name can be a made-up word. However, game dynamics are constant across all games – e.g., there will never be a drinkable heat source.

Text in QAit is generated by the TextWorld engine according to English templates, so it does not express the full variation of natural language. However, taking inspiration from the bAbI tasks (Weston et al., 2015), we posit that controlled simplifications of natural language are useful for isolating more complex reasoning behaviors.

2.2 Available Information

At every game step, the environment returns an *observation string* describing the information visible to the agent, as well as the *command feedback*, which is text describing the response to the previously issued command.

Optional Information: Since we have access to the underlying state representation of a generated game, various optional information can be made available. For instance, it is possible to access the subset of commands that are valid at the current game step. Other available meta-information includes all objects that exist in the game, plus their locations, attributes, and states.

During training, one is free to use any optional information to guide the agent's learning, e.g., to shape the rewards. However, at test time, only the *observation string* and the *command feedback* are available.

2.3 Question Types and Difficulty Levels

Using the game information described above, we can generate questions with known ground truth answers for any given game.

2.3.1 Question Types

For this initial version of QAit we consider three straightforward question types.

Location: ("Where is the can of soda?") Given an object name, the agent must answer with the name of the container that most directly holds the object. This can be either a location, a holder within a location, or the player's inventory. For example, if the can of soda is in a fridge which is in the kitchen, the answer would be "fridge".

Existence: ("Is there a raw egg in the world?") Given the name of an object, the agent must learn to answer whether the object exists in the game environment e.

Attribute: ("Is *ghargh* edible?") Given an object name and an attribute, the agent must answer with the value of the given attribute for the given object. Note that all attributes in our dataset are binary-valued. To discourage an agent from simply memorizing attribute values given an object name (Anand et al., 2018) (e.g., apples are always edible so agents can answer without interaction), we replace object names with unique, randomly drawn made-up words for this question type.

2.3.2 Difficulty Levels

To better analyze the limitations of learning algorithms and to facilitate curriculum learning approaches, we define two difficulty levels based on the environment layout.

Fixed Map: The map (location names and layout) is fixed across games. Random objects are distributed across the map in each game. Statistics for this game configuration are shown in Table 3.

Random Map: Both map layouts and objects are randomly sampled in each game.

2.4 Action Space

We describe the action space of QAit by splitting it into two subsets: information-gathering actions and question-answering actions.

	Fixed Map	Random Map
# Locations, N_r	6	$N_r \sim \text{Uniform}[2, 12]$
# Entities, N_e	$N_e \sim \text{Uniform}[3 \cdot N_r, 6 \cdot N_r]$	
Actions / Game	17	17
Modifiers / Game	18.5	17.7
Objects / Game	26.7	27.5
# Obs. Tokens	93.1	89.7

Table 3: Statistics of the QAit dataset. Numbers are averaged over 10,000 randomly sampled games.

Information Gathering The player generates text commands word by word to navigate through and interact with the environment. On encountering an object, the player must interact with it to discover its attributes. To succeed, an agent must map the feedback received from the environment, in text, to a useful state representation. This is a form of reading comprehension.

To make the QAit task more tractable, all text commands are triplets of the form {action, modifier, object} (e.g., `open wooden door`). When there is no ambiguity, the environment understands commands without modifiers (e.g., `eat apple` will result in eating the "red apple" provided it is the only apple in the player's inventory). We list all supported commands in Appendix C.

Each game provides a set of three lexicons that divide the full vocabulary into actions, modifiers, and objects. Statistics are shown in Table 3. A model can generate a command at each game step by, e.g., sampling from a probability distribution induced over each lexicon. This reduces the size of the action space compared to a sequential, free-form setting where a model can pick any vocabulary word at any generation step.

An agent decides when to stop interacting with the environment to answer the question by generating a special `wait` command [2]. However, the number of interaction steps is limited: we use 80 steps in all experiments. When an agent has exhausted its available steps, the game terminates and the agent is forced to answer the question.

Question Answering Currently, all QAit answers are one word. For existence and attribute questions, the answer is either `yes` or `no`; for location questions, the answer can be any word in an observation string.

[2]We call it "wait" because when playing multiple games in a batch, batched environment will terminate only when all agents have issued the terminating command. Before that, some agent will wait. This is analogous to paddings in natural language processing tasks.

2.5 Evaluation Settings and Metrics

We evaluate an agent's performance on QAit by its accuracy in answering questions. We propose three distinct settings for the evaluation.

Solving Training Games: We use QA accuracy during training, averaged over a window of training time, to evaluate an agent's training performance. We provide 5 training sets for this purpose with [1, 2, 10, 100, 500] games, respectively. Each game in these sets is associated with multiple questions.

Unlimited Games: We implement a setup where games are randomly generated on the fly during training, rather than selected from a finite set as above. The distribution we draw from is controlled by a few parameters: number of locations, number of objects, type of map, and a random seed. From the **fixed map** game distribution described in Table 3, more than 10^{40} different games can be drawn. This means that a game is unlikely to be seen more than once during training. We expect that only a model with strong generalization capabilities will perform well in this setting.

Zero-shot Evaluation: For each game setting and question type, we provide 500 held out games that are never seen during training, each with one question. These are used to benchmark generalization in models in a reproducible manner, no matter the training setting. This set is analogous to the test set used in traditional supervised learning tasks, and can be used in conjunction with any training setting.

3 Baseline Models

3.1 Random Baseline

Our simplest baseline does not interact with the environment to answer questions; it samples an answer word uniformly from the QA action space (`yes` and `no` for attribute and existence questions; all possible object names in the game for location questions).

3.2 Human Baseline

We conducted a study with 21 participants to explore how humans perform on QAit in terms of

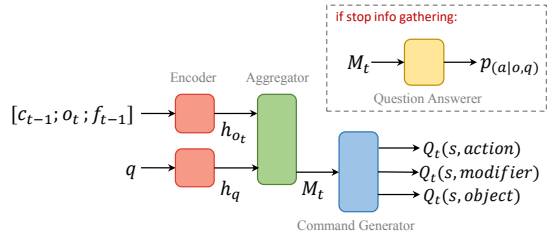

Figure 1: Overall architecture of our baseline agent.

QA accuracy. Participants played games they had not seen previously from a set generated by sampling 4 game-question pairs for each question type and difficulty level. The human results presented below always represent an average over 3 participants.

3.3 QA-DQN

We propose a neural baseline agent, QA-DQN, which takes inspiration from the work of Narasimhan et al. (2015) and Yu et al. (2018). The agent consists of three main components: an encoder, a command generator, and a question answerer. More precisely, at game step t, the encoder takes observation o_t and question q as input to generate hidden representations.[3] In the information gathering phase, the command generator generates Q-values for all action, modifier, and object words, with rankings of these Q-values used to generate text commands c_t. At any game step, the agent may decide to terminate information gathering and answer the question (or it is forced to do so if it has used up all of its moves). The question answerer uses the hidden representations at the final information-gathering step to generate a probability distribution over possible answers.

An overview of this architecture is shown in Figure 1 and full details are given in Appendix A.

3.3.1 Reward Shaping

We design the following two rewards to help QA-DQN learn more efficiently; both used for training the command generator. Note that these rewards are part of the design of QA-DQN, but are not used to evaluate its performance. Question answering accuracy is the only evaluation metric for QAit tasks.

Sufficient Information Bonus: To tackle QAit tasks, an intelligent agent should know when to stop interacting – it should stop as soon as it has gathered enough information to answer the question correctly. For guiding the agent to learn this behavior, we give an additional reward when the agent stops with sufficient information. Specifically, assuming the agent decides to stop at game step k:

- Location: reward is 1 if the entity mentioned in the question is a sub-string of o_k, otherwise it is 0. This means whenever an agent observes the entity, it has sufficient information to infer the entity's location.
- Existence: when the correct answer is `yes`, a reward of 1 is assigned only if the entity is a sub-string of o_k. When the correct answer is `no`, a reward between 0 and 1 is given. The reward value corresponds to the exploration coverage of the environment, i.e., how many locations the agent has visited, and how many containers have been opened.
- Attribute: we heuristically define a set of conditions to verify each attribute, and reward the agent based on its fulfilment of these conditions. For instance, determining if an object `x` is **sharp** corresponds to checking the outcome of a cut command (`slice`, `chop`, or `dice`) while holding the object `x` and a cuttable food item. If the outcome is successful then the object `x` is sharp otherwise it is not. Alternatively, if trying to take the object `x` results in a failure, then we can deduces it is not sharp as all sharp objects are portable. The list of conditions for each attribute used in our experiments is shown in Appendix D.

Episodic Discovery Bonus: Following Yuan et al. (2018), we use an episodic counting reward to encourage the agent to discover unseen game states. The agent is assigned a positive reward whenever it encounters a new state (in text-based games, states are simply represented as strings):

$$r(o_t) = \begin{cases} 1.0 & \text{if } n(o_t) = 1, \\ 0.0 & \text{otherwise,} \end{cases}$$

where $n(\cdot)$ is reset to zero after each episode.

3.3.2 Training Strategy

We apply different training strategies for the command generator and the question answerer.

Command Generation: Text-based games are sequential decision-making problems that can

[3] We concatenate o_t with the command generated at previous game step and the text feedback returned by the game, as described in Section 2.2.

be described naturally by partially observable Markov decision processes (POMDPs) (Kaelbling et al., 1998). We use the Q-Learning (Watkins and Dayan, 1992) paradigm to train our agent. Specifically, following Mnih et al. (2015), our Q-value function is approximated with a deep neural network. Beyond vanilla DQN, we also apply several extensions, such as Rainbow (Hessel et al., 2017), to our training process. Details are provided in Section 4.

Question Answering: During training, we push all question answering transitions (observation strings when interaction stops, question strings, ground-truth answers) into a replay buffer. After every 20 game steps, we randomly sample a mini-batch of such transitions from the replay buffer and train the question answerer with supervised learning (e.g., using negative log-likelihood (NLL) loss).

4 Experimental Results

In this section, we report experimental results by difficulty levels. All random baseline performance values are averaged over 100 different runs. In the following subsections, we use "DQN", "DDQN" and "Rainbow" to indicate QA-DQN trained with vanilla DQN, Double DQN with prioritized experience replay, and Rainbow, respectively. Training curves shown in the following figures represent a sliding-window average with a window size of 500. Moreover, each curve is the average of 3 random seeds. For evaluation, we selected the model with the random seed yielding the highest training accuracy to compute its accuracy on the test games. Due to space limitations, we only report some key results here. See Appendix E for the full experimental results.

4.1 Fixed Map

Figure 2 shows the training curves for the neural baseline agents when trained using 10 games, 500 games and the "unlimited" games settings. Table 4 reports their zero-shot test performance.

From Figure 2, we observe that when training data size is small (e.g., 10 games), our baseline agent trained with all the three RL methods successfully master the training games. Vanilla DQN and DDQN are particularly strong at memorizing the training games. When training on more games (e.g., 500 games and unlimited games), in which case memorization is more difficult, Rainbow agents start to show its superiority — it has similar accuracy as the other two methods, and even outperforms them in existence question type.

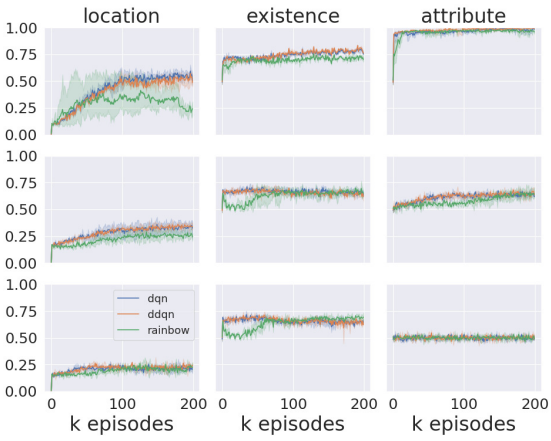

Figure 2: Training accuracy over episodes on **fixed map** setup. Upper row: 10 games; middle row: 500 games; lower row: unlimited games.

	Fixed Map			Random Map		
Model	Loc.	Exi.	Att.	Loc.	Exi.	Att.
Human	1.000	1.000	1.000	1.000	1.000	0.750
Random	0.027	0.497	0.496	0.034	0.500	0.499
10 games						
DQN	0.180	0.568	0.518	0.156	0.566	0.518
DDQN	0.188	0.566	0.516	0.142	0.606	0.500
Rainbow	0.156	0.590	0.520	0.144	0.586	**0.530**
500 games						
DQN	0.224	0.674	**0.534**	0.204	0.678	**0.530**
DDQN	0.218	0.626	0.508	0.222	0.656	0.486
Rainbow	0.190	0.656	0.496	0.172	0.678	0.494
unlimited games						
DQN	0.216	0.662	0.514	0.188	0.668	0.506
DDQN	0.258	0.628	0.480	0.206	**0.694**	0.482
Rainbow	**0.280**	**0.692**	0.514	**0.258**	0.686	0.470

Table 4: Agent performance on zero-shot test games when trained on 10 games, 500 games and "unlimited" games settings. Note Att. and Exi. are binary questions with expected accuracy of 0.5.

From Table 4 we see similar observation, when trained on 10 games and 500 games, DQN and DDQN performs better on test games but on the unlimited games setting, rainbow agent performs as good as them, and sometimes even better. We can also observe that our agents fail to generalize on attribute questions. In unlimited games setting as shown in Figure 2, all three agents produce an accuracy of 0.5; in zero-shot test as shown in Table 4, no agent performs significantly better than random. This suggests the agents memorize game-question-answer triples when data size is small, and fail to do so in unlimited games setting. This

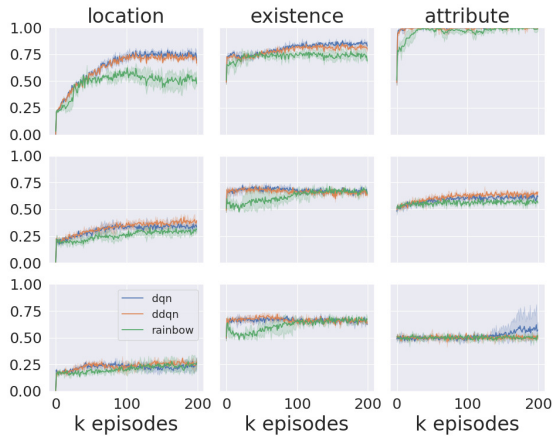

Figure 3: Training accuracy on the **random map** setup. Upper row: 10 games; middle row: 500 games; lower row: unlimited games.

Model	Fixed Map	Random Map
Random	14.7	16.5
10 games		
DQN	95.7	97.5
DDQN	90.4	92.2
Rainbow	91.8	84.7
500 games		
DQN	91.8	94.4
DDQN	95.6	90.2
Rainbow	96.9	96.6
unlimited games		
DQN	100.0	100.0
DDQN	100.0	100.0
Rainbow	100.0	100.0

Table 5: Test performance given sufficient information.

can also be observed in Appendix E, where in attribute question experiments, the training accuracy is high, and sufficient information bonus is low (even close to 0).

4.2 Random Map

Figure 3 shows the training curves for the neural baseline agents when trained using 10 games, 500 games and "unlimited" games settings. The trends of our agents' performance on random map games are consistent with on fixed map games. However, because there exist easier games (as listed in Table 3, number of rooms is sampled between 2 and 12), agents show better training performance in such setting than **fixed map** setting in general.

Interestingly, we observe one of the DQN agent starts to learn in the unlimited games, attribute question setting. This may be because in games with smaller map size and less objects, there is a higher chance to accomplish some sub-tasks (e.g., it is easier to find an object when there are less rooms), and the agent learn such skills and apply them to similar tasks. Unfortunately, as shown in Table 4 that agent does not perform significantly better than random on test set. We expect with more training episodes, the agent can have a better generalization performance.

4.3 Question Answering Given Sufficient Information

The challenge in QAit is learning the interactive procedure for arriving at a state with the information needed to answer the question. We conduct the following experiments on **location** questions to investigate this challenge.

Based on the results in Table 4, we compute an agent's test accuracy *only if* it has obtained sufficient information – i.e., when the sufficient information bonus is 1. Results shown in Table 5 support our assumption that the QA module can learn (and generalize) effectively to answer given sufficient information. Similarly, experiments show that when objects being asked about are in the current observation, the random baseline's performance goes up significantly as well. We report our baseline agents' question answering accuracy and sufficient information bonuses on all experiment settings in Appendix E.

4.4 Full Information Setup

To reframe the QAit games as a standard MRC task, we also designed an experimental setting that eliminates the need to gather information interactively. From a heuristic trajectory through the game environment that is guaranteed to observe sufficient information for q, we concatenate all observations into a static "document" d to build a $\{d, q, a\}$ triplet. A model then uses this fully observed document as input to answer the question. We split this data into training, validation, and test sets and follow the evaluation protocol for standard supervised MRC tasks. We take an off-the-shelf MRC model, Match-LSTM (Wang and Jiang, 2016), trained with negative log-likelihood loss as a baseline.

Unsurprisingly, Match-LSTM does fairly well on all 3 question types (86.4, 89.9 and 93.2 test accuracy on location, existence, and attribute questions, respectively). This implies that without the need to interact with the environment for information gathering, the task is simple enough that a word-matching model can answer questions with

high accuracy.

5 Related Work

5.1 MRC Datasets

Many large-scale machine reading comprehension and question answering datasets have been proposed recently. The datasets of Rajpurkar et al. (2016); Trischler et al. (2016) contain crowd-sourced questions based on single documents from Wikipedia and CNN news, respectively. Nguyen et al. (2016); Joshi et al. (2017); Dunn et al. (2017); Clark et al. (2018); Kwiatkowski et al. (2019) present question-answering corpora harvested from information retrieval systems, often containing multiple supporting documents for each question. This means a model must sift through a larger quantity of information and possibly reconcile competing viewpoints. Berant et al. (2013); Welbl et al. (2017); Talmor and Berant (2018) propose to leverage knowledge bases to generate question-answer pairs. Yang et al. (2018) focuses on questions that require multi-hop reasoning to answer, by building questions compositionally. Reddy et al. (2018); Choi et al. (2018) explore conversational question answering, in which a full understanding of the question depends on the conversation's history.

Most of these datasets focus on declarative knowledge and are static, with all information fully observable to a model. We contend that this setup, unlike QAit, encourages word matching. Supporting this contention, several studies highlight empirically that existing MRC tasks require little comprehension or reasoning. In Rychalska et al. (2018), it was shown that a question's main verb exerts almost no influence on the answer prediction: in over 90% of examined cases, swapping verbs for their antonyms does not change a system's decision. Jia and Liang (2017) show the accuracy of neural models drops from an average of 75% F_1 score to 36% F_1 when they manually insert adversarial sentences into SQuAD.

5.2 Interactive Environments

Several embodied or visual question answering datasets have been presented recently to address some of the problems of interest in our work, such as those of Brodeur et al. (2017); Das et al. (2017); Gordon et al. (2017). In contrast with these, our purely text-based environment circumvents challenges inherent to modelling interactions between separate data modalities. Furthermore, most visual question answering environments only support navigating and moving the camera as interactions. In text-based environments, however, it is relatively cheap to build worlds with complex interactions. This is because text enables us to model interactions abstractly without the need for, e.g., a costly physics engine.

Closely related to QAit is BabyAI (Chevalier-Boisvert et al., 2018). BabyAI is a gridworld environment that also features constrained language for generating simple home-based scenarios (i.e., instructions). However, observations and actions in BabyAI are not text-based. World of Bits (Shi et al., 2017) is a platform for training agents to interact with the internet to accomplish tasks like flight booking. Agents generally do not need to gather information in World of Bits, and the focus is on accomplishing tasks rather than answering questions.

5.3 Information Seeking

Information seeking behavior is an important capacity of intelligent systems that has been discussed for many years. Kuhlthau (2004) propose a holistic view of information search as a six-stage process. Schmidhuber (2010) discusses the connection between information seeking and formal notions of fun, creativity, and intrinsic motivation. Das et al. (2018) propose a model that continuously determines all entities' locations during reading and dynamically updates the associated representations in a knowledge graph. Bachman et al. (2016) propose a collection of tasks and neural methods for learning to gathering information efficiently in an environment.

To our knowledge, we are the first to consider interactive information-seeking tasks for question answering in worlds with complex dynamics. The QAit task was designed such that simple word matching methods do not apply, while more human-like information seeking models are encouraged.

6 Discussion and Future Work

Monitoring Information Seeking: In QAit, the only evaluation metric is question answering accuracy. However, the sufficient information bonus described in Section 3.3.1 is helpful for monitoring agents' ability to gather relevant information. We report its value for all experiments in

Appendix E. We observe that while the baseline agents can reach a training accuracy of 100% for answering attribute questions when trained on a few games, the sufficient information bonus is close to 0. This is a clear indication that the agent overfits to the question-answer mapping of the games rather than learning how to gather useful information. This aligns with our observation that the agent does not perform better than random on the unlimited games setting, because it fails to gather the needed information.

Challenges in QAit: QAit focuses on learning procedural knowledge from interactive environments, so it is natural to use deep RL methods to tackle it. Experiments suggest the dataset presents a major challenge for existing systems, including Rainbow, which set the state of the art on Atari games. As a simplified and controllable text-based environment, QAit can drive research in both the RL and language communities, especially where they intersect. Until recently, the RL community focused mainly on solving single environments (i.e., training and testing on the same game). Now, we see a shift towards solving multiple games and testing for generalization (Cobbe et al., 2018; Justesen et al., 2018). We believe QAit serves this purpose.

Templated Language: As QAit is based on TextWorld, it has the obvious limitation of using templated English. However, TextWorld provides approximately 500 *human-written* templates for describing rooms and objects, so some textual diversity exists, and since game narratives are generated compositionally, this diversity increases along with the complexity of a game. We believe simplified and controlled text environments offer a bridge to full natural language, on which we can isolate the learning of useful behaviors like information seeking and command generation. Nevertheless, it would be interesting to further diversify the language in QAit, for instance by having human writers paraphrase questions.

Future Work: Based on our present efforts to tackle QAit, we propose the following directions for future work.

A **structured memory** (e.g., a dynamic knowledge graph as proposed in Das et al. (2018); Ammanabrolu and Riedl (2019a)) could be helpful for explicitly memorizing the places and objects that an agent has observed. This is especially useful when an agent must revisit a location or object or should avoid doing so.

Likewise, a variety of **external knowledge** could be leveraged by agents. For instance, incorporating a pretrained language model could improve command generation by imparting knowledge of word and object affordances. In recent work, Hausknecht et al. (2019) show that pretrained modules together with handcrafted subpolicies help in solving text-based games, while Yin and May (2019) use BERT (Devlin et al., 2018) to inject 'weak common sense' into agents for text-based games. Ammanabrolu and Riedl (2019b) show that knowledge graphs and their associated neural encodings can be used as a medium for domain transfer across text-based games.

In finite game settings we observed significant overfitting, especially for attribute questions – as shown in Appendix E, our agent achieves high QA accuracy but low sufficient information bonus on the single-game setting. Sometimes attributes require long procedures to verify, and thus, we believe that denser rewards would help with this problem. One possible solution is to provide **intermediate rewards** whenever the agent achieves a sub-task.

Acknowledgments

The authors thank Romain Laroche, Rémi Tachet des Combes, Matthew Hausknecht, Philip Bachman, and Layla El Asri for insightful ideas and discussions. We thank Tavian Barnes, Wendy Tay, and Emery Fine for their work on the TextWorld framework. We also thank the anonymous EMNLP reviewers for their helpful feedback and suggestions.

A Details of QA-DQN

Notations

In this section, we use *game step* t to denote one round of interaction between an agent with the QAit environment. We use o_t to denote text observation at game step t, and q to denote question text. We use L to refer to a linear transformation. Brackets $[\cdot;\cdot]$ denote vector concatenation.

A.1 Encoder

We use a transformer-based text encoder, which consists of an embedding layer, two stacks of transformer blocks (denoted as encoder transformer blocks and aggregation transformer blocks), and an attention layer.

In the embedding layer, we aggregate both word- and character-level information to produce a vector for each token in text. Specifically, word embeddings are initialized by the 300-dimensional fastText (Mikolov et al., 2018) word vectors trained on Common Crawl (600B tokens), they are fixed during training. Character level embedding vectors are initialized with 32-dimensional random vectors. A convolutional layer with 64 kernels of size 5 is then used to aggregate the sequence of characters. We use a max pooling layer on the character dimension, then a multi-layer perceptron (MLP) of output size 64 is used to aggregate the concatenation of word- and character-level representations. Highway network (Srivastava et al., 2015) is applied on top of this MLP. The resulting vectors are used as input to the encoding transformer blocks.

Each encoding transformer block consists of a stack of convolutional layers, a self-attention layer, and an MLP. In which, each convolutional layer has 64 filters, each kernel's size is 7, there are 2 such convolutional layers that share weights. In the self-attention layer, we use a block hidden size of 64, as well as a single head attention mechanism. Layernorm and dropout are applied after each component inside the block. We add positional encoding into each block's input. We use one layer of such an encoding block.

At a game step t, the encoder processes text observation o_t and question q, context aware encoding $h_{o_t} \in \mathbb{R}^{L^{o_t} \times H_1}$ and $h_q \in \mathbb{R}^{L^q \times H_1}$ are generated, where L^{o_t} and L^q denote number of tokens in o_t and q respectively, H_1 is 64. Following (Yu et al., 2018), we use an context-query attention layer to aggregate the two representations h_{o_t} and h_q.

Specifically, the attention layer first uses two MLPs to convert both h_{o_t} and h_q into the same space, the resulting tensors are denoted as $h'_{o_t} \in \mathbb{R}^{L^{o_t} \times H_2}$ and $h'_q \in \mathbb{R}^{L^q \times H_2}$, in which H_2 is 64.

Then, a tri-linear similarity function is used to compute the similarities between each pair of h'_{o_t} and h'_q items:

$$S = W[h'_{o_t}; h'_q; h'_{o_t} \odot h'_q], \tag{1}$$

where $\odot$ indicates element-wise multiplication, W is trainable parameters of size 64.

Softmax of the resulting similarity matrix S along both dimensions are computed, this produces S^A and S^B. Information in the two representations are then aggregated by:

$$\begin{aligned} h_{oq} &= [h'_{o_t}; P; h'_{o_t} \odot P; h'_{o_t} \odot Q], \\ P &= S_q h'^{\top}_q, \\ Q &= S_q S^{\top}_{o_t} h'^{\top}_{o_t}, \end{aligned} \tag{2}$$

where h_{oq} is aggregated observation representation.

On top of the attention layer, a stack of aggregation transformer blocks is used to further map the observation representations to action representations and answer representations. The structure of aggregation transformer blocks are the same as the encoder transformer blocks, except the kernel size of convolutional layer is 5, and the number of blocks is 3.

Let $M_t \in \mathbb{R}^{L^{o_t} \times H_3}$ denote the output of the stack of aggregation transformer blocks, where H_3 is 64.

A.2 Command Generator

The command generator takes the hidden representations M_t as input, it estimates Q-values for all action, modifier, and object words, respectively. It consists of a shared Multi-layer Perceptron (MLP) and three MLPs for each of the components:

$$\begin{aligned} R_t &= \text{ReLU}(L_{\text{shared}}(\text{mean}(M_t)), \\ Q_{t,action} &= L_{\text{action}}(R_t), \\ Q_{t,modifier} &= L_{\text{modifier}}(R_t), \\ Q_{t,object} &= L_{\text{object}}(R_t). \end{aligned} \tag{3}$$

In which, the output size of L_{shared} is 64; the dimensionalities of the other 3 MLPs are depending on the number of the amount of action, modifier

and object words available, respectively. The overall Q-value is the sum of the three components:

$$Q_t = Q_{t,action} + Q_{t,modifier} + Q_{t,object}. \quad (4)$$

A.3 Question Answerer

Similar to (Yu et al., 2018), we append an extra stacks of aggregation transformer blocks on top of the aggregation transformer blocks to compute answer positions:

$$\begin{aligned} U &= \text{ReLU}(L_0[M_t; M'_t]). \\ \beta &= \text{softmax}(L_1(U)). \end{aligned} \quad (5)$$

In which $M'_t \in \mathbb{R}^{L^{o_t} \times H_3}$ is output of the extra transformer stack, L_0, L_1 are trainable parameters with output size 64 and 1, respectively.

For location questions, the agent outputs β as the probability distribution of each word in observation o_t being the answer of the question.

For binary classification questions, we apply an MLP, which takes weighted sum of matching representations as input, to compute a probability distribution $p(y)$ over both possible answers:

$$\begin{aligned} D &= \sum_i (\beta^i \cdot M'_t), \\ p(y) &= \text{softmax}(L_4(\tanh(L_3(D)))). \end{aligned} \quad (6)$$

Output size of L_3 and L_4 are 64 and 2, respectively.

A.4 Deep Q-Learning

In a text-based game, an agent takes an action a[4] in state s by consulting a state-action value function $Q(s, a)$, this value function is as a measure of the action's expected long-term reward. Q-Learning helps the agent to learn an optimal $Q(s, a)$ value function. The agent starts from a random Q-function, it gradually updates its Q-values by interacting with environment, and obtaining rewards. Following Mnih et al. (2015), the Q-value function is approximated with a deep neural network.

We make use of a replay buffer. During playing the game, we cache all transitions into the replay buffer without updating the parameters. We periodically sample a random batch of transitions from the replay buffer. In each transition, we update the parameters θ to reduce the discrepancy between the predicted value of current state $Q(s_t, a_t)$ and the expected Q-value given the reward r_t and the value of next state $\max_a Q(s_{t+1}, a)$.

We minimize the temporal difference (TD) error, δ:

$$\delta = Q(s_t, a_t) - (r_t + \gamma \max_a Q(s_{t+1}, a)), \quad (7)$$

in which, γ indicates the discount factor. Following the common practice, we use the Huber loss to minimize the TD error. For a randomly sampled batch with batch size B, we minimize:

$$\begin{aligned} \mathcal{L} &= \frac{1}{|B|} \sum \mathcal{L}(\delta), \\ \text{where } \mathcal{L}(\delta) &= \begin{cases} \frac{1}{2}\delta^2 & \text{for } |\delta| \leq 1, \\ |\delta| - \frac{1}{2} & \text{otherwise.} \end{cases} \end{aligned} \quad (8)$$

As described in Section 3.3.1, we design the sufficient information bonus to teach an agent to stop as soon as it has gathered enough information to answer the question. Therefore we assign this reward at the game step where the agent generates **`wait`** command (or it is forced to stop).

It is worth mentioning that for attribute type questions (considerably the most difficult question type in QAit, where the training signal is very sparse), we provide extra rewards to help QA-DQN to learn.

Specifically, we take a reward similar to as used in location questions: 1.0 if the agent has observed the object mentioned in the question. we also use a reward similar to as used in existence questions: the agent is rewarded by the coverage of its exploration. The two extra rewards are finally added onto the sufficient information bonus for attribute question, both with coefficient of 0.1.

B Implementation Details

During training with vanilla DQN, we use a replay memory of size 500,000. We use ϵ-greedy, where the value of ϵ anneals from 1.0 to 0.1 within 100,000 episodes. We start updating parameters after 1,000 episodes of playing. We update our network after every 20 game steps. During updating, we use a mini-batch of size 64. We use *Adam* (Kingma and Ba, 2014) as the step rule for optimization, The learning rate is set to 0.00025.

When our agent is trained with Rainbow algorithm, we follow Hessel et al. (2017) on most of the hyper-parameter settings. The four MLPs L_{shared}, L_{action}, L_{modifier} and L_{object} as described

[4] In our case, a is a triplet contains {action, modifier, object} as described in Section 2.4.

in Eqn. 3 are Noisy Nets layers (Fortunato et al., 2017) when the agent is trained in Rainbow setting. Detailed hyper-parameter setting of our Rainbow agent are shown in Table 6.

Parameter	Value
Exploration ϵ	0
Noisy Nets σ_0	0.5
Target Network Period	1000 episodes
Multi-step returns n	$n \sim \text{Uniform}[1, 3]$
Distributional atoms	51
Distributional min/max values	[-10, 10]

Table 6: Hyper-parameter setup for rainbow agent.

The model is implemented using PyTorch (Paszke et al., 2017).

C Supported Text Commands

All supported text commands are listed in Table 7.

D Heuristic Conditions for Attribute Questions

Here, we derived some heuristic conditions to determine when an agent has gathered enough information to answer a given attribute question. Those conditions are used as part of the reward shaping for our proposed agent (Section 3.3.1). In Table 8, for each attribute we list all the commands for which their outcome (pass or fail) gives enough information to answer the question correctly. Also, in order for a command's outcome to be informative, each command needs to be executed while some state conditions hold. For example, to determine if an object is indeed a **heat_source**, the agent needs to try to cook something that is cookable and uncooked while standing next to the given object.

E Full results

We provide full results of our agents on **fixed map** games in Table 9, and provide full results of our agents on **random map** games in Table 10. To help investigating the generalizability of the sufficient information bonus we used in our proposed agent, we also report the rewards during both training and test phases. Note during test phase, we do not update parameters with the rewards.

Command	Description
look	describe the current location
inventory	display the player's inventory
go ⟨**dir**⟩	move the player to north, east, south, or west
examine ...	examine something more closely
open ...	open a door or a container
close ...	close a door or a container
eat ...	eat edible object
drink ...	drink drinkable object
drop ...	drop an object on the floor
take ...	take an object from the floor, a container, or a supporter
put ...	put an object onto a supporter (supporter must be present at the location)
insert ...	insert an object into a container (container must be present at the location)
cook ...	cook an object (heat source must be present at the location)
slice ...	slice cuttable object (a sharp object must be in the player's inventory)
chop ...	chop cuttable object (a sharp object must be in the player's inventory
dice ...	dice cuttable object (a sharp object must be in the player's inventory)
wait	stop interaction

Table 7: Supported command list.

Attribute	Command	State	Pass	Fail	Explanation
sharp	**cut** *cuttable*	holding (*cuttable*) & uncut (*cuttable*) & holding (object)	1	1	Trying to cut something cuttable that hasn't been cut yet while holding the object.
	take object	reachable(object)	0	1	Sharp objects should be portable.
cuttable	**cut** object	holding (object) & holding (*sharp*)	1	1	Trying to cut the object while holding something sharp.
	take object	reachable (object)	0	1	Cuttable object should be portable.
edible	**eat** object	holding (object)	1	1	Trying to eat the object.
	take object	reachable (object)	0	1	Edible objects should be portable.
drinkable	**drink** object	holding (object)	1	1	Trying to drink the object.
	take object	reachable (object)	0	1	Drinkable objects should be portable.
holder	**–**	on (*portable*, object)	1	0	Observing object(s) on a supporter.
		in (*portable*, object)	1	0	Observing object(s) inside a container.
	take object	reachable (object)	1	0	Holder objects should not be portable.
portable	**–**	holding (object)	1	0	Holding the object means it is portable.
	take object	reachable (object)	1	1	Portable objects can be taken.
heat_source	**cook** *cookable*	holding (*cookable*) & uncooked (*cookable*) & reachable (object)	1	1	Trying to cook something cookable that hasn't been cooked yet while being next to the object.
	take object	reachable (object)	1	0	Heat source objects should not be portable.
cookable	**cook** object	holding (object) & reachable (*heat_source*)	1	1	Trying to cook the object while being next to a heat source.
	take object	reachable(object)	0	1	Cookable objects should be portable.
openable	**open** object	reachable (object) & closed (object)	1	1	Trying to open the closed object.
	close object	reachable (object) & open (object)	1	1	Trying to close the open object.

Table 8: Heuristic conditions for determining whether the agent has enough information to answer a given attribute question. We use "object" to refer to the object mentioned in the question. Words in italics represents placeholder that can be replaced by any object from the environment that has the appropriate attribute (e.g. carrot could be used as a *cuttable*). The columns Pass and Fail represent how much reward the agent will receive given the corresponding command's outcome (resp. success or failure). NB: **cut** can mean any of the following commands: **slice**, **dice**, or **chop**

Model	Location		Existence		Attribute

What's Missing: A Knowledge Gap Guided Approach for Multi-hop Question Answering

Abstract

Multi-hop textual question answering requires combining information from multiple sentences. We focus on a natural setting where, unlike typical reading comprehension, only *partial information* is provided with each question. The model must retrieve and use additional knowledge to correctly answer the question. To tackle this challenge, we develop a novel approach that explicitly identifies the *knowledge gap* between a key span in the provided knowledge and the answer choices. The model, GapQA, learns to fill this gap by determining the relationship between the span and an answer choice, based on retrieved knowledge targeting this gap. We propose jointly training a model to simultaneously fill this knowledge gap and compose it with the provided partial knowledge. On the OpenBookQA dataset, given partial knowledge, explicitly identifying what's missing substantially outperforms previous approaches.

1 Introduction

Reading Comprehension datasets (Richardson et al., 2013; Rajpurkar et al., 2016; Joshi et al., 2017) have gained interest as benchmarks to evaluate a system's ability to understand a document via question answering (QA). Since many of these early datasets only required a system to understand a single sentence, new datasets were specifically designed to focus on the problem of multi-hop QA, i.e., reasoning across sentences (Khashabi et al., 2018; Welbl et al., 2018; Yang et al., 2018).

While this led to improved language understanding, the tasks still assume that a system is provided with *all* knowledge necessary to answer the question. In practice, however, we often only have access to *partial knowledge* when dealing with such multi-hop questions, and must retrieve additional facts (the knowledge "gaps") based on the question and the provided knowledge. Our goal is to identify such gaps and fill them using an external knowledge source.

Question:
Which of these would let the most heat travel through?
A) a new pair of jeans.
B) a steel spoon in a cafeteria.
C) a cotton candy at a store.
D) a calvin klein cotton hat.
Core Fact:
Metal lets heat travel through.

Knowledge Gap (similar gaps for other choices):
steel spoon in a cafeteria _____ metal.

Filled Gap (relation identified using KB):
steel spoon in a cafeteria *is made of* metal.

Figure 1: A sample OpenBookQA question, the identified knowledge gap based on partial information in the core fact, and relation (*is made of*) identified from a KB to fill that gap.

The recently introduced challenge of *open book* question answering (Mihaylov et al., 2018) highlights this phenomenon. The questions in the corresponding dataset, OpenBookQA, are derived from a science fact in an "open book" of about 1300 facts. To answer these questions, a system must not only identify a relevant "core" science fact from this small book, but then also retrieve additional common knowledge from large external sources in order to successfully apply this core fact to the question. Consider the example in Figure 1. The core science fact *metal lets heat to travel through* points to *metal* as the correct answer, but it is not one of the 4 answer choices. Given this core fact (the "partial knowledge"), a system must still use broad external knowledge to fill the remaining gap, that is, identify which answer choice *contains* or *is made of* metal.

This work focuses on *QA under partial knowledge*. This turns out to be a surprisingly chal-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2814–2828, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

lenging task in itself; indeed, the partial knowledge models of Mihaylov et al. (2018) achieve a score of only 55% on OpenBookQA, far from human performance of 91%. Since this and several recent multi-hop datasets use the multiple-choice setting (Welbl et al., 2018; Khashabi et al., 2018; Lai et al., 2017), we assume access to potential answers to a question. While our current model relies on this for a direct application to span-prediction based RC datasets, the idea of identifying knowledge gaps can be used to create novel RC specific models.

We demonstrate that an intuitive approach leads to a strong model: first identify the knowledge gap and then fill this gap, i.e., identify the missing relation using external knowledge. We primarily focus on the OpenBookQA dataset since it is the only dataset currently available that provides partial context. However, we believe such an approach is also applicable to the broader setting of multi-hop RC datasets, where the system could start reasoning with one sentence and fill remaining gap(s) using sentences from other passages.

Our model operates in two steps. First, it predicts a key span in the core fact ("metal" in the above example). Second, it answers the question by identifying the relationship between the key span and answer choices, i.e., by *filling* the knowledge gap. This second step can be broken down further: (a) retrieve relevant knowledge from resources such as ConceptNet (Speer et al., 2017) and large-scale text corpora (Clark et al., 2018); (c) based on this, predict potential relations between the key span and an answer choice; and (d) compose the core fact with this filled gap.

We collect labels for knowledge gaps on ∼30% of the training questions, and train two modules capturing the two main steps above. The first exploits an existing RC model and large-scale dataset to train a span-prediction model. The second uses multi-task learning to train a separate QA model to jointly predict the relation representing the gap, as well as the final answer. For questions without labelled knowledge gaps, the QA model is trained based solely on the predicted answer.

Our model outperforms the previous state-of-the-art partial knowledge models by 6.5% (64.41 vs 57.93) on a targeted subset of OpenBookQA amenable to gap-based reasoning. Even without missing fact annotations, our model with a simple heuristic to identify missing gaps still outperforms previous models by 3.4% (61.38 vs. 57.93). It also generalizes to questions that were not its target, with 3.6% improvement (59.40 vs. 55.84) on the full OpenBookQA set.

Overall, the contributions of this work are: (1) an analysis and dataset[1] of knowledge gaps for QA under partial knowledge; (2) a novel two-step approach of first identifying and then filling knowledge gaps for multi-hop QA; (3) a model[1] that simultaneously learns to fill a knowledge gap using retrieved external knowledge and compose it with partial knowledge; and (4) new state-of-the-art results on QA with partial knowledge (+6.5% using annotations on only 30% of the questions).

2 Related Work

Text-Based QA. Reading Comprehension (RC) datasets probe language understanding via question answering. While several RC datasets (Rajpurkar et al., 2016; Trischler et al., 2017; Joshi et al., 2017) can be addressed with single sentence understanding, newer datasets (Weston et al., 2015; Welbl et al., 2018; Khashabi et al., 2018; Yang et al., 2018) specifically target multi-hop reasoning. In both cases, all relevant information, barring some linguistic knowledge, is provided or the questions are unanswerable (Rajpurkar et al., 2018). This allows using an attention-based approach of indirectly combining information (Dhingra et al., 2018; Cao et al., 2019; Song et al., 2018).

On the other hand, open domain question answering datasets (Clark et al., 2016, 2018) come with no context, and require first retrieving relevant knowledge before reasoning with it. Retrieving this knowledge from noisy textual corpora, while simultaneously solving the reasoning problem, can be challenging, especially when questions require multiple facts. This results in simple approaches (e.g. word-overlap/PMI-based approaches), that do not heavily rely on the retrieval quality, being competitive with other complex reasoning methods that assume clean knowledge (Clark et al., 2016; Jansen et al., 2017; Angeli et al., 2016). To mitigate this issue, semi-structured tables (Khashabi et al., 2016; Jansen et al., 2018) have been manually authored targeting a subset of these questions. However, these tables are expensive to create and these questions often need multiple hops (sometimes up to

[1]The code and associated dataset are available at https://github.com/allenai/missing-fact.

16 (Jansen et al., 2018)), making reasoning much more complex.

OpenBookQA dataset (Mihaylov et al., 2018) was proposed to limit the retrieval problem by providing a set of ∼1300 facts as an 'open book' for the system to use. Every question is based on one of the core facts, and in addition requires basic external knowledge such as hypernymy, definition, and causality. We focus on the task of question answering under partial context, where the core fact for each question is available to the system.

Knowledge-Based QA. Another line of research is answering questions (Bordes et al., 2015; Pasupat and Liang, 2015; Berant et al., 2013) over a structured knowledge base (KB) such as Freebase (Bollacker et al., 2008). Depending on the task, systems map questions to a KB query with varying complexity: from complex semantic parses (Krishnamurthy et al., 2017) to simple relational lookup (Petrochuk and Zettlemoyer, 2018). Our sub-task of filling the knowledge gap can be viewed as KB QA task with knowledge present in a KB or expected to be inferred from text.

Some RC systems (Mihaylov and Frank, 2018; Kadlec et al., 2016) and Textual Entailment (TE) models (Weissenborn et al., 2017; Inkpen et al., 2018) incorporate external KBs to provide additional context to the model for better language understanding. However, we take a different approach of using this background knowledge in an explicit inference step (i.e. hop) as part of a multi-hop QA model.

3 Knowledge Gaps

We now take a deeper look at categorizing knowledge gaps into various classes. While grounded in OpenBookQA, this categorization is relevant for other multi-hop question sets as well.[2] We will then discuss how to effectively annotate such gaps.

3.1 Understanding Gaps: Categorization

We analyzed the additional facts needed for answering 75 OpenBookQA questions. These facts naturally fall into three classes, based on the knowledge gap they are trying to fill: (1) Question-to-Fact, (2) Fact-to-Answer, and (3) Question-to-Answer(Fact). Figure 2 shows a high-level overview, with simplified examples of each class of knowledge gap in Figures 3, 4, and 5.

[2] As mentioned earlier, in the RC setting, the first relevant sentence read by the system can be viewed as the core fact.

Question-to-Fact Gap. This gap exists between concepts in the question and the core fact. For example, in Figure 3, the knowledge that "Kool-aid" is a liquid is needed to even recognize that the fact is relevant.

Fact-to-Answer Gap. This gap captures the relationship between concepts in the core fact and the answer choices. For example, in Figure 4, the knowledge "Heat causes evaporation" is needed to relate "evaporated" in the fact to the correct answer "heat". Note that it is often possible to find relations connecting the fact to even incorrect answer choices. For example, "rainfall" could be connected to the fact using "evaporation leads to rainfall". Thus, identifying the correct relation and knowing if it can be composed with the core fact is critical, i.e., "evaporation causes liquid to disappear" and "evaporation leads to rainfall" do not imply that "rainfall causes liquid to disappear".

Question-to-Answer(Fact) Gap. Finally, some questions need additional knowledge to connect concepts in the question to the answer, based on the core fact. For example, composition questions (Figure 5) use the provided fact to replace parts of the original question with words from the fact.

Notably Question-to-Fact and Fact-to-Answer gaps are more common in OpenBookQA (44% and 86% respectively[3]), while the Question-to-Answer(Fact) gap is very rare (<20%). While all three gap classes pose important problems, we focus on Fact-to-Answer gap and assume that the core fact is provided. This is still a challenging problem as one must not only identify and fill the gap, but also learn to compose this filled gap with the input fact.

3.2 Annotating Gaps: Data Collection

Due to space constraints, details of our crowdsourcing process for annotating knowledge gaps, including the motivation behind various design choices as well as several examples, are deferred to the Appendix (Section A). Here we briefly summarize the final crowdsourcing design.

Our early pilots revealed that straightforward approaches to annotate knowledge gaps for all OpenBookQA questions lead to noisy labels. To address this, we (a) identified a **subset of questions** suitable for this annotation task and (b) split

[3] Some questions have both of these classes of gaps.

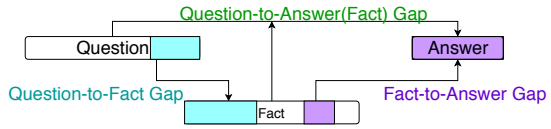

Figure 2: High-level overview of the kinds of knowledge gaps, assuming partial knowledge from the fact. In subsequent figures, the knowledge gap is indicated using highlighted text.

Question: What can cause liquid to disappear ?
Fact: If a liquid disappears then that liquid probably evaporated
Answer: Heat
Gap: Heat causes evaporation

Figure 4: Knowledge gap between the **fact** (evaporated) and the **answer** (Heat). While it is clear how to apply the knowledge, we need to know that "Heat causes evaporation" to identify the right answer.

Question: What can cause Kool-aid to disappear ?
Fact: If a liquid disappears then that liquid probably evaporated
Answer: Evaporation
Gap: Kool-aid is a liquid

Figure 3: Knowledge gap between the **question** (Kool-aid) and the **fact** (liquid). To apply the fact about liquids to the question, we need to know "Kool-aid is a liquid".

Question: What is the satellite of the blue planet ?
Fact: The blue planet refers to planet Earth
Answer: Moon
Gap: Moon is the satellite of Earth

Figure 5: Knowledge gap between the **question** and the **answer** using the **fact**. For some complex questions, the fact clarifies certain concepts in the question, (e.g., "blue planet"), leading to a reformulation of the question based on the fact (e.g., "What is the satellite of Earth?") which is captured by this gap.

Question	Fact	Span	Relation	Gap
Q: A light bulb turns on when it receives energy from **A:** gasoline	a light bulb converts *electrical energy* into light energy when it is turned on	electrical energy	provides^{-1}, enables^{-1}	(gasoline, provides, electrical energy)
Q: What makes the best wiring? **A:** Tungsten	wiring requires an *electrical conductor*	electrical conductor	isa^{-1}, madeof	(Tungsten, is an, electrical conductor)

Table 1: Examples from KGD dataset. Note that the knowledge gap is captured in the form of (Span, Relation, Answer) but not explicitly annotated. $^{-1}$ is used to indicate that the argument order should be flipped.

Fact-to-Answer gap annotation into **two steps**: key term identification and relation identification.

Question Subset. First, we identified valid question-fact pairs where the fact supports the correct answer (verified via crowdsourcing) but does not trivially lead to the answer (fact only overlaps with the correct answer). Second, we noticed that the Fact-to-Answer gaps were much noisier for longer answer options, where you could write multiple knowledge gaps or a single complex knowledge gap. So we created *OBQA-Short*, the subset of OpenBookQA where answer choices have at most two non-stopword tokens. This contains over 50% of the original questions and is also the target set of our approach.

Two-step Gap Identification. Starting with the above pairs of questions with valid partial knowledge, the second task is to author facts that close the Fact-to-Answer **knowledge gap**. Again, initial iterations of the task resulted in poor quality, with workers often writing noisy facts that restated part of the provided fact or directly connect the question to the answer (skipping over the provided fact[4]). We noticed that the core fact often contains a key span that hints at the final answer. So we broke the task into two steps: (1) identify key terms (preferably a span) in the core fact that could answer the question, and (2) identify one or more relations[5] that hold between the key terms and the correct answer choice but not the incorrect choices. Table 1 shows example annotations of the gaps obtained through this process.

Knowledge Gap Dataset: KGD

Our Knowledge Gap Dataset (KGD) contains key span and relation label annotations to capture knowledge gaps. To reduce noise, we only use knowledge gap annotations where at least two of three workers found a contiguous span from the core fact and a relation from our list. The final

[4]This was also noticed by the original authors of OpenBookQA dataset (Mihaylov et al., 2018).

[5]Workers preferably chose from a selected list of nine most common relations: {causes, definedAs, enables, isa, located in, made of, part of, provides, synonym of} and their inverses (except synonymy). These relations have also been found to be useful by prior approaches for science QA (Clark et al., 2014; Khashabi et al., 2016; Jansen et al., 2016, 2018).

	Train	Dev	Test
Total #questions	1151	117	121
Total #question-facts	1531	157	165
Avg. # spans	1.43	1.46	1.45
Avg. # relations	3.31	2.45	2.45

Table 2: Statistics of the train/dev/test split of the KGD dataset. The #question-fact pairs is higher than #questions as some questions may be supported by multiple facts. The average statistic computes the average number of unique spans and relations per question-fact pair.

dataset contains examples of the form {question, fact, spans, relations}, where each span is a substring of the input fact, and relations are the set of valid relations between the span and the correct answer (examples in Table 1 and stats in Table 2).

4 Knowledge-Gap Guided QA: GapQA

We first introduce the notation used to describe our QA system. For each question q and fact f, the selected span is given by s and the set of valid relations between this span and the correct choice is given by r. Borrowing notation from OpenBookQA, we refer to the question without the answer choices c as the stem q_s, i.e., $q = q_s\ c$. We use $\hat{s}$ to indicate the predicted span and $\hat{r}$ for the predicted relations. We use q_m and f_m to represent the tokens in the question stem and fact respectively. Following the Turk task, our model first identifies the key span from the fact and then identifies the relation using retrieved knowledge.

4.1 Key Span Identification Model

Since the span selected from the fact often tends to be the answer to the question (c.f. Table 1), we can use a reading comprehension model to identify this span. The fact serves as the input passage and the question stem as the input question to the reading comprehension model. We used the Bi-Directional Attention Flow (BiDAF) model (Seo et al., 2017), an attention-based span prediction model designed for the SQuAD RC dataset (Rajpurkar et al., 2016). We refer the reader to the original paper for details about the model.

4.2 Knowledge Retrieval Module

Given the predicted span, we retrieve knowledge from two sources: triples from ConceptNet (Speer et al., 2017) and sentences from ARC corpus (Clark et al., 2018). ConceptNet contain (subject, relation, object) triples with relations such as */r/IsA*, */r/PartOf* that closely align with the relations in our gaps. Since ConceptNet can be incomplete or vague (e.g. */r/RelatedTo* relation), we also use the ARC corpus of 14M science-relevant sentences to improve our recall.

Tuple Search. To find relevant tuples connecting the predicted span $\hat{s}$ to the answer choice c_i, we select tuples where at least one token[6] in the subject matches $\hat{s}$ and at least one token in the object matches c_i (or vice versa). We then score each tuple t using the Jaccard score[7] and pick the top k tuples for each c_i ($k = 5$ in our experiments).

Text Search. To find the relevant sentences for $\hat{s}$ and c_i, we used ElasticSearch[8] with the query: $\hat{s}$ + c_i (refer to Appendix D for more details). Similar to ConceptNet, we pick top 5 sentences for each answer choice. To ensure a consistent formatting of all knowledge sources, we convert the tuples into sentences using few hand-defined rules(described in Appendix C). Finally all the retrieved sentences are combined to produce the input KB for the model, K.

4.3 Question Answering Model

The question answering model takes as input the question q_s, answer choices c, fact f, predicted span, $\hat{s}$ and retrieved knowledge K. We use 300-dimensional 840B GloVe embeddings (Pennington et al., 2014) to embed each word in the inputs. We use a Bi-LSTM with 100-dimensional hidden states to compute the contextual encodings for each string, e.g., $\mathcal{E}_f \in \mathbb{R}^{f_m \times h}$. The question answering model selects the right answer using two components: (1) **Fact Relevance** module (2) **Relation Prediction** module.

Fact Relevance. This module is motivated by the intuition that a relevant fact will often capture a relation between concepts that align with the question and the correct answer (the cyan and magenta regions in Figure 2). To deal with the gaps between these concepts, this module relies purely on word embeddings while the next module will focus on using external knowledge.

We compute a question-weighted and answer-weighted representation of the fact to capture the part of the fact that links to the question and answer respectively. We compose these fact-based

[6] We use lower-cased, stemmed, non-stopword tokens.

[7] score(t) = jacc(tokens(t), tokens($\hat{s}$ + c_i)) where jacc(w1, w2) = $\frac{w1 \cap w2}{w1 \cup w2}$

[8] https://www.elastic.co/products/elasticsearch

representations to then identify how well the answer choice is supported by the fact.

To calculate the question-weighted fact representation, we first identify facts words with a high similarity to some question word ($\mathcal{V}_{q_s}(f)$) using the attention weights: $\mathcal{A}_{q_s,f} = \mathcal{E}_{q_s} \cdot \mathcal{E}_f \in \mathbb{R}^{q_m \times f_m}$

$$\mathcal{V}_{q_s}(f) = \text{softmax}_{f_m}\left(\max_{q_m} \mathcal{A}_{q_s,f}\right) \in \mathbb{R}^{1 \times f_m}$$

The final attention weights are similar to the Query-to-Context attention weights in BiDAF. The final question-weighted representation is:

$$\mathcal{S}_{q_s}(f) = \mathcal{V}_{q_s}(f) \cdot \mathcal{E}_f \in \mathbb{R}^{1 \times h} \quad (1)$$

We similarly compute the choice-weighted representation of fact as $\mathcal{S}_{c_i}(f)$. We compose these two representations by averaging[9] these two vectors $\mathcal{S}_{q_s c_i}(f) = (\mathcal{S}_{q_s}(f) + \mathcal{S}_{c_i}(f))/2$. We finally score the answer choice by comparing this representation with the aggregate fact representation, obtained by averaging too, as:

$$\text{score}_f(c_i) = \text{FF}\left(\bigotimes(\mathcal{S}_{q_s c_i}(f), \text{avg}(\mathcal{E}_f)\right)$$

where $\bigotimes(x, y) = [x - y; x * y] \in \mathbb{R}^{1 \times 2h}$ and FF is a feedforward neural network that outputs a scalar score for each answer choice.

Filling the Gap: Relation Prediction. The relation prediction module uses the retrieved knowledge to focus on the Fact-to-Answer gap by first predicting the relation between $\hat{s}$ and c_i and then compose it with the fact to score the choice. We first compute the span and choice weighted representation($\mathbb{R}^{1 \times h}$) for each sentence k_j in K using the same operations as above:

$$\mathcal{S}_{\hat{s}}(k_j) = \mathcal{V}_{\hat{s}}(k_j) \cdot \mathcal{E}_{k_j} \; ; \; \mathcal{S}_{c_i}(k_j) = \mathcal{V}_{c_i}(k_j) \cdot \mathcal{E}_{k_j}$$

These representations capture the contextual embeddings of the words in the k_j that most closely resemble words in $\hat{s}$ and c_i respectively. We predict the kb-based relation between them based on the composition of these representations :

$$\mathcal{R}_j(\hat{s}, c_i) = \text{FF}\left(\bigotimes(\mathcal{S}_{\hat{s}}(k_j), \mathcal{S}_{c_i}(k_j))\right) \in \mathbb{R}^{1 \times h}$$

We pool the relation representations from all the KB facts into a single prediction by averaging, i.e. $\mathcal{R}(\hat{s}, c_i) = \text{avg}_j \; \mathcal{R}_j(\hat{s}, c_i)$.

[9]We found this simple composition function performed better than other composition operations.

Relation Prediction Score. We first identify the potential relations that can be composed with the fact, given the question, e.g., in Figure 1, we can compose the fact with (steel spoon; *made of*; metal) relation but not (metal; *made of*; ions). We compose an aggregate representation of the question and fact encoding to capture this information:

$$\mathcal{D}(q_s, f) = \bigotimes(\max_{q_m} \mathcal{E}_{q_s}, \max_{f_m} \mathcal{E}_f) \in \mathbb{R}^{1 \times 2h}$$

We finally score the answer choice based on this representation and the relation representation:

$$\text{score}_r(c_i) = \text{FF}\left([\mathcal{D}(q_s, f); \mathcal{R}(\hat{s}, c_i)]\right)$$

The final score for each answer choice is computed by summing the fact relevance and relation prediction based scores i.e. $\text{score}(c_i) = \text{score}_f(c_i) + \text{score}_r(c_i)$. The final architecture of our QA model is shown in Figure 6.

4.4 Model Training

We use cross-entropy loss between the predicted answer scores $\hat{c}$ and the gold answer choice $\bar{c}$. Since we also have labels on the true relations between the gold span and the correct answer choice, we introduce an auxiliary loss to ensure the predicted relation $\mathcal{R}$ corresponds to the true relation between s and c_i. We use a single-layer feedforward network to project $\mathcal{R}(s, c_i)$ into a vector $\hat{r}_i \in \mathbb{R}^{1 \times l}$ where l is the number of relations. Since multiple relations can be valid, we create an n-hot vector representation $\bar{r} \in \mathbb{R}^{1 \times l}$ where $\bar{r}[k] = 1$ if r_k is a valid relation.

We use binary cross-entropy loss between the $\hat{r}_i$ and r for the correct answer choice. For the incorrect answer choice, we do not know if any of the unselected relations(i.e. where $r[k] = 0$) hold. But we do know that the relations selected by Turkers for the correct answer choice should not hold for the incorrect answer choice. To capture this, we compute the binary cross entropy loss between $\hat{r}_i$ and $1 - r$ for the incorrect answer choices but ignore the unselected relations.

Finally, the loss for each example, assuming c_i is the correct answer, is given as loss $= ce(\hat{c}, \bar{c}) + \lambda \cdot \big(bce(\hat{r}_i, \bar{r}) + \sum_{j \neq i} mbce(\hat{r}_j, 1 - \bar{r}, \bar{r})\big)$, where ce is cross-entropy loss, bce is binary cross-entropy loss, and $mbce$ is masked binary cross entropy loss, where unselected relations are masked.

We further augment the training data with questions in the OBQA-Short dataset using the predicted spans and ignoring the relation loss. Also,

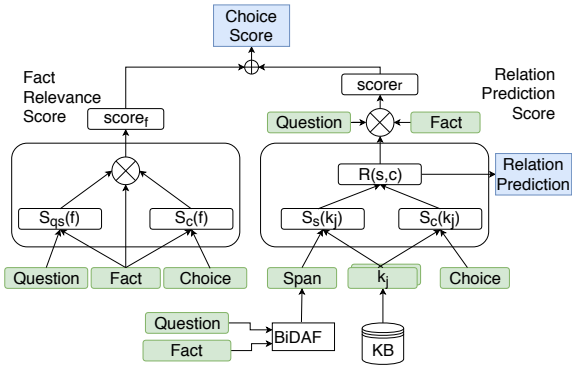

Figure 6: Overall architecture of the KGG question-answering model for each answer choice. The green nodes are the input to the model and the blue nodes are the model outputs that the losses are computed against. The model uses BiDAF to predict the key spans and retrieves KB facts based on the span and the input choice.

we assume the labelled core fact in the OpenBookQA dataset provides the partial knowledge needed to answer these questions.

Implementation details and parameter settings are deferred to Appendix B. A sample visualization of the attentions and knowledge used in the model are provided in Figure 10 in the Appendix.

5 Experimental Results

We present results of our proposed model, GapQA, on two question sets: (a) those with short answers,[10] OBQA-Short (290 test questions), and (b) the complete set, OBQA-Full (500 test questions). As we mentioned before, OBQA-Short subset is likely to have Fact-to-Answer gaps that can be targeted by our approach and we therefore expect larger and more meaningful gains on this subset.

5.1 Key Span Identification

We begin by evaluating three training strategies for the key span identification model, using the annotated spans in KGD for training. As seen in Table 3, the BiDAF model trained on the SQuAD dataset (Rajpurkar et al., 2016) performs poorly on our task, likely due to the different question style in OpenBookQA. While training on KGD (from scratch) substantially improves accuracy, we observe that using KGD to fine-tune BiDAF pretrained on SQuAD results in the best F1 (78.55) and EM (63.99) scores on the Dev set. All subsequent experiments use this fine-tuned model.

[10] Answers with at most two non-stopword tokens.

Training Data	Dev F1	Dev EM
SQuAD	54.67	41.40
KGD	72.99	58.60
SQuAD + KGD (tuning)	**78.55**	**63.69**

Table 3: BiDAF model performance on the span prediction task, under different choices of training data

5.2 OpenBookQA Results

We compare with three previous state-of-the-art **models** reported by Mihaylov et al. (2018). Two of these are Knowledge-free models (also referred to as No Context Baselines (Chen and Durrett, 2019)): (a) Question-to-Choice (**Q2Choice**) computes attention between the question and the answer choice, (b) **ESIM + ELMo**, uses ESIM (Chen et al., 2017) with ELMo (Peters et al., 2018) embeddings to compute question-choice entailment. The third is Knowledge Enhanced Reader (**KER**), which uses the core fact (f) and knowledge retrieved from ConceptNet to compute cross-attentions between the question, knowledge, and answer choices.

For **knowledge**, we consider four sources: (1) **ConceptNet (CN)**, the English subset of ConceptNet v5.6.0 tuples;[11] (2) **WordNet**, the WordNet subset of ConceptNet used by Mihaylov et al. (2018); (3) **OMCS**, the Open Mind Common Sense subset of ConceptNet used by Mihaylov et al. (2018); and (4) **ARC**, with 14M science-relevant sentences from the AI2 Reasoning Challenge dataset (Clark et al., 2018).

Following OpenBookQA, we train each model five times using different random seeds, and report the average score and standard deviation (without Bessel's correction) on the test set. For simplicity and consistency with prior work, we report one std. dev. from the mean using the $\mu \pm \sigma$ notation.

We train our model on the combined KGD and OBQA-Short question set with full supervision on examples in KGD and only QA supervision (with predicted spans) on questions in OBQA-Short. We train the baseline approaches on the entire question set as they have worse accuracies on both the sets when trained on the OBQA-Short subset. We do not use our annotations for any of the test evaluations. We use the core fact provided by the original dataset and use the predicted spans from the fine-tuned BiDAF model.

We present the test accuracies on the two ques-

Model	OBQA-Short	OBQA-Full
Q2Choice	47.10 ± 1.5	49.64 ± 1.3
ESIM + ELMo	45.93 ± 2.6	49.96 ± 2.5
KER (only f)	57.93 ± 1.4	55.80 ± 1.8
KER (f + WordNet)	54.83 ± 2.5	55.84 ± 1.7
KER (f + OMCS)	49.65 ± 2.0	52.50 ± 0.8
GapQA (f + KB) [Ours]	**64.41 ± 1.8***	**59.40 ± 1.3***

Table 4: Test accuracy on the the OBQA-Short subset and OBQA-Full dataset assuming core fact is given. $*$ denotes the results are statistically significantly better than all the baselines (p≤0.05, based on Wilson score intervals (Wilson, 1927)).

Knowledge Source	Model	OBQA-Short
f + WordNet	KER	54.83 ± 2.5
	GapQA	**60.69 ± 1.1***
f + OMCS	KER	49.65 ± 2.0
	GapQA	**60.90 ± 2.4***
f + CN + ARC	GapQA	**64.41 ± 1.8**

Table 5: Test accuracy on the OBQA-Short subset with different sources of knowledge. $*$ denotes the results are statistically significantly better than the corresponding KER result (p≤0.05, based on Wilson score intervals (Wilson, 1927)).

Model	OBQA-Short	Δ
GapQA	**64.41 ± 1.8**	—
No Annotations	58.90 ± 1.9	5.51
Heuristic Span Anns.	61.38 ± 1.5	3.03
No Relation Score	60.48 ± 1.1	3.93
No Spans (Model)	62.14 ± 2.1	2.27
No Spans (IR)	61.79 ± 1.0	2.62

Table 6: Average accuracy of various ablations, showing that each component of GapQA has an important role. No Annotations = Ignore Span & Relation Annotations, Heuristic Span Anns = Heuristically predict span annotations (no human annotations), No Relation Score = Ignore the relation-based score ($score_r$), No Spans (Model) = Ignore the span (use entire fact) to compute span-weighted representations, No Spans (IR) = Ignore the span (use entire fact) for retrieval.

tion sets in Table 4. On the targeted OBQA-Short subset, our proposed GapQA improves statistically significantly over the partial knowledge baselines by 6.5% to 14.4%. Even though the full OpenBookQA dataset contains a wider variety of questions not targeted by GapQA, we still see an improvement of 3+% relative to prior approaches.

It is worth noting that recent large-scale language models (LMs) (Devlin et al., 2019; Radford et al., 2018) have now been applied on this task, leading to improved state-of-the-art results (Sun et al., 2018; Banerjee et al., 2019; Pan et al., 2019). However, our knowledge-gap guided approach to QA is orthogonal to the underlying model. Combining these new LMs with our approach is left to future work.

Effect of input knowledge. Since the baseline models use different knowledge sources as input, we evaluate the performance of our model using the same knowledge as the baselines.[12] Even when our model is given the same knowledge, we see an improvement by 5.9% and 11.3% given only WordNet and OMCS knowledge respectively. This shows that we can use the available knowledge, even if limited, more effectively than previous methods. When provided with the full ConceptNet knowledge and large-scale text corpora, our model is able to exploit this additional knowledge and improve further by 4%.

5.3 Ablations

We next evaluate key aspects of our model in an ablation study, with average accuracies in Table 6.

No Annotations (No Anns): We ignore all collected annotations (span, relation, and fact) for training the model. We use the BiDAF(SQuAD) model for span prediction, and only the question answering loss for the QA model trained on the OBQA-Short subset.[13] Due to the noisy spans produced by the out-of-domain BiDAF model, this model performs worse that the full GapQA model by 5.5% (comparable performance to the KER models). This shows that our model does utilize the human annotations to improve on this task.

Heuristic Span Annotations: We next ask whether some of the above loss in accuracy can be recovered by heuristically producing the spans for training—a cost-effective alternative to human annotations. We find the longest subsequence of tokens (ignoring stop words) in f that is not mentioned in q and assume this span (including the intermediate stop words) to be the key term. To prevent noisy key terms, we only consider a subset of questions where 60% of the non-stopword stemmed tokens in f are covered by q. We fine-tune the BiDAF(SQuAD) model on this subset and then use it to predict the spans on the full set.[14]

[12] The baselines do not scale to large scale corpora and so can not be evaluated against our knowledge sources.

[13] Model still predicts the latent relation representation.

[14] We use the questions from the KGD + OBQA-Short set. Note we are only evaluating the impact of heuristic spans compared to human-authored spans, but assume that we have

Question	Fact	Predicted Answer	Reason
What vehicle would you use to travel on the majority of the surface of the planet on which we live? (A) Bike (B) **Boat** (C) Train (D) Car	oceans cover 70% of the surface of the earth	Bike	Predicted the **wrong span** "70%".
What contains moons? (A) ships (B)**space mass** (C) people (D) plants	the solar system contains the moon	ships	**Scores the relation for the incorrect answer higher** because of the facts connecting "systems" and "ships".
Cocoon creation occurs (A) **after the caterpillar stage** (B) after the chrysalis stage (C) after the eggs are laid (D) after the cocoon emerging stage	the cocoons being created occurs during the pupa stage in a life cycle	after the chrysalis stage	Does not model the **complex relation** (temporal ordering) between the key span: "pupa stage" and "caterpillar stage". Instead it predicts "chrysalis" due to the synonymy with "pupa".

Table 7: Sample errors made by the GapQA on questions from the OBQA-Short dataset. The correct answers are marked in **bold** within the question.

We train GapQA model on this dataset without any relation labels (and associated loss). This simple heuristic leads to a 3% drop compared to human annotations, but still out-performs previous approaches on this dataset, showing the value of the gap-based QA approach.

No Relation Score: We ignore the entire relation-based score ($score_r$) in the model and only rely on the fact-relevance score. The drop in score by 3.9% shows that the fact alone is not sufficient to answer the question using our model.

No Spans (Model): We ignore the spans in the model, i.e., we use the entire fact to compute the span-based representation $\mathcal{S}_{\hat{s}}(k_j)$. In effect, the model is predicting the gap between the entire fact and answer choice.[15] We see a drop of $\sim$2%, showing the value of spans for gap prediction.

No Spans (IR): Ignoring the span for retrieval, the knowledge is retrieved based on the entire fact (full GapQA model is used). The drop in accuracy by 2.6% shows the value of targeted knowledge-gap based retrieval.

5.4 Error Analysis

We further analyzed the performance of GapQA on 40 incorrectly answered questions from the dev set in the OBQA-Short dataset. Table 7 shows a few error examples. There were three main classes of errors:

Incorrect predicted spans (25%) often due to complex language in the fact or the Question-to-Fact gap needed to accurately identify the span.

Incorrect relation scores (55%) due to distracting facts for the incorrect answer or not finding relevant facts for the correct answer, leading to an incorrect answer scoring higher.

Out-of-scope gap relations (20%) where the knowledge gap relations are not handled by our model such as temporal relations or negations (e.g., is *not* made of).

Future work in expanding the dataset, incorporating additional relations, and better retrieval could mitigate these errors.

6 Conclusion

We focus on the task of question answering under partial knowledge: a novel task that lies in-between open-domain QA and reading comprehension. We identify classes of knowledge gaps when reasoning under partial knowledge and collect a dataset targeting one common class of knowledge gaps. We demonstrate that identifying the knowledge gap first and then reasoning by filling this gap outperforms previous approaches on the OpenBookQA task, with and even without additional missing fact annotation. This work opens up the possibility of focusing on other kinds of knowledge gaps and extending this approach to other datasets and tasks (e.g., span prediction).

A Annotating Gaps: Data Collection

We first identify relevant facts for questions and then collect annotations for fact-answer gap, given the relevant fact. However, straightforward approaches to annotate all questions led to noisy labels. To improve annotation quality, we identified question subsets most suitable for this task and split the fact-answer gap annotation into two steps.

Fact Relevance. The OpenBookQA dataset provides the core science fact used to create the question. However, in 20% of the cases, while the core science fact inspired the question, it is not needed to answer the question (Mihaylov et al., 2018). We also noticed that often multiple facts from the open book can be relevant for a question. So we first create an annotation task to identify the relevant facts from a set of retrieved facts. Also to ensure that there is a gap between the fact and the correct answer, we select facts that have no word overlap with the correct choice or have overlap with multiple answer choices. This ensures that the fact alone can not be trivially used to answer the question.

We ask Turkers to annotate these retrieved facts as (1) are they *relevant* to the question and (2) if relevant, do they point to a *unique* answer. We introduced the second category after noticing that some generic facts can be relevant but not point to a specific answer making identifying the knowledge gap impossible. E.g. The fact: "evaporation is a stage in the water cycle process" only eliminates one answer option from "The only stage of the water cycle process that is nonexistent is (A) evaporation (B) evaluation (C) precipitation (D) condensation". For each question, we selected facts that were marked as relevant and unique by at least two out of three turkers.

Knowledge Gap. In the second round of data collection, we asked Turkers to write the facts connecting the relevant fact to the correct answer choice. We restricted this task to Masters level Turkers with 95% approval rating and 5000 approved hits. However, we noticed that crowdsource workers would often re-state part of the knowledge mentioned in the original fact or directly connect the question to the answer. This issue was also mentioned by the authors of OpenBookQA who also noticed that the additional facts were "*noisy (incomplete, over-complete, or only distantly related)*" (Mihaylov et al., 2018). E.g. for the question: "In the desert, a hawk may enjoy an occasional (A) coyote (B) reptile (C) bat (D) scorpion" and core fact: "hawks eat lizards", one of the turk-authored additional fact: "Hawks hunt reptiles which live in the desert" is sufficient to answer the question on its own.

We also noticed that questions with long answer choices often have multiple fact-answer gaps leading to complex annotations, e.g. "tracking time" *helps with* "measuring how many marshmallows I can eat in 10 minutes". Collecting knowledge gaps for such questions and common-sense knowledge to capture these gaps are interesting directions of future research. We instead focus on questions where the answer choices have at most two non-stopword tokens. We refer to this subset of questions in OpenBookQA as *OBQA-Short*, which still forms more than 50% of the OpenBookQA set. This subset also forms the target question set of our approach.

Further to simplify this task, we broke the task of identifying the required knowledge into two steps (shown in Figure 7 in Appendix): (1) identify key terms in the core fact that could answer the question, and (2) identify the relationship between these terms and the correct answer choice. For key terms, we asked the Turkers to select spans from the core fact itself, to the extent possible. For the relation identification, we provided a list of relations and asked them to select all the relations that hold between the key term and the correct choice but do not hold for the incorrect answer choices. Based on our analysis, we picked nine most common relations: {causes, definedAs, enables, isa, located in, made of, part of, provides, synonym of} and their inverses (except synonymy).[16] If none of these relations were valid, they were allowed to enter the relation in a text box.

We note that the goal of this effort was to collect supervision for a subset of questions to guide the model and show the value of minimal annotation on this task. We believe our approach can be useful to collect annotations on other question sets as well, or can be used to create a challenge dataset for this sub-task. Moreover, the process of collecting this data revealed potential issues with collecting annotations for knowledge gaps and also inspired the design of our two-step QA model.

[16] These relations were also found to be important by prior approaches (Clark et al., 2014; Khashabi et al., 2016; Jansen et al., 2016, 2018) in the science domain.

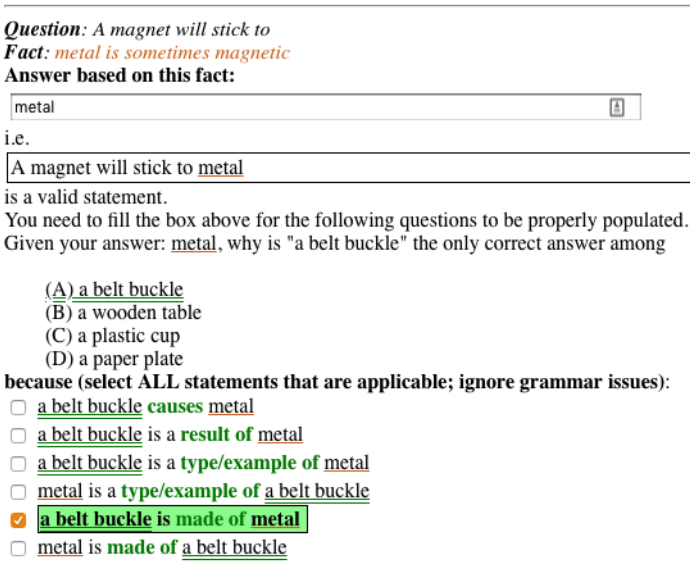

Figure 7: Interface provided to Turkers to annotate the missing fact. Entering the answer span from the fact, metal, in this example, automatically populates the interface with appropriate statements. The valid statements are selected by Turkers and capture the knowledge gap.

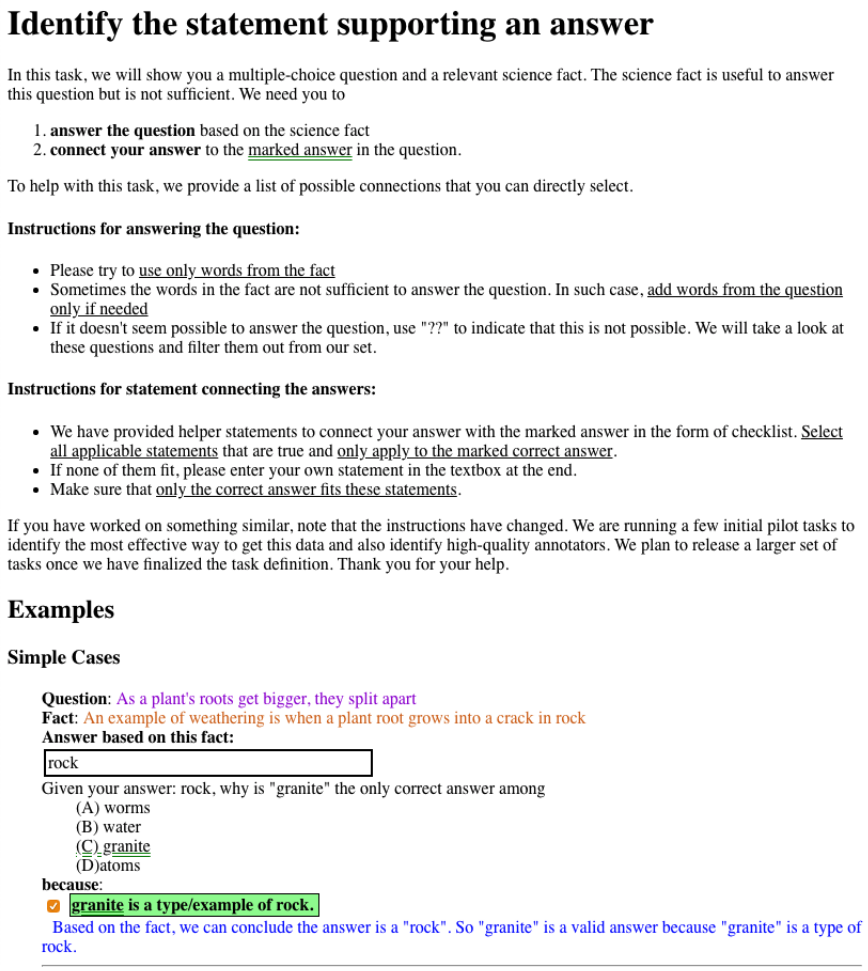

Figure 8: Basic Instructions for the task

Hard Cases

Writing your own statement: If none of the provided statements apply, write your own statment.

Question: What happens when a hemisphere is tilted away from the sun?
Fact: winter is when a hemisphere is tilted away from the sun.
Answer based on this fact:
winter
Given your answer, why is "cools" the only correct answer ?
(A) cools
(B) nothing
(C) heats
(D) warms
because:
If none of the above apply, write your own statement here using cools and winter
cools happens during winter ⟵
Since none of the pre-defined list of helper phrases fit, write your own.

Writing your own answer: If you can't find the right answer as a part of the fact, write your own answer.

Question: An animal living in an environment lacking in food resources
Fact: an animal requires enough nutrients to maintain good health
Answer based on this fact:
not maintain good health ⟵
Since the answer is the opposite of the "maintain good health" in the fact, we need to add a "not" to the answer.
Given your answer, why is "will be in poor shape" the only correct answer ?
(A) will be in poor shape
(B) will be thriving and lively
(C) will be switching to a new diet
(D) will hibernate until more food comes along
because: ☑ **will be in poor shape is synonymous with will maintain bad health.**

Adding words from the question: Sometimes words from the question need to be added to the statement to ensure that only the correct answer fits the statement.

Question: Which would be the result of the breeding of two wolves?
Fact: reproduction produces offspring
Answer based on this fact:
offspring
Given your answer, why is "wolf pups" the only correct answer ?
(A) kittens
(B) wolf pups
(C) fox pups
(D) dog pups
because:
If none of the above apply, write your own statement here using wolf pups and offspring
wolf pups are offsprings of wolves. ⟵
Since all the answers are offsprings, we additionally specify that the correct answer should be offspring of wolves.

Figure 9: Instructions for complex examples

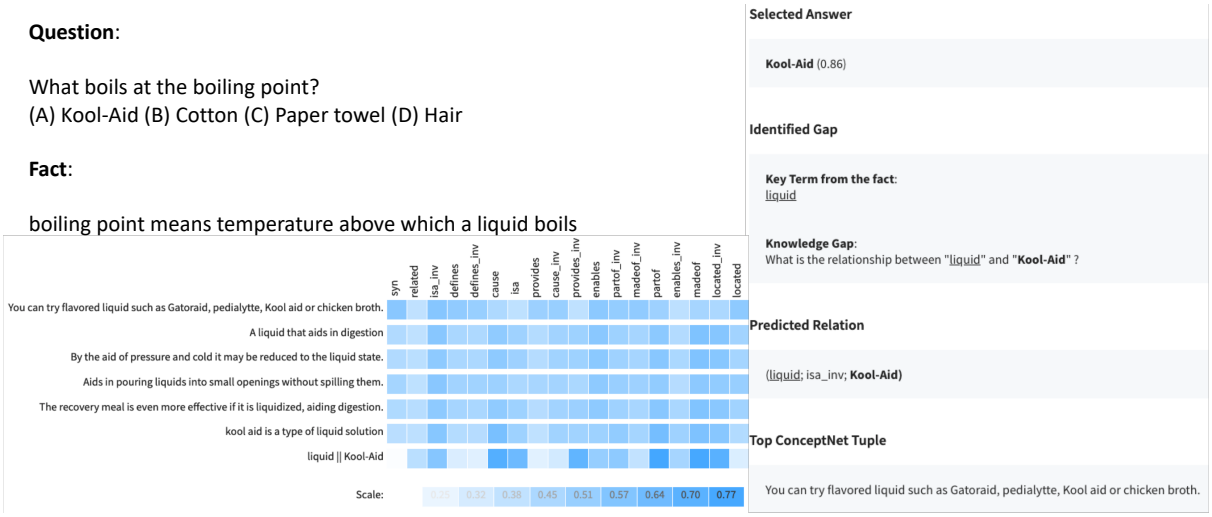

Figure 10: Visualization of the models behavior with the predicted span, top predicted relation, and the top fact used by model. The heat map shows the confidence of the model for all the relations for each input sentence (first five) and ConceptNet sentencized tuple (last but one) and the back-off tuple (last one) to capture the knowledge in the embeddings.

B Implementation Details

We implement all our models in Pytorch (Paszke et al., 2017) using the AllenNLP (Gardner et al., 2017) toolkit. We also used the AllenNLP implementation of the BiDAF model for span prediction. We use 300D 840B Glove (Pennington et al., 2014) embeddings and use 200 dimensional hidden representations for the BiLSTM shared between all inputs (each direction uses 100 dimensional hidden vectors). We use 100 dimensional representations for the relation prediction, $\mathcal{R}_j$. Each feedforward network, FF is a 2-layer network with relu activation, 0.5 dropout (Srivastava et al., 2014), 200 hidden dimensions on the first layer and no dropout on the output layer with linear activation. We use a variational dropout (Gal and Ghahramani, 2016) of 0.2 in all the BiLSTMs. The relation prediction loss is scaled by $\lambda = 1$. We used the Adam (Kingma and Ba, 2015) optimization with initial $lr = 0.001$ and a learning rate scheduler that halves the learning rate after 5 epochs of no change in QA accuracy. We tuned the hyper-parameters and performed early stopping based on question answering accuracy on the validation set. Specifically, we considered {50, 100, 200} dimensional representations, $\lambda \in \{0.1, 1, 10\}$, retrieving {10, 20} knowledge tuples and {[x - y; x*y], [x, y]} combination functions for $\bigotimes$ during the development of the model. The baseline models were developed for this dataset using hyper-parameter tuning; we do not perform any additional tuning. Our model code and pre-trained models are available at https://github.com/allenai/missing-fact.

C ConceptNet sentences

Given a tuple $t = (s, v, o)$, the sentence form is generated as "s is split(v) o" where split(v) splits the ConceptNet relation v into a phrase based on its camel-case notation. For example, (belt buckle, /r/MadeOf, metal) would be converted into "belt buckle is made of metal".

D Text retrieval

For each span $\hat{s}$ and answer choice c_i, we query an ElasticSearch [17] index on the input text corpus with the "$\hat{s}$ + c_i" as the query. We also require the matched sentence must contain both the span and the answer choice. We filter long sentences (>300 characters), sentences with negation and noisy sentences[18] from the retrieved sentences.

[17] https://www.elastic.co/

[18] Sentences are considered clean if they contain alphanumeric characters with standard punctuation, start with an alphabet or a number, are single sentence and only uses hyphens in hyphenated word pairs

KagNet: Knowledge-Aware Graph Networks for Commonsense Reasoning

Abstract

Commonsense reasoning aims to empower machines with the human ability to make presumptions about ordinary situations in our daily life. In this paper, we propose a textual inference framework for answering commonsense questions, which effectively utilizes external, structured commonsense knowledge graphs to perform *explainable* inferences. The framework first grounds a question-answer pair from the semantic space to the knowledge-based symbolic space as a schema graph, a related sub-graph of external knowledge graphs. It represents schema graphs with a novel knowledge-aware graph network module named KagNet, and finally scores answers with graph representations. Our model is based on graph convolutional networks and LSTMs, with a hierarchical path-based attention mechanism. The intermediate attention scores make it transparent and interpretable, which thus produce trustworthy inferences. Using ConceptNet as the only external resource for Bert-based models, we achieved state-of-the-art performance on the CommonsenseQA, a large-scale dataset for commonsense reasoning. We open-source our code[1] to the community for future research in knowledge-aware commonsense reasoning.

1 Introduction

Human beings are rational and a major component of rationality is the ability to reason. Reasoning is the process of combining facts and beliefs to make new decisions (Johnson-Laird, 1980), as well as the ability to manipulate knowledge to draw inferences (Hudson and Manning, 2018). Commonsense reasoning utilizes the basic knowledge that reflects our natural understanding of the world and human behaviors, which is common to all humans.

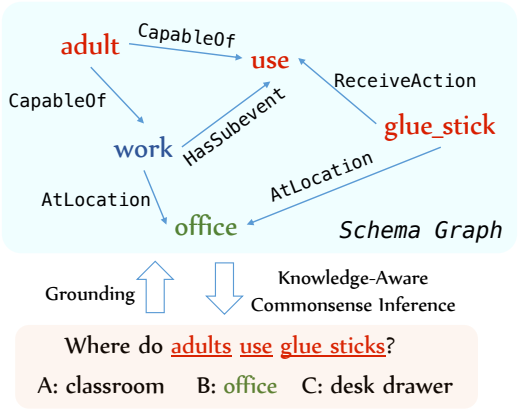

Figure 1: An example of using external commonsense knowledge (symbolic space) for inference in natural language commonsense questions (semantic space).

Empowering machines with the ability to perform commonsense reasoning has been seen as the bottleneck of artificial general intelligence (Davis and Marcus, 2015). Recently, there have been a few emerging large-scale datasets for testing machine commonsense with various focuses (Zellers et al., 2018; Sap et al., 2019b; Zellers et al., 2019). In a typical dataset, CommonsenseQA (Talmor et al., 2019), given a question like *"Where do adults use glue sticks?"*, with the answer choices being {classroom(✗), office (✓), desk drawer (✗)}, a commonsense reasoner is expected to differentiate the correct choice from other "distractive" candidates. False choices are usually highly related to the question context, but just less possible in real-world scenarios, making the task even more challenging. This paper aims to tackle the research question of how we can teach machines to make such commonsense inferences, particularly in the question-answering setting.

It has been shown that simply fine-tuning large, pre-trained language models such as Gpt (Radford et al., 2018) and Bert (Devlin et al., 2019)

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 2829–2839, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

can be a very strong baseline method. However, there still exists a large gap between performance of said baselines and human performance. Reasoning with neural models is also lacking in transparency and interpretability. There is no clear way as to how they manage to answer commonsense questions, thus making their inferences dubious.

Merely relying on pre-training large language models on corpora cannot provide well-defined or reusable structures for explainable commonsense reasoning. We argue that it would be more beneficial to propose reasoners that can exploit commonsense knowledge bases (Speer et al., 2017; Tandon et al., 2017; Sap et al., 2019a). Knowledge-aware models can explicitly incorporate external knowledge as relational inductive biases (Battaglia et al., 2018) to enhance their reasoning capacity, as well as to increase the transparency of model behaviors for more interpretable results. Furthermore, a knowledge-centric approach is extensible through commonsense knowledge acquisition techniques (Li et al., 2016; Xu et al., 2018).

We propose a knowledge-aware reasoning framework for learning to answer commonsense questions, which has two major steps: schema graph grounding (§3) and graph modeling for inference (§4). As shown in Fig. 1, for each pair of question and answer candidate, we retrieve a graph from external knowledge graphs (e.g. `ConceptNet`) in order to capture the relevant knowledge for determining the plausibility of a given answer choice. The graphs are named "schema graphs" inspired by the `schema theory` proposed by Gestalt psychologists (Axelrod, 1973). The grounded schema graphs are usually much more complicated and noisier, unlike the ideal case shown in the figure.

Therefore, we propose a knowledge-aware graph network module to further effectively model schema graphs. Our model `KagNet` is a combination of graph convolutional networks (Kipf and Welling, 2017) and LSTMs, with a hierarchical path-based attention mechanism, which forms a `GCN-LSTM-HPA` architecture for path-based relational graph representation. Experiments show that our framework achieved a new state-of-the-art performance[2] on the `CommonsenseQA` dataset. Our model also works better then other methods with limited supervision, and provides human-readable results via intermediate attention scores.

[2]The highest score on the leaderboard as of the time when we submitted the paper (May 2019).

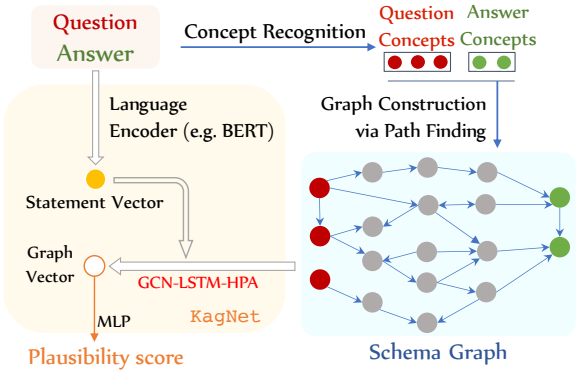

Figure 2: The overall workflow of the proposed framework with knowledge-aware graph network module.

2 Overview

In this section, we first formalize the commonsense question answering problem in a knowledge-aware setting, and then introduce the overall workflow of our framework.

2.1 Problem statement

Given a commonsense-required natural language question q and a set of N candidate answers $\{a_i\}$, the task is to choose one answer from the set. From a knowledge-aware perspective, we additionally assume that the question q and choices $\{a_i\}$ can be grounded as a **schema graph** (denoted as g) extracted from a large external knowledge graph G, which is helpful for measuring the plausibility of answer candidates. The knowledge graph $G = (V, E)$ can be defined as a fixed set of **concepts** V, and **typed edges** E describing semantic relations between concepts. Therefore, our goal is to effectively ground and model schema graphs to improve the reasoning process.

2.2 Reasoning Workflow

As shown in Fig. 2, our framework accepts a pair of question and answer (QA-pair) denoted as q and a. It first recognizes the mentioned concepts within them respectively from the concept set V of the knowledge graph. We then algorithmically construct the schema graph g by finding paths between pairs of mentioned concepts (§3).

The grounded schema graph is further encoded with our proposed knowledge-aware graph network module (§4). We first use a model-agnostic language encoder, which can either be trainable or a fixed feature extractor, to represent the QA-pair

as a statement vector. The statement vector serves as an additional input to a GCN-LSTM-HPA architecture for path-based attentive graph modeling to obtain a graph vector. The graph vector is finally fed into a simple multi-layer perceptron to score this QA-pair into a scalar ranging from 0 to 1, representing the plausibility of the inference. The answer candidate with the maximum plausibility score to the same question becomes the final choice of our framework.

3 Schema Graph Grounding

The grounding stage is three-fold: recognizing concepts mentioned in text (§3.1), constructing schema graphs by retrieving paths in the knowledge graph (§3.2), and pruning noisy paths (§3.3).

3.1 Concept Recognition

We match tokens in questions and answers to sets of mentioned concepts ($\mathcal{C}_q$ and $\mathcal{C}_a$ respectively) from the knowledge graph G (for this paper we chose to use ConceptNet due to its generality).

A naive approach to mentioned concept recognition is to exactly match n-grams in sentences with the surface tokens of concepts in V. For example, in the question "*Sitting too close to watch tv can cause what sort of pain?*", the exact matching result $\mathcal{C}_q$ would be {sitting, close, watch_tv, watch, tv, sort, pain, etc.}. We are aware of the fact that such retrieved mentioned concepts are not always perfect (e.g. "sort" is not a semantically related concept, "close" is a polysemous concept). How to efficiently retrieve contextually-related knowledge from noisy knowledge resources is still an open research question by itself (Weissenborn et al., 2017; Khashabi et al., 2017), and thus most prior works choose to stop here (Zhong et al., 2018; Wang et al., 2019b). We enhance this straightforward approach with some rules, such as soft matching with lemmatization and filtering of stop words, and further deal with noise by pruning paths (§3.3) and reducing their importance with attention mechanisms (§4.3).

3.2 Schema Graph Construction

ConceptNet. Before diving into the construction of schema graphs, we would like to briefly introduce our target knowledge graph ConceptNet. ConceptNet can be seen as a large set of triples of the form (h, r, t), like (ice, HasProperty, cold), where h and t represent head and tail concepts in the concept set V and r is a certain relation type from the pre-defined set R. We delete and merge the original 42 relation types into 17 types, in order to increase the density of the knowledge graph[3] for grounding and modeling.
