Abstract

Conventional word embeddings represent words with fixed vectors, which are usually trained based on co-occurrence patterns among words. In doing so, however, the power of such representations is limited, where the same word might be functionalized separately under different syntactic relations. To address this limitation, one solution is to incorporate relational dependencies of different words into their embeddings. Therefore, in this paper, we propose a multiplex word embedding model, which can be easily extended according to various relations among words. As a result, each word has a center embedding to represent its overall semantics, and several relational embeddings to represent its relational dependencies. Compared to existing models, our model can effectively distinguish words with respect to different relations without introducing unnecessary sparseness. Moreover, to accommodate various relations, we use a small dimension for relational embeddings and our model is able to keep their effectiveness. Experiments on selectional preference acquisition and word similarity demonstrate the effectiveness of the proposed model, and a further study of scalability also proves that our embeddings only need 1/20 of the original embedding size to achieve better performance.

1 Introduction

Representing words as distributed representations is an important way for machines to process lexical semantics, which attracts much attention in natural language processing (NLP) in the past few years (Mikolov et al., 2013; Pennington et al., 2014; Song et al., 2017, 2018b; Song and Shi, 2018) with respect to its usefulness in many downstream tasks, e.g., parsing (Chen and Manning, 2014), machine translation (Zou et al., 2013), coreference resolution (Lee et al., 2018), etc. Conventional word embeddings, e.g., word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), leverage the co-occurrence information among words to train a unified embedding for each word. Such models are popular and the resulting embeddings are widely used owing to their effectiveness and simplicity. However, these embeddings are not helpful for scenarios requiring words functionalizing separately under different situations, where selectional preference (SP) (Wilks, 1975) is a typical scenario.

In general, SP refers to that, given a word (predicate) and a dependency relation, human beings have certain preferences for the words (arguments) connecting to it. Such preferences are usually carried in dependency syntactic relations, for example, the verb 'sing' has plausible object words 'song' or 'rhythm' rather than other nouns such as 'house' or 'potato'. With such characteristic, SP is proven to be important in natural language understanding for many cases and widely applied over a variety of NLP tasks, e.g., sense disambiguation (Resnik, 1997), semantic role classification (Zapirain et al., 2013), and coreference resolution (Hobbs, 1978; Zhang et al., 2019b,c), etc.

Conventional SP acquisition methods are either based on counting (Resnik, 1997) or complex neural network (de Cruys, 2014), and the SP knowledge acquired in either way can not be directly leveraged into downstream tasks. On the other hand, the information captured by word embeddings can be seamlessly used in downstream tasks, which makes embedding a potential solution for the aforementioned problem. However, conventional word embeddings using one unified embedding for each word are not able to distinguish different relations types (such as various syntactic relations, which is crucial for SP) among words. For example, such embeddings

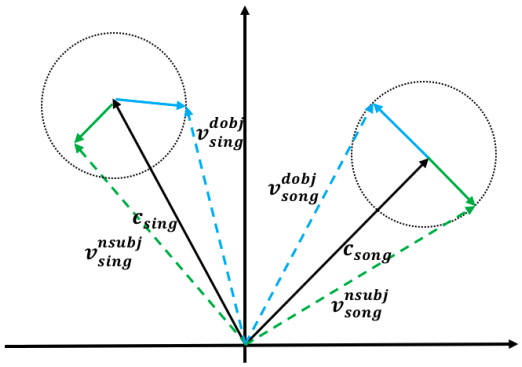

Figure 1: Illustration of the multiplex embeddings for 'sing' and 'song'. Black arrows present center embeddings for words' overall semantics; blue and green arrows refer to words' relational embeddings for relation-dependent semantics. All relational embeddings for each word are designed to near its center embedding. *nsubj* and *dobj* relations are used as examples.

treat 'food' and 'eat' as highly relevant words but never distinguish the function of 'food' to be a subject or an object to 'eat'. To address this problem, the dependency-based embedding model (Levy and Goldberg, 2014) is proposed to treat a word through separate ones, e.g., 'food@dobj' and 'food@nsubj', under different syntactic relations, with the skip-gram (Mikolov et al., 2013) model being used to train the final embeddings. However, this method is limited in two aspects. First, sparseness is introduced because each word is treated as two irrelevant ones (e.g., 'food@dobj' and 'food@nsubj'), so that the overall quality of learned embeddings is affected. Second, the resulting embedding size is too large[1], which is not appropriate either for storage or usage.

Therefore, in this paper, we propose a multiplex word embedding (MWE) model, which can be easily extended to various relations between two words. A multiplex network embedding model was originally proposed for modeling multiple relations among people in a social network (Zhang et al., 2018). Interestingly, we found it also useful in capturing various relations among different words. One example is shown in Figure 1. 'sing' and 'song' are highly related to each other with the 'predicate-objective' rather than the 'predicate-subject' relation. In our model, each word has a group of embeddings, including a center embedding representing its general semantics, and several embeddings representing their relation-dependent semantics. To ensure that the embeddings of the same word (under different relations) are similar to each other, we limit the Euclidean norm of relation-dependent embeddings within a small range, as shown in Figure 1. Moreover, considering that there could be many relations among words, if using a conventional dimension setting for embeddings to encode relations, the overall embedding size would be too big to be used in downstream tasks. To deal with it, we propose to use a small dimension for relation-dependent embeddings and use a transformation matrix for each relation to project them into the same space of the center embeddings. Thus the two types of embeddings can be jointly trained and the quality of the relation-dependent ones are guaranteed.

Experiments are conducted on SP acquisition over different dependency relations to evaluate whether the learned embeddings effectively capture words' semantics over these relations. In addition, the word similarity measurement is used to assess how well words' general semantics are learned in our model. Both evaluations confirm the superiority of our model, where the SP information is effectively preserved and the words' overall semantics are enhanced. Particularly, further analysis also indicates that our MWE embeddings are more powerful than all existing embedding methods in SP acquisition with around 1/20 in their size comparing to previous embeddings (Levy and Goldberg, 2014). All code and resulting embeddings are available at: https://github.com/HKUST-KnowComp/MWE.

2 Multiplex Word Embeddings

2.1 Model Overview

As introduced in Section 1, encoding selectional preference information into embeddings can be conducted by modeling word association patterns under different dependency relations. Similar to (Levy and Goldberg, 2014), the proposed MWE model also distinguishes different relations among words and learns separate embeddings for them on each dependency edge.

Formally, let $\mathcal{W}$ be the vocabulary set containing n words $w_1, w_2, ..., w_n$ and $\mathcal{R}$ the relations set containing m relations $r_1, r_2, ..., r_m$, the proposed model is expected to produce $m + 1$ embeddings for each word, where there are m relational embeddings representing relations and a center em-

[1] Assuming one has 200,000 words in the vocabulary and 20 dependency relations, and follow conventional approaches (Mikolov et al., 2013; Pennington et al., 2014) to set the embedding dimension to 300, the resulting embedding size will be about 10 Gigabytes.

bedding $\mathbf{c}$ for the general semantics. Particularly, each relational embedding has an overall and a local version, denoted as $\mathbf{v}$ and $\mathbf{u}$, where $\mathbf{u}$ records the difference between $\mathbf{v}$ and $\mathbf{c}$. For both the relational embeddings ($\mathbf{v}$ and $\mathbf{u}$) and the center embedding, we use a similar way as that in word2vec (Mikolov et al., 2013) that each one has two variants to represent the semantics of a word w being the head or tail in different relations. We denote the head and tail embeddings as $\mathbf{u}^r_{h,w} \in R^s$ and $\mathbf{u}^r_{t,w} \in R^s$ for the local embeddings of word w under relation type r and $\mathbf{c}_{w,h} \in R^d$ and $\mathbf{c}_{w,t} \in R^d$ for the center embedding, respectively, where s is the dimension for $\mathbf{u}$ and d the dimension for $\mathbf{c}$.

Although learning on similar information as that in (Levy and Goldberg, 2014), to reduce the sparseness of introducing m relational embeddings for each word, we do not treat each word as multiple separate prototypes. Instead, we use its center embedding to transfer information among different relations and the sum of the center embedding and a local embedding to represent the final embedding for the corresponding relation[2]. Moreover, considering there are various relations among words, we use a lower dimension s for storage compression, with $s < d$. Thus, a transformation matrix $\mathbf{X}$ is introduced to transform $\mathbf{u}$ into the same vector space of $\mathbf{c}$. As a result, the final embeddings $\mathbf{v}$ for head and tail of w under relation r are formulated as:

$$\begin{aligned} \mathbf{v}^r_{h,w} &= \mathbf{c}_{h,w} + \mathbf{X}^{rT}_h \mathbf{u}^r_{h,w}, \\ \mathbf{v}^r_{t,w} &= \mathbf{c}_{t,w} + \mathbf{X}^{rT}_t \mathbf{u}^r_{t,w}. \end{aligned} \tag{1}$$

2.2 Learning the MWE model

To train $\mathbf{v}^r_{h,w}$ and $\mathbf{v}^r_{t,w}$ for each w under r, we adopt the negative sampling strategy to conduct the learning process. Specifically, for each r, we use a relation tuple set $\mathcal{T}_r$, with each tuple $t = (w_h, r, w_t) \in \mathcal{T}_r$, where w_h is the head word and w_t the tail word. For each t, we randomly generate two negative tuples by replacing w_h and w_t with the randomly selected fake head w'_h and tail w'_t respectively. Then the learning process is expected to distinguish the positive tuple against the negative ones. Therefore, formally, we maximize

$$\mathcal{J} = \frac{1}{|\mathcal{T}_r|} \sum_{t \in \mathcal{T}_r} log \frac{e^{f(w_h,r,w_t)}}{e^{f(w_h,r,w_t)} + e^{f(w_h,r,w'_t)} + e^{f(w'_h,r,w_t)}}, \tag{2}$$

over all tuples in $\mathcal{T}_r$ for each r, with $f(\cdot)$ evaluating w_h and w_t being positive samples under r through

$$f(w_h, r, w_t) = {\mathbf{v}^r_{h,w_h}}^\top \cdot \mathbf{v}^r_{t,w_t}. \tag{3}$$

For each (w_h, w_t), we use cross entropy as the loss function

$$\begin{aligned} E = &- \log \sigma({\mathbf{v}^r_{h,w_h}}^\top \cdot \mathbf{v}^r_{t,w_t}) - \log \sigma(-{\mathbf{v}^r_{h,w_h}}^\top \cdot \mathbf{v}^r_{t,w'_t}) \\ &- \log \sigma(-{\mathbf{v}^r_{h,w'_h}}^\top \cdot \mathbf{v}^r_{t,w_t}), \end{aligned} \tag{4}$$

to measure the learning effect for Eq. (2), with σ denoting the sigmoid function.

Combined with Eq. (1), the training process is thus to update c, u^r, and X^r with the gradients passed from the loss function using stochastic gradient descent (SGD).

In detail, take w_h as an example, its center embedding $\mathbf{c}_{h,w_h}$ is updated by

$$\begin{aligned} \mathbf{c}_{h,w_h} &= \mathbf{c}_{h,w_h} - \lambda \cdot \eta \cdot \frac{\partial E}{\partial \mathbf{v}^r_{h,w_h}} \\ &= \mathbf{c}_{h,w_h} - \lambda \cdot \eta \cdot e(w_h, w_t) \cdot \mathbf{v}^r_{t,w_t}, \end{aligned} \tag{5}$$

where $e(w_h, w_t) = \sigma({\mathbf{e}^r_{h,w_h}}^\top \cdot \mathbf{e}^r_{t,w_t}) - t_k$, with $t_k = 1$ if (w_h, w_t) is positive sample and $t_k = 0$ for negative ones. η is the discounting learning rate. λ is an alternating weight to control the contribution of the gradient, ranging from 0 to 1.

Moreover, X^r and $\mathbf{u}^r$ are updated as follows:

$$\begin{aligned} \mathbf{u}^r_{h,w_h} &= \mathbf{u}^r_{h,w_h} - (1-\lambda) \cdot \eta \cdot \frac{\partial E}{\partial \mathbf{v}^r_{h,w_h}} \cdot \frac{\partial \mathbf{X}^r_h \mathbf{u}^r_{h,w_h}}{\partial \mathbf{u}^r_{h,w_h}} \\ &= \mathbf{u}^r_{h,w_h} - (1-\lambda) \cdot \eta \cdot e(w_h, w_t) \cdot \mathbf{X}^r_h \cdot \mathbf{v}^r_{t,w_t}, \end{aligned} \tag{6}$$

$$\begin{aligned} \mathbf{X}^r_h &= \mathbf{X}^r_h - (1-\lambda) \cdot \eta \cdot \frac{\partial E}{\partial \mathbf{v}^r_{h,w_h}} \cdot \frac{\partial \mathbf{X}^r_h \mathbf{u}^r_{h,w_h}}{\partial \mathbf{X}^r_h} \\ &= \mathbf{X}^r_h - (1-\lambda) \cdot \eta \cdot e(w_h, w_t) \cdot \mathbf{u}^r_{h,w_h} \cdot \mathbf{v}^r_{t,w_t}, \end{aligned} \tag{7}$$

Meanwhile, $\mathbf{c}_{t,w_t}$, $\mathbf{u}^r_{t,w_t}$, and $\mathbf{X}^r_t$ are updated in the same way of $\mathbf{c}_{h,w_h}$, $\mathbf{u}^r_{h,w_h}$, and $\mathbf{X}^r_h$ following Eqs. (5), (6), and (7).

The above learning process is conducted on all m relations at the same time. During the training, the Euclidean norm of $\mathbf{X}^T\mathbf{u}$ for all embeddings is constrained to have a maximum semantic

[2] Conceptually shown in Figure 1, to ensure the resulting final embeddings not too far away from the center embeddings, we add restriction to the Euclidean norm of the local relational embeddings.

Algorithm 1 Multiplex Word Embedding

Input: Relation specific tuple sets $\mathcal{T}_1, \ldots, \mathcal{T}_m$, d, s, a, and η.
Output: $\mathbf{c}_w$, $\mathbf{u}_w^r$, and $\mathbf{X}^r$.
Initialize $\mathbf{c}_w$, $\mathbf{u}_w^i$ and $\mathbf{X}^i$ randomly.
for *Each Iteration k* **do**
  Update λ.
  for *Each tuple* $t_p = (w_h, r, w_t) \in \mathcal{T}_r$ **do**
    Randomly generate the two negative examples $t_{n1} = (w'_h, r, w_t)$ and $t_{n2} = (w_h, r, w'_t)$.
    $\mathcal{T}_{tmp} = [t_p, t_{n1}, t_{n2}]$
    for $t \in \mathcal{T}_{tmp}$ **do**
      $e(w_h, w_t) = \sigma({\mathbf{v}'_{h,w_h}}^T \cdot \mathbf{v}^i_{t,n_t}) - t_k$
      Update $\mathbf{c}_{h,w_h}$, $\mathbf{u}^r_{h,w_h}$, $\mathbf{X}^r_h$, $\mathbf{c}_{t,w_t}$, $\mathbf{u}^r_{t,w_t}$, and $\mathbf{X}^r_t$ based on Eqs. (5), 6), and (7).
      if $\|{\mathbf{X}^r_h}^T \mathbf{u}^r_{h,w_h}\| > a$ **then**
        Update $\mathbf{X}^r_h$ and $\mathbf{u}^r_{h,w_h}$.
      end
      if $\|{\mathbf{X}^r_t}^T \mathbf{u}^r_{t,w_t}\| > a$ **then**
        Update $\mathbf{X}^r_t$ and $\mathbf{u}^r_{t,w_t}$.
      end
    end
  end
end

drifting range a, whose value controls the distance between the local relational embeddings and the center embedding. Specifically, if $\|\mathbf{X}^T\mathbf{u}\|$ equals to a', which is greater than a, we scale down $\mathbf{X}^T$ and $\mathbf{u}$ with $\sqrt{a' \cdot \frac{1}{ka}}$, where k is a scaling parameter set to 0.8 throughout this work.

The learning processing is summarized in Algorithm 1. For complexity analysis, it is obvious drawn that m relation types and n words result in $O(mn)$ and $O((d + s * m) * n)$ for time and space complexities, respectively.

2.3 The Alternating Optimization Strategy

To balance the learning process between the overall semantics and the relation-specific information, we adopt an alternating optimization strategy[3] (Bezdek and Hathaway, 2003) to adjust λ based on different stage of the training instead of using a fixed weight for λ. Specifically, considering $\mathbf{c}$ is more reliable and possesses more information while $\mathbf{u}$ is learned with shared $\mathbf{c}$, we alternatively update $\mathbf{c}$ and $\mathbf{u}$ upon the convergence of $\mathbf{c}$. As a result, we set λ to 1 in the first half of the training process and 0 afterwards.

[3] Alternating optimization was originally proposed to train different parameters in a sequential manner and applied in various areas.

3 Experiments

Experiments are conducted to evaluate how our embeddings are performed on SP acquisition and word similarity measurement.

3.1 Implementation Details

We use the English Wikipedia[4] as the training corpus. The Stanford parser[5] is used to obtain dependency relations among words. For the fair comparison, we follow existing work and set $d = 300$, $s = 10$, and $a = 1$. Following (Keller and Lapata, 2003) and (de Cruys, 2014), we select three dependency relations (*nsubj*, *dobj*, and *amod*) as follows:

- *nsubj*: The preference of subject for a given verb. For example, it is plausible to say 'dog barks' rather than 'stone barks'. The verb is viewed as the predicate (head) while the subject as the argument (tail).
- *dobj*: The preference of object for a given verb. For example, it is plausible for 'eat food' rather than 'eat house'. The verb is viewed as the predicate (head) while the object as the argument (tail).
- *amod*: The preference of modifier for a given noun. For example, it is plausible to say 'fresh air' rather than 'solid air'. The noun is viewed as the predicate (head) while the adjective as the argument (tail).

3.2 Baselines

We first compare the proposed multiplex embedding with the following embedding models. As it is trivial to apply these embedding models in downstream tasks, we label these models as downstream friendly.

- **word2vec**, the embedding model proposed by Mikolov et al. (2013). We use the skip-gram model for this baseline.
- **GloVe** (Pennington et al., 2014), learning word embeddings by matrix decomposition on word co-occurrences.

Table 1: Results on different SP acquisition evaluation sets. As Keller is created based on the PP distribution and has relatively small size while SP-10K is created based on random sampling and has a much larger size, we treat the performance on SP-10K as the main evaluation metric. Spearman's correlation between predicated plausibility and annotations are reported. The best performing models are denoted with bold font. † indicates statistical significant ($p < 0.005$) overall baseline methods.

- **D-embeddings**, the model proposed by Levy and Goldberg (2014) uses a skip-gram framework to encode dependencies into embeddings with multi-prototypes of words.

To investigate whether the SP knowledge can be captured by the pretrained contextualized word embedding models, we also treat following pretrained models as baselines.

- **ELMo** (Peters et al., 2018), a pretrained language model with contextual awareness. We use its static representations of words as the word embedding.
- **BERT** (Devlin et al., 2019), a pretrained bi-directional contextualized word embedding model with state-of-the-art performance on many NLP tasks.

Besides those embedding methods, we also compare with following conventional SP acquisition methods to demonstrate the effectiveness of the proposed multiplex embedding model, as it is still unclear how to leverage these methods in downstream tasks, we label these methods as downstream unfriendly.

- **Posterior Probability (PP)** (Resnik, 1997), a counting based method for the selectional preference acquisition task.
- **Distributional Similarity (DS)** (Erk et al., 2010), a method that uses the similarity of the embedding of the target argument and average embedding of observed golden arguments in the corpus to predict the preference strength.
- **Neural Network (NN)** (de Cruys, 2014), an NN-based method for the SP acquisition task. This model achieves the state-of-the-art performance on the pseudo-disambiguation task.

SP Evaluation Set	#W	#P
Keller (Keller and Lapata, 2003)	571	360
SP-10K (Zhang et al., 2019a)	2,500	6,000

Table 2: Statistics of Human-labeled SP Evaluation Sets. #W and #P indicate the numbers of words and pairs, respectively. As different datasets have different SP relations, we only report statistics about 'nsubj', 'dobj', and 'amod' (if available).

For word2Vec and GloVe, we use their released code. For D-embedding, we follow their original paper using the Gensim package[6]. The dimensions of the aforementioned embeddings are set to 300 according to their original settings. For ELMo and BERT, we use their pre-trained models. As BERT was not originally designed for word level semantics tasks, for the selectional preference acquisition task, we compare with two variations of the original BERT model: (1) BERT (static), which extracts static embedding from the BERT model in a similar way as that from the ELMo model; (2) BERT (dynamic), which takes a pair of

Table 3: Spearman's correlation of different embeddings for the WS measurement. 'nsubj', 'dobj', 'amod' represents the embeddings of the corresponding relation and 'center' indicates the center embeddings. h, t, h+t, and [h,t] refer to the head, tail, sum of two embeddings, and the concatenation of them, respectively. The best scores are marked in bold fonts.

words as input and produces a plausibility score for that pairs of words. The main difference between the static and dynamic version of BERT is that in the dynamic version, the contextual information can be fully utilized, which is more similar to the training objective of BERT.

3.3 Selectional Preference Acquisition

The first task in our experiment is SP acquisition. Currently, there are two methods that we can use to evaluate the quality of extracted SP knowledge: Pseudo-disambiguation (Ritter et al., 2010) and human labeled datasets (McRae et al., 1998; Keller and Lapata, 2003). However, as shown in (Zhang et al., 2019a), pseudo-disambiguation selects positive SP tuples from the corpus and generate negative SP tuples by randomly replacing the head/tail. As a result, pseudo-disambiguation only evaluates how good the model fits the corpus rather than evaluating the SP acquisition models based on ground truth. Thus, in this section, we evaluate different SP acquisition methods with ground truth (human labeled datasets). Two representative datasets, Keller (Keller and Lapata, 2003) and SP-10K (Zhang et al., 2019a), are selected as the benchmark datasets.

In each dataset, for each SP relation, various word pairs are provided. For each of the word pairs, the datasets also provide the annotated plausibility score of how likely a preference exists between that word pair under the corresponding SP relation. Thus the job for all the models is to predict the plausibility score for all word pairs under different SP relation settings. After that, we follow the conventional setting that uses the Spearman's correlation to assess the correspondence between the predicted plausibility scores and human annotations on all word pairs for all SP relations. The statistics of these datasets are shown in Table 2.

Model	WS	Dimension	Training Time
ELMo	0.434	512	≈40
BERT	0.486	768	≈300
MWE	0.476	300	4.17

Table 4: Comparison of MWE against language models on the WS task. Overall performance, embedding dimension, and training time (days) on a single GPU are reported.

For embedding based methods (word2vec, GloVe, D-embedding[7], and MWE[8]), we follow previous work (Mikolov et al., 2013; Levy and Goldberg, 2014) and use the cosine similarity between embeddings of head and tail words to predict their relations. For conventional SP acquisition methods (PP, DS, and NN), we follow their original paper to compute the plausibility scores.

The experimental results are shown in Table 1. As Keller is created based on the PP distribution and have relatively small size while SP-10K is created based on random sampling and has a much larger size, we treat the performance on SP-10K as the major evaluation. Our embeddings significantly outperform other baselines, especially embedding based baselines. The only exception is PP on the Keller dataset due to its biased distribution. In addition, there are other interesting observations. First, compared with 'dobj' and 'nsubj', 'amod' is simpler for word2vec and GloVe. The reason behind is that conventional embeddings only capture the co-occurrence information, which is enough to predict the selectional preference of

[7]For D-embedding, since it provides embeddings for different relations (e.g., 'food@nsubj', 'food@dobj), we follow their work and directly use embeddings over certain relations to predict the score for the tested pairs. For example, given the test tuple ('eat', *dobj*, 'food'), we compute the cosine similarity of 'eat' and 'food@dobj' rather than 'food@subj'.

[8]For the proposed model MWE, we use the cosine similarity between v_{h,w_h} and v_{t,w_t} as the predicted plausibility.

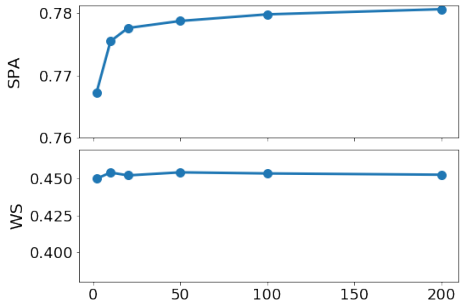

Figure 2: Effect of the different s on SP acquisition (SP-10K) and WS tasks.

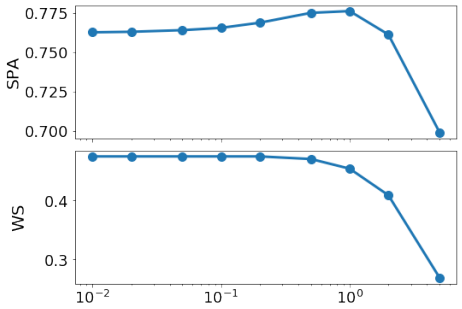

Figure 3: Effect of different a on SP acquisition (SP-10K) and WS tasks.

'amod' rather than 'nsubj' or 'dobj'[9]. Second, even though large-scale contextualized word embedding models like ELMo and BERT have been proved useful in many other tasks, they are still limited in learning specific and detailed semantics and thus perform inferior to our model in the SP acquisition task. For Example, ELMo and BERT can know that there is a strong semantic connection between 'eat' and 'food', but they do not know whether 'food' is a plausible subject or object of 'eat'. Third, surprisingly, although NN achieves the state-of-the-art performance on the pseudo-disambiguation task, its performance is not satisfying against human annotation, especially on Keller, which is probably because the NN model overfits the training data, whose distribution is different from human SP knowledge.

3.4 Word Similarity Measurement

In addition to SP acquisition, we also evaluate our embeddings on word similarity (WS) measurement to test whether the learned embedding can effectively capture the overall semantics. We use SimLex-999 (Hill et al., 2015) as the evaluation dataset for this task because it contains different word types, i.e., 666 noun pairs, 222 verb pairs, and 111 adjective pairs. We follow the conventional setting that uses the Spearman's correlation to assess the correspondence between the similarity scores and human annotations on all word pairs. Evaluations are conducted on the final embeddings $\mathbf{v}$ for each relation and the center ones.

Results are reported in Table 3 with several observations. First, our model achieves the best overall performance and significantly better on nouns, which can be explained by that nouns appear in all three relations while most of the verbs and adjectives only appear in one or two relations. This result is promising since it is analyzed by Solovyev et al. (2017) that two-thirds of the frequent words are nouns; thus there are potential benefits if our embeddings are used in downstream NLP tasks. Second, the center embeddings achieve the best performance against all the other relation-dependent embeddings, which demonstrates the effectiveness of our model in learning relation-dependent information over words and also enhancing their overall semantics.

We also compare MWE with pre-trained contextualized word embedding models in Table 4 for this task, with overall performance, embedding dimensions, and training times reported. It is observed that that MWE outperforms ELMo and achieves comparable results with BERT with smaller embedding dimension and much less training complexities.

4 Analysis

With the experiments on SP acquisition and word similarity measurement, we conduct further analysis for different settings for hyper-parameters and learning strategies, as well as the scalability of our model.

4.1 Effect of the Local Embedding Dimension

We investigating the performance of MWE on SPA (SP acquisition) and WS tasks with different s. As shown in Figure 2, the performance of our model is in an increasing trend when we increase the value of s. When the dimension reaches 10, the performance almost reaches the top, which confirms that the local relational embeddings can be effective in small dimensions (about 1/30 of the center dimension) when using center embeddings as the constraint.

[9]The only possible SP relation between nouns and adjectives is 'amod', while multiple SP relations could exist between nouns and verbs, and co_occurrence information cannot effectively distinguish them.

Training Strategy	Averaged SPA	Overall WS
$\lambda = 1$	0.762	0.476
$\lambda = 0$	0.073	0.018
$\lambda = 0.5$	0.493	0.323
Alternating optimization	0.775	0.476

Table 5: Comparisons of different training strategies.

4.2 Effect of the Semantic Drifting Range

Similar to s, we also investigate the model performance with the influence of different constraint a. It is observed in Figure 3 that, the constraint gets looser with the increase of a. For SP acquisition, in a small range, the model performance gradually improves along with the increasing value of a because these embeddings are more flexible to capture intense relation-dependent information. However, once the range passes a threshold (1 in our experiment), the embeddings get farther away from their general semantics and start to overfit, which is also observed in the WS experiment, and thus the performance drops monotonically.

4.3 Effect of Alternating Optimization

An analysis is also conducted to demonstrate the effectiveness of the alternating optimization strategy. As shown in Table 5, we compare our model with several different strategies. The first one is to put all weights to the center embedding (fix λ to 1), which never updates the local relational embeddings. As a result, it can achieve similar performance on word similarity measurement but is inferior in SP acquisition because no relation-dependent information is preserved. The second strategy is to put all weights to the local relational embeddings (fix λ to 0). In this case, it performs very poor owing to the loss of general semantics. Last but not least, the alternating optimization also outperforms the setting with a fixed $\lambda = 0.5$, which can be explained by alternating optimization can first get a good overall semantic representation and then acquire the SP knowledge on top of that. To summarize, the alternating optimization provides an effective solution to training our model with a smart process in adjusting the contribution of different embeddings as well as stabilizing their optimization.

4.4 Scalability

Scalability of embeddings is an important factor in real applications. Practically, GPU or similar computation support is required to accommodate embeddings to applying neural models. Normally, the current most affordable GPUs typically have a memory size limitation around 10 GB. Thus, to ensure the learned embeddings can be used in downstream tasks, their size becomes an important concern when evaluating different embedding models, especially when there exist many different relations between words in our model.

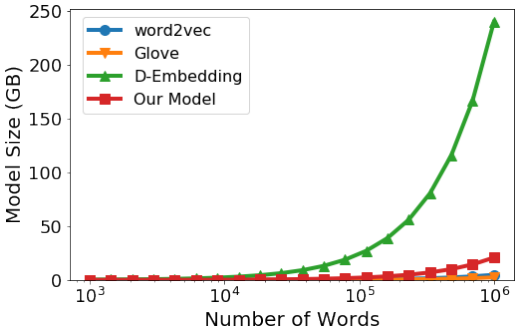

Figure 4: Scalability on embedding size against number of words.

Assuming that there are 20 relations among words, the size of all embedding models with the increasing word numbers in Figure 4. word2Vec and GloVe have the smallest size because they only train one embedding for each word while sacrificing the relation-dependent information among them. As a comparison, D-embeddings are trained on multiple prototypes for each word to record relation information, thus their size dramatically explodes with the increasing of the vocabulary. Consequently, it is easily computed for D-embeddings that 200,000 words will result in a 10GB model, which is unfeasible to be used in downstream tasks. Effectively with the small dimension for our local relational embeddings, relation information can be preserved in a small-sized model, which shows a compatible space requirement with the conventional embeddings.

5 Related Work

Learning word embeddings has become an important research topic in NLP (Bengio et al., 2003; Turney and Pantel, 2010; Collobert et al., 2011; Song and Shi, 2018), with the capability of embeddings demonstrated in different languages (Song et al., 2018a) and tasks such as parsing (Chen and Manning, 2014), machine translation (Zou et al., 2013), coreference resolution (Lee et al., 2018), etc. Conventional word embeddings (Mikolov et al., 2013; Pennington et al., 2014) often leverage

word co-occurrence patterns, resulting in a major limitation that they coalesce different relationships between words into a single vector space. To address this limitation, dependency-based embedding model (Levy and Goldberg, 2014) was proposed to represent each word with several separate embeddings, and then suffers from its sparseness and the huge size of the resulting embeddings. Alternatively, our MWE model uses a set of (constrained and small) embeddings for each word to encode its general and relation-dependent semantics to resolve the sparseness and the size problem.

Another line of work related to this paper is the research on SP, which is considered important in language understanding and has been proved helpful in various downstream tasks (Tang et al., 2016; Resnik, 1997; Hobbs, 1978; Inoue et al., 2016; Zapirain et al., 2013). Several studies attempted to acquire SP automatically from raw corpora (Resnik, 1997; Rooth et al., 1999; Erk et al., 2010; Santus et al., 2017). However, they are designed specifically for SP acquisition and are limited in leveraging SP knowledge for downstream tasks. Compared to them, the learned embeddings from our model are useful resources that incorporate SP knowledge and can be seamlessly leveraged in other NLP models.

6 Conclusion

In this paper, we present a multiplex word embedding model encoding selectional preference information from word dependency relations. Different from conventional embeddings, for each word, we proposed to use a set of embeddings to represent its general (center embedding) and relation-dependent (local relational embedding) semantics, where their combination present the final embedding for each word under particular relations. Experiments on SP acquisition and word similarity measurement illustrated that our model better encodes SP knowledge than different baselines without harming its capability in representing general semantics. Analysis is also conducted with respect to different settings and optimization strategies, as well as the effect of model size, which further illustrates the validity and effectiveness of the proposed model and its learning process.

MulCode: A Multiplicative Multi-way Model for Compressing Neural Language Model

Yukun Ma[1]*, **Pei-Hung(Patrick) Chen**[2*], **Cho-Jui Hsieh**[2]
[1]AIR Labs, Continental Automotive Group, Singapore [2]Department of Computer Science, UCLA

Abstract

It is challenging to deploy deep neural nets on memory-constrained devices due to the explosion of numbers of parameters. Especially, the input embedding layer and Softmax layer usually dominate the memory usage in an RNN-based language model. For example, input embedding and Softmax matrices in IWSLT-2014 German-to-English data set account for more than 80% of the total model parameters. To compress these embedding layers, we propose MulCode, a novel multi-way multiplicative neural compressor. MulCode learns an adaptively created matrix and its multiplicative compositions. Together with a prior weighted loss, MulCode is more effective than the state-of-the-art compression methods. On the IWSLT-2014 machine translation data set, MulCode achieved 17 times compression rate for the embedding and Softmax matrices, and when combined with quantization technique, our method can achieve 41.38 times compression rate with very little loss in performance.

1 Introduction

Deep neural language models with a large number of parameters have achieved great successes in facilitating a wide range of Natural Language Processing (NLP) applications. However, the overwhelming size of parameters used by these models stands out as the main obstacle hindering their deployment on memory-constrained devices. Given the over-parameterization of deep neural nets, the effective compression of them has been receiving increasing attention from the research community. The neural language models typically consist of three major components: the recurrent layers (e.g., a LSTM cell), an embedding layer for representing input tokens, and a Softmax layer for generating output tokens. The dimension of recurrent layers is typically small and independent of the size of input/output vocabulary. In contrast, the embedding layer and Softmax layer use a dense layer to map the vocabulary to a lower dimensional space, which grows linearly with the vocabulary size and contributes mostly to memory consumption. For example, the One Billion Word language modeling task (Chelba et al., 2013) has a vocabulary size around 800k, and more than 90% of the memory usage is used to store the input and Softmax matrices. Compressing the word embedding, therefore, is the key to reducing the memory usage of deep neural language models.

There exist several studies for compressing neural language models. In particular, quantization (Lin et al., 2016; Hubara et al., 2016) and group-wise low rank approximation (Chen et al., 2018a) achieve the state-of-the-art performance on tasks like language modeling and machine translation. However, these methods are rather computationally inspired than being motivated by intuitions of the semantic composition and thus suffer from poor interpretability. In contrast, deep compositional models (Shu and Nakayama, 2017; Chen et al., 2018b) have been explored to represent the original word vector with a set of discrete pseudo words and thus decompose the word vector to the addition of the corresponding pseudo word vectors learned in an end-to-end manner. These methods are seen as embracing the long-existing yet still, the most popular assumption (Foltz et al., 1998) on compositionality of semantics which states that the meaning of an element (e.g., a word, phrase, or sentence) can be obtained by taking the addition of its constituent parts.

Despite it's more semantically meaningful, current deep compositional models have several limitations. First, additive composition might turn to be counter-intuitive for that the addition does not bring new meaning beyond the individual element to the constructed element (Pinker, 2003; Mitchell and Lapata, 2009, 2008). Besides, exist-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5257–5266, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing deep code compressor is found hard to compress the output Softmax layer for that the conflicting codes (i.e. different words having same encoding) might make the language model less discriminative. Last, it is well-known that the distribution of word frequencies can be approximated by a power law. Defining importance of words in terms of frequencies in the corpus is also verified in (Chen et al., 2018a). However, current deep compositional frameworks encode every word equally without considering the frequency information.

In this paper, we propose MulCode, a novel and effective deep neural compressor to address the above issues. MulCode uses a multiplicative composition instead of addition. The multiplicative factors introduce a larger capacity empowering the encoding of more complicated semantic. From the perspective of semantic composition, this allows introducing new information to the base codebook vectors (sub-elements to compose a word vector), taking frequency information of each token into consideration. Technically, MulCode embraces the research line of dense matrix decomposition that has been investigated in many applications (Memisevic, 2011; Novikov et al., 2015). It trains the composition with weighted loss proportional to the frequency of each word. MulCode also adopts an adaptive way of constructing codebooks based on the frequency of each word.

MulCode outperforms state-of-the-arts methods on compressing language models and neural machine translation models. For example, on One-Billion-Word data set, MulCode achieves 18.2 times compression rate on embedding and Softmax matrices without losing much of performance. On IWSLT-14 DE-EN machine translation task, MulCode achieves 17 times compression with BLEU score difference smaller than one percent. Results can be further improved to 41.38 times compression rate when combined with quantization technique.

2.1 Model Compression for Convolutional Neural Network

Low-rank Approximation The original word embedding vectors can be viewed as a large matrix with the rows being the words and columns being the vector values. One natural way to approximate it is to obtain the low-rank approximation of the matrix using SVD. Based on this idea, (Sainath et al., 2013) compressed the fully connected layers in neural nets. For convolution layers, (Jaderberg et al., 2014; Denton et al., 2014) applied higher-order tensor decomposition to compress CNN. Similarly, (Howard et al., 2017) developed another structural approximation. (Kim et al., 2016) proposed an algorithm to select rank for each layer. (Yu et al., 2017) reconstructed the weight matrices by using sparse plus low-rank approximation.

Pruning Many algorithms have been proposed to remove those unimportant weights in deep neural nets. To do this, one needs to define the importance of each weight. (LeCun et al., 1990) showed that the importance can be estimated by using the Hessian of loss function. (Han et al., 2015b) considered adding ℓ_1 or ℓ_2 regularization and applied iterative thresholding approaches to achieve very good compression rates. Later on, (Han et al., 2015a) demonstrated that CNNs can be compressed by combining pruning, weight sharing and quantization.

Quantization Using lower precision representations to store parameters has been used for model compression. (Hubara et al., 2016) showed that a simple uniform quantization scheme effectively reduces both the model size and the prediction time of a deep neural net. (Lin et al., 2016) showed that non-uniform quantization can further improve the performance. Recently, several advanced quantization techniques have been proposed for CNN compression (Xu et al., 2018; Choi et al., 2018).

2.2 Model Compression for Neural Language Models

Despite model compression has been studied extensively for CNN models, fewer work have focused on the compression for deep neural nets for NLP applications. In fact, directly applying popular approaches to NLP problems does not provide a satisfactory result. (Hubara et al., 2016) showed that the naive quantization can only achieve less than 3X compression rate on PTB data with no performance loss. (Lobacheva et al., 2017) showed that for word-level LSTM models, the pruning approach can only achieve 4 times compression with more than 5% performance loss. Most recently, (Chen et al., 2018a) proposed a decomposition scheme based on block-wise low

rank approximation of embedding matrix. Although this method achieves competitive empirical results, the learned model does not have a strong semantic interpretation.

Additive Composition One of the most popular assumptions about the composition of semantics is called the additive composition stating that the meaning of a unit (e.g., word, phrase, or sentences) can be obtained by summing up the meaning of its constituents. At the word level, a word might be decomposed into a set of subword units. For example, "disagree" = "dis"+"agree". Alternatively, a word can also be represented by a set of relevant words, e.g., "king" = "man" + "crown". (Gittens et al., 2017) has validated this particular assumption for a popular word embedding approach (i.e., Skip-Gram (Mikolov et al., 2013)).

Based on this assumption, (Chen et al., 2016) created a codebook by splitting the vocabulary into two disjoint sets based on the word frequency: the most frequent words and the rest. Less frequent words are represented using a sparse linear combination of the vectors of more frequent words. Instead of using an explicit set of words, (Shu and Nakayama, 2017) designed the codebooks in a more data-driven fashion where the selection of pseudo words and code vectors are learned automatically using the Gumbel-Softmax trick (Jang et al., 2016). Following the same approach, (Chen et al., 2018b) propose additional training objective to integrate the learning of discrete codes with the training of the language model. Our method, based on the multiplicative composition rather than addition, follows this research line. The effectiveness of multiplicative composition is verified in some language modeling tasks (Mitchell and Lapata, 2009, 2008).

3 Proposed Method

3.1 Multi-way Multiplicative Codes

Compositional models start with defining a set of d_m dimensional vectors, which serve as basic codes to compose the targeted embedding matrix. These vectors could further be separated into M groups and say each group contains K vectors. We call each group a codebook, and each d_m dimensional vector in the codebook a codeword.

An 1-way codebook then is defined as a $R^{1\times M\times K\times d_m}$ tensor. Correspondingly, we define N-way codebooks as $U \in R^{N\times M\times K\times d_m}$, where each of the N ways consists of a set of M codebooks, each codebook contains K words, and each codeword is associated with a d_m dimensional vector representing its semantics.

Since U is a high-order tensor which is not memory-friendly, we model the composition of U as applying a customized multiplicative operator on two tensors $C \in R^{M\times K\times d_m}$ and $S \in R^{N\times M\times d_m}$ as

$$U = C \odot S,$$

where $\odot$ is a multiplicative operator defining that

$$U_{i,j,k} = C_{j,k} \circ \sigma(S_{i,j}),$$
$$\forall i \in [1,N], j \in [1,M], \text{and } k \in [1,K],$$

$\sigma(\cdot)$ stands for the tangent hyperbolic function, and $\circ$ is the Hadamard product (entry-wise product). Tensor C is referred to as the base codebook, consisting of M codebooks where each codebook contains K codeword vectors of d_m dimensions. S is called rescaling codebooks. Each codeword in the base codebook is injected with new meanings by a code vector in the rescaling codebook.

Despite rescaling codebook uses much less memory (O(NMd_m)) than simply creating a N times larger set of vectors (O($NMKd_m$)), using rescaling codebook still introduces additional costs of the memory. We propose to further reduce the cost by allowing rescaling code vectors to be shared. We replace S with a $\tilde{S} \in R^{N\times d_m}$. That is, for each of the N way codebook, we use only one d_m-dimensional vector to rescale the base codebook C. The number of parameters in S can thus be reduced and the computation of U becomes

$$U_{i,j,k} = C_{j,k} \circ \sigma(\tilde{S}_i),$$
$$\forall i \in [1,N], j \in [1,M], \text{and } k \in [1,K].$$

Now, with the N-way codebook defined by C and $\tilde{S}$, given an embedding matrix E with V vocabularies (i.e. $E \in R^{V\times d_m}$), we could represent E by finding an encoding $Q \in R^{V\times N\times M}$ to compose E from C and $\tilde{S}$. Q_i contains encoding of corresponding vocabulary V_i. From each of N-way n, and each of M codebooks m, $Q_{i,n,m}$ indicates which codeword to compose. Let the word vector for the ith word be e_i. We could construct e_i by

$$e_i \approx \hat{e}_i = \sum_{n=1}^{N}\sum_{m=1}^{M} U_{n,m,Q_{i,n,m}}$$
$$= \sum_{n=1}^{N}\sum_{m=1}^{M} C_{m,Q_{i,n,m}} \odot \sigma(\tilde{S}_n).$$

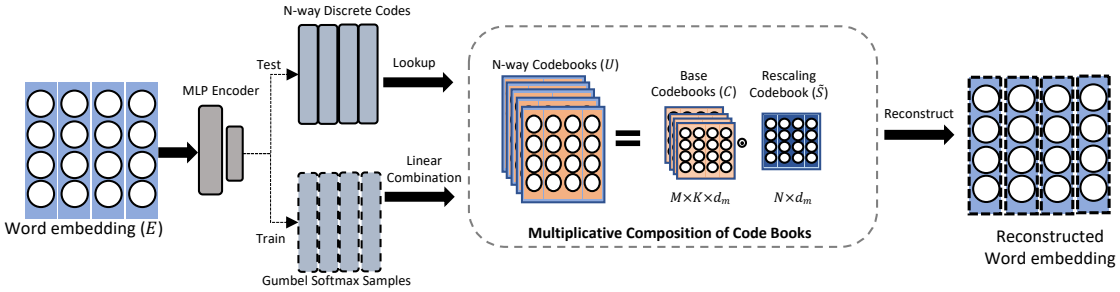

Figure 1: Overall architecture of the multi-way multiplicative compressor

The N-way discrete code could be learned in an end-to-end manner by using the Gumbel-Softmax trick (Jang et al., 2016). We first compute an encoding vector for the original word vector e_i by feeding it to a neural network

$$a_i = Softmax(\sigma(W^\top \phi(W'^\top e_i + b) + b')),$$

where W, W', b and b' are the parameters of the network, and ϕ is the softplus function. a_i represents a real value tensor in a shape $N \times M \times K$, which is then fed to the Gumbel-Softmax to generate a continuous approximation of drawing discrete samples with respect to the last dimension

$$\hat{D}_i = Softmax((\log a_i + g)/\tau),$$

where g is a random noise vector sampled from Gumbel distribution, and τ is the Softmax temperature controlling how close is the sample vector to a uniform distribution. $\hat{D}_i$ is an approximately one-hot out of K drawing for each way N and codebook M. We can then compute approximation of each dimension of e_i as

$$\hat{e}_{i,d} = U_{:,:,:,d} \odot \hat{D}_i$$

Note that during training $\hat{D}_i$ is generated as a continuous approximation of the N-way discrete code. At the testing phase, the fixed encoding Q_i of vector e_i is directly computed as $Q_{i,n,m} = \arg\max_k a_{n,m,k}$. More details on Gumbel-trick could be found in (Jang et al., 2016).

3.2 Group Adaptive Coding

Given the rescaling codebooks $\tilde{S}$ is small, the memory consumption mainly consists of two parts: code vectors C and discrete codes Q. On the one hand, the code vectors normally account for the major memory usage when dealing with relatively smaller vocabulary size. On the other hand, the size of discrete codes grows linearly with the size of vocabulary and the logarithm of K. To further reduce the memory usage, we propose to use codes of adaptive length and dimensions to deal with the linear dependency with vocabulary size. The intuition is to encode frequent words with a longer code length to achieve a relative lower reconstruction loss while representing rare words with fewer codes. To achieve this, we first sort the words according to their frequency and then split words into fixed number of groups G. The ith group could access only $\gamma_{G_i} = M \times (1 - \frac{i-1}{|G|})$ codebooks.

In the same time, we store the low-rank version of code vectors for some codebooks that were mainly used for representing rare words.

$$C_{i,j} = W_{G_i} c_i,$$

where $c_i \in R^{d_{G_i}}$ and $W_{G_i} \in R^{d_{G_i} \times d_m}$ is the linear transformation matrix to be shared by all the codebooks in the ith group. We resolve d_{G_i} in an intuitive way as shown in Algorithm 1.

In practice, high frequency words tend to get accesses to codebooks with higher rank while fewer frequent words can only access codebooks of lower dimension. Thanks to the long tail of rare words, this could actually help save considerable memory space. Normally, using a low compression rate results in $d_{G_i} \ll \gamma_{G_i} \times K$ so that it is guaranteed to reduce the number of parameters in the base codebook.

3.3 Prior-weighted Reconstruction Loss

According to Zipf's law, the frequency of words conforms to a power law distribution. It means that word which falls to the long tail may rarely appear in the sentence. It motivates the modification on the learning objective so that the compressor will be more focused on words with high frequency. In this paper, we use the distribution of

Sort set G according to frequency;
d': the minimum dimension ;
δ : targeted compression rate;
f_{G_i} : frequency of group G_i;
o_{G_i} : bits consumed by discrete code matrix Q for each word in G_i;
$n \leftarrow \delta \times V \times d_m \times 32(bits)$;
for $i \leftarrow 1$ *to* $|G|$ **do**
  compute a ratio based on frequency $\Delta_{G_i} \leftarrow \frac{f_{G_i}}{\sum_{i=1}^{|G|} f_{G_i}}$;
  calculate the dimension;
  $d_{G_i} \leftarrow (n - o_{G_i}) \times \Delta_{G_i} / (\gamma_{G_i} + d_m)$;
  ensure dimension is valid within (d', d_m);
  $d_{G_i} \leftarrow \min(\max(d_{G_i}, d'), d_m)$;
  update n by subtracting used bits;
  $n \leftarrow n - o_{G_i} - (\gamma_{G_i} - \gamma_{G_{i+1}} + d_m) \times d_{G_i}$
end

Algorithm 1: Algorithm to resolve the dimension of adaptive codebooks towards achieving a targeted compression rate.

the words in the training set as a prior knowledge to guide the learning of the compressor. In addition, similar to (Lin et al., 2017) we also want to let each of the N way encoding focus on different aspects of the original word embedding. The proposed training objective function then becomes

$$\mathcal{L} = \sum_{i=1}^{V} (-\log \hat{p}_i \|\hat{e}_i - e_i\|_2^2 + \lambda \|\hat{v}_i \hat{v}_i^\top - I\|_2^2 + \lambda \|\hat{v}_i^\top \hat{v}_i - I\|_2^2),$$

where $\hat{p}_i$ represents the empirical distribution of word V_i in the training set, e_i is original word vector, $\hat{e}_i$ is the reconstructed vector and $\hat{v}_i \in R^{N \times d_m}$ is a compilation of reconstrcuted vectors from all N-way codebooks in a matrix form (i.e. $\hat{v}_{i,n} = \sum_{m=1}^{M} C_{m,Q_{i,n,m}} \odot \sigma(\tilde{S}_n)$ is the reconstructed vector from nth-way codebook). The new objective function thus focuses on high-frequency words and in the meanwhile allows the N-way coding to encode different information.

4 Experiment

4.1 Data Sets and Models

Following the experimental protocol of (Chen et al., 2018a), we evaluate our proposed method with two important NLP tasks: language modeling and machine translation. Table 1 summarizes the key characteristics of the four data sets

Table 1: Statistics of data sets. The number in parenthesis shows the ratio of embedding layers (input plus Softmax) respective to the entire model size

Models	Vocab. Size	Dimension	Model Size
PTB-small	10k	200	17.7MB(85.8%)
PTB-large	10k	1500	251MB(45.4%)
OBW	793k	1024	6.8GB(91.2%)
NMT: DE-EN	30k	500	195MB(83.1%)

and models. PTB-small is using 2-layer LSTM-based language model built on Penn Tree Bank (PTB) data set. The vocabulary size is 10k. Input embedding layer and output Softmax layer are both set to 200 dimensions. PTB-large is trained on the same PTB data set as PTB-small except the dimensions for input and output are increased to 1500. Neural machine translation (NMT: DE-EN) is a Seq2seq model initialized using Pytorch checkpoints provided by Open-NMT (Klein et al., 2017). The model is to perform German to English translation tasks on IWSLT-14 (Cettolo et al., 2014) data set. One billion words (OBW) uses a 2-layer LSTM (referred to as "2-LAYER LSTM-8192-1024" by (Jozefowicz et al., 2016)) trained on the OBW data set and the vocabulary size is 793,471. For LSTM-based language models, the input embedding matrix and Softmax embedding matrix account for the major memory usage (up to 91.2%). Therefore, we target compressing both the input and Softmax embedding matrices.

4.2 Implementation Details

We compress both input embedding and Softmax matrices. We trained MulCode by using Adam optimizer with learning rate 0.001. For PTB data set, we group the vocabulary using 3 groups and 8 groups for OBW. To resolve the dimension of codebooks for adaptive coding, we use targeted compression rate $\delta = 0.2$ for PTB-small and $\delta = 0.05$ for the rest three models[1].

After approximation, we retrain the rest of parameters by SGD optimizer with initial learning rate 0.01. Whenever the validation perplexity does not drop down, we decrease the learning rate to an order smaller. We did not include results of fine-tuning on OBW for that the re-training process takes too long (few days) which is not compliant with our motivation to compress the given pre-trained embeddings.

[1]The original language models can be downloaded from https://github.com/mayktian/MulCode.git

The compression rate and corresponding performance could certainly be plotted as a spectrum graph. The more we compress, the larger the performance drop. In this paper, as far as BLEU score is concerned, we report results of compressed models when the BLEU falls within 3 percent difference from the original score. For PTB data set, we target 3 percent drop of perplexity (PPL) after retrain. For OBW data set, since it has a larger vocabulary size, we report results within 10 percent difference from the PPL achieved by the uncompressed model. For each method we tested various parameters and report the smallest model size of the compression fulfilling above criteria.

Notice that some previous methods compress model directly during training phase (Khrulkov et al., 2019; Wen et al., 2017). In contrast, our problem setup follows (Chen et al., 2018a; Shu and Nakayama, 2017; Chen et al., 2018b) that given a pre-trained model, we want to compress the model with limited fine-tuning.

4.3 Comparison with Baseline Models

We refer to our proposed method as MulCode (Mul stands for both multi-way and multiplicative composition). We mainly compare with two state-of-the-art baseline compressors targeting compressing the embedding layer.

1. **GroupReduce** We refer to the results reported in (Chen et al., 2018a).

2. **DeepCode** The additive composition model by (Shu and Nakayama, 2017). We use the pytorch code[2] released by (Shu and Nakayama, 2017) to produce the results.

Table 2 summarizes the comparison between the proposed methods and state-of-the-art baselines for the four benchmark data sets and LSTM models. MulCode manages to compress the input embedding layer and Softmax embedding layer 6 to 18 times without suffering a significant loss in the performance.

In comparison, all the baseline models achieve much lower compression rate with PTB-small which has only 200 dimensions. It is reasonable since embedding layers of PTB-small contains less redundant information and thus can be hardly compressed. As compared with DeepCode, our method achieves much higher compression rate[3] for all the four models. Our method also consistently and significantly outperforms GroupReduce.

4.4 Comparison with Quantization

Quantization has been proven to be a strong baseline. In fact, the discrete coding of MulCode can be considered equivalent to a trainable quantization. On the other hand, we need to point out that quantization is not orthogonal to MulCode. MulCode could be combined with quantization to achieve better performance. Specifically, the $M \times K$ base codebooks as well as the rescaling codebook could be quantized to further reduce the memory usage. We summarize the results in Table 3. Quantized MulCode could achieve more than 30.8 times compression for both input embedding and Softmax matrix in OBW. In addition, on machine translation task, it achieves 41.38X with BLEU score drops around only 1% after retraining. In particular, we observe that the effect of retraining is more prominent for MulCode and simple quantization compared to GroupReduce. This implies that local precision lost for low-rank basis in GroupReduce is more difficult to be recovered. In contrast, the collective information of MulCode due to the compositional property is more robust when imprecise local vectors present.

4.5 Ablation Analysis

We summarize the ablation analysis in Table 4. The major technical features of MulCode are rescaling codebooks (RC), prior-weighted reconstruction loss (PRL), and the group adaptive coding (GAC). Besides, we also consider using full rescaling books (Full) in place of the one shared across M codebooks. We remove or add these features one at a time. First, the rescaling codebook is shown contributing largely to the performance. On the other hand, since removing the rescaling codebook is equivalent to degrading to using pure additive composition, it also suggests the multiplicative composition is a better alternative to the additive composition. In the meantime, removing the rescaling codebook is equivalent to repeatedly selecting from the base codebook. It may force the codeword vector to encode the original meaning of

[2] https://github.com/zomux/neuralcompressor

[3] Aligned with what has been mentioned by (Shu and Nakayama, 2017) in their rebuttal, we found the DeepCode unable to work with the Softmax layer of OBW no matter how hard we have tuned it (99.5 as shown in Table 2).

Table 2: Compressed model evaluation with 3 language models and 1 machine translation model. Memory usage is reported as compared with the original input embedding and Softmax embedding. For example, 30x means the compressed embeddings use only 1/30 the memory space of the original embedding.

Model	Metric	Original	GroupReduce	DeepCode	MulCode
PTB-small	Memory	1X	4X	3.9X	6.5X
	PPL(before retrain)	112.28	115.38	120.05	115.38

	PPL(before retrain)	31.04	32.63	34.43	34.36

words as a mix of different aspects of the semantics, which may turn out hard to be recovered. In fact, we find it difficult to train a model that can achieve low perplexity loss (33) on OBW with the rescaling codebooks removed.

Removing the prior-weighted loss from the model results in only marginal loss in the performance except for PTB-small. It indicates that, given the limited capacity of codebooks, the performance of compressed model could benefit more from lower reconstruction loss for those words with the highest frequencies. For example, MulCode achieves 3.5% less perplexity loss compared to the model without using a prior-weighted reconstruction loss. Group adaptive coding is another key factor to reduce memory usage. It shows that it works well with all the four models. It handles the memory reduction in both ways: reducing the parameters in the code vectors and reducing the number of discrete codes to represent a word. For model with a very large vocabulary, it seems to achieve higher memory reduction than with a smaller model. We conjecture it is largely due to the prominent presence of rare words in data set like OBW. The significance of PRL and GAC verifies the importance of frequency in compressing natural words. Lastly, using the full tensor for rescaling codebook does not seem to be necessary. It fails to produce any improved performance of the compressed model at the expense of a non-trivial compression rate drop.

4.6 Selection of M,N and K

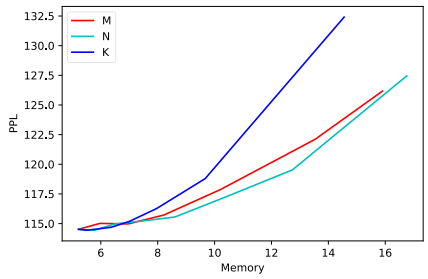

Figure 2: Influence of M, N, K for PTB-small.

To understand how the choices of M, N, K would affect the performance of the compressed model, we test the proposed model for PTB-small

Table 4: Ablation analysis of MulCode. We test the compression model by removing (or adding) one feature at a time. **-RC** stands for removing the rescaling codebook;**-PRL** stands for removing the prior-weighted reconstruction loss; **-GAC** means removing the group adaptive coding; **+ Full** means to use the untied tensor for rescaling codebook.

Model	Metric	-RC	-PRL	-GAC	+ Full	MulCode
PTB-small	Memory	3.95X	6.47X	5.68X	5.50X	6.47X
	PPL	124.78	115.58	115.65	115.96	115.38
PTB-large	Memory	5.64X	15.42X	13.08X	10.20X	17.1X
	PPL	84.72	84.82	84.60	84.36	83.85
NMT: DE-EN	Memory	9.02X	17.4X	11.24X	16X	17.44X
	BLEU	26.16	28.12	28.60	29.02	29.11
OBW	Memory	9.4X	23.8X	16.8X	23.4X	23.8X
	PPL	37.42	34.05	33.45	32.81	32.95

with varying setting of M, N, and K. The departure point of this experiment is using $M = 32, K = 32, N = 8$. We then adjust the three parameters one at a time while fixing the other two. In order to plot the results in a single figure, we set the x-axis as the memory usage instead of different values of the three parameters. As shown in Figure 2, adjusting the values of M, N, and K have similar effects on the PPL when the compression rate is low ($\leq$7X). With a larger compression rate, the performance becomes much more sensitive to the change of K. It suggests that it is safer to maintain a high value for K while tuning the rest two parameters for the purpose of securing a reasonable performance of the compressed model.

4.7 Understanding Composed Codes

At the core of our approach is the multiplicative composition from two sets of codebooks. Hence, it is interesting to investigate what has been encoded in the N-way codebooks. One assumption is that each code in the base codebooks encodes a mix of information which can be disentangled by the rescaling codebook. We encode all the words of OBW corpus by a $32 \times 8 \times 4$ codes. We compute the hamming distance of example query words (shown in Table 5) for each of the N-way codes. We select the top ones with the smallest hamming distance from the 10,000 most frequent words that are likely to have low reconstruction errors.

Since the N-way codings are generated by selecting from the base codebooks and modified by rescaling codebooks, each channel can be seen as meaningful subspace. It shows that each of the N-way codings might have encoded a different subspace of the original meaning of words, including tenses (e.g., halt v.s. halted), plurals (e.g., bank v.s. banks), synonyms (e.g., soccer v.s. football),

Word	1	2	3	4
tomorrow	today	Sunday	prompt	Tuesday
beautiful	elegant	iconic	great	fields
soccer	football	hockey	Ghana	basketball
where	when	experiencing	who	learn
bank	company	police	companies	banks
halt	stop	halted	afternoon	cover
like	just	Like	such	is

Table 5: Most similar word computed using Hamming distance for each of the N-way codings.

co-occurrence (like v.s. just), topical relatedness (soccer v.s. hockey). It verifies that the multiplicative composition used in our approach is able to introduce new information to the base codebook.

5 Conclusion

In this paper, we propose a novel compression method for neural language models. Our method applies multiplicative factors on end-to-end learned codebooks. Our method also considers the frequency information in the corpus by adding weighted loss according to the importance. At the same time, the coding scheme is made adaptive based on the frequency information. Experimental results show that our method outperforms the state-of-the-art compression methods by a large margin. In particular, on the IWSLT-14 data set, our method combined with quantization achieves 41.38 times compression rate for both the embedding and Softmax matrices. It will facilitate deployment of large neural language models on memory-constrained devices.

Abstract

This paper treats gender bias latent in word embeddings. Previous mitigation attempts rely on the operationalisation of gender bias as a projection over a linear subspace. An alternative approach is *Counterfactual Data Augmentation* (CDA), in which a corpus is duplicated and augmented to remove bias, e.g. by swapping all inherently-gendered words in the copy. We perform an empirical comparison of these approaches on the English Gigaword and Wikipedia, and find that whilst both successfully reduce direct bias and perform well in tasks which quantify embedding quality, CDA variants outperform projection-based methods at the task of drawing non-biased gender analogies by an average of 19% across both corpora. We propose two improvements to CDA: *Counterfactual Data Substitution* (CDS), a variant of CDA in which potentially biased text is randomly substituted to avoid duplication, and the Names Intervention, a novel name-pairing technique that vastly increases the number of words being treated. CDA/S with the Names Intervention is the only approach which is able to mitigate indirect gender bias: following debiasing, previously biased words are significantly less clustered according to gender (cluster purity is reduced by 49%), thus improving on the state-of-the-art for bias mitigation.

1 Introduction

Gender bias describes an inherent prejudice against a gender, captured both by individuals and larger social systems. Word embeddings, a popular machine-learnt semantic space, have been shown to retain gender bias present in corpora used to train them (Caliskan et al., 2017). This results in gender-stereotypical vector analogies à la Mikolov et al. (2013), such as *man*:*computer programmer* :: *woman*:*homemaker* (Bolukbasi et al., 2016), and such bias has been shown to materialise in a variety of downstream tasks, e.g. coreference resolution (Rudinger et al., 2018; Zhao et al., 2018).

By operationalising gender bias in word embeddings as a linear subspace, Bolukbasi et al. (2016) are able to debias with simple techniques from linear algebra. Their method successfully mitigates **direct bias**: *man* is no longer more similar to *computer programmer* in vector space than *woman*. However, the structure of gender bias in vector space remains largely intact, and the new vectors still evince **indirect bias**: associations which result from gender bias between not explicitly gendered words, for example a possible association between *football* and *business* resulting from their mutual association with explicitly masculine words (Gonen and Goldberg, 2019). In this paper we continue the work of Gonen and Goldberg, and show that another paradigm for gender bias mitigation proposed by Lu et al. (2018), Counterfactual Data Augmentation (CDA), is also unable to mitigate indirect bias. We also show, using a new test we describe (non-biased gender analogies), that WED might be removing too much gender information, casting further doubt on its operationalisation of gender bias as a linear subspace.

To improve CDA we make two proposals. The first, Counterfactual Data Substitution (CDS), is designed to avoid text duplication in favour of substitution. The second, the Names Intervention, is a method which can be applied to either CDA or CDS, and treats bias inherent in first names. It does so using a novel name pairing strategy that accounts for both name frequency and gender-specificity. Using our improvements, the clusters of the most biased words exhibit a reduction of cluster purity by an average of 49% across both corpora following treatment, thereby offering a partial solution to the problem of indirect bias as formalised by Gonen and Goldberg (2019). Additionally, although one could expect that the debiased embeddings

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5267–5275, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

might suffer performance losses in computational linguistic tasks, our embeddings remain useful for at least two such tasks, word similarity and sentiment classification (Le and Mikolov, 2014).

2 Related Work

The measurement and mitigation of gender bias relies on the chosen operationalisation of gender bias. As a direct consequence, how researchers choose to operationalise bias determines both the techniques at one's disposal to mitigate the bias, as well as the yardstick by which success is determined.

2.1 Word Embedding Debiasing

One popular method for the mitigation of gender bias, introduced by Bolukbasi et al. (2016), measures the genderedness of words by the extent to which they point in a **gender direction**. Suppose we embed our words into $\mathbb{R}^d$. The fundamental assumption is that there exists a linear subspace $B \subset \mathbb{R}^d$ that contains (most of) the gender bias in the space of word embeddings. (Note that B is a direction when it is a single vector.) We term this assumption the **gender subspace hypothesis**. Thus, by basic linear algebra, we may decompose any word vector $\mathbf{v} \in \mathbb{R}^d$ as the sum of the projections onto the bias subspace and its complement: $\mathbf{v} = \mathbf{v}_B + \mathbf{v}_{\perp B}$. The (implicit) operationalisation of gender bias under this hypothesis is, then, the magnitiude of the bias vector $||\mathbf{v}_B||_2$.

To capture B, Bolukbasi et al. (2016) first construct two sets, $\mathcal{D}_{male}$ and $\mathcal{D}_{female}$ containing the male- and female-oriented pairs, using a set of gender-definitional pairs, e.g., *man–woman* and *husband–wife*. They then define $\mathcal{D} = \mathcal{D}_{male} \cup \mathcal{D}_{female}$ as the union of the two sets. They compute the empirical covariance matrix

$$C = \sum_{w \in \mathcal{D}} (\vec{w} - \mu)(\vec{w} - \mu)^\top \quad (1)$$

where μ is the mean embeddings of the words in $\mathcal{D}$, then B is taken to be the k eigenvectors of C associated with the largest eigenvalues. Bolukbasi et al. set $k = 1$, and thus define a gender direction.

Using this operalisation of gender bias, Bolukbasi et al. go on to provide a linear-algebraic method (Word Embedding Debiasing, WED, originally "hard debiasing") to remove gender bias in two phases: first, for non-gendered words, the gender direction is removed ("neutralised"). Second, pairs of gendered words such as *mother* and *father* are made equidistant to all non-gendered words ("equalised"). Crucially, under the gender subspace hypothesis, it is only necessary to identify the subspace B as it is possible to perfectly remove the bias under this operationalisation using tools from numerical linear algebra.

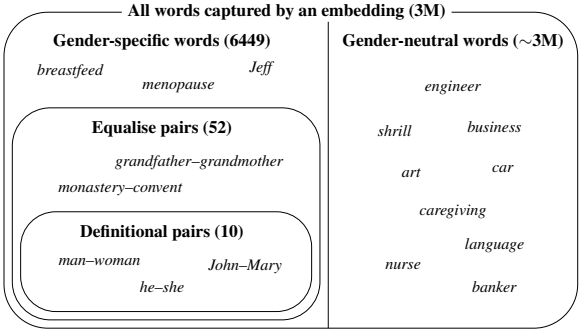

Figure 1: Word sets used by WED with examples

The method uses three sets of words or word pairs: 10 definitional pairs (used to define the gender direction), 218 gender-specific seed words (expanded to a larger set using a linear classifier, the compliment of which is neutralised in the first step), and 52 equalise pairs (equalised in the second step). The relationships among these sets are illustrated in Figure 1; for instance, gender-neutral words are defined as all words in an embedding that are not gender-specific.

Bolukbasi et al. find that this method results in a 68% reduction of stereotypical analogies as identified by human judges. However, bias is removed only insofar as the operationalisation allows. In a comprehensive analysis, Gonen and Goldberg (2019) show that the original structure of bias in the WED embedding space remains intact.

2.2 Counterfactual Data Augmentation

As an alternative to WED, Lu et al. (2018) propose Counterfactual Data Augmentation (CDA), in which a text transformation designed to invert bias is performed on a text corpus, the result of which is then appended to the original, to form a new bias-mitigated corpus used for training embeddings. Several interventions are proposed: in the simplest, occurrences of words in 124 gendered word pairs are swapped. For example, 'the woman cleaned the kitchen' would (counterfactually) become 'the man cleaned the kitchen' as *man–woman* is on the list. Both versions would then together be used in embedding training, in effect neutralising the *man–woman* bias.

The *grammar intervention*, Lu et al.'s improved intervention, uses coreference information to veto swapping gender words when they corefer to a proper noun.[1] This avoids *Elizabeth ... she ... queen* being changed to, for instance, *Elizabeth ... he ... king*. It also uses POS information to avoid ungrammaticality related to the ambiguity of *her* between personal pronoun and possessive determiner. In the context, 'her teacher was proud of her', this results in the correct sentence '*his* teacher was proud of *him*'.

3 Improvements to CDA

We prefer the philosophy of CDA over WED as it makes fewer assumptions about the operationalisation of the bias it is meant to mitigate.

3.1 Counterfactual Data Substitution

The duplication of text which lies at the heart of CDA will produce debiased corpora with peculiar statistical properties unlike those of naturally occurring text. Almost all observed word frequencies will be even, with a notable jump from 2 directly to 0, and a type–token ratio far lower than predicted by Heaps' Law for text of this length. The precise effect this will have on the resulting embedding space is hard to predict, but we assume that it is preferable not to violate the fundamental assumptions of the algorithms used to create embeddings.

As such, we propose to apply substitutions probabilistically (with 0.5 probability), which results in a non-duplicated counterfactual training corpus, a method we call **Counterfactual Data Substitution (CDS)**. Substitutions are performed on a per-document basis in order to maintain grammaticality and discourse coherence. This simple change should have advantages in terms of naturalness of text and processing efficiency, as well as theoretical foundation.

3.2 The Names Intervention

Our main technical contribution in this paper is to provide a method for better counterfactual augmentation, which is based on bipartite-graph matching of names. Instead of Lu et. al's (2018) solution of not treating words which corefer to proper nouns in order to maintain grammaticality, we propose an explicit treatment of first names. This is because we note that as a result of not swapping the gender of words which corefer with proper nouns, CDA could in fact reinforce certain biases instead of mitigate them. Consider the sentence 'Tom ... He is a successful and powerful executive.' Since *he* and *Tom* corefer, the counterfactual corpus copy will not replace *he* with *she* in this instance, and as the method involves a duplication of text, this would result in a stronger, not weaker, association between *he* and gender-stereotypic concepts present like *executive*. Even under CDS, this would still mean that biased associations are left untreated (albeit at least not reinforced). Treating names should in contrast effect a real neutralisation of bias, with the added bonus that grammaticality is maintained without the need for coreference resolution.

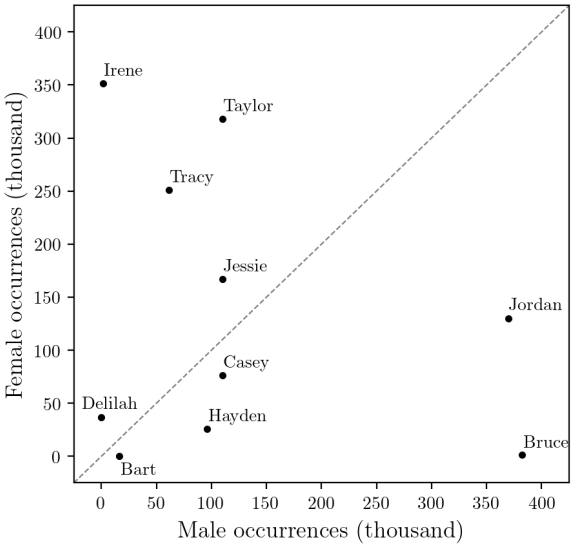

Figure 2: Frequency and gender-specificity of names in the SSA dataset

The United States Social Security Administration (SSA) dataset contains a list of all first names from Social Security card applications for births in the United States after 1879, along with their gender.[2] Figure 2 plots a few example names according to their male and female occurrences, and shows that names have varying degrees of gender-specificity.[3]

We fixedly associate pairs of names for swapping, thus expanding Lu et al.'s short list of gender pairs vastly. Clearly both name frequency and the degree of gender-specificity are relevant to this bipartite matching. If only frequency were considered, a more gender-neutral name (e.g. *Taylor*)

[1] We interpret Lu et al.'s (2018) phrase "cluster" to mean "coreference chain".

[2] https://www.ssa.gov/oact/babynames/background.html

[3] The dotted line represents gender-neutrality, and more frequent names are located further from the origin.

could be paired with a very gender-specific name (e.g. *John*), which would negate the gender intervention in many cases (namely whenever a male occurrence of *Taylor* is transformed into *John*, which would also result in incorrect pronouns, if present). If, on the other hand, only the degree of gender-specificity were considered, we would see frequent names (like *James*) being paired with far less frequent names (like *Sybil*), which would distort the overall frequency distribution of names. This might also result in the retention of a gender signal: for instance, swapping a highly frequent male name with a rare female name might simply make the rare female name behave as a new link between masculine contexts (instead of the original male name), as it rarely appears in female contexts.

Figure 3 shows a plot of various names' number of primary gender[4] occurances against their secondary gender occurrences, with red dots for primary-male and blue crosses for primary-female names.[5] The problem of finding name-pairs thus decomposes into a Euclidean-distance bipartite matching problem, which can be solved using the Hungarian method (Kuhn, 1955). We compute pairs for the most frequent 2500 names of each gender in the SSA dataset. There is also the problem that many names are also common nouns (e.g. *Amber*, *Rose*, or *Mark*), which we solve using Named Entity Recognition.

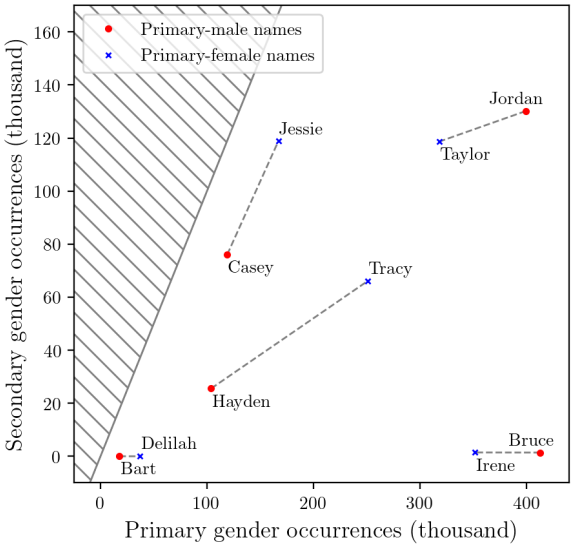

Figure 3: Bipartite matching of names by frequency and gender-specificity

4 Experimental Setup

We compare eight variations of the mitigation methods. **CDA** is our reimplementation of Lu et al.'s (2018) naïve intervention, **gCDA** uses their grammar intervention, and **nCDA** uses our new Names Intervention. **gCDS** and **nCDS** are variants of the grammar and Names Intervention using CDS. **WED40** is our reimplementation of Bolukbasi et al.'s (2016) method, which (like the original) uses a single component to define the gender subspace, accounting for $> 40\%$ of variance. As this is much lower than in the original paper (where it was 60%, reproduced in Figure 4), we define a second space, **WED70**, which uses a 2D subspace accounting for $> 70\%$ of variance. To test whether WED profits from additional names, we use the 5000 paired names in the names gazetteer as additional equalise pairs (**nWED70**).[6] As control, we also evaluate the unmitigated space (**none**).

We perform an empirical comparison of these bias mitigation techniques on two corpora, the Annotated English Gigaword (Napoles et al., 2012) and Wikipedia. Wikipedia is of particular interest, since though its Neutral Point of View (NPOV) policy[7] predicates that all content should be presented without bias, women are nonetheless less likely to be deemed "notable" than men of equal stature (Reagle and Rhue, 2011), and there are differences in the choice of language used to describe them (Bamman and Smith, 2014; Graells-Garrido et al., 2015). We use the annotation native to the Annotated English Gigaword, and process Wikipedia with CoreNLP (statistical coreference; bidirectional tagger). Embeddings are created using Word2Vec[8]. We use the original complex lexical input (gender-word pairs and the like) for each algorithm as we assume that this benefits each algorithm most. Expanding the set of gender-specific words for WED (following Bolukbasi et al., using a linear classifier) on Gigaword resulted in 2141 such words, 7146 for Wikipedia.[9]

[4]Defined as its most frequently occurring gender.

[5]The hatched area demarcates an area of the graph where no names can exist: if any name did then its primary and secondary gender would be reversed and it would belong to the alternate set.

[6]We use the 70% variant as preliminary experimentation showed that it was superior to WED40.

[7]https://en.wikipedia.org/wiki/Wikipedia:Neutral_point_of_view

[8]A CBOW model was trained over five epochs to produce 300 dimensional embeddings. Words were lowercased, punctuation other than underscores and hyphens removed, and tokens with fewer than ten occurrences were discarded.

[9]We modify or remove some phrases from the training data not included in the vocabulary of our embeddings.

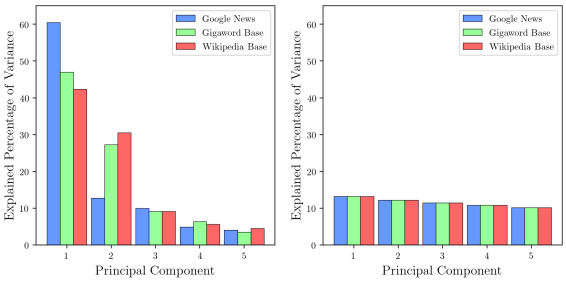

Figure 4: Variance explained by the top Principal Components of the definitional word pairs (left) and random unit vectors (right)

In our experiments, we test the degree to which the spaces are successful at mitigating direct and indirect bias, as well as the degree to which they can still be used in two NLP tasks standardly performed with embeddings, word similarity and sentiment classification. We also introduce one further, novel task, which is designed to quantify how well the embedding spaces capture an understanding of gender using non-biased analogies. Our evaluation matrix and methodology is expanded below.

Direct bias Caliskan et al. (2017) introduce the Word Embedding Association Test (WEAT), which provides results analogous to earlier psychological work by Greenwald et al. (1998) by measuring the difference in relative similarity between two sets of target words X and Y and two sets of attribute words A and B. We compute Cohen's d (a measure of the difference in relative similarity of the word sets within each embedding; higher is more biased), and a one-sided p-value which indicates whether the bias detected by WEAT within each embedding is significant (the best outcome being that no such bias is detectable). We do this for three tests proposed by Nosek et al. (2002) which measure the strength of various gender stereotypes: art–maths, arts–sciences, and careers–family.[10]

Indirect bias To demonstrate indirect gender bias we adapt a pair of methods proposed by Gonen and Goldberg (2019). First, we test whether the most-biased words prior to bias mitigation remain clustered following bias mitigation. To do this, we define a new subspace, $\vec{b}_{\text{test}}$, using the 23 word pairs used in the Google Analogy family test subset (Mikolov et al., 2013) following Bolukbasi et al.'s (2016) method, and determine the 1000 most biased words in each corpus (the 500 words most similar to $\vec{b}_{\text{test}}$ and $-\vec{b}_{\text{test}}$) in the unmitigated embedding. For each debiased embedding we then project these words into 2D space with tSNE (van der Maaten and Hinton, 2008), compute clusters with k-means, and calculate the clusters' V-measure (Rosenberg and Hirschberg, 2007). Low values of cluster purity indicate that biased words are less clustered following bias mitigation.

Second, we test whether a classifier can be trained to reclassify the gender of debiased words. If it succeeds, this would indicate that bias-information still remains in the embedding. We trained an RBF-kernel SVM classifier on a random sample of 1000 out of the 5000 most biased words from each corpus using $\vec{b}_{\text{test}}$ (500 from each gender), then report the classifier's accuracy when reclassifying the remaining 4000 words.

Word similarity The quality of a space is traditionally measured by how well it replicates human judgements of word similarity. The SimLex-999 dataset (Hill et al., 2015) provides a ground-truth measure of similarity produced by 500 native English speakers.[11] Similarity scores in an embedding are computed as the cosine angle between word-vector pairs, and Spearman correlation between embedding and human judgements are reported. We measure correlative significance at $\alpha = 0.01$.

Sentiment classification Following Le and Mikolov (2014), we use a standard sentiment classification task to quantify the downstream performance of the embedding spaces when they are used as a pretrained word embedding input (Lau and Baldwin, 2016) to Doc2Vec on the Stanford Large Movie Review dataset. The classification is performed by an SVM classifier using the document embeddings as features, trained on 40,000 labelled reviews and tested on the remaining 10,000 documents, reported as error percentage.

Non-biased gender analogies When proposing WED, Bolukbasi et al. (2016) use human raters to class gender-analogies as either *biased* (*woman*:*housewife* :: *man*:*shopkeeper*) or *appropriate* (*woman*:*grandmother* :: *man*::*grandfather*), and postulate that whilst biased analogies are undesirable, appropriate ones should remain. Our new analogy test uses the 506 analogies in the *fam-*

[10] In the careers–family test the gender dimension is expressed by female and male first names, unlike in the other sets, where pronouns and typical gendered words are used.

[11] It explicitly quantifies similarity rather than association or relatedness; pairs of entities like *coffee* and *cup* have a low rating.

Table 1: Direct bias results

ily analogy subset of the Google Analogy Test set (Mikolov et al., 2013) to define many such appropriate analogies that should hold even in a debiased environment, such as *boy*:*girl* :: *nephew*:*niece*.[12] We use a proportional pair-based analogy test, which measures each embedding's performance when drawing a fourth word to complete each analogy, and report error percentage.

5 Results

Direct bias Table 1 presents the d scores and WEAT one-tailed p-values, which indicate whether the difference in samples means between targets X and Y and attributes A and B is significant. We also compute a two-tailed p-value to determine whether the difference between the various sets is significant.[13]

On Wikipedia, nWED70 outperforms every other method ($p < 0.01$), and even at $\alpha = 0.1$ bias was undetectable. In all CDA/S variants, the Names Intervention performs significantly better than other intervention strategies (average d for nCDS across all tests 0.95 vs. 1.39 for the best non-names CDA/S variants). Excluding the Wikipedia careers–family test (in which the CDA and CDS

[12]The entire Google Analogy Test set contains 19,544 analogies, which are usually reported as a single result or as a pair of semantic and syntactic results.

[13]Throughout this paper, we test significance in the differences between the embeddings with a two-tailed Monte Carlo permutation test at significance interval $\alpha = 0.01$ with $r = 10,000$ permutations.

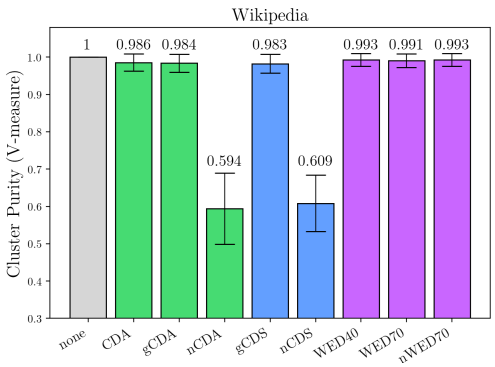

Figure 5: Most biased cluster purity results

variants are indistinguishable at $\alpha = 0.01$), the CDS variants are numerically better than their CDA counterparts in 80% of the test cases, although many of these differences are not significant.

Generally, we notice a trend of WED reducing direct gender bias slightly better than CDA/S. Impressively, WED even successfully reduces bias in the careers–family test, where gender information is captured by names, which were not in WED's gender-equalise word-pair list for treatment.

Indirect bias Figure 5 shows the V-measures of the clusters of the most biased words in Wikipedia for each embedding. Gigaword patterns similarly (see appendix). Figure 6 shows example tSNE projections for the Gigaword embeddings ("V" refers to their V-measures; these examples were chosen as they represent the best results achieved by Bolukbasi et al.'s (2016) method, Lu et al.'s (2018) method, and our new names variant). On both corpora, the new nCDA and nCDS techniques have significantly lower purity of biased-word cluster than all other evaluated mitigation techniques (0.420 for nCDS on Gigaword, which corresponds to a reduction of purity by 58% compared to the unmitigated embedding, and 0.609 (39%) on Wikipedia). nWED70's V-Measure is significantly higher than either of the other Names variants (reduction of 11% on Gigaword, only 1% on Wikipedia), suggesting that the success of nCDS and nCDA is not merely due to their larger list of gender-words.

Figure 7 shows the results of the second test of indirect bias, and reports the accuracy of a classifier trained to reclassify previously gender biased words on the Wikipedia embeddings (Gigaword patterns similarly).[14] These results reinforce the finding of the clustering experiment: once again,

[14]The 95% confidence interval is calculated by a Wilson score interval, i.e., assuming a normal distribution.

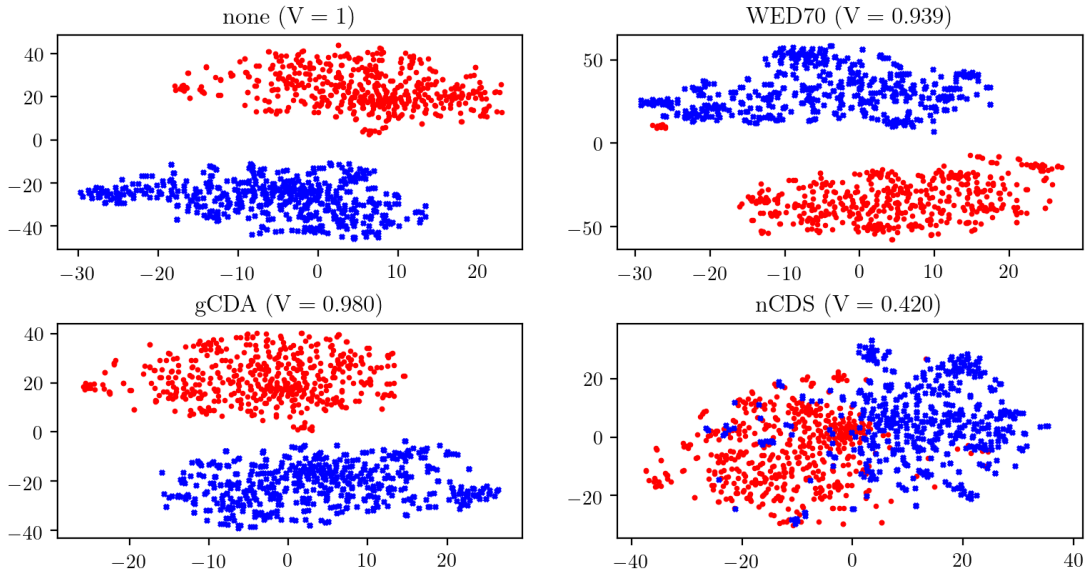

Figure 6: Clustering of biased words (Gigaword)

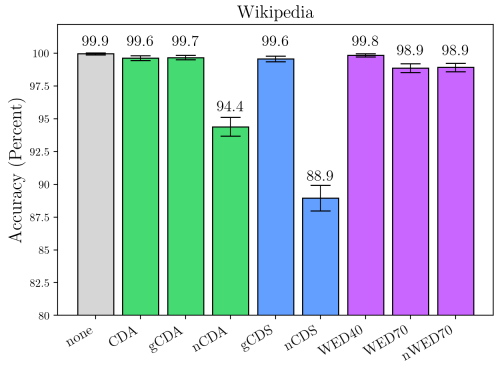

Figure 7: Reclassification of most biased words results

Method	r_s	
	Gigaword	**Wikipedia**
none	0.385	0.368
CDA	0.381	0.363
gCDA	0.381	0.363
nCDA	0.380	0.365
gCDS	0.382	0.366
nCDS	0.380	0.362
WED40	0.386	0.371
WED70	0.395	0.375
nWED70	0.384	0.367

Table 2: Word similarity Results

nCDS outperforms all other methods significantly on both corpora ($p < 0.01$), although it should be noted that the successful reclassification rate remains relatively high (e.g. 88.9% on Wikipedia).

We note that nullifying indirect bias associations entirely is not necessarily the goal of debiasing, since some of these may result from causal links in the domain. For example, whilst associations between *man* and *engineer* and between *man* and *car* are each stereotypic (and thus could be considered examples of direct bias), an association between *engineer* and *car* might well have little to do with gender bias, and so should not be mitigated.

Word similarity Table 2 reports the SimLex-999 Spearman rank-order correlation coefficients r_s (all are significant, $p < 0.01$). Surprisingly, the WED40 and 70 methods outperform the unmitigated embedding, although the difference in result is small (0.386 and 0.395 vs. 0.385 on Gigaword, 0.371 and 0.367 vs. 0.368 on Wikipedia). nWED70, on the other hand, performs worse than the unmitigated embedding (0.384 vs. 0.385 on Gigaword, 0.367 vs. 0.368 on Wikipedia). CDA and CDS methods do not match the quality of the unmitigated space, but once again the difference is small. It should be noted that since SimLex-999 was produced by human raters, it will reflect the human biases these methods were designed to remove, so worse performance might result from successful bias mitigation.

Sentiment classification Figure 8 shows the sentiment classification error rates for Wikipedia (Gigaword patterns similarly). Results are somewhat inconclusive. While WED70 significantly improves the performance of the sentiment classifier from the unmitigated embedding on both corpora ($p < 0.05$), the improvement is small (never more than 1.1%). On both corpora, nothing outperforms WED70 or the Names Intervention variants.

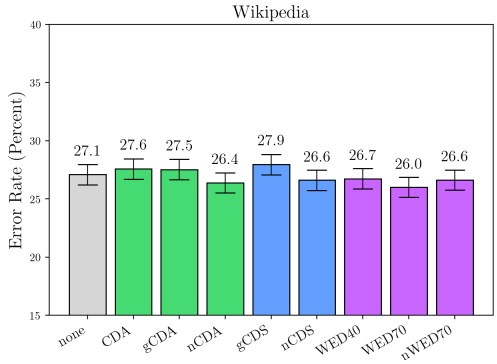

Figure 8: Sentiment classification results

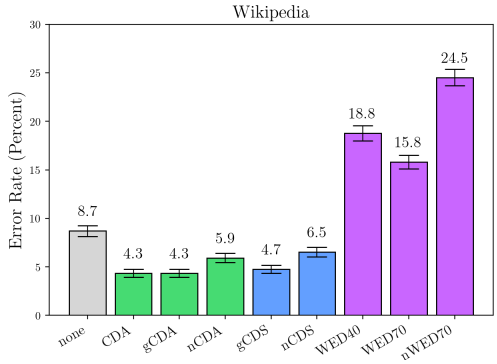

Figure 9: Non-biased gender analogy results

Non-biased gender analogies Figure 9 shows the error rates for non-biased gender analogies for Wikipedia. CDA and CDS are numerically better than the unmitigated embeddings (an effect which is always significant on Gigaword, shown in the appendices, but sometimes insignificant on Wikipedia). The WED variants, on the other hand, perform significantly worse than the unmitigated sets on both corpora (27.1 vs. 9.3% for the best WED variant on Gigaword; 18.8 vs. 8.7% on Wikipedia). WED thus seems to remove too much gender information, whilst CDA and CDS create an improved space, perhaps because they reduce the effect of stereotypical associations which were previously used incorrectly when drawing analogies.

6 Conclusion

We have replicated two state-of-the-art bias mitigation techniques, WED and CDA, on two large corpora, Wikipedia and the English Gigaword. In our empirical comparison, we found that although both methods mitigate direct gender bias and maintain the interpretability of the space, WED failed to maintain a robust representation of gender (the best variants had an error rate of 23% average when drawing non-biased analogies, suggesting that too much gender information was removed). A new variant of CDA we propose (the Names Intervention) is the only to successfully mitigate indirect gender bias: following its application, previously biased words are significantly less clustered according to gender, with an average of 49% reduction in cluster purity when clustering the most biased words. We also proposed Counterfactual Data Substitution, which generally performed better than the CDA equivalents, was notably quicker to compute (as Word2Vec is linear in corpus size), and in theory allows for multiple intervention layers without a corpus becoming exponentially large.

A fundamental limitation of all the methods compared is their reliance on predefined lists of gender words, in particular of pairs. Lu et al.'s pairs of *manager*::*manageress* and *murderer*::*murderess* may be counterproductive, as their augmentation method perpetuates a male reading of *manager*, which has become gender-neutral over time. Other issues arise from differences in spelling (e.g. *mum* vs. *mom*) and morphology (e.g. *his* vs. *her* and *hers*). Biologically-rooted terms like *breastfeed* or *uterus* do not lend themselves to pairing either. The strict use of pairings also imposes a gender binary, and as a result non-binary identities are all but ignored in the bias mitigation literature.

Future work could extend the Names Intervention to names from other languages beyond the US-based gazetteer used here. Our method only allows for there to be an equal number of male and female names, but if this were not the case one ought to explore the possibility of a many-to-one mapping, or perhaps a probablistic approach (though difficulties would be encountered sampling simultaneously from two distributions, frequency and gender-specificity). A mapping between nicknames (not covered by administrative sources) and formal names could be learned from a corpus for even wider coverage, possibly via the intermediary of coreference chains. Finally, given that names have been used in psychological literature as a proxy for race (e.g. Greenwald et al.), the Names Intervention could also be used to mitigate racial biases (something which, to the authors' best knowledge, has never been attempted), but finding pairings could prove problematic. It is important that other work looks into operationalising bias beyond the subspace definition proposed by Bolukbasi et al. (2016), as it is becoming increasingly evident that gender bias is not linear in embedding space.

Abstract

Recent studies have shown that word embeddings exhibit gender bias inherited from the training corpora. However, most studies to date have focused on quantifying and mitigating such bias only in English. These analyses cannot be directly extended to languages that exhibit morphological agreement on gender, such as Spanish and French. In this paper, we propose new metrics for evaluating gender bias in word embeddings of these languages and further demonstrate evidence of gender bias in bilingual embeddings which align these languages with English. Finally, we extend an existing approach to mitigate gender bias in word embedding under both monolingual and bilingual settings. Experiments on modified Word Embedding Association Test, word similarity, word translation, and word pair translation tasks show that the proposed approaches effectively reduce the gender bias while preserving the utility of the embeddings.

1 Introduction

Word embeddings are widely used in modern natural language processing tools. By virtue of their being trained on large, human-written corpora, recent studies have shown that word embeddings, in addition to capturing a word's semantics, also encode gender bias in society (Bolukbasi et al., 2016; Caliskan et al., 2017). As a result of this bias, the embeddings may cause undesired consequences in the resulting models (Zhao et al., 2018a; Font and Costa-jussà, 2019). Therefore, extensive effort has been put toward analyzing and mitigating gender bias in word embeddings (Bolukbasi et al., 2016; Zhao et al., 2018b; Dev and Phillips, 2019; Ethayarajh et al., 2019).

Existing studies on gender bias almost exclusively focus on English (EN) word embeddings. Unfortunately, the techniques used to mitigate bias in English word embeddings cannot be directly applied to languages with grammatical gender[1], where all nouns are assigned a gender class and the corresponding dependent articles, adjectives, and verbs must agree in gender with the noun (e.g. in Spanish: *la buena enfermera* the good female nurse, *el buen enfermero* the good male nurse) (Corbett, 1991, 2006). This is because most existing approaches define bias in word embeddings based on the projection of a word on a gender direction (e.g. "nurse" in English is biased because its projection on the gender direction inclines towards female). When the grammatical gender exists, such bias definition is problematic as masculine and feminine words naturally carry gender information. For example, "enfermero" (male nurse) and "enfermera" (female nurse) lean toward male and female, respectively. This is due to morphological agreement and should not be considered as a stereotype.

However, gender bias in the embeddings of languages with grammatical gender indeed exists. For example, when we align Spanish (ES) embeddings to English embeddings, the word "abogado" (male lawyer) is closer to "lawyer" than "abogada" (female lawyer). This observation implies a discrepancy in semantics between the masculine and feminine forms of the same occupation in Spanish word embeddings. A similar observation is also found in other languages, such as French (FR).

In this paper, we refer languages that have gender distinctions for all nouns (e.g., Spanish and German) as *gendered languages* and others that do not mark grammatical gender as *languages without grammatical gender* (e.g., English). We use Spanish and French as running examples and pro-

[1]Grammatical gender is a complicated linguistic phenomenon; many languages contain more than two gender classes. In this paper, we focus on languages with masculine and feminine classes. For gender in semantics, we follow the literature and address only binary gender.

pose quantitative methods for evaluating bias in word embeddings of gendered languages and bilingual word embeddings that align a gendered language with English. We first define gender bias in the word embeddings of gendered languages by constructing two gender directions: the semantic gender direction and the grammatical gender direction. We then analyze gender bias in bilingual embeddings using a similar approach.

To mitigate gender bias in these embeddings, we propose two approaches. One is shifting words along the semantic gender direction with respect to an anchor point and the other is mitigating English first and then aligning the embedding spaces. Results show that a hybrid of these two approaches effectively mitigate bias in Spanish and French word embeddings as well as ES-EN, FR-EN bilingual word embeddings. We also show through word similarity and word translation experiments that the utility of the original monolingual and bilingual word embeddings is preserved.

Our contributions are summarized in the following. (1) We show that word embeddings of gendered languages such as Spanish and French contain gender bias and bilingual word embeddings aligning these languages to English also inherit the bias. (2) Based on the observation, we propose new definitions of gender bias by constructing two gender directions. (3) We propose methods to reduce gender bias for both monolingual and bilingual embeddings and show that they effectively mitigate bias while preserving the original utility of embeddings. Source code and data are available at https://github.com/shaoxia57/Bias_in_Gendered_Languages.

2 Gender Bias Analysis

This section discusses how to analyze bias in embeddings of gendered languages and bilingual word embeddings.

2.1 Bias in Gendered Languages

In gendered languages, all nouns are assigned a gender class. However, inanimate objects (e.g., water and spoon) do not carry the meaning of male or female. To address this issue, we define two gender directions: (1) *semantic gender*, which is defined by a set of gender definition words (e.g., man, male, waitress) and (2) *grammatical gender*, which is defined by a set of masculine and feminine nouns (e.g., water, table, woman). Most analysis of gender bias assumes that the language (e.g,. English) only has the former direction. However, when analyzing languages like Spanish and French, considering the second is necessary. We discuss these two directions in detail as follows.

Semantic Gender Following Bolukbasi et al. (2016), we collect a set of gender-definition pairs (e.g., "mujer" (woman) and "hombre" (man) in Spanish). Then, the gender direction is derived by conducting principal component analysis (PCA) (Jolliffe, 2011) over the differences between male- and female-definition word vectors. Similar to the analysis in English, we observe that there is one major principal component carrying the meaning of gender in French and Spanish and we define it as the semantic gender direction $\vec{d}_{PCA}$.

Grammatical Gender The number of grammatical gender classes ranges from two to several tens (Corbett, 1991). To simplify the discussion, we focus on noun class systems where two major gender classes are feminine and masculine. However, the proposed approach can be generalized to languages with multiple gender classes (e.g., German). To identify grammatical gender direction, we collect around 3,000 common nouns that are grammatically masculine and 3,000 nouns that are feminine. Since most nouns (e.g., water) do not have a paired word in the other gender class, we do not have pairs of words to represent different grammatical genders. Therefore, instead of applying PCA, we learn the grammatical gender direction $\vec{d}_g$ by Linear Discriminant Analysis (LDA) (Fisher, 1936), which is a standard approach for supervised dimension reduction. The model achieves an average accuracy of 0.92 for predicting the grammatical gender in Spanish and 0.83 in French with 5-fold cross-validation.

Comparing $\vec{d}_{PCA}$ with $\vec{d}_g$, the cosine similarity between them is 0.389, indicating these two directions are overlapped to some extent but not identical. This is reasonable because words such as "mujer (woman)", "doctor (female doctor)" are both semantically and grammatically marked as feminine. To better distinguish between these two directions, we project out the grammatical gender component in the computed gender direction to make the semantic gender direction $\vec{d}_s$ orthogonal to the grammatical gender direction:

$$\vec{d}_s = \vec{d}_{PCA} - \left\langle \vec{d}_{PCA}, \vec{d}_g \right\rangle \vec{d}_g,$$

where $\langle \vec{x}, \vec{y} \rangle$ represents the inner product of two vectors.

Visualizing and Analyzing Bias in Spanish We take Spanish as an example and analyze gender bias in Spanish fastText word embeddings (Bojanowski et al., 2017) pre-trained on Spanish Wikipedia. For simplicity, we assume that the embeddings contain all gender forms of the words. To show bias, we randomly select several pairs of gender-definition and occupation words as well as inanimate nouns in Spanish and visualize them on the two gender directions defined above.

Figure 1 shows that the inanimate nouns lie near the origin point on the semantic gender direction, while the masculine and feminine forms of the occupation words are on the opposite sides for both directions. However, while projections of occupation words on the grammatical gender direction are symmetric with respect to the origin point, they are asymmetric when projected on the semantic gender direction. Along the semantic gender direction, female occupation words incline more to the feminine side than the male occupation words to the masculine side. This discrepancy shows that the embeddings carry unequal information for two genders.

Quantification of Gender Bias To quantify gender bias in English embeddings, Caliskan et al. (2017) propose Word Embedding Association Test (WEAT), which measures the association between two sets of target concepts and two sets of attributes. Let X and Y be equal-sized sets of target concept embeddings (e.g., words related to mathematics and art) and let A and B be sets of attribute embeddings (e.g., male and female definition words such as "man", "girl"). Let $\cos(\vec{a}, \vec{b})$ denote the cosine similarity between vectors $\vec{a}$ and $\vec{b}$. The test statistic is a difference between sums over the respective target concepts,

$$s(X, Y, A, B) = \sum_{\vec{x} \in X} s(\vec{x}, A, B) - \sum_{\vec{y} \in Y} s(\vec{y}, A, B),$$

where $s(\vec{w}, A, B)$ is the difference between average cosine similarities of the respective attributes,

$$s(\vec{w}, A, B) = \frac{1}{|A|} \sum_{\vec{a} \in A} \cos(\vec{w}, \vec{a}) - \frac{1}{|B|} \sum_{\vec{b} \in B} \cos(\vec{w}, \vec{b}).$$

In the following, we extend the definition to quantify individual words in gendered languages.

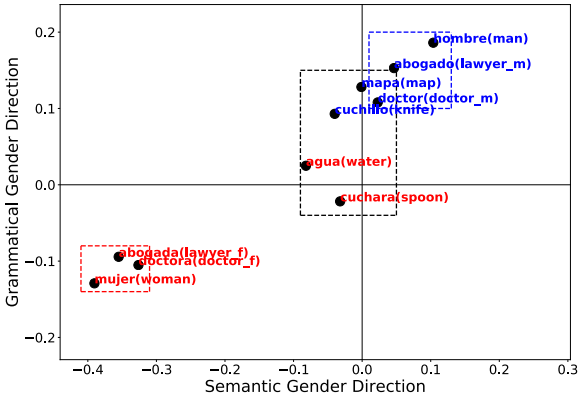

Figure 1: Projections of selected words in Spanish on grammatical and semantic directions with masculine nouns in blue and feminine nouns in red. We find that: (1) Most inanimate nouns (e.g., map, spoon; enclosed by black dotted lines) lie near the origin point of the semantic gender axis; (2) Masculine definition and occupation words (blue dotted lines) lie in the masculine side for both gender directions and so do feminine words (red dotted lines). But the feminine words are farther on the feminine side on the semantic gender direction compared to masculine words.

We consider two types of words. One is *inanimate nouns*, like "agua" (water, feminine). They are assigned as either a masculine or feminine noun. The other is *animate nouns* that usually have two gender forms, like "doctor" (male doctor) and "doctora" (female doctor).[2]

For inanimate nouns that should not be semantically leaning towards one gender, we can quantify the gender bias for word w simply using WEAT,

$$\mathrm{b}_w = |s(\vec{w}, A, B)|,$$

which measures the association strength of the word w with the gender concepts. The larger b_w is, the stronger its association with the gender concepts.

For nouns with two gender forms, we test if their masculine ($\vec{w}_m$) and feminine ($\vec{w}_f$) forms are symmetrical with respect to gender definition terms.

$$\mathrm{b}_w = ||s(\vec{w}_m, A, B)| - |s(\vec{w}_f, A, B)||. \quad (1)$$

The larger the value is, the larger gender bias presents. For example, if "doctor" (male doctor) leans more toward to masculine (i.e., close to masculine definition words like "el" (he) and far away

[2]Note that some animate nouns in certain languages, like "médecin" (male doctor) in French, only have one gender form. We omit such cases in this paper for the sake of simplicity.

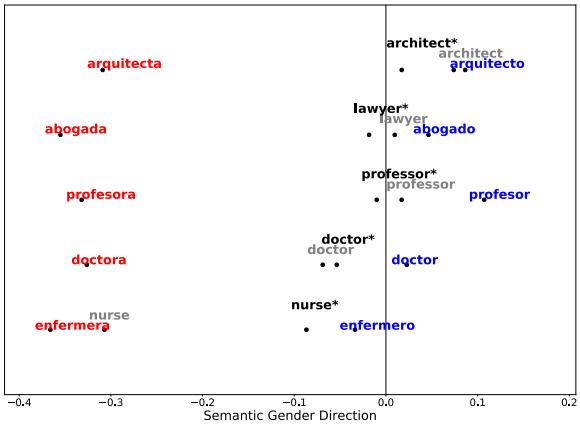

Figure 2: Projections of occupation words on the semantic gender direction in two gender forms (blue for male and red for female) in Spanish, the original English word (grey), and the bias-mitigated version of the English word (black with "*"). We find that feminine occupations are farther away from the English counterparts as well as the neutral position (indicated by the vertical line) compared to masculine words.

from feminine definition words like "ella" (she)) than "doctora" leans toward to feminine, then embeddings of "doctor" and "doctora" are biased. We will discuss detailed quantitative analysis using this metric in Section 4.

2.2 Bias in Bilingual Word Embeddings

Bilingual word embeddings are used widely in tasks such as multilingual transfer. It is essential to quantify and mitigate gender bias in these embeddings to avoid them from affecting downstream applications. We focus on bilingual word embeddings that align a grammatical gender language like Spanish with a language without grammatical gender like English. The definitions of the two gender directions are similar: we construct the grammatical gender direction using the same sets of words in the gendered language since the other language does not mark grammatical gender. We combine the gender-definition words for both languages and remove the grammatical gender component to get the semantic gender direction similarly.

We use bilingual word embeddings from MUSE (Conneau et al., 2018) that align English and Spanish fastText embeddings together in a single vector space. Figure 2 shows the projections of 5 occupation words on the semantic gender direction. First, we notice that the embeddings of some English occupations are much closer to one gender form than the other in Spanish. For example, "nurse" in English is closer to "enfermera" (female nurse) than "enfermero" (male nurse) in Spanish. We further separate out the bias in English embedding in the analysis by mitigating the English embeddings using "hard-debiasing" approach proposed in Bolukbasi et al. (2016) and aligning Spanish embedding with the bias-reduced English embedding (words annotated with "*"). Results in Figure 2 demonstrate another type of gender unequal in bilingual embedding: masculine occupation words are closer to the corresponding English occupation words than the feminine counterparts. This result aligns with the observation in Figure 1.

More quantitative analyses about gender bias in bilingual embedding will be discussed in Section 4.3.

3 Mitigation Methods

In the following, we first describe the optimization objectives for mitigating gender bias. Then, we present mitigation methods under two settings: (1) *monolingual setting*, where we only have access to word embeddings of the gendered language, and (2) *bilingual setting*, where the embeddings of a language without grammatical gender (e.g. English) aligned in the same space are also provided. Specifically, for the bilingual setting, we can use English word vectors to facilitate the bias mitigation.

3.1 Mitigation Objectives

For inanimate nouns, we project out their semantic gender component as they should not carry semantic gender. Equivalently, we minimize the inner product

$$\left\langle \vec{w}, \vec{d_s} \right\rangle \tag{2}$$

between the inanimate word vector $\vec{w}$ and the semantic gender direction $\vec{d_s}$.

For nouns with both gender forms, we aim at removing the gender inequality on the semantic gender direction as shown in Figure 1 and Figure 2. Specifically, we minimize the difference between the distance of feminine form of the word $\vec{w_f}$ and the masculine form of the word $\vec{w_m}$ to an anchor point (e.g., the origin point) on the semantic gender direciton d_s:

$$\left|\left|\left\langle \vec{w}_m, \vec{d_s} \right\rangle - \left\langle \vec{w}_a, \vec{d_s} \right\rangle\right| - \left|\left\langle \vec{w}_f, \vec{d_s} \right\rangle - \left\langle \vec{w}_a, \vec{d_s} \right\rangle\right|\right|. \tag{3}$$

Note that for most cases, $\vec{w_m}$ and $\vec{w_f}$ lie on the opposite sides of the anchor point on the semantic

gender axis. Therefore, we can simplify Eq. (3) as

$$\left|\left\langle \vec{w}_m, \vec{d}_s \right\rangle + \left\langle \vec{w}_f, \vec{d}_s \right\rangle - 2\left\langle \vec{w}_a, \vec{d}_s \right\rangle\right|. \quad (4)$$

Intuitively, this measures how much we need to move the word pair on the semantic gender direction so that they are symmetric with respect to the anchor point. If the anchor point is the origin point (i.e. $\left\langle \vec{w}_a, \vec{d}_s \right\rangle = 0$), this objective is the absolute value of the sum of two projections.

3.2 Monolingual Setting

Shifting Along Semantic Gender Direction (Shift) We mitigate bias by minimizing Eq. (4) and Eq. (2) in a post-processing manner. Effectively, for inanimate nouns, we remove the semantic gender component from the embeddings. For nouns with two gender forms (e.g., occupations), we shift the two forms along the semantic gender direction so that they have the same distance to the anchor point. For monolingual setting, we use the origin point on the gender direction as the anchor point and call the method Shift_Ori.

Note that Gonen and Goldberg (2019) show that mitigating gender bias in word embeddings by moving on the gender direction is not sufficient and words with gender bias still tend to group together. Similairly, our approach might not entirely remove the gender bias. However, the approach in Gonen and Goldberg (2019) to test the remainder bias cannot be applied directly for gendered languages, because grouping of the embeddings of masculine and feminine words does not always indicate bias due to grammatical gender .

3.3 Bilingual Setting

Mitigating Before Alignment (De-Align) As gender bias can be observed when aligning gendered languages with language without grammatical gender, we consider using English to facilitate mitigating bias. Specifically, we first apply the "hard-debasing" approach Bolukbasi et al. (2016) to English embedding and then align gendered language with the bias-reduced English. Because most words with both gender forms align to the same word in English (e.g., "enfermero" and "enfermera" in Spanish both align to "nurse" in English), the alignment places the two gender forms of the words in a more symmetric positions in the vector space after the alignment.

Shifting Along Semantic Gender Direction (Shift) We consider using English words as anchor positions when mitigating bias using Eq (4). We call this approach Shift_EN. For example, when applying Eq. (4) to re-position "enfermero" and "enfermera" in Spanish we take English word "nurse" aligned in the same space as the anchor position.

Hybrid Method (Hybrid) We also consider a hybrid method that integrates the aforementioned two approaches. In particular, we first mitigate English embeddings, align English embeddings with the embeddings of gendered languages, and then shift words in languages with grammatical gender along the semantic gender direction. We consider two variants based on how the anchor positions are chosen: (1) Hybrid_Ori uses the origin point as the anchor position; and (2) Hybrid_EN uses the corresponding bias-reduced English word as an anchor position when shifting a pair of words with different gender forms.

4 Experiments

We evaluate gender bias mitigation methods in both monolingual and bilingual settings and test the utility of the bias-reduced embeddings in word-level translation tasks Conneau et al. (2018). Following other analyses on gender bias (Bolukbasi et al., 2016; Caliskan et al., 2017), we quantify the gender bias based on a set of animate nouns including occupations and gender-definition words. These words are representative to the major challenge when quantifying and mitigating gender bias. Different from previous analyses in English, most occupation words in gendered languages have more than one forms and their embeddings are inherently different from each other due to morphological agreement.

4.1 Data and Configuration

We apply the proposed mitigation methods on Spanish-English and French-English bilingual embeddings from MUSE (Conneau et al., 2018) that align the fastText monolingual embeddings pretrained on Wikipedia corpora together in a single vector space. We collect 58 occupation words in Spanish from the occupation list provided by Font and Costa-jussà (2019) and 23 in French (some occupations in French do not distinguish between two forms) for the bias mitigation experiments. We use WEAT word lists from Caliskan et al. (2017) for

Lang.	Metric	Original	Shift_Ori	Shift_EN	De-Align	Hybrid_Ori	Hybrid_EN
ES	MWEAT–Diff	3.6918	0.3090	0.3324	3.5748	**0.3090**	2.2494
ES	MWEAT–p-value	0.0000	0.1130	0.0010	0.0010	**0.7330**	0.0020
FR	MWEAT–Diff	2.3437	0.2446	0.3882	2.3436	**0.2446**	1.1758
FR	MWEAT–p-value	0.0000	0.1470	0.0010	0.0020	**0.5290**	0.0910
ES	Word Similarity	**0.7392**	0.7363	0.7359	**0.7392**	0.7358	0.7356
FR	Word Similarity	**0.7294**	0.7218	0.7218	0.7156	0.7218	0.7218

Table 1: Analyses on Spanish and French monolingual embeddings before and after bias mitigation. Results show that the original Spanish and French embeddings exhibit strong bias and Hybrid_Ori significantly reduces the bias in the embedding to to an insignificant level (p-value > 0.05).

male and female attribute words for our WEAT experiments and translate them to Spanish and French. For the word pair translation task, we use 7 common adjectives and pair every adjective with each occupation, resulting in 406 pairs for Spanish and 161 for French.

4.2 Monolingual Experiments

Modified Word Embedding Association Test (MWEAT) As discussed in Section 2, we evaluate the gender bias using modified WEAT and we treat the absolute value of the sum of differences between mean cosine similarities of the two gender attributes for these occupation words $\left|\sum_{\vec{x}\in X} s(\vec{x}, A, B)\right|$ as the association of male occupation target concepts X with the gender attributes. Similarly, we use $\left|\sum_{\vec{y}\in Y} s(\vec{y}, A, B)\right|$ as the association of female occupation words with the gender attributes. Finally our test statistic is

$$\left|\left|\sum_{\vec{x}\in X} s(\vec{x}, A, B)\right| - \left|\sum_{\vec{y}\in Y} s(\vec{y}, A, B)\right|\right|,$$

which measures the difference in the association strength for two target sets with the two attribute sets occupation words. We then calculate the one-side p-value of the permutation test.

Word Similarity We test the quality of the embeddings after mitigation on the SemEval 2017 word similarity task (Camacho-Collados et al., 2017) for monolingual embeddings. This task evaluates how well the cosine similarity between two words correlates with a human-labeled score for which we report the Pearson correlation score.

Results Table 1 shows that Hybrid_Ori significantly decreases the difference of association between two genders as indicated by MWEAT–Diff and p-value. Other methods only show marginal

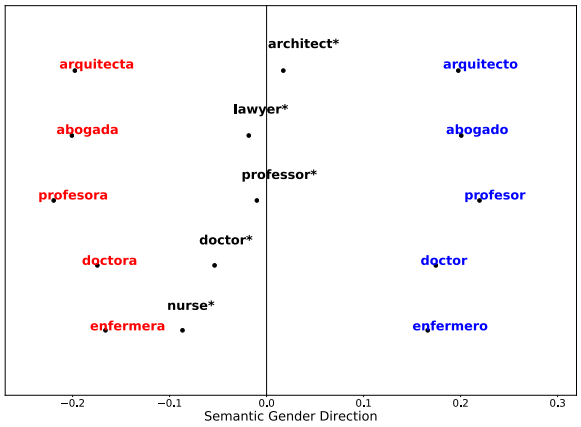

Figure 3: Projections of occupations words on the semantic gender direction after hybrid mitigation with origin as the anchor point. The two forms of occupations are a lot more symmetric.

mitigation effects in terms of p-value. We also find that the performance of our mitigation methods on word similarity is largely preserved as indicated by the Pearson correlation scores.

4.3 Cross-lingual Experiments

Word Translation We use word translation to examine whether our mitigation approaches preserve the utility of the bilingual word embedidings. This task aims to retrieve the translation of a source word in the target language. We use the test set provided by Conneau et al. (2018), which contains 200,000 randomly selected candidate words for 1,500 query words. We translate a query word and report the precision at k (i.e., fraction of correct translations that are ranked not larger than k) by retrieving its k nearest neighbours in the target language. We report both results with $k = 1$ and $k = 5$.

Word Pair Translation by Analogy We propose a word pair translation task to evaluate the bias

Task	Metric	Original	Shift_Ori	Shift_EN	De-Align	Hyrid_Ori	Hyrid_EN

Table 2: Results on word translation and word pair translation based on Spanish-English and French-English bilingual embeddings. We find that the original bilingual embeddings have a large discrepancy between the two genders, indicated by the average cosine similarity difference (ASD) and mean reciprocal ranks (MRR) difference. After applying the mitigation methods, both ASD and MRR difference drop.

in gendered languages. In languages with grammatical gender, word forms of articles and adjectives need to agree with the gender of nouns they are associated with. For example, the word "good" has two forms in Spanish: "bueno" (masculine form) and "buena" (feminine form). Following the notion of analogy, we design an evaluation task to test how bilingual word embeddings translate an English occupation with the presence of another word. Specifically, given an English word E_i (a noun, an adjective or a verb), an English occupation word E_o, and the corresponding Spanish/French translation S_i of E_i, we adopt the analogy test "E_i:E_o = S_i:?" (e.g., "good:doctor = buena: ?") to rank all the words S_o in Spanish/French based on the cosine similarity: $\cos(S_o, E_o - E_i + S_i)$. Ideally, the correct translation of E_o that agree with gender of S_i should be ranked on the top ("doctora" in the above example). Quantitatively, we use the mean reciprocal ranks (MRR) to evaluate the performance of the ranking. If the bilingual embedding is not biased, the model should perform similarly on answering the translation of masculine and feminine occupations. Based on this, we use the gap between the performances on two form of genders to quantify the bias in the bilingual embedding space. Besides, we also report the average cosine similarity difference (ASD) of occupation words between two different gender forms.

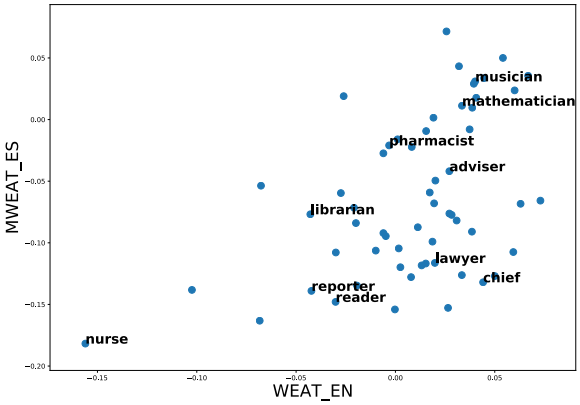

Figure 4: (M)WEAT scores for occupations in English and Spanish. For both axes, the smaller the number, the occupation is more leaning towards to female.

Results Table 2 shows the results. Results on word translation shows that the mitigation approaches do not harm the utility of bilingual word embedding and words in different languages still align well. From the results of word pair translation, the original bilingual embedding exhibits strong bias and the gap between two genders are around 0.49 in MRR in both ES-EN and FR-EN bilingual embeddings and the average cosine similarity difference is larger than 0.1. Hybrid_Ori results in smallest difference for cosine similarity and MRR gap between two gender forms. However, the discrepancy between two forms is not completely removed.

To visualize the effect of bias mitigation, we

project the bias-reduced embeddings of occupation words on the semantic gender direction as shown in Figure 2. Figure 3 shows that after debiasing using Hybrid_Ori, the two gender forms of occupation words are more symmteric with respect to the corresponding English embedding.

4.4 Bias Correlation between Languages

Finally, we compute the WEAT/MWEAT scores[3] for each occupation and show the commonality and difference of gender bias between English and Spanish embedding. Results in Figure 4 shows that occupations ("nurse" and "mathematician") lean towards the same gender in both languages. However, some occupations (e.g., "chef") lean to different genders in different languages. In general, there is a strong correlation between gender bias in English and Spanish embedding (Spearman correlation=0.45 with p-value=0.0004).

5 Related Work

Previous work has proposed to quantify bias in English Embedding definitions for gender bias in English word embeddings. Besides the aforementioned studies (Bolukbasi et al., 2016; Caliskan et al., 2017) in quantifying bias in English embedding, McCurdy and Serbeti (2017) examine grammatical gender bias in word embeddings of gendered languages by computing the WEAT association score (Caliskan et al., 2017) between gendered object nouns (e.g. moon-sun) and gender-definition words. They propose to mitigate bias by applying lemmatization to remove gender information from the training corpus. However, their focus is different from us as our approaches aim at keeping the grammatical gender information and only removing the bias in semantic genders. A few recent studies focus on measuring and reducing gender bias in contextualized word embeddings (Zhao et al., 2019; May et al., 2019; Basta et al., 2019). However, they only focus on English embeddings in which the gender is mostly only expressed by pronouns (Stahlberg et al., 2007). An interesting future direction is to extend their analyses to language with grammatical gender.

Regarding bias mitigation appraoches, Zhao et al. (2018b) mitigate bias by saving one dimension of the word vector for gender. Bordia and Bowman (2019) propose a regularization loss term for word-level language models. Zhang et al. (2018) use an adversarial network to mitigate bias in word embeddings. All these approaches consider only English embeddings. Moreover, Gonen and Goldberg (2019) show that mitigation methods based on gender directions are not sufficient, since the embeddings of socially-biased words still cluster together.

Bias in word embedding may affect the downstream applications (Zhao et al., 2018a; Rudinger et al., 2018; Font and Costa-jussà, 2019). Besides the gender bias in word embeddings, implicit stereotypes have been shown in other real world applications, such as online reviews (Wallace and Paul, 2016), advertisement (Sweeney, 2013) and web search (Kay et al., 2015).

6 Conclusion and Future Work

We analyze gender bias in the embeddings of languages with grammatical gender and bilingual word embeddings that align such a language with a language without grammatical gender. We propose new methods to evaluate and mitigate gender bias for languages with grammatical gender and bilingual word embeddings and results show that our methods can mitigate gender bias while preserving the quality of original embeddings.

Directions for future work include testing monolingual and bilingual word embeddings on downstream tasks like machine translation to measure bias and also test the performance for mitigation methods. Moreover, the number of noun classes for other languages with grammatical gender ranges from two to several tens (Corbett, 1991) and future work can extend methods proposed in this paper to address grammatical gender in languages with more gender forms.

Abstract

Words in different languages rarely cover the exact same semantic space. This work characterizes differences in meaning between words across languages using semantic relations that have been used to relate the meaning of English words. However, because of translation ambiguity, semantic relations are not always preserved by translation. We introduce a cross-lingual relation classifier trained only with English examples and a bilingual dictionary. Our classifier relies on a novel attention-based distillation approach to account for translation ambiguity when transferring knowledge from English to cross-lingual settings. On new English-Chinese and English-Hindi test sets, the resulting models largely outperform baselines that more naïvely rely on bilingual embeddings or dictionaries for cross-lingual transfer, and approach the performance of fully supervised systems on English tasks.

1 Introduction

Natural Language Processing (NLP) often uses translation lexicons for projecting models and data from one language to another under the assumption that words and their translations in these lexicons are synonyms (Mayhew et al., 2017; Tsvetkov et al., 2014). However, translation lexicons include semantic relations other than synonymy in practice, as can be seen (Table 1) in examples drawn from the MUSE dictionary (Lample et al., 2018). Peirsman and Padó (2011) show that distributional translation lexicons contain hyponyms and co-hyponyms, and that treating all translations as synonyms hurts cross-lingual projection performance. In the Paraphrase Database (Ganitkevitch et al., 2013), Pavlick et al. (2015) find that the diversity of semantic relations discovered in word-aligned parallel corpora yields paraphrases that span the lexical relations defined in the natural logic framework of MacCartney and Manning (2009). These non-synonymous translations are not just noise. They can be found even in high-quality parallel corpora, since the strategies used by professional translators to deal with words that do not have a direct equivalent in the target language include replacement by near-synonyms, hypernyms or negated antonyms (Baker, 2011; Venuti, 2012; Chesterman, 2016).

Lexicon Entry	Semantic Relation
writer, रचनाकार	*writer* is more specific than रचनाकार (creator)
council, मंत्रिपरिषड	*council* is more general than मंत्रिपरिषड (council of ministers)
father, चचा	*father* is mutually exclusive to चचा (father's brother)

Table 1: Semantic relations between word pairs in an English-Hindi lexicon (Lample et al., 2018)

In this work, we classify semantic relations between words in different languages. Given a word pair (water, पय), the classification task is to select one of the five entailment classes (Figure 1) defined under the natural logic framework of MacCartney and Manning (2009). This cross-lingual task cannot be solved by translation, as translation does not preserve semantic relations. We also cannot assume that labeled examples exist for all language pairs and learning from English labeled examples is complicated by translation ambiguity (Figure 1).

We introduce BILEXNET, a neural classifier for semantic relations based on cross-lingual distributional and path-based features inspired by the monolingual LEXNET model (Shwartz and Dagan, 2016a,b) (Section 3). We then design a novel training procedure for BILEXNET that leverages weak supervision in the form of examples translated from English via a knowledge distillation technique guided by translation dic-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5285–5296, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

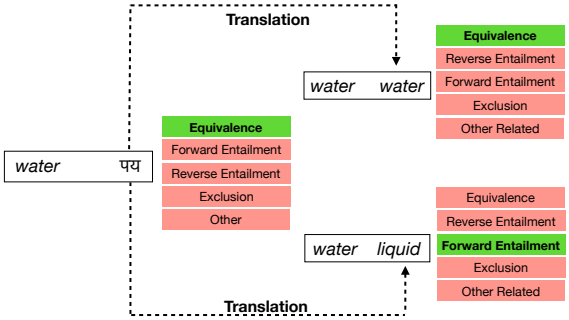

Figure 1: On the left, we illustrate cross-lingual semantic relation classification: given the pair (*water*, पय) as input, the task is to select the `Equivalence` class (in bold/green) from the five possible relations. On the right, we show that semantic relations change by translation. पय translates to *liquid* and *water*, and their respective semantic relations with *water* differ.

tionaries (Hinton et al., 2014) (Section 4). We collect and release MULTILEXREL, a crowd-sourced benchmark to evaluate models for this task on a high-resource (English-Chinese) and a low-resource (English-Hindi) language pair (Section 5). Experiments show that BILEXNET substantially outperforms translation baselines and approaches the performance of a fully supervised English semantic relation classifier (Section 7). Code for BILEXNET and the MULTILEXREL dataset are available at `https://github.com/yogarshi/BiLexNet/`.

2 Related Work

Cruse (1986) describes how lexical relations can be organized into congruence relations of identity (synonymy: dog-canine), inclusion (hyponymy: dog-animal), overlap (compatibility: dog-pet), disjunction (incompatibility: cat-dog), and antonyms (open-shut), and how these relations can be used to characterize differences in meaning. Variations on these fundamental relations have been used within semantic networks such as WordNet (Fellbaum, 1998), or as the basis of a framework for inference without formal logic representations (MacCartney and Manning, 2009). Recent work on semantic relation prediction largely focuses on a single relation between words in the same language (mostly English) (Nastase et al., 2013; Vulić and Mrkšić, 2018; Glavaš and Ponzetto, 2017; Ono et al., 2015). Methods that deal with multiple semantic relations are fewer (Pantel and Pennacchiotti, 2006; Pennacchiotti and Pantel, 2006; Turney, 2008), and recent shared tasks have shown that this is a challenging problem, especially when ontologies and other structured resources are not available, and models are trained only on raw corpora (Santus et al., 2016).

In cross-lingual settings, studies of semantic relations between words are mostly limited to the translation equivalence relation. Dictionary induction aims to automatically discover words that are translations of each other using monolingual or comparable corpora (Rapp, 1995; Fung and Yee, 1998; Irvine and Callison-Burch, 2017). The task is typically framed as unsupervised learning, and models rely on distributional properties to discover words that have the same meaning in the two languages. Recently, dictionary induction has also been used to evaluate multilingual word embeddings (Lample et al., 2018; Artetxe et al., 2018; Søgaard et al., 2018), leading to significant advances on the state-of-the-art.

However, Peirsman and Padó (2011) show that automatically induced bilingual lexicons exhibit multiple semantic relations including not only synonymy, but also hypernymy and co-hyponymy. This has prompted work on identifying hypernymy in cross-lingual settings (Vyas and Carpuat, 2016; Upadhyay et al., 2018). This paper broadens the scope of relations studied in cross-lingual settings, and addresses for the first time the task of distinguishing between multiple semantic relations for words in different languages.

Previous work studying semantic relations in multiple languages has focused on the different task of cross-lingual transfer. In such settings, the focus is on identifying semantic relations between two words in the *same* language, without training data in that language. There are broadly two strategies to solve this problem. One line of work (Glavaš and Vulić, 2018; Mrkšić et al., 2017) uses model transfer, where a single model is trained on data from a high-resource language, and is then ported to the target language using cross-lingual embeddings. In contrast, Roth and Upadhyay (2019) translate training data from English into a target language using a combination of unsupervised cross-lingual embeddings (Artetxe et al., 2018) and monolingual information from the target language.

Our approach for cross-lingual semantic relation classification builds on the monolingual classifier LEXNET (Shwartz and Dagan, 2016a,b), which achieved the highest performance (45 F1)

among participating teams on the CogALex-V shared task on identification of semantic relations (Santus et al., 2016) without ontologies or structured information. We adapt LEXNET to make cross-lingual predictions by proposing to model cross-lingual relations using lexico-syntactic paths from both languages.

Finally, our training procedure uses knowledge distillation (Hinton et al., 2014) to alleviate the lack of annotated cross-lingual pairs. Knowledge distillation has been proposed to compress a model with many parameters (the *teacher* model) to a model with fewer parameters (the *student* model). It has also been used successfully to learn mappings between languages (Nakashole and Flauger, 2017) or to transfer knowledge from models trained on one language to a different target language for text classification (Xu and Yang, 2017) and belief tracking (Chen et al., 2018a), in settings where the classification labels are translation invariant. This work adapts distillation to a setting where labels might change when samples are translated.

3 BILEXNET: a Classifier for Cross-Lingual Semantic Relations

The task of classifying semantic relations is a multi-class classification problem, where the classes are the set of five semantic relations from Pavlick et al. (2015): `Equivalence` (X is the same as Y), `Forward Entail` (X is more specific than/ is a type of Y), `Backward Entail` (X is more general than/encompasses Y), `Exclusion` (X is mutually exclusive with/is opposite to Y), and `Other` (X is not related or related in other ways to Y). We choose these relations as they have been useful in describing lexical relations between English paraphrases (Pavlick et al., 2015), and in downstream natural language inference systems (MacCartney and Manning, 2007, 2009).

Our classifier, BILEXNET, adapts the LEXNET English classifier (Shwartz and Dagan, 2016a,b) to cross-lingual settings. BILEXNET represents the input word pair (x, y) by a feature vector $\mathbf{v}_{xy}$, consisting of complementary distributional and path-based features i.e. $\mathbf{v}_{xy}$= [$\mathbf{v}_x$;$\mathbf{v}_y$;$\mathbf{v}_{paths(x,y)}$]. The *distributional semantic* properties of x and y are captured by bilingual word embeddings $\mathbf{v}_x$ and $\mathbf{v}_y$. $\mathbf{v}_{paths(x,y)}$ encodes *lexico-syntactic paths* that represent the relation between words x and y in context (Hearst, 1992; Snow et al., 2004; Shwartz et al., 2016). For classification, $\mathbf{v}_{xy}$ is input to a multi-class classifier, parameterized as a feed-forward neural network with a single hidden layer.

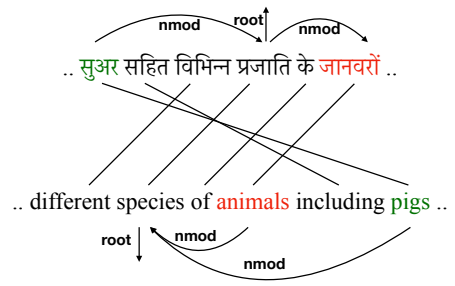

Figure 2: The English path between *animals* and *pigs* has three edges: [`X/NOUN/nmod/>`, `species/NOUN/root/^`, and `Y/NOUN/nmod/>`]. The path between animals and सुअर is defined as a combination of the English path and the Hindi path between जानवरों and सुअर.

$$\begin{aligned} \mathbf{l}_{out} &= \mathbf{W}_2 * \text{ReLU}(\mathbf{W}_1 * \mathbf{v}_{xy}) \\ \hat{l}_i &= \frac{\exp(l_{out,i})}{\sum_{j=1}^{k} \exp(l_{out,j})} \\ l_{pred} &= \arg\max_i \hat{l}_i \end{aligned} \quad (1)$$

$\mathbf{W}_1$ and $\mathbf{W}_2$ are the weights of the network, and the biases have been omitted for simplicity.

3.1 Cross-lingual Paths

In LEXNET, a lexico-syntactic path is the *sequence* of edges that lead from x to y in the dependency tree of a sentence. Each edge contains the word and part-of-speech tag of the source node, the dependency label of the edge, and the edge direction between two subsequent nodes (see Figure 2 for an example of the path connecting *pigs* and *animals*). The vector representation of each edge is formed by the concatenation of the vectors of these four components. $\mathbf{v}_{paths(x,y)}$ is obtained by encoding the sequence of edges using an LSTM (Hochreiter and Schmidhuber, 1997).

In English, these paths are extracted from sentences where x and y co-occur. However, when x and y are in different languages, a new path definition is required. For a cross-lingual pair (x_e,y_f), we extract cross-lingual paths $\mathbf{v}_{paths(x_e,y_f)}$ from a word-aligned parallel corpus (Figure 2). We first extract all parallel sentences which contain x_e on the source side and y_f on the target side. For each sentence, using word alignments, we can extract x_f, the target word aligned to x_e, and y_e the source

word aligned to y_f. We then extract a path connecting the two word in the source sentence i.e. x_e and y_e. Similarly, we also extract a corresponding path connecting the two word in the target sentence i.e. x_f and y_f, since different languages can encode the same information differently due to structural divergences (Dorr, 1994). Thus, if the parallel corpus contains m sentence pairs where x_e occurs on the source side and y_f on the target side, we extract a total of $2m$ paths. All of the $2m$ paths paths are encoded using a single LSTM, and averaged to form $\mathbf{v}_{paths(x_e,y_f)}$.

Two special cases arise from this definition. First, a path can be a single alignment link if x_e and y_f are aligned to each other i.e. $x_f = y_f$ and $y_e = x_e$. Second if no path is found in the corpus, $\mathbf{v}_{paths(x_e,y_f)}$ is set to the zero vector.

4 Weakly Supervised Training via Knowledge Distillation

Cross-lingual examples that would enable fully supervised training of BILEXNET are hard to obtain: examples of relations such as synonymy or hypernymy can be derived from multilingual WordNets (Bond and Foster, 2013), but such resources are not available for many languages, and only cover a subset of semantic relations. Instead, we introduce a dictionary-guided variant of *knowledge distillation* to train BILEXNET. This procedure only relies on a set of monolingual labeled examples that are readily available for various lexical relations in English, and a translation dictionary that maps words in the source language to the target language.

Our approach transfers knowledge from a monolingual *teacher model* to a cross-lingual *student model*. The **teacher model** is a monolingual LEXNET model (say M_e) trained on the source-language examples $S = \{(x_{e;i}, y_{e;i}, \mathbf{l}_i)\}$. Here, $x_{e;i}$ and $y_{e;i}$ are a pair of words in the same language and $\mathbf{l}_i \in \mathbb{R}^c$ is a one-hot encoding of the relation between $x_{e;i}$ and $y_{e;i}$ (the number of possible relations is c). Given $(x_{e;i}, y_{e;i}, \mathbf{l}_i) \in S$, M_e is trained by minimizing the cross-entropy loss between the predicted output $\hat{\mathbf{l}}^{e\to e}$ and the gold label $\hat{\mathbf{l}}_i$:

$$L_1 = -\sum_{j=1}^{c} l_{ij} \log \hat{l}_j^{e\to e} \tag{2}$$

BILEXNET plays the role of the **student model** (denoted M_{ef}) and is trained to make predictions that agree with those of the teacher model. The student model is trained using **weak supervision** which is obtained by using a bilingual dictionary D to translate the right side of each training pair into the target language S to obtain $S' = \{(x_{e;i}, T_i, \mathbf{l}_i)\}$, where $T_i = \{t_{i1}, t_{i2}, .., t_{in}\}$ is the set of translations of $y_{e;i}$ in D. S' serves as weak supervision because semantic relations are not translation invariant (Figure 1), and hence the label $\mathbf{l}_i$ is not correct for every $(x_{e;i}, t_{ik})$ pair.

To extract useful training signals from the weak supervision, we use an **attention mechanism** which guides the model to attend to translations that preserve the monolingual label. The attention component constructs the input representation for the cross-lingual model M_{ef} in Equation 1 by averaging representations for all translation candidates, giving more weight to those that are likely to preserve the monolingual label. Given a training sample $(x_{e;i}, T_i, \mathbf{l}_i) \in S'$ with $T_i = \{t_{i1}, t_{i2}, .., t_{in}\}$, the score for a candidate translation t_{ik} is calculated using the word embeddings of $x_{e;i}$ and t_{ik}, along with $\mathbf{l}$, an embedding of the gold label $\mathbf{l}_i$ as features to a feed-forward network f (with one hidden layer). $\mathbf{l}$ is provided to help select translations that are consistent with the correct label for the monolingual pair. The scores for all translations are converted to probabilities using the softmax function, and the input features $\mathbf{v}'_{x_{e;i}y_{e;i}}$ for the student model M_{ef} are a sum of the features obtained from each of these translations, weighted by the probabilities.

$$score((x_{e;i}, t_{ik}), \mathbf{l}_i) = f([\mathbf{x}_i; \mathbf{t}_{ik}; \mathbf{l}]) \tag{3}$$

$$p(t_{ik}) = \frac{\exp(score(t_{ik}))}{\sum_{j=1}^{n} \exp(score(t_{ij}))}$$

$$\mathbf{v}'_{x_{e;i}y_{e;i}} = \sum_{k=1}^{n} p(t_{ik}) \mathbf{v}_{x_{e;i}t_{ik}} \tag{4}$$

The student model is then trained to maximize the **distillation objective**:

$$L_2 = -\sum_{j=1}^{c} [(1-\alpha)\, l_{ij} \log \hat{l}_j^{e\to f} + \alpha\, \hat{l}_j^{e\to e} \log(\frac{\hat{l}_j^{e\to f}}{\hat{l}_j^{e\to e}})] \tag{5}$$

where $\hat{\mathbf{l}}^{e\to e}$ is calculated using M_e, $\hat{\mathbf{l}}^{e\to f}$ is calculated using the attended representation $\mathbf{v}'_{x_{e;i}y_{e;i}}$ as input to M_{ef} and α is an interpolation parameter. The first term is again a cross-entropy loss

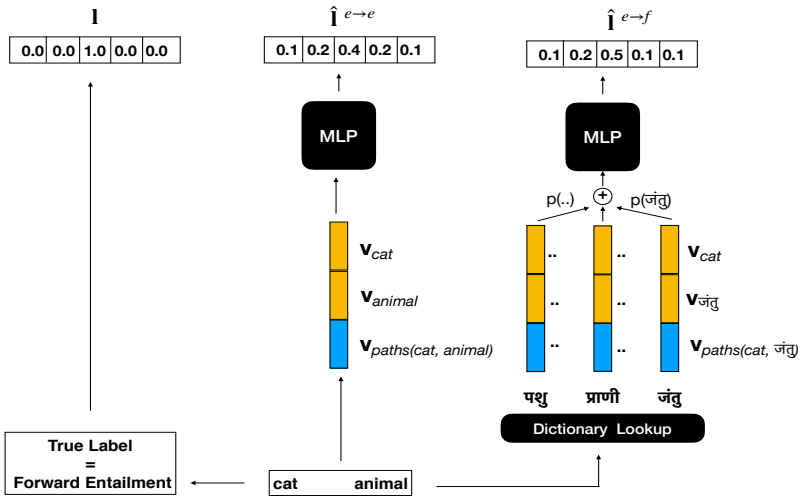

Figure 3: Illustration of weakly supervised training: For a given English example (*cat*, *animal*), we generate predictions $\hat{\mathbf{l}}^{e \to e}$ using the monolingual English teacher model. Simultaneously, we also generate predictions $\hat{\mathbf{l}}^{e \to f}$ using the cross-lingual *student* model after translating one of the two English words using a dictionary. The cross-lingual classifier attends to all translation candidates and predicts a class based on a weighted average of their features. The loss is defined as CROSS-ENTROPY($\hat{\mathbf{l}}^{e \to e}$, l) + CROSS-ENTROPY($\hat{\mathbf{l}}^{e \to f}$, l) + KL-DIVERGENCE($\hat{\mathbf{l}}^{e \to f}$, $\hat{\mathbf{l}}^{e \to e}$).

that aims to measure how well the cross-lingual model M_{ef} predicts the relation given $\mathbf{v}'_{x_{e;i}y_{e;i}}$. The second term uses KL-Divergence (Kullback and Leibler, 1951) to penalize differences in predictions by M_{ef} on the cross-lingual input $\mathbf{v}'_{x_{e;i}y_{e;i}}$ and the predictions by M_e on the monolingual input $\mathbf{v}_{x_{e;i}y_{e;i}}$. As is typical in distillation, we flatten the softmax of both inputs to the KL-Divergence term with a temperature parameter τ.

5 MULTILEXREL: A Dataset for Cross-lingual Semantic Relations

Existing resources containing annotated cross-lingual lexical relations are limited in scope, quality, and quantity. For instance, in previous work (Upadhyay et al., 2018), we provide datasets annotated cross-lingual hypernymy, but do not consider other relations. On the other hand, resources such as bilingual dictionaries or the Open Multilingual WordNet (Bond and Foster, 2013) can be mined for examples of synonyms, hypernyms and hyponyms, but these are likely to be noisy as these resources are created in a semi-automatic way.

In this work, we crowdsource[1] MULTILEXREL, a set of new high-quality annotations for English-Hindi (En-Hi) and English-Chinese (En-Zh) word pairs using the natural logic relations laid out in Section 3. We leverage monolingual annotations

Relation	En-Hi	En-Zh
Equivalence	158	174
Forward Entail	220	240
Backward Entail	215	236
Exclusion	124	154
Other	323	94
Total	1040	898

Table 2: Distribution of the five semantic relations for the two crowdsourced test sets.

to speed up the process and enable comparisons between monolingual and cross-lingual models. We use Google Translate to translate one side of a randomly sampled subset of the gold-standard dataset of semantic relations created by Pavlick et al. (2015), and ask crowdworkers whether the semantic relation holds after translation. Each example is annotated by five annotators and annotations are aggregated using MACE (Hovy et al., 2013), a Bayesian model that estimates the trustworthiness of annotators and accordingly assigns a label to each instance. The distributions of the five relations for each language pair are shown in Table 2. 40-45% of the examples shown to annotators were deemed to not preserve the monolingual relation after translation. The final test sets consist of the remaining 55-60% examples.[2]

[2] A detailed description is in the appendix.

6 Experimental Settings

MULTILEXREL is used as a test set to evaluate our models. Training only requires English labeled examples, and other resources derived from raw monolingual and parallel corpora.

6.1 Data

English Supervision The English training samples are derived from the English Lexical-XXXL PPDB. After filtering away pairs containing non-alphabetic characters, we choose a random sample as training pairs. The number of samples for all classes is balanced, except `Exclusion` (since there are fewer examples of this class in PPDB). All in all, the size of the training set is ∼20K pairs. Like previous work (Levy et al., 2015), we ensure a lexical split where the English words in the test data are not seen in the training data. This makes the task challenging as it prevents the model from memorizing patterns of words such as their "prototypicality" for certain relations i.e. whether certain words are likely to appear in specific relations.

Validation data Since we assume no access to labeled cross-lingual examples, we need to define a validation set using the resources available to us. We construct a validation set by randomly removing 1000 pairs from the training data, and automatically translating the right side of each example with the bilingual dictionary used for training. This process yields a noisy validation set, which is solely used for tuning hyper-parameters.

Unlabeled Resources The bilingual dictionary for knowledge distillation is obtained from the MUSE project (Lample et al., 2018) for En-Hi, while the MDBG dictionary is used for En-Zh.[3] We use FastText bilingual embeddings (Bojanowski et al., 2017).[4] We extract English paths for the monolingual model from a dump of the English Wikipedia.[5] Cross-lingual paths are extracted from a random sample of the WMT18 parallel corpora[6] for En-Zh (∼5M sentences) and the IIT Bombay English-Hindi corpus (Kunchukuttan et al., 2018) for En-Hi (∼1M sentences). All corpora are parsed using YaraParser (Rasooli and Tetreault, 2015) trained on the treebank of the corresponding language from the Universal Dependencies (v2.2) project (McDonald et al., 2013). Tokenization is performed using the Moses tokenizer for English (Koehn et al., 2007), the Indic NLP tokenizer for Hindi,[7] and the Jieba word segmenter for Chinese.[8]

6.2 Model Configurations and Baselines

Model Configuration The path-encoder LSTM has two layers with 60 hidden units each, with dropout (Srivastava et al., 2014) applied after the first layer. All feed-forward neural networks have a single hidden layer with 50 hidden units and dropout regularization. All models are trained in mini-batches of size 4 using the Adam optimizer (Kingma and Ba, 2015) with initial learning rate set to 10^{-3}. The temperature parameter τ for knowledge distillation is tuned over $\{1.0, 1.5, 2.0, 5.0\}$, and the interpolation parameter α over $\{0.75, 0.90\}$.

English-only Model: EnLexNet We also use a vanilla LEXNET model applied to a monolingual test set in order to measure the gap between cross-lingual performance and monolingual performance. ENLEXNET is trained on the same English samples used for training the BILEXNET model, and evaluated on the En-En examples used to generate cross-lingual examples in Section 5.[9]

Baselines Our experiments aim to assess how the direct cross-lingual modeling of semantic relations in BILEXNET impacts predictions, and to isolate the impact of key training components: knowledge distillation and translation selection via attention. We compare against the following baselines:

RANDOM BASELINE: Randomly assign one of the five semantic relations to each word pair.

TRANSLATION BASELINE: This baseline combines dictionary translation and the English-only system ENLEXNET to gauge the relative difficulty of predicting semantic relations across languages rather than in English only. Each pair (x_e, y_f) in the test set is translated into English using the bilingual dictionary D. Since y_f can have multiple

[9] We re-implement the LEXNET model and verify its accuracy by replicating results on the CogALex dataset.

translations, we pair x_e with each of these translations, and use ENLEXNET to predict the relation for each of these pairs. The relation for (x_e, y_f) is then chosen as the most general relation among those predicted for the translated pairs according to the order in which they appear in Table 2.[10]

BILEXNET (NO DISTILLATION) A simple strategy for cross-lingual transfer consists of seeding a vanilla LEXNET model with bilingual embeddings in the source and target languages before training. This strategy has been successfully used for other NLP tasks (Klementiev et al., 2012; Guo et al., 2015, *inter alia*). By keeping the embeddings fixed, we can use source language data to train the monolingual LEXNET model using features based on source embeddings and source language paths as usual. At inference time, the model uses both the source and target embeddings as input, and the cross-lingual paths defined above.

SPECIALIZED TENSOR MODEL (STM) How does a model that has primarily been used for comparing words in the same language perform on cross-lingual comparisons? Our final baseline aims to answer this question. Proposed by Glavaš and Vulić (2018), STM is a neural architecture for identifying semantic relations that achieves state-of-the-art performance on two English dataset. STM is based on the hypothesis that specialized word embeddings are necessary to accurately disambiguate between semantic relations.

More precisely, STM assumes that different specializations of generic word embeddings are needed to recognize different relations and that interactions between the specialized vectors can be used to identify the semantic relations. These different specializations are implemented using K feed-forward neural networks. Given a word pair, STM takes in as input a pair of generic word embeddings for the word pair which are then specialized by the K transformations. Each pair of corresponding specialized embeddings is used to calculate a score based on a non-linear transformation of their bilinear product. Finally, the K scores obtained from K pairs of specialized embeddings are used as features to train a multi-class classifier.

Besides English, STM has also been used for cross-lingual *transfer*, where a model trained on one language (say English) is used to test on word-pairs in another language (say German). Here, we use STM in a new setting to predict the semantic relation between two words in different languages.

We use the official implementation of STM[11] with the same bilingual embeddings used by BILEXNET. We tune three hyperparameters on the validation set (a) The size of the specialized tensors {100, 200, 300, 500} (b) The number of specialization functions {3, 5, 7}, and (c) The learning rate {0.0001, 0.0003}. Default values are used for all other hyper-parameters.

7 Results

Tables 3 summarizes results obtained on the MULTILEXREL test sets. BILEXNET achieves F1 scores that are roughly double of those obtained by the random baseline for 5-way classification.

Impact of cross-lingual modeling We assess the impact of direct cross-lingual modeling in BILEXNET by comparing against the TRANSLATION BASELINE. Using a translation dictionary to naïvely convert cross-lingual relation prediction to an English-only task, the translation baseline F1 scores are 8 to 13 points higher than RANDOM for both language pairs. This difference can be attributed to easy examples where English semantic relations are preserved by simple dictionary translation. BILEXNET further improves F1 by 8 to 15 points over the TRANSLATION BASELINE, primarily by improving recall.

Supervised English system Without cross-lingual training samples, we cannot compare weakly supervised and fully supervised training for BILEXNET in a controlled fashion. However, the supervised monolingual ENLEXNET model (Section 6) evaluated on the En-En test set offers a reference point: remarkably the F1 scores of BILEXNET are only 1 to 3 points lower than those obtained by the supervised English model ($\sim$44 on the En-En test set).

Impact of knowledge distillation We compare the full BILEXNET model to the naïve baseline (BILEXNET (NO DISTILLATION)) that only relies on embeddings for cross-lingual transfer and does not perform cross-lingual distillation. This approach performs on par with or a little better than the translation baseline, but $\sim$9 points worse than the full BILEXNET model, losing on both

[10] We also experimented with a voting based approach for combination, but it generally performed worse.

Model	En-Hi			En-Zh		
	P	R	F	P	R	F
RANDOM BASELINE	22.9 ± 1.3	20.9 ± 2.5	21.4 ± 1.4	22.9 ± 1.3	20.9 ± 2.5	21.4 ± 1.4
TRANSLATION BASELINE	30.1 ± 1.7	26.3 ± 1.3	28.3 ± 1.5	50.1 ± 2.2	32.8 ± 0.8	33.0 ± 1.0
STM (Glavaš and Vulić, 2018)	32.0	33.0	29.0	20.0	15.0	16.0
BILEXNET (No distillation)	34.9 ± 1.2	34.3 ± 0.6	32.2 ± 0.8	41.7 ± 6.4	33.5 ± 6.2	32.6 ± 7.2
BILEXNET (No attention)	47.2 ± 1.0	42.9 ± 1.8	41.9 ± 2.3	45.0 ± 1.5	40.8 ± 1.8	39.8 ± 0.8
BILEXNET (Full)	47.7 ± 1.2	44.2 ± 0.8	**43.3 ± 1.0**	48.3 ± 1.6	41.6 ± 1.1	**41.1 ± 0.9**

Table 3: Precision (P), Recall (R) and F1-score (F) for BILEXNET and contrastive baselines on the two MULTILEXREL test sets. All configurations (except STM) are trained with five random seeds. We report the mean score and standard deviation. The full BILEXNET model performs best and is consistently better with attention.

precision and recall. This result confirms the benefit of aligning training and test conditions for our model with knowledge distillation and not relying solely on embeddings. These results are consistent with prior findings on distributional representations:

- Distributional representations have difficulties in discriminating between multiple semantic relations (Chersoni et al., 2016). As such, relying solely on word embeddings for cross-lingual transfer can cause loss of knowledge during transfer.
- Syntactic divergences cause differences in paths in the source and target languages. This can cause a distribution shift between the features seen by the classifier during training and test time, thereby affecting performance. Again, word embeddings are not sufficient to bridge the gap between the distributions of the two languages (Chen et al., 2018b).

Impact of attention We test the impact of the attention model in BILEXNET by removing it, and instead translating training samples for distillation using the single most frequent translation. Removing attention yields small but consistent degradations, suggesting that attending to multiple translations is beneficial, but leaves room for improvement. We analyze the behavior of the attention model in the next section.

Specialization Finally, we observe F1 scores of STM are significantly worse than those of BILEXNET. In fact, it is the weakest model for En-Zh, and is only 3 points better than the translation baseline for En-Hi. The relatively poor performance of STM highlights that our cross-lingual task, which directly compares words in two languages, is fundamentally different from the cross-lingual transfer task, where models trained in one language are ported to other languages. Thus, models such as STM, which have been designed for transfer, may not be directly suitable for our task.

8 Analysis

This section further breaks down the results, and highlight some successes and failures of BILEXNET to guide future work on cross-lingual semantic relation classification.

Performance Per Class We break down the performance of the BILEXNET model per target relation (Table 4). The `Equivalence` and `Exclusion` classes are the hardest to predict correctly, which is consistent with our monolingual results and those from prior work (Shwartz and Dagan, 2016a): distributional models have trouble distinguishing synonyms from antonyms (Yih et al., 2012) and synonyms rarely occur in the same sentence, and hence path-based methods are less useful for this class. However, in BILEXNET, words of the `Equivalence` class can occur in a parallel sentence pair where they are aligned to each other. Thus, there is a direct signal for examples of this class which helps discriminate between `Equivalence` and `Exclusion`.

The largest fraction of errors are caused by the model predicting `Other` instead of a specific relation. This suggests that special treatment of this class might improve performance, perhaps by using a multi-step process which filters out pairs not related under the relations that we are targeting, and then performs 4-way classification for the remaining examples. This is similar to the the Co-

Class	En-Hi	En-Zh	En-En
Equivalence	33	30	31
Exclusion	33	28	23
Forward Entail	47	48	48
Backward Entail	45	58	48
Other	51	29	53

Table 4: Per-class F1 scores for median En-Hi and En-Zh BILEXNET model and the ENLEXNET model.

gALex shared task (Santus et al., 2016), where the first part of the task is to eliminate *completely unrelated* pairs, before predicting relations on the remaining pairs. However, filtering out *unrelated* pairs is an easier task than filtering pairs in the Other category.

Missing cross-lingual paths Cross-lingual paths might not exist for all word pairs, particularly for language pairs with limited parallel data such as En-Hi. BILEXNET would then only rely on word embeddings as features to predict semantic relations. We assess the impact of missing paths by comparing the classification performance on pairs which have cross-lingual paths (70% of the test), against pairs which do not have paths in the En-Hi setting. The former subset has a higher F1 score (44.6) than the latter (40.2), mainly due to differences in recall. This difference in performance also confirms that the cross-lingual paths complement word embeddings, in the same way that monolingual paths do.

Attention Analysis We complement ablation experiments in Table 3 by examining a random sample of 25 monolingual training pairs (x_e, y_e) where y_e has multiple translations in the bilingual dictionary. We manually check for how many pairs the model places the highest attention weight on a translation that preserves the relation label of the monolingual pair. This happens in 64% of the cases (16 out of 25). The attention model is often able to modulate the choice of the right translation of y_e based on the context provided by x_e and the gold label. For example, given the monolingual example (*drop*, *fall*, Forward Entail) the model places the highest weight on the Hindi word गिरा, which captures the "moving downward" sense. On the other hand, for the example (*autumn*, *fall*, Equivalence), the model correctly identifies पतझड as the right translation.

There still remains a lot of overhead for improving the attention component. Some failure cases in the 25 examples occur for pairs where the set of translations of y_e contains an incorrect translation which is totally unrelated to x_e or y_e. For example, given (*country*, *uganda*), the model chooses the word कैंडल (transliteration for *candle*) and not युगांडा (transliteration for *uganda*). Of course, this is an extreme example, but such errors are also more likely to occur when the noisy translation is in the same domain as x_e and y_e. Fixing such errors can help improve the training process.

9 Conclusion

This work contributes data and models to the task of classifying semantic relations between words in different languages with only monolingual English supervision. We introduced MULTILEXREL, a dataset of about 1000 English-Hindi and 900 English-Chinese word pairs annotated with the natural logic lexical entailment classes of MacCartney and Manning (2007), and BILEXNET, a cross-lingual relation classification model.

We also proposed a knowledge distillation algorithm for BILEXNET, which only needs annotated monolingual examples and a bilingual dictionary. Unlike previous uses of knowledge distillation for cross-lingual transfer, our approach does not assume that labels are translation invariant, and relies on an attention mechanism to select translations that best explain a given label. Experiments show that this method largely outperforms baselines that use bilingual embeddings or dictionaries more naïvely for cross-lingual transfer, and that it approaches the performance of fully supervised systems on an English-only version of the task.

gan_weechung@u.nus.edu

Abstract

Contextualized word representations are able to give different representations for the same word in different contexts, and they have been shown to be effective in downstream natural language processing tasks, such as question answering, named entity recognition, and sentiment analysis. However, evaluation on word sense disambiguation (WSD) in prior work shows that using contextualized word representations does not outperform the state-of-the-art approach that makes use of non-contextualized word embeddings. In this paper, we explore different strategies of integrating pre-trained contextualized word representations and our best strategy achieves accuracies exceeding the best prior published accuracies by significant margins on multiple benchmark WSD datasets.

1 Introduction

Word sense disambiguation (WSD) automatically assigns a pre-defined sense to a word in a text. Different senses of a word reflect different meanings a word has in different contexts. Identifying the correct word sense given a context is crucial in natural language processing (NLP). Unfortunately, while it is easy for a human to infer the correct sense of a word given a context, it is a challenge for NLP systems. As such, WSD is an important task and it has been shown that WSD helps downstream NLP tasks, such as machine translation (Chan et al., 2007a) and information retrieval (Zhong and Ng, 2012).

A WSD system assigns a sense to a word by taking into account its context, comprising the other words in the sentence. This can be done through discrete word features, which typically involve surrounding words and collocations trained using a classifier (Lee et al., 2004; Ando, 2006; Chan et al., 2007b; Zhong and Ng, 2010). The classifier can also make use of continuous word representations of the surrounding words (Taghipour and Ng, 2015; Iacobacci et al., 2016). Neural WSD systems (Kågebäck and Salomonsson, 2016; Raganato et al., 2017b) feed the continuous word representations into a neural network that captures the whole sentence and the word representation in the sentence. However, in both approaches, the word representations are independent of the context.

Recently, pre-trained contextualized word representations (Melamud et al., 2016; McCann et al., 2017; Peters et al., 2018; Devlin et al., 2019) have been shown to improve downstream NLP tasks. Pre-trained contextualized word representations are obtained through neural sentence encoders trained on a huge amount of raw texts. When the resulting sentence encoder is fine-tuned on the downstream task, such as question answering, named entity recognition, and sentiment analysis, with much smaller annotated training data, it has been shown that the trained model, with the pre-trained sentence encoder component, achieves new state-of-the-art results on those tasks.

While demonstrating superior performance in downstream NLP tasks, pre-trained contextualized word representations are still reported to give lower accuracy compared to approaches that use non-contextualized word representations (Melamud et al., 2016; Peters et al., 2018) when evaluated on WSD. This seems counter-intuitive, as a neural sentence encoder better captures the surrounding context that serves as an important cue to disambiguate words. In this paper, we explore different strategies of integrating pre-trained contextualized word representations for WSD. Our best strategy outperforms prior methods of incorporating pre-trained contextualized word representations and achieves new state-of-the-art accuracy on multiple benchmark WSD datasets.

The following sections are organized as follows.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5297–5306,

Section 2 presents related work. Section 3 describes our pre-trained contextualized word representation. Section 4 proposes different strategies to incorporate the contextualized word representation for WSD. Section 5 describes our experimental setup. Section 6 presents the experimental results. Section 7 discusses the findings from the experiments. Finally, Section 8 presents the conclusion.

2 Related Work

Continuous word representations in real-valued vectors, or commonly known as word embeddings, have been shown to help improve NLP performance. Initially, exploiting continuous representations was achieved by adding real-valued vectors as classification features (Turian et al., 2010). Taghipour and Ng (2015) fine-tuned non-contextualized word embeddings by a feed-forward neural network such that those word embeddings were more suited for WSD. The fine-tuned embeddings were incorporated into an SVM classifier. Iacobacci et al. (2016) explored different strategies of incorporating word embeddings and found that their best strategy involved exponential decay that decreased the contribution of surrounding word features as their distances to the target word increased.

The neural sequence tagging approach has also been explored for WSD. Kågebäck and Salomonsson (2016) proposed bidirectional long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) for WSD. They concatenated the hidden states of the forward and backward LSTMs and fed the concatenation into an affine transformation followed by softmax normalization, similar to the approach to incorporate a bidirectional LSTM adopted in sequence labeling tasks such as part-of-speech tagging and named entity recognition (Ma and Hovy, 2016). Raganato et al. (2017b) proposed a self-attention layer on top of the concatenated bidirectional LSTM hidden states for WSD and introduced multi-task learning with part-of-speech tagging and semantic labeling as auxiliary tasks. However, on average across the test sets, their approach did not outperform SVM with word embedding features. Subsequently, Luo et al. (2018) proposed the incorporation of glosses from WordNet in a bidirectional LSTM for WSD, and reported better results than both SVM and prior bidirectional LSTM models.

A neural language model (LM) is aimed at predicting a word given its surrounding context. As such, the resulting hidden representation vector captures the context of a word in a sentence. Melamud et al. (2016) designed *context2vec*, which is a one-layer bidirectional LSTM trained to maximize the similarity between the hidden state representation of the LSTM and the target word embedding. Peters et al. (2018) designed ELMo, which is a two-layer bidirectional LSTM language model trained to predict the next word in the forward LSTM and the previous word in the backward LSTM. In both models, WSD was evaluated by nearest neighbor matching between the test and training instance representations. However, despite training on a huge amount of raw texts, the resulting accuracies were still lower than those achieved by WSD approaches with pre-trained non-contextualized word representations.

End-to-end neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015) learns to generate an output sequence given an input sequence, using an encoder-decoder model. The encoder captures the contextualized representation of the words in the input sentence for the decoder to generate the output sentence. Following this intuition, McCann et al. (2017) trained an encoder-decoder model on parallel texts and obtained pre-trained contextualized word representations from the encoder.

3 Pre-Trained Contextualized Word Representation

The contextualized word representation that we use is BERT (Devlin et al., 2019), which is a bidirectional transformer encoder model (Vaswani et al., 2017) pre-trained on billions of words of texts. There are two tasks on which the model is trained, i.e., masked word and next sentence prediction. In both tasks, prediction accuracy is determined by the ability of the model to understand the context.

A transformer encoder computes the representation of each word through an attention mechanism with respect to the surrounding words. Given a sentence x_1^n of length n, the transformer computes the representation of each word x_i through a multi-head attention mechanism, where the query vector is from x_i and the key-value vector pairs are from the surrounding words $x_{i'}$ ($1 \leq i' \leq n$). The word representation produced by the transformer

captures the contextual information of a word.

The attention mechanism can be viewed as mapping a query vector $\mathbf{q}$ and a set of key-value vector pairs $(\mathbf{k}, \mathbf{v})$ to an output vector. The attention function $A(\cdot)$ computes the output vector which is the weighted sum of the value vectors and is defined as:

$$A(\mathbf{q}, \mathbf{K}, \mathbf{V}, \rho) = \sum_{(\mathbf{k},\mathbf{v})\in(\mathbf{K},\mathbf{V})} \alpha(\mathbf{q}, \mathbf{k}, \rho)\mathbf{v} \quad (1)$$

$$\alpha(\mathbf{q}, \mathbf{k}, \rho) = \frac{\exp(\rho \mathbf{k}^\top \mathbf{q})}{\sum_{\mathbf{k}'\in\mathbf{K}} \exp(\rho \mathbf{k}'^\top \mathbf{q})} \quad (2)$$

where $\mathbf{K}$ and $\mathbf{V}$ are matrices, containing the key vectors and the value vectors of the words in the sentence respectively, and $\alpha(\mathbf{q}, \mathbf{k}, \rho)$ is a scalar attention weight between $\mathbf{q}$ and $\mathbf{k}$, re-scaled by a scalar ρ.

Two building blocks for the transformer encoder are the multi-head attention mechanism and the position-wise feed-forward neural network (FFNN). The multi-head attention mechanism with H heads leverages the attention function in Equation 1 as follows:

$$\text{MH}(\mathbf{q}, \mathbf{K}, \mathbf{V}, \rho) = \mathbf{W}_{\text{MH}} \bigoplus_{\eta=1}^{H} \text{head}_\eta(\mathbf{q}, \mathbf{K}, \mathbf{V}, \rho) \quad (3)$$

$$\text{head}_\eta(\mathbf{q}, \mathbf{K}, \mathbf{V}, \rho) = A(\mathbf{W}^{\mathbf{Q}}_\eta \mathbf{q}, \mathbf{W}^{\mathbf{K}}_\eta \mathbf{K}, \mathbf{W}^{\mathbf{V}}_\eta \mathbf{V}, \rho) \quad (4)$$

where $\oplus$ denotes concatenation of vectors, $\mathbf{W}_{\text{MH}} \in \mathbb{R}^{d_{\text{model}} \times H d_{\mathbf{v}}}$, $\mathbf{W}^{\mathbf{Q}}_\eta, \mathbf{W}^{\mathbf{K}}_\eta \in \mathbb{R}^{d_{\mathbf{k}} \times d_{\text{model}}}$, and $\mathbf{W}^{\mathbf{V}}_\eta \in \mathbb{R}^{d_{\mathbf{v}} \times d_{\text{model}}}$. The input vector $\mathbf{q} \in \mathbb{R}^{d_{\text{model}}}$ is the hidden vector for the ambiguous word, while input matrices $\mathbf{K}, \mathbf{V} \in \mathbb{R}^{d_{\text{model}} \times n}$ are the concatenation of the hidden vectors of all words in the sentence. For each attention head, the dimension of both the query and key vectors is $d_{\mathbf{k}}$ while the dimension of the value vector is $d_{\mathbf{v}}$. The encoder model dimension is d_{model}.

The position-wise FFNN performs a non-linear transformation on the attention output corresponding to each input word position as follows:

$$\text{FF}(\mathbf{u}) = \mathbf{W}_{\text{FF2}}(\max(0, \mathbf{W}_{\text{FF1}}\mathbf{u} + \mathbf{b}_{\text{FF1}})) + \mathbf{b}_{\text{FF2}} \quad (5)$$

in which the input vector $\mathbf{u} \in \mathbb{R}^{d_{\text{model}}}$ is transformed to the output vector with dimension d_{model} via a series of linear projections with the ReLU activation function.

For the hidden layer l ($1 \leq l \leq L$), the self-attention sub-layer output $\mathbf{f}^l_i$ is computed as follows:

$$\mathbf{f}^l_i = \text{LayerNorm}(\chi^l_{\mathbf{h},i} + \mathbf{h}^{l-1}_i)$$

$$\chi^l_{\mathbf{h},i} = \text{MH}^l_{\mathbf{h}}(\mathbf{h}^{l-1}_i, \mathbf{h}^{l-1}_{1:n}, \mathbf{h}^{l-1}_{1:n}, \frac{1}{\sqrt{d_{\mathbf{v}}}})$$

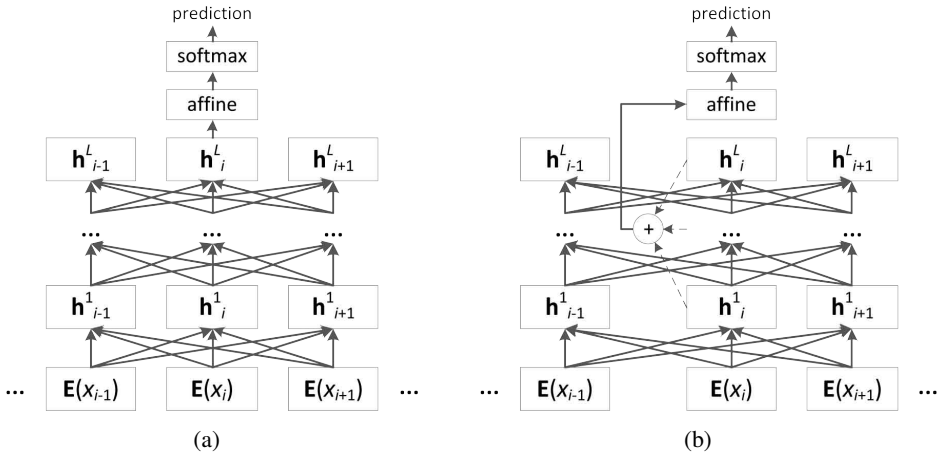
where LayerNorm refers to layer normalization (Ba et al., 2016) and the superscript l and subscript $\mathbf{h}$ indicate that each encoder layer l has an independent set of multi-head attention weight parameters (see Equations 3 and 4). The input for the first layer is $\mathbf{h}^0_i = \mathbf{E}(x_i)$, which is the non-contextualized word embedding of x_i.

The second sub-layer consists of the position-wise fully connected FFNN, computed as:

$$\mathbf{h}^l_i = \text{LayerNorm}(\text{FF}^l_{\mathbf{h}}(\mathbf{f}^l_i) + \mathbf{f}^l_i)$$

where, similar to self-attention, an independent set of weight parameters in Equation 5 is defined in each layer.

4 Incorporating Pre-Trained Contextualized Word Representation



As BERT is trained on the masked word prediction task, which is to predict a word given the surrounding (left and right) context, the pre-trained model already captures the context. In this section, we describe different techniques of leveraging BERT for WSD, broadly categorized into nearest neighbor matching and linear projection of hidden layers.

4.1 Nearest Neighbor Matching

A straightforward way to disambiguate word sense is through 1-nearest neighbor matching. We compute the contextualized representation of each word in the training data and the test data through BERT. Given a hidden representation $\mathbf{h}^L_i$ at the L-th layer for word x_i in the test data, nearest neighbor matching finds a vector $\mathbf{h}^*$ in the L-th layer from the training data such that

$$\mathbf{h}^* = \arg\max_{\mathbf{h}'} \cos(\mathbf{h}^L_i, \mathbf{h}') \quad (6)$$

where the sense assigned to x_i is the sense of the word whose contextualized representation is $\mathbf{h}^*$. This WSD technique is adopted in earlier work on contextualized word representations (Melamud et al., 2016; Peters et al., 2018).

(a) (b)

Figure 1: Illustration of WSD models by linear projection of (a) the last layer and (b) the weighted sum of all layers.

4.2 Linear Projection of Hidden Layers

Apart from nearest neighbor matching, we can perform a linear projection of the hidden vector $\mathbf{h}_i$ by an affine transformation into an output sense vector, with its dimension equal to the number of senses for word x_i. The output of this affine transformation is normalized by softmax such that all its values sum to 1. Therefore, the predicted sense $\mathbf{s}_i$ of word x_i is formulated as

$$\mathbf{s}_i = \text{softmax}(\mathbf{W}^{\text{lexelt}(x_i)}\mathbf{h}_i + \mathbf{b}^{\text{lexelt}(x_i)}) \quad (7)$$

where $\mathbf{s}_i$ is a vector of predicted sense distribution for word x_i, while $\mathbf{W}^{\text{lexelt}(x_i)}$ and $\mathbf{b}^{\text{lexelt}(x_i)}$ are respectively the projection matrix and bias vector specific to the lexical element (lexelt) of word x_i, which consists of its lemma and optionally its part-of-speech tag. We choose the sense corresponding to the element of $\mathbf{s}_i$ with the maximum value.

Training the linear projection model is done by the back-propagation algorithm, which updates the model parameters to minimize a cost function. Our cost function is the negative log-likelihood of the softmax output value that corresponds to the tagged sense in the training data. In addition, we propose two *novel* ways of incorporating BERT's hidden representation vectors to compute the sense output vector, which are described in the following sub-subsections.

4.2.1 Last Layer Projection

Similar to the nearest neighbor matching model, we can feed the hidden vector of BERT in the last layer, $\mathbf{h}_i^L$, into an affine transformation followed by softmax. That is, $\mathbf{h}_i$ in Equation 7 is instantiated by $\mathbf{h}_i^L$. The last layer projection model is illustrated in Figure 1(a).

4.2.2 Weighted Sum of Hidden Layers

BERT consists of multiple layers stacked one after another. Each layer carries a different representation of word context. Taking into account different hidden layers may help the WSD system to learn from different context information encoded in different layers of BERT.

To take into account all layers, we compute the weighted sum of all hidden layers, $\mathbf{h}_i^l$, where $1 \leq l \leq L$, corresponding to a word position i, through attention mechanism. That is, $\mathbf{h}_i$ in Equation 7 is replaced by the following equation:

$$\mathbf{h}_i = A(\mathbf{m}, \mathbf{W}^{\mathbf{s}}\mathbf{h}_i^{1:L}, \mathbf{h}_i^{1:L}, 1) \quad (8)$$

where $\mathbf{m} \in \mathbb{R}^{d_{\text{model}}}$ is a projection vector to obtain scalar values with the key vectors. The model with weighted sum of all hidden layers is illustrated in Figure 1(b).

4.2.3 Gated Linear Unit

While the contextualized representations in the BERT hidden layer vectors are features that determine the word sense, some features are more useful than the others. As such, we propose filtering the vector values by a gating vector whose values range from 0 to 1. This mechanism is known as the gated linear unit (GLU) (Dauphin et al., 2017), which is formulated as

$$\text{GLU}(\mathbf{h}) = (\mathbf{h}+\mathbf{W}^{\mathbf{h}}\mathbf{h}+\mathbf{b}^{\mathbf{h}})\odot\sigma(\mathbf{W}^{\mathbf{g}}\mathbf{h}+\mathbf{b}^{\mathbf{g}}) \quad (9)$$

where $\mathbf{W}^{\mathbf{h}}$ and $\mathbf{W}^{\mathbf{g}}$ are separate projection matrices and $\mathbf{b}^{\mathbf{h}}$ and $\mathbf{b}^{\mathbf{g}}$ are separate bias vectors. The

symbols $\sigma(\cdot)$ and $\odot$ denote the sigmoid function and element-wise vector multiplication operation respectively.

GLU transforms the input vector $\mathbf{h}$ by feeding it to two separate affine transformations. The second transformation is used as the sigmoid gate to filter the input vector, which is summed with the vector after the first affine transformation.

5 Experimental Setup

We conduct experiments on various WSD tasks. The description and the statistics for each task are given in Table 1. For English, a lexical element (lexelt) is defined as a combination of lemma and part-of-speech tag, while for Chinese, it is simply the lemma, following the OntoNotes setup.

We exploit English $\text{BERT}_{\text{BASE}}$ for the English tasks and Chinese BERT for the Chinese task. We conduct experiments with different strategies of incorporating BERT as described in Section 4, namely 1-nearest neighbor matching (**1-nn**) and linear projection. In the latter technique, we explore strategies including **simple** last layer projection, layer weighting (**LW**), and gated linear unit (**GLU**).

In the linear projection model, we train the model by the Adam algorithm (Kingma and Ba, 2015) with a learning rate of 10^{-3}. The model parameters are updated per mini-batch of 16 sentences. As update progresses, we pick the best model parameters from a series of neural network updates based on accuracy on a held-out development set, disjoint from the training set.

The state-of-the-art supervised WSD approach takes into account features from the neighboring sentences, typically one sentence to the left and one to the right apart from the current sentence that contains the ambiguous words. We also exploit this in our model, as BERT supports inputs with multiple sentences separated by a special `[SEP]` symbol.

For English all-words WSD, we train our WSD model on SemCor (Miller et al., 1994), and test it on Senseval-2 (SE2), Senseval-3 (SE3), SemEval 2013 task 12 (SE13), and SemEval 2015 task 13 (SE15). This common benchmark, which has been annotated with WordNet-3.0 senses (Raganato et al., 2017a), has recently been adopted in English all-words WSD. Following (Raganato et al., 2017b), we choose SemEval 2007 Task 17 (SE07) as our development data to pick the best model parameters after a number of neural network updates, for models that require back-propagation training.

Task	# Instances	# Lexelts
English all-words		
- SemCor (train)	226,036	22,436
- SemEval-2007 (dev)	455	330
- Senseval-2 (test)	2,282	1,093
- Senseval-3 (test)	1,850	977
- SemEval 2013 (test)	1,664	751
- SemEval 2015 (test)	1,022	512
English lexical sample		
- Senseval-2 (train)	8,611	177
- Senseval-2 (test)	4,328	146
- Senseval-3 (train)	8,022	57
- Senseval-3 (test)	3,944	57
Chinese OntoNotes		
- Train	66,409	431
- Dev	9,523	341
- BC (test)	1,769	160
- BN (test)	3,227	253
- MZ (test)	1,876	223
- NW (test)	1,483	143
- All (test)	8,355	324

Table 1: Statistics of the datasets used for the English all-words task, English lexical sample task, and Chinese OntoNotes WSD task in terms of the number of instances and the number of distinct lexelts. For Chinese WSD task, "All" refers to the concatenation of all genres BC, BN, MZ, and NW.

We also evaluate on Senseval-2 and Senseval-3 English lexical sample tasks, which come with pre-defined training and test data. For each word type, we pick 20% of the training instances to be our development set and keep the remaining 80% as the actual training data. Through this development set, we determine the number of epochs to use in training. We then re-train the model with the whole training dataset using the number of epochs identified in the initial training step.

While WSD is predominantly evaluated on English, we are also interested in evaluating our approach on Chinese, to evaluate the effectiveness of our approach in a different language. We use OntoNotes Release 5.0[1], which contains a number of annotations including word senses for Chinese. We follow the data setup of Pradhan et al. (2013) and conduct an evaluation on four genres, i.e., broadcast conversation (BC), broadcast news (BN), magazine (MZ), and newswire (NW), as well as the concatenation of all genres. While the training and development datasets are divided into genres, we train on the concatenation of all genres and test on each individual genre.

Table 2: English all-words task results in F1 measure (%), averaged over three runs. SemEval 2007 Task 17 (SE07) test set is used as the development set. We show the results of nearest neighbor matching (**1nn**) and linear projection, by **simple** last layer linear projection, layer weighting (**LW**), and gated linear units (**GLU**). Apart from BERT representation of one sentence (*1sent*), we also show BERT representation of one sentence plus one surrounding sentence to the left and one to the right (*1sent+1sur*). The best result in each dataset is shown in bold. Statistical significance tests by bootstrap resampling ($*$: $p < 0.05$) compare 1nn (1sent+1sur) with each of Simple (1sent+1sur), LW (1sent+1sur), GLU (1sent+1sur), and GLU+LW (1sent+1sur).

For Chinese WSD evaluation, we train IMS (Zhong and Ng, 2010) on the Chinese OntoNotes dataset as our baseline. We also incorporate pre-trained non-contextualized Chinese word embeddings as IMS features (Taghipour and Ng, 2015; Iacobacci et al., 2016). The pre-trained word embeddings are obtained by training the *word2vec* skip-gram model on Chinese Gigaword Fifth Edition[2], which after automatic word segmentation contains approximately 2 billion words. Following (Taghipour and Ng, 2015), we incorporate the embedding features of words within a window surrounding the target ambiguous word. In our experiments, we take into account 5 words to the left and right.

6 Results

We present our experimental results and compare them with prior baselines.

6.1 English All-Words Tasks

For English all-words WSD, we compare our approach with three categories of prior approaches. Firstly, we compare our approach with the supervised SVM classifier approach, namely IMS (Zhong and Ng, 2010). We compare our approach with both the original IMS without word embedding features and IMS with non-contextualized word embedding features, that is, *word2vec* with exponential decay (Iacobacci et al., 2016). We also compare with SupWSD (Papandrea et al., 2017), which is an alternative implementation of IMS. Secondly, we compare our approach with the neural WSD approaches that leverage bidirectional LSTM (bi-LSTM). These include the

bi-LSTM model with attention trained jointly with lexical semantic labeling task (Raganato et al., 2017b) (BiLSTMatt+LEX) and the bi-LSTM model enhanced with gloss representation from WordNet (GAS). Thirdly, we show comparison with prior contextualized word representations for WSD, pre-trained on a large number of texts, namely *context2vec* (Melamud et al., 2016) and ELMo (Peters et al., 2018). In these two models, WSD is treated as nearest neighbor matching as described in Section 4.1.

Table 2 shows our WSD results in F1 measure. It is shown in the table that with the nearest neighbor matching model, BERT outperforms *context2vec* and ELMo. This shows the effectiveness of BERT's pre-trained contextualized word representation. When we include surrounding sentences, one to the left and one to the right, we get improved F1 scores consistently.

We also show that linear projection to the sense output vector further improves WSD performance, by which our best results are achieved. While BERT has been shown to outperform other pre-trained contextualized word representations through the nearest neighbor matching experiments, its potential can be maximized through linear projection to the sense output vector. It is worthwhile to note that our more advanced linear projection, by means of layer weighting (§4.2.2 and gated linear unit (§4.2.3) gives the best F1 scores on all test sets.

All our BERT WSD systems outperform gloss-enhanced neural WSD, which has the best overall score among all prior systems.

6.2 English Lexical Sample Tasks

For English lexical sample tasks, we compare our approach with the original IMS (Zhong and Ng, 2010) and IMS with non-contextualized word embedding features. The embedding features incorporated into IMS include CW embeddings (Collobert et al., 2011), obtained from a convolutional language model, fine-tuned (adapted) to WSD (Taghipour and Ng, 2015) (+*adapted CW*), and *word2vec* skip-gram (Mikolov et al., 2013) with exponential decay (Iacobacci et al., 2016) (+*w2v+expdecay*). We also compare our approach with the bi-LSTM, on top of which sense classification is defined (Kågebäck and Salomonsson, 2016), and *context2vec* (Melamud et al., 2016), which is a contextualized pre-trained bi-LSTM model trained on 2B words of text. Finally, we also compare with a prior multi-task and semi-supervised WSD approach learned through alternating structure optimization (ASO) (Ando, 2006), which also utilizes unlabeled data for training.

System	SE2	SE3
Reported		
IMS	65.2	72.3
IMS+adapted CW	66.2	73.4
IMS+w2v+expdecay	69.9	75.2
BiLSTM	66.9	73.4
context2vec	–	72.8
ASO+multitask+semisup	–	74.1
BERT nearest neighbor (ours)		
1nn (1sent)	67.7	72.7
1nn (1sent+1sur)	71.5	75.7
BERT linear projection (ours)		
Simple (1sent)	73.3	78.6
Simple (1sent+1sur)	**76.9***	**80.0***
LW (1sent+1sur)	76.7*	**80.0***
GLU (1sent+1sur)	75.1*	79.4*
GLU+LW (1sent+1sur)	74.2*	79.8*

Table 3: English lexical sample task results in accuracy (%), averaged over three runs. Best accuracy in each dataset is shown in bold. Statistical significance tests by bootstrap resampling ($*$: $p < 0.05$) compare 1nn (1sent+1sur) with each of Simple (1sent+1sur), LW (1sent+1sur), GLU (1sent+1sur), and GLU+LW (1sent+1sur).

As shown in Table 3, our BERT-based WSD approach with linear projection model outperforms all prior approaches. *context2vec*, which is pre-trained on a large amount of texts, performs worse than the prior semi-supervised ASO approach on Senseval-3, while our best result outperforms ASO by a large margin.

Neural bi-LSTM performs worse than IMS with non-contextualized word embedding features. Our neural model with pre-trained contextualized word representations outperforms the best result achieved by IMS on both Senseval-2 and Senseval-3.

6.3 Chinese OntoNotes WSD

We compare our approach with IMS without and with word embedding features as the baselines. The results are shown in Table 4.

Across all genres, BERT outperforms the baseline IMS with word embedding (non-contextualized word representation) features (Taghipour and Ng, 2015). The latter also improves over the original IMS without word embedding features (Zhong and Ng, 2010). Linear

System	BC	BN	MZ	NW	All
Baseline					
IMS	79.8	85.7	83.0	91.0	84.8
IMS+w2v	80.2	86.4	82.3	92.0	85.2
BERT					
1nn	81.7	88.5	85.1	93.3	87.1
Simple	84.6*	**90.4***	**88.9***	93.9	**89.5***
LW	**84.7***	90.3*	88.8*	**94.0**	**89.5***
GLU	84.6*	90.0*	88.3*	93.3	89.0*
GLU+LW	84.6*	90.2*	88.2*	93.4	89.2*

Table 4: Chinese OntoNotes WSD results in accuracy (%), averaged over three runs, for each genre. All BERT results in this table are obtained from the representation of one sentence plus one surrounding sentence to the left and to the right (*1sent+1sur*). We show results of various BERT incorporation strategy, namely nearest neighbor matching (**1nn**), **simple** projection, projection with layer weighting (**LW**) and gated linear unit (**GLU**). Best accuracy in each genre is shown in bold. Statistical significance tests by bootstrap resampling ($*$: $p < 0.05$) compare 1nn with each of Simple, LW, GLU, and GLU+LW.

projection approaches consistently outperform nearest neighbor matching by a significant margin, similar to the results on English WSD tasks.

The best overall result for the Chinese OntoNotes test set is achieved by the models with simple projection and hidden layer weighting.

7 Discussion

Across all tasks (English all-words, English lexical sample, and Chinese OntoNotes), our experiments demonstrate the effectiveness of BERT over various prior WSD approaches. The best results are consistently obtained by linear projection models, which project the last hidden layer or the weighted sum of all hidden layers to an output sense vector.

We can view the BERT hidden layer outputs as contextual features, which serve as useful cues in determining the word senses. In fact, the attention mechanism in transformer captures the surrounding words. In prior work like IMS (Zhong and Ng, 2010), these contextual cues are captured by the manually-defined surrounding word and collocation features. The features obtained by the hidden vector output are shown to be more effective than the manually-defined features.

We introduced two advanced linear projection techniques, namely layer weighting and gated linear unit (GLU). While Peters et al. (2018) showed that the second biLSTM layer results in better WSD accuracy compared to the first layer (nearer to the individual word representation), we showed that taking into account different layers by means of the attention mechanism is useful for WSD. GLU as an activation function has been shown to be effective for better convergence and to overcome the vanishing gradient problem in the convolutional language model (Dauphin et al., 2017). In addition, the GLU gate vector, with values ranging from 0 to 1, can be seen as a filter for the features from the hidden layer vector.

Compared with two prior contextualized word representations models, *context2vec* (Melamud et al., 2016) and ELMo (Peters et al., 2018), BERT achieves higher accuracy. This shows the effectiveness of the attention mechanism used in the transformer model to represent the context.

Our BERT WSD models outperform prior neural WSD models by a large margin. These prior neural WSD models perform comparably with IMS with embeddings as classifier features, in addition to the discrete features. While neural WSD approaches (Kågebäck and Salomonsson, 2016; Raganato et al., 2017b; Luo et al., 2018) exploit non-contextualized word embeddings which are trained on large texts, the hidden layers are trained only on a small amount of labeled data.

8 Conclusion

For the WSD task, we have proposed novel strategies of incorporating BERT, a pre-trained contextualized word representation which effectively captures the context in its hidden vectors. Our experiments show that linear projection of the hidden vectors, coupled with gating to filter the values, gives better results than the prior state of the art. Compared to prior neural and feature-based WSD approaches that make use of non-contextualized word representations, using pre-trained contextualized word representation with our proposed incorporation strategy achieves significantly higher scores.

Do NLP Models Know Numbers? Probing Numeracy in Embeddings

Abstract

The ability to understand and work with numbers (numeracy) is critical for many complex reasoning tasks. Currently, most NLP models treat numbers in text in the same way as other tokens—they embed them as distributed vectors. Is this enough to capture numeracy? We begin by investigating the numerical reasoning capabilities of a state-of-the-art question answering model on the DROP dataset. We find this model excels on questions that require numerical reasoning, i.e., it already captures numeracy. To understand how this capability emerges, we probe token embedding methods (e.g., BERT, GloVe) on synthetic list maximum, number decoding, and addition tasks. A surprising degree of numeracy is naturally present in standard embeddings. For example, GloVe and word2vec accurately encode magnitude for numbers up to 1,000. Furthermore, character-level embeddings are even more precise—ELMo captures numeracy the best for all pre-trained methods—but BERT, which uses sub-word units, is less exact.

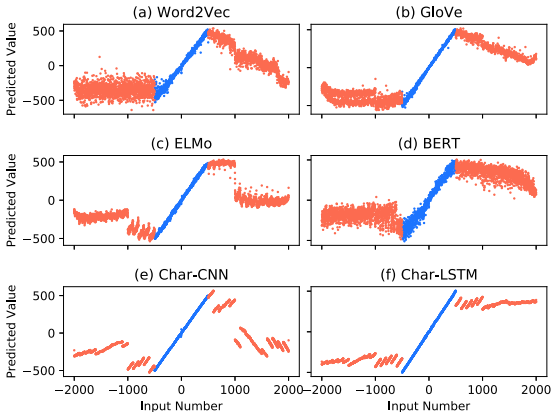

Figure 1: We train a probing model to decode a number from its word embedding over a random 80% of the integers from [-500, 500], e.g., "71" → 71.0. We plot the model's predictions for all numbers from [-2000, 2000]. The model accurately decodes numbers within the training range (in blue), i.e., pre-trained embeddings like GloVe and BERT capture numeracy. However, the probe fails to extrapolate to larger numbers (in red). The Char-CNN (e) and Char-LSTM (f) are trained jointly with the probing model.

1 Introduction

Neural NLP models have become the de-facto standard tool across language understanding tasks, even solving basic reading comprehension and textual entailment datasets (Yu et al., 2018; Devlin et al., 2019). Despite this, existing models are incapable of complex forms of reasoning, in particular, we focus on the ability to reason *numerically*. Recent datasets such as DROP (Dua et al., 2019), EQUATE (Ravichander et al., 2019), or Mathematics Questions (Saxton et al., 2019) test numerical reasoning; they contain examples which require comparing, sorting, and adding numbers in natural language (e.g., Figure 2).

The first step in performing numerical reasoning over natural language is *numeracy*: the ability to understand and work with numbers in either digit or word form (Spithourakis and Riedel, 2018). For example, one must understand that the string "23" represents a bigger value than "twenty-two". Once a number's value is (perhaps implicitly) represented, reasoning algorithms can then process the text, e.g., extracting the list of field goals and computing that list's maximum (first question in Figure 2). Learning to reason numerically over paragraphs with only question-answer supervision appears daunting for end-to-end models; our work seeks to understand *if* and *how* "out-of-the-box" neural NLP models already learn this.

We begin by analyzing the state-of-the-art NAQANet model (Dua et al., 2019) for DROP—testing it on a subset of questions that evaluate numerical reasoning (Section 2). To our surprise,

[*]Equal contribution; work done while interning at AI2.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5307–5315,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the model exhibits excellent numerical reasoning abilities. Amidst reading and comprehending natural language, the model successfully computes list maximums/minimums, extracts superlative entities (argmax reasoning), and compares numerical quantities. For instance, despite NAQANet achieving only 49 F1 on the entire validation set, it scores 89 F1 on numerical comparison questions. We also stress test the model by perturbing the validation paragraphs and find one failure mode: the model struggles to extrapolate to numbers outside its training range.

We are especially intrigued by the model's ability to learn numeracy, i.e., how does the model know the value of a number given its embedding? The model uses standard embeddings (GloVe and a Char-CNN) and receives no direct supervision for number magnitude/ordering. To understand how numeracy emerges, we probe token embedding methods (e.g., BERT, GloVe) using synthetic list maximum, number decoding, and addition tasks (Section 3).

We find that all widely-used pre-trained embeddings, e.g., ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), and GloVe (Pennington et al., 2014), capture numeracy: number magnitude is present in the embeddings, even for numbers in the thousands. Among all embeddings, character-level methods exhibit stronger numeracy than word- and sub-word-level methods (e.g., ELMo excels while BERT struggles), and character-level models learned directly on the synthetic tasks are the strongest overall. Finally, we investigate why NAQANet had trouble extrapolating—was it a failure in the model or the embeddings? We repeat our probing tasks and test for model extrapolation, finding that neural models struggle to predict numbers outside the training range.

2 Numeracy Case Study: DROP QA

This section examines the state-of-the-art model for DROP by investigating its accuracy on questions that require numerical reasoning.

2.1 DROP Dataset

DROP is a reading comprehension dataset that tests numerical reasoning operations such as counting, sorting, and addition (Dua et al., 2019). The dataset's input-output format is a superset of SQuAD (Rajpurkar et al., 2016): the answers are paragraph spans, as well as question spans, number answers (e.g., 35), and dates (e.g., 03/01/2014). The only supervision provided is the question-answer pairs, i.e., a model must learn to reason numerically while simultaneously learning to read and comprehend.

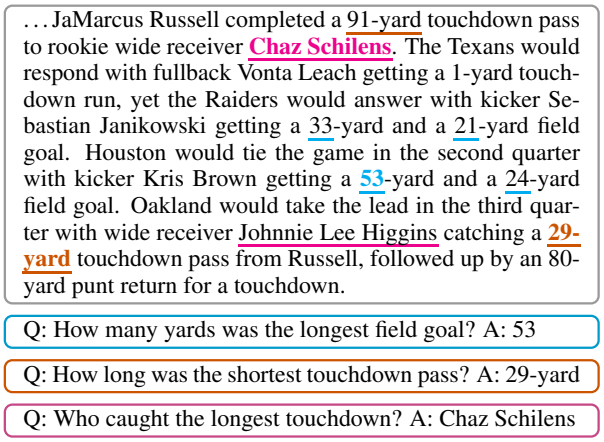

Figure 2: Three DROP questions that require numerical reasoning; the state-of-the-art NAQANet answers every question correct. Plausible answer candidates to the questions are underlined and the model's predictions are shown in bold.

2.2 NAQANet Model

Modeling approaches for DROP include both semantic parsing (Krishnamurthy et al., 2017) and reading comprehension (Yu et al., 2018) models. We focus on the latter, specifically on Numerically-augmented QANet (NAQANet), the current state-of-the-art model (Dua et al., 2019).[1] The model's core structure closely follows QANet (Yu et al., 2018) except that it contains four output branches, one for each of the four answer types (passage span, question span, count answer, or addition/subtraction of numbers.)

Words and numbers are represented as the concatenation of GloVe embeddings and the output of a character-level CNN. The model contains no auxiliary components for representing number magnitude or performing explicit comparisons. We refer readers to Yu et al. (2018) and Dua et al. (2019) for further details.

2.3 Comparative and Superlative Questions

We focus on questions that NAQANet requires numeracy to answer, namely *Comparative* and *Superlative* questions.[2] Comparative questions

[1] Result as of May 21st, 2019.

[2] DROP addition, subtraction, and count questions do not require numeracy for NAQANet, see Appendix A.

Question Type	Example	Reasoning Required
Comparative (Binary)	Which country is a bigger exporter, Brazil or Uruguay?	Binary Comparison
Comparative (Non-binary)	Which player had a touchdown longer than 20 yards?	Greater Than
Superlative (Number)	How many yards was the shortest field goal?	List Minimum
Superlative (Span)	Who kicked the longest field goal?	Argmax

Table 1: We focus on DROP *Comparative* and *Superlative* questions which test NAQANet's numeracy.

probe a model's understanding of quantities or events that are "larger", "smaller", or "longer" than others. Certain comparative questions ask about "either-or" relations (e.g., first row of Table 1), which test binary comparison. Other comparative questions require more diverse comparative reasoning, such as greater than relationships (e.g., second row of Table 1).

Superlative questions ask about the "shortest", "largest", or "biggest" quantity in a passage. When the answer type is a *number*, superlative questions require finding the maximum or minimum of a list (e.g., third row of Table 1). When the answer type is a *span*, superlative questions usually require an argmax operation, i.e., one must find the superlative action or quantity and then extract the associated entity (e.g., fourth row of Table 1). We filter the validation set to comparative and superlative questions by writing templates to match words in the question.

2.4 Emergent Numeracy in NAQANet

NAQANet's accuracy on comparative and superlative questions is significantly higher than its average accuracy on the validation set (Table 2).[3]

NAQANet achieves 89.0 F1 on binary (either-or) comparative questions, approximately 40 F1 points higher than the average validation question and within 7 F1 points of human test performance. The model achieves a lower, but respectable, accuracy on non-binary comparisons. These questions require multiple reasoning steps, e.g., the second question in Table 1 requires (1) extracting all the touchdown distances, (2) finding the distance that is greater than twenty, and (3) selecting the player associated with the touchdown of that distance.

We divide the superlative questions into questions that have number answers and questions with span answers according to the dataset's provided answer type. NAQANet achieves nearly 70 F1 on superlative questions with number answers, i.e., it can compute list maximum and minimums.

[3]We have a public NAQANet demo available https://demo.allennlp.org/reading-comprehension.

Question Type	Count	EM	F1
Human (Test Set)	9622	92.4	96.0
Full Validation	9536	46.2	49.2
Number Answers	5842	44.3	44.4
Comparative	704	73.6	76.4
Binary (either-or)	477	86.0	89.0
Non-binary	227	47.6	49.8
Superlative Questions	861	64.6	67.7
Number Answers	475	68.8	69.2
Span Answers	380	59.7	66.3

Table 2: NAQANet achieves higher accuracy on questions that require numerical reasoning (*Superlative* and *Comparative*) than on standard validation questions. Human performance is reported from Dua et al. (2019).

The model answers about two-thirds of superlative questions with span answers correctly (66.3 F1), i.e., it can perform argmax reasoning.

Figure 2 shows examples of superlative questions answered correctly by NAQANet. The first two questions require computing the maximum/minimum of a list: the model must recognize which digits correspond to field goals and touchdowns passes, and then extract the maximum/minimum of the correct list. The third question requires argmax reasoning: the model must first compute the longest touchdown pass and then find the corresponding receiver "Chaz Schilens".

2.5 Stress Testing NAQANet's Numeracy

Just how far does the numeracy of NAQANet go? Here, we stress test the model by automatically modifying DROP validation paragraphs.

We test two phenomena: larger numbers and word-form numbers. For larger numbers, we generate a random positive integer and multiply or add that value to the numbers in each paragraph. For word forms, we replace every digit in the paragraph with its word form (e.g., "75" → "seventy-five"). Since word-form numbers are usually small in magnitude when they occur in DROP, we perform word replacements for integers in the range [0, 100]. We guarantee the ground-truth answer is

Stress Test Dataset	All Questions F1	All Questions Δ	Superlative F1	Superlative Δ
Original Validation Set	49.2	-	67.7	-
Add [1, 20]	47.7	-1.5	64.1	-3.6
Add [21, 100]	41.4	-7.8	40.4	-27.3
Multiply [2, 10]	41.1	-8.1	39.3	-28.4
Multiply [11, 100]	38.8	-10.4	32.0	-35.7
Digits to Words [0, 20]	45.5	-3.7	63.8	-3.9
Digits to Words [21, 100]	41.9	-7.3	46.1	-21.6

Table 3: We stress test NAQANet's numeracy by manipulating the numbers in the validation paragraphs. *Add* or *Multiply [x, y]* indicates adding or multiplying all of the numbers in the passage by a random integer in the range [x, y]. *Digits → Words [x, y]* converts all integers in the passage within the range [x, y] to their corresponding word form (e.g., "75" → "seventy-five").

still valid by only modifying NAQANet's internal representation (Appendix E).

Table 3 shows the results for different paragraph modifications. The model exhibits a tiny degradation in performance for small magnitude changes (e.g., NAQANet drops 1.5 F1 overall for Add [1,20]) but severely struggles on larger changes (e.g., NAQANet drops 35.7 F1 on superlative questions for Multiply [11,200]). Similar trends hold for word forms: the model exhibits small drops in accuracy when converting small numbers to words (3.9 degradation on Digits to Words [0,20]) but fails on larger magnitude word forms (21.6 F1 drop over [21,100]). These results show that NAQANet has a strong understanding of numeracy for numbers in the training range, but, the model can fail to extrapolate to other values.

2.6 Whence this behavior?

NAQANet exhibits numerical reasoning capabilities that exceed our expectations. What enables this behavior? Aside from reading and comprehending the passage/question, this kind of numerical reasoning requires two components: numeracy (i.e., representing numbers) and comparison algorithms (i.e., computing the maximum of a list).

Although the natural emergence of comparison algorithms is surprising, previous results show neural models are capable of learning to count and sort synthetic lists of scalar values when given explicit supervision (Weiss et al., 2018; Vinyals et al., 2016). NAQANet demonstrates that a model can learn comparison algorithms while simultaneously learning to read and comprehend, even with only question-answer supervision.

How, then, does NAQANet know numeracy? The source of numerical information eventually lies in the token embeddings themselves, i.e., the character-level convolutions and GloVe embeddings of the NAQANet model. Therefore, we can understand the source of numeracy by isolating and probing these embeddings.

3 Probing Numeracy of Embeddings

We use synthetic numerical tasks to probe the numeracy of token embeddings.

3.1 Probing Tasks

We consider three synthetic tasks to evaluate numeracy (Figure 3). Appendix C provides further details on training and evaluation.

List Maximum Given a list of the embeddings for five numbers, the task is to predict the index of the maximum number. Each list consists of values of similar magnitude in order to evaluate fine-grained comparisons (see Appendix C). As in typical span selection models (Seo et al., 2017), an LSTM reads the list of token embeddings, and a weight matrix and softmax function assign a probability to each index using the model's hidden state. We use the negative log-likelihood of the maximum number as the loss function.

Decoding The decoding task probes whether number magnitude is captured (rather than the relative ordering of numbers as in list maximum). Given a number's embedding, the task is to regress to its value, e.g., the embedding for the string "five" has a target of 5.0. We consider a linear regression model and a three-layer fully-connected network with ReLU activations. The models are trained using a mean squared error (MSE) loss.

Addition The addition task requires number manipulation—given the embeddings of two numbers, the task is to predict their sum. Our model concatenates the two token embeddings and feeds the result through a three-layer fully-connected network with ReLU activations, trained using MSE loss. Unlike the decoding task, the model needs to capture number magnitude internally without direct label supervision.

Training and Evaluation We focus on a numerical *interpolation* setting (we revisit extrapolation

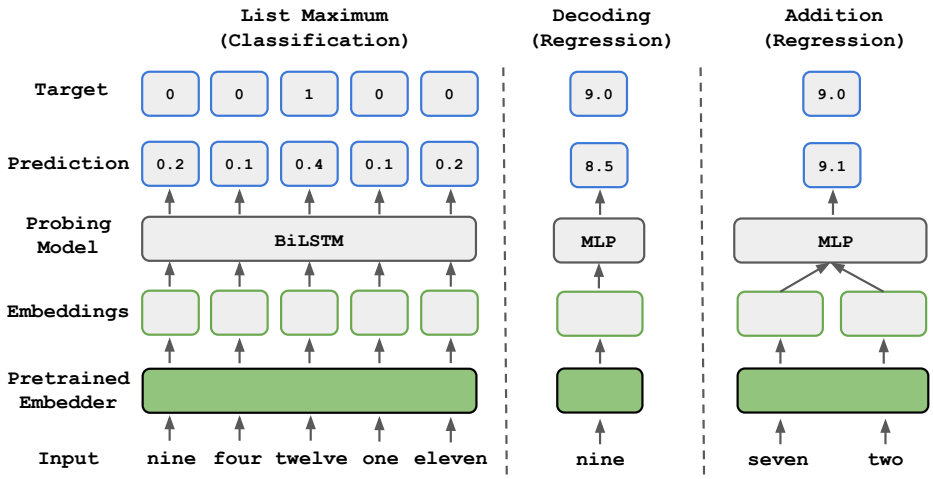

Figure 3: Our probing setup. We pass numbers through a pre-trained embedder (e.g., BERT, GloVe) and train a probing model to solve numerical tasks such as finding a list's maximum, decoding a number, or adding two numbers. If the probing model generalizes to held-out numbers, the pre-trained embeddings must contain numerical information. We provide numbers as either words (shown here), digits ("9"), floats ("9.1"), or negatives ("-9").

in Section 3.4): the model is tested on values that are within the training range. We first pick a range (we vary the range in our experiments) and randomly shuffle the integers over it. We then split 80% of the numbers into a training set and 20% into a test set. We report the mean and standard deviation across five different random shuffles for a particular range, using the exact same shuffles across all embedding methods.

Numbers are provided as integers ("75"), single-word form ("seventy-five"), floats ("75.1"), or negatives ("-75"). We consider positive numbers less than 100 for word-form numbers to avoid multiple tokens. We report the classification accuracy for the list maximum task (5 classes), and the Root Mean Squared Error (RMSE) for decoding and addition. Note that larger ranges will naturally amplify the RMSE error.

3.2 Embedding Methods

We evaluate various token embedding methods.

Word Vectors We use 300-dimensional GloVe (Pennington et al., 2014) and word2vec vectors (Mikolov et al., 2018). We ensure all values are in-vocabulary for word vectors.

Contextualized Embeddings We use ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) embeddings.[4] ELMo uses character-level convolutions of size 1–7 with max pooling. BERT represents tokens via sub-word pieces; we use lowercased BERT-base with 30k pieces.

NAQANet Embeddings We extract the GloVe embeddings and Char-CNN from the NAQANet model trained on DROP. We also consider an ablation that removes the GloVe embeddings.

Learned Embeddings We use a character-level CNN (Char-CNN) and a character-Level LSTM (Char-LSTM). We use left character padding, which greatly improves numeracy for character-level CNNs (details in Appendix B).

Untrained Embeddings We consider two untrained baselines. The first baseline is random token vectors, which trivially fail to generalize (there is no pattern between train and test numbers). These embeddings are useful for measuring the improvement of pre-trained embeddings. We also consider a randomly initialized and untrained Char-CNN and Char-LSTM.

Number's Value as Embedding The final embedding method is simple: map a number's embedding directly to its value (e.g., "seventy-five" embeds to [75]). We found this strategy performs poorly for large ranges; using a base-10 logarithmic scale improves performance. We report this as *Value Embedding* in our results.[5]

[4]Since our inputs are numbers, not natural sentences, language models may exhibit strange behavior. We experimented with extracting the context-independent feature vector immediately following the character convolutions for ELMo but found little difference in results.

[5]We suspect the failures result from the raw values being too high in magnitude and/or variance for the model. We also experimented with normalizing the values to mean 0 and variance 1; a logarithmic scale performed better.

All pre-trained embeddings (all methods except the Char-CNN and Char-LSTM) are fixed during training. The probing models are trained on the synthetic tasks on top of these embeddings.

3.3 Results: Embeddings Capture Numeracy

We find that all pre-trained embeddings *contain* fine-grained information about number magnitude and order. We first focus on integers (Table 4).

Word Vectors Succeed Both word2vec and GloVe significantly outperform the random vector baseline and are among the strongest methods overall. This is particularly surprising given the training methodology for these embeddings, e.g., a continuous bag of words objective can teach fine-grained number magnitude.

Character-level Methods Dominate Models which use character-level information have a clear advantage over word-level models for encoding numbers. This is reflected in our probing results: character-level CNNs are the best architecture for capturing numeracy. For example, the NAQANet model without GloVe (only using its Char-CNN) and ELMo (uses a Char-CNN) are the strongest pre-trained methods, and a learned Char-CNN is the strongest method overall. The strength of the character-level convolutions seems to lie in the architectural prior—an *untrained* Char-CNN is surprisingly competitive. Similar results have been shown for images (Saxe et al., 2011): random CNNs are powerful feature extractors.

Sub-word Models Struggle BERT struggles for large ranges (e.g., 52% accuracy for list maximum for [0,9999]). We suspect this results from sub-word pieces being a poor method to encode digits: two numbers which are similar in value can have very different sub-word divisions.

A Linear Subspace Exists For small ranges on the decoding task (e.g., [0,99]), a linear model is competitive, i.e., a linear subspace captures number magnitude (Appendix D). For larger ranges (e.g., [0,999]), the linear model's performance degrades, especially for BERT.

Value Embedding Fails The Value Embedding method fails for large ranges. This is surprising as the embedding directly provides a number's value, thus, the synthetic tasks *should* be easy to solve. However, we had difficulty training models for large ranges, even when using numerous architecture variants (e.g., tiny networks with 10 hidden units and tanh activations) and hyperparameters. Trask et al. (2018) discuss similar problems and ameliorate them using new neural architectures.

Words, Floats, and Negatives are Captured Finally, we probe the embeddings on word-form numbers, floats, and negatives. We observe similar trends for these inputs as integers: pre-trained models exhibit natural numeracy and learned embeddings are strong (Tables 5, 6, and 10). The ordering of the different embedding methods according to performance is also relatively consistent across the different input types. One notable exception is that BERT struggles on floats, which is likely a result of its sub-word pieces. We do not test word2vec and GloVe on floats/negatives because they are out-of-vocabulary.

3.4 Probing Models Struggle to Extrapolate

Thus far, our synthetic experiments evaluate on held-out values *within* the same range as the training data (i.e., numerical interpolation). In Section 2.5, we found that NAQANet struggles to extrapolate to values *outside* the training range. Is this an idiosyncrasy of NAQANet or is it a more general problem? We investigate this using a numerical extrapolation setting: we train models on a specific integer range and test them on values greater than the largest training number and smaller than the smallest training number.

Extrapolation for Decoding and Addition For decoding and addition, models struggle to extrapolate. Figure 1 shows the predictions for models trained on 80% of the values from [-500,500] and tested on held-out numbers in the range [-2000, 2000] for six embedding types. The embedding methods fail to extrapolate in different ways, e.g., predictions using word2vec decrease almost monotonically as the input increases, while predictions using BERT are usually near the highest training value. Trask et al. (2018) also observe that models struggle outside the training range; they attribute this to failures in neural models themselves.

Extrapolation for List Maximum For the list maximum task, accuracies are closer to those in the interpolation setting, however, they still fall short. Table 7 shows the accuracy for models trained on the integer range [0,150] and tested on

Interpolation	**List Maximum (5-classes)**			**Decoding (RMSE)**			**Addition (RMSE)**		
Integer Range	[0,99]	[0,999]	[0,9999]	[0,99]	[0,999]	[0,9999]	[0,99]	[0,999]	[0,9999]
Random Vectors	0.16	0.23	0.21	29.86	292.88	2882.62	42.03	410.33	4389.39
Untrained CNN	0.97	0.87	0.84	2.64	9.67	44.40	1.41	14.43	69.14
Untrained LSTM	0.70	0.66	0.55	7.61	46.5	210.34	5.11	45.69	510.19
Value Embedding	**0.99**	0.88	0.68	**1.20**	11.23	275.50	**0.30**	15.98	654.33
Pre-trained									
Word2Vec	0.90	0.78	0.71	2.34	18.77	333.47	0.75	21.23	210.07
GloVe	0.90	0.78	0.72	2.23	13.77	174.21	0.80	16.51	180.31
ELMo	0.98	0.88	0.76	2.35	13.48	62.20	0.94	15.50	45.71
BERT	0.95	0.62	0.52	3.21	29.00	431.78	4.56	67.81	454.78
Learned									
Char-CNN	0.97	**0.93**	**0.88**	2.50	**4.92**	**11.57**	1.19	**7.75**	**15.09**
Char-LSTM	0.98	0.92	0.76	2.55	8.65	18.33	1.21	15.11	25.37
DROP-trained									
NAQANet	0.91	0.81	0.72	2.99	14.19	62.17	1.11	11.33	90.01
- GloVe	0.88	0.90	0.82	2.87	5.34	35.39	1.45	9.91	60.70

Table 4: *Interpolation with integers (e.g., "18").* All pre-trained embedding methods (e.g., GloVe and ELMo) surprisingly capture numeracy. The probing model is trained on a randomly shuffled 80% of the *Integer Range* and tested on the remaining 20%. The probing model architecture and train/test splits are equivalent across all embeddings. We show the mean over 5 random shuffles (standard deviation in Appendix D).

Interpolation	**List Maximum (5-classes)**	
Float Range	[0.0,99.9]	[0.0,999.9]
Rand. Vectors	0.18 ± 0.03	0.21 ± 0.04
ELMo	0.91 ± 0.03	0.59 ± 0.01
BERT	0.82 ± 0.05	0.51 ± 0.04
Char-CNN	0.87 ± 0.04	0.75 ± 0.03
Char-LSTM	0.81 ± 0.05	0.69 ± 0.02

Table 5: *Interpolation with floats (e.g., "18.1") for list maximum.* Pre-trained embeddings capture numeracy for float values. The probing model is trained on a randomly shuffled 80% of the *Float Range* and tested on the remaining 20%. See the text for details on selecting decimal values. We show the mean alongside the standard deviation over 5 different random shuffles.

Interpolation	**List Maximum (5-classes)**
Integer Range	[-50,50]
Rand. Vectors	0.23 ± 0.12
Word2Vec	0.89 ± 0.02
GloVe	0.89 ± 0.03
ELMo	0.96 ± 0.01
BERT	0.94 ± 0.02
Char-CNN	0.95 ± 0.07
Char-LSTM	0.97 ± 0.02

Table 6: *Interpolation with negatives (e.g., "-18") on list maximum.* Pre-trained embeddings capture numeracy for negative values.

the ranges [151,160], [151,180], and [151,200]; all methods struggle, especially token vectors.

Augmenting Data to Aid Extrapolation Of course, in many real-word tasks it is possible to ameliorate these extrapolation failures by augmenting the training data (i.e., turn extrapolation into interpolation). Here, we apply this idea to aid in training NAQANet for DROP. For each superlative and comparative example, we duplicate the example and modify the numbers in its paragraph using the *Add* and *Multiply* techniques described in Section 2.5. Table 11 shows that this data augmentation can improve both interpolation and extrapolation, e.g., the accuracy on superlative questions with large numbers can *double*.

Extrapolation	List Maximum (5-classes)		
Test Range	[151,160]	[151,180]	[151,200]
Rand. Vectors	0.17	0.22	0.15
Untrained CNN	0.80	0.47	0.41
Pre-trained			
Word2Vec	0.14	0.16	0.11
GloVe	0.19	0.17	0.21
ELMo	0.65	0.57	0.38
BERT	0.35	0.11	0.14
Learned			
Char-CNN	0.81	0.75	0.73
Char-LSTM	**0.88**	**0.84**	**0.82**
DROP			
NAQANet	0.31	0.29	0.25
- GloVe	0.58	0.53	0.48

Table 7: *Extrapolation on list maximum.* The probing model is trained on the integer range [0,150] and evaluated on integers from the *Test Range*. The probing model struggles to extrapolate when trained on the pre-trained embeddings.

4 Discussion and Related Work

An open question is how the training process elicits numeracy for word vectors and contextualized embeddings. Understanding this, perhaps by tracing numeracy back to the training data, is a fruitful direction to explore further (c.f., influence functions (Koh and Liang, 2017; Brunet et al., 2019)).

More generally, numeracy is one type of emergent knowledge. For instance, embeddings may capture the size of objects (Forbes and Choi, 2017), speed of vehicles, and many other "commonsense" phenomena (Yang et al., 2018). Vendrov et al. (2016) introduce methods to encode the order of such phenomena into embeddings for concepts such as hypernymy; our work and Yang et al. (2018) show that a relative ordering naturally emerges for certain concepts.

In concurrent work, Naik et al. (2019) also explore numeracy in word vectors. Their methodology is based on variants of nearest neighbors and cosine distance; we use neural network probing classifiers which can capture highly non-linear dependencies between embeddings. We also explore more powerful embedding methods such as ELMo, BERT, and learned embedding methods.

Probing Models Our probes of *numeracy* parallel work in understanding the linguistic capabilities (*literacy*) of neural models (Conneau et al., 2018; Liu et al., 2019). LSTMs can remember sentence length, word order, and which words were present in a sentence (Adi et al., 2017). Khandelwal et al. (2018) show how language models leverage context, while Linzen et al. (2016) demonstrate that language models understand subject-verb agreement.

Numerical Value Prediction Spithourakis and Riedel (2018) improve the ability of language models to *predict* numbers, i.e., they go beyond categorical predictions over a fixed-size vocabulary. They focus on improving models; our focus is probing embeddings. Kotnis and García-Durán (2019) predict numerical attributes in knowledge bases, e.g., they develop models that try to predict the population of Paris.

Synthetic Numerical Tasks Similar to our synthetic numerical reasoning tasks, other work considers sorting (Graves et al., 2014), counting (Weiss et al., 2018), or decoding tasks (Trask et al., 2018). They use synthetic tasks as a testbed to prove or design better models, whereas we use synthetic tasks as a probe to understand token embeddings. In developing the Neural Arithmetic Logic Unit, Trask et al. (2018) arrive at similar conclusions regarding extrapolation: neural models have difficulty outputting numerical values outside the training range.

5 Conclusion

How much do NLP models know about numbers? By digging into a surprisingly successful model on a numerical reasoning dataset (DROP), we discover that pre-trained token representations naturally encode numeracy.

We analyze the limits of this numeracy, finding that CNNs are a particularly good prior (and likely the cause of ELMo's superior numeracy compared to BERT) and that it is difficult for neural models to extrapolate beyond the values seen during training. There are still many fruitful areas for future research, including discovering *why* numeracy naturally emerges in embeddings, and what other properties are similarly emergent.

Abstract

Context-dependent semantic parsing has proven to be an important yet challenging task. To leverage the advances in context-independent semantic parsing, we propose to perform follow-up query analysis, aiming to restate context-dependent natural language queries with contextual information. To accomplish the task, we propose STAR, a novel approach with a well-designed two-phase process. It is parser-independent and able to handle multifarious follow-up scenarios in different domains. Experiments on the FollowUp dataset show that STAR outperforms the state-of-the-art baseline by a large margin of nearly 8%. The superiority on parsing results verifies the feasibility of follow-up query analysis. We also explore the extensibility of STAR on the SQA dataset, which is very promising.

1 Introduction

Recently, Natural Language Interfaces to Databases (NLIDB) has received considerable attention, as they allow users to query databases by directly using natural language. Current studies mainly focus on context-independent semantic parsing, which translates a single natural language sentence into its corresponding executable form (e.g. Structured Query Language) and retrieves the answer from databases regardless of its context. However, context does matter in real world applications. Users tend to issue queries in a coherent way when communicating with NLIDB. For example, after the query "How much money has Smith earned?" (**Precedent Query**), users may pose another query by simply asking "How about Bill Collins?" (**Follow-up Query**) instead of the complete "How much money has Bill Collins earned?" (**Restated Query**). Therefore, contextual information is essential for more accurate and robust semantic parsing, namely context-dependent semantic parsing.

Compared with context-independent semantic parsing, context-dependent semantic parsing has received less attention. Several attempts include a statistical model with parser trees (Miller et al., 1996), a linear model with context-dependent logical forms (Zettlemoyer and Collins, 2009) and a sequence-to-sequence model (Suhr et al., 2018). However, all these methods cannot apply to different domains, since the ATIS dataset (Dahl et al., 1994) they rely on is domain-specific. A search-based neural method DynSP* arises along with the SequentialQA (SQA) dataset (Iyyer et al., 2017), which takes the first step towards cross-domain context-dependent semantic parsing. Nevertheless, DynSP* focuses on dealing with relatively simple scenarios. All the aforementioned methods design context-dependent semantic parser from scratch. Instead, inspired by Liu et al. (2019), we propose to directly leverage the technical advances in context-independent semantic parsing. We define *follow-up query analysis* as restating the follow-up queries using contextual information in natural language, then the restated queries can be translated to the corresponding executable forms by existing context-independent parsers. In this way, we boost the performance of context-dependent semantic parsing.

In this paper, we focus on follow-up query analysis and present a novel approach. The main idea is to decompose the task into two phases by introducing a learnable intermediate structure *span*: two queries first get split into several spans, and then undergo the recombination process. As no intermediate annotation is involved, we design re-

*Work done during an internship at Microsoft Research.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5316–5326,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

wards to jointly train the two phases by applying reinforcement learning (RL) (Sutton and Barto, 1998). Our major contributions are as follows:

- We propose a novel approach, named **S**pli**T**-**A**nd-**R**ecombine (STAR)[1], to restate follow-up queries via two phases. It is parser-independent and can be seamlessly integrated with existing context-independent semantic parsers.
- We conduct experiments on the FollowUp dataset (Liu et al., 2019), which covers multifarious cross-domain follow-up scenarios. The results demonstrate that our approach significantly outperforms the state-of-the-art baseline.
- We redesign the recombination process and extend STAR to the SQA dataset, where the annotations are answers. Experiments show promising results, that demonstrates the extensibility of our approach.

2 Methodology

In this section, we first give an overview of our proposed method with the idea of two-phase process, then introduce the two phases in turn.

2.1 Overview of Split-And-Recombine

Let $\mathbf{x} = (x_1, \ldots, x_n)$, $\mathbf{y} = (y_1, \ldots, y_m)$ and $\mathbf{z} = (z_1, \ldots, z_l)$ denote the precedent query, follow-up query and restated query respectively, each of which is a natural language sentence. Our goal is to interpret the follow-up query $\mathbf{y}$ with its precedent query $\mathbf{x}$ as context, and generate the corresponding restated query $\mathbf{z}$. The restated query has the same meaning with the follow-up query, but it is complete and unambiguous to facilitate better downstream parsing. Formally, given the pair $(\mathbf{x}, \mathbf{y})$, we aim to learn a model $P_{\text{model}}(\mathbf{z}|\mathbf{x}, \mathbf{y})$ and maximize the objective:

$$\mathcal{L} = \mathbb{E}_{(\mathbf{x},\mathbf{y},\mathbf{z})\sim\mathcal{D}}[\log P_{\text{model}}(\mathbf{z}|\mathbf{x}, \mathbf{y})], \quad (1)$$

where $\mathcal{D}$ represents the set of training data. As to $P_{\text{model}}(\mathbf{z}|\mathbf{x}, \mathbf{y})$, since $\mathbf{z}$ always overlaps a great with $\mathbf{x}$ and $\mathbf{y}$, it is intuitively more straightforward to find a way to merge $\mathbf{x}$ and $\mathbf{y}$. To this end, we design a two-phase process and present a novel approach STAR to perform follow-up query analysis with reinforcement learning.

A concrete example of the two-phase process is shown in Figure 1. Phase I is to **Split** input queries

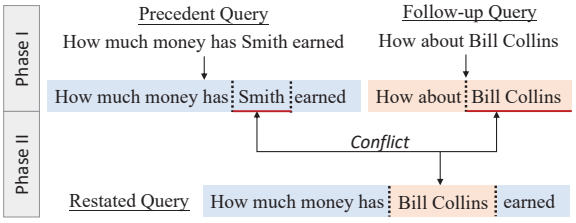

Figure 1: The two-phase process of an example from the FollowUp dataset (More real cases of diverse follow-up scenarios can be found in Table 3).

into several spans. For example, the precedent query is split into 3 spans: "How much money has", "Smith" and "earned". Let q denote a kind of way to split $(\mathbf{x}, \mathbf{y})$, then Phase I can be formulated as $P_{\text{split}}(q|\mathbf{x}, \mathbf{y})$. Phase II is to **Recombine** the spans by finding out the most probable *conflicting way*, and generating the final output by restatement, denoted as $P_{\text{rec}}(\mathbf{z}|q)$. Two spans being conflicting means they are semantically similar. For example, "Smith" conflicts with "Bill Collins". A conflicting way contains all conflicts between the precedent and follow-up spans. Backed by the two-phase idea of splitting and recombination, the overall likelihood of generating $\mathbf{z}$ given $\mathbf{x}, \mathbf{y}$ is:

$$P_{\text{model}}(\mathbf{z}|\mathbf{x}, \mathbf{y}) = \sum_{q\in\mathcal{Q}} P_{\text{split}}(q|\mathbf{x}, \mathbf{y}) P_{\text{rec}}(\mathbf{z}|q), \quad (2)$$

where $\mathcal{Q}$ represents the set of all possible ways to split $(\mathbf{x}, \mathbf{y})$. Due to the lack of annotations for splitting and recombination, it is hard to directly perform supervised learning. Inspired by Liang et al. (2017), we employ RL to optimize P_{model}. Denoting the predicted restated query by $\tilde{\mathbf{z}}$, simplifying $\mathbb{E}_{(\mathbf{x},\mathbf{y},\mathbf{z})\sim\mathcal{D}}$ as $\mathbb{E}$, the goal of the RL training is to maximize following objective:

$$\mathcal{L}_{\text{rl}} = \mathbb{E}[\sum_{\tilde{\mathbf{z}}\in\mathcal{Z}}\sum_{q\in\mathcal{Q}} P_{\text{split}}(q|\mathbf{x}, \mathbf{y}) P_{\text{rec}}(\tilde{\mathbf{z}}|q) r(\mathbf{z}, \tilde{\mathbf{z}})], \quad (3)$$

where $\mathcal{Z}$ is the space of all restated query candidates and r represents the reward defined by comparing $\tilde{\mathbf{z}}$ and the annotation $\mathbf{z}$. However, the overall candidate space $\mathcal{Q}\times\mathcal{Z}$ is vast, making it impossible to exactly maximize $\mathcal{L}_{\text{rl}}$. The most straightforward usage of the REINFORCE algorithm (Williams, 1992), sampling both q and $\tilde{\mathbf{z}}$, also poses challenges for learning. To alleviate the problem, we propose to sample q and enumerate all candidate $\tilde{\mathbf{z}}$ after q is determined. It could shrink the sampling space with an acceptable computational cost, which will be discussed in Sec-

[1]Code is available at http://github.com/microsoft/EMNLP2019-Split-And-Recombine.

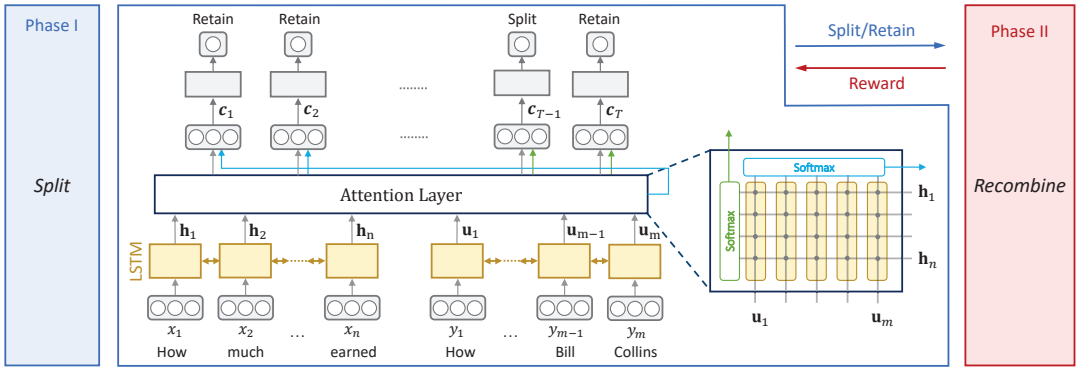

Figure 2: The overview of STAR with two phases.

tion 3.2.2. Thus the problem turns to design a reward function $R(q, \mathbf{z})$ to evaluate q and guide the learning. To achieve it, we reformulate Equation 3 as:

$$\mathcal{L}_{\text{rl}} = \mathbb{E}[\sum_{q \in \mathcal{Q}} P_{\text{split}}(q|\mathbf{x}, \mathbf{y}) \sum_{\tilde{\mathbf{z}} \in \mathcal{Z}} P_{\text{rec}}(\tilde{\mathbf{z}}|q) r(\mathbf{z}, \tilde{\mathbf{z}})], \quad (4)$$

and set the $R(q, \mathbf{z})$ as:

$$\sum_{\tilde{\mathbf{z}} \in \mathcal{Z}} P_{\text{rec}}(\tilde{\mathbf{z}}|q) r(\mathbf{z}, \tilde{\mathbf{z}}). \quad (5)$$

The overview of STAR is summarized in Figure 2. Given $\mathbf{x}, \mathbf{y}$, during training of Phase I (in blue), we fix P_{rec} to provide the reward $R(q, \mathbf{z})$, then P_{split} can be learnt by the REINFORCE algorithm. During training of Phase II (in red), we fix P_{split} and utilize it to generate q, P_{rec} is trained to maximize Equation 5. In this way, P_{split} and P_{rec} can be jointly trained. The details are introduced below.

2.2 Phase I: Split

As mentioned above, fixed P_{rec}, Phase I updates P_{split}, the Split Neural Network (**SplitNet**). Taking the precedent query and follow-up query as input, as shown in Figure 2, splitting spans can be viewed as a sequence labeling problem over input. For each word, SplitNet outputs a label *Split* or *Retain*, indicating whether a split operation will be performed after the corresponding word. A label sequence uniquely identifies a way of splitting $(\mathbf{x}, \mathbf{y})$, mentioned as q in Section 2.1. Figure 3 gives an example on the bottom. In the precedent query, two split operations are performed after "has" and "Smith" , since their labels are *Split*.

2.2.1 Split Neural Network

Intuitively, only after obtaining information from both the precedent query and follow-up query can SplitNet get to know the reasonable way to split spans. Inspired by BiDAF (Seo et al., 2017), we apply a bidirectional attention mechanism to capture the interrelations between the two queries.

Embedding Layer We consider embedding in three levels: character, word and sentence, respectively denoted as ϕ_c, ϕ_w and ϕ_s. Character-level embedding maps each word to a vector in a high-dimensional space using Convolutional Neural Networks (Kim, 2014). Word-level embedding is initialized using GloVe (Pennington et al., 2014), and then it is updated along with other parameters. Sentence-level embedding is a one-hot vector designed to distinguish between precedent and follow-up queries. Then, the overall embedding function is $\phi = [\phi_c; \phi_w; \phi_s]$.

Context Layer On top of the embedding layer, Bidirectional Long Short-Term Memory Network (BiLSTM) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) is applied to capture contextual information within one query. For word $x_i (i = 1, \ldots, n)$ in the precedent query $\mathbf{x}$, the hidden state $\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]$ is computed, where the forward hidden state is:

$$\overrightarrow{\mathbf{h}}_i = \overrightarrow{\text{LSTM}}(\phi(x_i); \overrightarrow{\mathbf{h}}_{i-1}). \quad (6)$$

Similarly, a hidden state $\mathbf{u}_j$ is computed for word $y_j (j = 1, \ldots, m)$. The BiLSTMs for $\mathbf{x}$ and $\mathbf{y}$ share the same parameters.

Attention Layer The interrelations between the precedent and follow-up queries are captured via attention layer. Let $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n]$ and $\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_m]$ denote the hidden states of two queries respectively, the similarity matrix is:

$$\mathbf{A} = \cos(\mathbf{H}^\top \mathbf{U}), \quad (7)$$

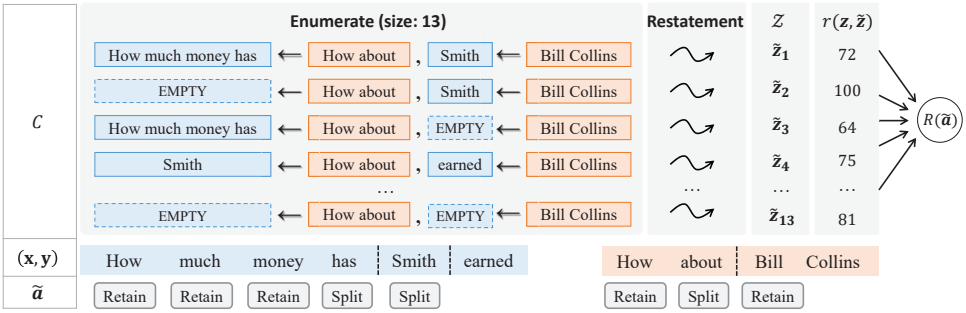

Figure 3: Illustration of reward computation in Phase II.

where $\mathbf{A} \in \mathbb{R}^{n \times m}$ and the entry $A_{i,j}$ represents the similarity between words x_i and y_j. Then the softmax function is used to obtain the precedent-to-follow **(P2F)** attention and the follow-to-precedent **(F2P)** attention. P2F attention represents y_j using the similarities between y_j and every word in $\mathbf{x}$. Specifically, let $\mathbf{f}_j = \mathrm{softmax}(\mathbf{A}_{:,j})$, where $\mathbf{f}_j \in \mathbb{R}^n$ denotes the attention weights on $\mathbf{x}$ according to y_j. Then y_j can be represented by a precedent-aware vector $\tilde{\mathbf{u}}_j = \sum_{k=1}^{n} \mathbf{f}_j[k] \cdot \mathbf{h}_k$. Similarly, F2P attention computes the attention weights on $\mathbf{y}$ according to x_i, and represents x_i as $\tilde{\mathbf{h}}_i$.

Output Layer Combining the outputs of the context layer and the attention layer, we design the final hidden state as follows:

$$\mathbf{c}^{x_i} = [\mathbf{h}_i;\ \mathbf{h}_i \circ \tilde{\mathbf{h}}_i;\ \mathbf{h}_{i+1} \circ \tilde{\mathbf{h}}_{i+1}], \quad (8)$$

$$\mathbf{c}^{y_j} = [\mathbf{u}_j;\ \mathbf{u}_j \circ \tilde{\mathbf{u}}_j;\ \mathbf{u}_{j+1} \circ \tilde{\mathbf{u}}_{j+1}], \quad (9)$$

where $i \in \{1, \ldots, n-1\}, j \in \{1, \ldots, m-1\}$ and $\circ$ denotes element-wise multiplication (Lee et al., 2017). Let $\mathbf{c} = (\mathbf{c}_t)_{t=1}^{T} = (\mathbf{c}^{x_1}, ..., \mathbf{c}^{x_{n-1}}, \mathbf{c}^{y_1}, ..., \mathbf{c}^{y_{m-1}})$ denote the final hidden state sequence. At each position t, the probability of *Split* is $\sigma(\mathbf{W} * \mathbf{c}_t + b)$, where σ denotes the *sigmoid* function and $\{\mathbf{W}, b\}$ denotes the parameters.

2.2.2 Training

It is difficult to train RL model from scratch. Therefore, we propose to initialize SplitNet via pre-training, and then use reward to optimize it.

Pre-training We obtain the pre-training annotation $\mathbf{a}$ by finding the common substrings between $(\mathbf{x}, \mathbf{y})$ and $\mathbf{z}$. One $\mathbf{a}$ is a label sequence, each of which is *Split* or *Retain*. Given the pre-training data set $\mathcal{D}_{\mathrm{pre}}$ whose training instance is as $(\mathbf{x}, \mathbf{y}, \mathbf{a})$, the objective function of pre-training is:

$$\mathcal{L}_{\mathrm{pre}}(\theta) = \mathbb{E}_{(\mathbf{x},\mathbf{y},\mathbf{a}) \sim \mathcal{D}_{\mathrm{pre}}} [\log p_\theta(\mathbf{a} | \mathbf{x}, \mathbf{y})], \quad (10)$$

where θ is the parameter of SplitNet.

Policy Gradient After pre-training, we treat the label sequence as a variable $\tilde{\mathbf{a}}$. The reward $R(\tilde{\mathbf{a}}, \mathbf{z})$ (details in Section 2.3) is used to optimize the parameter θ with policy gradient methods (Sutton et al., 1999). SplitNet is trained to maximize the following objective function:

$$\mathcal{L}_{\mathrm{rl}}(\theta) = \mathbb{E}_{(\mathbf{x},\mathbf{y},\mathbf{z}) \sim \mathcal{D}} [\mathbb{E}_{\tilde{\mathbf{a}} \sim p_\theta(\tilde{\mathbf{a}} | \mathbf{x}, \mathbf{y})} R(\tilde{\mathbf{a}}, \mathbf{z})]. \quad (11)$$

In practice, REINFORCE algorithm (Williams, 1992) is applied to approximate Equation 11 via sampling $\tilde{\mathbf{a}}$ from $p_\theta(\tilde{\mathbf{a}} | \mathbf{x}, \mathbf{y})$ for M times, where M is a hyper-parameter representing the sample size. Furthermore, subtracting a baseline (Weaver and Tao, 2001) on $R(\tilde{\mathbf{a}}, \mathbf{z})$ is also applied to reduce variance. The final objective function is as follows:

$$\mathcal{L}_{\mathrm{rl}}(\theta) = \mathbb{E}_{(\mathbf{x},\mathbf{y},\mathbf{z}) \sim \mathcal{D}} \Big[\sum_{i=1}^{M} p_\theta(\tilde{\mathbf{a}}_i | \mathbf{x}, \mathbf{y}) \big(R(\tilde{\mathbf{a}}_i, \mathbf{z}) - \bar{R} \big) \Big],$$

$$\text{where } \bar{R} = \frac{1}{M} \sum_{i=1}^{M} R(\tilde{\mathbf{a}}_i, \mathbf{z}). \quad (12)$$

2.3 Phase II: Recombine

Here we present Phase II with two questions: (1) Receiving the sampled label sequence $\tilde{\mathbf{a}}$, how to compute its reward $R(\tilde{\mathbf{a}}, \mathbf{z})$; (2) How to do training and inference for P_{rec}.

2.3.1 Reward Computation

Receiving the label sequence $\tilde{\mathbf{a}}$, we first enumerate all conflicting way candidates. Following the example in Figure 3, once we get a deterministic $\tilde{\mathbf{a}}$, the split of $(\mathbf{x}, \mathbf{y})$ is uniquely determined. Here $\mathbf{x}$ and $\mathbf{y}$ are split into 3 and 2 spans respectively. Treating spans as units, we enumerate all conflicting way candidates methodically. We act up to the one-to-one conflicting principle, which means a

span either has no conflict (denoted as *EMPTY*) or has only one conflict with a span in another query. Let $\mathcal{C}$ denote the set of all conflicting way candidates, the size of which is 13 in Figure 3.

For each conflicting way, we deterministically generate a restated query via the process named **Restatement**. In general, we simply replace spans in the precedent query with their conflicting spans to generate the restated query. For example, in Figure 3, the first one in $\mathcal{C}$ is restated as "How about Bill Collins earned". For spans in the follow-up query, if they contain column names or cell values and do not have any conflict, they are appended to the tail of the precedent query. It is designed to remedy the sub-query situation where there is no conflict (e.g. "Which opponent received over 537 attendance" and "And which got the result won 5-4"). Specially, if a span in the follow-up query contains a pronoun, we will in reverse replace it with its conflicting span to obtain the restated query.

Finally, the reward can be computed. Here we use BLEU and SymAcc[2] to build the reward function, expanding $r(\mathbf{z}, \tilde{\mathbf{z}})$ in Equation 5 as:

$$r(\mathbf{z}, \tilde{\mathbf{z}}) = \alpha \cdot \text{BLEU}(\mathbf{z}, \tilde{\mathbf{z}}) + \beta \cdot \text{SymAcc}(\mathbf{z}, \tilde{\mathbf{z}}), \quad (13)$$

where $\alpha, \beta > 0$ and $\alpha + \beta = 1$. The reward for $\tilde{\mathbf{a}}$ can be obtained using Equation 5.

2.3.2 Training and Inference

Besides the reward computation, the recombination model P_{rec} needs to be trained to maximize Equation 5. To achieve this, we define a conflicting probability matrix $\mathbf{F} \in \mathbb{R}^{N_x \times N_y}$, where N_x and N_y denote the number of spans in $\mathbf{x}$ and $\mathbf{y}$ respectively. The entry $\mathbf{F}_{u,v}$, the conflicting probability between the u-th span in $\mathbf{x}$ and the v-th span in $\mathbf{y}$, is obtained by normalizing the cosine similarity between their representations. Here the span representation is the subtraction representation (Wang and Chang, 2016; Cross and Huang, 2016), which means that span $(x_i, \ldots, x_k)$ is represented by $[\overrightarrow{\mathbf{h}_k} - \overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i} - \overleftarrow{\mathbf{h}_k}]$ from the same BiLSTM in the context layer in Section 2.2.1. Given a conflicting way denoted as $\tilde{c} \in \mathcal{C}$, the probability of generating its corresponding $\tilde{\mathbf{z}}$ can be written as the multiplication over $g(u, v)$:

$$P_{\text{rec}}(\tilde{\mathbf{z}}|\tilde{\mathbf{a}}) = P(\tilde{c}|\mathbf{F}) = \prod_{u=1}^{N_x} \prod_{v=1}^{N_y} g(u, v), \quad (14)$$

where $g(u, v) = \mathbf{F}_{u,v}$ if the u-th span in $\mathbf{x}$ conflicts with the v-th span in $\mathbf{y}$; otherwise, $g(u, v) = 1 - \mathbf{F}_{u,v}$. With the above formulation, we can maximize Equation 5 through automatic differentiation. To reduce the computation, we only maximize $P_{\text{rec}}(\tilde{\mathbf{z}}^*|\tilde{\mathbf{a}})$, the near-optimal solution to Equation 5, where $\tilde{\mathbf{z}}^* = \arg\max_{\tilde{\mathbf{z}} \in \mathcal{Z}}(r(\mathbf{z}, \tilde{\mathbf{z}}))$ denotes the best predicted restated query so far.

Guided by the golden restated query $\mathbf{z}$, in training, we find out $\tilde{\mathbf{z}}^*$ by computing the reward of each candidate. However in inference, where there is no golden restate query, we can only obtain $\tilde{\mathbf{z}}^*$ from $\mathbf{F}$. Specially, for the v-th span in the follow-up query, we find $u^* = \arg\max_u \mathbf{F}_{u,v}$. That means, compared to other spans in the precedent query, the u^*-th span has the highest probability to conflict with the v-th span in the follow-up query. Moreover, similar to Lee et al. (2017), if $\mathbf{F}_{u^*,v} < \lambda$, then the v-th span in the follow-up query has no conflict. The hyper-parameter $\lambda > 0$ denotes the threshold.

2.4 Extension

So far, we have introduced the whole process of STAR. Next we explore its extensibility. As observed, when the annotations are restated queries, STAR is parser-independent and can be incorporated into any context-independent semantic parser. But what if the annotations are answers to follow-up queries? Assuming we have an ideal semantic parser, a predicted restated query $\tilde{\mathbf{z}}$ can be converted into its corresponding answer $\tilde{w}$. For example, given $\tilde{\mathbf{z}}$ as "where are the players from", $\tilde{w}$ could be "Las Vegas". Therefore, revisiting Equation 3, in theory STAR is able to be extended by redesigning r as $r(w, \tilde{w})$, where w denotes the answer annotation. We conduct an extension experiment to verify it, as discussed in Section 3.3.

3 Experiments

In this section, we demonstrate the effectiveness of STAR on the FollowUp dataset[3] with restated query annotations, and its promising extensibility on the SQA dataset[4] with answer annotations.

3.1 Implementation details

We utilize PyTorch (Paszke et al., 2017) and AllenNLP (Gardner et al., 2018) for implementation, and adopt Adam (Kingma and Ba, 2015) as

[2]Their definitions along with the motivations of using them will be explained in Section 3.2.

the optimizer. The dimensions of word embedding and hidden state are both 100. Variational dropout (Blum et al., 2015) is employed at embedding layer for better generalization ability (with probability 0.5). The learning rate is set to be 0.001 for pre-training, 0.0001 for RL training on FollowUp, and 0.0002 for SQA. In the implementation of the REINFORCE algorithm, we set M to be 20. Finally, for hyper-parameters, we set $\alpha = 0.5$, $\beta = 0.5$ and $\lambda = 0.6$. All the results are averaged over 5 runs with random initialization.

3.2 Results on FollowUp dataset

The FollowUp dataset contains 1000 natural language query triples $(\mathbf{x}, \mathbf{y}, \mathbf{z})$. Each triple belongs to a single database table, and there are 120 tables in several different domains. Following the previous work, we split them into the sets of size 640/160/200 for train/dev/test. We evaluate the methods using both answer level and query level metrics. *AnsAcc* is to check the answer accuracy of predicted queries manually. Concretely, 103 golden restated queries can be successfully parsed by COARSE2FINE (Dong and Lapata, 2018). We parse their corresponding predicted queries into SQL using COARSE2FINE and manually check the answers. Although AnsAcc is most convincing, it cannot cover the entire test set. Therefore, we apply two query level metrics: *SymAcc* detects whether all the SQL-related words are correctly involved in the predicted queries, for example column names, cell values and so on. It reflects the approximate upper bound of AnsAcc, as the correctness of SQL-related words is a prerequisite of correct execution in most cases; *BLEU*, referring to the cumulative 4-gram BLEU score, evaluates how similar the predicted queries are to the golden ones (Papineni et al., 2002). SymAcc focuses on limited keywords, so we introduce BLEU to evaluate quality of the entire predicted query.

3.2.1 Model Comparison

Our baselines fall into two categories. **Generation-based methods** conform to the architecture of sequence-to-sequence (Sutskever et al., 2014) and generate restated queries by decoding each word from scratch. SEQ2SEQ (Bahdanau et al., 2015) is the sequence-to-sequence model with attention, and COPYNET further incorporates a copy mechanism. COPY+BERT incorporates the latest pre-trained BERT model (Devlin et al., 2019) as the encoder of COPYNET. **Rewriting-based methods** obtain restated queries by rewriting precedent and follow-up queries. CONCAT directly concatenates the two queries. E2ECR (Lee et al., 2017) obtain restated queries by performing coreference resolution in follow-up queries. FANDA (Liu et al., 2019) utilizes a structure-aware model to merge the two queries. Our method STAR also belongs to this category.

Answer Level Table 1 shows AnsAcc results of competitive baselines on the test set. Compared with them, STAR achieves the highest, 65.05%, which demonstrates its superiority. Meanwhile, it verifies the feasibility of follow-up query analysis in cooperating with context-independent semantic parsing. Compared with CONCAT, our approach boosts over 39.81% on COARSE2FINE for the capability of context-dependent semantic parsing.

Query Level Table 1 also shows SymAcc and BLEU of different methods on the dev and test sets. As observed, STAR significantly outperforms all baselines, demonstrating its effectiveness. For example, STAR achieves an absolute improvement of 8.03% BLEU over the state-of-the-art baseline FANDA on testing. Moreover, the rewriting-based baselines, even the simplest CONCAT, perform better than the generation-based

Variant	SymAcc (%)	BLEU (%)
STAR	55.38	67.62
– Phase I	40.63	61.82
– Phase II	23.12	48.65
– RL	41.25	60.19
+ Basic Reward	43.13	58.48
+ Oracle Reward	45.20	63.04
+ Uniform Reward	53.40	66.93

Table 2: Variant results on FollowUp dev set.

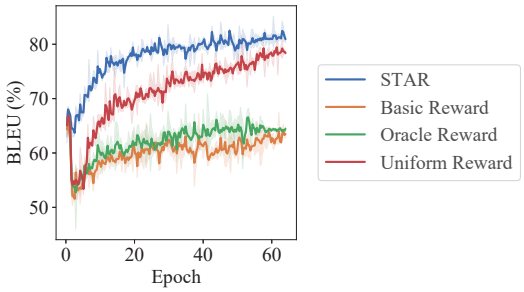

Figure 4: Learning curve on FollowUp train set.

ones. It suggests that the idea of rewriting is more reasonable for the task, where precedent and follow-up queries are of full utilization.

3.2.2 Variant Analysis

Besides baselines, we also conduct experiments with several variants of STAR to further validate the design of our model. As shown in Table 2, there are three variants with ablation: "– Phase I" takes out SplitNet and performs Phase II on word level; "– Phase II" performs random guess in the recombination process for testing; and "– RL" only contains pre-training. The SymAcc drops from about 55% to 40% by ablating Phase I, and to 23% by ablating Phase II. Their poor performances indicate both of the two phases are indispensable. "– RL" also performs worse, which again demonstrates the rationality of applying RL.

Three more variants are presented with different designs of $R(q, \mathbf{z})$ to prove the efficiency and effectiveness of Equation 5 as a reward. "+ Basic Reward" represents the most straightforward REINFORCE algorithm, which samples both $q \in \mathcal{Q}$ and $\tilde{\mathbf{z}} \in \mathcal{Z}$, then takes $r(\mathbf{z}, \tilde{\mathbf{z}})$ as $R(q, \mathbf{z})$. "+ Oracle Reward" assumes the conflicts are always correct and rewrites $R(q, \mathbf{z})$ as $\max_{\tilde{\mathbf{z}} \in \mathcal{Z}}(r(\mathbf{z}, \tilde{\mathbf{z}}))$. "+ Uniform Reward" assigns the same probability to all $\tilde{\mathbf{z}}$ and obtains $R(q, \mathbf{z})$ as $\text{mean}(\sum_{\tilde{\mathbf{z}} \in \mathcal{Z}} r(\mathbf{z}, \tilde{\mathbf{z}}))$. As shown in Table 2 and Figure 4, STAR learns better and faster than the variants due to the reasonable reward design. In fact, as mentioned in Section 2.1, the vast action space of the most straightforward REINFORCE algorithm leads to poor learning. STAR shrinks the space from $|\mathcal{Q}| \cdot |\mathcal{Z}|$ down to $|\mathcal{Q}|$ by enumerating $\tilde{\mathbf{z}}$. Meanwhile, statistics show that STAR obtains a $15\times$ speedup over "+ Basic Reward" on the convergence time.

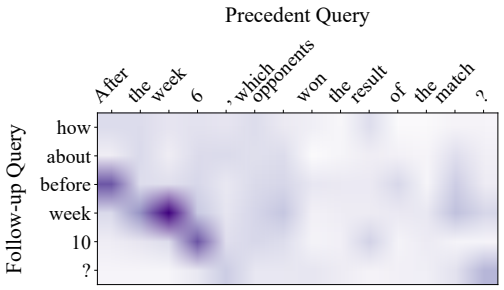

Figure 5: An example of similarity matrix in SplitNet.

3.2.3 Case Study

Figure 5 shows a concrete example of the similarity matrix $\mathbf{A}$ on attention layer of SplitNet. The span "before week 10" is evidently more similar to "After the week 6" than to others, which meets our expectations. Moreover, the results of three real cases are shown in Table 3. The spans in blue are those have conflicts, and the histograms represent the conflict probabilities to all the spans in precedent queries. In Case 1, "glebe park", "hampden park" and "balmoor" are all cell values in the database table with similar meanings. STAR correctly finds out the conflict between "compared to glebe park" and "compared to balmoor" with the highest probability. Case 2 shows STAR can discover the interrelation of words, where "the writer Nancy miller" is learnt as a whole span to replace "Nancy miller" in the precedent query. As for Case 3, STAR successfully performs coreference resolution and interprets "those two films" as "greatest love and promised land". Benefiting from two phases, STAR is able to deal with diverse follow-up scenarios in different domains.

3.2.4 Error Analysis

Our approach works well in most cases except for few ones, where SplitNet fails. For example, given the precedent query "what's the biggest zone?" and the follow-up query "the smallest one", STAR prefers to recognize "the biggest zone" and "the smallest one" as two spans, rather

No	Case Analysis	
1	*Precedent*	: [compared to glebe park] [, does] [hampden park] [holds more attendances at capacity ?]
	Follow-up	: [how about] [compared to balmoor]
	STAR	: compared to balmoor , does hampden park holds more attendances at capacity ?
2	*Precedent*	: [Is there any book which belongs to] [Nancy miller]
	Follow-up	: [I mean] [the writer Nancy miller]
	STAR	: Is there any book which belongs to the writer Nancy miller
3	*Precedent*	: [show directors of] [greatest love and promised land]
	Follow-up	: [show air date of] [those two films]
	STAR	: show air date of greatest love and promised land

Table 3: Case analysis of STAR on FollowUp dataset. Square brackets denote different spans.

Model	Precedent	Follow-up
DynSP (Iyyer et al., 2017)	70.9	35.8
NP (Neelakantan et al., 2016)	58.9	35.9
NP + STAR	58.9	38.1
DynSP + STAR	70.9	39.5
DynSP* (Iyyer et al., 2017)	70.4	41.1

Table 4: Answer accuracy on SQA test set.

than perform split operations inside them. The SplitNet fails probably because the conflicting spans, "the biggest" ↔ "the smallest" and "zone" ↔ "one", are adjacent, which makes it difficult to identify span boundaries well.

3.3 Extension on SQA dataset

Finally, we demonstrate STAR's extensibility in working with different annotations. As mentioned in Section 2.4, by designing $r(w, \tilde{w})$, STAR can cooperate with the answer annotations. We conduct experiments on the SQA dataset, which consists of 6066 query sequences (5042/1024 for train/test). Each sequence contains multiple natural language queries and their answers, where we are only interested in the first query and the immediate follow-up one. As discussed in (Iyyer et al., 2017), every answer can be represented as a set of cells in the tables, each of which is a multi-word value, and the intentions of the follow-up queries mainly fall into three categories. *Column selection* means the follow-up answer is an entire column; *Subset selection* means the follow-up answer is a subset of the precedent answer; and *Row selection* means the follow-up answer has the same rows with the precedent answer.

We employ two context-independent parsers, DynSP (Iyyer et al., 2017) and NP (Neelakantan et al., 2016), which are trained on the SQA dataset to provide relatively reliable answers for reward computing. Unfortunately, they both perform poorly for the restated queries, as the restated queries are quite different from the original queries in SQA. To address the problem, we redesign the recombination process. Instead of generating the restated query, we recombine the predicted precedent answer $\tilde{w}_x$ and the predicted follow-up answer $\tilde{w}_y$ to produce the restated answer $\tilde{w}$. Therefore, the objective of Phase II is to assign an appropriate intention to each follow-up span via an additional classifier. The goal of Phase I turns to split out spans having obvious intentions such as "of those". The way of recombining answer is determined by the voting from intentions on all spans. If the intention column selection wins, then $\tilde{w} = \tilde{w}_y$; for subset selection, we obtain the subset $\tilde{w}$ by taking the rows of $\tilde{w}_y$ as the constraint and applying it to $\tilde{w}_x$; and for row selection, we take the rows of $\tilde{w}_x$ and the columns of $\tilde{w}_y$ as the constraints, then apply them to the whole database table to obtain the answer $\tilde{w}$ retrieved by the predicted SQL. The reward $r(w, \tilde{w})$ is computed based on Jaccard similarity between the gold answer w and $\tilde{w}$ as in (Iyyer et al., 2017), and the overall training process remains unchanged.

Table 4 shows the answer accuracy of precedent and follow-up queries on test set. DynSP* (Iyyer et al., 2017) is designed for SQA by introducing a special action *Subsequent* to handle follow-up queries based on DynSP. DynSP* is incapable of being extended to work with the annotation of the restated queries. We attempt to apply DynSP* (trained on SQA) directly on FollowUp test set, which results in an extremely low AnsAcc. On the contrary, STAR is extensible. "+STAR" means our method STAR is incorporated into the context-independent parser and empowers them with the ability to perform follow-up query analysis. As observed, integrating STAR consistently improves

performance for follow-up queries, which demonstrates the effectiveness of STAR in collaborating with different semantic parsers. The comparable results of DynSP+STAR to DynSP* further verifies the promising extensibility of STAR.

4 Related Work

Our work is closely related to two lines of work: context-dependent sentence analysis and reinforcement learning. From the perspective of context-dependent sentence analysis, our work is related to researches like reading comprehension in dialogue (Reddy et al., 2019; Choi et al., 2018), dialogue state tracking (Williams et al., 2013), conversational question answering in knowledge base (Saha et al., 2018; Guo et al., 2018), context-dependent logic forms (Long et al., 2016), and non-sentential utterance resolution in open-domain question answering (Raghu et al., 2015; Kumar and Joshi, 2017). The main difference is that we focus on the context-dependent queries in NLIDB which contain complex scenarios. As for the most related context-dependent semantic parsing, Zettlemoyer and Collins (2009) proposes a context-independent CCG parser and then conduct context-dependent substitution, Iyyer et al. (2017) presents a search-based method for sequential questions, and Suhr et al. (2018) presents a sequence-to-sequence model to solve the problem. Compared to their methods, our work achieves context-dependent semantic parsing via learnable restated queries and existing context-independent semantic parsers.

Moreover, the technique of reinforcement learning has also been successfully applied to natural language tasks in dialogue, such as hyper-parameters tuning for coreference resolution (Clark and Manning, 2016), sequential question answering (Iyyer et al., 2017) and coherent dialogue responses generation (Li et al., 2016). In this paper, we employ reinforcement learning to capture the structures of queries, which is similar to Zhang et al. (2018) for text classification.

5 Conclusion and Future Work

We present a novel method, named Split-And-Recombine (STAR), to perform follow-up query analysis. A two-phase process has been designed: one for splitting precedent and follow-up queries into spans, and the other for recombining them. Experiments on two different datasets demonstrate the effectiveness and extensibility of our method. For future work, we may extend our method to other natural language tasks.

Text2Math: End-to-end Parsing Text into Math Expressions

Yanyan Zou and **Wei Lu**
StatNLP Research Group
Singapore University of Technology and Design
yanyan_zou@mymail.sutd.edu.sg, luwei@sutd.edu.sg

Abstract

We propose Text2Math, a model for semantically parsing text into math expressions. The model can be used to solve different math related problems including arithmetic word problems (Roy and Roth, 2017; Liang et al., 2018) and equation parsing problems (Roy et al., 2016). Unlike previous approaches, we tackle the problem from an end-to-end structured prediction perspective where our algorithm aims to predict the complete math expression at once as a tree structure, where minimal manual efforts are involved in the process. Empirical results on benchmark datasets demonstrate the efficacy of our approach.

1 Introduction

Designing computer algorithms that can automatically solve math word problems is a challenge for the AI research community (Bobrow, 1964). Two representative tasks have been proposed and studied recently – solving arithmetic word problems (Wang et al., 2017; Roy and Roth, 2018; Zou and Lu, 2019b) and equation parsing (Roy et al., 2016), as illustrated in Figure 1. The former task focuses on mapping the input paragraph (which may involve multiple sentences) into a target math expression, from which an answer can be calculated. The latter task focuses on mapping a description (usually a single sentence) into a math equation that typically involves one or more unknowns. As we can observe from Figure 1, in both cases, the output can be represented as a tree structure.

Earlier approaches to solving arithmetic word problems focused on rule-based methods where hand-crafted rules have been used (Mukherjee and Garain, 2008; Hosseini et al., 2014). Recently, learning-based approaches based on statistical classifiers (Kushman et al., 2014; Roy and Roth, 2015; Roy et al., 2016; Liang et al., 2018) or

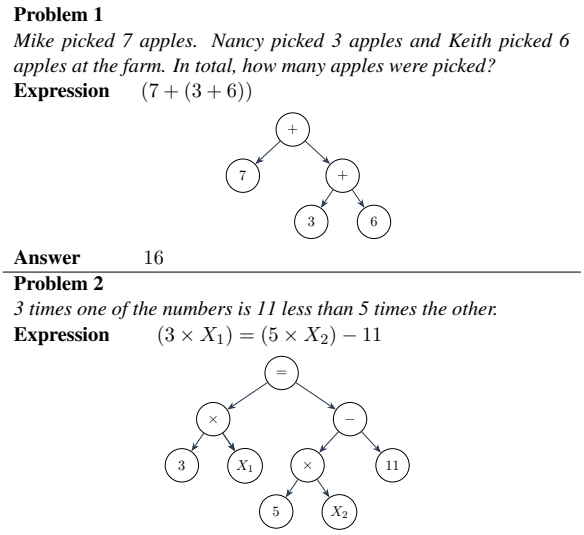

Figure 1: An example arithmetic word problem (top) and an example equation parsing problem (bottom) where the outputs can be represented as trees.

neural networks (Wang et al., 2017, 2018b) have been used for making decisions in the expression[1] construction process. However, these models do not focus on predicting the target tree as a complete structure at once, but locally trained classifiers are often used and local decisions are then combined. Such local classifiers often make predictions on the choice of the underlying operator between two operands (e.g., numbers) appearing in the text in a particular order. As a result, special treatments of the non-commutative operators such as *subtraction* ($-$) and *division* ($\div$) are often involved, where the introduction of inverse operators is typically required[2]. Shi et al. (2015) tackled the problem from a structured prediction perspective, where a semantic parsing algorithm us-

[1] In this work, we use the term *expression* to refer to a math expression (for arithmetic word problem) or an equation (for equation parsing).

[2] For example, the inverse operator $-_i$ applied to two operands a followed by b is used to denote $b - a$.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5327–5337, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ing context-free grammars (CFG) was used. However, their approach relies on semi-automatically generated rules and involves a manual step for interpreting the semantic representation they used.

While all these approaches focused on solving arithmetic word problems only, separate models have been developed for the task of equation parsing (Roy et al., 2016). It is not clear how easy each of these models specifically designed for one task can be adapted for the other task. Motivated by the observation that both problems involve mapping a text sequence to a tree structured representation, we propose `Text2Math` which regards both tasks as a class of structured prediction problems, and tackle them from a semantic parsing perspective. We make use of an end-to-end latent-variable approach to automatically produce the target math expression at once as a complete structure, where no prior knowledge on the operators (such as whether an operator is non-commutative) is required. Our model outperforms all baselines on two benchmark datasets. To the best of our knowledge, this is the first approach based on semantic parsing that tackles both arithmetic word problems and equation parsing with a single model. Our code is available at `http://statnlp.org/research/ta`.

2 Approach

2.1 Expression Tree

We first define tree representations for math expressions, which will then be regarded as the semantic representations used in the standard semantic parsing setup.

The nodes involved in the math expression trees can be classified into two categories, namely, *operator* and *quantity* nodes. Specifically, operator nodes are the tree nodes that define the types of operations involved in expressions. In this work we consider ADD (*addition*, $+$), SUB (*subtraction*, $-$), MUL (*multiplication*, $\times$) and DIV (*division*, $\div$). We also regard the equation sign ($=$) as an operation involved in math expressions and use EQU to denote it. We consider two types of quantity nodes: CON denoting constants, and VAR for unknown variables. Table 1 lists the above nodes. Each tree node comes with an *arity* which specifies the number of direct child nodes that should appear below the given node. For example, the operator node SUB with arity 2 is expecting two child nodes below it in the expression tree, while CON with arity 0 is supposed to be a leaf node. The two math expressions in Figure 1 can be equivalently represented by expression trees consisting of such nodes, as illustrated in Figure 2.

Category	Node	Interpretation	Arity
Operator	EQU	n_i EQU $n_j \Leftrightarrow (n_i = n_j)$	2
	ADD	n_i ADD $n_j \Leftrightarrow (n_i + n_j)$	2
	SUB	n_i SUB $n_j \Leftrightarrow (n_i - n_j)$	2
	MUL	n_i MUL $n_j \Leftrightarrow (n_i \times n_j)$	2
	DIV	n_i DIV $n_j \Leftrightarrow (n_i \div n_j)$	2
Quantity	CON	A constant	0
	VAR	A variable	0

Table 1: Expression tree nodes with interpretations, where n_i (n_j) refers to the first (second) operand.

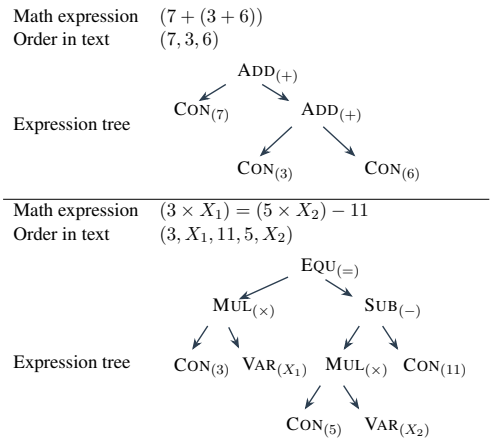

Figure 2: Expression trees for the two math expressions in Figure 1. "Order in text" refers to the order that the textual expressions of operands appear in the problem text. We use subscripts to indicate the actual semantic interpretations.

2.2 Latent Text-Math Tree

With the specifically designed expression trees for representing the math expressions, we will now be able to design a model for parsing the text into the expression tree. This is essentially a semantic parsing task. One of the key assumptions made by the various semantic parsing algorithms is the intermediate joint representation used for connecting the words and semantics (Wong and Mooney, 2006; Zettlemoyer and Collins, 2007; Lu et al., 2008; Artzi and Zettlemoyer, 2013b). In this work, we adopt an approach that is inspired by (Lu et al., 2008; Lu, 2014), which learns a latent joint representation for words and semantics in the form of *hybrid trees* where word-semantics correspondence information is captured. Specifically, we introduce a *text-math tree* representation that jointly encodes both text and the math expression tree.

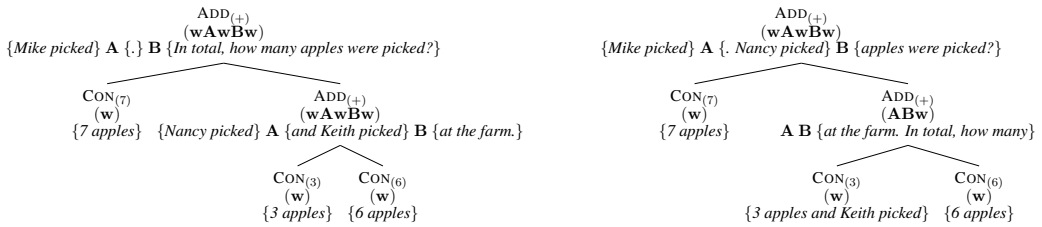

Figure 3: Example text-math trees for the arithmetic word problem example in Figure 1. The left tree captures the semantic correspondence well, while the right tree fails to capture the correct correspondence.

Such joint representations can be understood as a modified expression tree where each semantic node is now augmented with additional word information from the corresponding text.

From the joint representations we would be able to recover the semantic level correspondence information between words and math expressions. Possible joint representations of the two examples in Figure 1 are illustrated in Figure 3 and Figure 4 (left), respectively. Consider Problem 1 in Figure 1. We illustrate two possible text-math expression trees in Figure 3. Here each node in such joint representations is essentially a node in the original expression trees augmented with words from the problem text. For example, consider the left tree in Figure 3, the root node is an operator (the root node of the original expression tree) paired with discontiguous sequence of words "{*Mike picked*}...{.}...{*In total, how many apples were picked?*}" that appear in the problem text. This way, such a text-math tree is able to capture the semantic correspondence between words and basic units involved in the math expressions (i.e., operators, quantities). However, the text-math trees are not explicitly given during the training phase. For example, the right side of Figure 3 gives an alternative text-math tree that can also serve as a joint representation of both the text and the expression tree. Comparing both trees we may see the one on the left appears to be better at capturing the true semantic level correspondence between words and math expressions. Since there is no gold text-math tree explicitly given, we model it with a latent-variable approach.

Formally, given a text $\boldsymbol{x}$, paired with the expression $\boldsymbol{y}$ (or equivalently, the expression tree), we assume there exists a latent joint text-math representation in the form of text-math tree, that comprises exactly $\boldsymbol{x}$ and $\boldsymbol{y}$, denoted as $\boldsymbol{t}$. Each node is a word-semantics association $\langle x, y, p\rangle$ where x is a (possibly discontiguous) word sequence of $\boldsymbol{x}$ and y is an individual expression tree node from $\boldsymbol{y}$, and p is the word association pattern that is used to specify how words interact with the expression tree (further details will be provided in Sec. 2.3). Intuitively, such a joint text-math representation should precisely contain the exact information associated with the text and its corresponding math expression and nothing else. We will defer the discussion on how to exactly construct such joint representations until Sec. 2.3.

The training corpus provides both the problem text $\boldsymbol{x}$ and its math expression, which we represent with an expression tree $\boldsymbol{y}$. The joint representation $\boldsymbol{t}$ is not available in the training data, which we model as a latent variable. The conditional random fields (CRF) (Lafferty et al., 2001) has been successfully applied to many tasks in the NLP community (Lample et al., 2016; Zou and Lu, 2018, 2019a). In this work, we also apply CRF to model the conditional probability of the latent variable $\boldsymbol{t}$ and output expression $\boldsymbol{y}$, conditioned on the input $\boldsymbol{x}$. The objective is defined as follows:

$$P_{\Lambda,\Theta}(\boldsymbol{y}|\boldsymbol{x}) = \sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{x},\boldsymbol{y})} P_{\Lambda,\Theta}(\boldsymbol{y},\boldsymbol{t}|\boldsymbol{x})$$
$$= \frac{\sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{x},\boldsymbol{y})} e^{[\Lambda\cdot\Phi(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})+G_\Theta(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})]}}{\sum_{\boldsymbol{y}',\boldsymbol{t}'\in\mathcal{T}(\boldsymbol{x},\boldsymbol{y}')} e^{[\Lambda\cdot\Phi(\boldsymbol{x},\boldsymbol{y}',\boldsymbol{t}')+G_\Theta(\boldsymbol{x},\boldsymbol{y}',\boldsymbol{t}')]}} \quad (1)$$

where $\Phi(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})$ returns a list of discrete features defined over the tuple $(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})$, Λ is the feature weight vector, G_Θ is a neural scoring function parameterized by Θ and $\mathcal{T}(\boldsymbol{x},\boldsymbol{y})$ is a set of possible joint representations (i.e., text-math trees) for the pair $(\boldsymbol{x},\boldsymbol{y})$.

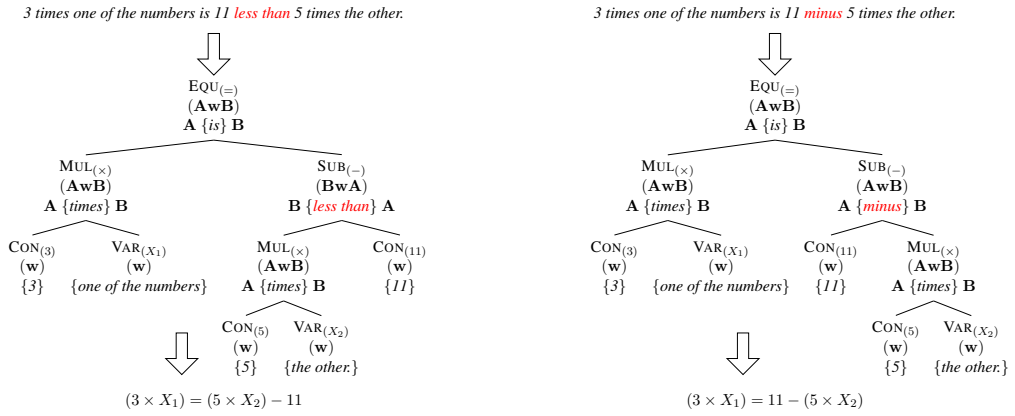

Figure 4: Left: example text-math tree for the equation parsing example in Figure 1, where the word association pattern **BwA** in the example is used for modeling reordering. Right: another example for a slightly different instance where the reordering is not required.

2.3 Inference

One challenge associated with the inference procedure in both training and decoding is how to handle the large space of latent structures defined by $\mathcal{T}(\boldsymbol{x}, \boldsymbol{y})$ and $\mathcal{T}(\boldsymbol{x})$. Without any constraints, searching or calculation that involves all possible structures within this space may be intractable. We therefore introduce some assumptions on the set of allowable structures, such that tractable inference can be applied to such structures.

We first introduce three symbols **A**, **B** and **w**. The symbol **A** refers to a placeholder for the left sub-tree (rooted by the left child node), and similarly **B** is a placeholder for the right sub-tree. The symbol **w** refers to a contiguous sequence of (1 or more) words. We will then use these three symbols to define the set of *word association patterns*, which are used to specify how the words interact with the sub-trees of the current node. Specifically, for expression tree nodes with arity 0 (i.e., quantity nodes), only one pattern **w** is allowed to be attached to them, indicating that a contiguous word sequence from a given problem text is associated with such expression tree nodes. As for expression tree nodes with arity 2 (i.e., operator nodes), we define 16 allowable patterns denoted as $\{[\mathbf{w}]\mathbf{A}[\mathbf{w}]\mathbf{B}[\mathbf{w}], [\mathbf{w}]\mathbf{B}[\mathbf{w}]\mathbf{A}[\mathbf{w}]\}$, where [] denotes optional. Based on such word association patterns, we will be able to define a set of possible text-math trees for a particular text-expression pair that we regard as valid.

Before we formally define what is a valid text-math tree, let us look at an example in Figure 3 which shows two valid trees. First of all, we can verify that, if we exclude the words from both trees, we arrive at the math expression that corresponds to the text. Second, we can also recover the text information from such a joint representation. Let us look at the right tree in Figure 3. Consider the right sub-tree of the complete tree rooted by the node $\langle x, y, p\rangle = \langle \{$*at the farm. In total, how many*$\}$, ADD, **ABw**$\rangle$. If we replace the placeholders **A** and **B** with the word sequences associated with its left and right sub-trees, respectively, we will arrive at the word sequence "*3 apples and Keith picked 6 apples at the farm. In total, how many*". Recursively performing such a rewriting procedure in a bottom-up manner, we will end up with a word sequence which is exactly the original input text as illustrated at the top of Figure 3.

Based on the above discussion, we can define $\mathcal{T}(\boldsymbol{x}, \boldsymbol{y})$ as a set that consists of the valid trees:

Definition 2.1 *For a given text* $\boldsymbol{x}$ *and an expression tree* $\boldsymbol{y}$*, a* ***valid text-math tree*** *satisfies the following two properties: 1) the semantics portion of the tree gives exactly* $\boldsymbol{y}$*, and 2) the text obtained through the recursive rewriting procedure discussed above gives exactly* $\boldsymbol{x}$[3].

Given the definition of the valid text-math trees, we will be able to use a bottom-up procedure to construct the set $\mathcal{T}(\boldsymbol{x}, \boldsymbol{y})$. Similarly, we will be able to construct the set $\mathcal{T}(\boldsymbol{x})$ by considering a forest-structured semantic representation that encodes all possible expression trees following (Lu, 2015). One nice property associated with considering only such joint representations is that there are known algorithms that can be used for performing efficient inference. Indeed, the resulting text-math trees are similar to the *hybrid tree* representations used in (Lu et al., 2008; Lu,

[3]We regard words that appear at different positions in $\boldsymbol{x}$ as distinct words, regardless of their string forms.

2014)[4], where dynamic programming based inference algorithms have been developed. Such algorithms allow $\mathcal{O}(n^3m)$ time complexity for inference where n is the text length and m is the number of grammar rules[5] associated with the latent text-math trees.

We note that some prior systems (Roy and Roth, 2017, 2018) require extra inverse operators – inverse subtraction "$-_r$" and inverse division "$\div_r$" to handle the scenarios where the order of quantities appearing in the text is not consistent with the order that they appear in the expression. Exemplified by the example in the left of Figure 4, by introducing two operators $-_r$ and $\div_r$ to take their operands in a reverse order, the equation on the left is represented as "$(3 \times X_1) = 11 -_r (5 \times X_2)$". However, we do not need such two inverse operators. The two group patterns $[\mathbf{w}]\mathbf{A}[\mathbf{w}]\mathbf{B}[\mathbf{w}]$ and $[\mathbf{w}]\mathbf{B}[\mathbf{w}]\mathbf{A}[\mathbf{w}]$ are capable to capture both orders. A pattern from the first group handles the order that is consistent with the problem text, while a pattern from the second group is able to capture reordering of operands below an operator. Exemplified by Figure 4, reordering is required for the first example, but not for the second, though their texts only differ slightly. Unlike the second example, instead of using the pattern $\mathbf{AwB}$, the first joint representation adopts the pattern $\mathbf{BwA}$ for the SUB expression node. Thus, our model is able to work without the underlying knowledge on whether an operator is commutative or not.

2.4 Features

Discrete Features. The feature function $\Phi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t})$ is defined over each node $\langle x, y, p\rangle$ in the joint tree as well as the complete expression tree $\boldsymbol{y}$. For each node $\langle x, y, p\rangle$, we extract word n-gram, the word association pattern, and POS tags for words (Manning et al., 2014). The knowledge that whether a number is relevant to the question (if available in the annotated data) is also taken as a binary feature. To assess the quality of the structure associated with the expression tree (i.e., features defined over $\boldsymbol{y}$), we extract parent-child relational information (y_a, y_b) from $\boldsymbol{y}$, where y_a is the parent of y_b, as features. Following previous works (Roy et al., 2016; Liang et al., 2018), we also consider incorporating a lexicon in our model so as to make a fair comparison with such works, although we would like to stress that our model does not strictly require such lexicons for learning. More details are in supplementary material.

Neural Features. We design neural features over the pair of the L-sized window surrounding the target word x_i in $\boldsymbol{x}$ and an expression tree node y_j. The network takes as input the contiguous word sequence $(x_{i-L}, \ldots, x_i, \ldots, x_{i+L})$, whose distributed representation is a simple concatenation of embeddings of each word. The hidden layer applies an affine transformation with an element-wise nonlinear activation function, like tanh and ReLU. The final output layer contains as many nodes as there are expression tree nodes in the training set. The output is a score vector that gives a score for the input word sequence $(x_{i-L}, \ldots, x_i, \ldots, x_{i+L})$ and an expression tree node y_j. The neural scoring function is defined as follows:

$$G_\Theta(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t}) = \sum_{(x,y)\in\mathcal{W}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})} c(x, y, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t}) \times \psi(x, y)$$

where $\mathcal{W}(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t})$ is the set of (x, y) pairs extracted from $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t})$, c returns the number of occurrences and $\psi(x, y)$ is a score of the target word x with L-sized windows and the expression tree node y, returned by the neural network. We regard L as a hyperparameter.

2.5 Algorithms

Given the complete training set, the log-likelihood is calculated as:

$$\begin{aligned}\mathcal{L}(\Lambda, \Theta) &= \sum_i \log P_{\Lambda,\Theta}(\boldsymbol{y}_i|\boldsymbol{x}_i) \\ &= \sum_i \log \sum_{\boldsymbol{t}\in\mathcal{T}(\boldsymbol{x}_i,\boldsymbol{y}_i)} P_{\Lambda,\Theta}(\boldsymbol{y}_i, \boldsymbol{t}|\boldsymbol{x}_i) \qquad (2)\end{aligned}$$

where $(\boldsymbol{x}_i,\boldsymbol{y}_i)$ refers to i-th instance in the training set. The additional L_2 regularization term can be introduced to avoid over-fitting. Here, we omit it for brevity.

The goal is to find optimal model parameters, i.e., Λ and Θ, which maximize the objective. We first consider the computation of gradients for Λ. Assuming $\Lambda = \langle\lambda_1, \lambda_2, \ldots, \lambda_N\rangle$, to learn the optimal feature weight values, we can calculate the

[4]They need to handle semantic nodes with arity 1 (which requires special constraints for properly defining $\mathcal{T}(\boldsymbol{x})$ (Lu, 2015)), and their semantic nodes are also assumed to convey semantic type information for guiding the expression tree construction process, while we do not need to consider them.

[5]The grammars are related to the word association patterns. The possible latent text-math trees are constructed based on such grammar rules.

gradient for each λ_k in Λ as:

$$\frac{\partial \mathcal{L}(\Lambda, \Theta)}{\partial \lambda_k} = \sum_i \sum_{\boldsymbol{t}} \boldsymbol{E}_{P_{\Lambda,\Theta}(\boldsymbol{t}|\boldsymbol{x}_i, \boldsymbol{y}_i)}[\phi_k(\boldsymbol{x}_i, \boldsymbol{y}_i, \boldsymbol{t})] - \sum_i \sum_{\boldsymbol{y},\boldsymbol{t}} \boldsymbol{E}_{P_{\Lambda,\Theta}(\boldsymbol{y},\boldsymbol{t}|\boldsymbol{x}_i)}[\phi_k(\boldsymbol{x}_i, \boldsymbol{y}, \boldsymbol{t})] \quad (3)$$

where $\phi_k(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t})$ is the number of occurrences for the k-th feature extracted from $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{t})$.

We then compute the gradient for the neural network parameters Θ. For an input word window x and a semantic unit y, the gradient is defined as:

$$\frac{\partial \mathcal{L}(\Lambda, \Theta)}{\partial \psi(x, y)} = \sum_i \sum_{\boldsymbol{t}} \boldsymbol{E}_{P_{\Lambda,\Theta}(\boldsymbol{t}|\boldsymbol{x}_i, \boldsymbol{y}_i)}[c(x, y, \boldsymbol{x}_i, \boldsymbol{y}_i, \boldsymbol{t})] - \sum_i \sum_{\boldsymbol{y},\boldsymbol{t}} \boldsymbol{E}_{P_{\Lambda,\Theta}(\boldsymbol{y},\boldsymbol{t}|\boldsymbol{x}_i)}[c(x, y, \boldsymbol{x}_i, \boldsymbol{y}, \boldsymbol{t})] \quad (4)$$

The gradients (3,4) can be efficiently calculated by applying a generalized forward-backward algorithm, which allows us to conduct exact inference using the dynamic programming algorithm described in (Lu, 2014). Next, standard methods like gradient descent, L-BFGS (Liu and Nocedal, 1989) can be used to find optimal values for model parameters.

During decoding, the optimal equation tree $\boldsymbol{y}^*$ for a new input $\boldsymbol{x}$ can be calculated by:

$$\begin{aligned} \boldsymbol{y}^* &= \arg\max_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x}) \\ &= \arg\max_{\boldsymbol{y}} \sum_{\boldsymbol{t} \in \mathcal{T}(\boldsymbol{x},\boldsymbol{y})} e^{F_{\Lambda,\Theta}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})} \\ &\approx \arg\max_{\boldsymbol{y},\boldsymbol{t} \in \mathcal{T}(\boldsymbol{x},\boldsymbol{y})} e^{F_{\Lambda,\Theta}(\boldsymbol{x},\boldsymbol{y},\boldsymbol{t})} \end{aligned} \quad (5)$$

where $\mathcal{T}(\boldsymbol{x}, \boldsymbol{y})$ refers to the set of all possible text-math trees that contain $\boldsymbol{x}$ and $\boldsymbol{y}$.

Instead of directly computing the summation over all possible latent text-math structures, we essentially replace the $\sum$ by the $\max$ operation inside the $\arg\max$. In other words, we first find the latent text-math tree $\boldsymbol{t}^*$ which yields the highest score and contains the input text $\boldsymbol{x}$. Then, the optimal expression tree $\boldsymbol{y}^*$ can be automatically extracted from $\boldsymbol{t}^*$.

An efficient dynamic programming based inference algorithm similar to the work of Lu (2014) was leveraged to find the optimal latent structure $\boldsymbol{t}^*$. We then obtain the optimal expression tree $\boldsymbol{y}^*$ from $\boldsymbol{t}^*$, which is the output of our system for the input problem text $\boldsymbol{x}$.

2.6 Comparisons with Roy et al. (2016)

It is worth noting that Roy et al. (2016) also proposed a system that maps text into an equation tree. Unlike this work that maps math problem texts into math expressions in an end-to-end fashion, Roy et al. (2016) designed three classifiers which sequentially make local decisions, namely identifying relevant numbers, recognizing possible variables and producing equations. They also require extra inverse operators to handle the non-commutative operation issues, which is not necessary for our model. Generating equations via a sequence of local classification decisions may propagate errors and even limit the ability to wholisticly understand the underlying semantics of problem texts which is important for predicting correct mathematical operations. In this work, we regard equation parsing problem as a structure prediction task that allows to parse the text to equations from a semantic parsing perspective. Moreover, `Text2Math` is capable to handle both tasks of equation parsing and arithmetic word problems, while the system of Roy et al. (2016) is specific to equation parsing.

3 Experiments

Datasets. Following prior works (Roy and Roth, 2015; Liang et al., 2018), we focus on two commonly-used benchmark datasets for arithmetic word problems, AI2 (Hosseini et al., 2014) and IL (Roy and Roth, 2015). We consider mathematical relations among numbers and calculate numerical values of the predicted expressions. For equation parsing, we also evaluate our model on the data released by (Roy et al., 2016). A predicted equation is regarded as a correct one if it is mathematically equivalent to the gold equation.

3.1 Empirical Results

Arithmetic Word Problem. Following previous work (Liang et al., 2018), we conduct 3-fold and 5-fold cross-validation on AI2 and IL, respectively, and report the accuracy scores, as shown in Table 2. Our method achieves competitive results on AI2 and IL. Overall, it performs better than previous systems in terms of average scores.

Ablation tests have been done to investigate the effectiveness of different components, such as POS tags, the lexicon and number relevance, as indicated by "-POS", "-LEX", "-ID" in Table 2. By eliminating POS tag features, we achieve

System		AI2	IL	Average
∗Liang et al. (2018) (Statistical)		81.5	81.0	81.25
∗Liang et al. (2018) (DNN)		69.8	70.6	70.20
∗Roy and Roth (2017)		76.2	71.0	73.60
Roy and Roth (2015)		78.0	73.9	75.95
Koncel-Kedziorski et al. (2015)		52.4	72.9	62.65
Roy et al. (2015)		-	52.7	-
Kushman et al. (2014)		64.0	73.7	68.85
Hosseini et al. (2014)		77.7	-	-
NON-NEURAL	Text2Math	85.8	80.4	83.10
	-POS	**86.0**	**81.0**	**83.50**
	-LEX	76.8	69.4	73.10
	-ID	75.4	78.1	76.75
NEURAL	$L = 0$	84.8	79.7	82.25
	$L = 1$	84.5	80.3	82.40
	$L = 2$	85.5	80.3	82.90
	$L = 3$	86.2	80.9	83.55
	$L = 4$	85.5	80.0	82.75
	$L = 5$	85.2	**81.4**	83.30
	$L = 6$	**86.5**	81.0	**83.75**

Table 2: **Arithmetic Word Problem**: Accuracy (%) on the two benchmark datasets. (-POS, -LEX, -ID mean that the model excludes POS tags feature, lexicon, or the number relevance feature.) ∗ indicates model uses prior knowledge, such as lexcion and inference rules.

new state-of-the-art results on two datasets, which shows POS tag features do not appear to be helpful in this case. Without using lexicon, the performance drops a lot as expected, but the results are still comparable with most previous systems. These figures demonstrate the effectiveness of the lexicon. It is worth noting that the work of Liang et al. (2018) that achieve previous state-of-the-art results leverage inference rules during the inference phase. Their approach can be regarded as a different way of using the lexicon similar to ours. We also consider the effects of neural features (see Sec. 2.4) with different window sizes $L \in \{0, 1, 2, 3, 4, 5, 6\}$. According to empirical results, a larger window size tends to give better results. One possible reason is that an arithmetic word problem often consists of several sentences, where a large word window is required to capture mathematical semantics.

Equation Parsing. We compare our model with previous work (Roy et al., 2016) on the equation parsing dataset, as shown in Table 3. Our method yields competitive results. Unlike the work of Roy et al. (2016), annotations of unknown variables are not required in our model. As reported in (Roy et al., 2016), they trained SPF (Artzi and Zettlemoyer, 2013a), a publicly available semantic parser, with sentence-equation pairs and a seed lexicon for mathematical terms. But it only obtained 3.1% accuracy. The result taken from (Roy et al., 2016) shows that it might be difficult for such a semantic parser in handling the equation

System		Equation
∗Roy et al. (2016) (Pipeline)		71.3
∗Roy et al. (2016) (Joint)		60.9
∗ SPF (Artzi and Zettlemoyer, 2013a)		3.1
NON-NEURAL	Text2Math	71.4
	-POS	69.1
	-LEX	71.4
	+G	**73.2**
	+G-LEX	**73.2**
NEURAL	$L = 0$	71.4
	$L = 1$	71.9
	$L = 2$	73.8
	$L = 3$	73.5
	$L = 4$	**74.5**
	$L = 5$	74.0
	$L = 6$	73.2

Table 3: **Equation Parsing**: Accuracy (%) on equation parsing dataset. -POS: without POS tag features; -LEX: without Lexicon; +G: with gold identification for numbers. ∗ indicates model uses lexicon. Result of SPF (Artzi and Zettlemoyer, 2013a) is taken from Roy et al. (2016).

parsing task even with a high precision lexicon. One possible reason is that mapping text into a math equation is essentially a structure prediction problem. Our model is capable to make guaranteed decisions from a structure prediction perspective. Different from arithmetic word problems, where numbers are explicitly given in the form of digits, some texts from equation parsing corpus describe numbers in string forms. Hence, a structured predictor is used to identify the numbers in the sentence, which achieves 95.3% accuracy. The identifications of numbers are taken as features. We also consider the gold label of numbers, indicated by (+G). The performance improves a lot, which shows that the accurate identification of numbers is necessary to in order to obtain a good performance. By removing POS tag features, there is a slight drop in accuracy. On the other hand, it is worth noting that even without the high precision lexicon, our model can still achieve new state-of-the-art accuracy in this task, while the previous work (Roy et al., 2016) always requires a high precision lexicon to boost performance. Incorporating neural features leads to new state-of-the-art accuracy of 74.5% when $L = 4$.

Expression Construction. In arithmetic word problems, the expression consists of several numbers only, exemplified by Problem 1 in Figure 1. In practice, an unknown variable X, representing the goal that the problem aims to calculate, can be appended to the expression to form an equation. We further investigate two constructions: appending the unknown variable X to the beginning or to the end of an expression. Results are listed in the first block of Table 4. For instance,

Variants	AI2	IL	Average
Text2Math	85.8	80.4	83.10
Prefix X	84.3	81.0	82.65
Suffix X	84.3	**81.2**	82.75
Text2Math + Inverse	**86.3**	80.1	**83.20**
Prefix X + Inverse	84.0	79.9	80.45
Suffix X + Inverse	84.0	80.5	82.25

Table 4: Performance of different constructions for expression of arithmetic word problems and the effects of incorporating inverse operators.

two new constructions of the running example are $X = (29 + (16 + 20))$ as indicated by "Prefix X", and $(29 + (16 + 20)) = X$ reported as "Suffix X". It is interesting that including an X and its position influences the performance. Overall, excluding X works the best which is adopted in this work.

Inverse Operators. As we discussed in Sec. 2.3, one distinct advantage of our approach, as compared to others, is that we do not need inverse operators, such as "$-_r$" and "$\div_r$". Our designed word association patterns are capable to handle the reordering issue. Here, we consider model variants by introducing two inverse expression tree nodes, SUB_r and DIV_r, to represent "$-_r$" and "$\div_r$", respectively. Empirical results, reported in the second block in Table 4, show that Text2Math (without including inverse operators) can obtain comparative results compared to the model variants with inverse operators. These results confirm that our model does not require additional knowledge of the semantics of operands, which is a unique property of our approach.

3.2 Qualitative Analysis

Output Comparisons. Equation parsing is more challenging than arithmetic word problems, since it requires generating unknown variables mapped to phrases residing in the text. We analyze output of this task to investigate the source that leads to better performance. Comparing predictions made by Pipeline (Roy et al., 2016) and our approach, we found that Text2Math can better capture the meaning of the problem text. We illustrate two examples in Table 5. The Pipeline approach fails to capture the meaning of "*rises to 36% from 3.4%*" which implies subtraction of two numbers, while our model is capable to capture such knowledge. In the second example, Pipeline misunderstands the meaning of "*five more than three*", although it seems correct in a local context. However, an equation should be mapped from the complete sentence that captures mathematical relations in a global perspective. Our model holds such a capability and makes more guaranteed predictions, which proves the efficacy of solving math problems from a structure prediction perspective.

Input:	*Japan January jobless rate rises to* 3.6% *from* 3.4%.
Gold:	$X_1 = 0.036 - 0.034$
Pipeline:	$X_1 \times 0.036 = 0.034$
Text2Math:	$X_1 = 0.036 - 0.034$
Input:	*The number of baseball cards he has is five more than three times the number of football cards.*
Gold:	$X_1 = 5 + (3 \times X_2)$
Pipeline:	$X_1 \times X_2 = 5 - 3$
Text2Math:	$X_1 = 5 + (3 \times X_2)$

Table 5: Comparison between predictions made by the previous state-of-the-art system (Roy et al., 2016) (denoted as Pipeline) and Text2Math.

Robustness. To further investigate the property of our model, we studied outputs. We found that our method is able to conduct self-correction. Exemplified by Example 3 in Table 6, considering the sentence *"Germany's DAX opens 0.7% lower at 18,842."* with annotated equation $X_1 + (0.007 \times X_1) = 18,842$, the prediction made by our method is $X_1 - (0.007 \times X_1) = 18,842$. It can be seen that the prediction made by our method is supposed to be the correct one, while the annotation is actually wrong. To make a fair comparison with previous works, we did not count such cases as correct during evaluation, which implies that accuracy reported in Table 3 is in fact higher.

Error Analysis. For arithmetic word problem, it is interesting that the operand of two operands should be addition/subtraction (multiplication/division), while the prediction is subtraction/addition (division/multiplication). Consider Example 4 and 5 in Table 6. Descriptions of such two problems share many words, such as *each*, *how many*, *there are*, etc. Slight difference in problem descriptions may lead to different results, which makes it a challenge.

As for equation parsing, the work of Roy et al. (2016) requires annotations on which phrases should be mapped to unknowns during the training phase. However, such supervised knowledge is not required for our method. In our setup, we did not make hard constraint that each prediction must contain one or two variables. Therefore, missing or redundant variables appearing in the predicted equations are one of the major error sources. Example 6 and 7 from Table 6 illustrate such cases. On the other hand, lack of professional background information also leads to miss-

Example 3:	*Germany's DAX opens 0.7% lower at 10,842.*
Gold:	$X_1 + (0.007 \times X_1) = 10842$
Text2Math:	$X_1 - (0.007 \times X_1) = 10842$
Example 4:	*Each child has 5 bottle caps. If there are 9 children, how many bottle caps are there in total?*
Gold:	5×9
Text2Math:	$5 \div 9$
Example 5:	*The school is planning a field trip. There are 14 students and 2 seats on each school bus. How many buses are needed to take the trip?*
Gold:	$14 \div 2$
Text2Math:	14×2
Example 6:	*530 pesos can buy 4 kilograms of fish and 2 kilograms of pork.*
Gold:	$530 = (4 \times X_1) + (2 \times X_2)$
Text2Math:	$530 \times X_3 = (4 \times X_1) + (2 \times X_2)$
Example 7:	*Flying with the wind , a bird was able to make 150 kilometers per hour.*
Gold:	$X_1 + X_2 = 150$
Text2Math:	$X_1 = 150$

Table 6: Examples with wrong predictions. Gold denotes the annotated correct equations and Text2Math refers to output equations generated by our method.

ing variables. Consider Example 6. Without world knowledge, it might be difficult for the algorithm to recognize that "*Flying with the wind*" implies the speed of the wind which should be considered as a variable of the equation.

4 Related Work

Math Word Problems. Mukherjee and Garain (2008) surveyed related approaches to this task in literature. Hosseini et al. (2014); Mitra and Baral (2016) solved the task by categorizing verbs or problems. The first method that can handle general arithmetic problems with multiple steps was proposed by Roy and Roth (2015), which was further extended by introducing (Roy and Roth, 2017, 2018). Zou and Lu (2019b,c) is the first work that proposed a sequence labelling approach to solving arithmetic word problems, which focuses on addition-subtraction word problems. Other systems include semantic parsing based approaches (Liang et al., 2018) and neural methods (Wang et al., 2017, 2018a,b). Unlike arithmetic word problems, the goal of algebra word problems is to map the text to an equation set (Kushman et al., 2014; Shi et al., 2015). Other types of problems have also been investigated, including probability problems (Dries et al., 2017), logic puzzle problems (Mitra and Baral, 2015; Chesani et al., 2017) and geometry problems (Seo et al., 2014, 2015). Besides the benchmark datasets used in this work, other popular datasets include Dolphin18K (Shi et al., 2015) and AQuA (Ling et al., 2017) for algebra word problems which are not the focus in this work. Roy et al. (2016) first proposed the Equation Parsing task and designed a pipeline method with three structured predictors.

Semantic Parsing. Another line of related works is semantic parsing (Wong and Mooney, 2006; Zettlemoyer and Collins, 2007; Kwiatkowksi et al., 2010; Liang et al., 2011; Dong and Lapata, 2018; Zou and Lu, 2018), which aims to map sentences into logic forms, including CCG-based lambda calculus expressions (Zettlemoyer and Collins, 2007; Kwiatkowksi et al., 2010; Artzi and Zettlemoyer, 2013b; Dong and Lapata, 2016), FunQL (Kate et al., 2005; Wong and Mooney, 2006; Jones et al., 2012), lambda-DCS (Liang et al., 2011; Berant et al., 2013; Jia and Liang, 2016), graph queries (Harris et al., 2013; Holzschuher and Peinl, 2013) and SQL (Yin et al., 2015; Sun et al., 2018). In this work, we adopt a text-math semantic representation encoding words and the expression tree.

5 Conclusion

In this work, we propose a unified structured prediction approach, Text2Math, to solving both arithmetic word problems and equation parsing tasks. We leverage a novel joint representation to automatically learn the correspondence between words and math expressions which reflects semantic closeness. Different from many existing models, Text2Math is agnostic of the semantics of operands and learns to map from text to math expressions in an end-to-end manner based on a data-driven approach. Experiments demonstrate the efficacy of our model. In the future, we would like to investigate how such an approach can be applied to more complicated math word problems, like algebra word problems where a problem usually maps to an equation set. Another interesting direction is to investigate how to incorporate world knowledge into the graph-based approach to boost the performance.

Abstract

We focus on the cross-domain context-dependent text-to-SQL generation task. Based on the observation that adjacent natural language questions are often linguistically dependent and their corresponding SQL queries tend to overlap, we utilize the interaction history by editing the previous predicted query to improve the generation quality. Our editing mechanism views SQL as sequences and reuses generation results at the token level in a simple manner. It is flexible to change individual tokens and robust to error propagation. Furthermore, to deal with complex table structures in different domains, we employ an utterance-table encoder and a table-aware decoder to incorporate the context of the user utterance and the table schema. We evaluate our approach on the SParC dataset and demonstrate the benefit of editing compared with the state-of-the-art baselines which generate SQL from scratch. Our code is available at https://github.com/ryanzhumich/sparc_atis_pytorch.

1 Introduction

Generating SQL queries from user utterances is an important task to help end users acquire information from databases. In a real-world application, users often access information in a multi-turn interaction with the system by asking a sequence of related questions. As the interaction proceeds, the user often makes reference to the relevant mentions in the history or omits previously conveyed information assuming it is known to the system.

Therefore, in the context-dependent scenario, the contextual history is crucial to understand the follow-up questions from users, and the system often needs to reproduce partial sequences generated in previous turns. Recently, Suhr et al. (2018) proposes a context-dependent text-to-SQL model including an interaction-level encoder and an attention mechanism over previous utterances. To reuse what has been generated, they propose to copy complete segments from the previous query. While their model is successful to reason about explicit and implicit references, it does not need to explicitly address different database schemas because the ATIS contains only the flight-booking domain. Furthermore, the model is confined to copy whole segments which are extracted by a rule-based procedure, limiting its capacity to utilize the previous query when only one or a few tokens are changed in the segment.

To exploit the correlation between sequentially generated queries and generalize the system to different domains, in this paper, we study an editing-based approach for cross-domain context-dependent text-to-SQL generation task. We propose query generation by editing the query in the previous turn. To this end, we first encode the previous query as a sequence of tokens, and the decoder computes a switch to change it at the token level. This sequence editing mechanism models token-level changes and is thus robust to error propagation. Furthermore, to capture the user utterance and the complex database schemas in different domains, we use an utterance-table encoder based on BERT to jointly encode the user utterance and column headers with co-attention, and adopt a table-aware decoder to perform SQL generation with attentions over both the user utterance and column headers.

We evaluate our model on SParC (Yu et al., 2019b), a new large-scale dataset for cross-domain semantic parsing in context consisting of coherent question sequences annotated with SQL queries over 200 databases in 138 domains. Experiment results show that by generating from the previous query, our model delivers an improvement of 7% question match accuracy and 11% interaction

Table 2: % of SQL queries that contain a particular SQL component.

Database: student dormitory containing 5 tables.

Goal: Find the first and last names of the students who are living in the dorms that have a TV Lounge as an amenity.

Q1: How many dorms have a TV Lounge?

S1:
```
SELECT COUNT(*) FROM dorm AS T1 JOIN has_amenity AS T2 ON T1.dormid = T2.dormid JOIN dorm_amenity AS T3
ON T2.amenid = T3.amenid WHERE T3.amenity_name = 'TV Lounge'
```

Q2: What is the total capacity of these dorms?

S2:
```
SELECT SUM(T1.student_capacity) FROM dorm AS T1 JOIN has_amenity AS T2 ON T1.dormid = T2.dormid JOIN
dorm_amenity AS T3 ON T2.amenid = T3.amenid WHERE T3.amenity_name = 'TV Lounge'
```

Q3: How many students are living there?

S3:
```
SELECT COUNT(*) FROM student AS T1 JOIN lives_in AS T2 ON T1.stuid = T2.stuid WHERE T2.dormid
IN (SELECT T3.dormid FROM has_amenity AS T3 JOIN dorm_amenity AS T4 ON T3.amenid = T4.amenid
WHERE T4.amenity_name = 'TV Lounge')
```

Q4: Please show their first and last names.

S4:
```
SELECT T1.fname, T1.lname FROM student AS T1 JOIN lives_in AS T2 ON T1.stuid = T2.stuid WHERE T2.dormid
IN (SELECT T3.dormid FROM has_amenity AS T3 JOIN dorm_amenity AS T4 ON T3.amenid = T4.amenid
WHERE T4.amenity_name = 'TV Lounge')
```

Table 3: SParC example.

match accuracy over the previous state-of-the-art. Further analysis shows that our editing approach is more robust to error propagation than copying segments, and the improvement becomes more significant if the basic text-to-SQL generation accuracy (without editing) improves.

2 Cross-Domain Context-Depencent Semantic Parsing

2.1 Datasets

We use SParC [1] (Yu et al., 2019b), a large-scale cross-domain context-dependent semantic parsing dataset with SQL labels, as our main evaluation benchmark. A SParC example is shown in Table 3. We also report performance on ATIS (Hemphill et al., 1990; Dahl et al., 1994a) for direct comparison to Suhr et al. (2018). In addition, we evaluate the cross-domain context-independent text-to-SQL ability of our model on Spider[2] (Yu et al., 2018c), which SParC is built on.

We summarize and compare the data statistics in Table 1 and Table 2. While the ATIS dataset has been extensively studied, it is limited to a particular domain. By contrast, SParC is both context-dependent and cross-domain. Each interaction in SParC is constructed using a question in Spider as the interaction goal, where the annotator asks inter-related questions to obtain information that completes the goal. SParC contains interactions over 200 databases and it follows the same database split as Spider where each database appears only in one of train, dev and test sets. In summary, SParC introduces new challenges to context-dependent text-to-SQL because it (1) contains more complex context dependencies, (2) has greater semantic coverage, and (3) adopts a cross-domain task setting.

2.2 Task Formulation

Let X denote a natural language utterance and Y denote the corresponding SQL query. Context-

[1] https://yale-lily.github.io/sparc

[2] https://yale-lily.github.io/spider

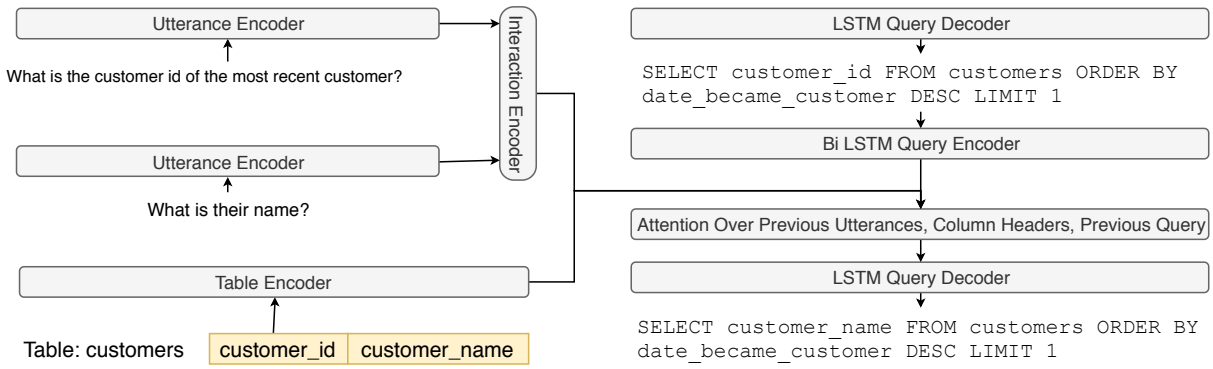

Figure 1: Model architecture of editing the previous query with attentions to the user utterances, the table schema, and the previously generated query.

independent semantic parsing considers individual (X, Y) pairs and maps X to Y. In context-dependent semantic parsing, we consider an interaction I consisting of n utterance-query pairs in a sequence:

$$I = [(X_i, Y_i)]_{i=1}^{n}$$

At each turn t, the goal is to generate Y_t given the current utterance X_t and the interaction history

$$[(X_1, Y_1), (X_2, Y_2), \ldots, (X_{t-1}, Y_{t-1})]$$

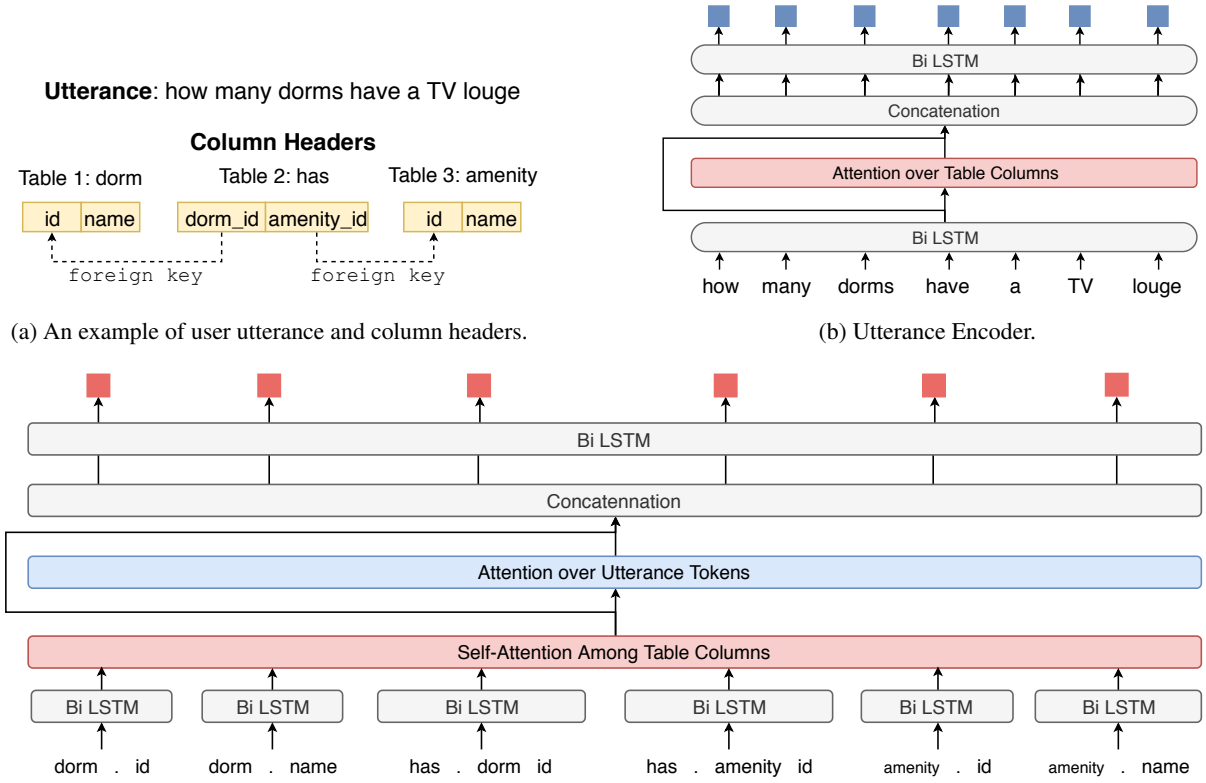
Furthermore, in the cross-domain setting, each interaction is grounded to a different database. Therefore, the model is also given the schema of the current database as an input. We consider relational databases with multiple tables, and each table contains multiple column headers:

$$T = [c_1, c_2, \ldots, c_l, \ldots, c_m]$$

where m is the number of column headers, and each c_l consists of multiple words including its table name and column name (§ 3.1).

3 Methodology

We employ an encoder-decoder architecture with attention mechanisms (Sutskever et al., 2014; Luong et al., 2015) as illustrated in Figure 1. The framework consists of (1) an utterance-table encoder to explicitly encode the user utterance and table schema at each turn, (2) A turn attention incorporating the recent history for decoding, (3) a table-aware decoder taking into account the context of the utterance, the table schema, and the previously generated query to make editing decisions.



3.1 Utterance-Table Encoder

An effective encoder captures the meaning of user utterances, the structure of table schema, and the relationship between the two. To this end, we build an utterance-table encoder with co-attention between the two as illustrated in Figure 2.

Figure 2b shows the utterance encoder. For the user utterance at each turn, we first use a bi-LSTM to encode utterance tokens. The bi-LSTM hidden state is fed into a dot-product attention layer (Luong et al., 2015) over the column header embeddings. For each utterance token embedding, we get an attention weighted average of the column header embeddings to obtain the most relevant columns (Dong and Lapata, 2018). We then concatenate the bi-LSTM hidden state and the column attention vector, and use a second layer bi-LSTM to generate the utterance token embedding $\mathbf{h}^E$.

Figure 2c shows the table encoder. For each column header, we concatenate its table name and its column name separated by a special dot token (i.e., `table name . column name`). Each column header is processed by a bi-LSTM layer. To better capture the internal structure of the table schemas (e.g., foreign key), we then employ a self-attention (Vaswani et al., 2017) among all column headers. We then use an attention layer to capture the relationship between the utterance and the table schema. We concatenate the self-attention vector and the utterance attention vector, and use a second layer bi-LSTM to generate the column header embedding $\mathbf{h}^C$.

Note that the two embeddings depend on each other due to the co-attention, and thus the column header representation changes across different utterances in a single interaction.

(a) An example of user utterance and column headers.

(b) Utterance Encoder.

(c) Table Encoder.

Figure 2: Utterance-Table Encoder for the example in (a).

Utterance-Table BERT Embedding. We consider two options as the input to the first layer bi-LSTM. The first choice is the pretrained word embedding. Second, we also consider the contextualized word embedding based on BERT (Devlin et al., 2019). To be specific, we follow Hwang et al. (2019) to concatenate the user utterance and all the column headers in a single sequence separated by the `[SEP]` token:

$$\texttt{[CLS]}, X_i, \texttt{[SEP]}, c_1, \texttt{[SEP]}, \ldots, c_m, \texttt{[SEP]}$$

This sequence is fed into the pretrained BERT model whose hidden states at the last layer is used as the input embedding.

3.2 Interaction Encoder with Turn Attention

To capture the information across different utterances, we use an interaction-level encoder (Suhr et al., 2018) on top of the utterance-level encoder. At each turn, we use the hidden state at the last time step from the utterance-level encoder as the utterance encoding. This is the input to a unidirectional LSTM interaction encoder:

$$\begin{aligned} \mathbf{h}_i^U &= \mathbf{h}_{i,|X_i|}^E \\ \mathbf{h}_{i+1}^I &= \text{LSTM}^I(\mathbf{h}_i^U, \mathbf{h}_i^I) \end{aligned}$$

The hidden state of this interaction encoder $\mathbf{h}^I$ encodes the history as the interaction proceeds.

Turn Attention When issuing the current utterance, the user may omit or explicitly refer to the previously mentioned information. To this end, we adopt the turn attention mechanism to capture correlation between the current utterance and the utterance(s) at specific turn(s). At the current turn t, we compute the turn attention by the dot-product attention between the current utterance and previous utterances in the history, and then add the weighted average of previous utterance embeddings to the current utterance embedding:

$$\begin{aligned} s_i &= \mathbf{h}_t^U \mathbf{W}_{\text{turn-att}} \mathbf{h}_i^U \\ \alpha^{\text{turn}} &= \text{softmax}(s) \\ \mathbf{c}_t^{\text{turn}} &= \mathbf{h}_t^U + \sum_{i=1}^{t-1} \alpha_i^{\text{turn}} \times \mathbf{h}_i^U \end{aligned} \tag{1}$$

The $\mathbf{c}_t^{\text{turn}}$ summarizes the context information and the current user query and will be used as the initial decoder state as described in the following.

3.3 Table-aware Decoder

We use an LSTM decoder with attention to generate SQL queries by incorporating the interaction

history, the current user utterance, and the table schema.

Denote the decoding step as k, we provide the decoder input as a concatenation of the embedding of SQL query token $\mathbf{q}_k$ and a context vector $\mathbf{c}_k$:

$$\mathbf{h}^D_{k+1} = \text{LSTM}^D([\mathbf{q}_k; \mathbf{c}_k], \mathbf{h}^D_k)$$

where $\mathbf{h}^D$ is the hidden state of the decoder LSTM^D, and the hidden state $\mathbf{h}^D_0$ is initialized by $\mathbf{c}^{\text{turn}}_t$. When the query token is a SQL keyword, $\mathbf{q}_k$ is a learned embedding; when it is a column header, we use the column header embedding given by the table-utterance encoder as $\mathbf{q}_k$. The context vector $\mathbf{c}_k$ is described below.

Context Vector with the Table and User Utterance. The context vector consists of attentions to both the table and the user utterance. First, at each step k, the decoder computes the attention between the decoder hidden state and the column header embedding.

$$\begin{aligned} s_l &= \mathbf{h}^D_k \mathbf{W}_{\text{column-att}} \mathbf{h}^C_l \\ \alpha^{\text{column}} &= \text{softmax}(s) \\ \mathbf{c}^{\text{column}}_k &= \sum_l \alpha^{\text{column}}_l \times \mathbf{h}^C_l \end{aligned} \tag{2}$$

where l is the index of column headers and $\mathbf{h}^C_l$ is its embedding. Second, it also computes the attention between the decoder hidden state and the utterance token embeddings:

$$\begin{aligned} s_{i,j} &= \mathbf{h}^D_k \mathbf{W}_{\text{utterance-att}} \mathbf{h}^E_{i,j} \\ \alpha^{\text{utterance}} &= \text{softmax}(s) \\ \mathbf{c}^{\text{token}}_k &= \sum_{i,j} \alpha^{\text{utterance}}_{i,j} \times \mathbf{h}^E_{i,j} \end{aligned} \tag{3}$$

where i is the turn index, j is the token index, and $\mathbf{h}^E_{i,j}$ is the token embedding for the j-th token of i-th utterance. The context vector $\mathbf{c}_k$ is a concatenation of the two:

$$\mathbf{c}_k = [\mathbf{c}^{\text{column}}_k; \mathbf{c}^{\text{token}}_k]$$

Output Distribution. In the output layer, our decoder chooses to generate a SQL keyword (e.g., `SELECT`, `WHERE`, `GROUP BY`, `ORDER BY`) or a column header. This is critical for the cross-domain setting where the table schema changes across different examples. To achieve this, we use separate layers to score SQL keywords and column headers, and finally use the softmax operation

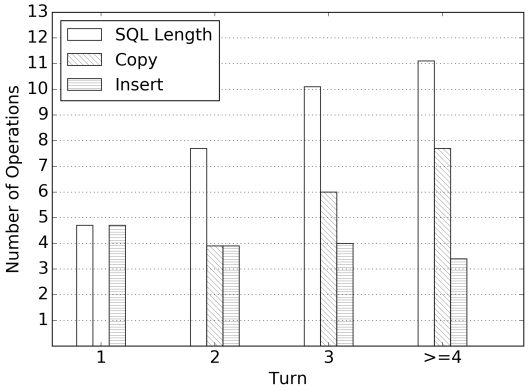


Figure 3: Number of operations at different turns.

to generate the output probability distribution:

$$\begin{aligned} \mathbf{o}_k &= \tanh([\mathbf{h}^D_k; \mathbf{c}_k]\mathbf{W}_o) \\ \mathbf{m}^{\text{SQL}} &= \mathbf{o}_k \mathbf{W}_{\text{SQL}} + \mathbf{b}_{\text{SQL}} \\ \mathbf{m}^{\text{column}} &= \mathbf{o}_k \mathbf{W}_{\text{column}} \mathbf{h}^C \\ P(y_k) &= \text{softmax}([\mathbf{m}^{\text{SQL}}; \mathbf{m}^{\text{column}}]) \end{aligned} \tag{4}$$

3.4 Query Editing Mechanism

In an interaction with the system, the user often asks a sequence of closely related questions to complete the final query goal. Therefore, the query generated for the current turn often overlaps significantly with the previous ones.

To empirically verify the usefulness of leveraging the previous query, we consider the process of generating the current query by applying copy and insert operations to the previous query[3]. Figure 3 shows the SQL query length and the number of copy and insert operations at different turns. As the interaction proceeds, the user question becomes more complicated as it requires longer SQL query to answer. However, more query tokens overlap with the previous query, and thus the number of new tokens remains small at the third turn and beyond.

Based on this observation, we extend our tableware decoder with a query editing mechanism. We first encode the previous query using another bi-LSTM, and its hidden states are the query token embeddings $\mathbf{h}^Q_{i,j'}$ (i.e., the j'-th token of the i-th query). We then extend the context vector with the attention to the previous query:

$$\mathbf{c}_k = [\mathbf{c}^{\text{column}}_k; \mathbf{c}^{\text{token}}_k; \mathbf{c}^{\text{query}}_k]$$

where $\mathbf{c}^{\text{query}}_k$ is produced by an attention to query tokens $\mathbf{h}^Q_{i,j'}$ in the same form as Equation 3.

[3]We use a diffing algorithm from https://github.com/paulgb/simplediff

At each decoding step, we predict a switch p_{copy} to decide if we need copy from the previous query or insert a new token.

$$\begin{aligned} p_{\text{copy}} &= \sigma(\mathbf{c}_k \mathbf{W}_{\text{copy}} + \mathbf{b}_{\text{copy}}) \\ p_{\text{insert}} &= 1 - p_{\text{copy}} \end{aligned} \tag{5}$$

Then, we use a separate layer to score the query tokens at turn $t-1$, and the output distribution is modified as the following to take into account the editing probability:

$$\begin{aligned} P_{\text{prev_SQL}} &= \text{softmax}(\mathbf{o}_k \mathbf{W}_{\text{prev_SQL}} \mathbf{h}_{t-1}^{Q}) \\ \mathbf{m}^{\text{SQL}} &= \mathbf{o}_k \mathbf{W}_{\text{SQL}} + \mathbf{b}_{\text{SQL}} \\ \mathbf{m}^{\text{column}} &= \mathbf{o}_k \mathbf{W}_{\text{column}} \mathbf{h}^{C} \\ P_{\text{SQL} \bigcup \text{column}} &= \text{softmax}([\mathbf{m}^{\text{SQL}}; \mathbf{m}^{\text{column}}]) \\ P(y_k) &= p_{\text{copy}} \cdot P_{\text{prev_SQL}}(y_k \in \text{prev_SQL}) \\ &+ p_{\text{insert}} \cdot P_{\text{SQL} \bigcup \text{column}}(y_k \in \text{SQL} \bigcup \text{column}) \end{aligned} \tag{6}$$

While the copy mechanism has been introduced by Gu et al. (2016) and See et al. (2017), they focus on summarization or response generation applications by copying from the source sentences. By contrast, our focus is on editing the previously generated query while incorporating the context of user utterances and table schemas.

4 Related Work

Semantic parsing is the task of mapping natural language sentences into formal representations. It has been studied for decades including using linguistically-motivated compositional representations, such as logical forms (Zelle and Mooney, 1996; Clarke et al., 2010) and lambda calculus (Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2011), and using executable programs, such as SQL queries (Miller et al., 1996; Zhong et al., 2017) and other general-purpose programming languages (Yin and Neubig, 2017; Iyer et al., 2018). Most of the early studies worked on a few domains and small datasets such as GeoQuery (Zelle and Mooney, 1996) and Overnight (Wang et al., 2015).

Recently, large and cross-domain text-to-SQL datasets such as WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018c) have received an increasing amount of attention as many data-driven neural approaches achieve promising results (Dong and Lapata, 2016; Su and Yan, 2017; Iyer et al., 2017; Xu et al., 2017; Finegan-Dollak et al., 2018; Yu et al., 2018a; Huang et al., 2018; Dong and Lapata, 2018; Sun et al., 2018; Gur et al., 2018; Guo et al., 2018; Yavuz et al., 2018; Shi et al., 2018). Most of them still focus on *context-independent* semantic parsing by converting single-turn questions into executable queries.

Relatively less effort has been devoted to *context-dependent* semantic parsing on datasets including ATIS (Hemphill et al., 1990; Dahl et al., 1994b), SpaceBook (Vlachos and Clark, 2014), SCONE (Long et al., 2016; Guu et al., 2017; Fried et al., 2018; Suhr and Artzi, 2018; Huang et al., 2019), SequentialQA (Iyyer et al., 2017), SParC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a). On ATIS, Miller et al. (1996) maps utterances to semantic frames which are then mapped to SQL queries; Zettlemoyer and Collins (2009) starts with context-independent Combinatory Categorial Grammar (CCG) parsing and then resolves references to generate lambda-calculus logical forms for sequences of sentences. The most relevant to our work is Suhr et al. (2018), who generate ATIS SQL queries from interactions by incorporating history with an interaction-level encoder and copying segments of previously generated queries. Furthermore, SCONE contains three domains using stack- or list-like elements and most queries include a single binary predicate. SequentialQA is created by decomposing some complicated questions in WikiTableQuestions (Pasupat and Liang, 2015). Since both SCONE and SequentialQA are annotated with only denotations but not query labels, they don't include many questions with rich semantic and contextual types. For example, SequentialQA (Iyyer et al., 2017) requires that the answer to follow-up questions must be a subset of previous answers, and most of the questions can be answered by simple SQL queries with `SELECT` and `WHERE` clauses.

Concurrent with our work, Yu et al. (2019a) introduced CoSQL, a large-scale cross-domain conversational text-to-SQL corpus collected under the Wizard-of-Oz setting. Each dialogue in CoSQL simulates a DB querying scenario with a crowd worker as a user and a college computer science student who is familiar with SQL as an expert. Question-SQL pairs in CoSQL reflect greater diversity in user backgrounds compared to other corpora and involve frequent changes in user intent between pairs or ambiguous questions that require user clarification. These features pose new chal-

lenges for text-to-SQL systems.

Our work is also related to recently proposed approaches to code generation by editing (Hayati et al., 2018; Yin et al., 2019; Hashimoto et al., 2018). While they follow the framework of generating code by editing the relevant examples retrieved from training data, we focus on a context-dependent setting where we generate queries from the previous query predicted by the system itself.

5 Experimental Results

5.1 Metrics

On both Spider and SParC, we use the exact set match accuracy between the gold and the predicted queries [4]. To avoid ordering issues, instead of using simple string matching, Yu et al. (2018c) decompose predicted queries into different SQL clauses such as `SELECT`, `WHERE`, `GROUP BY`, and `ORDER BY` and compute scores for each clause using set matching separately. On SparC, we report two metrics: question match accuracy which is the score average over all questions and interaction match accuracy which is average over all interactions.

5.2 Baselines

SParC. We compare with the two baseline models released by Yu et al. (2019b).

(1) Context-dependent Seq2Seq (CD-Seq2Seq): This model is adapted from Suhr et al. (2018). The original model was developed for ATIS and does not take the database schema as input hence cannot generalize well across domains. Yu et al. (2019b) adapt it to perform context-dependent SQL generation in multiple domains by adding a bi-LSTM database schema encoder which takes bag-of-words representations of column headers as input. They also modify the decoder to select between a SQL keyword or a column header.

(2) SyntaxSQL-con: This is adapted from the original context-agnostic SyntaxSQLNet (Yu et al., 2018b) by using bi-LSTMs to encode the interaction history including the utterance and the associated SQL query response. It also employs a column attention mechanism to compute representations of the previous question and SQL query.

Spider. We compare with the results as reported in Yu et al. (2018b). Furthermore, we also include recent results from Lee (2019) who propose to use recursive decoding procedure, Bogin et al. (2019) introducing graph neural networks for encoding schemas, and Guo et al. (2019) who achieve state-of-the-art performance by using an intermediate representation to bridge natural language questions and SQL queries.

	Dev Set	Test Set
SQLNet (Xu et al., 2017)	10.9	12.4
SyntaxSQLNet (Yu et al., 2018b)	18.9	19.7
+data augmentation (Yu et al., 2018b)	24.8	27.2
Lee (2019)	28.5	24.3
GNN (Bogin et al., 2019)	40.7	39.4
IRNet (Guo et al., 2019)	53.2	46.7
IRNet (BERT) (Guo et al., 2019)	61.9	54.7
Ours	36.4	32.9
+ utterance-table BERT Embedding	57.6	53.4

Table 4: Spider results on dev set and test set.

5.3 Implementation Details

Our model is implemented in PyTorch (Paszke et al., 2017). We use pretrained 300-dimensional GloVe (Pennington et al., 2014) word embedding. All LSTM layers have 300 hidden size, and we use 1 layer for encoder LSTMs, and 2 layers for decoder LSTMs. We use the ADAM optimizer (Kingma and Ba, 2015) to minimize the token-level cross-entropy loss with a batch size of 16. Model parameters are randomly initialized from a uniform distribution $U[-0.1, 0.1]$. The main model has an initial learning rate of 0.001 and it will be multiplied by 0.8 if the validation loss increases compared with the previous epoch. When using BERT instead of GloVe, we use the pretrained small uncased BERT model with 768 hidden size[5], and we fine tune it with a separate constant learning rate of 0.00001. The training typically converges in 10 epochs.

5.4 Overall Results

Spider. Table 4 shows the results on Spider dataset. Since each question is standalone, we don't use interaction-level decoder or query editing. Our method can achieve the performance of 36.4% on dev set and 32.9% on test set, serving as a strong model for the context-independent cross-domain text-to-SQL generation. This demonstrates the effectiveness of our utterance-table encoder and table-aware decoder to handle the semantics of user utterances and the complexity of table schemas to generate complex SQL queries in unseen domains.

Furthermore, adding the utterance-table BERT

	Question Match		Interaction Match	
	Dev	Test	Dev	Test
SyntaxSQL-con (Yu et al., 2019b)	18.5	20.2	4.3	5.2
CD-Seq2Seq (Yu et al., 2019b)*	21.9	23.2	8.1	7.5
+ segment copy (w/ predicted query)	21.7	20.3	9.5	8.1
+ segment copy (w/ gold query)	27.3	26.7	10.0	8.4
Ours	31.4	–	14.7	–
+ query attention and sequence editing (w/ predicted query)	33.0	–	16.4	–
+ query attention and sequence editing (w/ gold query)	40.6	–	17.3	–
Ours + utterance-table BERT Embedding	40.4	–	18.1	–
+ query attention (w/ predicted query)	42.7	–	21.6	–
+ query attention and sequence editing (w/ predicted query)	**47.2**	**47.9**	**29.5**	**25.3**
+ query attention and sequence editing (w/ gold query)	53.4	54.5	29.2	25.0

Table 5: SParC results. For our models, we only report test set results of our best model on the dev set. *We improve the CD-Seq2Seq performance over Yu et al. (2019b) by separating and parsing the column names (e.g., stu_fname → student first name) and using the schema-specific output vocabulary during decoding.

	Dev Set			Test Set		
	Query	Relaxed	Strict	Query	Relaxed	Strict
FULL (Suhr et al., 2018)	$37.5_{\pm 0.9}$	$63.0_{\pm 0.7}$	$62.5_{\pm 0.9}$	$43.6_{\pm 1.0}$	$69.3_{\pm 0.8}$	$69.2_{\pm 0.8}$
Ours	36.2	60.5	60.0	43.9	68.5	68.1

Table 6: ATIS results on dev set and test set.

embedding gives significant improvement, achieving 57.6% on dev set and 53.4% on test set, which is comparable to the state-of-the-art results from IRNet with BERT. We attribute our BERT model's high performance to (1) the empirically powerful text understanding ability of pretrained BERT model and (2) the early interaction between utterances and column headers when they are concatenated in a single sequence as the BERT input.

SParC. Table 5 shows the results on SParC dataset. Similar to Spider, our model without previous query as input already outperforms SyntaxSQL-con, achieving 31.4% question matching accuracy and 14.7% interaction matching accuracy. In addition, compared with CD-Seq2Seq, our model enjoys the benefits of the table-utterance encoder, turn attention, and the joint consideration of utterances and table schemas during the decoding stage. This boosts the performance by 10% question accuracy and 6% interaction accuracy.

Furthermore, we also investigate the effect of copying segment. We use the same segment copy procedure as Suhr et al. (2018): first deterministically extract segments from the previous query and encode each segment using an LSTM, then generate a segment by computing its output probability based on its segment encoding. However, since the segment extraction from Suhr et al. (2018) is exclusively designed for the ATIS dataset, we implement our own segment extraction procedure by extracting `SELECT`, `FROM`, `GROUP BY`, `ORDER BY` clauses as well as different conditions in `WHERE` clauses. In this way, 3.9 segments can be extracted per SQL on average. We found that adding segment copying to CD-Seq2Seq gives a slightly lower performance on question matching and a small gain on interaction matching, while using segments extracted from the gold query can have much higher results. This demonstrates that segment copy is vulnerable to error propagation. In addition, it can only copy whole segments hence has difficulty capturing the changes of only one or a few tokens in the query.

To better understand how models perform as the interaction proceeds, Figure 4 (Left) shows the performance split by turns on the dev set. The questions asked in later turns are more difficult to answer given longer context history. While the baselines have lower performance as the turn number increases, our model still maintains 38%-48% accuracy for turn 2 and 3, and 20% at turn 4 or beyond. Similarly, Figure 4 (Right) shows the performance split by hardness levels with the frequency of examples. This also demonstrates our model is more competitive in answering hard and extra hard questions.

ATIS. We also report our model performance

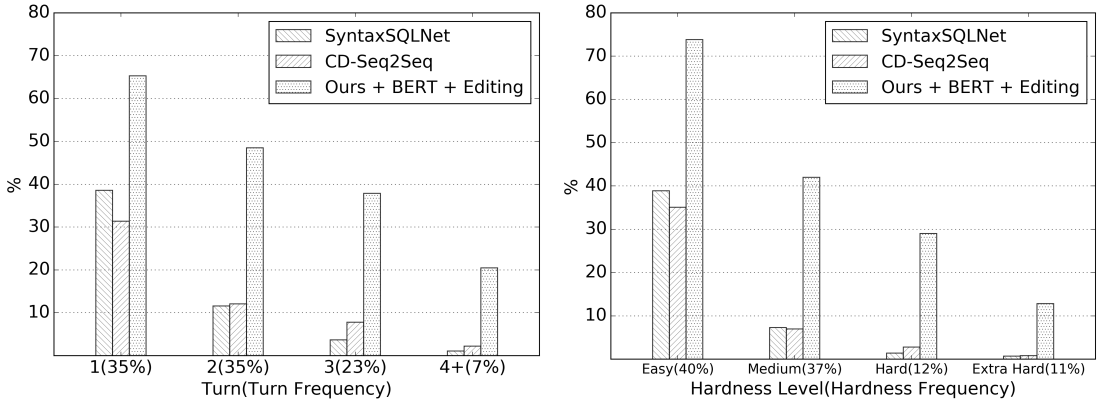

Figure 4: Performance split by different turns (Left) and hardness levels (Right) on SParC dev set.

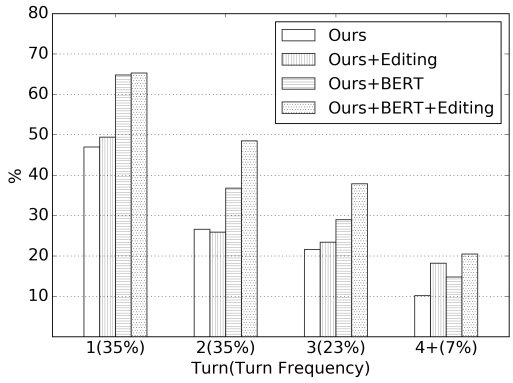

Figure 5: Effect of query editing at different turns on SParC dev set.

on ATIS in Table 6. Our model achieves 36.2% dev and 43.9% test string accuracy, comparable to Suhr et al. (2018). On ATIS, we only apply our editing mechanism and reuse their utterance encoder instead of the BERT utterance-table encoder, because ATIS is single domain.

5.5 Effect of Query Editing

We further investigate the effect of our query editing mechanism. To this end, we apply editing from both the gold query and the predicted query on our model with or without the utterance-table BERT embedding. We also perform an ablation study to validate the contribution of query attention and sequence editing separately.

As shown in Table 5, editing the gold query consistently improves both question match and interaction match accuracy. This shows the editing approach is indeed helpful to improve the generation quality when the previous query is the oracle.

Using the predicted query is a more realistic setting, and in this case, the model is affected by error propagation due to the incorrect queries produced by itself. For the model without the utterance-table BERT embedding, using the predicted query only gives around 1.5% improvement. As shown in Figure 5, this is because the editing mechanism is more helpful for turn 4 which is a small fraction of all question examples. For the model with the utterance-table BERT embedding, the query generation accuracy at each turn is significantly improved, thus reducing the error propagation effect. In this case, the editing approach delivers consistent improvements of 7% increase on question matching accuracy and 11% increase on interaction matching accuracy. Figure 5 also shows that query editing with BERT benefits all turns.

Finally, as an ablation study, Table 5 also reports the result with only query attention (use predicted query) on the dev set. This improves over our vanilla BERT model without query attention and achieves 42.7% question and 21.6% interaction matching accuracy. With query editing, our best model further improves to 47.2% question and 29.5% interaction matching accuracy. This demonstrates the effectiveness of our query attention and query editing separately, both of which are essential to make use of the previous query.

6 Conclusions

In this paper, we propose an editing-based encoder-decoder model to address the problem of context-dependent cross-domain text-to-SQL generation. While being simple, empirical results demonstrate the benefits of our editing mechanism. The approach is more robust to error propagation than copying segments, and its performance increases when the basic text-to-SQL generation quality (without editing) is better.

Abstract

Recently, semantic role labeling (SRL) has earned a series of success with even higher performance improvements, which can be mainly attributed to syntactic integration and enhanced word representation. However, most of these efforts focus on English, while SRL on multiple languages more than English has received relatively little attention so that is kept underdevelopment. Thus this paper intends to fill the gap on multilingual SRL with special focus on the impact of syntax and contextualized word representation. Unlike existing work, we propose a novel method guided by syntactic rule to prune arguments, which enables us to integrate syntax into multilingual SRL model simply and effectively. We present a unified SRL model designed for multiple languages together with the proposed uniform syntax enhancement. Our model achieves new state-of-the-art results on the CoNLL-2009 benchmarks of all seven languages. Besides, we pose a discussion on the syntactic role among different languages and verify the effectiveness of deep enhanced representation for multilingual SRL.

1 Introduction

Semantic role labeling (SRL) aims to derive the meaning representation such as an instantiated predicate-argument structure for a sentence. The currently popular formalisms to represent the semantic predicate-argument structure are based on dependencies and spans. Their main difference is that dependency SRL annotates the syntactic head of argument rather than the entire constituent (span), and this paper will focus on the dependency-based SRL. Be it dependency or span, SRL plays a critical role in many natural language processing (NLP) tasks, including information extraction (Christensen et al., 2011), machine translation (Xiong et al., 2012) and question answering (Yih et al., 2016).

Almost all of traditional SRL methods relied heavily on syntactic features, which suffered the risk of erroneous syntactic input, leading to undesired error propagation. To alleviate this inconvenience, researchers as early as Zhou and Xu (2015) propose neural SRL models without syntactic input. Cai et al. (2018) employ the biaffine attentional mechanism (Dozat and Manning, 2017) for dependency-based SRL. In the meantime, a series of studies (Roth and Lapata, 2016; Marcheggiani and Titov, 2017; Strubell et al., 2018; Li et al., 2018) have introduced syntactic clue in creative ways for further performance improvement, which achieve favorable results. However, applying the k-order syntactic tree pruning of He et al. (2018) to the biaffine SRL model (Cai et al., 2018) does not boost the performance as expected, which indicates that exploiting syntactic clue in state-of-the-art SRL models still deserves deep exploration.

Besides, most of SRL literature is dedicated to impressive performance gains on English and Chinese, but other multiple languages have received relatively little attention. We even observe that to date the best reported results of some languages (Catalan and Japanese) are still from the initial CoNLL-2009 shared task (Hajič et al., 2009). Therefore, we launch this multilingual SRL study to fill the obvious gap ignored since a long time ago. Especially, we attempt to improve the overall performance of multilingual SRL by incorporating syntax and introducing contextualized word representation, and explore syntactic effect on other multiple languages.

Multilingual SRL needs to be carefully han-

dled for the diversity of syntactic and semantic representations among quite different languages. Despite such a diversity, in this paper, we manage to develop a simple and effective neural SRL model to integrate syntactic information by applying argument pruning method in a uniform way. Specifically, we introduce new pruning rule based on syntactic parse tree unlike the k-order pruning of He et al. (2018), which is only simply determined by the relative distance of predicate and argument. Furthermore, we propose a novel method guided by syntactic rule to prune arguments for dependency SRL, different from the existing work. With the help of the proposed pruning method, our model can effectively alleviate the imbalanced distribution of arguments and non-arguments, achieving faster convergence during training.

To verify the effectiveness and applicability of the proposed method, we evaluate the model on all seven languages of CoNLL-2009 datasets. Experimental results indicate that our argument pruning method is generally effective for multilingual SRL over our unified modeling. Moreover, our model using contextualized word representation achieves the new best results on all seven datasets, which is the first overall update since 2009. To the best of our knowledge, this is the first attempt to study seven languages comprehensively in deep learning models.

2 Model

Given a sentence, SRL can be decomposed into four classification subtasks, predicate identification and disambiguation, argument identification and classification. Since the CoNLL-2009 shared task has indicated all predicates beforehand, we focus on identifying arguments and labeling them with semantic roles. Our model builds on a recent syntax-agnostic SRL model (Cai et al., 2018) by introducing argument pruning and enhanced word representation. In this work, we handle argument identification and classification in one shot, treating the SRL task as word predicate-argument pair classification. Figure 1 illustrates the overall architecture of our model, which consists of three modules, (1) a bidirectional LSTM (BiLSTM) encoder, (2) an argument pruning layer which takes as input the BiLSTM representations, and (3) a biaffine scorer which takes as input the predicate and its argument candidates.

2.1 BiLSTM Encoder

Given a sentence and marked predicates, we adopt the bidirectional Long Short-term Memory neural network (BiLSTM) (Hochreiter and Schmidhuber, 1997) to encode sentence, which takes as input the word representation. Following Cai et al. (2018), the word representation is the concatenation of five vectors: randomly initialized word embedding, lemma embedding, part-of-speech (POS) tag embedding, pre-trained word embedding and predicate-specific indicator embedding.

Besides, the latest work (Li et al., 2018) has demonstrated that the contextualized representation ELMo (Embeddings from Language Models) (Peters et al., 2018) could boost performance of dependency SRL model on English and Chinese. To explore whether the deep enhanced representation can help other multiple languages, we further enhance the word representation by concatenating an external embedding from the recent successful language models, ELMo and BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018), which are both contextualized representations. It is worth noting that we use ELMo or BERT to obtain pre-trained contextual embeddings rather than fine-tune the model, which are fixed contextual representations.

2.2 Argument Pruning Layer

For word pair classification modeling, one major performance bottleneck is caused by unbalanced data, especially for SRL, where more than 90% of argument candidates are non-arguments. A series of pruning methods are then proposed to alleviate the imbalanced distribution, such as the k-order pruning (He et al., 2018). However, it does not extend well to other languages, and even hinders the syntax-agnostic SRL model as Cai et al. (2018) has experimented with different k values on English. The reason might be that this pruning method breaks up the whole sentence, leading the BiLSTM encoder to take the incomplete sentence as input and fail to learn sentence representation sufficiently.

To alleviate such a drawback from the previous syntax-based pruning methods, we propose a novel pruning rule extraction method based on syntactic parse tree, which generally suits multilingual cases at the same time. In detailed model implementation, we add an argument pruning layer guided by syntactic rule following BiL-

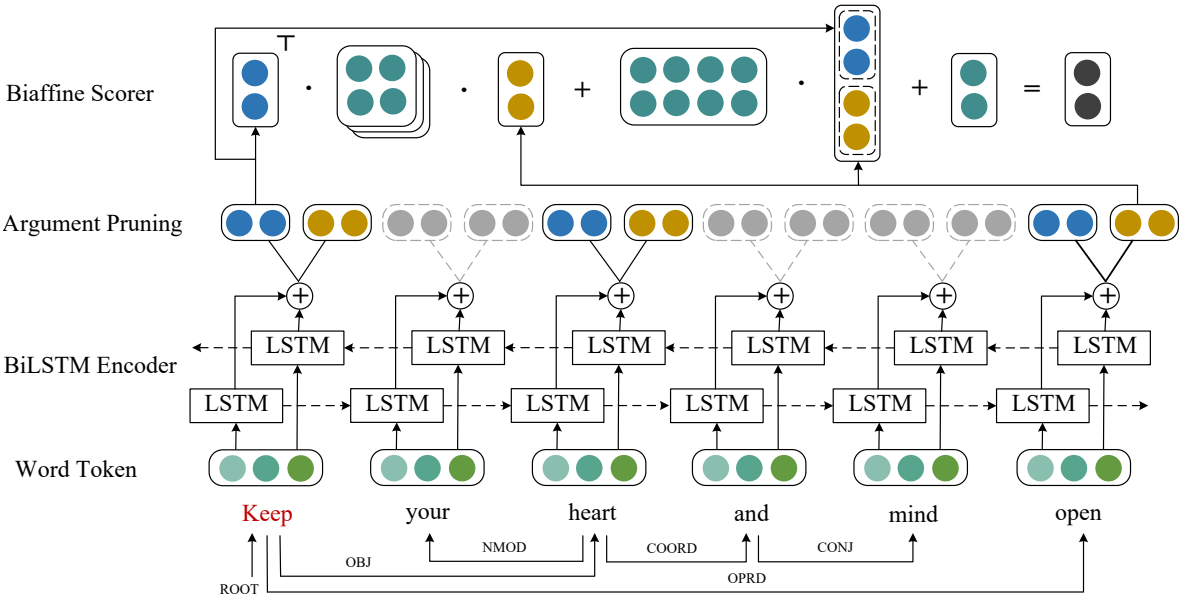

Figure 1: Overall architecture of our SRL model. Red denotes the given predicate, and gray indicates that these units are dropped according to syntactic rule. The bottom is syntactic dependency.

STM layers, which can absorb the syntactic clue simply and effectively.

Syntactic Rule Considering that all arguments are predicate-specific instances, it has been generally observed that the distances between predicate and its arguments on syntactic tree are within a certain range for most languages. Therefore, we introduce language-specific rule based on syntactic dependency parses to prune some unlikely arguments, henceforth syntactic rule. Specifically, given a predicate p and its argument a, we define d_p and d_a to be the distance from p and a to their nearest common ancestor node (namely, the root of the minimal subtree which includes p and a) respectively. For example, 0 denotes that predicate or argument itself is their nearest common ancestor, while 1 represents that their nearest common ancestor is the parent of predicate or argument. Then we use the distance tuple (d_p, d_a) as their relative position representation inside the parse tree. Finally, we make a list of all tuples ordered according to how many times that each distance tuple occurs in the training data, which is counted for each language independently.

It is worth noting that our syntactic rule is determined by the top-k frequent distance tuples. During training and inference, the syntactic rule takes effect by excluding all candidate arguments whose predicate-argument relative position in parse tree is not in the list of top-k frequent tuples.

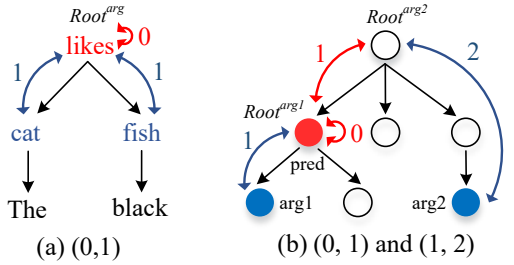

Figure 2: Syntactic parse tree examples (dependency relations are omitted). Red represents the current predicate, and blue indicates its arguments.

Figure 2 shows simplified examples of syntactic dependency tree. Given an English sentence in (a), the current predicate is *likes*, whose arguments are *cat* and *fish*. For *likes* and *cat*, the predicate (*likes*) is their common ancestor (denoted as $Root^{arg}$) according to the syntax tree. Therefore, the relative position representation of predicate and argument is $(0, 1)$, so it is for *likes* and *fish*. As for the right one in (b), suppose the marked predicate has two arguments$-arg1$ and $arg2$, the common ancestors of predicate and arguments are respectively $Root^{arg1}$ and $Root^{arg2}$. In this case, the relative position representations are $(0, 1)$ and $(1, 2)$.

Argument Pruning Method To maintain the integrity of sequential inputs from the whole sentence, we propose a novel syntax-based method to prune arguments, unlike most existing work (Xue and Palmer, 2004; Zhao et al., 2009a; He et al.,

2018) which prunes argument candidates in the pre-processing stage. As shown in Figure 1, the way to perform argument pruning strategy is very straightforward. In the argument pruning layer, our model drops these candidate arguments (more exactly, BiLSTM representations) which do not comply with the syntactic rule. In other words, only the predicates and arguments that satisfy the syntactic rule will be output to next layer.

For example (in Figure 1), given the sentence *Keep your heart and mind open*, the predicate *Keep* and the corresponding syntactic dependency (bottom), by definition, $(0, 1)$ is inside the syntactic rule on this occasion. Therefore, these candidate arguments (i.e., *your*, *and*, *mind*) will be pruned by the argument pruning layer.

2.3 Biaffine Scorer

As mentioned above, our model treats SRL task as a word pair classification problem, tackling argument identification and classification in one shot. To label arguments of given predicates, we employ a scorer with biaffine attention (Dozat and Manning, 2017) (biaffine scorer for short) as role classifier on top of argument pruning layer for the final prediction, similar to Cai et al. (2018). Biaffine scorer takes as input the BiLSTM hidden states of predicate and candidate arguments filtered by argument pruning layer, denoted by h_p and h_a respectively, and then computes the probability of corresponding semantic labels using biaffine transformation as follows:

$$\begin{aligned}\Phi_r(p, a) &= \textit{Biaffine}(h_p, h_a) \\ &= \{h_p\}^T \mathbf{W}_1 h_a + \mathbf{W}_2^T (h_p \oplus h_a) + \mathbf{b}\end{aligned}$$

where $\oplus$ represents concatenation operator, $\mathbf{W}_1$ and $\mathbf{W}_2$ denote the weight matrix of the bilinear and the linear terms respectively, and $\mathbf{b}$ is the bias item. Note that the predicate itself is also included in its own argument candidate list and will be applied to compute scores, because a nominal predicate sometimes takes itself as its own argument.

3 Experiments

Our model[1] is evaluated on the CoNLL-2009 benchmark datasets, including Catalan, Chinese, Czech, English, German, Japanese and Spanish. The statistics of the training datasets can be seen in Table 1. For the predicate disambiguation task, we follow previous work, using models (Zhao et al., 2009a) for Catalan and Spanish, and the ones (Björkelund et al., 2009) for other languages. Besides, we use the officially predicted POS tags and syntactic parses provided by CoNLL-2009 shared-task for all languages.[2] As for the contextualized representation, ELMo, we employ the multilingual version from Che et al. (2018). For BERT, this work uses the BERT-Base, Multilingual Cased model (Devlin et al., 2018). For syntactic rule in argument pruning layer, to ensure more than 99% coverage of true arguments in pruning output, we use the top-120 distance tuples on Japanese and top-20 on other multiple languages for a better trade-off between computation and coverage.

Dataset	#sent	#token	#pred	#arg

3.1 Model Setup

In our experiments, all real vectors are randomly initialized, including 100-dimensional word, lemma, POS tag embeddings and 16-dimensional predicate-specific indicator embedding (He et al., 2018). The pre-trained word embedding is 100-dimensional GloVe vectors (Pennington et al., 2014) for English, 300-dimensional fastText vectors (Grave et al., 2018) trained on Common Crawl and Wikipedia for other languages, while the dimension of ELMo or BERT word embedding is 1024. Besides, we use 3 layers BiLSTM with 400-dimensional hidden states, applying dropout with an 80% keep probability between time-steps and layers. For biaffine scorer, we employ two 300-dimensional affine transfor-

[1]The code is available at https://github.com/bcmi220/multilingual_srl.

[2]There were two tracks in the CoNLL-2009 shared task, SRL-only and joint. For the former, all participants did not have to develop their own syntactic parsers and focused on the SRL model development, while for the latter, the participants had to build their own syntactic parser as well. For the sake of focusing the SRL work, in this work, we will take the official syntax provided by CoNLL-2009.

mations with the ReLU non-linear activation, also setting the dropout probability to 0.2. During training, we use the categorical cross-entropy as objective, with Adam optimizer (Kingma and Ba, 2015) initial learning rate $2e^{-3}$. All models are trained for up to 500 epochs with batch size 64.

3.2 Results and Discussion

In Table 2, we compare our single model (**AP** is an acronym for argument pruning) against previous work on English in-domain data and Chinese test set. Our baseline is a modification to the model of Cai et al. (2018) which uniformly handled the predicate disambiguation. For English, our baseline gives slightly weaker performance than the work of Li et al. (2019), which used ELMo and employed a sophisticated span selection model for predicting predicates and arguments jointly. Our model with the proposed argument pruning layer (**+ AP**) brings absolute improvements of 0.35% and 0.5% F_1 on English and Chinese, respectively, which is on par with the best published scores. Moreover, we introduce deep enhanced representation based on the argument pruning. Our model utilizing BERT (**+ AP + BERT**) achieves the new best results on English and Chinese benchmarks.

Table 3 presents all test results on seven languages of CoNLL-2009 datasets. So far, the best previously reported results of Catalan, Japanese and Spanish are still from CoNLL-2009 shared task. Compared with previous methods, our baseline yields strong performance on all datasets except German. Especially for Catalan, Czech, Japanese and Spanish, our baseline performs better than existing methods with a large margin of 3.5% F_1 on average. Nevertheless, applying our argument pruning to the strong syntax-agnostic baseline can still boost the model performance, which demonstrates the effectiveness of proposed method. On the other hand, it indicates that syntax is generally beneficial to multiple languages, and can enhance the multilingual SRL performance with effective syntactic integration.

Besides, we report the scores of leveraging ELMo and BERT for multiple languages (the last three rows in Table 3). The use of contextualized word representation further improves model performance, which overwhelmingly outperforms previously published best results and achieves the new state of the art in multilingual SRL for the first time. Furthermore, we find that ELMo promotes the overall performance of SRL model, but BERT gives more significant performance increase than ELMo on all languages, which suggests that BERT is better at enriching contextual information. More interestingly, we observe that the performance gains from the proposed argument pruning method or these deep enhanced representations are relatively marginal on Japanese, one possible reason is the relatively small size of

its training set. This observation also indicates that ELMo or BERT is more suitable for learning on large annotated corpus.

3.3 End-to-end SRL

As mentioned above, we combine the predicate sense output of previous work to make results directly comparable, since the official evaluation script includes such prediction in the F_1-score calculation. However, predicate disambiguation is considered a simpler task with higher semantic F_1-score and deserves more further research. To this end, we present a full end-to-end neural model for multilingual SRL, namely *Biaffine SRL*, following Cai et al. (2018).

Unlike most of SRL work treating the predicate sense disambiguation and semantic role assignment tasks as independent, we jointly handle predicate disambiguation and argument labeling in one shot by introducing a virtual node $<VR>$ as the nominal semantic head of predicate. It should be noted that the predicate sense annotation of Czech and Japanese is simply the lemmatized token of the predicate, a one-to-one predicate-sense mapping. Therefore, we ignore them and conduct experiments on other five languages.

Table 4 shows the results of end-to-end setting. Compared to the baseline, our full end-to-end model (*Biaffine SRL*) yields slightly higher precision of predicate disambiguation as a whole, which gives rise to a corresponding gain of semantic F_1. What is more, our model (using argument pruning and BERT) reaches the highest scores on the five benchmarks. Besides, experiments indicate that argument pruning promotes role labeling performance while BERT significantly improves the performance of predicate disambiguation.

4 Analysis

In this section, we perform further analysis to better understand our model, exploring the impact of language features, syntactic rule and syntac-

Dataset	baseline	w/o POS tag	w/o lemma

German	78.36	78.54 (88.91)	*78.56*
Japanese	83.08	83.12 (92.29)	*83.20*
Spanish	83.47	83.70 (89.39)	*84.82*

Table 7: Syntactic contribution to multilingual SRL. *predicted* and *gold* denote the use of syntactic parse. The UAS of predicted syntax is in parenthesis.

tic contribution for multilingual SRL. Since recent work well studied dependency SRL on English and Chinese, we focus on other five languages, and these analyses are performed on CoNLL-2009 test sets without using ELMo or BERT embeddings.

4.1 Effectiveness of Language Feature

As Marcheggiani et al. (2017) point out, POS tag information is highly beneficial for English. Consequently, we conduct an ablation study on in-domain test set to explore how the language features impact our model. Table 5 reports the F_1 scores of model which removes POS tag or lemma from the baseline. Results show that omitting POS tag or lemma leads to slight performance degradation (-0.5% and -0.32% F_1 on average, respectively), indicating that both can help improve performance of multilingual SRL. Interestingly, we see a drop of 1.0% F_1 for Japanese not using POS tag, which demonstrates its importance.

4.2 Effectiveness of Syntactic Rule

According to our statistics of syntactic rule on training data for seven languages, which is based on the automatically predicted parse provided by CoNLL-2009 shared task, the total number of distance tuples in syntactic rule is no more than 120 in these languages except that Japanese is about 260. It is in favor of previous hypothesis that the relative distances between predicate and its arguments are within a certain range. Besides, $(0, 1)$ is the most frequently occurring relationships in all languages except Japanese, which indicates that arguments most frequently appear to be the children of their predicate in dependency syntax tree.

Figure 3 shows F_1 scores on test set by top-k argument pruning for German, Catalan and Japanese,[3] where k = 0 represents the baseline without pruning. We observe that the case of k = 20 yields the best performance on German and Catalan. As for Japanese, it falls short of the baseline in our current observation range, but our experiment has shown that the setting of top-120 can achieve the best results.

To reveal the strengths of proposed syntactic rule, we conduct further experiments, replacing our syntactic rule based pruning with the k-order argument pruning of He et al. (2018). Following their setting, we use the tenth-order pruning for pursuing the best performance. Table 6 shows the performance gaps between two pruning methods. Comparing with syntactic rule, the k-order prun-

[3]Note that the maximum values of k for German, Catalan and Japanese are 36, 50 and 260, respectively. We thus show only the top 50 for Japanese due to the limited space.

ing declines model performance by 0.2% F_1 on average, showing that our syntactic rule based pruning method is more effective and can be extended well to multiple languages especially for Japanese.

4.3 Syntactic Impact

In this part, we attempt to explore the syntactic impact on other five languages. To investigate the most contribution of syntax to multilingual SRL, we perform experiments using the gold syntactic parse also officially provided by the CoNLL-2009 shared task instead of the predicted one.[4] To be more precise, the syntactic rule is counted based on gold syntactic tree and applied to argument pruning layer. The corresponding results of our syntax-agnostic and syntax-aware models are summarized in Table 7. We also report the unlabeled attachment scores (UAS) of predicted syntax as syntactic accuracy measurement, considering that we do not use the dependency labels.

Results indicate that high-quality syntax can further improve model performance, showing syntactic information is generally effective for multilingual SRL. In particular, based on gold syntax, the top-1 argument pruning for Catalan and Spanish has reached 100 percent coverage (namely, for Catalan and Spanish, all arguments are the children of predicates in gold dependency syntax tree), and hence our syntax-aware model obtains significant gains of 1.43% and 1.35%, respectively.

In addition, combining the results of Tables 6 and 7, we find that applying the k-order argument pruning of He et al. (2018) to syntax-agnostic model results in better performance on most languages. However, Cai et al. (2018) argue that k-order pruning does not boost the performance for English. One reason to account for this finding is the lack of effective approaches for incorporating syntactic information into sequential neural networks. Nevertheless, syntactic contribution is overall limited for multilingual SRL in this work, due to strong syntax-agnostic baseline. Therefore, more effective methods to incorporate syntax into neural SRL model are worth exploring. Besides, utilization of syntactic dependency labels information is also a promising direction and we leave it for future work.

[4] In this work, we use gold syntax rather than other better parse to explore the greatest syntactic contribution, considering the current state-of-the-art syntactic parsers are being upgraded so fast now.

5 Related Work

In early work of semantic role labeling, most of researchers were dedicated to feature engineering (Pradhan et al., 2005; Punyakanok et al., 2008; Zhao et al., 2009b, 2013). The first neural SRL model was proposed by Collobert et al. (2011), which used convolutional neural network but their efforts fell short. Later, Foland and Martin (2015) effectively extended their work by using syntactic features as input. Roth and Lapata (2016) introduced syntactic paths to guide neural architectures for dependency SRL.

However, putting syntax aside has sparked much research interest since Zhou and Xu (2015) employed deep BiLSTMs for span SRL. A series of neural SRL models without syntactic inputs were proposed. Marcheggiani et al. (2017) applied a simple LSTM model with effective word representation, achieving encouraging results on English, Chinese, Czech and Spanish. Cai et al. (2018) built a full end-to-end SRL model with biaffine attention and provided strong performance on English and Chinese. Li et al. (2019) also proposed an end-to-end model for both dependency and span SRL with a unified argument representation, obtaining favorable results on English.

Despite the success of syntax-agnostic SRL models, more recent work attempts to further improve performance by integrating syntactic information, with the impressive success of deep neural networks in dependency parsing (Zhang et al., 2016; Zhou and Zhao, 2019). Marcheggiani and Titov (2017) used graph convolutional network to encode syntax into dependency SRL. He et al. (2018) proposed an extended k-order argument pruning algorithm based on syntactic tree and boosted SRL performance. Li et al. (2018) presented a unified neural framework to provide multiple methods for syntactic integration. Our method is closely related to the one of He et al. (2018), designed to prune as many unlikely arguments as possible.

Multilingual SRL To promote NLP applications, the CoNLL-2009 shared task advocated performing SRL for multiple languages. Among the participating systems, Zhao et al. (2009a) proposed an integrated approach by exploiting large-scale feature set, while Björkelund et al. (2009) used a generic feature selection procedure. Until now, only a few of work (Lei et al., 2015;

Swayamdipta et al., 2016; Mulcaire et al., 2018) seriously considered multilingual SRL. Among them, Mulcaire et al. (2018) built a polyglot model (training one model on multiple languages) for multilingual SRL, but their results were far from satisfactory. Therefore, this work aims to complete the overall upgrade since CoNLL-2009 shared task and leaves polyglot training as our future work.

6 Conclusion

This paper is dedicated to filling the long-term performance gap of multilingual SRL since a long time ago with a newly proposed syntax-based argument pruning method. Experimental results demonstrate its effectiveness and shed light on a new perspective for many NLP tasks to incorporate syntax simply and effectively. Besides, our model substantially boosts multilingual SRL performance by introducing deep enhanced representation, achieving new state-of-the-art results on the in-domain CoNLL-2009 benchmark for Catalan, Chinese, Czech, English, German, Japanese and Spanish. These results further show that syntactic information and deep enhanced representation can also promote multiple languages rather than only the case of English.

Facebook AI Research
Menlo Park, CA and Seattle, WA

Abstract

We present a new approach for pretraining a bi-directional transformer model that provides significant performance gains across a variety of language understanding problems. Our model solves a cloze-style word reconstruction task, where each word is ablated and must be predicted given the rest of the text. Experiments demonstrate large performance gains on GLUE and new state of the art results on NER as well as constituency parsing benchmarks, consistent with BERT. We also present a detailed analysis of a number of factors that contribute to effective pretraining, including data domain and size, model capacity, and variations on the cloze objective.

1 Introduction

Language model pretraining has recently been shown to provide significant performance gains for a range of challenging language understanding problems (Dai and Le, 2015; Peters et al., 2018; Radford et al., 2018). However, existing work has either used unidirectional (left-to-right) language models (LMs) (Radford et al., 2018) or bi-directional (both left-to-right and right-to-left) LMs (BiLMs) where each direction is trained with an independent loss function (Peters et al., 2018). In this paper, we show that even larger performance gains are possible by jointly pretraining both directions of a large language-model-inspired self-attention cloze model.

Our bi-directional transformer architecture predicts *every* token in the training data (Figure 1). We achieve this by introducing a cloze-style training objective where the model must predict the center word given left-to-right and right-to-left context representations. Our model separately computes both forward and backward states with a masked self-attention architecture, that closely resembles a language model. At the top of the network, the forward and backward states are combined to jointly predict the center word. This approach allows us to consider both contexts when predicting words and to incur loss for every word in the training set, if the model does not assign it high likelihood.

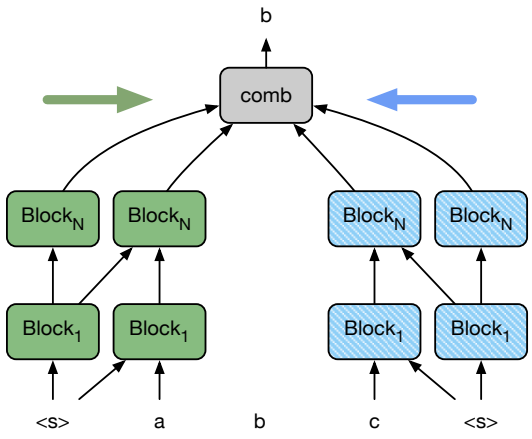

Figure 1: Illustration of the model. Block$_i$ is a standard transformer decoder block. Green blocks operate left to right by masking future time-steps and blue blocks operate right to left. At the top, states are combined with a standard multi-head self-attention module whose output is fed to a classifier that predicts the center token.

Experiments on the GLUE (Wang et al., 2018) benchmark show strong gains over the state of the art for each task, including a 9.1 point gain on RTE over Radford et al. (2018). These improvements are consistent with, if slightly behind, BERT (Devlin et al., 2018), which we will discuss in more detail in the next section. We also show that it is possible to stack task-specific architectures for NER and constituency parsing on top of our pretrained representations, and achieve new state-of-the-art performance levels for both tasks. We also present extensive experimental analysis to better

*Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5360–5369, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

understand these results, showing that (1) having multiple sentences in each training example is crucial for many tasks; (2) pre-training continues to improve performance with up to 18B tokens and would likely continue to improve with more data; and finally (3) our novel cloze-driven training regime is more effective than predicting left and right tokens separately.

2 Related work

There has been much recent work on learning sentence-specific representations for language understanding tasks. McCann et al. (2017) learn contextualized word representations from a sequence to sequence translation task and uses the representations from the encoder network to improve a variety of language understanding tasks. Subsequent work focused on language modeling pretraining which has been shown to be more effective and which does not require bilingual data (Zhang and Bowman, 2018).

Our work was inspired by ELMo (Peters et al., 2018) and the generative pretraining (GPT) approach of Radford et al. (2018). ELMo introduces language models to pretrain word representations for downstream tasks including a novel mechanism to learn a combination of different layers in the language model that is most beneficial to the current task. GPT relies on a left to right language model and an added projection layer for each downstream task without a task-specific model. Our approach mostly follows GPT, though we show that our model also works well with an ELMo module on NER and constituency parsing.

The BERT model (Devlin et al., 2018) is a transformer encoder model that captures left and right context. There is significant overlap between their work and ours but there are also significant differences: our model is a bi-directional transformer language model that predicts every single token in a sequence. Our model has two unidirectional components encoding either the left or right context and both are combined to predict center words. BERT is also a transformer encoder that has access to the entire input but this choice requires a special training regime. In particular, they multi-task between predicting a subset of masked input tokens, similar to a denoising autoencoder, and a next sentence prediction task. In comparison, we optimize a single loss function that requires the model to predict each token of an input sentence given all surrounding tokens. We use all tokens as training targets and therefore extract learning signal from every single token in the sentence and not just a subset. Melamud et al. (2016) follow a similar approach to ours by predicting the center word but their architecture is based on LSTMs and we include the center word when we actually fine-tune on downstream tasks.

BERT tailors pretraining to capture dependencies between sentences via a next sentence prediction task as well as by constructing training examples of sentence-pairs with input markers that distinguish between tokens of the two sentences. Our model is trained similarly to a classical language model since we do not adapt the training examples to resemble the end task data and we do not solve a denoising task during training.

Finally, BERT as well as Radford et al. (2018) consider only a single data source to pretrain their models, either BooksCorpus (Radford et al., 2018), or BooksCorpus and additional Wikipedia data (Devlin et al., 2018), whereas our study ablates the effect of various amounts of training data as well as different data sources.

3 Two tower model

Our cloze model represents a probability distribution $p(t_i|t_1, \ldots, t_{i-1}, t_{i+1}, \ldots, t_n)$ for a sentence with n tokens $t_1, \ldots, t_n$. There are two self-attentional towers each consisting of N stacked blocks: the *forward* tower operates left-to-right and the *backward* tower operates in the opposite direction. To predict a token, we combine the representations of the two towers, as described in more detail below, taking care that neither representation contains information about the current target token.

The forward tower computes the representation F_i^l for token i at layer l based on the forward representations of the previous layer $F_{\leq i}^{l-1}$ via self-attention; the backward tower computes representation B_i^l based on information from the opposite direction $B_{\geq i}^{l-1}$. When examples of uneven length are batched, one of the towers may not have any context at the beginning. We deal with this issue by adding an extra zero state over which the self-attention mechanism can attend.

We pretrain on individual examples as they occur in the training corpora (§5.1). For News Crawl this is individual sentences while on Wikipedia, Bookcorpus, and Common Crawl examples are

paragraph length. Sentences are prepended and appended with sample boundary markers $< s >$.

3.1 Block structure

The structure of the blocks follows most of the architectural choices described in Vaswani et al. (2017). Each block consists of two sub-blocks: the first is a multi-head self-attention module with $H = 16$ heads for which we mask out any subsequent time-steps, depending on if we are dealing with the forward or backward tower. The second sub-block is a feed-forward module (FFN) of the form $ReLU(\boldsymbol{W}_1\boldsymbol{X} + b_1)\boldsymbol{W}_2 + b_2$ where $\boldsymbol{W}_1 \in \mathbb{R}^{e \times f}$, $\boldsymbol{W}_1 \in \mathbb{R}^{f \times e}$. Different to Vaswani et al. (2017) we apply layer normalization before the self-attention and FFN blocks instead of after, as we find it leads to more effective training. Sub-blocks are surrounded by a residual connection (He et al., 2015). Position is encoded via fixed sinusoidal position embeddings and we use a character CNN encoding of the input tokens for word-based models (Kim et al., 2016). Input embeddings are shared between the two towers.

3.2 Combination of representations

The forward and backward representations computed by the two towers are combined to predict the ablated word. To combine them we use a self-attention module which is followed by an FFN block (§3.1). The output of the FFN block f is projected by $\mathbf{W}$ into V classes representing the types in the vocabulary: $\mathbf{W}^T f$ to which a softmax is applied. When the model predicts token i, the input to the attention module are forward states $F_1^L \dots F_{i-1}^L$ and backward states $B_{i+1}^L \dots B_n^L$ where n is the length of the sequence and L is the number of layers. We implement this by masking $B_{\leq i}^L$ and $F_{\geq i}^L$. The attention query for token i is a combination of F_{i-1}^L and B_{i+1}^L. For the base model we sum the two representations and for the larger models they are concatenated. Keys and values are based on the forward and backward states fed to the attention module. In summary, this module has access to information about the entire input surrounding the current target token. During training, we predict every token in this way. The output of this module is fed to an output classifier which predicts the center token. We use an adaptive softmax for the output classifier (Grave et al., 2017) for the word based models and regular softmax for the BPE based models.

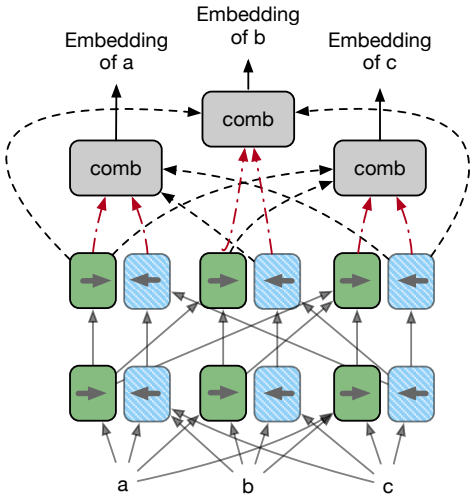

Figure 2: Illustration of fine-tuning for a downstream task. For classification problems, output of the first and last token is fed to a task-specific classifier. Masking for the final combination layer (comb) is removed which results in representations based on all forward and backward states (cf. Figure 1). The red dot-dashed arrows show connections that are masked during training, but unmasked for fine-tuning.

While all states that contain information about the current target word are masked in the final self-attention block during training, we found it beneficial to disable this masking when fine tuning the pretrained model for downstream tasks. This is especially true for tasks that label each token, such as NER, as this allows the model to access the full context including the token itself.

4 Fine-tuning

We use the following approach to fine-tune the pretrained two tower model to specific downstream tasks (Figure 2).

Classification and regression tasks. For single sentence classification tasks, we consider the language model outputs for the boundary tokens $< s >$ which we add before the start and end of each sentence. The language model outputs are the representations f just before the final softmax layer (§3.2). The outputs are of dimension $d = 1024$ and we concatenate them to project to the number of classes C in the downstream task with $W_1 \in \mathbb{R}^{C \times 2d}$ (Radford et al., 2018); we add a bias term $b \in \mathbb{R}^C$ and initialize all weights as well as the bias to zero. The output of the projection is softmax-normalized and the model is optimized with cross-entropy for classification tasks. Re-

gression tasks such as the Semantic Textual Similarity benchmark (STS-B; Cer et al., 2017) use $C = 1$ and are trained with mean squared error. For tasks involving sentence-pairs, we concatenate them and add a new separator token $< sep >$ between them. We add the output of this token to the final projection $W_2 \in \mathbb{R}^{C \times 3d}$.

Structured prediction tasks. For named entity recognition and parsing we use task-specific architectures which we fine-tune together with the language model but with different learning rate. The architectures are detailed in the respective results sections. The input to the architectures are the output representations of the pretrained language model.

No Masking. For fine-tuning, we found it beneficial to remove masking of the current token in the final layer that pools the output of the two towers. This is different than in the actual pretraining. It is important to have access to information about the token to be classified for token level classification tasks such as NER but we also found this to perform better for sentence classification tasks. In practice, we completely disable masking in the combination layer so that it operates over all forward and backward states. However, disabling masking below the combination layer does not perform well.

Optimization. During fine-tuning we use larger learning rates for the new parameters, that is W_1, W_2, b or the task-specific architecture, compared to the pretrained model. For GLUE tasks, we do so by simply scaling the output of the language model before the W_1 and W_2 projections by a factor of 16. For structured prediction tasks, we explicitly use different learning rates for the pretrained model and the task-specific parameters.

We fine tune with the Adam optimizer (Kingma and Ba, 2015). For GLUE tasks, we disable dropout in the language model and add 0.1 dropout between language model output and the final output projection; for structured prediction tasks, we use 0.3 at all levels (within the pretrained model, within the task-specific architecture, and on the weights connecting them). In all settings, we use a batch size of 16 examples. We use a cosine schedule to linearly warm up the learning rate from 1e-07 to the target value over the first 10% of training steps, and then anneal the learning rate to 1e-06, following the cosine curve for the remaining steps. For GLUE tasks, we tuned the learning rate for each task and chose the best value over three settings: 1e-04, 5e-05 and 3e-05. For structured prediction tasks, we tuned on the pairs of learning rate, see the results section for details. For GLUE tasks, we train three seeds for each learning rate value for three epochs and choose the model after each epoch that performs best on the validation set. For structured prediction tasks, we train for up to 25 epochs and stop if the validation loss does not improve over the previous epoch.

5 Experimental setup

5.1 Datasets for pretraining

We train the two tower model on several datasets.

Common Crawl. We consider various subsets of Common Crawl which is web data. We follow the same pre-processing as Grave et al. (2018) which is based on the May 2017 Common Crawl dump. This setup add 20 copies of English Wikipedia resulting in about 14% of the final dataset to be Wikipedia. We subsample up to 18B tokens. All experiments use Common Crawl subsampled to 9B tokens, except §6.4.

News Crawl. We use up to 4.5B words of English news web data distributed as part of WMT 2018 (Bojar et al., 2018).

BooksCorpus + Wikipedia. This is similar to the training data used by BERT which comprises the BooksCorpus (Zhu et al., 2015) of about 800M words plus English Wikipedia data of 2.5B words.

5.2 Pretraining hyper-parameters

We adapt the transformer implementation available in the fairseq toolkit to our two tower architecture (Ott et al., 2019). For hyper-parameter and optimization choices we mostly follow Baevski and Auli (2018). Our experiments consider three model sizes shown in Table 1: There are two CNN input models in a base and large configuration as well as a Byte-Pair-Encoding based model (BPE; Sennrich et al., 2016). The CNN models have unconstrained input vocabulary, and an output vocabulary limited to 1M most common types for the large model, and 700K most common types for the base model. CNN models use an adaptive softmax in the output: the head band contains the 60K most frequent types with dimensionality

Model	Parameters	Updates	Blocks	FFN Dim	Attn Heads (final layer)	Query formation (final layer)	Train time (days)
CNN Base	177M	600K	6	4096	12	Sum	6
CNN Large	330M	1M	12	4096	32	Concat	10
BPE Large	370M	1M	12	4096	32	Concat	4.5

Table 1: Hyper-parameters for our models. Parameter count excludes the (adaptive) softmax layer. Train time as measured on 128 Volta GPUs for the CNN models and 64 Volta GPUs for the BPE model.

1024, followed by a 160K band with dimensionality 256. The remaining types have dimensionality 64; there are 480K types for the small model and 780K for the large model. The BPE model uses a vocabulary of 55K types and we share input and output embeddings in a flat softmax with dimension 1024 (Inan et al., 2016; Press and Wolf, 2017). The BPE vocabulary was constructed by applying 30K merge operations over the training data, then applying the BPE code to the training data and retaining all types occurring at least three times.

Every setup uses model dimensionaltiy $d = 1024$ with $H = 16$ attention heads for all but the final attention layer. Model based on character inputs use character embedding size 128 and we apply six filters of size 1x128, 2x256, 3x384, 4x512, 5x512, 6x512 followed by a single highway layer. The models are trained with model and attention dropout rate of 0.1 and ReLU dropout rate of 0.05.

Different to Vaswani et al. (2017) we use Nesterov's accelerated gradient method (Sutskever et al., 2013) with a momentum of 0.99 and we renormalize gradients if their norm exceeds 0.1 (Pascanu et al., 2013). The learning rate is linearly warmed up from 10^{-7} to 1 for 16K steps and then annealed using a cosine learning rate schedule with a single phase to 0.0001 (Loshchilov and Hutter, 2016).

We run experiments on DGX-1 machines with 8 NVIDIA V100 GPUs and machines are interconnected by Infiniband. We also use the NCCL2 library and the torch.distributed package for inter-GPU communication. We train models with 16-bit floating point precision, following Ott et al. (2018). The BPE model trains much faster than the character CNN models (Table 1).

6 Results

6.1 GLUE

First, we conduct experiments on the general language understanding evaluation benchmark (GLUE; Wang et al., 2018) and present a short overview of the tasks. More information can be found in Wang et al. (2018). There are two single-sentence classification tasks: First, the Corpus of Linguistic Acceptability (CoLA; Warstadt et al., 2018) is a binary task to judge sentence grammaticality; evaluation is in terms of the Matthews correlation coefficient (mcc). Second, the Stanford Sentiment Treebank (SST-2; Socher et al., 2013) requires to judge if movie reviews have positive or negative sentiment; evaluation is in terms of accuracy (acc).

There are three tasks assessing sentence similarity: The Microsoft Research Paragraph Corpus (MRPC; Dolan and Brockett, 2015) and the Quora Question Pairs benchmark (QQP); we evaluate in terms of F1. The Semantic Textual Similarity Benchmark (STS-B; Cer et al., 2017) requires predicting a similarity score between 1 and 5 for a sentence pair; we report the Spearman correlation coefficient (scc).

Finally, there are four natural language inference tasks: the Multi-Genre Natural Language Inference (MNLI; Williams et al., 2018), the Stanford Question Answering Dataset (QNLI; Rajpurkar et al., 2016), the Recognizing Textual Entailment (RTE; Dagan et al., 2006, Bar Haim et al., 2006, Ciampiccolo et al., 2007 Bentivogli et al., 2009). We exclude the Winograd NLI task from our results similar to Radford et al. (2018); Devlin et al. (2018) and report accuracy. For MNLI we report both matched (m) and mismatched (mm) accuracy on test.

We also report an average over the GLUE metrics. This figure is not comparable to the average on the official GLUE leaderboard since we exclude Winograd and do not report MRPC accuracy

	CoLA (mcc)	SST-2 (acc)	MRPC (F1)	STS-B (scc)	QQP (F1)	MNLI-(m/mm) (acc)	QNLI (acc)	RTE (acc)	Avg
OpenAI GPT	45.4	91.3	82.3	80.0	70.3	82.1/81.4	88.1	56.0	75.2
CNN Base	53.1	93.6	81.3	82.2	70.5	82.5/82.2	89.5	64.6	77.7
CNN Large	52.8	94.6	83.7	83.4	71.7	84.3/83.8	89.8	63.7	78.6
BPE Large	51.8	94.0	83.0	84.2	70.6	82.9/82.2	89.3	65.1	78.1

Table 2: Test results as per the GLUE evaluation server. The average column does not include the WNLI test set. mcc = Matthews correlation, acc = Accuracy, scc = Spearman correlation.

STS-B Pearson correlation as well as QQP accuracy.

Table 2 shows results for three configurations of our approach (cf. Table 1). The BPE model has more parameters than the CNN model but does not perform better in aggregate, however, it is faster to train. All our models outperform the unidirectional transformer (OpenAI GPT) of Radford et al. (2018), however, our model is about 50% larger than their model. We also show results for STILTs (Phang et al., 2018) and BERT (Devlin et al., 2018). Our CNN base model performs as well as STILTs in aggregate, however, on some tasks involving sentence-pairs, STILTs performs much better (MRPC, RTE); there is a similar trend for BERT.

STILTs adds another fine-tuning step on another downstream task which is similar to the final task. The technique is equally applicable to our approach. Training examples for our model are Common Crawl paragraphs of arbitrary length. We expect that tailoring training examples for language model pretraining to the end tasks to significantly improve performance. For example, BERT trains on exactly two sentences while as we train on entire paragraphs.

6.2 Structured Prediction

We also evaluated performance on two structured predictions tasks, NER and constituency parsing. For both problems, we stacked task-specific architectures from recent work on top of our pretrained two tower models. We evaluate two ways of stacking: (1) ELMo-style, where the pretrained models are not fine-tuned but are linearly combined at different depths, and (2) with fine-tuning, where we set different learning rates for the task-specific layers but otherwise update all of the parameters during the task-specific training.

Model	**dev F1**	**test F1**
ELMo$_{BASE}$	95.7	92.2
CNN Large + ELMo	96.4	93.2
CNN Large + fine-tune	96.9	93.5
BERT$_{BASE}$	96.4	92.4
BERT$_{LARGE}$	96.6	92.8

Table 3: CoNLL-2003 Named Entity Recognition results. Test result was evaluated on parameter set with the best dev F1.

Model	**dev F1**	**test F1**
ELMo$_{BASE}$	95.2	95.1
CNN Large + ELMo	95.1	95.2
CNN Large + fine-tune	95.5	95.6

Table 4: Penn Treebank Constituency Parsing results. Test result was evaluated on parameter set with the best dev F1.

6.2.1 Named Entity Recognition

We evaluated span-level F1 performance on the CoNLL 2003 Named Entity Recognition (NER) task, where spans of text must be segmented and labeled as Person, Organization, Location, or Miscellaneous. We adopted the NER architecture in Peters et al. (2018), a biLSTM-CRF, with two minor modifications: (1) instead of two layers of biLSTM, we only used one, and (2) a linear projection layer was added between the token embedding and biLSTM layer. We did grid search on the pairs of learning rate, and found that projection-biLSTM-

	CoLA (mcc)	SST-2 (acc)	MRPC (F1)	STS-B (scc)	QQP (F1)	MNLI-m (acc)	QNLI (acc)	RTE (acc)	Avg
cloze	55.1	92.9	88.3	88.3	87.2	82.3	86.5	66.4	80.9
bilm	50.0	92.4	86.6	87.1	86.1	81.7	84.0	66.4	79.3
cloze + bilm	52.6	93.2	88.9	87.9	87.2	82.1	86.1	65.5	80.4

Table 5: Different loss functions on the development sets of GLUE (cf. Table 2). Results are based on the CNN base model (Table 1)

CRF with 1E-03 and pretrained language model with 1E-05 gave us the best result.

Table 3 shows the results, with comparison to previous published ELMo$_{BASE}$ results (Peters et al., 2018) and the BERT models. Both of our stacking methods outperform the previous state of the art, but fine tuning gives the biggest gain.

6.2.2 Constituency Parsing

We also report parseval F1 for Penn Treebank constituency parsing. We adopted the current state-of-the-art architecture (Kitaev and Klein, 2018). We again used grid search for learning rates and number of layers in parsing encoder, and used 8E-04 for language model finetuning, 8E-03 for the parsing model parameters, and two layers for encoder.

Table 4 shows the results. Here, fine tuning is required to achieve gains over the previous state of the art, which used ELMo embeddings.

6.3 Objective functions for pretraining

The two-tower model is trained to predict the current token given representations of the entire left and right context (cloze). Next we compare this choice to two alternatives: First, Peters et al. (2018) train two language models operating left-to-right and right-to-left to predict the next word for each respective direction. We change the two-tower model to predict the next word using the individual towers only and remove the combination module on top of the two towers (bilm); however, we continue to jointly train the two towers.

Second, we combine the cloze loss with the bilm loss to obtain a triplet loss which trains the model to predict the current word given both left and right context, as well as just right or left context. The latter is much harder than the cloze loss since less context is available and therefore gradients for the bilm loss are much larger: the cloze model achieves perplexity of about 4 while as for the bilm it is 27-30, depending on the direction. This results in the bilm loss dominating the triplet loss and we found that scaling the bilm term by a factor of 0.15 results in better performance.

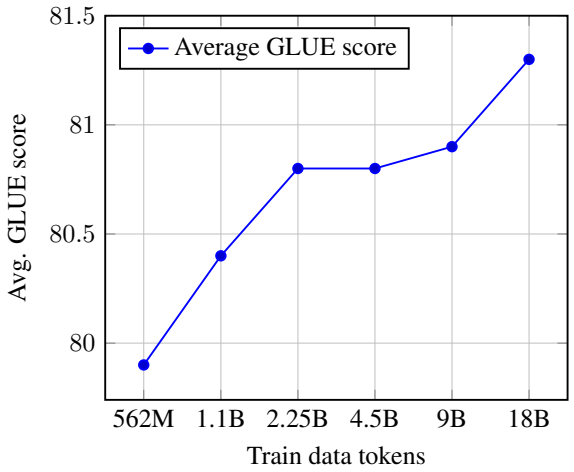

Figure 3: Average GLUE score with different amounts of Common Crawl data for pretraining.

Table 5 shows that the cloze loss performs significantly better than the bilm loss and that combining the two loss types does not improve over the cloze loss by itself. We conjecture that individual left and right context prediction tasks are too different from center word prediction and that their learning signals are not complementary enough.

6.4 Domain and amount of training data

Next we investigate how much pretraining benefits from larger training corpora and how the domain of the data influences end-task performance.

Figure 3 shows that more training data can significantly increase accuracy. We train all models with the exact same hyper-parameter settings on Common Crawl data using the CNN base architecture for 600K updates. We train on up to 18B Common Crawl tokens and the results suggest that more training data is likely to further increase performance.

Table 6 shows a breakdown into individual

	train data (M tok)	CoLA (mcc)	SST-2 (acc)	MRPC (F1)	STS-B (scc)	QQP (F1)	MNLI-m (acc)	QNLI (acc)	RTE (acc)	Avg

	18000	56.3	93.1	88.0	88.8	87.2	82.3	86.3	68.4	81.3
news crawl	562	50.9	92.8	81.4	78.2	84.9	79.1	82.0	55.7	75.6
	1125	51.4	93.0	83.0	82.3	85.2	79.7	82.8	53.9	76.4
	2250	54.8	92.9	83.5	82.8	85.4	80.4	82.4	54.8	77.1
	4500	53.9	93.6	83.8	83.1	85.5	80.4	83.6	54.2	77.3
BWiki - sent	3300	53.5	91.6	86.4	86.2	86.9	82.3	86.9	63.8	79.7
BWiki - blck	3300	50.6	91.9	86.4	87.1	86.8	81.9	86.2	60.4	78.9

Table 6: Effect of different domains and amount of data for pretraining on the on the development sets of GLUE (cf. Table 2). Results are based on the CNN base model (Table 1).

GLUE tasks. For pretraining on Common Crawl, CoLA and RTE benefit most from additional training data. The same table also shows results for News Crawl which contains newswire data. This data generally performs less well than Common Crawl, even on MRPC which is newswire. A likely reason is that News Crawl examples are *individual sentences* of 23 words on average which compares to several sentences or 50 words on average for Common Crawl. Mutli-sentence training examples are more effective for end-tasks based on sentence pairs, e.g., there is a 14 point accuracy gap on RTE between News Crawl and Common Crawl with 4.5B tokens. More News Crawl data is most beneficial for CoLA and STS-B.

We also experiment with BooksCorpus (Zhu et al., 2015) as well as English Wikipedia, similar to Devlin et al. (2018). Examples in BooksCorpus are a mix of individual sentences and paragraphs; examples are on average 36 tokens. Wikipedia examples are longer paragraphs of 66 words on average. To reduce the effect of training on examples of different lengths, we adopted the following strategy: we concatenate all training examples into a single string and then crop blocks of 512 consecutive tokens from this string. We train on a batch of these blocks (BWiki - blck). It turns out that this strategy did not work better compared to our existing strategy of simply using the data as is (BWiki - sent). BooksCorpus and Wikipedia performs very well on QNLI and MNLI but less well on other tasks.

In summary, more data for pretraining improves performance, keeping everything else equal. Also pretraining on corpora that retains paragraph structure performs better than individual sentences.

7 Conclusion

We presented a pretraining architecture based on a bi-directional transformer model that predicts every token in the training data. The model is trained with a cloze-style objective and predicts the center word given all left and right context.

Results on the GLUE benchmark show large gains over Radford et al. (2018) for each task, while experiments with model stacking set new state of the art performance levels for parsing and named entity recognition. We also did extensive experimental analysis to better understand these results, showing that (1) having multiple sentences in each training example is crucial for many tasks; (2) pre-training continues to improve performance up to 18B tokens and would likely continue to improve with more data; and finally (3) our novel cloze-driven training regime is more effective than predicting left and right tokens separately.

In future work, we will investigate variations of our architecture. In particular, we had initial success sharing the parameters of the two towers which allows training much deeper models without increasing the parameter count.

Abstract

A core problem of information retrieval (IR) is *relevance matching*, which is to rank documents by relevance to a user's query. On the other hand, many NLP problems, such as question answering and paraphrase identification, can be considered variants of *semantic matching*, which is to measure the semantic distance between two pieces of short texts. While at a high level both relevance and semantic matching require modeling textual similarity, many existing techniques for one cannot be easily adapted to the other. To bridge this gap, we propose a novel model, HCAN (Hybrid Co-Attention Network), that comprises (1) a hybrid encoder module that includes ConvNet-based and LSTM-based encoders, (2) a relevance matching module that measures soft term matches with importance weighting at multiple granularities, and (3) a semantic matching module with co-attention mechanisms that capture context-aware semantic relatedness. Evaluations on multiple IR and NLP benchmarks demonstrate state-of-the-art effectiveness compared to approaches that do not exploit pretraining on external data. Extensive ablation studies suggest that relevance and semantic matching signals are complementary across many problem settings, regardless of the choice of underlying encoders.

1 Introduction

Neural networks have achieved great success in many NLP tasks, such as question answering (Rao et al., 2016; Chen et al., 2017a), paraphrase detection (Wang et al., 2017), and textual semantic similarity modeling (He and Lin, 2016). Many of these tasks can be treated as variants of a *semantic matching (SM)* problem, where two pieces of texts are jointly modeled through distributed representations for similarity learning. Various neural network architectures, e.g., Siamese networks (He et al., 2016) and attention (Seo et al., 2017; Tay et al., 2019b), have been proposed to model semantic similarity using diverse techniques.

A core problem of information retrieval (IR) is *relevance matching (RM)*, where the goal is to rank documents by relevance to a user's query. Though at a high level semantic and relevance matching both require modeling similarities in pairs of texts, there are fundamental differences. Semantic matching emphasizes "meaning" correspondences by exploiting lexical information (e.g., words, phrases, entities) and compositional structures (e.g., dependency trees), while relevance matching focuses on keyword matching. It has been observed that existing approaches for textual similarity modeling in NLP can produce poor results for IR tasks (Guo et al., 2016), and vice versa (Htut et al., 2018).

Specifically, Guo et al. (2016) point out three distinguishing characteristics of relevance matching: exact match signals, query term importance, and diverse matching requirements. In particular, exact match signals play a critical role in relevance matching, more so than the role of term matching in, for example, paraphrase detection. Furthermore, in document ranking there is an asymmetry between queries and documents in terms of length and the richness of signals that can be extracted; thus, symmetric models such as Siamese architectures may not be entirely appropriate.

To better demonstrate these differences, we present examples from relevance and semantic matching tasks in Table 1. Column 'Label' denotes whether sentence A and B are relevant or duplicate. The first example from tweet search shares many common keywords and is identified as relevant, while the second pair from Quora shares all words except for the subject and is *not* considered a duplicate pair. An approach based on keyword matching alone is unlikely to be able to distinguish

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5370–5381, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Task	Label	Sentence A	Sentence B
Tweet Search	1	2022 FIFA soccer	2022 world cup FIFA could be held at the end of year in Qatar
Duplicate Detection	0	Does RBI send its employees for higher education, like MBA?	Does EY send its employees for higher education, like MBA?
Question Answering	1	What was the monetary value of the Nobel peace prize in 1989 ?	Each Nobel prize is worth $469,000 .

Table 1: Sample sentence pairs from TREC Microblog 2013, Quora, and TrecQA.

between these cases. In contrast, the third example is judged as a relevant QA pair because different terms convey similar semantics.

These divergences motivate different architectural choices. Since relevance matching is fundamentally a matching task, most recent neural architectures, such as DRMM (Guo et al., 2016) and Co-PACRR (Hui et al., 2018), adopt an interaction-based design. They operate directly on the similarity matrix obtained from products of query and document embeddings and build sophisticated modules on top to capture additional n-gram matching and term importance signals. On the other hand, many NLP problems, such as question answering and textual similarity measurement, require more semantic understanding and contextual reasoning rather than specific term matches. Context-aware representation learning, such as co-attention methods (Seo et al., 2017), has been proved effective in many benchmarks. Though improvements have been shown from adding exact match signals into representation learning, for example, the Dr.QA model of Chen et al. (2017a) concatenates exact match scores to word embeddings, it remains unclear to what extent relevance matching signals can further improve models primarily designed for semantic matching.

To this end, we examine two research questions: (1) Can existing approaches to relevance matching and semantic matching be easily adapted to the other? (2) Are signals from relevance and semantic matching complementary? We present a novel neural ranking approach to jointly model both the relevance matching process and the semantic matching process. Our model, **HCAN** (**H**ybrid **C**o-**A**ttention **N**etwork), comprises three major components:

1. A hybrid encoder module that explores three types of encoders: *deep*, *wide*, and *contextual*, to obtain contextual sentence representations.
2. A relevance matching module that measures soft term matches with term weightings between pairs of texts, starting from word-level to phrase-level, and finally to sentence-level.
3. A semantic matching module with co-attention mechanisms applied at each encoder layer to enable context-aware representation learning at multiple semantic levels.

Finally, all relevance and semantic matching signals are integrated using a fully-connected layer to yield the final classification score.

Contributions. We see our work as making the following contributions:

- We highlight and systematically explore important differences between relevance matching and semantic matching on short texts, which lie at the core of many of IR and NLP problems.
- We propose a novel model, HCAN (Hybrid Co-Attention Network), to combine best practices in neural modeling for both relevance and semantic matching.
- Evaluations on multiple IR and NLP tasks, including answer selection, paraphrase identification, semantic similarity measurement, and tweet search, demonstrate state-of-the-art effectiveness compared to approaches that do not exploit pretraining on external data. Ablation studies show that relevance and semantic matching signals are complementary in many problems, and combining them can be more data efficient.

2 HCAN: Hybrid Co-Attention Network

The overview of our model is shown in Figure 1. It is comprised of three major components: (1) a hybrid encoder module that explores three types of encoders: *deep*, *wide*, and *contextual* (Sec. 2.1);

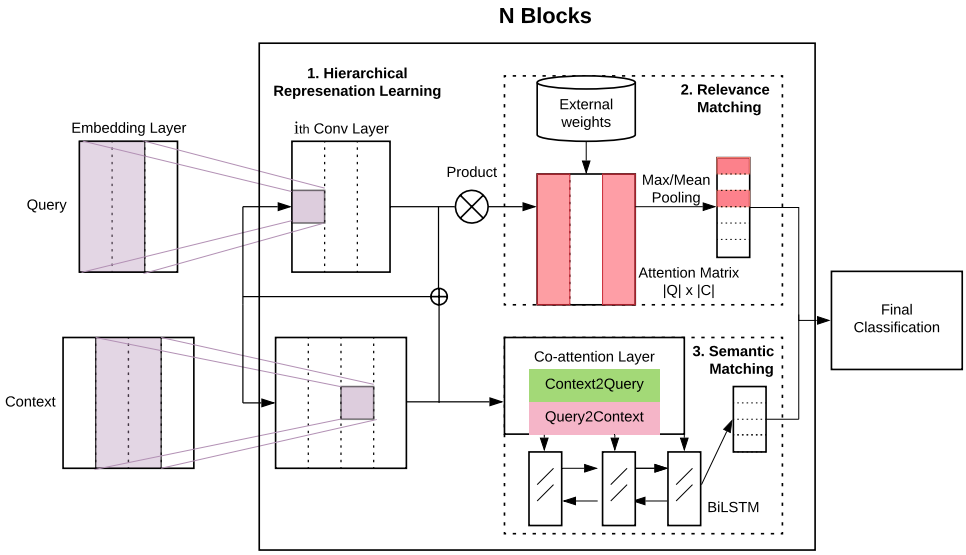

Figure 1: Overview of our Hybrid Co-Attention Network (HCAN). The model consists of three major components: (1) a hybrid encoder module that explores three types of encoders: *deep*, *wide*, and *contextual*; (2) a relevance matching module with external weights for learning soft term matching signals; (3) a semantic matching module with co-attention mechanisms for context-aware representation learning.

(2) a relevance matching module with external weights for learning soft term matching signals (Sec. 2.2); (3) a semantic matching module with co-attention mechanisms for context-aware representation learning (Sec. 2.3). Note that the relevance and semantic matching modules are applied at each encoder layer, and all signals are finally aggregated for classification.

2.1 Hybrid Encoders

Without loss of generality, we assume that inputs to our model are sentence pairs (q, c), where (q, c) can refer to a (query, document) pair in a search setting, a (question, answer) pair in a QA setting, etc. The query q and context c are denoted by their words, $\{w_1^q, w_2^q, ..., w_n^q\}$ and $\{w_1^c, w_2^c, ..., w_m^c\}$, respectively, where n and m are the number of words in the query and the context. A word embedding layer converts both into their embedding representations $\mathbf{Q} \in \mathbb{R}^{n \times L}$ and $\mathbf{C} \in \mathbb{R}^{m \times L}$, where L is the dimension of the embeddings.

To learn effective phrase-level representations, we explore three different types of encoders: *deep*, *wide*, and *contextual*, detailed below.

Deep Encoder: This design consists of multiple convolutional layers stacked in a hierarchical manner to obtain higher-level k-gram representations. A convolutional layer applies convolutional filters to the text, which is represented by an embedding matrix $\mathbf{U}$ ($\mathbf{Q}$ or $\mathbf{C}$). Each filter is moved through the input embedding incrementally as a sliding window (with window size k) to capture the compositional representation of k neighboring terms. Assuming a convolutional layer has F filters, this CNN layer (with padding) produces an output matrix $\mathbf{U}^o \in \mathbb{R}^{\|U\| \times F}$.

For notational simplicity, we drop the superscript o from all output matrices and add a superscript h to denote the output of the h-th convolutional layer. Stacking N CNN layers therefore corresponds to obtaining the output matrix of the h-th layer $\mathbf{U}^h \in \mathbb{R}^{\|U\| \times F^h}$ via:

$$\mathbf{U}^h = \text{CNN}^h(\mathbf{U}^{h-1}), h = 1, \ldots, N,$$

where $\mathbf{U}^{h-1}$ is the output matrix of the $(h-1)$-th convolutional layer. Note that $\mathbf{U}^0 = \mathbf{U}$ denotes the input matrix ($\mathbf{Q}$ or $\mathbf{C}$) obtained directly from the word embedding layer. The parameters of each CNN layer are shared by the query and the context.

Wide Encoder: Unlike the deep encoder that stacks multiple convolutional layers hierarchically, the wide encoder organizes convolutional layers in parallel, with each convolutional layer having a different window size k to obtain the corresponding k-gram representations. Given N convolutional layers, the window sizes of the CNN layers will be in $[k, k+1, ..., k+N-1]$.

Contextual Encoder: Different from both the deep and wide encoders that capture k-gram patterns with convolutions, the contextual encoder

leverages Bi-directional LSTMs to extract long-range contextual features. Given N BiLSTM layers, the output at the h-th layer is computed as:

$$\mathbf{U}^h = \text{BiLSTM}^h(\mathbf{U}^{h-1}), h = 1, \ldots, N,$$

The three encoders represent different tradeoffs. The deep and wide encoders are easier for performing inference in parallel and are much faster to train than the contextual encoder. Additionally, the use of CNN layers allows us to explicitly control the window size for phrase modeling, which has been shown to be critical for relevance matching (Dai et al., 2018; Rao et al., 2019). On the other hand, the contextual encoder enables us to obtain long-distance contextual representations for each token. Comparing the deep and wide encoders, the deep encoder saves more parameters by reusing representations from the previous layer. The effectiveness of each encoder is an empirical question we will experimentally answer.

2.2 Relevance Matching

This section describes our efforts to capture keyword matching signals for relevance matching. We calculate the relevance score between the query and the context at each encoder layer by multiplying the query representation matrix $\mathbf{U}_q$ and the context representation matrix $\mathbf{U}_c$:

$$\mathbf{S} = \mathbf{U}_q {\mathbf{U}_c}^T, \mathbf{S} \in \mathbb{R}^{n \times m},$$

where $\mathbf{S}_{i,j}$ can be considered the similarity score by matching the query phrase vector $\mathbf{U}_q[i]$ with the context phrase vector $\mathbf{U}_c[j]$. Since the query and the context share the same encoder layers, similar phrases will be placed closer in a high-dimensional embedding space and their product will produce larger scores. Next, we obtain a normalized similarity matrix $\tilde{\mathbf{S}}$ by applying a *softmax* function over the context columns of $\mathbf{S}$ to normalize the similarity scores into the $[0, 1]$ range.

For each query phrase i, the above *softmax* function normalizes its matching scores over all phrases in the context and helps discriminate matches with higher scores. An exact match will dominate others and contribute a similarity score close to 1.0. We then apply *max* and *mean* pooling to the similarity matrix to obtain discriminative feature vectors:

$$\begin{aligned} \mathit{Max}(\mathbf{S}) &= [\max(\tilde{\mathbf{S}}_{1,:}), ..., \max(\tilde{\mathbf{S}}_{n,:})], \\ \mathit{Mean}(\mathbf{S}) &= [mean(\tilde{\mathbf{S}}_{1,:}), ..., mean(\tilde{\mathbf{S}}_{n,:})], \\ \mathit{Max}(\mathbf{S}), \mathit{Mean}(\mathbf{S}) &\in \mathbb{R}^n \end{aligned}$$

Each score generated from pooling can be viewed as matching evidence for a specific query phrase in the context, where the value denotes the significance of the relevance signal. Compared to *Max* pooling, *Mean* pooling is beneficial for cases where a query phrase is matched to multiple relevant terms in the context.

It's worth noting that term importance modeling can be important for some search tasks (Guo et al., 2016); therefore, we inject external weights as priors to measure the relative importance of different query terms and phrases. We multiply the score after pooling with the weights of that specific query term/phrase. These are provided as feature inputs to the final classification layer, denoted by $\mathbf{O}_{RM}$:

$$\begin{aligned} \mathbf{o}_{RM} = \{&wgt(q) \odot \mathit{Max}(\mathbf{S}), wgt(q) \odot \mathit{Mean}(\mathbf{S})\}, \\ &\mathbf{O}_{RM} \in 2 \cdot \mathbb{R}^n, \end{aligned} \tag{1}$$

where $\odot$ is an element-wise product between the weights of the query terms/phrases with the pooling scores, and $wgt(q)^i$ denotes the weight of the i-th term/phrase in the query; its value changes in the intermediate encoder layers since deeper/wider encoder layers capture longer phrases. We choose inverse document frequency (IDF) as our weighting function. A higher IDF weight implies a rarer occurrence in the collection and thus greater discriminative power. The weighting method also allows us to reduce the impact of large matching scores for common words like stopwords.

2.3 Semantic Matching

In addition to relevance matching, we aim to capture semantic matching signals via co-attention mechanisms on intermediate query and context representations. Our semantic matching method behaves similarly to the transformer (Vaswani et al., 2017), which also uses attention (specifically, self-attention) over hierarchical blocks to capture semantics at different granularities.

Given $\mathbf{U}_q \in \mathbb{R}^{n \times F}$ and $\mathbf{U}_c \in \mathbb{R}^{m \times F}$ generated by an intermediate encoder layer, we first calculate the bilinear attention as follows:

$$\begin{aligned} \mathbf{A} = \mathit{REP}(\mathbf{U}_q \mathbf{W}_q) + \mathit{REP}(\mathbf{U}_c \mathbf{W}_c) + \mathbf{U}_q \mathbf{W}_b \mathbf{U}_c^T \\ \mathbf{A} = \mathit{softmax}_{\text{col}}(\mathbf{A}) \\ \mathbf{A} \in \mathbb{R}^{n \times m} \end{aligned}$$

where $\mathbf{W}_q, \mathbf{W}_c \in \mathbb{R}^F$, $\mathbf{W}_b \in \mathbb{R}^{F \times F}$, and the *REP* operator converts the input vector to a $\mathbb{R}^{n \times m}$ matrix by repeating elements in the missing dimen-

sions. $\text{Softmax}_{\text{col}}$ is the column-wise softmax operator. Similar to Seo et al. (2017), we perform co-attention from two directions: query-to-context and context-to-query, as follows:

$$\tilde{\mathbf{U}}_q = \mathbf{A}^T \mathbf{U}_q$$
$$\tilde{\mathbf{U}}_c = \mathit{REP}(\max_{\text{col}}(\mathbf{A})\mathbf{U}_c)$$
$$\tilde{\mathbf{U}}_q \in \mathbb{R}^{m \times F}, \tilde{\mathbf{U}}_c \in \mathbb{R}^{m \times F}$$

where $\max_{\text{col}}$ is the column-wise max-pooling operator. $\tilde{\mathbf{U}}_q$ denotes query-aware context embeddings by attending the raw query representations to the attention weights, while $\tilde{\mathbf{U}}_c$ indicates the weighted sum of the most important words in the context with respect to the query.

We then take an enhanced concatenation to explore the interaction between $\tilde{\mathbf{U}}_q$ and $\tilde{\mathbf{U}}_c$, as in Equation 2. Finally, we apply an additional BiLSTM to the concatenated contextual embeddings $\mathbf{H}$ to capture contextual dependencies in the sequence, and use the last hidden state (with dimension d) as the output features of the semantic matching module $\mathbf{O}_{\text{SM}}$:

$$\begin{aligned} \mathbf{H} &= [\mathbf{U}_c; \tilde{\mathbf{U}}_q; \mathbf{U}_c \otimes \tilde{\mathbf{U}}_q; \tilde{\mathbf{U}}_c \otimes \tilde{\mathbf{U}}_q] \\ \mathbf{O}_{\text{SM}} &= \text{BiLSTM}(\mathbf{H}) \\ \mathbf{H} &\in \mathbb{R}^{m \times 4F}, \mathbf{O}_{\text{SM}} \in \mathbb{R}^{d} \end{aligned} \tag{2}$$

2.4 Final Classification

Given the relevance and semantic matching features $\{\mathbf{O}^l_{\text{RM}}, \mathbf{O}^l_{\text{SM}}\}$ (from Equations 1 and 2) learned at each encoder layer l, we concatenate them together and use a two-layer fully-connected layer with ReLU activation to generate the final prediction vector o. During training, we minimize the negative log likelihood loss L summed over all samples (o_i, y_i) below:

$$\begin{aligned} o =& \mathit{softmax}(\text{MLP}(\{\mathbf{O}^l_{\text{RM}}, \mathbf{O}^l_{\text{SM}}\})), \\ l =& 1, 2, ..., N \quad \text{and} \quad o \in \mathbb{R}^{\|class\|} \\ L =& -\sum_{(o_i, y_i)} \log o_i[y_i], \end{aligned}$$

where N is the number of encoder layers.

3 Experimental Setup

3.1 Benchmarks and Metrics

We evaluated our proposed HCAN model on three NLP tasks and two IR datasets, as follows:

Answer Selection. This task is to rank candidate answer sentences based on their similarity to the question. We use the TrecQA (Wang et al., 2007) dataset (raw version)[1] with 56k question-answer pairs. We report mean average precision (MAP) and mean reciprocal rank (MRR).

Paraphrase Identification. This task is to identify whether two sentences are paraphrases of each other. We use the TwitterURL (Lan et al., 2017) dataset with 50k sentence pairs. We report the unweighted average of F1 scores on the positive and negative classes (macro-F1).

Semantic Textual Similarity (STS). This task is to measure the degree of semantic equivalence between pairs of texts. We use the Quora (Iyer et al., 2017) dataset with 400k question pairs collected from the Quora website. We report class prediction accuracy.

Tweet Search. This task is to rank candidate tweets by relevance with respect to a short query. We use the TREC Microblog 2013–2014 datasets (Lin and Efron, 2013; Lin et al., 2014), as prepared by Rao et al. (2019), where each dataset contains around 50 queries and 40k query-tweet pairs. We report MAP and precision at rank 30 (P@30).

3.2 Baselines and Implementations

For the answer selection, paraphrase identification, and STS tasks, we compared against the following baselines: InferSent (Conneau et al., 2017), ESIM (Chen et al., 2017b), DecAtt (Parikh et al., 2016), and PWIM (He and Lin, 2016). Additionally, we report state-of-the-arts results on each dataset from published literature. We also include the current state-of-the-art BERT (Devlin et al., 2019) results on each dataset.

For the tweet search task, we mostly follow the experimental setting in Rao et al. (2019). Baselines include the classic query likelihood (QL) method, RM3 query expansion (Abdul-Jaleel et al., 2004), learning to rank (L2R), as well as a number of neural ranking models: DRMM (Guo et al., 2016), DUET (Mitra et al., 2017), K-NRM (Xiong et al., 2017b), and PACRR (Hui et al., 2017). For the neural baselines, we used implementations in MatchZoo.[2] For L2R, we used LambdaMART (Burges, 2010) on the same feature sets as Rao et al. (2019): text-based, URL-

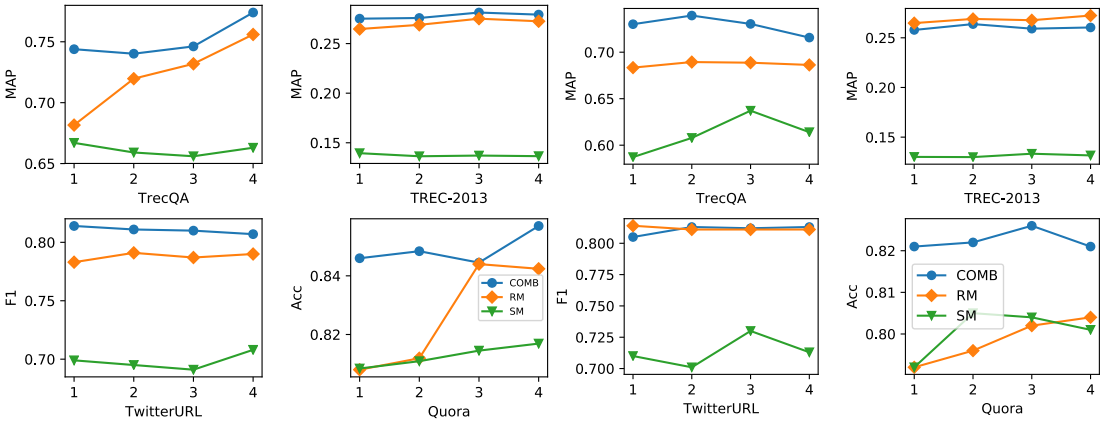
based, and hashtag-based. Finally, we include the BERT results from Yang et al. (2019b).

In our experiments, we use trainable 300d word2vec (Mikolov et al., 2013) embeddings with the SGD optimizer. For out-of-vocabulary words, we initialize their word embeddings with a uniform distribution from [0, 0.1]. Since our model also uses external weights, we calculate the IDF values from the training corpus. The number of convolutional layers N is set to 4, and the convolutional filter size k is set to 2. Hidden dimension d is set to 150. We tune the learning rate in [0.05, 0.02, 0.01], the number of convolutional filters F in [128, 256, 512], batch size in [64, 128, 256], and the dropout rate between 0.1 and 0.5. Our code and datasets are publicly available.[3]

4 Results

Our main results on the TrecQA, TwitterURL, and Quora datasets are shown in Table 2 and results on TREC Microblog 2013–2014 are shown in Table 3. The best numbers for each dataset (besides BERT) are bolded. We compare to three variants of our HCAN model: (1) only relevance matching signals (RM), (2) only semantic matching signals (SM), and (3) the complete model (HCAN). In these experiments, we use the *deep* encoder.

From Table 2, we can see that on all three datasets, relevance matching (RM) achieves significantly higher effectiveness than semantic matching (SM). It beats other competitive baselines (InferSent, DecAtt and ESIM) by a large margin on the TrecQA dataset, and is still comparable to those baselines on TwitterURL and Quora. This finding suggests that soft term matching signals alone are fairly effective for many textual similarity modeling tasks. However, SM performs much worse on TrecQA and TwitterURL, while the gap between SM and RM is reduced on Quora. By combining SM and RM signals, we observe consistent effectiveness gains in HCAN across all three datasets, establishing new state-of-the-art (non-BERT) results on TrecQA.



In Table 3, we observe that the query expansion method (RM3) outperforms most of the neural ranking models except for BERT, which is consistent with Yang et al. (2019a). We suggest two reasons: (1) tweets are much shorter and the informal text is "noisier" than longer documents in the web or newswire settings, which are what the previous neural models were designed for; (2) most neural baselines build directly on top of the embedding similarity matrix without any representation learning, which can be less effective.

Comparing our proposed approaches in Table 3, RM achieves fairly good scores while SM is not effective at all, affirming our hypothesis that term matching signals are essential to IR tasks. This finding further supports our motivation for bridging SM and RM. Indeed, semantic matching methods alone are ineffective when queries are comprised of only a few keywords, without much semantic information to exploit. However, the

context-aware representations learned from SM *do* contribute to RM, leading to the superior results of our complete HCAN model.

4.1 Encoder Comparisons

We report results with the three different encoders from Sec 2.1 in Table 4. Overall, the effectiveness of the *deep* and *wide* encoders are quite close, given that the two encoders capture the same types of n-gram matching signals. The *contextual* encoder performs worse than the other two on TrecQA, but is comparable on all other datasets. This finding is consistent with Rao et al. (2017a), which shows that keyword matching signals are important for TrecQA. Also, we notice that the gaps between RM and SM are smaller for all encoders on Quora. We suspect that SM is more data-hungry than RM given its larger parameter space (actually, the RM module has no learnable parameters) and Quora is about 10× larger than the other datasets. For all encoders, combing RM and SM consistently improves effectiveness, affirming that relevance and semantic matching signals are complementary regardless of the underlying encoder choice.

To better understand the different encoder mechanisms, we vary the number of encoder layers for the *deep* and *contextual* encoders in Figure 2 (since the *wide* encoder behaves similarly to the *deep* encoder, we omit the analysis here). Our complete HCAN model has $N = 4$. In Figure 2a, we can see overall increases in effectiveness for the RM and HCAN (comb) as N increases, showing that long-range phrase modeling is critical. However, increasing context window lengths don't help SM on the TrecQA and TREC-2013 datasets, likely because of dominant bigram matching signals ($N = 1$). Also, the complete HCAN model is consistently better than SM and RM alone in most settings, affirming its superior effectiveness, consistent with results in the above tables. In contrast, increasing the number of Bi-LSTM layers can sometimes even hurt, as shown in Figure 2b. This is not a surprise since a sin-

(a) Validation losses w.r.t. number of batches. **(b)** Effectiveness w.r.t. different percentage of training data.

Figure 3: Experiments exploring learning efficiency.

gle BiLSTM layer ($N = 1$) can already capture long-range contextual information and increasing the number of layers can introduce more parameters and lead to overfitting.

4.2 Learning Efficiency

We also designed two experiments to examine whether the complete HCAN model is learning more efficiently than SM or RM alone. In these experiments, we used the *deep* encoder. First, we show validation losses for different numbers of batches in Figure 3a. Second, we vary the training data size by randomly selecting different percentages (from 20% to 100%) of the original training set, shown in Figure 3b.

In Figure 3a, we can see that the validation loss for the complete model drops much faster than RM and SM alone, especially on TwitterURL and Quora. In Figure 3b, we can see that, as expected, all methods in general achieve higher scores when more data are used for training. An exception is SM on the TREC-2013 Twitter dataset, which we see is not effective in Table 3. Another important finding is that both RM and HCAN are more data efficient: for TREC-2013 and TwitterURL, both can achieve effectiveness comparable to the full training set with only 20% data.

4.3 Qualitative Sample Analysis

We present sample outputs in Table 5 to gain more insight into model behavior. For space considerations, we only show the Quora dataset, but our analysis reveals similar findings on the other datasets. The column "label" denotes the label of the sentence pair: 1 means semantically equivalent and 0 means not equivalent. For each model, we output its predicted label along with its confidence score; phrases with large attention weights are highlighted in orange and red.

In the first example, SM is able to correctly identify that the two sentences convey the same meaning with high confidence, while RM fails as the two sentences have no influential phrase matches (with high IDF weights). The sentence pair in the second example has a large text overlap. It is no surprise that RM would predict a high relevance score, while SM fails to capture their relatedness. In both examples, HCAN is able to integrate SM and RM to make correct predictions. Since the third example presents a similar pattern, we omit a detailed explanation. Overall, our quantitative and qualitative analyses show that relevance matching is better at capturing overlap-based signals, while combining semantic matching signals improve representation learning.

5 Related Work

5.1 Neural Relevance Matching

Recently, deep learning has achieved great success in many NLP and IR applications (He and Lin, 2016; Sutskever et al., 2014; Yin et al., 2016; Rao et al., 2017b). Current neural models for IR can be divided into representation-based and interaction-based approaches, discussed below:

Early neural IR models mainly focus on representation-based modeling between the query and documents, such as DSSM (Huang et al., 2013), C-DSSM (Shen et al., 2014), and SM-CNN (Severyn and Moschitti, 2015). These meth-

Label	SM Score	RM Score	HCAN Score	Sample Pair
1	1, 0.9119	0, 0.9353	1, 0.5496	- How does it feel to kill a human ? - How does it feel to be a murderer ?

0	0, 0.9927	1, 0.8473	1, 0.7280	- Does RBI send its employees for higher education such as MBA , like sponsoring the education or allowing paid / unpaid leaves ? - Does EY send its employees for higher education such as MBA , like sponsoring the education or allowing paid / unpaid leaves ?

Table 5: Sample pairs from Quora. Phrases with large attention weights are highlighted in orange and red.

ods directly learn from query and document representations, and have been found to be ineffective when data is scarce.

Interaction-based approaches build on the similarity matrix computed from word pairs between the query and the document, often with count-based techniques to address data sparsity. For example, DRMM (Guo et al., 2016) introduced a pyramid pooling technique to convert the similarity matrix into histogram representations, on top of which a term gating network aggregates weighted matching signals from different query terms. Inspired by DRMM, Xiong et al. (2017b) proposed K-NRM, which introduced a differentiable kernel-based pooling technique to capture matching signals at different strength levels. Sharing similarities with our architecture is Rao et al. (2019), who developed a multi-perspective relevance matching method with a hierarchical convolutional encoder to capture character-level to sentence-level relevance signals from heterogeneous sources.

5.2 Neural Semantic Matching

Semantic matching is a fundamental problem for a variety of NLP tasks. For example, in paraphrase identification, SM is used to determine whether two sentences or phrases convey the same meaning. In question answering or reading comprehension (Xiong et al., 2017a; Tay et al., 2019a), SM can help identify the correct answer span given a question. Semantic understanding and reasoning for two pieces of texts lie at the core of SM. Existing state-of-the-art techniques for SM usually comprise three major components: (1) sequential sentence encoders that incorporate word context and sentence order for better sentence representations; (2) interaction and attention mechanisms (Tay et al., 2019b; Seo et al., 2017; Parikh et al., 2016; Conneau et al., 2017; Gong et al., 2018) to emphasize salient word pair interactions; (3) structure modeling (Chen et al., 2017b).

6 Conclusion

In this work, we examine the relationship between relevance matching and semantic matching, and highlight a few important differences between them. This is an important problem that lies at the core of many NLP and IR tasks. We propose the HCAN model with a relevance matching module to capture weighted n-gram matching signals and a semantic matching module for context-aware representation learning.

Thorough experiments show that relevance matching alone performs reasonably well for many NLP tasks, while semantic matching alone is not effective for IR tasks. We show that relevance matching and semantic matching are complementary, and HCAN combines the best of both worlds to achieve competitive effectiveness across a large number of tasks, in some cases, achieving the state of the art for models that do not exploit large-scale pretraining. We also find that our model can learn in a data efficient manner, further demonstrating the complementary nature of relevance matching and semantic matching signals.

kirosummer.nlp@gmail.com, {zhli13, minzhang}@suda.edu.cn

Abstract

Semantic role labeling (SRL) aims to identify the predicate-argument structure of a sentence. Inspired by the strong correlation between syntax and semantics, previous works pay much attention to improve SRL performance on exploiting syntactic knowledge, achieving significant results. Pipeline methods based on automatic syntactic trees and multi-task learning (MTL) approaches using standard syntactic trees are two common research orientations. In this paper, we adopt a simple unified span-based model for both span-based and word-based Chinese SRL as a strong baseline. Besides, we present a MTL framework that includes the basic SRL module and a dependency parser module. Different from the commonly used hard parameter sharing strategy in MTL, the main idea is to extract implicit syntactic representations from the dependency parser as external inputs for the basic SRL model. Experiments on the benchmarks of Chinese Proposition Bank 1.0 and CoNLL-2009 Chinese datasets show that our proposed framework can effectively improve the performance over the strong baselines. With the external BERT representations, our framework achieves new state-of-the-art 87.54 and 88.5 F1 scores on the two test data of the two benchmarks, respectively. In-depth analysis are conducted to gain more insights on the proposed framework and the effectiveness of syntax.

1 Introduction

Semantic role labeling (SRL) is a fundamental and important task in natural language processing (NLP), which aims to identify the semantic structure (*Who* did *what* to *whom*, *when* and *where*, etc.) of each given predicate in a sentence. Semantic knowledge has been widely exploited in many down-stream NLP tasks, such as information extraction (Bastianelli et al., 2013), machine translation (Liu and Gildea, 2010; Gao and Vogel, 2011) and question answering (Shen and Lapata, 2007; Wang et al., 2015a).

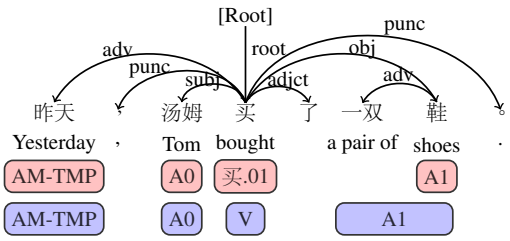

Figure 1: Example of span-based (blue blocks) and word-based (red blocks) SRL formulations in a sentence, where the top part is its dependency tree.

There are two formulations of SRL in the community according to the definition of semantic roles. The first is called *span-based* SRL, which employs a continuous word span as a semantic role and follows the manual annotations in the PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004). The second is *word-based* SRL (Surdeanu et al., 2008), also called *dependency-based* SRL, whose semantic role is usually syntactic or semantic head word of the manually annotated word span. Figure 1 gives an example of the two forms in a sentence, where "bought" is the given predicate.

Intuitively, syntax and semantics are strongly correlative. For example, the semantic *A0* and *A1* roles are usually the syntactic subject and object, as shown in Figure 1. Inspired by the correlation, researchers try to improve SRL performance by exploring various ways to integrate syntactic knowledge (Roth and Lapata, 2016; He et al., 2018b; Swayamdipta et al., 2018). In contrast, some recent works (He et al., 2017; Tan et al., 2018; Cai et al., 2018) propose deep neural models for SRL without considering any syntactic in-

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

formation, achieving promising results. Most recently, He et al. (2018a); Li et al. (2019) extend the span-based models to jointly tackle the predicate and argument identification sub-tasks of SRL.

Compared with the large amount of research for English SRL, Chinese SRL works are rare, mainly because of the limited amount of data and lack of attention of Chinese researchers. For Chinese, the commonly used datasets are Chinese Proposition Bank 1.0 (CPB1.0) (span-based) (Xue, 2008) and CoNLL-2009 Chinese (word-based) (Hajič et al., 2009). The CPB1.0 dataset follows the same annotation guideline with the English PropBank benchmark (Palmer et al., 2005). Wu and Palmer (2015) present a top model based selection preference approach to improve Chinese SRL. Since the amount of CPB1.0 dataset is small, Xia et al. (2017) exploit heterogeneous SRL data to improve the performance via a progressive learning approach. The CoNLL-2009 benchmark is released by the CoNLL-2009 shared task (Hajič et al., 2009). Previous works (Marcheggiani et al., 2017; He et al., 2018b; Cai et al., 2018) mainly focus on building more powerful models or exploring the usage of external knowledge on this dataset.

Inspired by the development of neural models and exploration of syntactic information, this paper proposes a MTL framework to extract syntactic representations as the external input features for the simple unified SRL model. The contributions of our paper are three-folds:

1. We introduce a simple unified model for span-based and word-based Chinese SRL.
2. We propose a MTL framework to extract implicit syntactic representations for SRL model, which significantly outperforms the baseline model.
3. Detailed analysis gains crucial insights on the effectiveness of our proposed framework.

We conduct experiments on the benchmarks of CPB1.0 and CoNLL-2009. The results show that our framework achieves new state-of-the-art 87.54 and 88.5 F1 scores on the two test data, respectively.

2 Basic SRL Model

Motivated by the recently presented span-based models (He et al., 2018a; Li et al., 2019) for jointly predicting predicates and arguments, we introduce a simple unified span-based model. Formally, given a sentence $s = w_1, w_2, ..., w_n$, the span-based model aims to predict a set of labeled predicate-argument relationships $\mathcal{Y} \subseteq \mathcal{P} \times \mathcal{A} \times \mathcal{R}$, where $\mathcal{P} = \{w_1, w_2, ..., w_n\}$ is the set of all candidate predicates, $\mathcal{A} = \{(w_i, ..., w_j) | 1 \leq i \leq j \leq n\}$ is the set of all candidate arguments, and $\mathcal{R}$ is the set of the semantic roles. Following He et al. (2018a), we also include a null label ϵ in the role set $\mathcal{R}$ indicating no relation between the focused predicate and argument. The model objective is to optimize the probability of the predicate-argument-role tuples $y \in \mathcal{Y}$ in a sentence s, which is formulated as:

$$
\begin{aligned}
P(y|s) &= \prod_{p \in \mathcal{P}, a \in \mathcal{A}, r \in \mathcal{R}} P(y_{(p,a,r)}|s) \\
&= \prod_{p \in \mathcal{P}, a \in \mathcal{A}, r \in \mathcal{R}} \frac{e^{\phi(p,a,r)}}{\sum_{r' \in \mathcal{R}} e^{\phi(p,a,r')}}
\end{aligned} \tag{1}
$$

where $\phi(p, a, r) = \phi_p(p) + \phi_a(a) + \phi_r(p, a)$ is the score of the predicate-argument-relation tuple. We directly adopt the model architecture of He et al. (2018a) as our basic SRL model with a modification on the argument representation. The architecture of the basic SRL module is shown in the right part of Figure 2, and we will describe it in the following subsections.

2.1 Input Layer

Following He et al. (2018a); Li et al. (2019), we employ CNNs to encode Chinese characters for each word w_i into its character representation, denoted as $\boldsymbol{rep}_i^{char}$. Then, we concatenate $\boldsymbol{rep}_i^{char}$ with the word embedding $\boldsymbol{emb}_i^{word}$ to represent the word-level features as our basic model input. In addition, we also employ BERT representations (Devlin et al., 2019) to boost the performance of our baseline model, which we denote as $\boldsymbol{rep}_i^{BERT}$. Formally, the input representation of w_i is:

$$
\boldsymbol{x}_i = \boldsymbol{rep}_i^{char} \oplus \boldsymbol{emb}_i^{word} \oplus \boldsymbol{rep}_i^{BERT} \tag{2}
$$

, where $\oplus$ is the concatenation operation. Our basic SRL model and BERT-enhanced baseline depend on whether including the BERT representation $\boldsymbol{rep}_i^{BERT}$ or not.

2.2 BiLSTM Encoder

Over the input layer, we employ the BiLSTMs with highway connections (Srivastava et al., 2015;

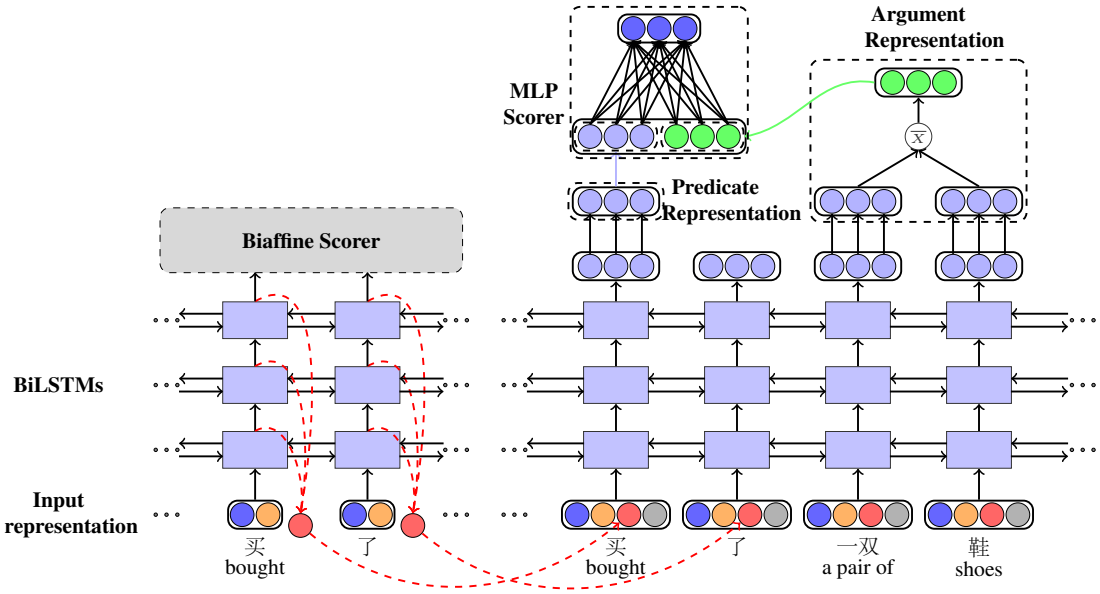

Figure 2: The detailed architecture of our proposed framework, where the left part is the dependency parser and the right part is the basic SRL module, respectively.

Zhang et al., 2016b) to encode long-range dependencies and obtain rich representations denoted as $\boldsymbol{h}_i$ for time stamp i. The highway connections are used to alleviate the gradient vanishing problem when training deep neural networks.

2.3 Predicate and Argument Representations

We directly employ the output of the top BiLSTM as the predicate representation at each time stamp. For all the candidate arguments, we simplify the representations by employing the mean operation over the BiLSTM outputs within the corresponding argument spans, which achieves similar results compared with the attention-based span representations (He et al., 2018a) on English SRL in our preliminary experiments. Formally,

$$\begin{aligned} \boldsymbol{rep}^p_i &= \boldsymbol{h}_i \\ \boldsymbol{rep}^a_{j,k} &= mean(\boldsymbol{h}_j, ..., \boldsymbol{h}_k) \\ & (1 \leq i \leq n; 1 \leq j \leq k \leq n) \end{aligned} \tag{3}$$

Specifically, for word-based SRL, we only need to set the length of candidate arguments to be 1.

2.4 MLP Scorer

We employ the MLP scorers as the scoring functions to determine whether the candidate predicates or arguments need to be pruned. Another MLP scorer is employed to compute the score of whether the focused candidate predicate and argument can compose a semantic relation.

$$\begin{aligned} \phi_p(p) &= \mathbf{w}_\mathbf{p}^\top \mathbf{MLP}_\mathbf{p}(\boldsymbol{rep}^p_i) \\ \phi_a(a) &= \mathbf{w}_\mathbf{a}^\top \mathbf{MLP}_\mathbf{a}(\boldsymbol{rep}^a_{j,k}) \\ \phi_r(p,a) &= \mathbf{w}_\mathbf{r}^\top \mathbf{MLP}_\mathbf{r}([\boldsymbol{rep}^p_i; \boldsymbol{rep}^a_{j,k}]) \end{aligned} \tag{4}$$

3 Proposed Framework

Our framework includes two modules, a basic SRL module and a dependency parser module, as shown in Figure 2. In this section, we will first describe the architecture of the employed dependency parser, and then illustrate the integration of the syntactic parser into the basic SRL model.

3.1 Dependency Parser Module

We employ the state-of-the-art biaffine parser proposed by Dozat and Manning (2017) as the dependency parser module in our framework, as shown by the left part of Figure 2. In order to better fit the dependency parser into our framework, we make some modifications on the original model architecture. First, we remove the Part-of-Speech (PoS) tagging embeddings and add the Chinese character CNN representations, so the resulting input representation is the same as the SRL module. Second, we substitute the BiLSTMs in the original biaffine parser with the same 3-layer highway BiLSTMs used in our SRL module. The biaffine scorer is proposed to compute the score of candidate syntactic head and modifier, which remains unchanged.

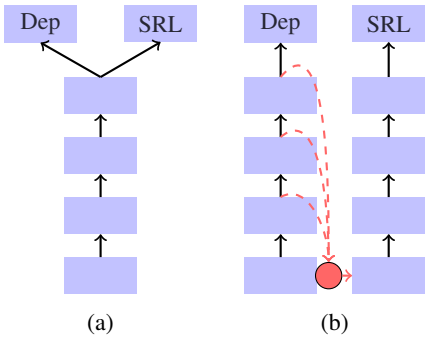

Figure 3: Comparison between the architectures of hard parameter sharing (a) and our proposed implicit representation integration (b).

3.2 Details of Integration

Multi-task learning (MTL) approaches can effectively exploit the standard dependency trees to improve the SRL performance, regarding dependency parsing as the auxiliary task. Hard parameter sharing (Ruder, 2017) is the most commonly used method in MTL, which shares several common layers between tasks and keeps the task-specific output layers, as illustrated by the sub-figure a in Figure 3. We propose a better way to integrate the focused two tasks in this work. In the following, we will describe the intuition and details of the integration on the two tasks.

As is well known, the hard parameter sharing approach can provide representations for all the shared tasks and reduce the probability of overfitting on the main task. However, this kind of sharing strategy somewhat weakens the representation framework maintains distinct model parameters for each task, due to the neutralization of knowledge introduced by the auxiliary task. Different from the hard parameter sharing strategy, we propose to integrate the syntactic information into the input layer of the basic SRL module, as illustrated by sub-figure b of Figure 3. And Figure 2 shows the detailed architecture. First, we extract all the 3 BiLSTM hidden outputs of the dependency parser as the syntactic representations. Second, we employ the normalized weights to sum the extracted representations as the final syntactic representation for word w_i, denoted as $\boldsymbol{rep}_i^{syn}$. Formally,

$$\boldsymbol{rep}_i^{syn} = \sum_{1 \le j \le N} \alpha_j * \boldsymbol{h}_i^j \tag{5}$$

where N is the layer number of the highway BiLSTMs, and α_j is the $j-$th softmax weight. Finally, the extracted syntactic representations are fed into the input layer of the SRL module, and concatenated with the original SRL module input. We design this framework for several considerations: 1) the proposed framework keeps the own model parameters for each task, thereby maximizing task-specific information for the main task, 2) the dependency parser module can be updated by the gradients returned from the extracted syntactic representations, which can encourage it to produce semantic preferred representations.

3.3 Training Objective

Given the sets of SRL data $\mathcal{S}$ and dependency data $\mathcal{D}$, the framework loss function is defined as the sum of the negative log-likelihood loss of the two tasks:

$$-\Big(\sum_{(Y_s^*, X_s) \in \mathcal{S}} \log P(Y_s^* | X_s) + \alpha \sum_{(Y_d^*, X_d) \in \mathcal{D}} \log P(Y_d^* | X_d) \Big) \tag{6}$$

where Y_s^* and Y_d^* are gold semantic and syntactic structures respectively, and α is a corpus weighting factor to control the loss contribution of the dependency data in each batch as discussed in the experiments.

4 Experiments

4.1 Settings

We evaluate the proposed MTL framework on two commonly used benchmark datasets of Chinese: Chinese Proposition Bank 1.0 (CPB1.0) (span-based) (Xue, 2008) and CoNLL-2009 (word-based) (Hajič et al., 2009). Following previous works, we report the results of span-based SRL in two setups: *pre-identified predicates* and *end-to-end*. For word-based SRL, we only report the results in the *pre-identified predicates* setting. Following Roth and Lapata (2016), we employ the mate-tools[1] (Björkelund et al., 2010) for the predicate disambiguation, which achieves 94.87% and 94.91% F1 scores on the CoNLL-2009 Chinese development and test data respectively.

Dependency Parsing Data. We employ the Chinese Open Dependency Treebank[2] constructed at Soochow University. The treebank construction

[1] https://code.google.com/archive/p/mate-tools/
[2] http://hlt.suda.edu.cn/index.php/CODT

project aims to continually build a large-scale Chinese dependency treebank that covers up-to-date texts from different domains and sources (Peng et al., 2019). So far, CODT contains 67,679 sentences from 9 different domains or sources.

BERT Representations. Recently, BERT (Bidirectional Encoder Representations from Transformers) is proposed by Devlin et al. (2019), which makes use of Transformers to learn contextual representations between words. In this paper, we use the pre-trained Chinese model[3] to extract the BERT representations for our span-based and word-based SRL datasets. We extract the fixed BERT representations from the last four hidden layers of the pre-trained model. Finally, we also employ the normalized weighted sum operation to obtain the final BERT representation for each word w_i, denoted as $\boldsymbol{rep}_i^{BERT}$.

Hyperparameters. We employ word2vec (Mikolov et al., 2013) to train the Chinese word embeddings on the Chinese Gigaword dataset[4]. The Chinese char embeddings are randomly initialized, and the dimension is 100. We employ the CNN to get the Chinese char representations, which has window size of 3, 4 and 5, and the output channel size is 100. For other parameter settings in the SRL module, we mostly follow the work of He et al. (2018a). As for the pruning of candidate predicates and arguments, we choose the pruning ratios according to the training data, using $\lambda_p = 0.4$ for predicates and $\lambda_a = 0.8$ for arguments with up to 30 words.

Training Criterion. We choose Adam (Kingma and Ba, 2015) optimizer with 0.001 as the initial learning rate and 0.1% as the decay rate for every 100 steps. Each data batch is composed of both SRL and dependency instances. We randomly shuffle the SRL and dependency training datasets if the smaller SRL data is used up. All baseline models are trained for at most 180,000 steps, and 100,000 steps for other models. In addition, we pick the best model on the development data for testing. We apply 0.5 dropout to the word embeddings and Chinese character representations and 0.2 dropout to all hidden layers. We employ variational dropout masks that are shared across all timesteps (Gal and Ghahramani, 2016) for the highway BiLSTMs, with 0.4 dropout rate.

Evaluation. We adopt the official scripts provided by CoNLL-2005[5] and CoNLL-2009[6] for span-based and word-based SRL evaluation, respectively. We conduct significant tests using the Dan Bikel's randomized parsing evaluation comparer.

4.2 Syntax-aware Methods

To illustrate the effectiveness and advantage of our proposed framework[7] (Integration of Implicit Representations, IIR), we conduct several experiments with the recently employed syntax-aware methods on CPB1.0 dataset for comparison:

- **Tree-GRU** Xia et al. (2019) investigate several syntax-aware methods for the English span-based SRL, showing the effectiveness of introducing syntactic knowledge into the SRL task. We only compare with the Tree-GRU method, since the other methods are all predicate-specific and hence not fit into our basic SRL model.

- **FIR** Following Yu et al. (2018) and Zhang et al. (2019), we extract the outputs of BiLSTMs as the fixed implicit representations (FIR) from a pre-trained biaffine parser. In detail, we train the biaffine parser with the same training data used in our framework, and employ the combination of development data of CDT (997 sentences) and PCTB7 (998 sentences) as the development data. The biaffine parser achieves 79.71% UAS and 74.74% LAS on the combined development data.

- **HPS** We employ the commonly used hard parameter sharing (HPS) strategy of MTL as a strong baseline, which shares the word and char embeddings and 3-layer BiLSTMs between the dependency parser and the basic SRL module.

4.3 Main Results

Results of Syntax-aware Methods. Table 1 shows the results of these syntax-aware methods on CPB1.0 dataset. First, the first line shows the results of our baseline model, which only employs the word embeddings and char representations as the inputs of the basic SRL model. Second, the

Methods	Dev			Test		
	P	R	F1	P	R	F1
Baseline	81.52	82.17	81.85	80.95	80.01	80.48
Baseline + Dep (Tree-GRU)	82.35	80.24	81.28	82.10	78.11	80.06
Baseline + Dep (FIR)	**83.56**	83.05	83.30	83.38	81.93	82.65
Baseline + Dep (HPS)	82.58	**84.15**	83.36	83.22	**83.81**	83.51
Baseline + Dep (IIR)	83.12	83.66	**83.39**	**84.49**	83.34	**83.91**

Table 1: Experimental results of syntax-aware methods we compare on CPB1.0 dataset.

Tree-GRU method only achieves 80.06 F1 score on the test data, which even didn't catch up with the baseline model. We think this is caused by the relatively low accuracy in Chinese dependency parsing. Third, the FIR approach outperforms the baseline by 2.17 F1 score on the test data, demonstrating the effectiveness of introducing fixed implicit syntactic representations. Forth, the HPS strategy achieves more significant performance by 83.51 F1 score. Finally, our proposed framework achieves the best performance of 83.91 F1 score among these methods, outperforming the baseline by 3.43 F1 score. All the improvements are statistically significant ($p < 0.0001$). From these experimental results, we can conclude that: 1) the quality of syntax has a crucial impact on the methods which depend on the systematic dependency trees, like Tree-GRU, 2) the implicit syntactic features have the potential to improve the down-stream NLP tasks, and 3) learning the syntactic features with the main task performs better than extract them from a fixed dependency parser.

Results on CPB1.0. Table 2 shows the results of our baseline model and proposed framework using external dependency trees on CPB1.0, as well as the corresponding results when adding BERT representations. It is clear that adding dependency trees into the baseline SRL model can effectively improve the performance ($p < 0.0001$), no matter whether employ the BERT representations or not. Especially, our proposed framework (IIR) consistently outperforms the hard parameter sharing strategy. So we only report the results of our proposed framework in later experiments. Our final results outperforms the best previous model (Xia et al., 2017) by 7.87 and 4.24 F1 scores with BERT representations or not, respectively.

Table 3 shows the results of our framework in the *end-to-end* setting. To our best knowledge, we are the first to present the results of *end-to-end* on the CPB1.0 dataset. We achieve the result of 85.57 in F1 score, which is a strong baseline for later works. It is clear that our framework can still achieve better results compared with the strong baseline, which employs BERT representations as the external input.

formance with Cai et al. (2018), which is an end-to-end neural model that consists of BiLSTM encoder and biaffine scorer. Our proposed framework outperforms the best reported result (Cai et al., 2018) by 0.8 F1 score and brings a significant improvement ($p < 0.0001$) of 0.9 F1 score over our baseline model. Our experimental result boosts to 88.5 F1 score when the framework is enhanced with BERT representations. However, compared with the results in the settings without BERT, the improvement is fairly small (88.53 - 88.47 = 0.06 F1 score, $p > 0.1$)[8] of the proposed framework, which we will discuss in Section 5.3.

5 Analysis

In this section, we conduct detailed analysis to understand the improvements introduced by our proposed framework.

5.1 Long-distance Dependencies

To analyze the effect of the proposed framework regarding to the distance of sentence lengths, we report the F1 scores of different sets of sentence lengths, as shown in Figure 4. We can see that improvements are obtained for nearly all sets of sentences, especially on the sentences with long-distance. It demonstrate that *syntactic knowledge is beneficial for SRL and effective to capture long-distance dependencies*.

[8] Following previous works, we only retrain the experimental results with one decimal point

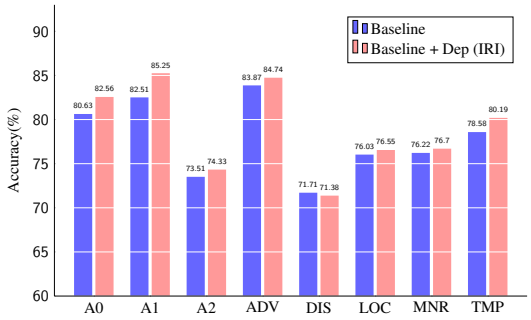

Figure 5: Accuracy comparison of different semantic roles between *Baseline* and *Baseline + Dep (IIR)* on CoNLL-2009 dev data.

5.2 Improvements on Semantic Roles

To find which semantic roles benefit from our syntax-aware framework, we report the F1 scores on several semantic role labels in Figure 5. We can see that syntax helps most on the *A0* and *A1* roles, which is consistent with the intuition that the semantic *A0* and *A1* roles are usually the syntactic subject and object of a verb predicate. Other adjunct semantic roles like *ADV*, *LOC*, *MNR* and *TMP* all benefit from the introduction of syntactic information. There is an interesting finding that the *DIS* role obtains worse performance when introduce syntactic information. We conduct error analysis on this phenomena, and we found that the framework mostly confuses *DIS* with *ADV*. The possible reason is that the two semantic roles are both labeled as *adv* in syntax.

5.3 Integration with BERT

BERT is employed to boost the performance of our basic SRL model and our proposed framework. Compared with results in the settings without BERT, the improvements of our framework over the BERT-enhanced baseline are fairly small on CoNLL-2009, as shown by the last two lines in Table 4. To analyze the difference between the two models (*Baseline + BERT* and *Baseline + BERT + Dep (IIR)*), we conduct an analysis on the sentence performance comparison between them, which is inspired by Zhang et al. (2016a). As shown in Fig-

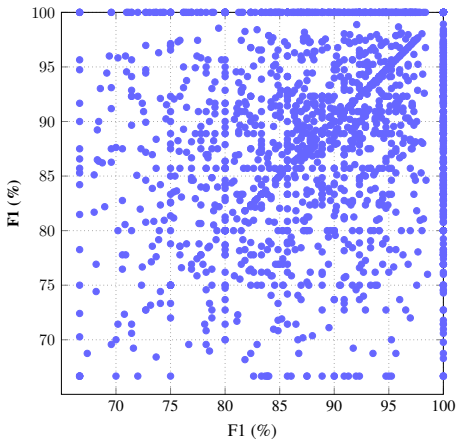

Figure 6: Sentence F1 scores comparison on CoNLL-2009 Chinese test data, where the x axis presents the F1 scores of *Baseline + BERT* and y axis shows the F1 scores of *Baseline + BERT + Dep (IIR)*, respectively.

ure 6, we can see that most of the scatter points are off the diagonal line, demonstrating strong differences between the two models. Based on this finding, how to better integrate syntactic knowledge and BERT representations becomes an interesting and meaningful question, and we leave it for future work.

6 Related Work

Traditional discrete-feature-based SRL works (Swanson and Gordon, 2006; Zhao et al., 2009) mainly make heavy use of syntactic information. Along with the impressive development of neural-network-based approaches in the NLP community, much attention has been paid to build more powerful neural model without considering any syntactic information. Zhou and Xu (2015) employ deep stacked BiLSTMs and achieve strong performance for span-based English SRL. He et al. (2017) extend their work (Zhou and Xu, 2015) by employing several advanced practices in recent deep learning literature, leading to significant improvements. Tan et al. (2018) present a strong self-attention based model, achieving significant improvements. Inspired by the span-based model proposed by Lee et al. (2017) for coreference resolution, He et al. (2018a); Ouchi et al. (2018) present similar span-based models for SRL which can exploit span-level features. For word-based SRL, Marcheggiani et al. (2017) propose a simple and fast syntax-agnostic model with rich input representations. Cai et al. (2018) present an end-to-end model with BiLSTMs and biaffine scorer to jointly handle the predicate disambiguation and the argument labeling sub-tasks.

Apart from the above syntax-free works, researchers also pay much attention on improving the neural-based SRL approaches by introducing syntactic knowledge. Roth and Lapata (2016) introduce the dependency path embeddings to the neural-based model and achieve substantial improvements. Marcheggiani and Titov (2017) employ the graph convolutional neural networks on top of the BiLSTM encoder to encode syntactic information. He et al. (2018b) propose a k-th order argument pruning algorithm based on systematic dependency trees. Strubell et al. (2018) propose a self-attention based neural MTL model which incorporate dependency parsing as a auxiliary task for SRL. Swayamdipta et al. (2018) propose a MTL framework using hard parameter strategy to incorporate constituent parsing loss into semantic tasks, i.e. SRL and coreference resolution, which outperforms their baseline by +0.8 F1 score. Xia et al. (2019) investigate and compare several syntax-aware methods on span-based SRL, showing the effectiveness of integrating syntactic information.

Compared with the large amount of works on English SRL, Chinese SRL works are rare, mainly because of the limitation of datasize and lack of attention of Chinese researchers. Sun et al. (2009) treat the Chinese SRL as a sequence labeling problem and build a SVM-based model by exploiting morphological and syntactic features. Wang et al. (2015b) build a basic BiLSTM model and introduce a way to exploit heterogeneous data by sharing word embeddings. Xia et al. (2017) propose a progressive model to learn and transfer knowledge from heterogeneous SRL data. The above works are all focus on the span-based Chinese SRL, and we compare with their results in Table 2. Different from them, we propose a MTL framework to integrate implicit syntactic representations into a simple unified model on both span-based and word-based SRL, achieving substantial improvements.

In addition to the hard parameter sharing strategy that we discuss in Section 3.2, partial parameter sharing strategy is also a commonly studied approach in MTL and domain adaptation. Kim et al. (2016) introduce simple neural extensions of feature argumentation by employing a global LSTM used across all domains and independent LSTMs used within individual domains. Peng

et al. (2017) explore a multitask learning approach which shares parameters across formalisms for semantic dependency parsing. In addition, Peng et al. (2018) present a multi-task approach for frame-semantic parsing and semantic dependency parsing with latent structured variables.

7 Conclusion

This paper proposes a syntax-aware MTL framework to integrate implicit syntactic representations into a simple unified SRL model. The experimental results show that our proposed framework can effectively improve the basic SRL model, even when the basic model is enhanced with BERT representations. Especially, our proposed framework is more effective at utilizing syntactic information, compared with the hard parameter sharing strategy of MTL. By utilizing BERT representations, our framework achieves new state-of-the-art performance on both span-based and word-based Chinese SRL benchmarks, i.e. CPB1.0 and CoNLL-2009 respectively. Detailed analysis shows that syntax helps most on the long sentences, because of the long-distance dependencies captured by syntax trees. Moreover, the comparison of sentence performance indicates that there is still a lot of work to do to better integrate syntactic information and BERT representation.

Abstract

A semantic equivalence assessment is defined as a task that assesses semantic equivalence in a sentence pair by binary judgment (*i.e.*, paraphrase identification) or grading (*i.e.*, semantic textual similarity measurement). It constitutes a set of tasks crucial for research on natural language understanding. Recently, BERT realized a breakthrough in sentence representation learning (Devlin et al., 2019), which is broadly transferable to various NLP tasks. While BERT's performance improves by increasing its model size, the required computational power is an obstacle preventing practical applications from adopting the technology. Herein, we propose to inject phrasal paraphrase relations into BERT in order to generate suitable representations for semantic equivalence assessment instead of increasing the model size. Experiments on standard natural language understanding tasks confirm that our method effectively improves a smaller BERT model while maintaining the model size. The generated model exhibits superior performance compared to a larger BERT model on semantic equivalence assessment tasks. Furthermore, it achieves larger performance gains on tasks with limited training datasets for fine-tuning, which is a property desirable for transfer learning.

1 Introduction

Paraphrase identification and semantic textual similarity (STS) measurements aim to assess semantic equivalence in sentence pairs. These tasks are central problems in natural language understanding research and its applications. In this paper, these tasks are defined as semantic equivalence assessments.

Sentence representation learning is the basis of assessing semantic equivalence. Unsupervised learning is becoming the preferred approach because it only requires plain corpora, which are now abundantly available. In this approach, a model is pre-trained to generate generic sentence representations that are broadly transferable to various natural language processing (NLP) tasks. Subsequently, it is fine-tuned to generate specific representations for solving a target task using an annotated corpus. Considering the high costs of annotation, a pre-trained model that efficiently fits the target task with a smaller amount of annotated corpus is desired.

Recently, Bidirectional Encoder Representations from Transformers (BERT) realized a breakthrough, which dramatically improved sentence representation learning (Devlin et al., 2019). BERT pre-trains its encoder using language modeling and by discriminating surrounding sentences in a document from random ones. Pre-training in this manner allows distributional relations between sentences to be learned. Intensive efforts are currently being made to pre-train larger models by feeding them enormous corpora for improvement (Radford et al., 2019; Yang et al., 2019). For example, a large model of BERT has 340M parameters, which is 3.1 times larger than its smaller alternative. Although such a large model achieves performance gains, the required computational power hinders its application to downstream tasks.

Given the importance of natural language understanding research, we focus on sentence representation learning for semantic equivalence assessment. Instead of increasing the model size, we propose the injection of semantic relations into a pre-trained model, namely BERT, to improve performance. Phang et al. (2019) showed that BERT's performance on downstream tasks improves by simply inserting extra training on data-rich supervised tasks. Unlike them, we inject semantic relations of finer granularity using phrasal paraphrase alignments automatically iden-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5393–5404,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tified by Arase and Tsujii (2017) to improve semantic equivalent assessment tasks. Specifically, our method learns to discriminate phrasal and sentential paraphrases on top of the representations generated by BERT. This approach explicitly introduces the concept of the phrase to BERT and supervises semantic relations between phrases. Due to studies on sentential paraphrase collection (Lan et al., 2017) and generation (Wieting and Gimpel, 2018), a million-scale paraphrase corpus is ready for use. We empirically show that further training of a pre-trained model on relevant tasks transfers well to downstream tasks of the same kind, which we name as *transfer fine-tuning*.

The contributions of our paper are:

- We empirically demonstrate that transfer fine-tuning using paraphrasal relations allows a smaller BERT to generate representations suitable for semantic equivalence assessment. The generated model exhibits superior performance to the larger BERT while maintaining the small model size.
- Our experiments indicate that phrasal paraphrase discrimination contributes to representation learning, which complements simpler sentence-level paraphrase discrimination.
- Our model exhibits a larger performance gain over the BERT model for a limited amount of fine-tuning data, which is an important property of transfer learning.

We hope that this study will open up one of the crucial research directions that will make the approach of pre-trained models more practically useful. Our codes, datasets, and the trained models will be made publicly available at our web site.

2 Related Work

Sentence representation learning is an active research area due to its importance in various downstream tasks. Early studies employed supervised learning where a sentence representation is learned in an end-to-end manner using an annotated corpus. Among these, the importance of phrase structures in representation learning has been discussed (Tai et al., 2015; Wu et al., 2018). In this paper, we use structural relations in sentence pairs for sentence representations. Specifically, we employ phrasal paraphrase relations that introduce the notion of a phrase to the model.

The research focus of sentence representation learning has moved toward unsupervised learning in order to exploit the gigantic corpus. Skip-Thought, which was an early learning attempt, learns to generate surrounding sentences given a sentence in a document (Kiros et al., 2015). This can be interpreted as an extension of the distributional hypothesis on sentences. Quick-Thoughts, a successor of Skip-Thought, conducts classification to discriminate surrounding sentences instead of generation (Logeswaran and Lee, 2018). GenSen combines these approaches in massive multi-task learning (Subramanian et al., 2018) based on the premise that learning dependent tasks enriches sentence representations.

Embeddings from Language Models (ELMo) made a significant step forward (Peters et al., 2018). ELMo uses language modeling with bidirectional recurrent neural networks (RNN) to improve word embeddings. ELMo's embedding contributes to the performance of various downstream tasks. OpenAI GPT (Radford et al., 2018) replaced ELMo's bidirectional RNN for language modeling with the Transformer (Vaswani et al., 2017) decoder. More recently, BERT combined the approaches of Quick-Thoughts (*i.e.*, a next-sentence prediction approach) and language modeling on top of the deep bidirectional Transformer. BERT broke the records of the previous state-of-the-art methods in eleven different NLP tasks. While BERT's pre-training generates generic representations that are broadly transferable to various NLP tasks, we aim to fit them for semantic equivalence assessment by injecting paraphrasal relations. Liu et al. (2019) showed that BERT's performance improves when fine-tuning with a multi-task learning setting, which is applicable to our trained model for further improvement.

3 Background

3.1 Phrase Alignment for Paraphrases

In order to obtain phrasal paraphrases, we used the phrase alignment method proposed in (Arase and Tsujii, 2017) and apply it to our paraphrase corpora. The alignment method aligns phrasal paraphrases on the parse forests of a sentential paraphrase pair as illustrated in Fig. 1.

According to the evaluation results reported in (Arase and Tsujii, 2017), the precision and recall of alignments are 83.6% and 78.9%, which are 89% and 92% of those of humans, respec-

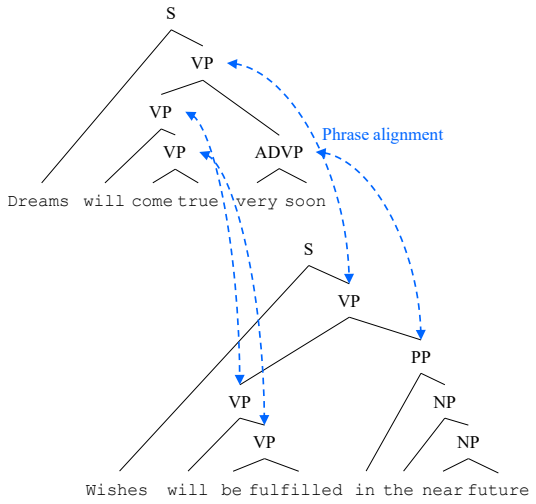

Figure 1: Phrasal paraphrases are obtained from (Arase and Tsujii, 2017); arrows indicate phrase alignments.

tively. Although alignment errors occur, previous studies show that neural networks are relatively robust against noise in a training corpus and still benefit from extra supervisions as demonstrated in (Edunov et al., 2018; Prabhumoye et al., 2018).

We collect all the spans of phrases in a sentential paraphrase pair and their alignments as pairs of phrase spans. Because the phrase alignment method allows unaligned phrases, not all of the phrases have aligned counterparts.

3.2 Pre-Training on BERT

BERT is a bidirectional Transformer that generates a sentence representation by conditioning both the left and right contexts of a sentence. A pre-trained BERT model can be easily fine-tuned for a wide range of tasks by just adding a fully-connected layer, without any task-specific architectural modifications. BERT achieved state-of-the-art performances for eleven NLP tasks, thereby outperforming the previous state-of-the-art methods by a large margin.

Pre-training in BERT accomplishes two tasks. The first task is masked language modeling, where some words in a sentence are randomly masked and the model then predicts them from the context. This task design allows the representation to fuse both the left and the right context. The second task predicts whether a pair of sentences are consecutive in a document to learn the relation between the sentences. Specifically, as illustrated in Fig. 2, BERT takes two sentences as input that are concatenated by a special token `[SEP]`.[1] The first token of every input is always the special token of `[CLS]`. The final hidden state corresponding to this `[CLS]` token is regarded as an aggregated representation of the input sentence pair. This is used to predict whether the sentence pair is composed of consecutive sentences in a document or not during pre-training.

BERT has a deep architecture. The BERT-base model has 12 layers of 768 hidden size and 12 self-attention heads. The BERT-large model has 24 layers of 1024 hidden size and 16 self-attention heads. Both BERT-bese and BERT-large models were pre-trained using BookCorpus (Zhu et al., 2015) and English Wikipedia (in total 3.3B words).

Algorithm 4.1 Paraphrasal Relation Injection

Input: Paraphrase sentence pairs $P = \{\langle s, t\rangle\}$, a pre-trained BERT model

Obtain a set of phrase alignments A as pairs of spans for each $\langle s, t\rangle \in P$
WordPiece tokenization of P
Accommodate phrase spans in A to BERT's token indexing: $A = \{\langle (j, k), (m, n)\rangle\}$
repeat
  for all mini-batch $b_t \in \{\langle P_i, A_i\rangle\}$ **do**
    Encode b_t by the BERT model
    Compute loss: L(Θ)
      For phrasal paraphrase task: $L_p(\Theta)$
      For sentential paraphrase task: $L_s(\Theta)$
      $L(\Theta) = L_p(\Theta) + L_s(\Theta)$
    Compute gradient: $\nabla(\Theta)$
    Update the model parameters
until convergence

4 Transfer Fine-Tuning with Paraphrasal Relation Injection

We inject semantic relations between a sentence pair into a pre-trained BERT model through classification of phrasal and sentential paraphrases. After the training, the model can be fine-tuned in exactly the same manner as with BERT models.

4.1 Overview

Algorithm 4.1 provides an overview of our method. It takes a sentential paraphrase pair $\langle s, t\rangle$ as an input, which are referred to as the source and target, respectively, for the sake of clarity. First, a set of phrase alignments A is obtained for $\langle s, t\rangle$

[1] Throughout the paper, `typewriter font` represents tokens and labels.

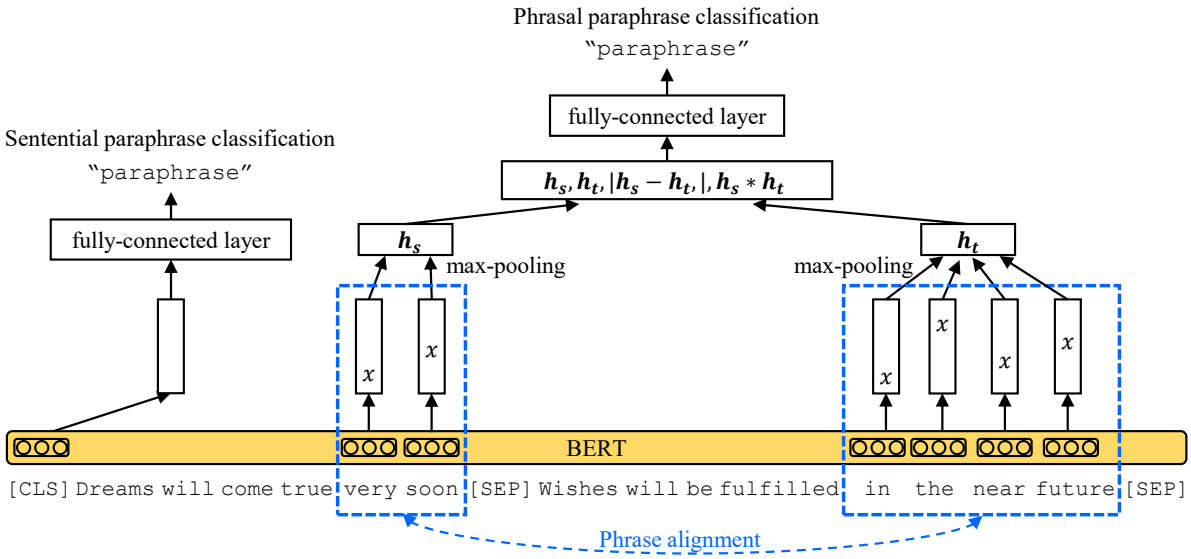

Figure 2: Our method injects semantic relations to sentence representations through paraphrase discrimination.

(line 1) as described in Sec. 3.1. Because BERT uses sub-words as a unit instead of words, all the input sentences are tokenized (line 2) by WordPiece (Wu et al., 2016). In addition, t is concatenated to s when being input to the BERT model, where the first token should always be `[CLS]` and the sentence pair is separated by `[SEP]` as described in Sec. 3.2. In order to accommodate to these factors, phrase spans in alignments A are adjusted accordingly (line 3).

Our method learns to discriminate phrasal and sentential paraphrases simultaneously as illustrated in Fig. 2. Cross-entropy is used as the loss functions for both tasks (line 8, 9).

Phrasal Paraphrase Classification The middle part of Fig. 2 illustrates phrasal paraphrase classification. We first generate phrase embedding for each aligned phrase as follows. The tokenized sentence pair is encoded by the BERT model. For the input sequence of N tokens $\{w_i\}_{i=1,\ldots,N}$, we obtain the final hidden states $\{\mathbf{h}_i\}_{i=1,\ldots,N}$ (*i.e.*, output of the bidirectional Transformer):

$$\mathbf{h}_i = \text{Transformer}(w_1, \ldots, w_N),$$

where $\mathbf{h}_i \in \mathbb{R}^\lambda$ and λ is the hidden size. We then combine $\{\mathbf{h}_i\}_i$ for a phrase pair with an alignment $\langle (j,k),(m,n)\rangle$ where $2 \leq j < k < m < n \leq N-1$ represent indexes of the beginning and ending of phrases (recall that the first and last tokens are always special tokens in BERT). As a combination function, we apply max-pooling that showed strong performance in (Conneau et al., 2017) to generate a representation of source and target phrases:

$$\mathbf{h}_s = \text{max-pooling}(\mathbf{h}_j, \ldots, \mathbf{h}_k), \quad (1)$$
$$\mathbf{h}_t = \text{max-pooling}(\mathbf{h}_m, \ldots, \mathbf{h}_n). \quad (2)$$

The max-pooling$(\cdot)$ function selects the maximum value over each dimension of the hidden units.

Then $\mathbf{h}_s$ and $\mathbf{h}_t$ are converted to a single vector. To extract relations between $\mathbf{h}_s$ and $\mathbf{h}_t$, three matching methods are used (Conneau et al., 2017): (a) concatenating the representations $(\mathbf{h}_s, \mathbf{h}_t)$, (b) taking the element-wise product $\mathbf{h}_s * \mathbf{h}_t$, and (c) finding the absolute element-wise difference $|\mathbf{h}_s - \mathbf{h}_t|$. The final vector of $\mathbb{R}^{4\lambda}$ is fed into a classifier.[2]

Because our method aims to generate representations for semantic equivalence assessment, the classifier should be simple (Logeswaran and Lee, 2018). Otherwise, a sophisticated classifier would fit itself with the task instead of the representations. We use a single fully-connected layer culminating in a softmax layer as our classifier.

Previous studies have calculated interactions between words (He and Lin, 2016) and phrases (Chen et al., 2017) using the final hidden states of bidirectional RNN or recursive neural networks when composing a sentence representation. Our approach differs from these by giving explicit supervision of which phrase pairs have semantic interactions (*i.e.*, paraphrases).

[2]Our follow-up study confirms that a simpler feature generation improves the generality of our model to contribute not only to semantic equivalent assessment but also natural language inference. For details, please refer to the Appendix.

Negative Example Selection In paraphrase identification, non-paraphrases with large lexical differences are easy to discriminate. Discrimination becomes far more difficult when they contain a number of identical or related words. To effectively supervise the model by solving difficult discrimination problems, we designed a three-way classification task: discrimination of `paraphrase`, `random`, and `in-paraphrase` pairs.

The `random` examples are generated by pairing s to a random sentence t' from the training corpus, and then pairing all phrases in s to randomly chosen phrases in t'. The `in-paraphrase` examples aim to make the discrimination problem difficult, which requires distinguishing true paraphrases and phrases in the paraphrasal sentence pair t. These may provide sub-phrases or ancestor phrases of true paraphrases as difficult negative examples, which tend to retain the same topic and similar wordings. To prepare such examples, for each phrase pair $\langle (j,k),(m,n)\rangle \in A$, the target span (m,n) is replaced by a randomly chosen phrase span in t.

Phrasal paraphrase classification aims to give explicit supervision of semantic relations among phrases in representation learning. It also introduces structures in sentences, which is completely missed in BERT's pre-training. Swayamdipta et al. (2018) showed that supervision of phrase-based syntax improves the performance of a task relevant to semantics, *e.g.*, semantic role labeling.

Sentential Paraphrase Classification The left side of Fig. 2 illustrates the sentential paraphrase classification. The process is simple; the final hidden state of the `[CLS]` token, *i.e.*, $\mathbf{h}_1$, is fed into a classifier to discriminate whether a sentence pair is a paraphrase or a random sentence combination. Note that these random sentence pairs provide `random` phrases for the phrasal paraphrase classification described above.

4.2 Training Setting

We collected paraphrases from various sources as summarized in Table 1, which shows the numbers of sentential and phrasal paraphrase pairs after phrase alignment.[3] All the datasets were downloaded from the Linguistic Data Consortium (LDC) or authors' websites. The following bullets describe the sources.

Source	Sentence	Phrase
NIST OpenMT	47k	711k
Simple Wikipedia	97k	1.4M
Twitter URL corpus	50k	396k
Para-NMT	3.9M	26.7M
Total	4.1M	29.2M

Table 1: Numbers of sentential and phrasal paraphrases after the phrase alignment process.

- NIST OpenMT[4]: We randomly paired reference translations of the same source sentence as was done in (Arase and Tsujii, 2017).
- Twitter URL corpus (Lan et al., 2017): This corpus was collected from Twitter by linking tweets through shared URLs. We used a three-month collection of paraphrases.[5]
- Simple Wikipedia (Kauchak, 2013): This corpus aligned English Wikipedia and Simple English Wikipedia for text simplification. We used "sentence-aligned, version 2.0."[6]
- Para-NMT (Wieting and Gimpel, 2018): This corpus was created by translating the Czech side of a large Czech-English parallel corpus and pairing the translated English and originally target-side English as paraphrases. We used "Para-nmt-5m-processed."[7]

Note that these sentential and phrasal paraphrases are obtained by automatic methods. On the contrary, dataset creation for downstream tasks generally requires expensive human annotation.

We employed the pre-trained BERT-base model[8] and conducted paraphrase classification using the collected paraphrase corpora. Adam (Kingma and Ba, 2015) was applied as an optimizer with a learning rate of $5\mathrm{e}-5$. A dropout probability was 0.2 for the fully-connected layers in the classifiers. A development set and a test

[3] The numbers of sentential paraphrase pairs were reduced due to parsing and alignment failures.

[8] https://github.com/google-research/bert

set, each with 50k sentence pairs, were subtracted from the paraphrase corpus. The rest of the corpus was used for training. The training was conducted on four NVIDIA Tesla V100 GPUs with a batch-size of 100. Early stopping was applied to stop training at the second time decrease in the accuracy of the phrasal paraphrase classification, which was measured on the development set. The final test-set accuracies were 98.1% and 99.9% for phrasal and sentential paraphrase classification, respectively.

5 Evaluation Setting

5.1 Hypotheses to Verify

BERT's pre-training learns to generate sentence representations broadly transferable to different NLP tasks. In contrast, our method gives more direct supervision to generate representations suitable for semantic equivalence assessment tasks. We set up the following hypotheses on features of our method, which will be empirically verified through evaluation:

- H1 Our method contributes to semantic equivalence assessment tasks.
- H2 Our method achieves improvement on downstream tasks that only have small amounts of training datasets for fine-tuning.
- H3 Our method moderately improves tasks if they are relevant to semantic equivalence assessment.
- H4 Our training does not transfer to distant downstream tasks that are independent to semantic equivalence assessment.
- H5 Phrasal and sentential paraphrase classification complementarily benefits sentence representation learning.

5.2 GLUE Datasets

We empirically verified the hypotheses H1 to H5 using the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019)[9], which is the standard benchmark and provides collections of datasets for natural language understanding tasks. Table 2 summarizes the tasks and evaluation metrics at GLUE. All the scores reported in this paper are computed at the GLUE evaluation server unless stated otherwise. Accuracies on MRPC and QQP and Spearman correlation on STS-B are omitted due to space limitations. Note that they showed the same trends as F1 and Pearson correlation, respectively, in our experiment. WNLI was excluded because the GLUE web site reports its issues.[10]

Corpus	Task	Metrics
MRPC	paraphrase	F1
STS-B	STS	Pearson corr.
QQP	paraphrase	F1
MNLI-m	in-domain NLI	accuracy
MNLI-mm	cross-domain NLI	accuracy
RTE	NLI	accuracy
QNLI	QA/NLI	accuracy
SST	sentiment	accuracy
CoLA	acceptability	Matthews corr.

Table 2: GLUE tasks and evaluation metrics.

GLUE tasks can be categorized according to their aims as follows.

Semantic Equivalence Assessment Tasks (MRPC, STS-B, QQP) These are the primary targets of our method, which are used to verify hypothesis H1. Paraphrase identification assesses semantic equivalence in a sentence pair by binary judgments. Microsoft Paraphrase Corpus (MRPC) (Dolan et al., 2004) consists of sentence pairs drawn from news articles, while Quora Question Pairs (QQP)[11] consists of question pairs from the community QA website.

STS assesses semantic equivalence by grading. STS benchmark (STS-B) (Cer et al., 2017) provides sentence pairs drawn from heterogeneous sources, which are human-annotated with a level of equivalence from 1 to 5.

NLI Tasks (MNLI-m/mm, RTE, QNLI) We use natural language inference (NLI) tasks to verify hypothesis H3 because they constitute a class of problems relevant to semantic equivalence assessment. NLI tasks are different from semantic equivalence assessment in that they often require logical inference and understanding of commonsense knowledge. The Multi-Genre Natural Language Inference Corpus (MNLI) (Williams et al., 2018) is a crowd-sourced corpus and covers heterogeneous domains. MNLI-m is an in-domain

Task / Model	Semantic Equivalence			NLI			Single-Sent.	
	MRPC	STS-B	QQP	MNLI (m/mm)	RTE	QNLI	SST	CoLA
BERT-base	88.3	84.7	71.2	84.3/83.0	59.8	89.1	93.3	52.7
BERT-large	88.6	86.0	**72.1**	**86.2/85.5**	**65.5**	**92.7**	**94.1**	**55.7**
Transfer Fine-Tuning	**89.2**	**87.4**	71.2	83.9/83.1	64.8	89.3	93.1	47.2

Table 3: GLUE test results scored by the GLUE evaluation server. The best scores are represented in **bold** and scores higher than those of BERT-base are underlined.

NLI task while MNLI-mm is a cross-domain NLI task. The Recognizing Textual Entailment (RTE) corpus[12] was created from news and Wikipedia. Question-answering NLI (QNLI) was created from The Stanford Question Answering Dataset (Rajpurkar et al., 2016) on which all the sentences were drawn from Wikipedia.

Single-Sentence Tasks (SST, CoLA) We use these tasks to verify hypothesis H4. They aim to estimate features in a single sentence, which has little interaction with semantic equivalence assessment in a sentence pair. The Stanford Sentiment Treebank (SST) (Socher et al., 2013) task is a binary sentiment classification, while The Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2018) task is a binary classification of grammatical acceptability.

5.3 Fine-Tuning on Downstream Tasks

Once trained, our model can be used in exactly the same manner as the pre-trained BERT models. For fine-tuning our models and replicating BERT's results under the same setting, we set the hyper-parameter values to those recommended in (Devlin et al., 2019): a batch size of 32, a learning rate of $3e-5$, the number of training epochs to 4, and a dropout probability of 0.1. We fine-tuned all the models on downstream tasks using the script provided in the Pytorch version of BERT.[13] For STS-B, we modified the script slightly to conduct regression instead of classification. All other hyper-parameters were set to the default values defined in the BERT's fine-tuning script.

For fair comparison, we kept the same hyper-parameter settings described above across all tasks and models. Phang et al. (2019) discussed that BERT performances become unstable when a training dataset with fine-tuning is small. In our evaluation, performances were stable when setting the same hyper-parameters, but further investigation is our future work.

6 Results and Discussion

6.1 Effect on Semantic Equivalence Assessment Tasks

Table 3 shows fine-tuning results on GLUE; our model, denoted as Transfer Fine-Tuning, is compared against BERT-base and BERT-large. The first set of columns shows the results of semantic equivalence assessment tasks. Our model outperformed BERT-base on MRPC (+0.9 points) and STS-B (+2.7 points). Furthermore, it outperformed even BERT-large by 0.6 points on MRPC and by 1.4 points on STS-B, despite BERT-large having 3.1 times more parameters than our model. Devlin et al. (2019) described that the next-sentence prediction task in BERT's pre-training aims to train a model that understands sentence relations. Herein, we argue that such relations are effective at generating representations broadly transferable to various NLP tasks, but are too generic to generate representations for semantic equivalence assessment tasks. Our method allows semantic relations between sentences and phrases that are directly useful for this class of tasks to be learned.

These results support hypothesis H1, indicating that our approach is more effective than blindly enlarging the model size. A smaller model size is desirable for practical applications. We have also applied our method on the BERT-large model, but its performance was not much improved to warrant the larger model size. Further investigation regarding pre-trained model sizes is our future work.

6.2 Effect of the Amount of Fine-Tuning Datasets

Our method did not improve upon BERT-base for QQP. We consider this is because a large QQP training set (364k sentence pairs) allows the BERT model to converge to a certain optimum. This also

[13] run_classifier.py in https://github.com/huggingface/pytorch-pretrained-BERT

Task	Train. size	BERT-base	Transfer Fine-Tuning
MRPC	1k	81.6	88.1 (+6.5)
	all (3.7k)	89.4	90.2 (+0.8)
STS-B	1k	83.4	86.2 (+2.8)
	all (5.7k)	88.1	90.1 (+2.0)
QQP	1k	69.9	71.4 (+1.5)
	5k	75.5	76.3 (+0.8)
	10k	77.0	77.6 (+0.6)
	20k	79.6	79.5 (−0.1)
	all (364k)	87.7	87.7 (±0.0)

Table 4: Development set scores of the BERT-base model and our model (and their differences) that were fine-tuned using subsamples and full-size training sets.

relates to hypothesis H2.

To investigate the effect of the sizes of training sets, we fine-tuned our model and BERT-base for semantic equivalence assessment tasks using randomly subsampled training sets. Table 4 shows scores on the development sets.[14] The result clearly indicates that our method is more beneficial when a training dataset is limited on a downstream task, which supports hypothesis H2. This property is preferable for a transfer learning scenario that unsupervised sentence representation learning assumes.

Another factor that may affect the performance is domain mismatch between our paraphrase corpora and QQP corpus. The former was mostly collected from news while the latter was extracted from a social QA forum. In the future, we will investigate the effects of domains by generating multi-domain paraphrase corpora using a method proposed by Wieting and Gimpel (2018).

6.3 Effect on NLI Tasks

The second set of columns in Table 3 shows the results on NLI tasks. Our model presents moderate improvements on most NLI tasks, which supports hypothesis H3. We consider this is because the majority of NLI tasks that require inferences in one-direction, contrary to bi-directional entailment relations of paraphrases, are uni-directional.

Another reason is that our elaborate feature generation for the phrasal paraphrase classifier tightly fits the model for paraphrase identification. This contributes to performance improvements on this task, but sacrifices the model's generality on relevant tasks. We tackle this issue in our follow-up study reported in the Appendix.

Among NLI tasks, our model largely outperformed BERT-base by 5.0 point on RTE. This may be again due to the property of our method that brings improvement on tasks with a limited training set as RTE has only 2.5k training sentence pairs.

6.4 Effect on Single-Sentence Tasks

The last two columns of Table 3 show results on single-sentence tasks; SST and CoLA, which are the most distant tasks from paraphrase classification. Our model presents a slightly lower score on SST compared to BERT-base and performed poorly on CoLA.

One potential reason for this degradation is that our training takes a sentence pair as input, which may weaken the ability to model a single sentence. Another cause is attributable to similarities between our training and fine-tuning tasks. For SST, sentiment analysis could be adversarial toward paraphrase discrimination tasks. Although paraphrasal sentences tend to have the same sentiments, sentences with the same sentiments do not generally hold paraphrastic relations. For CoLA, semantic relations unlikely contribute to determining grammatical acceptability, as required by CoLA task.

Together with the results in Sec. 6.3, hypothesis H4 is supported; the effectiveness of our method depends on relevance between paraphrase discrimination and downstream tasks. Our future work will be to examine what characteristics of NLP tasks make our method less effective.

6.5 Ablation Study

To verify hypothesis H5, we conducted an ablation study that investigates independent effects of sentential and phrasal paraphrase classification. Table 5 shows the results; the last three rows show performances when conducting only sentential paraphrase classification, phrasal paraphrase classification, and binary classification of `paraphrase` and `in-paraphrase` pairs, respectively. All the models were fine-tuned in the same manner as described in Sec. 5.3.

First, the results support the hypothesis; sentential and phrasal paraphrase classification complements each other on sentence representation learning. Our model achieved its best scores

[14] We used the development set because the GLUE server allows only two submissions per day. Note that the number of training epochs for fine-tuning is fixed in our experiments, hence, the development set was not used for other purposes.

Task / Model	Semantic Equivalence			NLI			Single-Sent.	
	MRPC	STS-B	QQP	MNLI (m/mm)	RTE	QNLI	SST	CoLA
Transfer Fine-Tuning	**89.2**	87.4	**71.2**	83.9/**83.1**	64.8	89.3	93.1	47.2
BERT-base	88.3	84.7	**71.2**	**84.3**/83.0	59.8	89.1	**93.3**	**52.7**
+sentence	88.2	**87.6**	71.1	83.2/82.8	**66.2**	**90.2**	92.4	39.8
+3way-PP	88.2	85.8	70.9	82.9/81.9	65.8	88.0	91.3	32.6
+binary-PP	87.7	82.8	70.7	83.7/82.2	61.2	87.6	92.5	42.1

Table 5: Results of the ablation study where the best scores are represented in **bold** and scores higher than those of BERT-base are underlined. The last three rows show performances when conducting only sentential paraphrase classification (+sentence), phrasal paraphrase classification (+3way-PP), and binary classification of phrasal paraphrase (+binary-PP), respectively.

on MRPC, MNLI-m/mm, SST, and CoLA tasks by conducting both sentential and phrasal paraphrase classification simultaneously. Interestingly, these scores are higher than those when sentential and phrasal paraphrase classification are conducted independently. This is reasonable considering the process of fine-tuning. Sentential paraphrase classification directly affects the representation of `[CLS]`, which is the primary tuning factor in fine-tuning for downstream tasks. Alternatively, phrasal paraphrase classification affects representations of phrases, which are the basis for generating the `[CLS]` representation. Simultaneously conducting both sentential and phrasal paraphrase classification thus creates synergy.

It is also obvious that the three-way classification of phrasal paraphrases, on which the model discriminates paraphrases, random combinations of phrases from a random pair of sentences, and random combinations of phrases in a paraphrasal sentence pair, is superior to binary classification. This shows that discriminating random combinations of phrases, which is a simpler and easier task, also contributes to representation learning.

7 Conclusion

We empirically demonstrate that sentential and phrasal paraphrase relations help sentence representation learning. While BERT's pre-training aims to generate generic representations transferable to a broad range of NLP tasks, our method generates representations suitable for the class of semantic equivalence assessment tasks. Our method achieves performance gains while maintaining the model size. Furthermore, it exhibits improvement on downstream tasks with limited amounts of training datasets for fine-tuning, which is a property crucial for transfer learning.

In the future, we plan to investigate the effects of our method on different sizes of BERT models. Additionally, we will apply our model to improve the alignment quality of the phrase alignment model.

Acknowledgments

Appendix: Transfer Fine-Tuning with Simple Features

To further investigate effects of transfer fine-tuning using paraphrase relations on BERT, we designed a model that generates a simplest feature to input into the classifier in Fig. 2. We assume that this method transmits learning signals to the underlying BERT in a more effective manner. Specifically, we use mean-pooling to generate representations of source and target phrases in Eq. (1) and Eq. (2), respectively. These representations are simply concatenated as a feature representation and then fed into the classifier.

Table 6 compares this new model (denoted as Simple Transfer Fine-Tuning) to BERT models as well as our model with the elaborate feature generation described in Sec. 4 (denoted as Transfer Fine-Tuning) on semantic equivalent assessment and NLI tasks of GLUE benchmark. Table 7 reports an ablation study. The results and findings are summarized as follows.

- Our model with simple feature generation (Simple Transfer Fine-Tuning) on BERT-base outperformed BERT on both semantic equivalent assessment and NLI tasks. Furthermore, it performed on-par against BERT-large on MRPC and outperformed it on STS-B and RTE, despite BERT-large having 3.1 times more parameters than our model.

- The same trend was confirmed on the model trained on BERT-large, where our model outperformed BERT-large on all the tasks except QNLI.

- Simple Transfer Fine-Tuning also outperformed our model with elaborate feature generation (Transfer Fine-Tuning) on all semantic equivalent assessment and NLI tasks except MRPC. This result implies that elaborate feature generation tightly fits the model to paraphrase identification while sacrifices its generality to relevant tasks. Further investigation will be our future work.

- Sentential and phrasal paraphrase classification complements each other on sentence representation learning when using simple feature generation, as also confirmed when using the elaborate feature generation in Table 5. Simple Transfer Fine-Tuning achieved higher scores on STS-B, RTE, and QNLI tasks than models trained either with only sentential (+sentence) or phrasal paraphrase (+3way-PP [Simple Feature]) classification.

- Simple feature generation improves the performance of the model trained with only phrasal paraphrase classification; +3way-PP

Task / Model	Semantic Equivalence			NLI		
	MRPC	STS-B	QQP	MNLI (m/mm)	RTE	QNLI
BERT-base	88.3	84.7	71.2	84.3/83.0	59.8	89.1
Transfer Fine-tuning	89.2	87.4	71.2	83.9/83.1	64.8	89.3
Simple Transfer Fine-Tuning	88.6	**87.7**	71.5	84.7/83.6	67.0	91.1
BERT-large	88.6	86.0	72.1	86.2/85.5	65.5	**92.7**
Simple Transfer Fine-Tuning	**89.9**	87.1	**72.5**	**86.5/85.6**	**68.2**	92.2

Table 6: Test results on semantic equivalence assessment and NLI tasks scored by the GLUE evaluation server. The best scores for each task are represented in **bold**. The scores higher than those of BERT counterparts (against BERT-base and BERT-large, respectively) are underlined. Our models with simple feature generation (Simple Transfer Fine-Tuning) consistently outperformed the BERT models and achieved the best scores for six out of seven tasks.

Task / Model	Semantic Equivalence			NLI		
	MRPC	STS-B	QQP	MNLI (m/mm)	RTE	QNLI
Simple Transfer Fine-Tuning	88.6	**87.7**	**71.5**	**84.7/83.6**	**67.0**	**91.1**
BERT-base	88.3	84.7	71.2	84.3/83.0	59.8	89.1
+sentence	88.2	87.6	71.1	83.2/82.8	66.2	90.2
+3way-PP [Elaborate Feature]	88.2	85.8	70.9	82.9/81.9	65.8	88.0
+3way-PP [Simple Feature]	**89.0**	86.6	**71.5**	**84.7/83.6**	65.6	90.6

Table 7: Results of the ablation study where the best scores are represented in **bold** and scores higher than those of BERT-base are underlined. The third row shows performances when conducting only sentential paraphrase classification (+sentence) and the fourth row shows those when conducting only phrasal paraphrase classification with elaborate feature generation (+3way-PP [Elaborate Feature]), as reported in Table 5. The last row shows performances when conducing phrasal paraphrase classification with simple feature generation (+3way-PP [Simple Feature]). Results indicate that sentential and phrasal paraphrase classification complementarily contributes to Simple Transfer Fine-Tuning modeling.

[Simple Feature] outperformed +3way-PP [Elaborate Feature] on all tasks except RTE.

Data-Anonymous Encoding for Text-to-SQL Generation

Abstract

On text-to-SQL generation, the input utterance usually contains lots of tokens that are related to column names or cells in the table, called *table-related tokens*. These table-related tokens are troublesome for the downstream neural semantic parser because it brings complex semantics and hinders the sharing across the training examples. However, existing approaches either ignore handling these tokens before the semantic parser or simply use deterministic approaches based on string-match or word embedding similarity. In this work, we propose a more efficient approach to handle table-related tokens before the semantic parser. First, we formulate it as a sequential tagging problem and propose a two-stage anonymization model to learn the semantic relationship between tables and input utterances. Then, we leverage the implicit supervision from SQL queries by policy gradient to guide the training. Experiments demonstrate that our approach consistently improves performances of different neural semantic parsers and significantly outperforms deterministic approaches.

1 Introduction

Interacting with relational databases or tables through natural language is an important and challenging problem (Androutsopoulos et al., 1995; Li and Jagadish, 2014; Pasupat and Liang, 2015; Zhong et al., 2017; Yu et al., 2018c). To tackle this problem, the neural semantic parser has been widely studied (Dong and Lapata, 2016; Jia and Liang, 2016; Herzig and Berant, 2017; Dong and Lapata, 2018), which automatically maps the input natural language into the logical form (e.g., SQL query) following the typical encoder-decoder structure (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2015; Vinyals et al., 2015).

Semantic parsing usually tackles two kinds of problems (Goldman et al., 2018; Herzig and Berant, 2018), i.e., the *lexical problem* and the *structural problem*. On text-to-SQL generation, the lexical problem refers to mapping tokens in input utterances to constants in SQL queries, e.g., the column names or cells in SQL queries. The structural problem refers to mapping intentions conveyed by input utterances to operators in SQL queries, e.g., the aggregators or the existence of WHERE clause in SQL queries. Intuitively, the lexical problem can be formulated as a sequential tagging problem, called *anonymization*, where each token in the input utterance will be tagged as being related to a column name, a cell or nothing. For ease of reference, we call the tokens in input utterances related to column names or cells *table-related tokens*, and the tagged utterance *anonymous utterance*.

If the lexical problem can be reduced before the neural semantic parsing, the training difficulties will be greatly alleviated. The reason is two-fold. First, by anonymizing table-related tokens in the input utterance before the neural semantic parser, we can conceal the complex semantics of table-related tokens. Second, different input utterances, which have different table-related tokens but the same structure, can be reduced to the same anonymous utterance before they are fed into the parser. This will result in sharing across training data and thus alleviate training difficulties (Goldman et al., 2018; Herzig and Berant, 2018). For example, in Figure 1a and 1b, input utterances (denoted as x) seemingly ask different questions about country and college team, but they can be reduced to a similar anonymous utterance (denoted as $\tilde{x}$) by replacing the token related to the column name as c and the token related to the cell as v.

However, reducing the lexical problem before the neural semantic parser is far from being well-studied on text-to-SQL generation although it

(a) Example A (b) Example B (c) Example C

Figure 1: Examples for anonymizing table-related tokens on WikiSQL. For each subfigure, the upper box shows the utterance and the SQL query, while the lower box shows the table. In the upper box, x denotes the input utterance, $\tilde{x}$ denotes the anonymous utterance and y denotes the SQL query. In anonymous utterance $\tilde{x}$, we use c and v to replace the tokens that are related to column names and cells respectively. In addition, we use the color to indicate the correspondence of column names or cells among x, $\tilde{x}$ and the table.

has been demonstrated to be helpful on other tasks (Goldman et al., 2018; Herzig and Berant, 2018). First, most approaches ignores reducing the lexical problem (Zhong et al., 2017; Xu et al., 2017; Dong and Lapata, 2018; Shi et al., 2018; Wang et al., 2018a; Hwang et al., 2019). Without conducting anonymization before the neural semantic parser, these approaches cannot receive the aforementioned benefit, although they may have modules to predict the presence of column names and cells inside the parser. Second, a few studies have tried the anonymization by deterministic approaches, which compare the similarity based on string-match or word embedding between the input utterance and the table (Wang et al., 2018b; Yu et al., 2018a). These approaches cannot fully understand the semantic relationship between input utterances and tables, and ignore the relationship with components of SQL queries. For example, in Figure 1c, although the token 'player' is similar to the column name 'Player', it should not be tagged as a table-related token because the token "player" is just a non-sense demonstrative pronoun and the column 'Player' is not related to the SQL query.

To this end, we propose to use the learning-based approach to reduce the lexical problem, i.e., anonymize the table-related tokens. First, we propose a two-stage anonymization model to learn the semantic relationship between input utterances and tables. Then, considering that there is no labeled data for the anonymization, we propose to extract the set of column names and cells appearing in the SQL query and use this set as the supervision. Another benefit of leveraging such implicit supervision is that we can make the anonymization model consider the relationship with the components of the SQL query when it learns the semantic relationship, and thus avoid suffering the same disadvantage as deterministic approaches. Furthermore, to bridge the gap that our model is a sequential tagging model while the supervision extracted from the SQL query is an unordered set, we leverage the policy gradient (Williams, 1992) to train the model. Moreover, we train the anonymization model and the neural semantic parser as whole by a varational inference-like framework with the anonymous utterance as the hidden variable.

Experimental results demonstrate that our approach can consistently improve performances of different neural semantic parsers and significantly outperform typical deterministic approach on the anonymization problem.

2 Related Work

Semantic Parsing. Semantic parsing aims to map natural languages into executable programs. In the area of semantic parsing, the programs could be in various types, e.g., λ-calculus (Zettlemoyer and Collins, 2005), Python (Oda et al., 2015), SQL (Zhong et al., 2017), etc; the source of the knowledge can also be different, e.g., the knowledge base, the table, the image (Suhr et al., 2017), etc; and the supervision can take different forms as well, e.g., question-denotation pairs (Pasupat and Liang, 2015), question-program pairs,

etc. In this work, we focus on text-to-SQL generation with the table as the source of the knowledge and with question-SQL query pairs as supervision.

Reducing Lexical Problem. On tasks other than text-to-SQL generation, some studies have tried to reduce lexical problem by anonymizing tokens that are related to the program constants. Goldman et al. (2018) lifts tokens in utterances to an abstract form by referring to fixed mappings on visual reasoning task. Herzig and Berant (2018) employs a rule-based method to transform content words in utterances to an abstract representation. Although these studies inspire us to consider reducing lexical problem on text-to-SQL generation, the rules they employed cannot be directly applied to text-to-SQL generation.

On text-to-SQL generation, a few studies tried to anonymize table-related tokens although they do not aim at reducing lexical problem. To better understand rare entities, Yu et al. (2018a) used string match to recognize column names. To learn a domain-transferable semantic parser, Wang et al. (2018b) detected column names by measuring the closeness of edit distance and word embedding. As discussed in Section 1, these deterministic approaches can not fully understand the semantic relationship between input utterances and tables, and ignore the relationship with components of SQL queries.

Entity Linking. Our approach can be regarded as an implementation of entity linking on the concrete task, because general entity linking (Shen et al., 2015; Kolitsas et al., 2018) approaches fail to handle particular challenges in our scenario. On the one hand, there are lots of cases cannot be handled by the deterministic entity linking method which only relies on measuring the similarity; on the other hand, there is no labeled data for the learning-based entity linking method.

3 Problem Formulation

Denote the input utterance as $x = x_1 \dots x_{|x|}$ and the corresponding SQL query as $y = y_1 \dots y_{|y|}$. We formulate the lexical problem as a sequential tagging problem. Formally, for each token x_t in the input utterance, we give it a tag $\tilde{x}_t \in \{\text{COL}_1, \dots, \text{COL}_K, \text{CELL}, \text{UNK}\}$, where COL_k represents that x_t is related to the k-th column name in the table, CELL represents that x_t is related to a cell in the table and UNK represents that

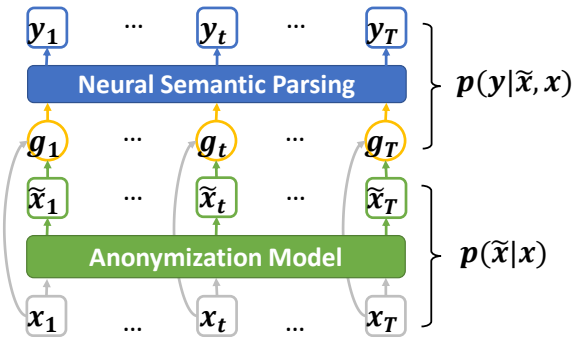

Figure 2: Framework.

x_t is not related to the table. Here K is the number of column names in the table. Note that indexes of column names cannot be ignored in the algorithm to better leverage the implicit supervision from SQL queries (see Section 4.2) although it is ignored when giving examples in Figure 1 and Table 4 for ease of read. For ease of reference, we call this sequential tagging problem *anonymization* and the tagged sequence $\tilde{x} = \tilde{x}_1 \dots \tilde{x}_{|x|}$ *anonymous utterance*.

The typical neural semantic parser aims to estimate $p(y|x)$. In our work, we decompose $p(y|x)$ into two processes (as shown in Figure 2), i.e.,

$$p(y|x) = \sum_{\tilde{x}} p(y|x, \tilde{x})\, p(\tilde{x}|x)\,. \tag{1}$$

Specifically, one process is to learn the anonymous utterance $\tilde{x}$ given the input utterance x for the purpose of reducing lexical problem, i.e.,

$$p(\tilde{x}|x) = \prod_t p(\tilde{x}_t|x)\,, \tag{2}$$

while the other process is to learn the neural semantic parser with anonymous utterance $\tilde{x}$ as the additional input, i.e.,

$$p(y|x, \tilde{x}) = \prod_t p(y_t|y_{<t}, x, \tilde{x})\,. \tag{3}$$

In the following, we will discuss how to learn the anonymous utterance (Eqn (2)) and how to learn the neural semantic parser with anonymous utterance as additional input (Eqn (1)) in detail.

4 Approach

4.1 Anonymization Model

The anonymization is a structural problem by nature. First, we need to differentiate whether the token is related column names, cells or not related to

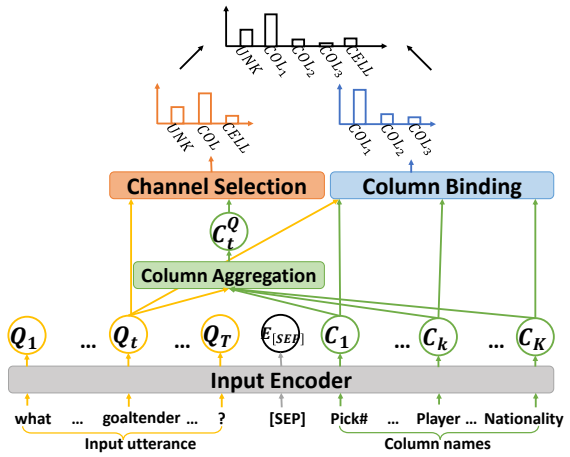

Figure 3: Illustration of the anonymization model when the table content is not available. We take the t-th token in the input utterance as the example.

the table. Second, we need to further recognize the concrete column/cell that the token is related to. Therefore, we design a model that uses two stages, i.e., *channel selection* stage and the *column/cell binding* stage, to tackle these two subproblems respectively. The probability distributions produced by these two stages together determine the result,

$$p\left(\tilde{x}_t|x\right) = \sum_{a_t} p_{\text{channel}}\left(a_t|x\right) p_{\text{binding}}\left(\tilde{x}_t|a_t, x\right), \tag{4}$$

where $a_t \in \{\text{COL}, \text{CELL}, \text{UNK}\}$ is the selected channel indicating that the token is related to column names, cells or nothing respectively, $p_{\text{channel}}\left(\cdot\right)$ is the probability produced by the channel selection stage, and $p_{\text{binding}}\left(\cdot\right)$ is the probability produced by the column/cell binding stage.

For ease of reference, we call the two-stage model *anonymization model*, and illustrate it in Figure 3. In the following, we introduce details of its different components.

Input Encoder. We leverage BiLSTM or BERT (Devlin et al., 2018) to encode both the input utterance and the table. Due to the privacy problem, the table content is not allowed to be used on most text-to-SQL tasks (Zhong et al., 2017; Yu et al., 2018c). Therefore, we use the concatenation of the embedding of the tokens in the input utterance, the embedding of the separator and the embedding of the column names in the table as the input for BiLSTM or BERT. We denote the output of input encoder as $\{Q_1, \ldots, Q_T, E_{[\text{SEP}]}, C_1, \ldots, C_K\}$, where $Q_t, t \in \{1, \ldots, T\}$ is the vector for the encoding of the t-th token in the input utterance, $E_{[\text{SEP}]}$ is the vector for the encoding of the separator, and $C_k, k \in \{1, \ldots, K\}$ is the vector for the encoding of the k-th column name in the table. Note that we run a BiLSTM or BERT between column names instead of over each column name. The reason is that Yu et al. (2018a) have shown that although the order of column names does not matter, running a BiLSTM or BERT between colomn names can capture relationships between them, which will benefit the accuracy and the training time.

Channel Selection. We implement a linear gate with encodings of the input utterance and aggregated encodings of column names as input:

$$p_{\text{channel}}\left(a_t|x\right) = \text{softmax}\left(W_{\text{gate}}\left[Q_t; C_t^Q\right]\right), \tag{5}$$

where W_{gate} stands for learnable parameters, C_t^Q is the aggregated encoding of column names, and $[Q_t; C_t^Q]$ is the concatenation of Q_t and C_t^Q.

Specifically, to obtain the most relevant column names for the t-th token in the input utterance, we leverage attention mechanism (Bahdanau et al., 2015) towards column names $\{C_1, \ldots, C_K\}$ to compute the aggregated encoding of the column names C_t^Q, i.e., $C_t^Q = \sum_{k=1}^{K} \alpha_t^k C_k$, where α_t^k is obtained through $u_t^k = v_1 \tanh\left(W_1 Q_t + W_2 C_k\right)$ and $\alpha_t^k = \text{softmax}\left(u_t^k\right)$, $k \in \{1, \ldots, K\}$. Here, v_1, W_1 and W_2 are learnable parameters.

Column/Cell Binding[1]**.** The probability distribution generated by this stage, i.e., $p_{\text{binding}}(\cdot)$, can be categorized into three types, i.e., $p_{\text{binding}}^{\text{COL}}(\cdot)$, $p_{\text{binding}}^{\text{CELL}}(\cdot)$ and $p_{\text{binding}}^{\text{UNK}}(\cdot)$, corresponding to the three channels in the first stage respectively. Obviously, $p_{\text{binding}}^{\text{UNK}}\left(\tilde{x}_t|a_t, x\right) = 1$.

For column names, we produce a probability distribution over the K columns in the table through measuring the relevance between the t-th token and the k-th column name:

$$p_{\text{binding}}^{\text{COL}_k}\left(\tilde{x}_t|a_t, x\right) = \text{softmax}\left(z_t^k\right), \tag{6}$$
$$z_t^k = v_2 \tanh\left(W_3 Q_t + W_4 C_k\right), \; k \in \{1, \ldots, K\},$$

where v_2, W_3 and W_4 are learnable parameters.

[1]For the situation that the input utterance contains table names or the table content is allowed to be used, we can handle table names or cells by the similar way of column names.

For cells, considering that table content is not available due to the privacy problem, we simply predict a substring from the input utterance. Specifically, we follow the longest match principle to merge consecutive tokens in the input utterance, which are labeled as CELL by the channel selection stage, to one cell. Therefore, the generated by column/cell binding stage is simply set as 1, i.e., $p^{\text{CELL}}_{\text{binding}}(\tilde{x}_t|a_t, x) = 1$.

4.2 Implicit Supervision from SQL Queries

To train the anonymization model, the ground truth for the anonymous utterance is indispensable. However, there is no such labeled data, and manually labeling the whole training data for each text-to-SQL task is unrealistic, especially when the amount of training data is tremendous.

To tackle this problem, we propose to extract the set of column names and cells appearing in the SQL query and use this set as the supervision to guide the training of the anonymization model. Another benefit of such approach is that we can make our model consider the relationship with components of the SQL query, and thus avoid suffering the same trouble as deterministic approaches. Concretely, for each SQL query y, we denote the set of column names and cells appearing in it as S_{SQL}, which consists of three parts, i.e., $S_{\text{SQL}} = S_{\text{sel_col}} \cup S_{\text{other_col}} \cup S_{\text{cell}}$:

1. $S_{\text{sel_col}}$ is the set of column names appearing in the SELECT clause;
2. $S_{\text{other_col}}$ is the set of column names appearing in other clauses;
3. S_{cell} is the set of cells appearing in the whole SQL query.

4.3 Policy Gradient for Sequential Tagging

Maximizing Expected Reward. Ideally, if we have the ground truth, we can train the anonymization model by minimizing the gap (e.g., KL divergence) between the predicted probabilities and the ground truth. Unfortunately, it is infeasible because the implicit supervision from SQL queries (i.e., S_{SQL}) takes a form of the unordered set while the anonymization model faces a sequential tagging task. To address this problem, we propose to encourage the set of column names and cells appearing in the predicted anonymous utterance, denoted as S_{pred}, to be similar to that extracted from the SQL query, i.e., S_{SQL}. To this end, we define a reward of the predicted anonymous utterance $r(\tilde{x})$ as the similarity between S_{pred} and S_{SQL}, and then train the anonymization model by maximizing expected reward,

$$J_{\text{ER}}(\theta) = \sum_{(x,\tilde{x})\in\mathcal{D}} \mathbb{E}_{\tilde{x}\sim p_\theta(\cdot|x)} r(\tilde{x}), \tag{7}$$

where $\mathcal{D}$ represents the set of training pairs.

However, directly computing expected reward requires traversing all the possible anonymous utterance $\tilde{x}$, which is unrealistic. Therefore, we leverage Monte Carlo estimate as the approximation of the expected reward. Concretely, we sample N anonymous utterances following probability distribution generated by the anonymization model, and then average the reward of the samples to estimate the expected reward,

$$J_{\text{ER}}(\theta) \approx \sum_{(x,\tilde{x})\in\mathcal{D}} \sum_{j=1}^{N} \frac{1}{N} r(\tilde{x}^j), \tag{8}$$

where $\tilde{x}^j$ denotes the j-th sample and $\tilde{x}^j \sim p_\theta(\cdot|x)$.

To maximize the above objective function by gradient descent, we employ REINFORCE (Williams, 1992) method, i.e,

$$\nabla_\theta J_{\text{ER}}(\theta) \approx \sum_{(x,\tilde{x})\in\mathcal{D}} \sum_{j=1}^{N} \frac{1}{N} r(\tilde{x}^j) \nabla_\theta \log p_\theta\left(\tilde{x}^j|x\right). \tag{9}$$

Measurement of Reward. For ease of reference, we decompose S_{pred} into two parts, i.e., $S_{\text{pred}} = S_{\text{pred_col}} \cup S_{\text{pred_cell}}$, where $S_{\text{pred_col}}$ and $S_{\text{pred_cell}}$ represent the set of column names and the set of cells appearing in the predicted anonymous utterance respectively.

The measurement of the reward $r(\tilde{x})$ is designed based on the similarity between S_{pred} and S_{SQL} by referring to the following principles:

1. The predicted anonymous utterance should contain the column names in the SELECT clause of the SQL query, i.e., $S_{\text{sel_col}} \subset S_{\text{pred_col}}$. The anonymization model will be punished when it misses the column names in $S_{\text{sel_col}}$. This is motivated by our preliminary analysis that almost every column name in the SELECT clause has the corresponding token in the input utterance.

2. The column names in the predicted anonymous utterance should be at least a subset of the column names appearing in the SQL query, i.e., $S_{\text{pred_col}} \subseteq S_{\text{sel_col}} \cup S_{\text{other_col}}$. Unlike $S_{\text{sel_col}}$, the column names appearing in other clauses of the

SQL query may possible not have corresponding tokens in the input utterance. For example, in Figure 1a, the column name 'Position' does not have corresponding tokens in the input utterance. Therefore, it is unreasonable to strictly force column names in the predicted anonymous utterance to be the same as that appearing in the SQL query. Instead, it is better to punish the anonymization model when it predicts column names outside the set of column names appearing in the SQL query.

3. The cell names in the predicted anonymous utterance should be the same as that appearing in the SQL query, i.e., $S_{\text{pred_cell}} = S_{\text{cell}}$. If there is any missing or extra cell in $S_{\text{pred_cell}}$, the anonymization model will be punished.

According to above principles, we design the reward $r(\tilde{x})$ as,

1. if $S_{\text{sel_col}} \subseteq S_{\text{pred_col}}$, $S_{\text{pred_cell}} = S_{\text{cell}}$ and $S_{\text{pred_col}} \subseteq S_{\text{sel_col}} \cup S_{\text{other_col}}$ are all true, $r(\tilde{x}) = 1$;
2. if one of $S_{\text{sel_col}} \nsubseteq S_{\text{pred_col}}$, $S_{\text{pred_cell}} \neq S_{\text{cell}}$ and $S_{\text{pred_col}} \nsubseteq S_{\text{sel_col}} \cup S_{\text{other_col}}$ is true, $r(\tilde{x}) = -1$.

4.4 Training and Inference

To train the anonymization model and the parser as a whole, we regard the anonymous utterance $\tilde{x}$ as the hidden variable for the neural semantic parser $p(y|x)$. Then, maximizing the log likelihood of $p(y|x)$ is equivalent to maximizing its Evidence Lower BOund (ELBO) (Kim et al., 2018), i.e.,

$$\text{ELBO}\,(\varphi, \theta) = \mathbb{E}_{q_\theta(\tilde{x}|x)} \left[\log \frac{p_\varphi(y, \tilde{x}|x)}{q_\theta(\tilde{x}|x)} \right] \quad (10)$$

One popular strategy to maximizing ELBO is the coordinate ascent. Specifically, it iteratively executes following two steps (Neal and Hinton, 1998): 1) *variational E-step*, which maximizes ELBO w.r.t. θ keeping φ fixed, i.e., $\theta^\star = \arg\min_\theta \mathbb{KL}\left(q_\theta(\tilde{x}|x) \| p_\varphi(\tilde{x}|y, x)\right)$; and 2) *variational M-step*, which maximizes ELBO w.r.t. φ keeping θ fixed, i.e., $\varphi^\star = \arg\max_\varphi \mathbb{E}_{q_\theta(\tilde{x}|x)} \left[\log p_\varphi(y, \tilde{x}|x)\right]$.

In our scenario, φ and θ refer to the learnable parameters in the neural semantic parser and the anonymization model respectively. For variational E-step, it usually finds the best variational approximation to the true posterior (Neal and Hinton, 1998). As discussed in Section 4.2, the true posterior we can obtain is in the form of the unordered set. Thus, we actually minimize the the expected reward, i.e., $J_{\text{ER}}(\theta)$, instead of the KL divergence (see Section 4.3). For variational M-step, to save training time, we simply sample one example greedily, which approximates to maximizing log likelihood of $p_\varphi(y, \tilde{x}|x)$, i.e., $J_{\text{MLE}}(\varphi)$. Moreover, since performing coordinate ascent on the entire dataset is too expensive, the variational E-step and M-step are usually performed over mini-batches (Hoffman et al., 2013). To further improve time efficiency, we optimize objectives of the variational E-step and M-step simultaneously instead of alternatively. Thus, the actual objective is,

$$J(\varphi, \theta) = \underbrace{\sum_{(x,y)\in\mathcal{D}} \log p_\varphi(y|\tilde{x}, x)}_{J_{\text{MLE}}(\varphi)} + \underbrace{\sum_{(x,\tilde{x})\in\mathcal{D}} \mathbb{E}_{\tilde{x}\sim q_\theta(\cdot|x)} r(\tilde{x})}_{J_{\text{ER}}(\theta)}, \quad (11)$$

where $J_{\text{MLE}}(\varphi)$ is the log likelihood of the generated SQL query given the input utterance and the anonymous utterance, and $J_{\text{ER}}(\theta)$ is the expected reward of the anonymous utterance given the input utterance (see Eqn (8) for details.)

Specifically, when optimizing $J_{\text{MLE}}(\varphi)$, we use the concatenation of the encoding of the input utterance (denoted as $e(x_t)$) and the encoding of the anonymous utterance (denoted as $h(\tilde{x}_t)$) as the input for the neural semantic parser, i.e., $g_t = [e(x_t); h(\tilde{x}_t)]$, $t \in \{1, \ldots, T\}$ (see Figure 2). For $e(x_t)$, it is determined by the parser itself. For $h(\tilde{x}_t)$, it is concatenated by two parts: 1) embedding of the channel name, i.e., COL, CELL and UNK, 2) embedding of index k when the channel is COL, indicating that the t-th token is related to the k-th column name in the table.

At test time, the prediction for input utterance x is obtained by $\hat{x} = \arg\max_{\tilde{x}'} p\left(\tilde{x}'|x\right)$ and $\hat{y} = \arg\max_{y'} p\left(y'|\hat{x}, x\right)$.

5 Experiments

5.1 Experimental Setup

We conduct experiments on the WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018c). Each example consists of a natural language question, a SQL query and a table. On WikiSQL, one question is only related to one table; while on Spider, one question is usually related to multiple tables.

Our model is implemented in PyTorch (Paszke et al., 2017). The type of the input encoder in the anonymization model (i.e., BiLSTM or BERT) is set the same as that in the concrete parser. Embedding vectors of the anonymous utterance are initiated by GloVe (Pennington et al., 2014). We

Method	Dev (%)		Test (%)

use the manually labeled training data (which is 10% of the whole training data) to initiate our anonymization model and then optimize the entire framework on the whole training data. All the other hyperparameters, e.g., the learning rate, hyperparameters in ADAM optimizer, the number of training epochs, etc., are tuned on the dev set[2].

5.2 Performance of Neural Semantic Parsing

First, we show that reducing the lexical problem through the anonymization model can improve the performance of neural semantic parser.

To this end, we add the anonymization model to typical neural semantic parsers as presented in Section 4. We use '[A]+DAE' to denote the neural semantic parser with the anonymization model, where A stands for the original name of the concrete parser and **DAE** is the abbreviated name of our approach, i.e., data-anonymous encoding.

[2]For Spider, we tune hyperparameters on training set and test the model on dev set.

On WikiSQL, the performance is evaluated by query-match accuracy (ACC_{QM}) and execution accuracy (ACC_{EX}), which measure accuracies of canonical representation and execution result matches between the predicted SQL and the ground truth respectively (Yu et al., 2018a). Table 1 shows the results. First, we can observe that query match accuracy on test data can be improved by 6.4% at most and 1.1% at least. Furthermore, for TypeSQL, query match accuracy can be further improved by 1.1% although it has used string-match based approach to anonymize table-related tokens. Moreover, we perform ablation studies by 1) removing the supervision for the anonymization model (denoted as '-Supervision' in Table 1), and 2) simply using the output of the trained anonymization model as the input for the parser without training them as a whole (denoted as '-Co-training' in Table 1). We can observe that the performance improvement is limited without supervision and co-training, indicating that both of them are indispensable.

On Spider, the performance is evaluated by exact-match accuracy on different difficulty levels of SQL queries, i.e., easy, medium, hard and extra hard. (Yu et al., 2018c). Table 2 shows the results. First, the overall accuracy can be improved by 3.2% and 2.5% respectively. Furthermore, per-

Table 5: Performances of different anonymization models on WikiSQL.

formances on medium, hard and extra hard SQL queries achieve more improvement than that on easy SQL queries, indicating that our approach is more helpful for solving complicated cases.

5.3 Performance of Reducing Input Utterances

To further demonstrate the effectiveness of reducing the lexical problem, we show that different input utterance can be reduced to the same anonymous utterance. To this end, we process input utterances and anonymous utterances by 1) converting the characters to the lowercase, 2) lemmatizing the tokens and 3) removing the articles.

Table 3 shows that by anonymizing table-related tokens, the number of distinct utterances is reduced from 8387 to 5488 on dev set and from 15828 to 9680 on test set. Furthermore, Table 4 shows three anonymous utterances that are most frequent on dev set and examples of corresponding input utterances. All of these indicate that although input utterances can hardly be identical, they often share the same anonymous utterance.

5.4 Performance of Anonymization Methods

In addition, we compare performances of different anonymization methods, including 1) TypeSQL, which uses exact string match to detect column names, 2) AnnotatedSeq2Seq, which detects column names by setting a threshold for the edit distance and the cosine similarity of word embedding, and 3) DAE, our learning-based approach[3].

Anonymization methods are evaluated by following metrics: 1) whether the column names in SELECT clause is included in the prediction ($ACC_{SC} = \frac{\sum_{i=1}^{Z} \mathbb{I}(S^i_{\text{sel_col}} \subseteq S^i_{\text{pred_col}})}{Z}$); 2) whether there is wrongly predicted column names ($ACC_{OC} = \frac{\sum_{i=1}^{Z} \mathbb{I}(S^i_{\text{pred_col}} \subseteq S^i_{\text{sel_col}} \cup S^i_{\text{other_col}})}{Z}$); and 3) whether all the cells in the SQL query are correctly predicted ($ACC_{CE} = \frac{\sum_{i=1}^{Z} \mathbb{I}(S^i_{\text{pred_cell}} = S^i_{\text{cell}})}{Z}$). Here, Z is the amount of test data, $\mathbb{I}(\cdot)$ is the indicator function, and superscript i is the index of data.

Table 5 shows that DAE significantly outperforms TypeSQL and AnnotatedSeq2Seq on all the evaluation metrics. First, for ACC_{SC}, DAE outperforms TypeSQL and AnotatedSeq2Seq by 16% and 3.5% on test data; for ACC_{OC}, DAE outperforms TypeSQL and AnnotatedSeq2Seq by 0.8% and 28% on test data. Moreover, DAE can achieve around 86% for ACC_{CE}, while other methods fail to recognize cells when the table content is not available due to the privacy problem.

6 Conclusion

In this work, we propose a learning-based approach to reduce the lexical problem before the

[3]For experiments in this subsection, to make our anonymization model in the same settings as the others, we use BiLSTM as the input encoder and do not train the anonymization model with neural semantic parser as a whole.

neural semantic parser on text-to-SQL generation. Specifically, we propose a two-stage anonymization model and leverage implicit supervision from SQL queries by policy gradient to guide its training. In the future, we plan to improve the performance of the anonymization model by exploring more efficient expected reward. In addition, we also plan to extend our approach to the tasks with question-denotation pairs as supervision.

Capturing Argument Interaction in Semantic Role Labeling with Capsule Networks

Abstract

Semantic role labeling (SRL) involves extracting propositions (i.e. predicates and their typed arguments) from natural language sentences. State-of-the-art SRL models rely on powerful encoders (e.g., LSTMs) and do not model non-local interaction between arguments. We propose a new approach to modeling these interactions while maintaining efficient inference. Specifically, we use Capsule Networks (Sabour et al., 2017): each proposition is encoded as a tuple of *capsules*, one capsule per argument type (i.e. role). These tuples serve as embeddings of entire propositions. In every network layer, the capsules interact with each other and with representations of words in the sentence. Each iteration results in updated proposition embeddings and updated predictions about the SRL structure. Our model substantially outperforms the non-refinement baseline model on all 7 CoNLL-2019 languages and achieves state-of-the-art results on 5 languages (including English) for dependency SRL. We analyze the types of mistakes corrected by the refinement procedure. For example, each role is typically (but not always) filled with at most one argument. Whereas enforcing this approximate constraint is not useful with the modern SRL system, iterative procedure corrects the mistakes by capturing this intuition in a flexible and context-sensitive way.[1]

1 Introduction

The task of semantic role labeling (SRL) involves the prediction of predicate-argument structure, i.e., both the identification of arguments and labeling them with underlying semantic roles. The shallow semantic structures have been shown beneficial in many natural language processing (NLP) applications, including information extraction (Christensen et al., 2011), question answering (Eckert and Neves, 2018) and machine translation (Marcheggiani et al., 2018).

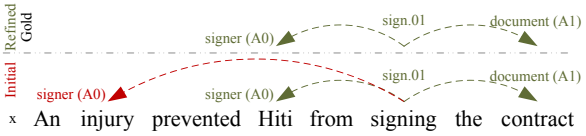

Figure 1: An example predicate-argument structure: green and red arcs denote correct and wrong predictions, respectively.

In this work, we focus on the dependency version of the SRL task (Surdeanu et al., 2008). An example of a dependency semantic-role structure is shown in Figure 1. Edges in the graph are marked with semantic roles, whereas predicates (typically verbs or nominalized verbs) are annotated with their senses.

Intuitively, there are many restrictions on potential predicate-argument structures. Consider the 'role uniqueness' constraint: each role is typically, but not always, realized at most once. For example, predicates have at most one *agent*. Similarly, depending on a verb class, only certain subcategorization patterns are licensed. Nevertheless, rather than modeling the interaction between argument labeling decisions, state-of-the-art semantic role labeling models (Marcheggiani and Titov, 2017; Cai et al., 2018; Li et al., 2019b) rely on powerful sentence encoders (e.g., multi-layer BiLSTMs (Zhou and Xu, 2015; Qian et al., 2017; Tan et al., 2018)). This contrasts with earlier work on SRL, which hinged on global declarative constraints on the labeling decisions (FitzGerald et al., 2015; Täckström et al., 2015; Das et al., 2012). Modern SRL systems are much more accurate and hence enforcing such hard and often approximate constraints is unlikely to be as beneficial (see our experiments in Section 7.2).

Instead of using hard constraints, we propose to use a simple iterative structure-refinement procedure. It starts with independent predictions and refines them in every subsequent iteration. When refining a role prediction for a given candidate argument, information about the assignment of roles to other arguments gets integrated. Our intuition is that modeling interactions through the output spaces rather than hoping that the encoder somehow learns to capture them, provides a useful inductive bias to the model. In other words, capturing this interaction explicitly should mitigate overfitting. This may be especially useful in a lower-resource setting but, as we will see in experiments, it appears beneficial even in a high-resource setting.

We think of semantic role labeling as extracting propositions, i.e. predicates and argument-role tuples. In our example, the proposition is `sign.01`(`Arg0:signer` = *Hiti*, `Arg1:document` = *contract*). Across the iterations, we maintain and refine not only predictions about propositions but also their embeddings. Each 'slot' (e.g., correspond to role `Arg0:signer`) is represented with a vector, encoding information about arguments assumed to be filling this slot. For example, if *Hiti* is predicted to fill slot `Arg0` in the first iteration then the slot representation will be computed based on the contextualized representation of that word and hence reflect this information. The combination of all slot embeddings (one per semantic role) constitutes the embedding of the proposition. The proposition embedding, along with the prediction about the semantic role structure, gets refined in every iteration of the algorithm.

Note that, in practice, the predictions in every iteration are soft, and hence proposition embeddings will encode current beliefs about the predicate-argument structure. The distributed representation of propositions provides an alternative ("dense-embedding") view on the currently considered semantic structure, i.e. information extracted from the sentence. Intuitively, this representation can be readily tested to see how well current predictions satisfy selection restrictions (e.g., *contract* is a very natural filler for `Arg1:document`) and check if the arguments are compatible.

To get an intuition how the refinement mechanism may work, imagine that both *Hiti* and *injury* are labeled as `Arg0` for `sign.01` in the first iteration. Hence, the representation of the slot `Arg0` will encode information about both predicted arguments. At the second iteration, the word *injury* will be aware that there is a much better candidate for filling the `signer` role, and the probability of assigning *injury* to this role will drop. As we will see in our experiments, whereas enforcing the hard uniqueness constraint is not useful, our iterative procedure corrects the mistakes of the base model by capturing interrelations between arguments in a flexible and context-sensitive way.

In order to operationalize the above idea, we take inspiration from the Capsule Networks (CNs) (Sabour et al., 2017). Note that we are not simply replacing Bi-LSTMs with generic CNs. Instead, we use CN to encode the structure of the refinement procedure sketched above. Each slot embedding is now a *capsule* and each proposition embedding is a tuple of capsules, one capsule per role. In every iteration (i.e. CN network layer), the capsules interact with each other and with representations of words in the sentence.

We experiment with our model on standard benchmarks for 7 languages from CoNLL-2019. Compared with the non-refinement baseline model, we observe substantial improvements from using the iterative procedure. The model achieves state-of-the-art performance in 5 languages, including English.

2 Base Dependency SRL Model

In dependency SRL, for each predicate p of a given sentence $x = \{x_1, x_2, \cdots, x_n\}$ with n words, the model needs to predict roles $y = \{y_1, y_2, \cdots, y_n\}$ for every word. The role can be *none*, signifying that the corresponding word is not an argument of the predicate.

We start with describing the factorized baseline model which is similar to that of Marcheggiani et al. (2017). It consists of three components: (1) an embedding layer; (2) an encoding layer and (3) an inference layer.

2.1 Embedding Layer

The first step is to map symbolic sentence x and predicate p into continuous embedded space:

$$\mathbf{e}_i = \text{Lookup}(x_i), \quad (1)$$

$$\mathbf{p} = \text{Lookup}(p), \quad (2)$$

where $\mathbf{e}_i \in \mathcal{R}^{d_e}$ and $\mathbf{p} \in \mathcal{R}^{d_e}$.

2.2 Encoding Layer

The encoding layer extracts features from input sentence x and predicate p. We extract features from input sentence x using stacked bidirectional LSTMs (Hochreiter and Schmidhuber, 1997):

$$\mathbf{x}_i = \text{Bi-LSTMs}(\mathbf{e}_i), \tag{3}$$

where $\mathbf{x}_i \in \mathcal{R}^{d_l}$. Then we represent each role logit of each word by a bi-linear operation with the target predicate:

$$b_{j|i} = \mathbf{x}_i \mathbf{W} \mathbf{p}, \tag{4}$$

where $\mathbf{W} \in \mathcal{R}^{d_l \times d_e}$ is a trainable parameter and $b_{j|i} \in \mathcal{R}$ is a scalar representing the logit of role j for word x_i.

2.3 Inference Layer

The probability $P(y|x,p)$ is then computed as

$$P(y|x,p) = \prod_i P(y_i|x,i,p), \tag{5}$$

$$= \prod_i \text{softmax}(\mathbf{b}_{\cdot|i})_{y_i}, \tag{6}$$

where $\mathbf{b}_{\cdot|i} = \{b_{1|i}, b_{2|i}, \cdots, b_{|\mathcal{T}||i}\}$ and $|\mathcal{T}|$ denotes the number of role types.

3 Dependency based Semantic Role Labeling using Capsule Networks

Inspired by capsule networks, we use capsule structure for each role state to maintain information across iterations and employ the dynamic routing mechanism to derive the role logits $b_{j|i}$ iteratively. Figure 2 illustrates the architecture of the proposed model.

3.1 Capsule Structure

We start by introducing two capsule layers: (1) the word capsule layer and (2) the role capsule layer.

3.1.1 Word Capsule Layer

The word capsule layer is comprised of capsules representing the roles of each word. Given sentence representation $\mathbf{x}_i$ and predicate embedding $\mathbf{p}$, the word capsule layer is derived as:

$$u^k_{j|i} = \mathbf{x}_i \mathbf{W}^k_j \mathbf{p}; \;\; k = 1, 2, \cdots, K, \tag{7}$$

where $\mathbf{W}^k_j \in \mathcal{R}^{d_l \times d_e}$ and $\mathbf{u}_{j|i} \in \mathcal{R}^K$ is the capsule vector for role j of word x_i. K denotes the capsule size. Intuitively, the capsule encodes the argument-specific information relevant to deciding if role j is suitable for the word. These capsules do not get iteratively updated.

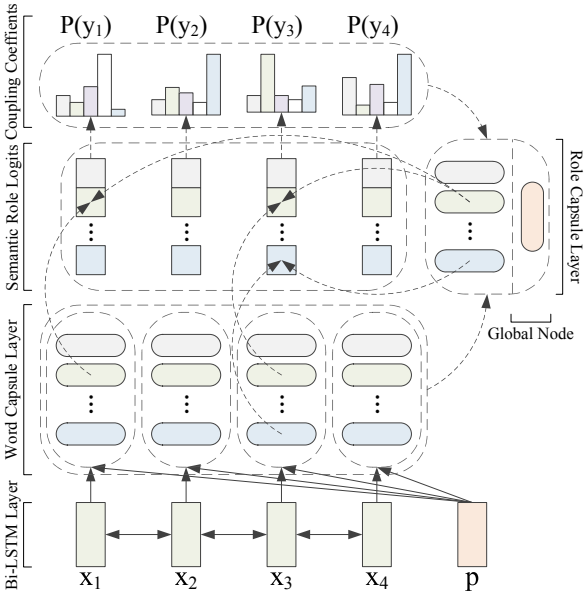

Figure 2: Architecture of the proposed CapsuleNet with the global capsule node. The dashed arcs are iterable.

3.1.2 Role Capsule Layer

As discussed in the introduction, the role capsule layer could be viewed as an embedding of a proposition. The capsule network generates the capsules in the layer using "routing-by-agreement". This process can be regarded as a pooling operation. Capsules in the role capsule layer at t-th iteration are derived as:

$$\mathbf{v}^{(t)}_j = \text{Squash}(\mathbf{s}^{(t)}_j) = \frac{||\mathbf{s}^{(t)}_j||^2}{1 + ||\mathbf{s}^{(t)}_j||^2} \frac{\mathbf{s}^{(t)}_j}{||\mathbf{s}^{(t)}_j||}, \tag{8}$$

where intermediate capsule $s^{(t)}_j$ is generated with the linear combination of capsules in the word capsule layer with weights $c^{(t)}_{ij}$:

$$\mathbf{s}^{(t)}_j = \sum_i c^{(t)}_{ij} \mathbf{u}_{j|i}. \tag{9}$$

Here, $c^{(t)}_{ij}$ are coupling coefficients, calculated by "softmax" function over role logits $b^{(t)}_{j|i}$. The coefficients $c^{(t)}_{ij}$ can be interpreted as the probability that word x_i is assigned role j:

$$\mathbf{c}^{(t)}_i = \text{softmax}(\mathbf{b}^{(t)}_{\cdot|i}). \tag{10}$$

The role logits $b^{(t)}_{j|i}$ are decided by the iterative *dynamic routing* process. The Squash operation will deactive capsules receiving small input $\mathbf{s}^{(t)}_j$ (i.e. roles not predicted in the sentence) by pushing them further to the $\mathbf{0}$ vector.

Input: # of iterations T, all capsules in l_w $\mathbf{u}_{j|i}$
Result: semantic role logits $b_{j|i}^{(T)}$
Initialization: $b_{j|i}^{(0)} = 0$;
for $t \in [0, 1, \cdots, T-1]$ **do**
  for all capsules in l_w: $\mathbf{c}_i^{(t)} = \text{softmax}(\mathbf{b}_{\cdot|i}^{(t)})$;
  for all capsules in l_r: $\mathbf{s}_j^{(t)} = \sum_i c_{ij}^{(t)} \mathbf{u}_{j|i}$;
  for all capsules in l_r: $\mathbf{v}_j^{(t)} = \text{Squash}(\mathbf{s}_j^{(t)})$;
  for all capsules in l_w and l_r: $b_{j|i}^{(t+1)} = b_{j|i}^{(t)} + \mathbf{v}_j^{(t)} \mathbf{W} \mathbf{u}_{j|i}$;
end

Algorithm 1: Dynamic routing algorithm. l_w and l_r denote word capsule layer and role capsule layer, respectively.

3.2 Dynamic Routing

The dynamic routing process involves T iterations. The role logits $b_{j|i}$ before first iteration are all set to zeros: $b_{j|i}^{(0)} = 0$. Then, the dynamic routing process updates the role logits $b_{j|i}$ by modeling agreement between capsules in two layers:

$$b_{j|i}^{(t+1)} = b_{j|i}^{(t)} + \mathbf{v}_j^{(t)} \mathbf{W} \mathbf{u}_{j|i}, \tag{11}$$

where $\mathbf{W} \in \mathcal{R}^{K \times K}$.

The whole dynamic routing process is shown in Algorithm 1. The dynamic routing process can be regarded as the role refinement procedure (see Section 5 for details).

4 Incorporating Global Information

When computing the j-th role capsule representation (Eq 9), the information originating from an i-th word (i.e. $u_{j|i}$) is weighted by the probability of assigning role j to word x_i (i.e. c_{ij}). In other words, the role capsule receives messages only from words assigned to its role. This implies that the only interaction the capsule network can model is competition between arguments for a role.[2] Note though that this is different from imposing the hard role-uniqueness constraint, as the network does this dynamically in a specific context. Still, this is a strong restriction.

In order to make the model more expressive, we further introduce a global node $\mathbf{g}^{(t)}$ to incorporate global information about all arguments at the current iterations. The global node is a compressed representation of the entire proposition, and used in the prediction of all arguments, thus permitting arbitrary interaction across arguments. The global node $\mathbf{g}^{(t)}$ at t-th iteration is derived as:

$$\mathbf{g}^{(t)} = \mathbf{W} \mathbf{s}^{(t)}, \tag{12}$$

where $\mathbf{W} \in \mathcal{R}^{K \times (K \cdot |\mathcal{T}|)}$. Here, $\mathbf{s}^{(t)} = \mathbf{s}_1^{(t)} \oplus \mathbf{s}_2^{(t)} \oplus \cdots \oplus \mathbf{s}_{|\mathcal{T}|}^{(t)} \in \mathcal{R}^{K \cdot |\mathcal{T}|}$ is the concatenation of all capsules in the role capsule layer.

We append an additional term for the role logits update in Eq (11):

$$b_{j|i}^{(t+1)} = b_{j|i}^{(t)} + \mathbf{v}_j^{(t)} \mathbf{W} \mathbf{u}_{j|i} + \mathbf{g}^{(t)} \mathbf{W}_g \mathbf{u}_{j|i}, \tag{13}$$

where $\mathbf{W} \in \mathcal{R}^{K \times K}$ and $\mathbf{W}_g \in \mathcal{R}^{K \times K}$.

5 Refinement

The dynamic routing process can be seen as iterative role refinement. Concretely, the coupling coefficients $\mathbf{c}_i^{(t)}$ in Eq (10) can be interpreted as the predicted distribution of the semantic roles for word x_i in Eq (5) at t-th iteration:

$$\mathbf{c}_i^{(t)} = P^{(t)}(\cdot | x, i, p). \tag{14}$$

Since dynamic routing is an iterative process, semantic role distribution $\mathbf{c}_i^{(t)}$ in iteration t will affect the semantic role distribution $\mathbf{c}_i^{(t+1)}$ in next iteration $t+1$:

$$\mathbf{c}_i^{(t+1)} = f(\mathbf{c}_i^{(t)}, x, i, p), \tag{15}$$

where $f(\cdot)$ denotes the refinement function defined by the operations in each dynamic routing iteration.

6 Training

We minimize the following loss function $\mathcal{L}(\theta)$:

$$\mathcal{L}(\theta) = -\frac{1}{n} \sum_i^n \log P^{(T)}(y_i | x, i, p; \theta) + \lambda ||\theta||_2^2, \tag{16}$$

where λ is a hyper-parameter for the regularization term and $P^{(T)}(y_i | x, i, p; \theta) = \mathbf{c}_i^{(T)}$. Unlike standard refinement methods (Belanger et al., 2017; Lee et al., 2018) which sum losses across all refinement iterations, our loss is only based on the prediction made at the last iteration. This encourages the model to rely on the refinement process rather than do it in one shot.

Our baseline model is trained analogously, but using the cross-entropy for the independent classifiers (Eq (5)).

[2] In principle, it can model the opposite, i.e. collaboration / attraction but it is unlikely to be useful in SRL.

Uniqueness Constraint Assumption As we discussed earlier, for a given target predicate, each semantic role will typically appear at most once. To encode this intuition, we propose another loss term $\mathcal{L}_u(\theta)$:

$$\mathcal{L}_u(\theta) = \frac{1}{|\mathcal{T}|} \sum_j \log \text{softmax}(\mathbf{b}_{j|\cdot}^{(T)}), \quad (17)$$

where $\mathbf{b}_{j|\cdot}^{(T)}$ are the semantic role logits in T-th iteration. Thus, the final loss $\mathcal{L}^*(\theta)$ is the combination of the two losses:

$$\mathcal{L}^*(\theta) = \mathcal{L}(\theta) + \eta \mathcal{L}_u(\theta), \quad (18)$$

where η is a discount coefficient.

7 Experiments

7.1 Datasets & Configuration

we conduct experiments on CoNLL-2009 (Hajič et al., 2009) for all languages, including Catalan (Ca), Chinese (Zh), Czech (Cz), English (En), German (De), Japanese (Jp) and Spanish (Es). As standard we do not consider predicate identification: the predicate position is provided as an input feature. We use the labeled 'semantic' F1 which jointly scores sense prediction and role labeling.

We use ELMo (Peters et al., 2018) (dimension d_e as 1024) for English, and FastText embeddings (Grave et al., 2018) (dimension d_e as 300) for all other languages on both the baseline model and the proposed CapsuleNet. LSTM state dimension d_l is 500. Capsule size K is 16. Batch size is 32. The coefficient for the regularization term λ is 0.0004. We employ Adam (Kingma and Ba, 2015) as the optimizer and the initial learning rate α is set to 0.0001. Syntactic information is not utilized in our model.

7.2 Model Selection

Table 1 shows the performance of our model trained with loss $\mathcal{L}^*(\theta)$ for different values of discount coefficient η on the English development set. The model achieves the best performance when η equals to 0. It implies that adding uniqueness constraint on loss actually hurts the performance. Thus, we use the loss $\mathcal{L}^*(\theta)$ with η equals to 0 in the rest of the experiments, which is equivalent to the loss $\mathcal{L}(\theta)$ in Eq (16). We also observe that the model with 2 refinement iterations performs the best (89.92% F1).

7.3 Overall Results

Table 2 compares our model with previous state-of-the-art SRL systems on English. Some of the systems (Lei et al., 2015; Li et al., 2018; Cai et al., 2018) only use local features, whereas others (Swayamdipta et al., 2016) incorporate global information at the expense of greedy decoding. Additionally, a number of systems exploit syntactic information (Roth and Lapata, 2016; Marcheggiani and Titov, 2017; He et al., 2018). Some of the results are obtained with ensemble systems (FitzGerald et al., 2015; Roth and Lapata, 2016).

As we observe, the baseline model (see Section 2) is quite strong, and outperforms the previous state-of-the-art systems on both in-domain and out-of-domain sets on English. The proposed CapsuleNet outperforms the baseline model on English (e.g. obtaining 91.06% F1 on the English test set), which shows the effectiveness of the cap-

sule network framework. The improvement on the out-of-domain set implies that our model is robust to domain variations.

7.4 Ablation

Table 3 gives the performance of models with ablation on some key components, which shows the contribution of each component in our model.

- The model **without the global node** is described in Section 3.
- The model that further **removes the role capsule layer** takes the mean of capsules $\mathbf{u}_{j|i}$ in Eq (7) of word capsule layer as the semantic role logits $b_{j|i}$:

$$b_{j|i} = \frac{1}{K} \sum_{k}^{K} \mathbf{u}^{k}_{j|i}, \tag{19}$$

  where K denotes the capsule size.
- The model that additionally **removes the word capsule layer** is exactly equivalent to the baseline model described in Section 2.

As we observe, CapsuleNet with all components performs the best on both development and test sets on English. The model without using the global node performs well too. It obtains 91.05% F1 on the English test set, almost the same performance as full CapsuleNet. But on the English out-of-domain set, without the global node, the performance drops from 82.72% F1 to 82.36% F1. It implies that the global node helps in model generalization. Further, once the role capsule layer is removed, the performance drops sharply. Note that the model without the role capsule layer does not use refinements and hence does not model argument interaction. It takes the mean of capsules $\mathbf{u}_{j|i}$ in the word capsule layer as the semantic role logits $b_{j|i}$ (see Eq (19)), and hence could be viewed as an enhanced ('ensembled') version of the baseline model. Note that we only introduced a very limited number of parameters for the dynamic routing mechanism (see Eq (11-13)). This suggests that the dynamic routing mechanism does genuinely captures interactions between argument labeling decisions and the performance benefits from the refinement process.

Table 4: Numbers of propositions with different sentence lengths and different numbers of arguments on the English test set.

7.5 Error Analysis

The performance of our model while varying the sentence length and the number of arguments per proposition is shown in Figure 3. The statistics of the subsets are in Table 4. Our model consistently outperforms the baseline model, except on sentences of between 50 and 59 words. Note that the subset is small (only 391 sentences), so the effect may be random.

7.6 Effect of Refinement

7.6.1 Refinement Performance

We take a CapsuleNet trained to perform refinements in two iterations and vary the number of iterations at test time (Figure 4). CapsuleNets with and without the global node perform very differently. CapsuleNet without the global node reduces the recall and increases the precision with every iteration. This corresponds to our expectations: the version of the network is only capable of modeling competition and hence continues with this filtering process. In contrast, CapsuleNet with the global

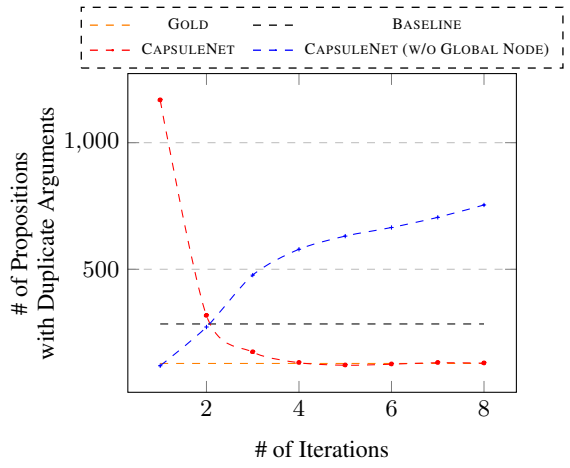
Figure 4: The performance of different models while varying the number of refinement iterations on the English development set.



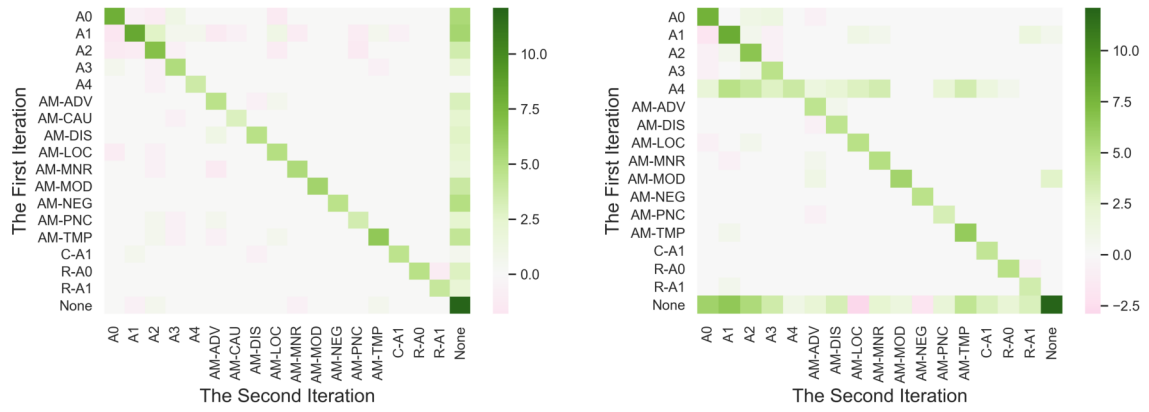


Figure 5: The number of propositions with duplicate arguments for various numbers of refinement iterations on the English development set.

node reduces the precision as the number of iteration grows. This model is less transparent, so it harder to see why it chooses this refinement strategy. As expected, the F1 scores for both models peak at the second iteration, the iteration number used in the training phase. The trend for the exact match score is consistent with the F1 score.

7.6.2 Duplicate Arguments

We measure the degree to which the role uniqueness constraint is violated by both models. We plot the number of violations as the function of the number of iterations (Figure 5). Recall that the violations do not imply errors in predictions as even the gold-standard data does not always satisfy the constraint (see the orange line in the figure). As expected, CapsuleNet without the global node captures competition and focuses on enforcing this constraint. Interestingly, it converges to keeping the same fraction of violations as the one observed in the gold standard data. In contrast, the full model increasingly ignores the constraint in later iterations. This is consistent with the over-generation trend evident from the precision and recall plots discussed above.

Figure 6 illustrates how many roles get changed between consecutive iterations of CapsuleNet, with and without the global node. Green indicates how many correct changes have been made, while red shows how many errors have been introduced. Since the number of changes is very large, we represent the non-zero number q in the

(a) Capsule Network w/o Global Node

Table 5: Labeled F1 score (including senses) for all languages on the CoNLL-2009 in-domain test sets. For previous best result, Japanese (Ja) is from Watanabe et al. (2010), Catalan (Ca) is from Zhao et al. (2009), Spanish (Es) and German (De) are from Roth and Lapata (2016), Czech (Cz) is from Henderson et al. (2013), Chinese (Zh) is from Cai et al. (2018) and English (En) is from Li et al. (2019b).

log space $\tilde{q} = \text{sign}(q)\log(|q|)$.

As we expected, for both models, the majority of changes are correct, leading to better overall performance. We can again see the same trends. CapsuleNet without the global node tends to filter our arguments by changing them to "None". The reverse is true for the full model.

7.7 Multilingual Results

Table 5 gives the results of the proposed CapsuleNet SRL (with global node) on the in-domain test sets of all languages from CoNLL-2009. As shown in Table 5, the proposed model consistently outperforms the non-refinement baseline model and achieves state-of-the-art performance on Catalan (Ca), Czech (Cz), English (En), Japanese (Jp) and Spanish (Es). Interestingly, the effectiveness of the refinement method does not seem to be dependent on the dataset size: the improvements on the smallest (Japanese) and the largest datasets (English) are among the largest.

8 Additional Related Work

The capsule networks have been recently applied to a number of NLP tasks (Xiao et al., 2018; Gong et al., 2018). In particular, Yang et al. (2018) represent text classification labels by a layer of capsules, and take the capsule actions as the classification probability. Using a similar method, Xia et al. (2018) perform intent detection with the capsule networks. Wang et al. (2018) and Li et al. (2019a) use capsule networks to capture rich features for machine translation. More closely to our work, Zhang et al. (2018) and Zhang et al. (2019) adopt the capsule networks for relation extraction. The previous models apply the capsule networks to problems that have a fixed number of components in the output. Their approach cannot be directly applied to our setting.

9 Conclusions & Future Work

State-of-the-art dependency SRL methods do not account for any interaction between role labeling decisions. We propose an iterative approach to

SRL. In each iteration, we refine both predictions of the semantic structure (i.e. a discrete structure) and also a distributed representation of the proposition (i.e. the predicate and its predicted arguments). The iterative refinement process lets the model capture interactions between the decisions. We relied on the capsule networks to operationalize this intuition. We demonstrate that our model is effective, and results in improvements over a strong factorized baseline and state-of-the-art results on standard benchmarks for 5 languages (Catalan, Czech, English, Japanese and Spanish) from CoNLL-2019. In future work, we would like to extend the approach to modeling interaction between multiple predicate-argument structures in a sentence as well as to other semantic formalisms (e.g., abstract meaning representations (Banarescu et al., 2013)).

Acknowledgments

We thank Diego Marcheggiani, Jonathan Mallinson and Philip Williams for constructive feedback and suggestions, as well as anonymous reviewers for their comments. Abstract

Programmers typically organize executable source code using high-level coding patterns or idiomatic structures such as nested loops, exception handlers and recursive blocks, rather than as individual code tokens. In contrast, state of the art (SOTA) semantic parsers still map natural language instructions to source code by building the code syntax tree one node at a time. In this paper, we introduce an iterative method to extract code idioms from large source code corpora by repeatedly collapsing most-frequent depth-2 subtrees of their syntax trees, and train semantic parsers to apply these idioms during decoding. Applying idiom-based decoding on a recent context-dependent semantic parsing task improves the SOTA by 2.2% BLEU score while reducing training time by more than 50%. This improved speed enables us to scale up the model by training on an extended training set that is 5× larger, to further move up the SOTA by an additional 2.3% BLEU and 0.9% exact match. Finally, idioms also significantly improve accuracy of semantic parsing to SQL on the ATIS-SQL dataset, when training data is limited.

1 Introduction

When programmers translate Natural Language (NL) specifications into executable source code, they typically start with a high-level plan of the major structures required, such as nested loops, conditionals, etc. and then proceed to fill in specific details into these components. We refer to these high-level structures (Figure 1 (b)) as code idioms (Allamanis and Sutton, 2014). In this paper, we demonstrate how learning to use code idioms leads to an improvement in model accuracy and training time for the task of semantic parsing, i.e., mapping intents in NL into general purpose source code (Iyer et al., 2017; Ling et al., 2016).

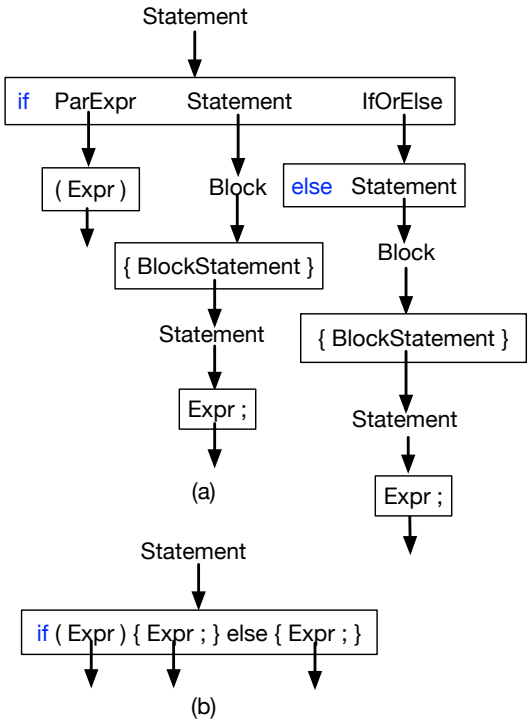

Figure 1: (a) Syntax tree based decoding for semantic parsing uses as many as 11 rules (steps) to produce the outer structure of a very frequently used `if-then-else` code snippet. (b) Direct application of an `if-then-else` idiom during decoding leads to improved accuracy and training time.

State-of-the-art semantic parsers are neural encoder-decoder models, where decoding is guided by the target programming language grammar (Yin and Neubig, 2017; Rabinovich et al., 2017; Iyer et al., 2018) to ensure syntactically valid programs. For general purpose programming languages with large formal grammars, this can easily lead to long decoding paths even for short snippets of code. For example, Figure 1 shows an intermediate parse tree for a generic `if-then-else` code snippet, for which the decoder requires as many as eleven decoding steps

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5426–5435, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

before ultimately filling in the slots for the `if` condition, the `then` expression and the `else` expression. However, the `if-then-else` block can be seen as a higher level structure such as shown in Figure 1 (b) that can be applied in one decoding step and reused in many different programs. In this paper, we refer to frequently recurring subtrees of programmatic parse trees as *code idioms*, and we equip semantic parsers with the ability to learn and directly generate idiomatic structures as in Figure 1 (b).

We introduce a simple iterative method to extract idioms from a dataset of programs by repeatedly collapsing the most frequent depth-2 subtrees of syntax parse trees. Analogous to the byte pair encoding (BPE) method (Gage, 1994; Sennrich et al., 2016) that creates new subtokens of words by repeatedly combining frequently occurring adjacent pairs of subtokens, our method takes a depth-2 syntax subtree and replaces it with a tree of depth-1 by removing all the internal nodes. This method is in contrast with the approach using probabilistic tree substitution grammars (pTSG) taken by Allamanis and Sutton (2014), who use the *explanation quality* of an idiom to prioritize idioms that are more interesting, with an end goal to suggest useful idioms to programmers using IDEs. Once idioms are extracted, we greedily apply them to semantic parsing training sets to provide supervision for learning to apply idioms.

We evaluate our approach on two semantic parsing tasks that map NL into 1) general-purpose source code, and 2) executable SQL queries, respectively. On the first task, i.e., context dependent semantic parsing (Iyer et al., 2018) using the CONCODE dataset, we improve the state of the art (SOTA) by 2.2% of BLEU score. Furthermore, generating source code using idioms results in a more than 50% reduction in the number of decoding steps, which cuts down training time to less than half, from 27 to 13 hours. Taking advantage of this reduced training time, we further push the SOTA on CONCODE to an EM of 13.4 and a BLEU score of 28.9 by training on an extended version of the training set (with 5× the number of training examples). On the second task, i.e., mapping NL utterances into SQL queries for a flight information database (ATIS-SQL; Iyer et al. (2017)), using idioms significantly improves denotational accuracy over SOTA models, when a limited amount of training data is used, and also marginally outperforms the SOTA when the full training set is used (more details in Section 7).

2 Related Work

Neural encoder-decoder models have proved effective in mapping NL to logical forms (Dong and Lapata, 2016) and also for directly producing general purpose programs (Iyer et al., 2017, 2018). Ling et al. (2016) use a sequence-to-sequence model with attention and a copy mechanism to generate source code. Instead of directly generating a sequence of code tokens, recent methods focus on constrained decoding mechanisms to generate syntactically correct output using a decoder that is either grammar-aware or has a dynamically determined modular structure paralleling the structure of the abstract syntax tree (AST) of the code (Rabinovich et al., 2017; Krishnamurthy et al., 2017; Yin and Neubig, 2017). Iyer et al. (2018) use a similar decoding approach but use a specialized context encoder for the task of context-dependent code generation. We augment these neural encoder-decoder models with the ability to decode in terms of frequently occurring higher level idiomatic structures to achieve gains in accuracy and training time.

Another different but related method to produce source code is using sketches, which are code snippets containing slots in the place of low-level information such as variable names, method arguments, and literals. Dong and Lapata (2018) generate such sketches using programming language-specific sketch creation rules and use them as intermediate representations to train token-based seq2seq models that convert NL to logical forms. Hayati et al. (2018) retrieve sketches from a large training corpus and modify them for the current input; Murali et al. (2018) use a combination of neural learning and type-guided combinatorial search to convert existing sketches into executable programs, whereas Nye et al. (2019) additionally also generate the sketches before synthesising programs. Our idiom-based decoder learns to produce commonly used subtrees of programming syntax-trees in one decoding step, where the non-terminal leaves function as slots that can be subsequently expanded in a grammer-aware fashion. Code idioms can be roughly viewed as a tree-structured generalization of sketches, that can be automatically extracted from large code corpora for any programming language, and unlike sketches, can

also be nested with other idioms or grammar rules.

More closely related to the idioms that we use for decoding is Allamanis and Sutton (2014), who develop a system (HAGGIS) to automatically mine idioms from large code bases. They focus on finding interesting and explainable idioms, e.g., those that can be included as preset code templates in programming IDEs. Instead, we learn frequently used idioms that can be easily associated with NL phrases in our dataset. The production of large subtrees in a single step directly translates to a large speedup in training and inference.

Concurrent with our research, Shin et al. (2019) also develop a system (PATOIS) for idiom-based semantic parsing and demonstrate its benefits on the Hearthstone (Ling et al., 2016) and Spider (Yu et al., 2018) datasets. While we extract idioms by collapsing frequently occurring depth-2 AST subtrees and apply them greedily during training, they use non-parametric Bayesian inference for idiom extraction and train neural models to either apply entire idioms or generate its full body.

3 Idiom Aware Encoder-Decoder Models

We aim to train semantic parsers having the ability to use idioms during code generation. To do this, we first extract frequently used idioms from the training set, and then provide them as supervision to the semantic parser's learning algorithm.

Formally, if a semantic parser decoder is guided by a grammar $\mathscr{G} = (N, \Sigma, R)$, where N and Σ are the sets of non-terminals and terminals respectively, and R is the set of production rules of the form $A \rightarrow \beta, A \in N, \beta \in \{N \cup \Sigma\}^*$, we would like to construct an idiom set I with rules of the form $B \rightarrow \gamma, B \in N, \gamma \in \{N \cup \Sigma\}^*$, such that $B \overset{\geq 2}{\Longrightarrow} \gamma$ under $\mathscr{G}$, i.e., γ can be derived in two or more steps from B under $\mathscr{G}$. For the example in Figure 1, R would contain rules for expanding each non-terminal, such as *Statement* $\rightarrow$ *if ParExpr Statement IfOrElse* and *ParExpr* $\rightarrow$ { *Expr* }, whereas I would contain the idiomatic rule *Statement* $\rightarrow$ *if (Expr) { Expr ; } else { Expr ; }* .

The decoder builds trees from $\hat{\mathscr{G}} = (N, \Sigma, R \cup I)$. Although the set of valid programs under both $\mathscr{G}$ and $\hat{\mathscr{G}}$ are exactly the same, this introduction of ambiguous rules into $\mathscr{G}$ in the form of idioms presents an opportunity to learn shorter derivations. In the next two sections, we describe the idiom extraction process, i.e., how I is chosen, and the idiom application process, i.e., how the decoder is trained to learn to apply idioms.

Procedure *Extract-Idioms($\mathscr{D}$, $\mathscr{G}$, n)*

  return Tree($root(s)$,frontier)
end

Algorithm 1: Idiom Extraction.

4 Idiom Extraction

Algorithm 1 describes the procedure to add idiomatic rules, I, to the regular production rules, R. Our goal is to populate the set I by identifying frequently occurring idioms (subtrees) from the programs in training set $\mathscr{D}$. Since enumerating all subtrees of every AST in the training set is infeasible, we observe that all subtrees s' of a frequently occurring subtree s are just as or more frequent than s, so we take a bottom-up approach by repeatedly collapsing the most frequent depth-2 subtrees. Intuitively, this can be viewed as a particular kind of generalization of the BPE (Gage, 1994; Sennrich et al., 2016) algorithm for sequences, where new subtokens are created by repeatedly combining frequently occurring adjacent pairs of subtokens. Note that subtrees of parse

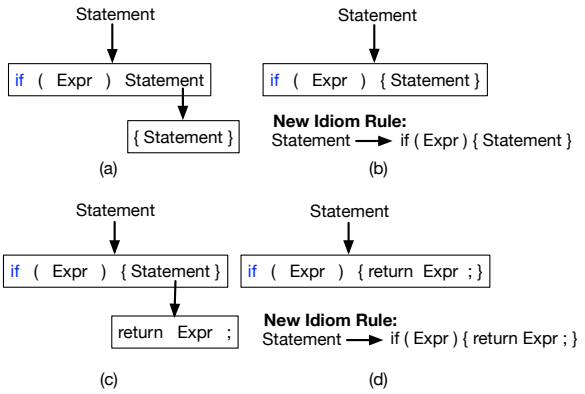

Figure 2: Two steps of the idiom extraction process described in Algorithm 1. (a) First, we find the most frequent depth-2 syntax subtree under Grammar $\mathscr{G}$ in dataset $\mathscr{D}$, collapse it to produce a new production rule (b), and replace all occurrences in the dataset with the collapsed version. Next, (c) is the most frequent depth-2 subtree which now happens to contain (b) within it. (c) is collapsed to form an idiom (d), which is effectively a depth-3 idiom.

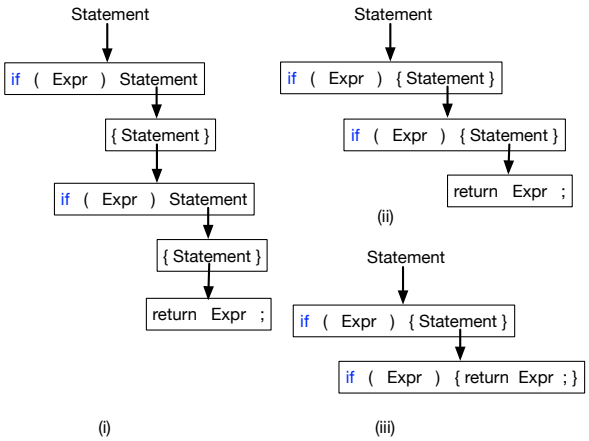

Figure 3: (i) Application of the two idioms extracted in Figure 2 on a new training example. (ii) We first perform two applications of the idiom in Figure 2b, (iii) followed by an application of the idiom in Figure 2d. The resulting tree can be represented with just 2 parsing rules instead of 5.

trees have an additional constraint, i.e., either all or none of the children of non-terminal nodes are included, since a grammar rule has to be used entirely or not at all.

We perform idiom extraction in an iterative fashion. We first populate T with all parse trees of programs in $\mathscr{D}$ using grammar $\mathscr{G}$ (Step 4). Each iteration then comprises retrieving the most frequent depth-2 subtree s from T (Step 8), followed by post-processing T to replace all occurrences of s in T with a collapsed (depth-1) version of s (Step 10 and 17). The collapse function (Step 20) simply takes a subtree, removes all its internal nodes and attaches its leaves directly to its root (Step 22). The collapsed version of s is a new idiomatic rule (a depth-1 subtree), which we add to our set of idioms, I (Step 12). We illustrate two iterations of this algorithm in Figure 2 ((a)-(b) and (c)-(d)). Assuming (a) is the most frequent depth-2 subtree in the dataset, it is transformed into the idiomatic rule in (b). Larger idiomatic trees are learned by combining several depth-2 subtrees as the algorithm progresses. This is shown in Figure 2 (c) which contains the idiom extracted in (b) within it owing to the post-processing of the dataset after idiom (b) is extracted (Step 10 of Algorithm 1) which effectively makes the idiom in (d), a depth-3 idiom. We perform idiom extraction for K iterations. In our experiments we vary the value of K based on the number of idioms we would like to extract.

5 Model Training with Idioms

Once a set of idioms I is obtained, we next train semantic parsing models to apply these idioms while decoding. We do this by supervising grammar rule generation in the decoder using a compressed set of rules for each example, using the idiom set I (see Algorithm 2). More concretely, we first obtain the parse tree t_i (or grammar rule set p_i) for each training program y_i under grammar $\mathscr{G}$ (Step 3) and then greedily collapse each depth-2 subtree in t_i corresponding to every idiom in I (Step 5). Once t_i cannot be further collapsed, we translate t_i into production rules r_i based on the collapsed tree, with $|r_i| \leq |p_i|$ (Step 7).

1 **Procedure** *Compress*($\mathscr{D}, \mathscr{G}, I$)
  Input: $\mathscr{D} \rightarrow$ Training Programs
  Input: $\mathscr{G} \rightarrow$ Parsing Grammar
  Input: $I \rightarrow$ Idiom set
2 **for** $d \in \mathscr{D}$ **do**
3 $t \leftarrow$ Parse-Tree$(d, \mathscr{G})$
4 **for** $i \in I$ **do**
5 $t \leftarrow$ Collapse-Subtree(t, i)
6 **end**
7 Train decoder using
  Production-Rules(t)
8 **end**
9 **end**

Algorithm 2: Training Example Compression.

This process is illustrated in Figure 3 where we

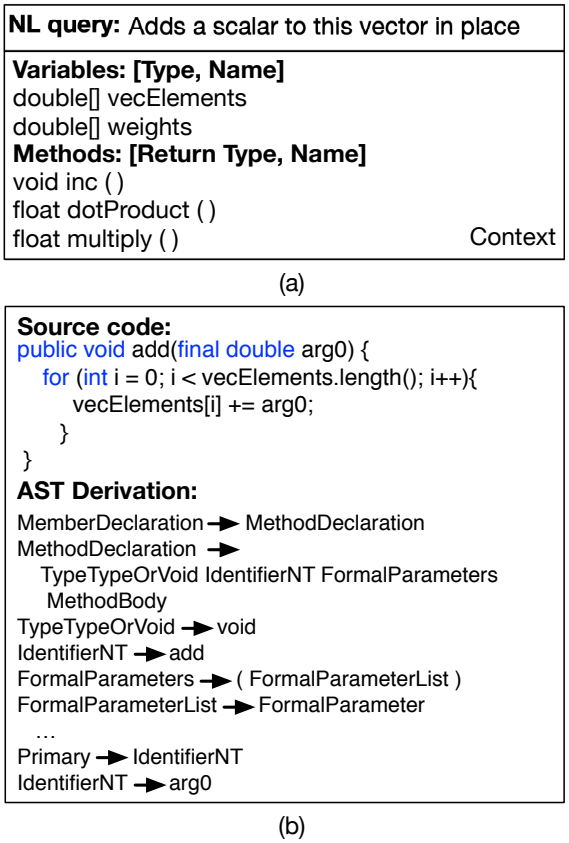

Figure 4: Context dependent code generation task of Iyer et al. (2018) that involves mapping an NL query together with a set of context variables and methods (each having an identifier name and data type) (a) into source code, represented as a sequence of grammar rules (b).

perform two applications of the first idiom from Figure 2 (b), followed by one application of the second idiom from Figure 2 (d), after which the tree cannot be further compressed using those two idioms. The final tree can be represented using $|r_i| = 2$ rules instead of the original $|p_i| = 5$ rules. The decoder is then trained similar to previous approaches (Yin and Neubig, 2017) using the compressed set of rules. We observe a rule set compression of more than 50% in our experiments (Section 7).

6 Experimental Setup

We apply our approach on 1) the context dependent encoder-decoder model of Iyer et al. (2018) on the CONCODE dataset, where we outperform an improved version of their best model, and 2) the task of mapping NL utterances to SQL queries on the ATIS-SQL dataset (Iyer et al., 2017) where an idiom-based model using the full training set outperforms the SOTA, also achieving significant

gains when using a reduced training set.

6.1 Context Dependent Semantic Parsing

The CONCODE task involves mapping an NL query together with a class context comprising a list of variables (with types) and methods (with return types), into the source code of a class member function. Figure 4 (a) shows an example where the context comprises variables and methods (with types) that would normally exist in a class that implements a vector, such as `vecElements` and `dotProduct()`. Conditioned on this context, the task involves mapping the NL query *Adds a scalar to this vector in place* into a sequence of parsing rules to generate the source code in Figure 4 (b).

Formally, the task is: Given a NL utterance q, a set of context variables $\{v_i\}$ with types $\{t_i\}$, and a set of context methods $\{m_i\}$ with return types $\{r_i\}$, predict a set of parsing rules $\{a_i\}$ of the target program. Their best performing model is a neural encoder-decoder with a context-aware encoder and a decoder that produces a sequence of Java grammar rules.

Baseline Model We follow the approach of Iyer et al. (2018) with three major modifications in their encoder, which yields improvements in both speed and accuracy (Iyer-Simp). First, in addition to camel-case splitting of identifier tokens, we use byte-pair encoding (BPE) (Sennrich et al., 2016) on all NL tokens, identifier names and types and embed all these BPE tokens using a single embedding matrix. Next, we replace their RNN that contextualizes the subtokens of identifiers and types with an average of the subtoken embeddings instead. Finally, we consolidate their three separate RNNs for contextualizing NL, variable names with types, and method names with types, into a single shared RNN, which greatly reduces the number of model parameters. Formally, let

$\{q_i\}$ represent the set of BPE tokens of the NL, and $\{t_{ij}\}$, $\{v_{ij}\}, \{r_{ij}\}$ and $\{m_{ij}\}$ represent the jth BPE token of the ith variable type, variable name, method return type, and method name respectively. First, all these elements are embedded using a BPE token embedding matrix B to give us $\mathbf{q_i}$, $\mathbf{t_{ij}}$, $\mathbf{v_{ij}}$, $\mathbf{r_{ij}}$ and $\mathbf{m_{ij}}$. Using Bi-LSTM f, the encoder then computes:

$$h_1, \cdots, h_z = f(\mathbf{q_1}, \ldots, \mathbf{q_z}) \quad (1)$$

$$\mathbf{v_i} = Avg(\mathbf{v_{i1}}, \ldots, \mathbf{v_{ij}}) \quad (2)$$

$$\text{Similarly, compute } \mathbf{m_i}, \mathbf{t_i}, \mathbf{r_i} \quad (3)$$

$$\hat{t_i}, \hat{v_i} = f(\mathbf{t_i}, \mathbf{v_i}) \quad (4)$$

$$\hat{r_i}, \hat{m_i} = f(\mathbf{r_i}, \mathbf{m_i}) \quad (5)$$

Then, $h_1, \ldots, h_z$, and $\hat{t_i}, \hat{v_i}, \hat{r_i}, \hat{m_i}$ are passed to the attention mechanism in the decoder, exactly as in Iyer et al. (2018). The decoder remains the same as described in Iyer et al. (2018), and produces a probability distribution over grammar rules at each time step (full details in Supplementary Materials). This forms our baseline model (Iyer-Simp).

Idiom Aware Training To utilize idioms, we augment this decoder by retrieving the top-K most frequent idioms from the training set (Algorithm 1), followed by post-processing the training set by greedily applying these idioms (Algorithm 2; we denote this model as Iyer-Simp-K). We evaluate all our models on the CONCODE dataset which was created using Java source files from `github.com`. It contains 100K tuples of (NL, code, context) for training, 2K tuples for development, and 2K tuples for testing. We use a BPE vocabulary of 10K tokens (for matrix B) and get the best validation set results using the original hyperparameters used by Iyer et al. (2018). Since idiom aware training is significantly faster than without idioms, it enables us to train on an additional 400K training examples that Iyer et al. (2018) released as part of CONCODE. We report exact match accuracy, corpus level BLEU score (which serves as a measure of partial credit) (Papineni et al., 2002), and training time for all these configurations.

6.2 Semantic Parsing to SQL

This task involves mapping NL utterances into executable SQL queries. We use the ATIS-SQL dataset (Iyer et al., 2017) that contains NL questions posed to a flight database, together with their SQL queries and a database with 25 tables to execute them against (Figure 5 shows an example). The dataset is split into 4,379 training, 491 validation, and 448 testing examples following Kwiatkowski et al. (2011).

The SOTA by Iyer et al. (2017) is a Seq2Seq model with attention and achieves a denotational accuracy of 82.5% on the test set. Since using our idiom-based approach requires a model that uses grammar-rule based decoding, we use a modified version of the Seq2Prod model described in Iyer et al. (2018) (based on Yin and Neubig (2017)) as a baseline model (Seq2Prod), and augment the decoder with SQL idioms (Seq2Prod-K).

Seq2Prod is an encoder-decoder model, where the encoder executes an n-layer bi-LSTM over NL embeddings and passes the final layer LSTM

Model	Exact	BLEU
Seq2Seq†	3.2 (2.9)	23.5 (21.0)
Seq2Prod†	6.7 (5.6)	21.3 (20.6)
Iyer et al. (2018)†	8.6 (7.1)	22.1 (21.3)
Iyer-Simp	12.5 (9.8)	24.4 (23.2)
Iyer-Simp + 200 idioms	12.2 (9.8)	**26.6 (24.0)**

Table 1: Exact Match and BLEU scores for our simplified model (Iyer-Simp) with and without idioms, compared with results from Iyer et al. (2018)† on the test (validation) set of CONCODE. Iyer-Simp achieves significantly better EM and BLEU score and reduces training time from 40 hours to 27 hours. Augmenting the decoding process with 200 code idioms further pushes up BLEU and reduces training time to 13 hours.

Model	Exact	BLEU	Training Time (h)
Seq2Seq†	2.9	21.0	12
Seq2Prod†	5.6	20.6	36
Iyer et al. (2018)†	7.1	21.3	40
Iyer-Simp	9.8	23.2	27
+ 100 idioms	9.8	24.5	15
+ 200 idioms	9.8	24.0	13
+ 300 idioms	9.6	23.8	12
+ 400 idioms	9.7	23.8	11
+ 600 idioms	9.9	22.7	11

Table 2: Variation in Exact Match, BLEU score, and training time on the validation set of CONCODE with number of idioms used. After top-200 idioms are used, accuracies start to reduce, since using more specialized idioms can hurt model generalization. Training time plateaus after considering top-600 idioms.

Model	Exact	BLEU
1× Train	12.0 (9.7)	26.3 (23.8)
2× Train	13.0 (10.3)	28.4 (25.2)
3× Train	13.3 (10.4)	28.6 (26.5)
5× Train	13.4 (11.0)	28.9 (26.6)

Table 3: Exact Match and BLEU scores on the test (validation) set of CONCODE by training Iyer-Simp-400 on the extended training set released by Iyer et al. (2018). Significant improvements in training speed after incorporating idioms makes training on large amounts of data possible.

hidden states to an attention mechanism in the decoder. Note that the Seq2Prod encoder described in Iyer et al. (2018) encodes a concatenated sequence of NL and context, but ATIS-SQL instances do not include contextual information. Thus, if q_i represents each lemmatized token of the NL, they are first embedded using a token embedding matrix B to give us $\mathbf{q_i}$. Using Bi-LSTM f, the encoder then computes:

$$h_1, \cdots, h_z = f(\mathbf{q_1}, \ldots, \mathbf{q_z}) \quad (6)$$

Then, $h_1, \ldots, h_z$ are passed to the attention mechanism in the decoder.

The sequential LSTM-decoder uses attention and produces a sequence of grammar rules $\{a_t\}$. The decoder hidden state at time t, s_t, is computed based on an embedding of the current non-terminal n_t to be expanded, an embedding of the previous production rule a_{t-1}, an embedding of the parent production rule, par(n_t), that produced n_t, the previous decoder state s_{t-1}, and the decoder state of the LSTM cell that produced n_t, denoted as s_{n_t}.

$$s_t = \text{LSTM}_f(n_t, a_{t-1}, \text{par}(n_t), s_{t-1}, s_{n_t}) \quad (7)$$

s_t is then used for attention and finally, produces a distribution over grammar rules.

We make two modifications in this decoder. First, we remove the dependence of LSTM$_f$ on the parent LSTM cell state s_{n_t}. Second, instead of using direct embeddings of rules a_{t-1} and par(n_t) in LSTM$_f$, we use another Bi-LSTM across the left and right sides of the rule (using separator symbol SEP) and use the final hidden state as inputs to LSTM$_f$ instead. More concretely, if a grammar rule is represented as $A \to B_1 \ldots B_n$, then:

$$\begin{aligned} &\text{Emb}(A \to B_1 \ldots B_n) = \\ &\qquad \text{LSTM}_g(\{A, \text{SEP}, B_1, \ldots, B_n\}) \\ &s_t = \text{LSTM}_f(n_t, \text{Emb}(a_{t-1}), \text{Emb}(\text{par}(n_t)), \\ &\qquad\qquad s_{t-1}) \end{aligned} \quad (8)$$

This modification can help the LSTM$_f$ cell locate the position of n_t within rules a_{t-1} and par(n_t), especially for lengthy idiomatic rules. We present a full description of this model with all hyperparameters in the supplementary materials.

Idiom Aware Training As before, we augment the set of decoder grammar rules with top-K idioms extracted from ATIS-SQL. To represent SQL queries as grammar rules, we use the python `sqlparse` package.

Model	Accuracy
Iyer et al. (2017)†	82.5
Seq2Prod	79.1
Seq2Prod + 400 idioms	**83.2**

Table 4: Denotational Accuracy for Seq2Prod with and without idioms, compared with results from Iyer et al. (2017)† on the test set of ATIS using SQL queries. Results averaged over 3 runs.

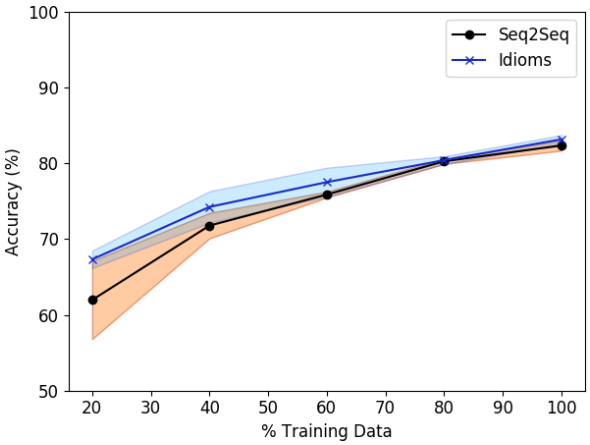

Figure 6: Accuracy of the Seq2Seq baseline (Iyer et al., 2017) compared with Seq2Prod-K, on the test set of ATIS-SQL for varying fractions of training data. Idioms significantly boost accuracy when training data is scarce. (Mean and Std. Dev. computed across 3 runs). 20-40% use 100 idioms and the rest use 400 idioms.

7 Results and Discussion

Table 1 presents exact match and BLEU scores on the original CONCODE train/validation/test split.

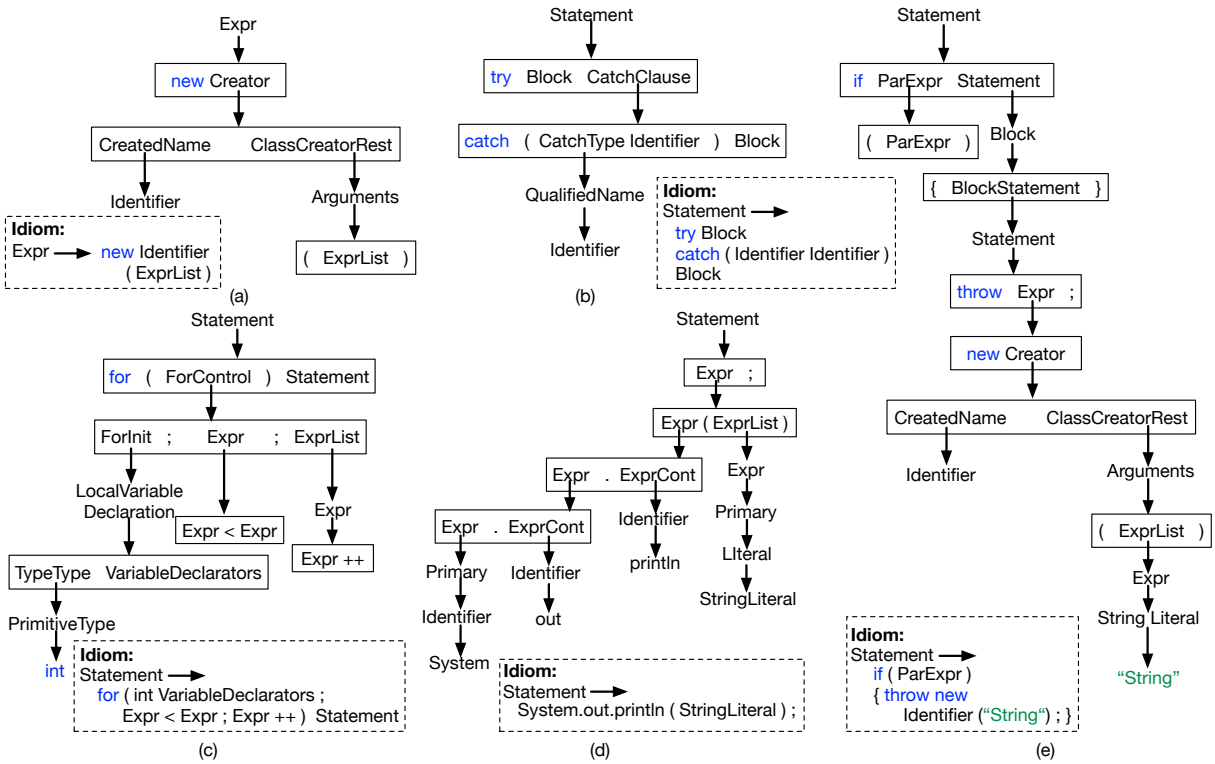

Figure 7: Examples of idioms learned from CONCODE. (a)-(c) represent idioms for instantiation of a new object, exception handling and integer-based looping respectively. (d) represents an idiom for applying a very commonly used library method (`System.out.println`). (e) is a combination of various idioms viz. an if-then idiom, an idiom for throwing exceptions and finally, reusing idiom (a) for creating new objects.

Iyer-Simp yields a large improvement of 3.9 EM and 2.2 BLEU over the best model of Iyer et al. (2018), while also being significantly faster (27 hours for 30 training epochs as compared to 40 hours). Using a reduced BPE vocabulary makes the model memory efficient, which allows us to use a larger batch size that in turn speeds up training. Furthermore, using 200 code idioms further improves BLEU by 2.2% while maintaining comparable EM accuracy. Using the top-200 idioms results in a target AST compression of more than 50%, which results in fewer decoder RNN steps being performed. This reduces training time further by more than 50%, from 27 hours to 13 hours.

In Table 2, we illustrate the variations in EM, BLEU and training time with the number of idioms. We find that 200 idioms performs best overall in terms of balancing accuracy and training time. Adding more idioms continues to reduce training time, but accuracy also suffers. Since we permit idioms to contain identifier names to capture frequently used library methods, having too many idioms hurts generalization, especially since the test set is built using repositories disjoint from the training set. Finally, the amount of compression, and therefore the training time, plateaus after the top-600 idioms are incorporated.

Compared to the model of Iyer et al. (2018), our significantly reduced training time enables us to train on their extended training set. We run Iyer-Simp using 400 idioms (taking advantage of even lower training time) on up to 5 times the amount of data, while making sure that we do not include in training any NL from the validation or the test sets. Since the original set of idioms learned from the original training set are quite general, we directly use them rather than relearn the idioms from scratch. We report EM and BLEU scores for different amounts of training data on the same validation and test sets as CONCODE in Table 3. In general, accuracies increase with the amount of data with the best model achieving a BLEU score of 28.9 and EM of 13.4.

Figure 7 shows example idioms extracted from CONCODE: (a) is an idiom to construct a new object with arguments, (b) represents a `try-catch` block, and, (c) is an integer-based `for` loop. In (e), we show how small idioms are combined to

form larger ones; it combines an `if-then` idiom with a `throw-exception` idiom, which throws an object instantiated using idiom (a). The decoder also learns idioms to directly generate common library methods such as `System.out.println( StringLiteral )` in one decoding step (d).

For the NL to SQL task, we report denotational accuracy in Table 4. We observe that Seq2Prod underperforms the Seq2Seq model of Iyer et al. (2017), most likely because a SQL query parse is much longer than the original query. This is remedied by using top-400 idioms, which compresses the decoded sequence size, marginally outperforming the SOTA (83.2%). Finegan-Dollak et al. (2018) observed that the SQL structures in ATIS-SQL are repeated numerous times in both train and test sets, thus facilitating Seq2seq models to memorize these structures without explicit idiom supervision. To test a scenario with limited repetition of structures, we compare Seq2Seq with Seq2Prod-K for limited training data (increments of 20%) and observe that (Figure 6) idioms are additionally helpful with lesser training data, consistent with our intuition.

8 Conclusions

We presented a general approach to make semantic parsers aware of target idiomatic structures, by first identifying frequently used idioms, followed by providing models with supervision to apply these idioms. We demonstrated this approach on the task of context dependent code generation where we achieved a new SOTA in EM accuracy and BLEU score. We also found that decoding using idioms significantly reduces training time and allows us to train on significantly larger datasets. Finally, our approach also outperformed the SOTA for a semantic parsing to SQL task on ATIS-SQL, with significant improvements under a limited training data regime.

Paul G. Allen School of Computer Science and Engineering, Univ. of Washington, Seattle, WA
{rajas, sviyer, lsz}@cs.washington.edu

Abstract

Interactive programming with interleaved code snippet cells and natural language markdown is recently gaining popularity in the form of Jupyter notebooks, which accelerate prototyping and collaboration. To study code generation conditioned on a long context history, we present JuICe, a corpus of 1.5 million examples with a curated test set of 3.7K instances based on online programming assignments. Compared with existing contextual code generation datasets, JuICe provides refined human-curated data, open-domain code, and an order of magnitude more training data. Using JuICe, we train models for two tasks: (1) generation of the API call sequence in a code cell, and (2) full code cell generation, both conditioned on the NL-Code history up to a particular code cell. Experiments using current baseline code generation models show that both context and distant supervision aid in generation, and that the dataset is challenging for current systems.

1 Introduction

Interactive computing (IC) is a software engidneering paradigm where programmers write source code scripts in an incremental fashion, one block at a time, taking decisions based on the output of execution of previously written blocks. An increasingly adopted platform for IC is the Jupyter notebook (Kluyver et al., 2016), which additionally encourages the use of markdown in natural language (NL) between code snippets as a means of documentation (Figure 1). Under the framework of IC, models that automatically generate future code blocks based on NL instructions, have the potential to provide significant assistance and speed up development. In this paper, we collect and release a new large-scale dataset based off of

Figure 1: This Python Jupyter notebook, comprising of interleaved NL markdown and code cells, loads data from a file and trains a decision tree classifier. We aim to generate the target code cell (blue) based on the previous NL markdown *Create and train the model* and the prior NL and code history. To the left of each cell, *d* represents its distance from the target cell.

Jupyter notebooks named JuICe (for Jupyter Interactive Computing). We also present experiments to demonstrate baseline performance for the task of incremental context-based code generation.

Figure 1 presents part of a Jupyter notebook for training a decision tree classifier using Python, which includes a title, followed by interleaved NL markdown and code cells. The markdown typically describes the goal of the code cells that follow and often is of high quality, since notebooks are frequently used for sharing and collaboration amongst teams. The first two code cells import packages and perform data loading, and following this, the user would typically inspect the data and proceed to train the model by first writing the markdown as *Create and train the model*. Our goal is to train models that assist the user at this particular stage i.e. to generate the API calls `DecisionTreeClassifier()` and `fit()` and the source code contained in the blue cell in Figure 1 (which trains a Decision tree clas-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5436–5446, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

sifier), based on the previous markdown, and NL and code context. The closest NL utterance alone does not specify that a Decision Tree model must be trained, or which variables should be used as train and test data. Automatically making these decisions conditioned on prior history is one of the main challenges of this task.

Existing tasks for mapping NL to source code primarily use a single NL utterance (Zettlemoyer and Collins, 2005; Iyer et al., 2017) to generate database queries (semantic parsing), single line python code (Yin et al., 2018; Oda et al., 2015), multi-line domain-specific code (Ling et al., 2016; Rabinovich et al., 2017), or sequences of API calls (Gu et al., 2016b). A recent task by Iyer et al. (2018) on the CONCODE dataset maps a single utterance to an entire method, conditioned on environment variables and methods. In contrast, we tackle the task of general purpose code generation in an interactive setting, using an entire sequence of prior NL and code blocks as context. More closely related to our task is the context dependent semantic parsing task on the ATIS dataset (Zettlemoyer and Collins, 2009; Suhr et al., 2018) for mapping NL to database queries based on a prior history of NL and query pairs. One main difference is that while future queries can be built by modifying queries in previous utterances, code snippets in our task are almost always disjoint from previously generated code.

We collect an open-domain large-scale dataset (JuICe) of over 659K publicly available Jupyter notebooks from `github.com` to train models for our task. Each notebook contains an average of 39 NL/code cells and uses python packages from thousands of domains. Since obtaining source-code with NL annotations is expensive, most large NL-code datasets rely on noisy automatically scraped data from source code forums or repositories online (Yin et al., 2018; Iyer et al., 2018). However, this also results in excessively noisy test sets and thus, a persistent challenge has been the creation of high quality code generation test sets. For our dataset, we capitalize on the availability of nbgrader (Hamrick, 2016) notebooks, which are high-quality Jupyter notebooks that are manually created by instructors as programming assignments for classes. These notebooks contain accurate and detailed sequences of NL and code blocks, with blank code-cells intended to be filled in by students and later evaluated. We collect and release 13,905 nbgrader notebooks to evaluate models for code generation tasks, which, together with the training set, forms the first dataset for general purpose code generation in an interactive setting.

We define two code generation related tasks using JuICe: (1) generating API sequences, and (2) full code generation. The first task is more relaxed and aims to assist users by generating a sequence of all function calls (Gu et al., 2016b) needed to achieve the goal of the cell. The second task measures the ability of models to learn to generate fully functioning complete code snippets. For both tasks, we investigate strong neural baselines and study performance improvements obtained by varying the size of prior NL and code context considered, as well as varying training data size. In summary, we introduce the task of code generation under the paradigm of IC. We collect and release a new large-scale dataset together with a manually curated test set based on nbgrader. Finally, we evaluate strong neural baselines on two code generation tasks, which achieve reasonable performance, with significant room for improvement.

2 Related Work

There is significant existing research on mapping single NL utterances directly to executable programs in the form of logical forms (Zettlemoyer and Collins, 2005), λ-DCS (Liang et al., 2013), regular expressions (Kushman and Barzilay, 2013; Locascio et al., 2016), database queries (Iyer et al., 2017; Zhong et al., 2017) and general purpose programs (Balog et al., 2016; Allamanis et al., 2015). Ling et al. (2016) generate Java and Python source code from NL for card games, conditioned on categorical card attributes. Iyer et al. (2018) generate Java class methods using a single NL instruction and conditioned on a list of class environment variables and methods. Yin et al. (2018) mine a large NL-code dataset from Stackoverflow to train models to map a NL programming question into a short example solution snippet. Gu et al. (2016c) use neural models to map Java documentation strings to a sequence of API calls. In this work, we introduce a new task of mapping NL to source code under an interactive programming paradigm i.e., conditioned on a sequence of past NL and code cells representing past exploratory interactions.

Models for mapping NL to code have been evaluated on datasets containing templated code for

Dataset	Context Based	Open Domain	Large Scale	Curated Dev/Test

Table 1: Comparison of JuICe with various recently released NL-code datasets along four dimensions. Most datasets that condition on historical natural language and code are small and domain specific, while large scale datasets only use human curated test sets for simple single line NL-code generation.

card games (Hearthstone & MTG; Ling et al., 2016), or manually labeled per-line comments (DJANGO; Oda et al., 2015). These datasets contain ∼20,000 programs with short textual descriptions possibly paired with categorical data and are highly domain specific with limited context. In this work, we collect the first large scale dataset containing over 1.5M source code cells paired with a sequence of NL and code cells that represents past exploratory interactions. Although various large scale datasets (Allamanis and Sutton, 2013, 2014; Allamanis et al., 2016; Iyer et al., 2018) to study code generation have been created from Github, their development and test set are randomly created from the same dataset since human curation is prohibitively expensive. Similarly, Yin et al. (2018) collect a large dataset from Stackoverflow.com (CoNaLa) for training, but only manage to curate a small portion (∼ 2,900 examples) of single line NL and code snippets for evaluation. We take advantage of nbgrader assignment notebooks to create an inexpensive high-quality human-curated test set of 3,725 NL statements with interactive history.

Neural encoder-decoder models have proved effective in mapping NL to logical forms and also for directly producing general purpose programs. Ling et al. (2016) use a sequence-to-sequence model with attention and a copy mechanism (Gu et al., 2016a) to generate source code. Recent methods focus on constrained decoding mechanisms to generate syntactically correct output using a decoder that is either grammar-aware or has a dynamically-determined modular structure paralleling the structure of the abstract syntax tree of the code (Dong and Lapata, 2016; Rabinovich et al., 2017; Krishnamurthy et al., 2017; Yin and Neubig, 2017; Iyer et al., 2018). Iyer et al. (2018) use a specialized context encoder that uses sub-word units (Sennrich et al., 2016) for representing code tokens and a grammar-aware decoder that attends to both NL and context to produce source code parses. Although syntax aware models are more accurate, they are significantly slower than Seq2Seq to train on large datasets. We present strong Seq2seq baselines with sub-word units for our task, that take interactive context into account and scale to large datasets.

	Train	Dev/Test
# Examples	1,518,049	1,744/1,981
Avg Context Cells	29.9	28.3
Avg NL Tokens	39.6	57.2
Avg Code Tokens	38.8	33.7
# Unique NL Token	851,127	11,142
# Unique Code Token	1,001,289	5,113

% Use methods above	6.4	8.2
% Contextual	48.2	61.9
% Multi-cell	19.7	29.0

Table 2: Statistics for the JuICe dataset. The dev/test sets are obtained from high-quality programming assignments. Expanded descriptions for the bottom four rows are: % Examples using variables defined above, % Examples using methods declared above, % Examples using a variable or method from above (i.e. contextual), % Examples where the variables/methods come from at least 2 different code cells. To accurately measure contextual reasoning, we only consider those variables/methods that are not mentioned in the NL above.

3 Dataset Collection

We aim to study code generation in an interactive setting, conditioned on prior history of NL and code cells. Jupyter notebooks are a popular platform for exploratory programming that encourage users to write code one cell at a time and to make programming decisions by executing

previous cells and examining the output. Since these notebooks are heavily used for sharing and collaboration, they are typically well documented with high quality NL. The intent of the NL (markdown) is typically to describe the functionality of the code cells that follow, as opposed to code comments, which primarily describe why code is written in a certain way. We collect a large scale training set to serve as distant supervision for our human-curated dev/test sets based on programming assignments and exercises.

3.1 Training Set Creation

To create JuICe we first collect all publicly available Jupyter notebooks from `github.com` created before May 2019 and filter for notebooks having NL markdown in English and Python 2/3 as their kernel type. We observe that the presence of NL markdown is correlated with notebook quality and remove any notebooks that have more than three times the number of code cells as the number of NL cells, leaving us with $\sim$ 659K notebooks.

Within these notebooks, each code cell is a potential training example, and we define the sequence of NL and code cells above it as its context. We only consider code cells that have NL markdown in the immediate previous cell (henceforth, target NL), as target cells. For our dataset, we include target cells that have syntactically valid Python and at most one method definition (for cells containing methods). Following Iyer et al. (2018), we canonicalize strings in the target cell and truncate them to a maximum of 120 code tokens. This amounts to over 4 million (target cell, context) examples that can be used for training, which we downsample to 1.5 million by ensuring that each target cell and context is unique. Table 2 presents dataset statistics for JuICe.

3.2 Human Curated Dev/Test Set

While existing large scale NL-code datasets have leveraged noisy online code repositories/forums to create training sets, obtaining a human curated test set has always been prohibitively expensive, and is typically done only for simple single line NL to code tasks. For our dataset, we take advantage of programming assignments written in Jupyter notebooks to build a high quality dev/test set. Specifically, we collect 1,510 code context examples from assignments created with nbgrader (Hamrick, 2016), and mine an additional 2,215 examples from in-class exercise notebooks.

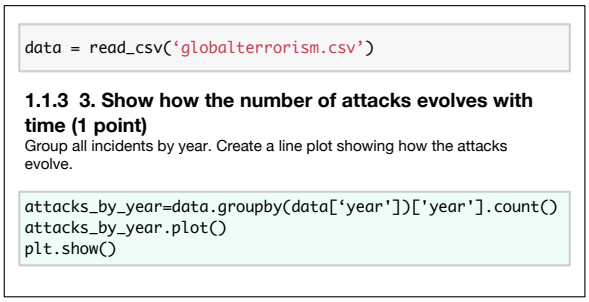

Figure 2: This example nbgrader problem prepared by an instructor prompts the student to fill in the blue colored cell with code to perform operations on previously loaded data. We leverage such notebooks with embedded solutions, posted on Github, to create a high quality dev and test set for JuICe.

Nbgrader Assignments Instructors use nbgrader to create and grade programming assignments within Jupyter notebooks. Figure 2 presents one such nbgrader assignment, where the student must wrangle some data that has been loaded earlier in the notebook to create a plot, and enter the solution in the cell in blue. Behind the scenes, nbgrader stores the following properties within each code cell's metadata: (1) the number of points its worth, (2) a unique code cell ID, (3) whether it's to be autograded or manually graded, (4) boilerplate code, (5) whether it is an instructor solution or a student submission. While students are expected to confidentially send their completed assignment to instructors, the solutions are often later posted on Github.

Taking advantage of this, we search Github for nbgrader notebooks with embedded metadata and collect 13,905 such notebooks, each containing multiple prompts and target code cells, with multiple student submissions for the same assignment. Based on the problem IDs and point values, we group together all student submissions that answer the same instructor prompt. Each prompt written by an instructor has an average of 8.9 different student submissions. If the metadata of any solution notebook indicates a successful execution on all the test cases without generating errors in the output, we select that as one of the correct submissions. If there are multiple correct submissions we select one at random, and wrong solutions are discarded. If the instructor provided boilerplate within the target cell, it is extracted and placed into the context above. Thus, each prompt is paired with one solution, which forms our target cell.

In-Class Exercises While instructors use

nbgrader for creating formal programming assignments, they often use vanilla Jupyter notebooks for creating informal in-class exercises. In this case, an instructor can release an exercise notebook intended for students to complete and a companion solution notebook to provide immediate feedback. The students are free to solve the exercise and upload the notebooks to their git repositories.

We use the following procedure to extract high quality solution target code cells from these notebooks. First, we collect notebooks containing the word *solution* in the title, and pair it with an exercise notebook from the same repository if over 50% of the cells are the same and *solution* is not in the exercise notebook's title. We find 170K such notebook pairs. If corresponding code cells in the two notebooks differ, then the exercise cell contains the student solution and the other, the instructor solution. We consider these cells as potential target cells, and to verify the instructor solution, we confirm that the same notebook and solution exist in at least 2 other Github repositories.

We find a total of 1,510 nbgrader assignment problems and 2,215 in-class exercise problems and split them randomly into the dev and test sets. We perform the same checks on the target cell as we do on the training set and additionally convert any solutions written in Python 2 to Python 3. Table 2 shows the dataset statistics. We release this, together with our training set, as the first large scale dataset to study code generation with prior NL and code history. Table 1 compares JuICe with various recently released code generation datasets on four different dimensions: interactive history, domain specificity, scale, and human annotation.

4 Data Statistics

Our quantitative and qualitative analysis of examples in JuICe show that the NL is diverse, the code broadly covers data science applications, and that context is important for generating the target cells.

NL Analysis Since assignment prompts tend to be more detailed in order to provide specific instructions for students, the average NL length in dev/test is ∼20 tokens longer than that in train (Table 2). Table 3 presents statistics of 50 target NL cells classified into overlapping categories. A high percentage (43%) of the NL is abstract language in the declarative or interrogative form, while 27% explicitly state which variables/functions to use, and 16% have a line-by-line correspondence between each line of language and code. For the latter two categories we believe that getting full exact match is possible since the procedure is clearly specified. The last three rows of Table 3 present interesting NL phenomenon. 11% refer to markdown far above in the same notebook, 9% show examples of the desired inputs and outputs of the code to clarify challenging language, and 7% use mathematical equations to formally specify the intended mathematical operations to be performed.

Code Analysis Table 4 presents statistics of 50 code cells sampled from the dev set. Majority of code cells are geared towards data science applications. The *Data Exploration* category covers scenarios for computing statistics or queries to gain new insights about the data, and the *Machine Learning* category covers training models, as well as tensor operations. 13% of code cells are used for plotting figures and the *Miscellaneous* category covers a broad range of utility functions.

Quality Evaluation We estimate the quality of our dataset using a sample of 50 examples from our train and dev splits. A good quality example is one in which there is enough signal to generate the full target code cell using the NL and the context. We find that 68% examples from train and 96% examples from dev are solvable. Most of the noise in the training set arises from the target NL referring to another code cell (for example, the cell above the NL). Other examples require sophisticated background knowledge e.g. the mathematical processes behind music composition.

Contextual Reasoning An analysis of 50 examples reveals the diverse types of contextual reasoning required to generate the target cell. Most examples require using variables or methods defined above (similar to statistics in Table 2). 39% require understanding the creation and usage of data structures in the context. For example, in row 2 of Table 5, knowing that `unemployment` stores the rates for every quarter in the array, suggests the use of the `diff` function which finds the difference between every consecutive value. In other cases, knowing the column names of tables is necessary and these are often specified as positional arguments while loading the data. Being able to condition on loaded table columns and values as in Krishnamurthy et al. (2017) using stored in-notebook variable outputs is an interesting area for future work. 25% examples require reusing idioms spe-

NL Type	%	Example
High-level Declarative	43	Analyze the Average prices(open, high, low, close) for all stocks in the Month of May
Variables/Functions	27	Convert all categorical variables in `bank_features` into indicator variables
Arguments Mentioned	20	Use unigrams, bigrams, trigrams ... english stopwords
Question	18	Which is the cheapest video game ?
Line-by-line	16	Create a histogram. Use default settings. Add the label...
Long References	11	3d) Transform reviews...using the tfidf vectorizer we created in part 2 . Save the transformed...
Input/Output	9	...Given strings a and b, return a single string with a and b separated by a space, except swap the first 2 chars of each string. e.g. (`mix, pod` → `pox mid` and (`dog, dinner` → `dig, donner`)
Equation	7	Solve the system $C_\epsilon \theta_\epsilon = b_\epsilon$ for θ_ϵ. Store the result in a variable, `theta_eps`.

Table 3: Qualitative analysis of NL from the dev set of JuICe. A large percentage of the NL is abstract and describes the code at a high level. Furthermore, instructors use a variety of additional modalities to elucidate the prompt, including input-output examples and equations.

Code Type	%
Data Exploration	25
Data Wrangling	23
Machine Learning	20
Miscellaneous	16
Visualization	13
Systems	3

Table 4: JuICe includes code for various real world applications, primarily for data science/machine learning.

cific to the notebook to tailor the code to the programmer's style or to leverage efficient primitives that the user has defined. For example, the implementation for `countEvenDigits` (row 3) can reuse the efficient list comprehension defined in a similar method above. Lastly, 23% of examples require multi-cell reasoning where the model must incorporate elements from at least 3 cells. In row 4 of Table 5, the `GridSearch` object created in one cell needs to be used to select the best hyperparameter values, and retrain the model using the same procedure found in another code cell.

Finally, using rule-based metrics, we find that 61% examples are contextual i.e. use a token from the context (from Table 2), whereas 86% examples required contextual reasoning that includes reasoning from data and idioms as well.

5 Problem formulation

We investigate two tasks for target cell generation in notebooks, conditioned on the context cells up to the target cell: (1) The Full code generation task, which involves generating the entire code snippet in the target cell. (2) The API sequence task, which involves generating only the sequence of constructor and method calls within the target cell, without having to generate variables and arguments. This task is more relaxed and can itself be very helpful to developers under an interactive setting. We do not aim to generate keyword functions such as *range* as these are very commonly used. Figure 1 presents an example for our code generation task, where our goal is to learn models that will map the NL *Create and train the model*, together with the context cells above, into either the the full code snippet (in blue) that reuses previously defined variables `X_train` and `y_train`, or the API sequence, *DecisionTreeClassifier fit*.

Formally, let $a^{(i)}$ denote the API sequence, and $s^{(i)}$ denote the code token sequence of the target cell in the ith training example. Further, if $c_d^{(i)}$ represents the context cell at a distance $d, d > 0$, above the target cell of example i, our tasks are to generate $a^{(i)}$ and $s^{(i)}$, conditioned on the context cells. Note that $c_d^{(i)}$ can be a sequence of NL words or code tokens. In models that we present in later sections, we limit d to a maximum of K cells.

6 Baselines

We train and evaluate a selection of neural (using fairseq: Ott et al. (2019)) and non-neural baselines that are known to perform well for code generation tasks, particularly on large scale datasets.

6.1 Retrieval

This baseline presents the programmer with an existing code cell from elsewhere in the training corpus as a possible prediction for the target code cell, located using only the NL markdown immediately before the target cell i.e. c_1. We evaluate two variants: (1) Ret-Train uses the code cell underneath the NL markdown cell from the entire training set,

Type	%	Example

Incorporates **Variables** or **Functions** declared or used above.	48	*d = 2* **NL:** Find all prices in the following test sentence.
		d = 1
		`test_string = """The iPhone X costs over $999, while the Android competitor comes in at around $550"""`
		Target
		`pattern = '\$\d+'`
		`re.findall(pattern, test_string)`

Requires understanding the properties of the **data** and its underlying structure to perform logic.	39	*d = 6* **NL:** Each number in the array `unemployment` is the unemployment rate at the start of one quarter (a 3-month period) of a year. *d = 1* **NL:** **Question 3.** What was the biggest increase in the unemployment rate from one quarter to the next? *Target* `biggest_increase = max(np.diff(unemployment))`

Incorporates coding patterns or **idioms** specific to the notebooks.	25	*d = 3*
		`def sumDigits(number):`
		`  listn = [int(i) for i in str(number)]`
		`  ...`
		d = 1 **NL:** Complete the function to output the sum of even number digits of the input number.
		Target
		`def countEvenDigits(number):`
		`  listn = [int(i) for i in str(number)]`
		`  count = 0`
		`  for i in listn:`
		`  if i%2 == 0:`
		`  ...`

Multi-cell reasoning involves reasoning over at least 3 context cells.	23	*d = 4*
		`def cv_optimize_ridge(X, y, n_folds=4):`
		`  est = Ridge()`
		`  parameters = {"alpha": [1e-8, 1e-6, 1e-4, 1e-3, 1e-2, 1e-1, 1.0]}`
		`  gs = GridSearchCV(est, param_grid=parameters, cv=n_folds)`
		`  gs.fit(X, y)`
		`  return gs`
		d = 3
		`fitmodel = cv_optimize_ridge(Xtrain, ytrain, n_folds=4)`
		d = 1 **NL:** Assign to variable est the classifier obtained by fitting the entire training set using the best alpha found above.
		Target
		`alphawechoose = fitmodel.best_params_['alpha']`
		`est = Ridge(alpha=alphawechoose).fit(Xtrain,ytrain)`

Table 5: Types of contextual reasoning required for target cell generation. Overall, 86% of examples require contextual reasoning.

that is most similar to c_1, (2) Ret-Context uses the code cell underneath the most similar NL cell amongst all c_d (context above). The similarity between two NL cells is computed by representing both NL sequences as vectors using tf-idf representations for their dimensions and measuring the cosine distance between these vectors. We convert the retrieved code cell to an API sequence for the API sequence task.

6.2 LSTM with Attention

This baseline is a neural encoder-decoder model where the encoder computes contextualized representations of input sequence embeddings using an n-layer BiLSTM, and an LSTM-based decoder produces a sequence of code (API) tokens, while attending to the encoder representations at every time step t. We make use of the general global attention mechanism by Luong et al. (2015). To use this model for our task, we concatenate all K context cells, $c_{1...K}$, using the type of each cell as separator symbols i.e. `CODE` or `MARKDOWN`. The output sequence is supervised to be either an API sequence or a sequence of code tokens.

6.3 Transformer

This baseline utilizes the Transformer (Vaswani et al., 2017) architecture where the encoder and decoder consist of multiple layers of multi-headed self-attention and position-wise feed forward layers. The inputs and outputs are the same as the LSTM model described above.

7 Experiments

We run code generation experiments to evaluate our baselines on JuICe and to study the effects of

Models	K	N	Dev Full Code Bleu	Dev Full Code EM	Test Full Code Bleu	Test Full Code EM
Ret-Train	-	100,000	5.52	0.82	4.76	0.48
Ret-Context	$\|c\|$	-	3.42	0.12	3.24	0.00
Transformer	1	100,000	3.57	0.00	3.21	0.00
Transformer	3	100,000	10.90	0.27	11.08	0.38
LSTM	1	100,000	7.35	0.05	7.92	0.14
LSTM	3	100,000	15.88	1.42	17.03	1.33
LSTM	**3**	**1,518,049**	**21.66**	**5.57**	**20.92**	**5.71**

Table 6: Exact Match and BLEU score for the full code generation task on both the dev and test sets of JuICe for all baselines. All models benefit with additional code context ($K = 3$), which permits conditioning on variables and methods defined previously. Training on additional data further pushes up performance.

Models	K	N	Dev API Precision	Dev API Recall	Test API Precision	Test API Recall
LSTM	1	100,000	34.15	29.19	30.38	26.98
LSTM	3	100,000	37.09	31.48	37.44	33.23
LSTM	**3**	**1,518,049**	**51.34**	**44.83**	**52.60**	**46.46**

Table 7: Precision and Recall for the API sequence task on the dev/test sets of JuICe for all baselines

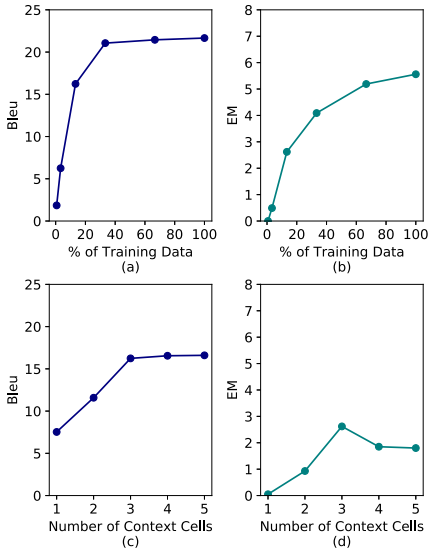

Figure 3: (a) and (b) show the effects of training data on LSTM(3-ctx) performance. Feeding the model more JuICe consistently improves EM accuracy. (c) and (d) show the effects of context cells on performance of LSTM trained with 200K examples. Performance improves for up to 3 cells, after which reasoning over long contexts becomes challenging for current methods.

context size K and dataset size N.

To study the effect of context, we consider two configurations for our neural approaches, $K = 1$ which consists of only the NL markdown above the target cell, and $K = 3$. For both cases, we truncate the contents of each context cell to 75 tokens, except for the target NL cell, which remains as is. We consider $K = |c|$ for the retrieval baseline as it is allowed to access all context cells above. We train these configurations for the Seq2Seq models on a subset of 100K examples from the training set, and use the best settings to train on the full training set.

7.1 Hyperparameters

For Seq2Seq models, we use an embedding size of 1024 for the input and output tokens. We consolidate the NL and code vocabularies and apply BPE with 10,000 merges. Both encoder and decoder LSTMs use 2 layers with a hidden size of 1024. We use dropout $p = 0.5$ in between LSTM layers and over the decoder output. The model is trained for 40 epochs using gradient based methods using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001, and we use beam search based decoding with a beam size of 5 during inference. The Transformer model uses 6 layers and 4 attention heads. The dimension of the model is 512 and the dimension of the feed forward network is 1024. We use a learning rate of 0.0005 with 2,000 warmup steps, train for 200 epochs, and pick the model at the epoch with highest validation performance.

7.2 Metrics

Similar to prior code generation tasks, we use Exact Match (EM) accuracy and corpus-level BLEU score (Papineni et al., 2002) as performance metrics for full code generation. While EM is a strict metric measuring the ability of models to generate fully functioning code, BLEU serves as a measure of partial credit for models that can provide users with a partially correct snippet.

For the API sequence task, we find BLEU and EM inadequately measure performance since the average API sequence length for our target code is 3.8. We therefore treat the predicted API calls as a set of values and compute precision/recall metrics against the gold set of API calls.

8 Results and Discussion

We present EM and BLEU scores for the code generation task in Table 6, and precision/recall for the API sequence task in Table 7, on both the dev

and test sets of JuICe for all our baselines.

All LSTM models outperform both retrieval baselines by more than 2% BLEU score. We find that increasing the amount of training data and the context length helps all models for both tasks. Our best model was trained on 1.5 million examples with a context length of 3 (Table 6). The improvement with context is most likely owing to the interactive nature of the notebook, where variables (methods) defined in previous code cells are operated upon (called) in future cells. However, note that the retrieval model which is given access to the full context performs significantly worse, suggesting that the code above is different than the target code and the model needs to reason over which pieces of it to incorporate.

Figure 3 illustrates the effects of varying training data size and context length on our LSTM model. We find that increasing the amount of training data helps significantly up to 200K examples, after which, performance begins to plateau. Furthermore, the model improves with more context up to 3 cells and then struggles to incorporate additional cells as the average input sequence length exceeds 156 tokens.

Using student notebook solutions for a subset of the test set, we estimate a human performance of 60% BLEU and 23% EM (can be much higher with identifier canonicalization) for the code generation task, and 84% precision and 85% recall for the API sequence task.

8.1 Error Analysis

We conduct a qualitative error analysis using 50 erroneous predictions of our top performing model - **LSTM K=3, N=1,518,049** on dev set examples (Table 8). We find that for 39% of cases, the model misunderstands the core intent of the NL and generates totally incorrect code. In 17% cases, it misses some positional arguments in the code. For example, *Use unigrams, bigrams, and trigrams. Use English stop words* should result in a Vectorizer object with arguments: `stop_words="english", ngram_range=(1,3)`. 26% of cases represent an inadequate understanding of the context and 10% require more cells than the 3 presented to the model. Retrieving relevant context cells far above the target is an interesting area for future work. 26% cases are partially correct i.e. they contain some correct code lines but miss some details. For example, for the NL *Create a histogram of all people's ages. Use the default settings. Add the label Age on the x-axis and Count on the y-axis*, the model generates the code for plotting the histogram but misses labeling the axes. For 15% of cases the model generates semantically equivalent code but is different at the surface level. In the future, executing the code to compare outputs or verifying that the nbgrader tests pass would alleviate this issue but requires the model to generate valid strings (currently strings are canonicalized).

Error Category	%
Challenging NL Reasoning	39
Arguments Missed	17
Contextual Reasoning	26
Needs Longer Context	10
Partially Correct	26
Semantically Equivalent	15

Table 8: Qualitative error analysis on 50 incorrectly generated code cells from our dev set for our best performing baseline. The first category represents cases where the model output was totally incorrect. Over 30% of errors require deeper contextual reasoning.

9 Conclusion

In this paper, we introduced the task of code generation under the paradigm of interactive computing, conditioned on a context of interleaved code snippet cells and NL markdown. To train models for this task, we collected a new large scale open-domain dataset (JuICe) from publicly available Jupyter notebooks, consisting of target code cells paired with sequences of NL and code context. Furthermore, we gathered a high quality evaluation set using nbgrader and in-class programming assignment notebooks with solutions to reliably test code generation models. We evaluated a variety of baseline models for two context dependent code generation tasks, API sequence generation and full code generation. Experiments showed that performance improves on using an increased amount of code context and training data, with significant room for improvement.

Abstract

As a promising paradigm, *interactive semantic parsing* has shown to improve both semantic parsing accuracy and user confidence in the results. In this paper, we propose a new, unified formulation of the interactive semantic parsing problem, where the goal is to design a *model-based* intelligent agent. The agent maintains its own state as the current predicted semantic parse, decides whether and where human intervention is needed, and generates a clarification question in natural language. A key part of the agent is a world model: it takes a percept (either an initial question or subsequent feedback from the user) and transitions to a new state. We then propose a simple yet remarkably effective instantiation of our framework, demonstrated on two text-to-SQL datasets (WikiSQL and Spider) with different state-of-the-art base semantic parsers. Compared to an existing interactive semantic parsing approach that treats the base parser as a black box, our approach solicits less user feedback but yields higher run-time accuracy.[1]

1 Introduction

Natural language interfaces that allow users to query data and invoke services without programming have been identified as a key application of semantic parsing (Berant et al., 2013; Thomason et al., 2015; Dong and Lapata, 2016; Zhong et al., 2017; Campagna et al., 2017; Su et al., 2017). However, existing semantic parsing technologies often fall short when deployed in practice, facing several challenges: (1) user utterances can be inherently ambiguous or vague, making it difficult to get the correct result in one shot, (2) the accuracy of state-of-the-art semantic parsers are still not high enough for real use, and (3) it is hard for users to validate the semantic parsing results, especially with mainstream neural network models that are known for the lack of interpretability.

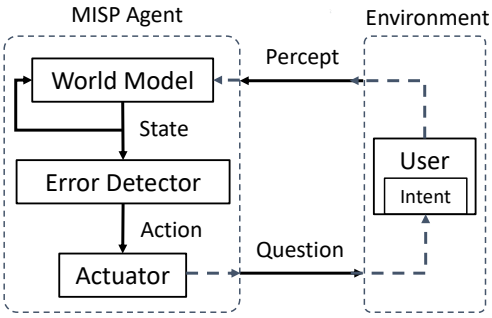

Figure 1: Model-based Interactive Semantic Parsing (MISP) framework.

In response to these challenges, *interactive semantic parsing* has been proposed recently as a practical solution, which includes human users in the loop to resolve utterance ambiguity, boost system accuracy, and improve user confidence via human-machine collaboration (Li and Jagadish, 2014; He et al., 2016; Chaurasia and Mooney, 2017; Su et al., 2018; Gur et al., 2018; Yao et al., 2019). For example, Gur et al. (2018) built the DialSQL system to detect errors in a generated SQL query and request user selection on alternative options via dialogues. Similarly, Chaurasia and Mooney (2017) and Yao et al. (2019) enabled semantic parsers to ask users clarification questions while generating an If-Then program. Su et al. (2018) showed that users overwhelmingly preferred an interactive system over the non-interactive counterpart for natural language interfaces to web APIs. While these recent studies successfully demonstrated the value of interactive semantic parsing in practice, they are often bound to a certain type of formal language or dataset, and the designs are thus ad-hoc and not easily generalizable. For example, DialSQL only applies

*Work started while at AI2

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5447–5458, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

to SQL queries on the WikiSQL dataset (Zhong et al., 2017), and it is non-trivial to extend it to other formal languages (e.g., λ-calculus) or even just to more complex SQL queries beyond the templates used to construct the dataset.

Aiming to develop a general principle for building interactive semantic parsing systems, in this work we propose model-based interactive semantic parsing (MISP), where the goal is to design a *model-based intelligent agent* (Russell and Norvig, 2009) that can interact with users to complete a semantic parsing task. Taking an utterance (e.g., a natural language question) as input, the agent forms the semantic parse (e.g., a SQL query) in steps, potentially soliciting user feedback in some steps to correct parsing errors. As illustrated in Figure 1, a MISP agent maintains its *state* as the current semantic parse and, via an *error detector*, decides whether and where human intervention is needed (the *action*). This action is performed by a *question generator* (the *actuator*), which generates and presents to the user a human-understandable question. A core component of the agent is a *world model* (Ha and Schmidhuber, 2018) (hence *model-based*), which incorporates user feedback from the environment and transitions to a new agent state (e.g., an updated semantic parse). This process repeats until a terminal state is reached. Such a design endows a MISP agent with three crucial properties of interactive semantic parsing: (1) being *introspective* of the reasoning process and knowing when it may need human supervision, (2) being able to *solicit user feedback* in a human-friendly way, and (3) being able to *incorporate user feedback* (through state transitions controlled by the world model).

The MISP framework provides several advantages for designing an interactive semantic parser compared to the existing ad-hoc studies. For instance, the whole problem is conceptually reduced to building three key components (i.e., the world model, the error detector, and the actuator), and can be handled and improved separately. While each component may need to be tailored to the specific task, the general framework remains unchanged. In addition, the formulation of a model-based intelligent agent can facilitate the application of other machine learning techniques like reinforcement learning.

To better demonstrate the advantages of the MISP framework, we propose a simple yet remarkably effective instantiation for the text-to-SQL task. We show the effectiveness of the framework based on three base semantic parsers (SQLNet, SQLova and SyntaxSQLNet) and two datasets (WikiSQL and Spider). We empirically verified that with a small amount of targeted, test-time user feedback, interactive semantic parsers improve the accuracy by 10% to 15% absolute. Compared to an existing interactive semantic parsing system, DialSQL (Gur et al., 2018), our approach, despite its much simpler yet more general system design, achieves better parsing accuracy by asking only half as many questions.

2 Background & Related Work

Semantic Parsing. Mapping natural language utterances to their formal semantic representations, semantic parsing has a wide range of applications, including question answering (Berant et al., 2013; Dong and Lapata, 2016; Finegan-Dollak et al., 2018), robot navigation (Artzi and Zettlemoyer, 2013; Thomason et al., 2015) and Web API calling (Quirk et al., 2015; Su et al., 2018). The target application in this work is text-to-SQL, which has been popularized by the WikiSQL dataset (Zhong et al., 2017). One of the top-performing models on WikiSQL is SQLNet (Xu et al., 2017), which leverages the pre-defined SQL grammar sketches on WikiSQL and solves the SQL generation problem via "slot filling." By augmenting SQLNet with a table-aware BERT encoder (Devlin et al., 2019) and by revising the value prediction in `WHERE` clauses, SQLova (Hwang et al., 2019) advances further the state of the art. Contrast to WikiSQL, the recently released Spider dataset (Yu et al., 2018c) focuses on complex SQL queries containing multiple keywords (e.g., `GROUP BY`) and may join multiple tables. To handle such complexity, Yu et al. (2018b) proposed SyntaxSQLNet, a syntax tree network with modular decoders, which generates a SQL query by recursively calling a module following the SQL syntax. However, because of the more realistic and challenging setting in Spider, it only achieves 20% in accuracy.

We experiment our MISP framework with the aforementioned three semantic parsers on both WikiSQL and Spider. The design of MISP allows naturally integrating them as the base parser. For example, when SQLNet fills a sequence of slots to produce a SQL query, a "state" in MISP corresponds to a partially generated SQL query and it

transitions as SQLNet fills the next slot.

Interactive Semantic Parsing. To enhance parsing accuracy and user confidence in practical applications, interactive semantic parsing has emerged as a promising solution (Li and Jagadish, 2014; He et al., 2016; Chaurasia and Mooney, 2017; Su et al., 2018; Gur et al., 2018; Yao et al., 2019). Despite their effectiveness, existing solutions are somewhat ad-hoc and bound to a specific formal language and dataset. For example, DialSQL (Gur et al., 2018) is curated for WikiSQL, where SQL queries all follow the same and given grammar sketch. Similarly, (Yao et al., 2019) relies on a pre-defined two-level hierarchy among components in an If-Then program and cannot generalize to formal languages with a deeper structure. In contrast, MISP aims for a general design principle by explicitly identifying and decoupling important components, such as error detector, question generator and world model. It also attempts to integrate and leverage a strong base semantic parser, and transforms it to a natural interactive semantic parsing system, which substantially reduces the engineering cost.

3 Model-based Interactive Semantic Parsing

We now discuss the MISP framework (Figure 1) in more detail. Specifically, we highlight the function of each major building block and the relationships among them, and leave the description of a concrete embodiment to Section 4.

Environment. The *environment* consists of a user with a certain intent, which corresponds to a semantic parse that the user expects the agent to produce. Based on this intent, the user gives an initial natural language utterance u_0 to start a semantic parsing *session* and responds to any clarification question from the agent with feedback u_t at interaction turn t.

Agent State. The *agent state* s is an agent's internal interpretation of the environment based on all the available information. A straightforward design of the agent state is as the currently predicted semantic parse. It can also be endowed with meta information of the parsing process such as prediction probability or uncertainty to facilitate error detection.

World Model. A key component of a MISP agent is its *world model* (Ha and Schmidhuber, 2018), which compresses the historical percepts throughout the interaction and predicts the future based on the agent's knowledge of the world. More specifically, it models the transition of the agent state, $p(s_{t+1}|s_t, u_t)$, where u_t is the user feedback at step t and s_{t+1} is the new state. The transition can be deterministic or stochastic.

Error Detector. A MISP agent introspects its state and decides whether and where human intervention is needed. The *error detector* serves this role. Given the current state s_t (optionally the entire interaction history) and a set of *terminal states*, it decides on an *action* a_t: If the agent is at a terminal state, it terminates the session, executes the semantic parse, and returns the execution results to the user; otherwise, it determines a span in the current semantic parse that is likely erroneous and passes it, along with necessary context information needed to make sense of the error span, to the actuator.

Actuator. An *actuator* has a user-facing interface and realizes an agent's actions in a user-friendly way. In practice, it can be a natural language generator (NLG) (He et al., 2016; Gur et al., 2018; Yao et al., 2019) or an intuitive graphical user interface (Su et al., 2018; Berant et al., 2019), or the two combined.

4 MISP-SQL: An Instantiation of MISP for Text-to-SQL

Under the MISP framework, we design an interactive semantic parsing system (Figure 2), named MISP-SQL, for the task of text-to-SQL translation. MISP-SQL assumes a base text-to-SQL parser and leverages it to design the world model and the error detector. The world model is essentially a wrapper that takes the user input and changes the behavior of the base semantic parser (e.g., by changing the probability distribution or removing certain prediction paths). The error detector makes decisions based on the *uncertainty* of the predictions: if the parser is uncertain about a prediction, it is more likely to be an error. The actuator is a template-based natural language question generator developed for the general SQL language. Figure 2 shows an example of the MISP-SQL agent.

4.1 Agent State

For ease of discussion, we assume the base parser generates the SQL query by predicting a sequence

of SQL components,[2] as in many state-of-the-art systems (Xu et al., 2017; Wang et al., 2018; Yu et al., 2018a; Hwang et al., 2019). Agent state s_t is thus defined as a *partial* SQL query, i.e., s_t=$\{o_1, o_2, ..., o_t\}$, where o_t is the predicted SQL component at time step t, such as `SELECT place` in Figure 2. What constitutes a SQL component is often defined differently in different semantic parsers, but typically dictated by the SQL syntax. To support introspection and error detection, each prediction is associated with its uncertainty, which is discussed next.

4.2 Error Detector

The error detector in MISP-SQL is introspective and greedy. It is introspective because it examines the uncertainty of the predictions as opposed to the predictions themselves. On the other hand, it is greedy because its decisions are solely based on the last prediction o_t instead of the entire state s_t.

We experiment with two uncertainty measures, based on the probability of o_t estimated by the base semantic parser, as well as its standard deviation under Bayesian dropout (Gal and Ghahramani, 2016), respectively.

Probability-based Uncertainty. Intuitively if the base semantic parser gives a low probability to the top prediction at a step, it is likely uncertain about the prediction. Specifically, we say a prediction o_t needs user clarification if its probability is lower than a threshold p^*, i.e.,

$$p(o_t) < p^*.$$

This strategy is shown to be strong in detecting misclassified and out-of-distribution examples (Hendrycks and Gimpel, 2017).

Dropout-based Uncertainty. Dropout (Srivastava et al., 2014) has been used as a Bayesian approximation for estimating model uncertainty (Gal and Ghahramani, 2016) in several tasks (Dong et al., 2018; Siddhant and Lipton, 2018; Xiao and Wang, 2019). Different from its standard application to prevent models from overfitting in training time, we use it at test time to measure model uncertainty, similar to (Dong et al., 2018). The intuition is that if the probability on a prediction varies dramatically (as measured by the standard deviation) across different perturbations under dropout, the model is likely uncertain about it. Specifically, the uncertainty on prediction o_t is calculated as:

$$\text{STDDEV}\{p(o_t|W_i)\}_{i=1}^{N},$$

where W_i is the parameters of the base semantic parser under the i-th dropout perturbation, and the uncertainty score is the standard deviation of the prediction probabilities over N random passes. We say o_t needs user clarification if its uncertainty score is greater than a threshold s^*.

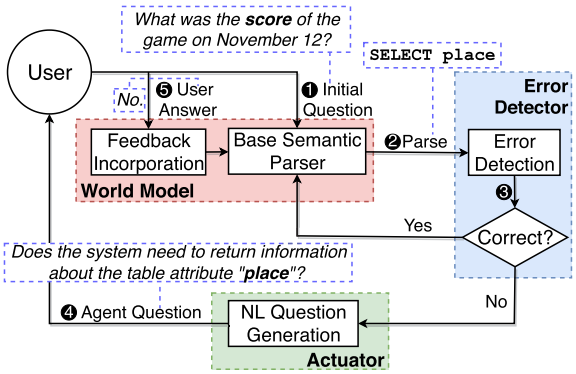

Figure 2: MISP-SQL Agent. The base semantic parser incrementally parses the user question (Step 1) into a SQL query by first selecting a column from the table (Step 2). This partial parse is examined by the error detector (Step 3), who determines that the prediction is incorrect (because the uncertainty is high) and triggers the actuator to ask the user a clarification question (Step 4). The user feedback is then incorporated into the world model (Step 5) to update the agent state. If the prediction was correct, Step 2 would be repeated to continue the parsing.

Terminal State. The only terminal state is when the base semantic parser indicates end of parsing.

4.3 Actuator: An NL Generator

The MISP-SQL agent performs its action (e.g., validating the column "*place*") via asking users *binary* questions, hence the actuator is a natural language generator (NLG). Although there has been work on describing a SQL query with an NL statement (Koutrika et al., 2010; Ngonga Ngomo et al., 2013; Iyer et al., 2016; Xu et al., 2018), few work studies generating *questions* about a certain SQL component in a systematic way.

Inspired by (Koutrika et al., 2010; Wang et al., 2015), we define a rule-based NLG, which consists of a seed lexicon and a grammar for deriving questions. Table 1 shows rules covering

[2] In practice this assumption may not be necessary as long as there is a reasonable way to chunk the semantic parse to calculate uncertainty and formulate clarification questions.

[Lexicon]
is greater than|equals to|is less than → OP[>|=|<]
sum of values in|average value in|number of|minimum value in|maximum value in → AGG[sum|avg|count|min|max]
[Grammar]
"*col*" → COL[*col*]
Does the system need to return information about COL[*col*] ? → Q[*col*‖SELECT *agg*? *col*]
Does the system need to return AGG[*agg*] COL[*col*] ? → Q[*agg*‖SELECT *agg col*]
Does the system need to return a value after any mathematical calculations on COL[*col*] ? → Q[*agg*=None‖SELECT *col*]
Does the system need to consider any conditions about COL[*col*] ? → Q[*col*‖WHERE *col op val*]
The system considers the following condition: COL[*col*] OP[*op*] a value. Is this condition correct? → Q[*op*‖WHERE *col op val*]
The system considers the following condition: COL[*col*] OP[*op*] *val*. Is this condition correct? → Q[*val*‖WHERE *col op val*]

Table 1: Domain-general lexicon and grammar for NL generation in MISP-SQL (illustrated for WikiSQL; a more comprehensive grammar for Spider can be found in Appendix A).

SQL queries on WikiSQL (Zhong et al., 2017). The seed lexicon defines NL descriptions for basic SQL elements in the form of "$n \rightarrow t[p]$", where n is an NL phrase, t is a pre-defined syntactic category and p is either an aggregator (e.g., `avg`) or an operator (e.g., $>$). For example, "is greater than $\rightarrow$ OP[$>$]" specifies a phrase "is greater than" to describe the operator "$>$". In MISP-SQL, we consider four syntactic categories: AGG for aggregators, OP for operators, COL for columns and Q for generated questions. However, it can be extended with more lexicon entries and grammar rules to accommodate more complex SQL in Spider (Yu et al., 2018c), which we show in Appendix A.

The grammar defines rules to derive questions. Each column is described by itself (i.e., the column name). Rules associated with each Q-typed item "Q[v‖`Clause`]" constructs an NL question asking about v in `Clause`. The `Clause` is the necessary context to formulate meaningful questions. Figure 3 shows a derivation example. Note that, both the lexicon and the grammar in our system are domain-agnostic in the sense that it is not specific to any database. Therefore, it can be reused for new domains in the future. Database-specific rules, such as naming each column with a more canonical phrase (rather than the column name), are also possible.

4.4 World Model

The agent incorporates user feedback and updates its state with a world model. Different from DialSQL which trains an additional neural network, the MISP-SQL agent directly employs the base semantic parser to transition states, which saves additional training efforts.

As introduced in Section 4.3, the agent raises a binary question to the user about a predicted SQL component o_t. Therefore, the received user feedback either confirms the prediction or negates it. In the former case, the state is updated by proceeding to the next decoding step, i.e., s_{t+1}={o_1, ..., o_t, o_{t+1}}, where o_{t+1} is the predicted next component and s_{t+1} shows the updated partial parse. In the latter case, the user feedback is incorporated to constrain the search space of the base parser (i.e., forbidding the parser from making the same wrong prediction), based on which the parser refreshes its prediction and forms a new state s_{t+1}={o_1, ..., o_{t-1}, o_{t+1}}, where o_{t+1} is a predicted alternative to replace o_t. To avoid being trapped in a large search space, for each SQL component, we consider a maximum number of K alternatives (in addition to the original prediction) to solicit user feedback on.

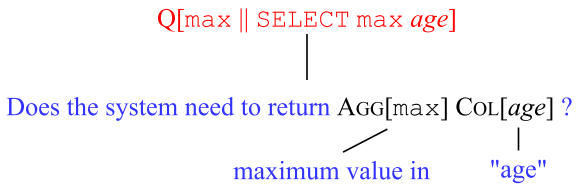

Figure 3: Deriving an NL question about the aggregator `max` in the clause "`SELECT max`(age)" from the rooted Q-typed item .

5 Experiments

We apply our approach to the task of mapping natural language questions to SQL queries. In this section, we first describe the basic setup, including the datasets and the base semantic parsers, followed by the system results on both simulated and real users.

5.1 Experimental Setup

We evaluate our proposed MISP-SQL agent on WikiSQL (Zhong et al., 2017), which contains 80,654 hand-annotated pairs of ⟨NL question,

System	SQLNet Acc_{qm}	SQLNet Acc_{ex}	SQLNet Avg. #q	SQLova Acc_{qm}	SQLova Acc_{ex}	SQLova Avg. #q
no interaction	0.615	0.681	N/A	0.797	0.853	N/A
DialSQL	0.690	N/A	2.4	N/A	N/A	N/A
MISP-SQL$^{\text{Unlimit10}}$	0.932	0.948	7.445	0.985	0.991	6.591
MISP-SQL$^{\text{Unlimit3}}$	0.870	0.900	7.052	0.955	0.974	6.515
MISP-SQL$^{p^*=0.95}$	0.782	0.824	1.713	0.912	0.939	0.773
MISP-SQL$^{p^*=0.8}$	0.729	0.779	1.104	0.880	0.914	0.488

Table 2: Simulation evaluation of MISP-SQL (based on SQLNet or SQLova) on WikiSQL Test set. "MISP-SQL$^{p^*=\text{X}}$" denotes our agent with probability-based error detection (threshold at X). "MISP-SQL$^{\text{UnlimitK}}$" denotes a variant that asks questions for every component, with up to $K+1$ questions per component.

SQL query⟩, distributed across 24,241 tables from Wikipedia. Our experiments follow the same data split as in (Zhong et al., 2017).

We experiment MISP-SQL with two base semantic parsers: SQLNet (Xu et al., 2017) and SQLova (Hwang et al., 2019). Unlike in DialSQL's evaluation (Gur et al., 2018), we do not choose Seq2SQL (Zhong et al., 2017) as a base parser but SQLova instead, because it achieves similar performance as SQLNet while SQLova is currently the best open-sourced model on WikiSQL, which can give us a more comprehensive evaluation. For each of the two base semantic parsers, we test our agent with two kinds of error detectors, based on prediction probability and Bayesian dropout, respectively (Section 4.2). We tune the threshold p^* within $0.5 \sim 0.95$ and s^* within $0.01 \sim 0.2$. Particularly for uncertainty-based detection measured by Bayesian dropout, the number of passes N is set to 10, with a dropout rate 0.1. The dropout layers are applied at the same positions as when each semantic parser is trained. When the agent interacts with users, the maximum number of alternative options (in addition to the original prediction) per component, K, is set to 3. If the user negates all the $K+1$ predicted candidates, the agent will keep the original prediction, as in (Gur et al., 2018).

5.2 Simulation Evaluation

In simulation evaluation, each agent interacts with a *simulated* user, who gives a yes/no answer based on the ground-truth SQL query. If the agent fails to correct its predictions in three consecutive interaction turns, the user will leave the interaction early and the agent has to finish the remaining generation without further help from the user.

Overall Comparison. We first compare MISP-SQL with the two base semantic parsers without interactions in Table 2. For SQLNet, we also compare our system with the reported performance of DialSQL (Gur et al., 2018, Table 4). However, since DialSQL is not open-sourced and it is not easy to reproduce it, we are unable to adapt it to SQLova for more comparisons. Following (Xu et al., 2017; Hwang et al., 2019), we evaluate the SQL query match accuracy ("**Acc_{qm}**", after converting the query into its canonical form) and the execution accuracy ("**Acc_{ex}**") of each agent. "**Avg. #q**" denotes the average number of questions per query. For any base parser, MISP-SQL improves their performance by interacting with users. Particularly for SQLNet, MISP-SQL outperforms the DialSQL system with only *half* the number of questions (1.104 vs. 2.4), and has a much simpler design without the need of training an extra model (besides training the base parser, which DialSQL needs to do as well). Our agent can even boost the strong performance of SQLova from 85% to 94% in execution accuracy, with merely 0.773 questions per query.

We also present an "upper-bounded" accuracy of our agent, when it does not adopt any error detector and asks questions about *every* component with at most 10 ("MISP-SQL$^{\text{Unlimit10}}$") or 3 ("MISP-SQL$^{\text{Unlimit3}}$") alternatives. Interestingly, even for the weaker SQLNet parser, most true predictions have already been contained within the top 10 options (giving 0.932 query match accuracy). When equipped with the stronger SQLova parser, the agent has a potential to boost the execution accuracy to around 100% by considering only the top 3 options of every prediction. The complete results can be found in Appendix B.

Error Detector Comparison. We then compare the probability-based and dropout-based error detectors in Figure 4, where each marker indicates

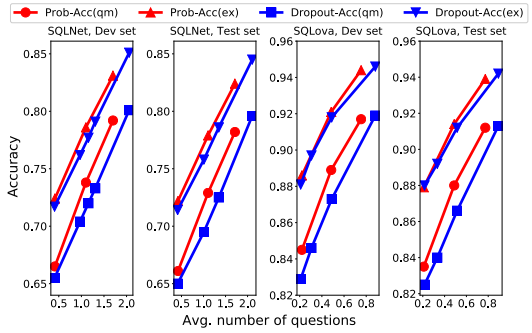

Figure 4: Comparison of probability- and dropout-based error detection.

the agent's accuracy and the average number of questions it needs under a certain error detection threshold. Consistently for both SQLNet and SQLova, the probability-based error detector can achieve the same accuracy with a lower number of questions than the dropout-based detector. It is also observed that this difference is greater in terms of query match accuracy, around 0.15 $\sim$ 0.25 for SQLNet and 0.1 $\sim$ 0.15 for SQLova. A more direct comparison of various settings under the same average number of questions can be found in Appendix C.

To better understand how each kind of error detectors works, we investigate the portion of questions that each detector spends on *right* predictions (denoted as "$\mathbf{Q_r}$"). An ideal system should ask fewer questions on right predictions while identify more truly incorrect predictions to fix the mistakes. We present the question distributions of the various systems in Table 3. One important conclusion drawn from this table is that probability-based error detection is much more effective on identifying incorrect predictions. Consider the system using probability threshold 0.5 for error detection (i.e., "p^*=0.5") and the one using dropout-based error detector with a threshold 0.2 (i.e., "s^*=0.2") on SQLNet. When both systems ask around the same number of questions during the interaction, the former spends only 16.9% of unnecessary questions on correct predictions (Q_r), while the latter asks twice amount of them (32.1%). Similar situations are also observed for SQLova. It is also notable that, when the probability threshold is lower (which results in a fewer total number of questions), the portion of questions on right actions drops significantly (e.g., from 23.0% to 16.9% when the threshold changes from 0.8 to 0.5 on SQLNet). However, this portion remains almost unchanged for dropout-based error detection.

SQLNet			SQLova		
System	**Avg. #q**	**Q_r%**	**System**	**Avg. #q**	**Q_r%**
p^*=0.8	1.099	23.0%	p^*=0.8	0.484	28.9%
p^*=0.5	0.412	16.9%	p^*=0.5	0.220	18.4%
s^*=0.07	1.156	34.5%	s^*=0.03	0.489	50.4%
s^*=0.2	0.406	32.1%	s^*=0.05	0.306	52.5%

Table 3: Portion of interaction questions on right predictions (Q_r%) for each agent setting on WikiSQL Dev set (smaller is better). "p^*/s^*=X" denotes our agent with probability/dropout-based error detection (threshold at X).

5.3 Extend to Complex SQL Generation

A remarkable characteristic of MISP-SQL is its generalizability, as it makes the best use of the base semantic parser and requires no extra model training. To verify it, we further experiment MISP-SQL on the more complex text-to-SQL dataset "Spider" (Yu et al., 2018c). The dataset consists of 10,181 questions on multi-domain databases, where SQL queries can contain complex keywords such as `GROUP BY` or join several tables. We extend the NLG lexicon and grammar (Section 4.3) to accommodate this complexity, with details shown in Appendix A.

We adopt SyntaxSQLNet (Yu et al., 2018b) as the base parser.[3] In our experiments, we follow the same database split as in (Yu et al., 2018c) and report the Exact Matching accuracy ("$\mathbf{Acc_{em}}$") on Dev set.[4] Other experimental setups remain the same as when evaluating MISP-SQL on WikiSQL. Table 4 shows the results.

We first observe that, via interactions with simulated users, MISP-SQL improves SyntaxSQLNet by 10% accuracy with reasonably 3 questions per query. However, we also realize that, unlike on WikiSQL, in this setting, the probability-based error detector requires more questions than the Bayesian uncertainty-based detector. This can be explained by the inferior performance of the base SyntaxSQLNet parser (merely 20% accuracy without interaction). In fact, the portion of questions that the probability-based detector spends on right predictions (Q_r) is still half of that the dropout-based detector asks (12.8% vs. 24.8%). However, it wastes around 60% of questions on unsolvable wrong predictions. This typically hap-

[3]We chose SyntaxSQLNet because it was the best model by the paper submission time. In principle, our framework can also be applied to more sophisticated parsers such as (Bogin et al., 2019; Guo et al., 2019).

[4]We do not report results on Spider test set since it is not publicly available.

System	Acc_{em}	Avg. #q
no interaction	0.190	N/A
MISP-SQL$^{\text{Unlimit10}}$	0.522	14.878
MISP-SQL$^{\text{Unlimit3}}$	0.382	11.055
MISP-SQL$^{p^*=0.95}$	0.300	3.908
MISP-SQL$^{p^*=0.8}$	0.268	3.056
MISP-SQL$^{s^*=0.01}$	0.315	3.815
MISP-SQL$^{s^*=0.03}$	0.290	2.905

Table 4: Simulation evaluation of MISP-SQL (built on SyntaxSQLNet) on Spider Dev set.

pens when the base parser is not strong enough, i.e., cannot rank the true option close to the top, or when there are unsolved wrong precedent predictions (e.g., in "`WHERE` *col op val*", when *col* is wrong, whatever *op*/*val* following it is wrong). This issue can be alleviated when more advanced base parsers are adopted in the future.

5.4 Human Evaluation

We further conduct human user study to evaluate the MISP-SQL agent. Our evaluation setting largely follows Gur et al. (2018). For each base semantic parser, we randomly sample 100 examples from the corresponding dataset (either WikiSQL Test set or Spider Dev set) and ask three human evaluators, who are graduate students with only rudimentary knowledge of SQL based on our survey, to work on each example and then report the averaged results. We present to the evaluators the initial natural language question and allow them to view the table headers to better understand the question intent. On Spider, we also show the name of the database tables. We select error detectors based on the simulation results: For SQLNet and SQLova, we equip the agent with a probability-based error detector (threshold at 0.95); for SyntaxSQLNet, we choose a Bayesian uncertainty-based error detector (threshold at 0.03). As in the simulation evaluation, we cannot directly compare with DialSQL in human evaluation because the code is not yet publicly available.

Table 5 shows the results. In all settings, MISP-SQL improves the base parser's performance, demonstrating the benefit of involving human interaction. However, we also notice that the gain is not as large as in simulation, especially on SQLova. Through interviews with the human evaluators, we found that the major reason is that they sometimes had difficulties understanding the true intent of some test questions that are ambiguous, vague, or contain entities they are not familiar with. We believe this reflects a general challenge of setting up human evaluation for semantic parsing that is close to the real application setting, and thus set forth the following discussion.

System	$Acc_{qm/em}$	Acc_{ex}	Avg. #q
SQLNet			
no interaction	0.580	0.660	N/A
MISP-SQL (simulation)	0.770	0.810	1.800
MISP-SQL (real user)	0.633	0.717	1.510
SQLova			
no interaction	0.830	0.890	N/A
MISP-SQL (simulation)	0.920	0.950	0.550
MISP-SQL (real user)	0.837	0.880	0.533
+ w/ full info.	0.907	0.937	0.547
SyntaxSQLNet			
no interaction	0.180	N/A	N/A
MISP-SQL (simulation)	0.290	N/A	2.730
MISP-SQL (real user)	0.230	N/A	2.647

Table 5: Human evaluation on 100 random examples for MISP-SQL agents based on SQLNet, SQLova and SyntaxSQLNet, respectively.

5.5 Discussion on Future Human Evaluation

Most human evaluation studies for (interactive) semantic parsers so far (Chaurasia and Mooney, 2017; Gur et al., 2018; Su et al., 2018; Yao et al., 2019) use pre-existing test questions (e.g., from datasets like WikiSQL). However, this introduces an undesired discrepancy, that is, human evaluators may not necessarily be able to understand the true intent of the given questions in an faithful way, especially when the question is ambiguous, vague, or containing unfamiliar entities.

This discrepancy is clearly manifested in our human evaluation with SQLova (Table 5). When the base parser is strong, many of the remaining incorrectly parsed questions are challenging not only for the base parser but also for human evaluators. We manually examined the situations where evaluators made a different choice than the simulator and found that 80% of such choices happened when the initial question is ambiguous or the gold SQL annotation is wrong. For example, for the question "*name the city for kanjiža*" it is unlikely for human evaluators to know that "kanjiža" is an "Urban Settlement" without looking at the table content or knowing the specific background knowledge beforehand. This issue has also been reported as the main limitation to further improve SQLova (Hwang et al., 2019), which

could in principle be resolved by human interactions if the users have a clear and consistent intent in mind. To verify this, we conduct an additional experiment with SQLova where human evaluators can view the table content as well as the gold SQL query before starting the interaction to better understand the true intent (denoted as "w/ full info" in Table 5). As expected, the MISP-SQL agent performs much better (close to simulation) when users know what they are asking. It further confirms that a non-negligible part of the accuracy gap between simulation and human evaluation is due to human evaluators not fully understanding the question intent and giving false feedback.

To alleviate this discrepancy, a common practice is to show human evaluators the schema of the underlying database, as Gur et al. (2018) and we did (Section 5.4), but it is still insufficient, especially for entity-related issues (e.g., "kanjiža"). On the other hand, while exposing human evaluators to table content helps resolve the entity-related issues, it is likely to introduce undesired biases in favor of the system under test (i.e., "overexposure"), since human evaluators may then be able to give more informative feedback than real users.

To further reduce the discrepancy between human evaluation and real use cases, one possible solution is to ask human evaluators to come up with questions from scratch (instead of using pre-existing test questions), which guarantees intent understanding. While this solution may still require exposure of table content to evaluators (such that they can have some sense of each table attribute), overexposure can be mitigated by showing them only part (e.g., just a few rows) of the table content, similar to the annotation strategy by Zhong et al. (2017). Furthermore, the reduced controllability on the complexity of the evaluator-composed questions can be compensated by conducting human evaluation in a larger scale. We plan to explore this setting in future work.

6 Conclusion and Future Work

This work proposes a new and unified framework for the interactive semantic parsing task, named MISP, and instantiates it successfully on the text-to-SQL task. We outline several future directions to further improve MISP-SQL and develop MISP systems for other semantic parsing tasks:

Improving Agent Components. The flexibility of MISP allows improving on each agent component separately. Take the error detector for example. One can augment the probability-based error detector in MISP-SQL with probability calibration, which has been shown useful in aligning model confidence with its reliability (Guo et al., 2017). One can also use learning-based approaches, such as a reinforced decision policy (Yao et al., 2019), to increase the rate of identifying wrong and solvable predictions.

Lifelong Learning for Semantic Parsing. Learning from user feedback is a promising solution for lifelong semantic parser improvement (Iyer et al., 2017; Padmakumar et al., 2017; Labutov et al., 2018). However, this may lead to a non-stationary environment (e.g., changing state transition) from the perspective of the agent, making its training (e.g., error detector learning) unstable. In the context of dialog systems, Padmakumar et al. (2017) suggests that this effect can be mitigated by jointly updating the dialog policy and the semantic parser batchwisely. We leave exploring this aspect in our task to future work.

Scaling Up. It is important for MISP agents to scale to larger backend data sources (e.g., knowledge bases like Freebase or Wikidata). To this end, one can improve MISP from at least three aspects: (1) using more intelligent interaction designs (e.g., free-form text as user feedback) to speed up the hypothesis space searching globally, (2) strengthening the world model to nail down a smaller set of plausible hypotheses based on both the initial question and user feedback, and (3) training the agent to learn to improve the parsing accuracy while minimizing the number of required human interventions over time.

Abstract

Recent studies on AMR-to-text generation often formalize the task as a sequence-to-sequence (seq2seq) learning problem by converting an Abstract Meaning Representation (AMR) graph into a word sequence. Graph structures are further modeled into the seq2seq framework in order to utilize the structural information in the AMR graphs. However, previous approaches only consider the relations between directly connected concepts while ignoring the rich structure in AMR graphs. In this paper we eliminate such a strong limitation and propose a novel structure-aware self-attention approach to better modeling the relations between indirectly connected concepts in the state-of-the-art seq2seq model, i.e., the *Transformer*. In particular, a few different methods are explored to learn structural representations between two concepts. Experimental results on English AMR benchmark datasets show that our approach significantly outperforms the state of the art with 29.66 and 31.82 BLEU scores on LDC2015E86 and LDC2017T10, respectively. To the best of our knowledge, these are the best results achieved so far by supervised models on the benchmarks.

1 Introduction

AMR-to-text generation is a task of automatically generating a natural language sentence from an Abstract Meaning Representation (AMR) graph. Due to the importance of AMR as a widely adopted semantic formalism in representing the meaning of a sentence (Banarescu et al., 2013), AMR has become popular in semantic representation and AMR-to-text generation has been drawing more and more attention in the last decade. As the example in Figure 1(a) shows, nodes, such as *he* and *convict-01*, represent semantic concepts and edges, such as ":ARG1" and ":quant", refer to semantic relations between the concepts. Since two concepts close in an AMR graph may map into two segments that are distant in the corresponding sentence, AMR-to-text generation is challenging. For example in Figure 1, the neighboring concepts *he* and *convict-01* correspond to the words *he* and *convicted* which locate at the different ends of the sentence.

To address the above mentioned challenge, recent studies on AMR-to-text generation regard the task as a sequence-to-sequence (seq2seq) learning problem by properly linearizing an AMR graph into a sequence (Konstas et al., 2017). Such an input representation, however, is apt to lose useful structural information due to the removal of reentrant structures for linearization. To better model graph structures, previous studies propose various graph-based seq2seq models to incorporate graphs as an additional input representation (Song et al., 2018; Beck et al., 2018; Damonte and Cohen, 2019). Although such graph-to-sequence models can achieve the state-of-the-art results, they focus on modeling one-hop relations only. That is, they only model concept pairs connected directly by an edge (Song et al., 2018; Beck et al., 2018), and as a result, ignore explicit structural information of indirectly connected concepts in AMR graphs, e.g. the relation between concepts *he* and *possible* in Figure 1.

To make better use of structural information in an AMR graph, we attempt to model arbitrary concept pairs no matter whether directly connected or not. To this end, we extend the encoder in the state-of-the-art seq2seq model, i.e., the Transformer (Vaswani et al., 2017) and propose structure-aware self-attention encoding approach. In particular, several distinct methods are proposed to learn structure representations for the new self-attention mechanism.

Empirical studies on two English benchmarks show that our approach significantly advances the state of the art for AMR-to-text generation, with the performance improvement of 4.16 BLEU score on LDC2015E86 and 4.39 BLEU score on LDC2017T10 respectively over the strong baseline. Overall, this paper makes the following contributions.

- To the best of our knowledge, this is the first work that applies the Transformer to the task of AMR-to-text generation. On the basis of the Transformer, we build a strong baseline that reaches the state of the art.
- We propose a new self-attention mechanism to incorporate richer structural information in AMR graphs. Experimental results on two benchmarks demonstrate the effectiveness of the proposed approach.
- Benefiting from the strong baseline and the structure-aware self-attention mechanism, we greatly advance the state of the art in the task.

2 AMR-to-Text Generation with Graph Structure Modeling

We start by describing the implementation of our baseline system, a state-of-the-art seq2seq model which is originally used for neural machine translation and syntactic parsing (Vaswani et al., 2017). Then we detail the proposed approach to incorporating structural information from AMR graphs.

2.1 Transformer-based Baseline

Transformer: Our baseline system builds on the Transformer which employs an encoder-decoder framework, consisting of stacked encoder and decoder layers. Each encoder layer has two sublayers: self-attention layer followed by a position-wise feed forward layer. Self-attention layer employs multiple attention heads and the results from each attention head are concatenated and transformed to form the output of the self-attention layer. Each attention head uses scaled dot-product attention which takes a sequence $x = (x_1, \cdots, x_n)$ of n elements as input and computes a new sequence $z = (z_1, \cdots, z_n)$ of the same length:

$$z = Attention\,(x) \quad (1)$$

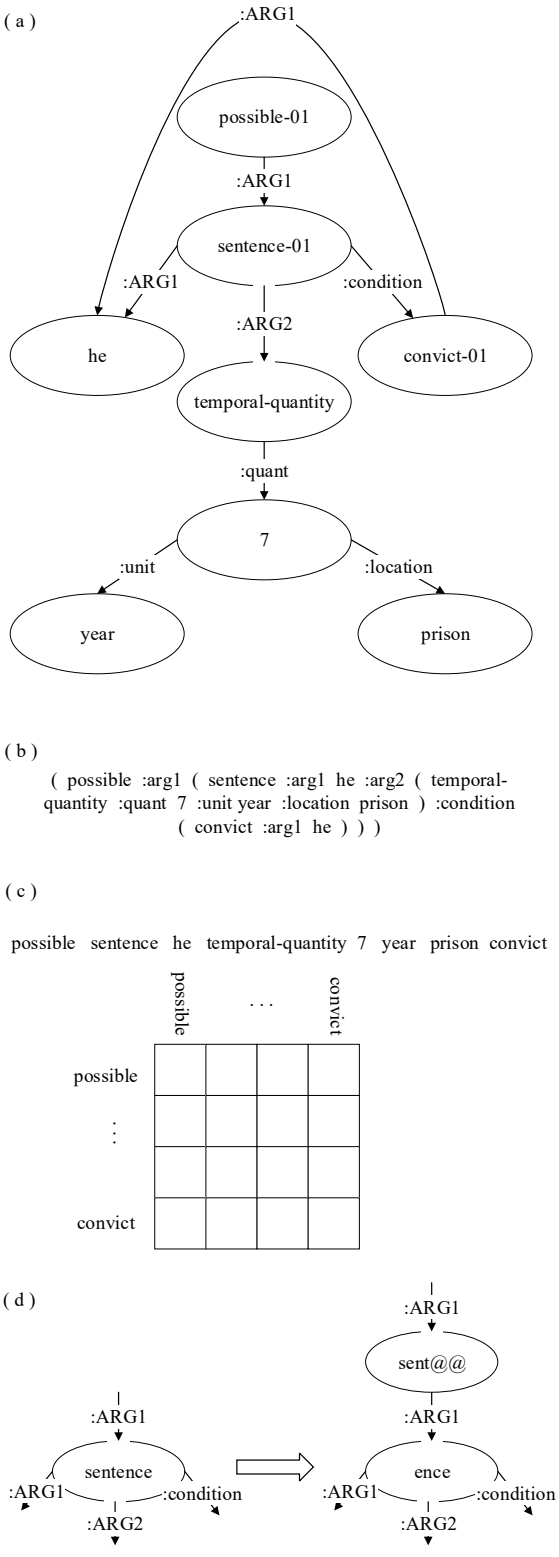

Figure 1: (a) An example of AMR graph for the sentence of *He could be sentenced to 7 years in prison if convicted.* (b) input to our baseline system, the seq2seq Transformer. (c) input to our proposed system based on structure-aware self-attention. (d) An example of graph structure extensions to sub-word units.

where $x_i \in \mathbb{R}^{d_x}$ and $z \in \mathbb{R}^{n \times d_z}$. Each output element z_i is a weighted sum of a linear transformation of input elements:

$$z_i = \sum_{j=1}^{n} \alpha_{ij} \left(x_j W^V \right) \quad (2)$$

where $W^V \in \mathbb{R}^{d_x \times d_z}$ is matrix of parameters. The vectors $\alpha_i = (\alpha_{i1}, \cdots, \alpha_{in})$ in Equation 2 are obtained by the self-attention model, which captures the correspondences between x_i and others. Specifically, the attention weight α_{ij} of each element x_j is computed using a softmax function:

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{n} exp(e_{ik})} \quad (3)$$

where

$$e_{ij} = \frac{\left(x_i W^Q \right) \left(x_j W^K \right)^T}{\sqrt{d_z}} \quad (4)$$

is an alignment function which measures how well the input elements x_i and x_j match. $W^Q, W^K \in \mathbb{R}^{d_x \times d_z}$ are parameters to be learned.

Input Representation: We use the depth-first traversal strategy as in Konstas et al. (2017) to linearize AMR graphs and to obtain simplified AMRs. We remove variables, wiki links and sense tags before linearization. Figure 1(b) shows an example linearization result for the AMR graph in Figure 1(a). Note that the reentrant concept *he* in Figure 1 (a) maps to two different tokens in the linearized sequence.

Vocabulary: Training AMR-to-text generation systems solely on labeled data may suffer from data sparseness. To attack this problem, previous works adopt techniques like anonymization to remove named entities and rare words (Konstas et al., 2017), or apply a copy mechanism (Gulcehre et al., 2016) such that the models can learn to copy rare words from the input sequence. In this paper we instead use two simple yet effective techniques. One is to apply Byte Pair Encoding (BPE) (Sennrich et al., 2016) to split words into smaller, more frequent sub-word units. The other is to use a shared vocabulary for both source and target sides. Experiments in Section 3.2 demonstrate the necessity of the techniques in building a strong baseline.

2.2 Modeling Graph Structures in Transformer

Input Representation: We also use the depth-first traversal strategy to linearize AMR graphs and to obtain simplified AMRs which only consist of concepts. As shown in Figure 1 (c), the input sequence is much shorter than the input sequence in the baseline. Besides, we also obtain a matrix which records the graph structure between every concept pair, which implies their semantic relationship (Section2.3).

Vocabulary: To be compatible with sub-words, we extend the original AMR graph, if necessary, to include the structures of sub-words. As *sentence-01* in Figure 1(a) is segmented into *sent@@ ence-01*, we split the original node into two connected ones with an edge labeled as the incoming edge of the first unit. Figure 1(d) shows the graph structure for sub-words *sent@@ ence-01*.

Structure-Aware Self-Attention: Motivated by Shaw et al. (2018), we extend the conventional self-attention architecture to explicitly encode the relation between an element pair (x_i, x_j) in the alignment model by replacing Equation 4 with Equation 5. Note that the relation $r_{ij} \in \mathbb{R}^{d_z}$ is the vector representation for element pair (x_i, x_j), and will be learned in Section 2.3.

$$e_{ij} = \frac{\left(x_i W^Q \right) \left(x_j W^K + r_{ij} W^R \right)^T}{\sqrt{d_z}} \quad (5)$$

where $W^R \in \mathbb{R}^{d_z \times d_z}$ is a parameter matrix. Then, we update Equation 2 accordingly to propagate structure information to the sublayer output by:

$$z_i = \sum_{j=1}^{n} \alpha_{ij} \left(x_j W^V + r_{ij} W^F \right) \quad (6)$$

where $W^F \in \mathbb{R}^{d_z \times d_z}$ is a parameter matrix.

2.3 Learning Graph Structure Representation for Concept Pairs

The above structure-aware self-attention is capable of incorporating graph structure between concept pairs. In this section, we explore a few methods to learn the representation for concept pairs. We use a sequence of edge labels, along the path from x_i to x_j to indicate the AMR graph structure between concepts x_i and x_j.[1] In order to distinguish the edge direction, we add a direction symbol to each label with $\uparrow$ for climbing up along the path, and $\downarrow$ for going down. Specifically, for the special case of $i == j$, we use *None* as the path. Table 1 demonstrates structural label sequences between a few concept pairs in Figure 1.

[1]While there may exist two or more paths connecting x_i and x_j, we simply choose the shortest one.

x_i	x_j	Structural label sequence
he	convict-01	:ARG1↑
he	7	:ARG1↑ :ARG2↓ :quant↓
he	he	None

Table 1: Examples of structural path between a few concept pairs in Figure 1.

Now, given a structural path with a label sequence $s = s_1, \cdots, s_k$ and its d_x-sized corresponding label embedding sequence $l = l_1, \cdots, l_k$, we use the following methods to obtain its representation vector r, which maps to r_{ij} in Equation 5 and Equation 6.

Feature-based

A natural way to represent the structural path is to view it as a string feature. To this end, we combine the labels in the structural path into a string. Unsurprisingly, this will end up with a large number of features. We keep the most frequent ones (i.e., 20K in our experiments) in the feature vocabulary and map all others into a special feature *UNK*. Each feature in the vocabulary will be mapped into a randomly initialized vector.

Avg-based

To overcome the data sparsity in the above feature-based method, we view the structural path as a label sequence. Then we simply use the averaged label embedding as the representation vector of the sequence, i.e.,

$$r = \frac{\sum_{i=1}^{k} l_i}{k} \tag{7}$$

Sum-based

Sum-based method simply returns the sum of all label embeddings in the sequence, i.e.,

$$r = \sum_{i=1}^{k} l_i \tag{8}$$

Self-Attention-based (SA-based for short)

As shown in Figure 2, given the label sequence $s = s_1, \cdots, s_k$, we first obtain the sequence e, whose element is the addition of a word embedding and the corresponding position embedding. Then we use the self-attention, as presented in Eq. 1 to obtain its hidden states h, i.e, $h = Attention(e)$, where $h_i \in \mathbb{R}^{d_z}$. Our aim is to encode a variable length sentence into a d_z-sized vector. Motivated by (Lin et al., 2017), we achieve this by choosing a linear combination of the k vectors in h. Computing the linear combination requires an attention mechanism which takes the whole hidden states h as input, and outputs a vector of weights α:

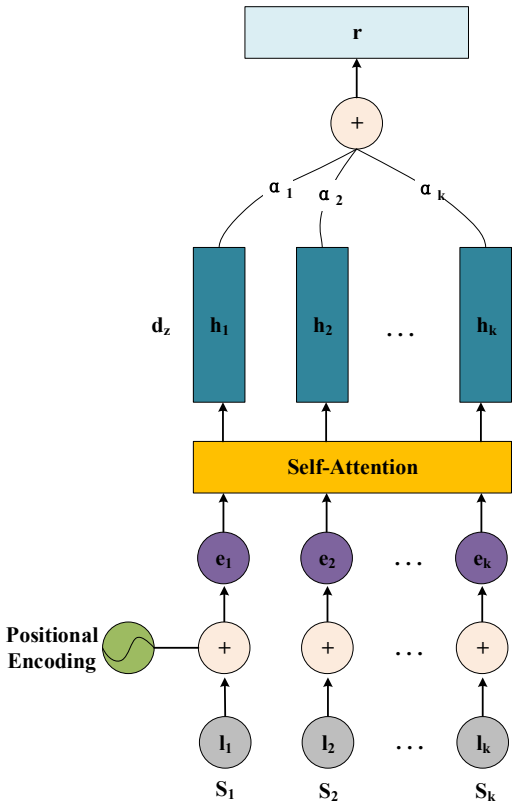

Figure 2: Self-Attention-based method.

$$\alpha = softmax(W^2 \tanh(W^1 h^T)) \tag{9}$$

where $W^1 \in \mathbb{R}^{d_w \times d_z}$ and $W^2 \in \mathbb{R}^{d_w}$. Then the label sequence representation vector is the weighted sum of its hidden states:

$$r = \sum_{i=1}^{k} \alpha_i h_i \tag{10}$$

CNN-based

Motivated by (Kalchbrenner et al., 2014), we use convolutional neural network (CNN) to convolute the label sequence l into a vector r, as follow:

$$\begin{aligned} conv = Conv1D(&kernel_size = (m), \\ &strides = 1, \\ &filters = d_z, \\ &input_shape = d_z \\ &activation =' relu') \end{aligned} \tag{11}$$

$$r = conv\,(l) \tag{12}$$

where kernel size m is set to 4 in our experiments.

3 Experimentation

3.1 Experimental Settings

For evaluation of our approach, we use the sentences annotated with AMRs from the LDC release LDC2015E86 and LDC2017T10. The two datasets contain 16,833 and 36,521 training AMRs, respectively, and share 1,368 development AMRs and 1,371 testing AMRs. We segment words into sub-word units by BPE (Sennrich et al., 2016) with 10K operations on LDC2015E86 and 20K operations on LDC2017T10.

For efficiently learning graph structure representation for concept pairs (except the feature-based method), we limit the maximum label sequence length to 4 and ignore the labels exceeding the maximum. In SA-based method, we set the filter size d_w as 128.

We use *OpenNMT* (Klein et al., 2017) as the implementation of the Transformer seq2seq model.[2] In parameter setting, we set the number of layers in both the encoder and decoder to 6. For optimization we use Adam with $\beta 1 = 0.1$ (Kingma and Ba, 2015). The number of heads is set to 8. In addition, we set the embedding and the hidden sizes to 512 and the batch token-size to 4096. Accordingly, the d_x and d_z in Section 2 are 64. In all experiments, we train the models for 300K steps on a single K40 GPU.

For performance evaluation, we use BLEU (Papineni et al., 2002), Meteor (Banerjee and Lavie, 2005; Denkowski and Lavie, 2014), and CHRF++ (Popovi, 2017) as metrics. We report results of single models that are tuned on the development set.

We make our code available at `https://github.com/Amazing-J/structural-transformer`.

3.2 Experimental Results

We first show the performance of our baseline system. As mentioned before, BPE and sharing vocabulary are two techniques we applied to relieving data sparsity. Table 2 presents the results of the ablation test on the development set of LDC2015E86 by either removing BPE, or vocabulary sharing, or both of them from the baseline system. From the results we can see that BPE and vocabulary sharing are critical to building our baseline system (an improvement from 18.77 to 24.93 in BLEU), revealing the fact that they are two effective ways to address the issue of data sparseness for AMR-to-text generation.

Model	BLEU	Meteor	CHRF++
Baseline	24.93	33.20	60.30
-BPE	23.02	31.60	58.09
-Share Vocab.	23.24	31.78	58.43
-Both	18.77	28.04	51.88

Table 2: Ablation results of our baseline system on the LDC2015E86 development set.

Table 3 presents the comparison of our approach and related works on the test sets of LDC2015E86 and LDC2017T10. From the results we can see that the Transformer-based baseline outperforms most of graph-to-sequence models and is comparable with the latest work by Guo et al. (2019). The strong performance of the baseline is attributed to the capability of the Transformer to encode global and implicit structural information in AMR graphs. By comparing the five methods of learning graph structure representations, we have the following observations.

- All of them achieve significant improvements over the baseline: the biggest improvements are 4.16 and 4.39 BLEU scores on LDC2015E86 and LDC2017T10, respectively.
- Methods using continuous representations (such as SA-based and CNN-based) outperform the methods using discrete representations (such as feature-based).
- Compared to the baseline, the methods have very limited affect on the sizes of model parameters (see the column of *#P (M)* in Table 3).

Finally, our best-performing models are the best among all the single and supervised models.

4 Analysis

In this section, we use LDC2017T10 as our benchmark dataset to demonstrate how our proposed approach achieves higher performance than the baseline. As representative, we use CNN-based method to obtain structural representation.

Table 3: Comparison results of our approaches and related studies on the test sets of LDC2015E86 and LDC2017T10. #P indicates the size of parameters in millions. * indicates seq2seq-based systems while † for graph-based models, and ‡ for other models. All our proposed systems are significant over the baseline at 0.01, tested by bootstrap resampling (Koehn, 2004).

System	BLEU
Baseline	27.43
Our approach	31.82
No indirectly connected concept pairs	29.92

Table 4: Performance on the test set of our approach with or without modeling structural information of indirectly connected concept pairs.

4.1 Effect of Modeling Structural Information of Indirectly Connected Concept Pairs

Our approach is capable of modeling arbitrary concept pairs no matter whether directly connected or not. To investigate the effect of modeling structural information of indirectly connected concept pairs, we ignore their structural information by mapping all structural label sequences between two indirectly connected concept pairs into *None*. In this way, the structural label sequence for *he* and *7* in Table 1, for example, will be *None*.

Table 4 compares the performance of our approach with or without modeling structural information of indirectly connected concept pairs. It shows that by modeling structural information of indirectly connected concept pairs, our approach improves the performance on the test set from 29.92 to 31.82 in BLEU scores. It also shows that even without modeling structural information of indirectly connected concept pairs, our approach achieves better performance than the baseline.

4.2 Effect on AMR Graphs with Different Sizes of Reentrancies

Linearizing an AMR graph into a sequence unavoidably loses information about reentrancies (nodes with multiple parents). This poses a challenge for the baseline since there exists on obvious sign that the first *he* and the second *he*, as shown in Figure 1 (b), refer to the same person. By contrast, our approach models reentrancies explicitly. Therefore, it is expected that the benefit of our approach is more evident for those AMR graphs containing more reentrancies. To test this hypothesis, we partition source AMR graphs to different groups by their numbers of reentrancies and evaluate their performance respectively. As shown in Figure 3, the performance gap be-

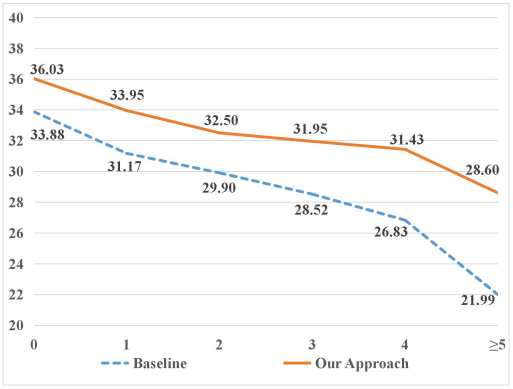

Figure 3: Performance (in BLEU) on the test set with respect to the reentrancy numbers of the input AMR graphs.

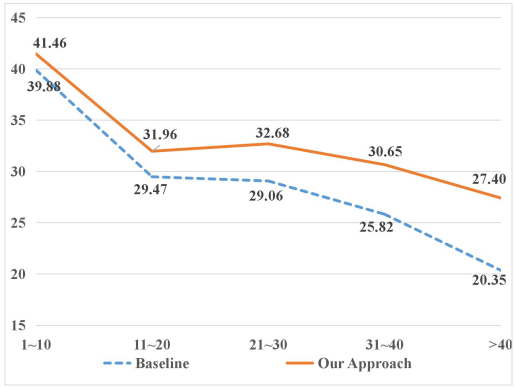

Figure 4: Performance (in BLEU) on the test set with respect to the size of the input AMR graphs.

tween our approach and the baseline goes widest for AMR graphs with more than 5 reentrancies, on which our approach outperforms the baseline by 6.61 BLEU scores.

4.3 Effect on AMR Graphs with Different Sizes

When we encode an AMR graph with plenty concepts, linearizing it into a sequence tends to lose great amount of structural information. In order to test the hypothesis that graphs with more concepts contribute more to the improvement, we partition source AMR graphs to different groups by their sizes (i.e., numbers of concepts) and evaluate their performance respectively. Figure 4 shows the results which indicate that modeling graph structures significantly outperforms the baseline over all AMR lengths. We also observe that the performance gap between the baseline and our approach increases when AMR graphs become big, revealing that the baseline seq2seq model is far from capturing deep structural details of big AMR graphs. Figure 4 also indicates that text generation becomes difficult for big AMR graphs. We think that the low performance on big AMR graphs is mainly attributed to two reasons:

- Big AMR graphs are usually mapped into long sentences while seq2seq model tends to stop early for long inputs. As a result, the length ratio[3] for AMRs with more than 40 concepts is 0.906, much lower than that for AMRs with less concepts.
- Big AMR graphs are more likely to have reentrancies, which makes the generation more challenging.

[3]Length ratio is the length of generation output, divided by the length of reference.

4.4 Case Study

In order to better understand the model performance, Figure 5 presents a few examples studied in Song et al. (2018) (Example (1)) and Damonte and Cohen (2019) (Examples (2) - (5)).

In Example (1), though our baseline recovers a propositional phrase for the noun *staff* and another one for the noun *funding*, it fails to recognize the anaphora and antecedent relation between the two propositional phrases. In contrast, our approach successfully recognizes *:prep-for c* as a reentrancy node and generates one propositional phrase shared by both nouns *staff* and *funding*. In Example (2), we note that although AMR graphs lack tense information, the baseline generates output with inconsistent tense (i.e., *do* and *found*) while our approach consistently prefers past tense for the two clauses. In Example (3), only our approach correctly uses *people* as the subject of the predicate *can*. In Example (4), the baseline fails to predict the direct object *you* for predicate *recommend*. Finally in Example (5), the baseline fails to recognize the subject-predicate relation between noun *communicate* and verb *need*. Overall, we note that compared to the baseline, our approach produces more accurate output and deal with reentrancies more properly.

Comparing the generation of our approach and graph-based models in Song et al. (2018) and Damonte and Cohen (2019), we observe that our generation is more close to the reference in sentence structure. Due to the absence of tense informa-

tion in AMR graphs, our model tends to use past tense, as *provided* and *did* in Example (1) and (2). Similarly, without information concerning singular form and plural form, our model is more likely to use plural nouns, as *centers* and *lawyers* in Example (1) and (5).

5 Related Work

Most studies in AMR-to-text generation regard it as a translation problem and are motivated by the recent advances in both statistical machine translation (SMT) and neural machine translation (NMT). Flanigan et al. (2016) first transform an AMR graph into a tree, then specify a number of tree-to-string transduction rules based on alignments that are used to drive a tree-based SMT model (Graehl and Knight, 2004). Pourdamghani et al. (2016) develop a method that learns to linearize AMR graphs into AMR strings, and then feed them into a phrase-based SMT model (Koehn et al., 2003). Song et al. (2017) use synchronous node replacement grammar (SNRG) to generate text. Different from synchronous context-free grammar in hierarchical phrase-based SMT (Chiang, 2007), SNRG is a grammar over graphs.

Moving to neural seq2seq approaches, Konstas et al. (2017) successfully apply seq2seq model together with large-scale unlabeled data for both text-to-AMR parsing and AMR-to-text generation. With special interest in the target side syn-

tax, Cao and Clark (2019) use seq2seq models to generate target syntactic structure, and then the surface form. To prevent the information loss in linearizing AMR graphs into sequences, (Song et al., 2018; Beck et al., 2018) propose graph-to-sequence models to encode graph structure directly. Focusing on reentrancies, Damonte and Cohen (2019) propose stacking encoders which consist of BiLSTM (Graves et al., 2013), TreeLSTMs (Tai et al., 2015), and Graph Convolutional Network (GCN) (Duvenaud et al., 2015; Kipf and Welling, 2016). Guo et al. (2019) propose densely connected GCN to better capture both local and non-local features. However, all the aforementioned graph-based models only consider the relations between nodes that are directly connected, thus lose the structural information between nodes that are indirectly connected via an edge path.

Recent studies also extend the Transformer to encode structural information for other NLP applications. Shaw et al. (2018) propose relation-aware self-attention to capture relative positions of word pairs for neural machine translation. Ge et al. (2019) extend the relation-aware self-attention to capture syntactic and semantic structures. Our model is inspired by theirs but aims to encode structural label sequences of concept pairs. Koncel-Kedziorski et al. (2019) propose graph Transformer to encode graph structure. Similar to the GCN, it focuses on the relations between directly connected nodes.

6 Conclusion and Future Work

In this paper we proposed a structure-aware self-attention for the task of AMR-to-text generation. The major idea of our approach is to encode long-distance relations between concepts in AMR graphs into the self-attention encoder in the Transformer. In the setting of supervised learning, our models achieved the best experimental results ever reported on two English benchmarks.

Previous studies have shown the effectiveness of using large-scale unlabelled data. In future work, we would like to do semi-supervised learning and use silver data to test how much improvements could be further achieved.

Abstract

Aspect level sentiment classication aims to identify the sentiment expressed towards an aspect given a context sentence. Previous neural network based methods largely ignore the syntax structure in one sentence. In this paper, we propose a novel target-dependent graph attention network (TD-GAT) for aspect level sentiment classification, which explicitly utilizes the dependency relationship among words. Using the dependency graph, it propagates sentiment features directly from the syntactic context of an aspect target. In our experiments, we show our method outperforms multiple baselines with GloVe embeddings. We also demonstrate that using BERT representations further substantially boosts the performance.

1 Introduction

Aspect level sentiment classification aims to identify the sentiment polarity (eg. positive, negative, neutral) of an aspect target in its context sentence. Compared to sentence-level sentiment classification, which tries to detect the overall sentiment in a sentence, it is a more fine-grained task. Aspect level sentiment classification can distinguish sentiment polarity for multiple aspects in a sentence with various sentiment polarity, while sentence-level sentiment classification often fails in these conditions (Jiang et al., 2011). For example, in a sentence "great food but the service was dreadful", the sentiment polarity for aspects "food" and "service" are positive and negative respectively. In this case, however, it is hard to determine the overall sentiment since the sentence is mixed with positive and negative expressions.

Typically, researchers use machine learning algorithms to classify the sentiment of given aspects in sentences. Some early work manually designs features, eg. sentiment lexicons and linguistic features, to train classifiers for aspect level sentiment classification (Jiang et al., 2011; Wagner et al., 2014). Later, various neural network-based methods became popular for this task (Tang et al., 2016b; Wang et al., 2016), as they do not require manual feature engineering. Most of them are based on long short-term memory (LSTM) neural networks (Tang et al., 2016a; Huang et al., 2018) and few of them use convolutional neural networks (CNN) (Huang and Carley, 2018; Xue and Li, 2018).

Most of these neural network based methods treat a sentence as a word sequence and embed aspect information into the sentence representation via various methods, eg. attention (Wang et al., 2016) and gate (Huang and Carley, 2018). These methods largely ignore the syntactic structure of the sentence, which would be beneficial to identify sentiment features directly related to the aspect target. When an aspect term is separated away from its sentiment phrase, it is hard to find the associated sentiment words in a sequence. For example, in a sentence "The food, though served with bad service, is actually great", the word "great" is much closer to the aspect "food" in the dependency graph than in the word sequence. Using the dependency relationship is also helpful to resolve potential ambiguity in a word sequence. In a simple sentence "Good food bad service", "good" and "bad" can be used interchangeably. Using an attention-based method, it is hard to distinguish which word is associated with "food" or "service" among "good" and "bad". However, a human reader with good grammar knowledge can easily recognize that "good" is an adjectival modifier for "food" while "bad" is the modifier for "service".

In this paper, we propose a novel neural network framework named target-dependent graph attention network (TD-GAT), which leverages the syn-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5469–5477,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tax structure of a sentence for aspect level sentiment classification. Unlike these previous methods, our approach represents a sentence as a dependency graph instead of a word sequence. In the dependency graph, the aspect target and related words will be connected directly. We employ a multi-layer graph attention network to propagate sentiment features from important syntax neighbourhood words to the aspect target. We further incorporate an LSTM unit in TD-GAT to explicitly capture aspect related information across layers during recursive neighbourhood expansion. Though some work tries to incorporate syntax knowledge using recursive neural networks (Dong et al., 2014), it has to convert the original dependency tree into a binary tree, which may move syntax related words away from the aspect term. Compared to (Dong et al., 2014), one advantage of our approach is that it keeps the original syntax order unchanged.

We apply the proposed method to laptop and restaurant datasets from SemEval 2014 (Pontiki et al., 2014). Our experiments show that our approach outperforms multiple baselines with GloVe embeddings (Pennington et al., 2014). We further demonstrate that using BERT representations (Devlin et al., 2018) boosts the performance a lot. In our analysis, we show that our model is lightweight in terms of model size. It achieves better performance and requires fewer computational resources and less running time than fine-tuning the original BERT model.

2 Related Work

Aspect level sentiment classification is a branch of sentiment analysis (Pang et al., 2008). The goal of this task is to identify the sentiment polarity of an aspect target within a given context sentence.

Some early work first converts an extensive set of features, eg. sentiment lexicons and parse context, into feature vectors, then train a classifier like support vector machine (SVM) based on these feature vectors. Wagner et al. (2014) combine sentiment lexicons, distance to the aspect target, and dependency path distance to train an SVM classifier. Kiritchenko et al. (2014) also propose a similar method and they show that adding parse context features could improve the prediction accuracy by more than one percent.

Later, many neural network based methods are introduced to approach this aspect level sentiment classification task. A majority of the work uses LSTM neural networks to model the word sequence in a sentence. Tang et al. (2016a) use two LSTMs to model the left and right contexts of an aspect target, then they take two final hidden states as classification features. Wang et al. (2016) introduce the attention mechanism into this task (Bahdanau et al., 2014). They use the aspect term embedding to generate an attention vector to select important aspect-related words in a sentence. Following this work, Huang et al. (2018) use two LSTM networks to model sentences and aspects in a joint way and explicitly capture the interaction between aspects and context sentences. From the sentence aspect correlation matrix, they find important words in aspects as well as in sentences. Li et al. (2018) further improve these attention-based methods by incorporating position information.

Except for these LSTM-based methods, there are some other neural methods existing in the literature. Tang et al. (2016b) propose a deep memory network which consists of multiple computation layers and each layer computes an attention vector over an external memory. There are also some attempts using convolutional neural networks (CNN) to approach this task (Huang and Carley, 2018; Xue and Li, 2018). Features generated from the aspect are used to control the information flow in the CNN applied to the sentence (Huang et al., 2018). Benefited from the rich linguistic knowledge learned from massive language modeling (Devlin et al., 2018), researchers show great progress on this task using BERT representations (Sun et al., 2019). Xu et al. (2019) utilizes additional in-domain datasets to post-train BERT's weights and then fine-tune it on this task. However, such a method requires a large corpus for post-training and the fine-tuning also takes a lot of computation resources and time.

Unlike previous discussed neural network-based methods, our approach explicitly utilizes the syntax structure among one sentence and these sentiment features are propagated towards the aspect target on the dependency graph instead of on the original word sequence. Some early work also tries to leverage the syntax structure (Dong et al., 2014; Nguyen and Shirai, 2015). They have to convert the original dependency tree into a binary tree first and place the aspect target at the root node. As a result, sentiment features can be propagated recursively from the leaf nodes to the root

node. However, such conversion may move modifying sentiment words farther away from the aspect target, while our approach keeps the original syntax order unchanged.

3 Method

3.1 Text Representation

Given a sentence $s = [w_1, w_2, ..., w_i, .., w_n]$ with length n and an aspect target w_i, we first map each word into a low-dimensional word embedding vector. For each word w_i, we get one vector $x_i \in R^d$ where d is the dimension of the word embedding space.

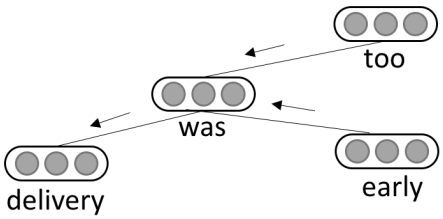

Figure 1: The dependency graph for "delivery was early too". Features can be propagated from neighbour nodes to the aspect node "delivery".

We transform the sentence into a dependency graph using an off-the-shelf dependency parser (Chen and Manning, 2014). Each node represents a word and is associated with an embedding vector as its local feature vector. An undirected edge between two words means these two words are syntactically related. In Figure 1, we show an example of the dependency graph for a sentence "delivery was early too". For the target "delivery", we can propagate features from its 2-hop neighbourhood to 1-hop neighbourhood and then to itself.

For an aspect target with more than one word, we first replace the whole target word sequence with a special symbol "__target__", then pass the modified sentence into the dependency parser. As a result, there is a meta-node representing the target sequence in the dependency graph and its local feature vector is the average of embedding vectors of words in the target.

3.2 Graph Attention Network

A graph attention network (GAT) (Veličković et al., 2017) is a variant of graph neural network (Scarselli et al., 2009) and is a key element in our method. It propagates features from an aspect's syntax context to the aspect node. Given a dependency graph with N nodes, where each node is associated with a local word embedding vector x, one GAT layer compute node representations by aggregating neighbourhood's hidden states. With an L-layer GAT network, features from L hops away can be propagated to the aspect target node.

Specifically, given a node i with a hidden state h_l^i at layer l and the node's neighbours $n[i]$ as well as their hidden states, a GAT updates the node's hidden state at layer $l+1$ using multi-head attentions (Vaswani et al., 2017). The update process is as follows

$$h_{l+1}^i = \Big\Vert_{k=1}^{K} \sigma\Big(\sum_{j \in n[i]} \alpha_{lk}^{ij} W_{lk} h_l^j\Big) \quad (1)$$

$$\alpha_{lk}^{ij} = \frac{exp(f(a_{lk}^T [W_{lk} h_l^i || W_{lk} h_l^j]))}{\sum_{u \in n[i]} exp(f(a_{lk}^T [W_{lk} h_l^i || W_{lk} h_l^u]))} \quad (2)$$

where $||$ represents vector concatenation, α_{lk}^{ij} is the attention coefficient of node i to its neighbour j in attention head k at layer l. $W_{lk} \in R^{\frac{D}{K} \times D}$ is a linear transformation matrix for input states. D is the dimension of hidden states. σ denotes a sigmoid function. $f(\cdot)$ is a LeakyReLU non-linear function (Maas et al., 2013). $a_{lk} \in R^{\frac{2D}{K}}$ is an attention context vector learned during training.

For simplicity, we can write such feature propagation process as

$$H_{l+1} = GAT(H_l, A; \Theta_l) \quad (3)$$

where $H_l \in R^{N \times D}$ is the stacked states for all nodes at layer l, $A \in R^{N \times N}$ is the graph adjacent matrix. Θ_l is the parameter set of the GAT at layer l.

3.3 Target-Dependent Graph Attention Network

To utilize the target information in such a GAT network explicitly, we further use an LSTM to model the dependency for the aspect target across layers, which is also helpful for overcoming noisy information in a graph (Huang and Carley, 2019). The basic idea is that at layer 0 the hidden state for an aspect target node h_0^t is only dependent on the target's local features and at each layer l information related with the target from l-hop neighbourhood is added into the hidden state by the LSTM unit.

Given the previous hidden state h_{l-1}^t and cell state c_{l-1}^t for any target node t, we first get a temporary hidden state $\hat{h}_l^t$ by aggregating its neighbour information using equation 1. Then we take this temporary hidden state as a new observation for an LSTM unit and update the hidden state at layer l as follows:

$$i_l = \sigma(W_i \hat{h}_l^t + U_i h_{l-1} + b_i) \quad (4)$$

$$f_l = \sigma(W_f \hat{h}_l^t + U_f h_{l-1} + b_f) \quad (5)$$

$$o_l = \sigma(W_o \hat{h}_l^t + U_o h_{l-1} + b_o) \quad (6)$$

$$\hat{c}_l = tanh(W_c \hat{h}_l^t + U_c h_{l-1} + b_c) \quad (7)$$

$$c_l = f_l \circ c_{l-1} + i_l \circ \hat{c}_l \quad (8)$$

$$h_l = o_l \circ tanh(c_l) \quad (9)$$

where $\sigma(\cdot)$ and $tanh(\cdot)$ are the sigmoid function and hyperbolic tangent function respectively. $W_i, U_i, W_f, U_f, W_o, U_o, W_c, U_c$ are parameter matrices and b_i, b_f, b_o, b_c are bias vectors to be learned during training. Symbol $\circ$ represents element-wise multiplication. i_t, f_t and o_t are input gate, forget gate and output gate, which control the information flow.

In summary, the feed-forward process of our target-dependent graph neural network can be written as

$$H_{l+1}, C_{l+1} = LSTM(GAT(H_l, A; \Theta_l), (H_l, C_l))$$
$$H_0, C_0 = LSTM(XW_p + [b_p]_N, (0, 0))$$

where C_l is the stacked cell states of the LSTM at layer l. The initial hidden state and cell state of the LSTM are set as 0. $W_p \in R^{d \times D}$ is the projection matrix that transforms stacked embedding vectors X into the dimension of hidden states and $[b_p]_N$ represents stacking the bias vector b_p N times and forms a bias matrix with dimension $R^{N \times D}$. Similarly, we can also replace the LSTM unit with a GRU unit to model the layer-wise dependency for the target.

3.4 Final Classification

With L layers of our TD-GAT networks, we get a final representation for our aspect target node. We just retrieve the corresponding hidden state h_L^t for the aspect target node from all the node representations H_L.

We map the hidden state h_L^t into the classification space by a linear transformation. Afterwards, the probability of a sentiment class c is computed by a softmax function:

$$P(y = c) = \frac{exp(W h_L^t + b)_c}{\sum_{i \in C} exp(W h_L^t + b)_i} \quad (10)$$

where W, b are the weight matrix and bias for the linear transformation, C is the set of sentiment classes.

The final predicted sentiment polarity of an aspect target is the label with the highest probability. We minimize the cross-entropy loss with L_2 regularization to train our model

$$loss = -\sum_{c \in C} I(y = c) \cdot log(P(y = c)) + \lambda ||\Theta||^2$$

where $I(\cdot)$ is an indicator function. λ is the L_2 regularization parameter and Θ is the set of all the parameters in our model.

4 Experiments

4.1 Datasets

We adopt two widely used datasets from SemEval 2014 Task 4 (Pontiki et al., 2014) to validate the effectiveness of our method. These are two domain-specific datasets collected from laptop and restaurant reviews. Each data point is a pair of a sentence and an aspect term. Experienced annotators tagged each pair with sentiment polarity. Following recent work (Tay et al., 2018; Huang and Carley, 2018), we first take 500 training instances as development set[1] to tune our model. We then combine the development dataset and training dataset to train our final model. Statistics of these two datasets are given in Table 1.

Dataset	Positive	Neutral	Negative
Laptop-Train	767	373	673
Laptop-Dev	220	87	193
Laptop-Test	341	169	128
Restaurant-Train	1886	531	685
Restaurant-Dev	278	102	120
Restaurant-Test	728	196	196

Table 1: Statistics of the datasets.

4.2 Implementation Details

We use the Stanford neural parser (Chen and Manning, 2014) to get dependency graphs. We

[1]The splits can be found at https://github.com/vanzytay/ABSA_DevSplits.

try two embedding methods in this paper. One is 300-dimensional GloVe embeddings (Pennington et al., 2014), where we just retrieve the corresponding embedding vector for each token in graphs. Another is BERT representations (Devlin et al., 2018), where we use the large uncased English model with dimension 1024 implemented in PyTorch [2]. The input of the BERT model is a text pair formatted as "[CLS]" + sentence + "[SEP]" + aspect + "[SEP]". The representations of the sentence are used for the downstream aspect-level sentiment classification task. Because the tokenizers used in the parser and BERT are different, we get the BERT representations for tokens in dependency graphs by averaging the corresponding representations of sub-word units ("wordpiece") from BERT. For example, the representation of the token "overload" is the average of representations of two sub-words "over" and "##load". Once the word representations are initialized, they are fixed during training.

We set the dimension of hidden states as 300 in our experiments. For the BERT representations, we first map word representations into 300 dimensional vectors by a linear projection layer. We use 6 attention heads in our model. We train our model with batch size of 32. We apply l_2 regularization with term λ 10^{-4} and dropout (Srivastava et al., 2014) on the input word embedding with rate 0.7. We first use Adam (Kingma and Ba, 2014) optimizer with learning rate 10^{-3} to train our model, then switch to stochastic gradient descent to fine-tune and stabilize our model.

We implemented our model using PyTorch Geometric (Fey and Lenssen, 2019) on a Linux machine with Titan XP GPUs.

4.3 Baseline Comparisons

To validate the effectiveness of our method, we compare it to following baseline methods:

Feature-based SVM utilizes n-gram features, parse features and lexicon features for aspect-level sentiment classification (Kiritchenko et al., 2014)

TD-LSTM is a direct competitor against our method. It uses two LSTM networks to model the preceding and following contexts surrounding the aspect term, while we use GAT to model the syntax context around an aspect. The last hidden states of these two LSTM networks are concatenated for predicting the sentiment polarity (Tang et al., 2016a).

AT-LSTM first models the sentence via a LSTM model. Then it combines the hidden states from the LSTM with the aspect term embedding to generate the attention vector. The final sentence representation is the weighted sum of the hidden states (Wang et al., 2016).

MemNet applies attention multiple times on the word embeddings, and the output of last attention is fed to softmax for prediction (Tang et al., 2016b).

IAN uses two LSTM networks to model the sentence and aspect term respectively. It uses the hidden states from the sentence to generate an attention vector for the target, and vice versa. Based on these two attention vectors, it outputs a sentence representation and a target representation for classification (Ma et al., 2017).

PG-CNN is a CNN based model where aspect features are used as gates to control the feature extraction on sentences (Huang and Carley, 2018).

AOA-LSTM introduces an attention-over-attention (AOA) based network to model aspects and sentences in a joint way and explicitly capture the interaction between aspects and context sentences (Huang et al., 2018).

BERT-AVG uses the average of the sentence representations to train a linear classifier.

BERT-CLS is a model where we directly use the representation of "[CLS]" as a classification feature to fine-tune the BERT model for paired sentence classification. We fine-tune it for 5 epochs using Adam optimizer with batch size 8 and learning rate 10^{-5}.

The comparison results are shown in Table 2. With GloVe embeddings, our approach TD-GAT-GloVe (k), where k is the number of layers, outperforms all these previous methods. Among these baselines, Feature-based SVM achieves strong performance on this task, which indicates the importance of feature engineering and syntax knowledge.

As one direct competitor, TD-LSTM propagates sentiment features from the beginning and the end of the sentence to the aspect target, while our model propagates features from syntax dependent words to the target on a dependency graph. Compared to TD-LSTM, our model shows superior performance, which directly proves the necessity of incorporating syntax information.

	Laptop	Restaurant
Feature+SVM	70.5	80.2
TD-LSTM	68.1	75.6
AT-LSTM	68.9	76.2
MemNet	72.4	80.3
IAN	72.1	78.6
PG-CNN	69.1	78.9
AOA-LSTM	72.6	79.7
TD-GAT-GloVe (3)	73.7	81.1
TD-GAT-GloVe (4)	**74.0**	80.6
TD-GAT-GloVe (5)	73.4	**81.2**
BERT-AVG	76.5	78.7
BERT-CLS	77.1	81.2
TD-GAT-BERT (3)	79.3	82.9
TD-GAT-BERT (4)	79.8	**83.0**
TD-GAT-BERT (5)	**80.1**	82.8

Table 2: Comparison results of different methods on laptop and restaurant datasets. Numbers in parentheses indicate number of layers in our model.

Using BERT representations further boosts the performance of our model. BERT-AVG, which uses BERT representations without fine-tuning, achieves surprisingly excellent performance on this task. After fine-tuning, the performance of BERT-CLS becomes even better. However, we observe that such fine-tuning is quite unstable. The model cannot converge in some trials.

Even though the original BERT model already provides strong prediction power, our model consistently improves over BERT-AVG and BERT-CLS, which indicates that our model can better utilize these semantic representations. The accuracy of our model reaches about 80% and 83% on the laptop and restaurant datasets respectively.

4.4 Effects of Target Information

In this section, we provide an ablation study to show the effects of explicitly capturing target information. In the ablated model, we remove the LSTM unit in our TD-GAT model, so that it cannot utilize the aspect target information explicitly. We denote this ablated model as GAT.

As shown in Table 3, explicitly capturing aspect target information consistently improves the performance of the TD-GAT-GloVe over the GAT-GloVe model. On average, the accuracy of TD-GAT-GloVe increased by 1.2 percentage points. Capturing aspect-related information explicitly across layer is also useful for the BERT-based model as well. Even though the target information has been embedded in the BERT representation because of the contextual language modeling, TD-GAT-BERT still outperforms the GAT-BERT model. On average, the explicit target information contributes 0.95 percentage points to the final performance of the TD-GAT-BERT.

Dataset	Laptop			Restaurant		
layer	3	4	5	3	4	5
GAT-GloVe	73.0	72.1	72.4	79.6	80.0	79.7
TD-GAT-GloVe	73.7	74.0	73.4	81.1	80.6	81.2
GAT-BERT	78.1	78.5	78.5	82.6	82.2	82.3
TD-GAT-BERT	79.3	79.8	80.1	82.9	83.0	82.8

Table 3: An ablation study shows the effect of explicit target information.

4.5 Effects of Model Depth

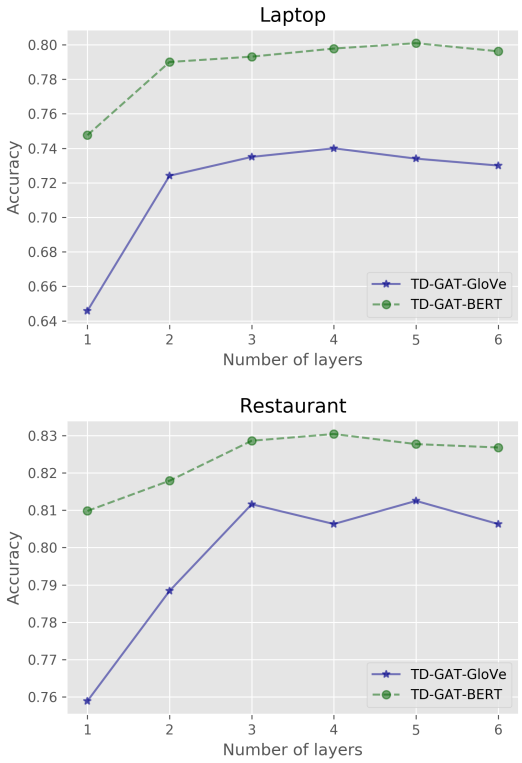

Figure 2: The impact of model depth (number of layers).

We explore the impact of model depth (number of layers) in this section. For our TD-GAT model, we vary its model depth ranging from 1 to 6. As shown in Figure 2, a one-layer TD-GAT model with GloVe embeddings does not work well, which implies target-related sentiment words are usually 2-hops away from the aspect target.

Increasing the model depth to 3 would greatly improve the performance of the TD-GAT-GloVe model.

Unlike the TD-GAT-GloVe model, our model with BERT representations are more robust to the model depth. Even a one-layer TD-GAT-BERT model still achieves satisfactory results on both datasets. One possible reason is that BERT representations already incorporate context words into these semantic representations. Hence nodes at one-hop away may consist of some global information. However, increasing the model depth still improve the performance in this case and our model reaches its optimal performance when model depth is larger than 3.

4.6 Model Size

We compare the model size of our TD-GAT model to various baseline methods as well as the BERT model. For these baseline methods, we use an open source PyTorch implementation [3] to measure their model sizes.

Models	Model size ($\times 10^6$)
TD-LSTM	1.45
MemNet (3)	**0.36**
IAN	2.17
AOA-LSTM	2.89
TD-GAT-GloVe (3)	1.00
TD-GAT-GloVe (4)	1.09
TD-GAT-GloVe (5)	1.18
BERT-CLS	335.14
TD-GAT-BERT (3)	**1.30**
TD-GAT-BERT (4)	1.39
TD-GAT-BERT (5)	1.49

Table 4: The model size (number of parameters) of our model as well as baselines.

The sizes of all these models are given in Table 4. Using the same dimension of hidden states, our TD-GAT-GloVe has a lower model size compared to these LSTM-based methods. MemNet is the model ranks the first in terms of the model size. The size of TD-GAT-BERT increases by 0.3×10^6 because of the linear projection layer applied on the input word representations. When we switch from GloVe embeddings to BERT representations, the training time for a three-layer TD-GAT model on the restaurant dataset only increases from 1.12 seconds/epoch to 1.15 seconds/epoch. On the contrary, fine-tuning the BERT model takes about 226.50 seconds for each training epoch. Training our TD-GAT-BERT model requires much fewer computation resources and less time compared to fine-tuning the original BERT model.

5 Conclusion

In this paper, we propose a novel target-dependent graph attention neural network for aspect level sentiment classification. It leverages the syntactic dependency structure of a sentence and uses the syntax context of an aspect target for classification. Compared to those methods applied on word sequences, our approach places modifying sentiment words closer to the aspect target and can resolve potential syntactic ambiguity. In our experiments, we demonstrate the effectiveness of our method on laptop and restaurant datasets from SemEval 2014. Using GloVe embeddings, our approach TD-GAT-GloVe outperforms various baseline models. After switching to BERT representations, we show that TD-GAT-BERT achieves much better performance. It is lightweight and requires fewer computational resources and less training time than fine-tuning the original BERT model.

To the best of our knowledge, this paper is the first attempt directly using the original dependency graph without converting its structure for aspect level sentiment classification. Many potential improvements could be made in this direction. In this work, the local feature vector of an aspect node is the average of embedding vectors of words in the aspect and each word in the aspect is equally important. Future work could consider using an attention mechanism to focus on important words in the aspect. Since this work only uses the dependency graph and ignores various types of relations in the graph, we plan to incorporate dependency relation types into our model and take part-of-speech tagging into consideration as well in the future. We would also like to combine such a graph-based model with a sequence-based model to avoid potential noise from dependency parsing errors.

Learning Explicit and Implicit Structures for Targeted Sentiment Analysis

Hao Li and **Wei Lu**
StatNLP Research Group
Singapore University of Technology and Design
hao_li@mymail.sutd.edu.sg
luwei@sutd.edu.sg

Abstract

Targeted sentiment analysis is the task of jointly predicting target entities and their associated sentiment information. Existing research efforts mostly regard this joint task as a sequence labeling problem, building models that can capture explicit structures in the output space. However, the importance of capturing implicit global structural information that resides in the input space is largely unexplored. In this work, we argue that both types of information (implicit and explicit structural information) are crucial for building a successful targeted sentiment analysis model. Our experimental results show that properly capturing both information is able to lead to better performance than competitive existing approaches. We also conduct extensive experiments to investigate our model's effectiveness and robustness[1].

1 Introduction

Targeted sentiment analysis (TSA) is an important task useful for public opinion mining (Pang and Lee, 2008; Liu, 2010; Ortigosa et al., 2014; Smailović et al., 2013; Li and Wu, 2010). The task focuses on predicting the sentiment information towards a specific target phrase, which is usually a named entity, in a given input sentence. Currently, TSA in the literature may refer to either of the two possible tasks under two different setups: 1) predicting the sentiment polarity for a given specific target phrase (Dong et al., 2014; Wang et al., 2016; Zhang et al., 2016; Xue and Li, 2018); 2) jointly predicting the targets together with the sentiment polarity assigned to each target (Mitchell et al., 2013; Zhang et al., 2015; Li and Lu, 2017; Ma et al., 2018). In this paper, we focus on the latter setup which was originally proposed by Mitchell et al. (2013). Figure 1 presents an example sentence containing three targets. Each target is associated with a sentiment, where we use $+$ for denoting positive polarity, 0 for neutral and $-$ for negative.

Figure 1: TSA with targets in bold and their associated sentiment on top. Boundaries for the sentiment scope are highlighted in dashed boxes.

Existing research efforts mostly regard this task as a sequence labeling problem by assigning a tag to each word token, where the tags are typically designed in a way that capture both the target boundary as well as the targeted sentiment polarity information together. Existing approaches (Mitchell et al., 2013; Zhang et al., 2015; Ma et al., 2018) build models based on conditional random fields (CRF) (Lafferty et al., 2001) or structural support vector machines (SSVM) (Taskar et al., 2005; Tsochantaridis et al., 2005) to explicitly model the sentiment information with structured outputs, where each targeted sentiment prediction corresponds to exactly one *fixed* output. While effective, such models suffer from their inability in capturing certain long-distance dependencies between sentiment keywords and their targets. To remedy this issue, Li and Lu (2017) proposed their "sentiment scope" model to learn flexible output representations. For example, three text spans with their corresponding targets in bold are presented in Figure 1, where each target's sentiment is characterized by the words appearing in the corresponding text span. They learn from data for each target a latent text span used for attributing its sentiment, resulting in *flexible* output structures.

However, we note there are two major limi-

[1]We release our code at http://www.statnlp.org/research/st.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5478–5488,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tations with the approach of Li and Lu (2017). First, their model requires a large number of handcrafted discrete features. Second, the model relies on a strong assumption that the latent sentiment spans do not overlap with one another. For example, in Figure 1, their model will not be able to capture the interaction between the target word "*OZ*" in the first sentiment span and the keyword "*amazing*" due to the assumptions made on the explicit structures in the output space. One idea to resolve this issue is to design an alternative mechanism to capture such useful structural information that resides in the input space.

On the other hand, recent literature shows that feature learning mechanisms such as self-attention have been successful for the task of sentiment prediction when targets are given (Wang and Lu, 2018; He et al., 2018; Fan et al., 2018) (i.e., under the first setup mentioned above). Such approaches essentially attempt to learn rich *implicit* structural information in the input space that captures the interactions between a given target and all other word tokens within the sentence. Such implicit structures are then used to generate sentiment summary representation towards the given target, leading to the performance boost.

However, to date capturing rich implicit structures in the joint prediction task that we focus on (i.e., the second setup) remains largely unexplored. Unlike the first setup, in our setup the targets are not given, we need to handle exponentially many possible combinations of targets in the joint task. This makes the design of an algorithm for capturing both implicit structural information from the input space and the explicit structural information from the output space challenging.

Motivated by the limitations and challenges, we present a novel approach that is able to efficiently and effectively capture the explicit and implicit structural information for TSA. We make the following key contributions in this work:

- We propose a model that is able to properly integrate both *explicit* and *implicit* structural information, called **EI**. The model is able to learn flexible explicit structural information in the output space while being able to efficiently learn rich implicit structures by LSTM and self-attention for exponentially many possible combinations of targets in a given sentence.
- We conducted extensive experiments to validate our claim that both explicit and implicit structures are indispensable in such a task, and demonstrate the effectiveness and robustness of our model.

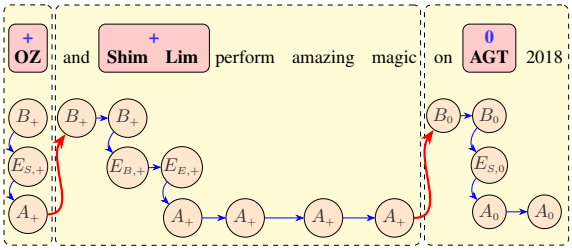

Figure 2: The structured output for representing entities and their sentiments with boundaries.

2 Approach

Our objective is to design a model to extract targets as well as their associated targeted sentiments for a given sentence in a joint manner. As we mentioned before, we believe that both explicit and implicit structures are crucial for building a successful model for TSA. Specifically, we first present an approach to learn flexible explicit structures based on latent CRF, and next present an approach to efficiently learn the rich implicit structures for exponentially many possible combinations of targets.

2.1 Explicit Structure

Motivated by Li and Lu (2017), we design an approach based on latent CRF to model flexible sentiment spans to capture better explicit structures in the output space. To do so, we firstly integrate target and targeted sentiment information into a label sequence by using 3 types of tags in our **EI** model: $\mathbf{B}_p$, $\mathbf{A}_p$, and $\mathbf{E}_{\epsilon,p}$, where $p \in \{+,-,0\}$ indicates the sentiment polarity and $\epsilon \in \{B,M,E,S\}$ denotes the *BMES* tagging scheme[2]. We explain the meaning of each type of tags as follows.

- $\mathbf{B}_p$ is used to denote that the current word is part of a sentiment span with polarity p, but appears before the target word or exactly as the first word of the target.

- $\mathbf{A}_p$ is used to denote that the current word is part of a sentiment span with polarity p, but appears after the target word or exactly as the last word of the target.

[2] *B* stands for the beginning of the target phrase, *M* for the middle, *E* for the end and *S* for a single-word target.

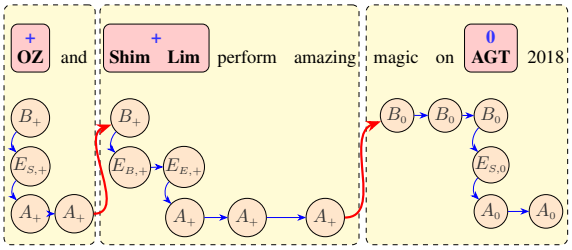

Figure 3: An alternative structured output for the same example with different sentiment boundaries.

- $\mathbf{E}_{\epsilon,p}$ is used to denote the current word is part of a sentiment span with polarity p, and is also a part of the target. The *BMES* sub-tag ϵ denotes the position information within the target phrase. For example, $\mathbf{E}_{B,+}$ represents that the current word appears as the first word of a target with the positive polarity.

We illustrate how to construct the label sequence for a specific combination of sentiment spans of the given example sentence in Figure 2, where three non-overlapping sentiment spans in yellow are presented. Each such sentiment span encodes the sentiment polarity in blue for a target in bold in pink square. At each position, we allow multiple tags in a sequence to appear such that the edge $\mathbf{A}_p\mathbf{B}_{p'}$ in red consistently indicates the boundary between two adjacent sentiment spans.

The first sentiment span with positive (+) polarity contains only one word which is also the target. Such a single word target is also the beginning and the end of the target. We use three tags $\mathbf{B}_+$, $\mathbf{E}_{S,+}$ and $\mathbf{A}_+$ to encode such information above.

The second sentiment span with positive (+) polarity contains a two-word target "*Shin Lim*". The word "and" appearing before such target takes a tag $\mathbf{B}_+$. The words "perform amazing magic" appearing after such target take a tag $\mathbf{A}_+$ at each position. As for the target, the word "Shin" at the beginning of the target takes tags $\mathbf{B}_+$ and $\mathbf{E}_{B,+}$, while the word "Lim" at the end of the target takes tags $\mathbf{E}_{E,+}$ and $\mathbf{A}_+$.

The third sentiment span with neutral (0) polarity contains a single-word target "AGT". Similarly, we use three tags $\mathbf{B}_0$, $\mathbf{E}_{S,0}$ and $\mathbf{A}_0$ to represent such single word target. The word "on" appearing before such target takes a tag $\mathbf{B}_0$. The word "2018" appearing afterwards takes a tag $\mathbf{A}_0$.

Note that if there exists a target with length larger than 2, the tag $\mathbf{E}_{M,p}$ will be used. For example in Figure 2, if the target phrase "Shin Lim" is replaced by "Shin Bob Lim", we will keep the tags at "Shin" and "Lim" unchanged. We assign a tag $\mathbf{E}_{M,+}$ at the word "Bob" to indicate that "Bob" appears in the middle of the target by following the *BMES* tagging scheme.

Finally, we represent the label sequence by connecting adjacent tags sequentially with edges. Notice that for a given input sentence and the output targets as well as the associated targeted sentiment, there exist exponentially many possible label sequences, each specifying a different possible combinations of sentiment spans. Figure 3 shows a label sequence for an alternative combination of the sentiment spans. Those label sequences representing the same input and output construct a latent variable in our model, capturing the flexible explicit structures in the output space.

We use a log-linear formulation to parameterize our model. Specifically, the probability of predicting a possible output $\mathbf{y}$, which is a list of targets and their associated sentiment information, given an input sentence $\mathbf{x}$, is defined as:

$$p(\mathbf{y}|\mathbf{x}) = \frac{\sum_{\mathbf{h}} \exp\left(s(\mathbf{x}, \mathbf{y}, \mathbf{h})\right)}{\sum_{\mathbf{y}', \mathbf{h}'} \exp(s(\mathbf{x}, \mathbf{y}', \mathbf{h}'))} \quad (1)$$

where $s(\mathbf{x}, \mathbf{y}, \mathbf{h})$ is a score function defined over the sentence $\mathbf{x}$ and the output structure $\mathbf{y}$, together with the latent variable $\mathbf{h}$ that provides all the possible combinations of sentiment spans for the $(\mathbf{x}, \mathbf{y})$ tuple. We define $E(\mathbf{x}, \mathbf{y}, \mathbf{h})$ as a set of all the edges appearing in all the label sequences for such combinations of sentiment spans. To compute $s(\mathbf{x}, \mathbf{y}, \mathbf{h})$, we sum up the scores of each edge in $E(\mathbf{x}, \mathbf{y}, \mathbf{h})$:

$$s(\mathbf{x}, \mathbf{y}, \mathbf{h}) = \sum_{e \in E(\mathbf{x}, \mathbf{y}, \mathbf{h})} \phi_{\mathbf{x}}(e)$$

where $\phi_{\mathbf{x}}(e)$ is a score function defined over an edge e for the input $\mathbf{x}$.

The overall model is analogous to that of a neural CRF (Peng et al., 2009; Do et al., 2010); hence the inference and decoding follow standard marginal and MAP inference procedures. For example, the prediction of $\mathbf{y}$ follows the Viterbi-like MAP inference procedure.

2.2 Implicit Structure

We propose a design for **EI** to efficiently learn rich implicit structures for exponentially many combinations of targets to predict. To do so, we explain the process to assign scores to each edge

e from our neural architecture. The three yellow boxes in Figure 4 compute scores for rich implicit structures from the neural architecture consisting of LSTM and self-attention.

Given an input token sequence $\mathbf{x} = \{x_1, x_2, \cdots, x_n\}$ of length n, we first compute the concatenated embedding $\mathbf{e}_k = [\mathbf{w}_k; \mathbf{c}_k]$ based on word embedding $\mathbf{w}_k$ and character embedding $\mathbf{c}_k$ at position k.

As illustrated on the left part in Figure 4, we then use a Bi-directional LSTM to encode context features and obtain hidden states $\mathbf{h}_k = \text{BiLSTM}(\mathbf{e_1}, \mathbf{e_2}, \cdots, \mathbf{e_n})$. We use two different linear layers f_t and f_s to compute scores for target and sentiment respectively. The linear layer f_t returns a vector of length 4, with each value in the vector indicating the score of the corresponding tag under the *BMES* tagging scheme. The linear layer f_s returns a vector of length 3, with each value representing the score of a certain polarity of $+, 0, -$. We assign such scores to each type of edge as follows:

$$\phi_{\mathbf{x}}(\mathbf{E}^k_{\epsilon,p}\mathbf{E}^{k+1}_{\epsilon',p}) = f_t(\mathbf{h}_k)_\epsilon$$

$$\phi_{\mathbf{x}}(\mathbf{E}^k_{\epsilon,p}\mathbf{A}^k_p) = f_t(\mathbf{h}_k)_\epsilon$$

$$\phi_{\mathbf{x}}(\mathbf{B}^k_p\mathbf{B}^{k+1}_p) = f_s(\mathbf{h}_k)_p$$

$$\phi_{\mathbf{x}}(\mathbf{A}^k_p\mathbf{A}^{k+1}_p) = f_s(\mathbf{h}_k)_p$$

$$\phi_{\mathbf{x}}(\mathbf{A}^k_p\mathbf{B}^{k+1}_{p'}) = f_s(\mathbf{h}_k)_p$$

Note that the subscript p and ϵ at the right hand side of above equations denote the corresponding index of the vector that f_t or f_s returns. We apply f_t on edges $\mathbf{E}^k_{\epsilon,p}\mathbf{E}^{k+1}_{\epsilon',p}$ and $\mathbf{E}^k_{\epsilon,p}\mathbf{A}^k_p$, since words at these edges are parts of the target phrase in a sentiment span. Similarly, we apply f_s on edges $\mathbf{B}^k_p\mathbf{B}^{k+1}_p$,$\mathbf{A}^k_p\mathbf{A}^{k+1}_p$ and $\mathbf{A}^k_p\mathbf{B}^{k+1}_{p'}$, since words at these edges contribute the sentiment information for the target in the sentiment span.

As illustrated in Figure 4, we calculate $\mathbf{a}_k$, the output of self-attention at position k:

$$\mathbf{a}_k = \sum_{j=1}^{n} \alpha_{k,j}\mathbf{e}_j$$

$$\alpha_{k,j} = \underset{j}{\text{softmax}}(\beta_{k,j})$$

$$\beta_{k,j} = U^T \text{ReLu}(W[\mathbf{e}_k; \mathbf{e}_j] + b)$$

where $\alpha_{k,j}$ is the normalized weight score for $\beta_{k,j}$, and $\beta_{k,j}$ is the weight score calculated by target

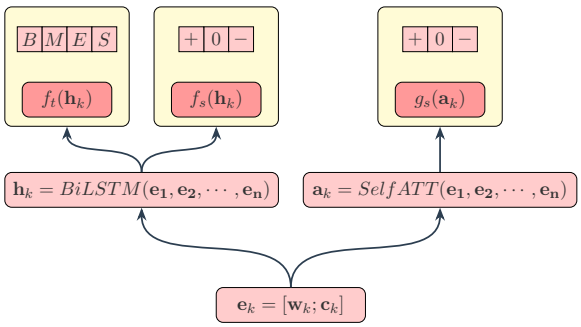

Figure 4: Neural Architecture

representation at position k and contextual representation at position j. In addition, W and b as well as the attention matrix U are the weights to be learned. Such a vector $\mathbf{a}_k$ encodes the implicit structures between the word x_k and each word in the remaining sentence.

Motivated by the character embeddings (Lample et al., 2016) which are generated based on hidden states at two ends of a subsequence, we encode such implicit structures for a target similarly. For any target starting at the position k_1 and ending at the position k_2, we could use $\mathbf{a}_{k_1}$ and $\mathbf{a}_{k_2}$ at two ends to represent the implicit structures of such a target. We encode such information on the edges $\mathbf{B}^{k_1}_p\mathbf{E}^{k_1}_{\epsilon,p}$ and $\mathbf{E}^{k_2}_{\epsilon,p}\mathbf{A}^{k_2}_p$ which appear at the beginning and the end of a target phrase respectively with sentiment polarity p. To do so, we assign the scores calculated from the self-attention to such two edges:

$$\phi_{\mathbf{x}}(\mathbf{B}^{k_1}_p\mathbf{E}^{k_1}_{\epsilon,p}) = g_s(\mathbf{a}_{k_1})_p$$

$$\phi_{\mathbf{x}}(\mathbf{E}^{k_2}_{\epsilon,p}\mathbf{A}^{k_2}_p) \mathrel{+}= g_s(\mathbf{a}_{k_2})_p$$

where g_s returns a vector of length 3 with scores of three polarities.

Note that $\mathbf{h}_k$ and $\mathbf{a}_k$ could be pre-computed at every position k and assigned to the corresponding edges. Such an approach allows us to maintain the inference time complexity $O(Tn)$, where T is the maximum number of tags at each position which is 9 in this work and n is the number of words in the input sentence. This approach enables **EI** to efficiently learn rich implicit structures from LSTM and self-attention for exponentially many combinations of targets.

3 Experimental Setup

Data

We mainly conduct our experiments on the datasets released by Mitchell et al. (2013). They

	#Target	#+	#−	#0
English	3,288	707	275	2,306
Spanish	6,658	1,555	1,007	4,096

(a) Statistics on polarity of named entities

Target length	1	2	3	>= 4
English	1,910	1,032	232	114
Spanish	4,201	1,794	417	246

(b) Statistics on target length

#Target	1	2	3	>= 4
English	1,692	465	135	58
Spanish	3,855	903	221	69

(c) Statistics on number of targets per sentence

Table 1: Corpus Statistics of Main Dataset

contain 2,350 English tweets and 7,105 Spanish tweets, with target and targeted sentiment annotated. See Table 1 for corpus statistics.

Evaluation Metrics

Following the previous works, we report the *precision* ($P.$), *recall* ($R.$) and F_1 scores for target recognition and targeted sentiment. Note that a correct target prediction requires the boundary of the target to be correct, and a correct targeted sentiment prediction requires both target boundary and sentiment polarity to be correct.

Hyperparameters

We adopt pretrained embeddings from Pennington et al. (2014) and Cieliebak et al. (2017) for English data and Spanish data respectively. We use a 2-layer LSTM (for both directions) with a hidden dimension of 500 and 600[3] for English data and Spanish data respectively. The dimension of the attention weight U is 300. As for optimization, we use the Adam (Kingma and Ba, 2014) optimizer to optimize the model with batch size 1 and dropout rate 0.5. All the neural weights are initialized by Xavier (Glorot and Bengio, 2010).

Training and Implementation

We train our model for a maximal of 6 epochs. We select the best model parameters based on the best F_1 score on the development data after each epoch. Note that we split 10% of data from the training data as the development data[4]. The selected model is then applied to the test data for evaluation. During testing, we map words not appearing in the training data to the *UNK* token. Following the previous works, we perform 10-fold cross validation and report the average results. Our models and variants are implemented using PyTorch (Paszke et al., 2017).

[3]We use a larger LSTM hidden size for Spanish since dimension of Spanish word embedding (200) is larger than dimension of English word embedding (100).

[4]Detailed split information is released with our code.

Baselines

We consider the following baselines:

- Pipeline (Zhang et al., 2015) and Collapse (Zhang et al., 2015) both are linear-chain CRF models using discrete features and embeddings. The former predicts targets first and calculate targeted sentiment for each predicted target. The latter outputs a tag at each position by collapsing the target tag and sentiment tag together.
- Joint (Zhang et al., 2015) is a linear-chain SSVM model using both discrete features and embeddings. Such a model jointly produces target tags and sentiment tags.
- Bi-GRU (Ma et al., 2018) and MBi-GRU (Ma et al., 2018) are both linear-chain CRF models using word embeddings. The former uses bi-directional GRU and the latter uses multi-layer bi-directional GRU.
- HBi-GRU (Ma et al., 2018) and HMBi-GRU (Ma et al., 2018) are both linear-chain CRF models using word embeddings and character embedding. The former uses bi-directional GRU and the latter uses multi-layer bi-directional GRU.
- SS (Li and Lu, 2017) and SS + *emb* (Li and Lu, 2017) are both based on a latent CRF model to learn flexible explicit structures. The former uses discrete features and the latter uses both discrete features and word embeddings.
- SA-CRF is a linear-chain CRF model with self-attention. Such a model concatenates the hidden state from LSTM and a vector constructed by self-attention at each position, and feeds them into CRF as features. The model attempts to capture rich implicit structures in the input space, but it does not put effort on explicit structures in the output space.
- **E-I** is a weaker version of **EI**. Such a model removes the *BMES* sub-tags in the **E** tag,

Table 2: Main Results. *fixed* stands for chain structures and *flexible* for latent structures. *discrete*, *emb* and *char* denote discrete features, word embeddings and character embeddings respectively. *SA* represents self-attention.

causing the model to learn less explicit structural information in the output space.

- **EI-** is a weaker version of **EI**. Such a model removes the self-attention from **EI**, causing the model to learn less expressive implicit structures in the input space.

4 Results and Discussion

4.1 Main Results

The main results are presented in Table 2, where explicit structures as well as implicit structures are indicated for each model for clear comparisons.

In general, our model **EI** outperforms all the baselines. Specifically, it outperforms the strongest baseline **EI-** significantly with $p < 0.01$ on the English and Spanish datasets in terms of F_1 scores[5]. Note that **EI-** which models flexible explicit structures and less implicit structural information, achieves better performance than most of the baselines, indicating flexible explicit structures contribute a lot to the performance boost.

Now let us take a closer look at the differences based on detailed comparisons. First of all, we compare our model **EI** with the work proposed by Zhang et al. (2015). The Pipeline model (based on CRF) as well as Joint and Collapse models (based on SSVM) in their work capture *fixed* explicit structures. Such two models rely on multi-layer perceptron (MLP) to obtain the local context features for implicit structures. These two models do not put much effort to capture better explicit structures and implicit structures. Our model **EI** (and even **EI-**) outperforms these two models significantly. We also compare our work with models in Ma et al. (2018), which also capture *fixed* explicit structures. Such models leverage different GRUs (single-layer or multi-layer) and different input features (word embeddings and character representations) to learn better contextual features. Their best result by HMBi-GRU is obtained with multi-layer GRU with word embeddings and character embeddings. As we can see, our model **EI** outperforms HMBi-GRU under all evaluation metrics. On the English data, **EI** obtains 6.50 higher F_1 score and 2.50 higher F_1 score on target recognition and targeted sentiment respectively. On Spanish, **EI** obtains 5.16 higher F_1 score and 0.50 higher F_1 score on target recognition and targeted sentiment respectively. Notably, compared with HMBi-GRU, even **EI-** capturing the flexible explicit structures achieves better performance on most of metrics and obtains the comparable results in terms of precision and F_1 score on Spanish. Since both **EI** and **EI-** models attempt to capture the *flexible* explicit structures, the comparisons above imply the importance of modeling such *flexible* explicit structures in the output space.

We also compare **EI** with **E-I**. The difference between these two models is that **E-I** removes the *BMES* sub-tags. Such a model captures less explicit structural information in the output space. We can see that **EI** outperforms **E-I**. Such results show that adopting *BMES* sub-tags in the output space to capture explicit structural information is beneficial.

Now we compare **EI** with SA-CRF which is a linear-chain CRF model with self-attention. Such a model attempts to capture rich implicit structures, and *fixed* explicit structures. The difference between **EI** and SA-CRF is that our model **EI** captures *flexible* explicit structures in the output space

[5]We have conducted significance test using the bootstrap resampling method (Koehn, 2004).

Model	Subj (+/-,o)			SA (+,-)		
	P.	*R.*	F_1	*P.*	*R.*	F_1
Zhang et al. (2015)	49.2	42.1	45.3	40.9	21.6	27.9
SS + *emb* (Li and Lu, 2017)	50.0	44.0	46.8	37.6	25.4	30.2
SA-CRF	44.8	45.2	44.9	35.2	25.6	29.3
EI-	49.7	45.8	47.6	**43.0**	24.9	30.2
EI	**50.5**	**46.5**	**48.4**	42.0	**25.6**	**31.5**

Table 3: Results on subjectivity as well as non-neutral sentiment analysis on the Spanish dataset. Subj(+/-,o): subjectivity for all polarities. SA(+,-): sentiment analysis for non-neutral polarities.

which model output representations as latent variables. We can see that **EI** outperforms SA-CRF on all the metrics. Such a comparison also implies the importance of capturing *flexible* explicit structures in the output space.

Next, we focus on the comparisons with SS (Li and Lu, 2017) and SS + *emb* (Li and Lu, 2017). Such two models as well as our models all capture the *flexible* explicit structures. As for the difference, both two SS models rely on hand-crafted discrete features to capture implicit structures, while our model **EI** and **EI-** learn better implicit structures by LSTM and self-attention. Furthermore, our models only require word embeddings and character embeddings as the input to our neural architecture to model rich implicit structures, leading to a comparatively simpler and more straightforward design. The comparison here suggests that LSTM and self-attention neural networks are able to capture better implicit structures than hand-crafted features.

Finally, we compare **EI** with **EI-**. We can see that the F_1 scores of targeted sentiment for both English and Spanish produced by **EI** are 0.95 and 0.97 points higher than **EI-**. The main difference here is that **EI** makes use of self-attention to capture richer implicit structures between each target phrase and all words in the complete sentence. The comparisons here indicate the importance of capturing rich implicit structures using self-attention on this task.

Robustness

Overall, all these comparisons above based on empirical results show the importance of capturing both *flexible* explicit structures in the output space and rich implicit structures by LSTM and self-attention in the input space.

We analyze the model robustness by assessing the performance on the targeted sentiment for targets of different lengths. For both English and Spanish, we group targets into 4 categories respectively, namely length of 1, 2, 3 and ≥ 4. Figure 5 reports the F_1 scores of targeted sentiment for such 4 groups on Spanish[6]. As we can see **EI** outperforms all the baselines on all groups.

Furthermore, following the comparisons in Zhang et al. (2015), we also measure the precision, recall and F_1 of subjectivity and non-neutral polarities on the Spanish dataset. Results are reported in Table 3[7]. The subjectivity measures whether a target phrase expresses an opinion or not according to Liu (2010). Comparing with the best-performing system's results reported in Zhang et al. (2015) and Li and Lu (2017), our model **EI** can achieve higher F_1 scores on subjectivity and non-neutral polarities.

Error Analysis

We conducted error analysis for our main model **EI**. We calculate F_1 scores based on the partial match instead of exact match. The F_1 scores for target partial match is 76.04 and 83.82 for English and Spanish respectively. We compare these two numbers against 63.48 and 71.17 which are the F_1 scores based on exact match. This comparison indicates that boundaries of many predicted targets do not match exactly with those of the correct targets. Furthermore, we investigate the errors caused by incorrect sentiment polarities. We found that the major type of errors is to incorrectly predict positive targets as neutral targets. Such errors contribute 64% and 36% of total errors for English and Spanish respectively. We believe they are mainly caused by challenging expressions in the tweet input text. Such challenging expressions such as "*below expectations*" are very sparse in the data, which makes effective learning for such phrases difficult.

4.2 Effect of Implicit Structures

In order to understand whether the implicit structures are truly making contributions in terms of the overall performance, we compare the performance among four models: **EI** and **EI-** as well as two variants **EI** (*i:MLP*) and **EI** (*i:Identity*) (where *i* indicates the implicit structure). Such two variants replace the implicit structure by other components:

[6] See the English results in the supplementary material.

[7] Only Spanish results are available in Zhang et al. (2015).

Model	English						Spanish					
	Target Recognition			Targeted Sentiment			Target Recognition			Targeted Sentiment		
	Prec.	Rec.	F_1	Prec.	Rec.	F_1	Prec.	Rec.	F_1	Prec.	Rec.	F_1
EI	**69.70**	**58.33**	**63.48**	**49.78**	**41.71**	**45.37**	**74.25**	**68.37**	**71.17**	**48.10**	**44.29**	**46.11**
EI (*i:MLP*)	64.47	56.58	60.20	46.23	40.48	43.12	70.95	65.80	68.27	43.64	40.46	41.98
EI (*i:Identity*)	63.24	55.73	59.20	45.10	39.79	42.24	69.38	66.27	67.77	43.66	41.68	42.63
EI-	68.67	57.52	62.54	48.73	40.89	44.42	72.62	66.97	69.61	47.06	43.45	45.14

Table 4: Effect of Implicit Structures

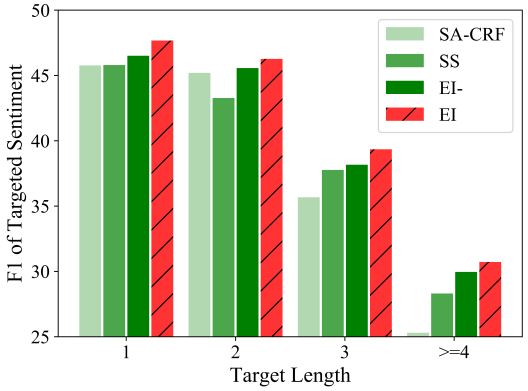

Figure 5: Results of different lengths on Spanish

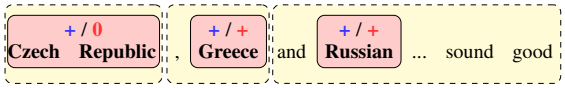

Figure 6: An example sentence in the test data.

- **EI** (*i:MLP*) replaces self-attention by multi-layer perceptron (MLP) for implicit structures. Such a variant attempts to capture implicit structures for a target phrase towards words restricted by a window of size 3 centered at the two ends of the target phrase.

- **EI** (*i:Identity*) replaces self-attention by an identity layer[8] as implicit structure. Such a variant attempts to capture implicit structures for a target phrase towards words at the two ends of the target phrase exactly.

Overall, those variants perform worse than **EI** on all the metrics. When the self-attention is replaced by MLP or the identity layer for implicit structures, the performance drops a lot on both target and targeted sentiment. Such two variants **EI** (*i:MLP*) and **EI** (*i:Identity*) consider the words within a small window centered at the two ends of the target phrase, which might not be capable of capturing the desired implicit structures. The **EI-** model capturing less implicit structural information achieves worse results than **EI**, but obtains better results than the two variants discussed above. This comparison implies that properly capturing implicit structures as the complement of explicit structural information is essential.

[8]The identity layer returns the identical input data.

4.3 Qualitative Analysis

We present an example sentence in the test data in Figure 6, where the gold targets are in bold, the predicted targets are in the pink boxes, the gold sentiment is in blue and predicted sentiment is in red. **EI** makes all correct predictions for three targets. **EI-** predicts correct boundaries for three targets and the targeted sentiment predictions are highlighted in Figure 6. As we can see, **EI-** incorrectly predicts the targeted sentiment on the first target as neural (0). The first target here is far from the sentiment expression "*sound good*" which is not in the first sentiment span, making **EI-** not capable of capturing such a sentiment expression. This qualitative analysis helps us to better understand the importance to capture implicit structures using both LSTM and self-attention.

4.4 Additional Experiments

We also conducted experiments on multi-lingual Restaurant datasets from SemEval 2016 Task 5 (Pontiki et al., 2016), where aspect target phrases and aspect sentiments are provided. [9] We regard each aspect target phrase as a target and assign such a target with the corresponding aspect sentiment polarity in the data. Note that we remove all the instances which contain no targets in the training data. Following the main experiment, we split 10% of training data as development set for the selection of the best model during training.

We report the F_1 scores of target and targeted sentiment for English, Dutch and Russian[10] respectively in Table 5. The results show that **EI**

[9]See the supplementary material for data statistics.

[10]We use the pretrained embedding for Dutch and Russian from https://github.com/Kyubyong/wordvectors.

achieves the best performance. The performance of SS (Li and Lu, 2017) is much worse on Russian due to the inability of discrete features in SS to capture the complex morphology in Russian.

5 Related Work

We briefly survey the research efforts on two types of TSA tasks mentioned in the introduction. Note that TSA is related to aspect sentiment analysis which is to determine the sentiment polarity given a target and an aspect describing a property of related topics.

Predicting sentiment for a given target

Such a task is typically solved by leveraging sentence structural information, such as syntactic trees (Dong et al., 2014), dependency trees (Wang et al., 2016) as well as surrounding context based on LSTM (Tang et al., 2016a), GRU (Zhang et al., 2016) or CNN (Xue and Li, 2018). Another line of works leverage self-attention (Liu and Zhang, 2017) or memory networks (Tang et al., 2016b) to encode rich global context information. Wang and Lu (2018) adopted the segmental attention (Kong et al., 2016) to model the important text segments to compute the targeted sentiment. Wang et al. (2018) studied the issue that the different combinations of target and aspect may result in different sentiment polarity. They proposed a model to distinguish such different combinations based on memory networks to produce the representation for aspect sentiment classification.

Jointly predicting targets and their associated sentiment

Such a joint task is usually regarded as sequence labeling problem. Mitchell et al. (2013) introduced the task of open domain targeted sentiment analysis. They proposed several models based on CRF such as the pipeline model, the collapsed model as well as the joint model to predict both targets and targeted sentiment information. Their experiments showed that the collapsed model and the joint model could achieve better results, implying the benefit of the joint learning on this task. Zhang et al. (2015) proposed an approach based on structured SVM (Taskar et al., 2005; Tsochantaridis et al., 2005) integrating both discrete features and neural features for this joint task. Li and Lu (2017) proposed the sentiment scope model motivated from a linguistic phenomenon to represent the structure information for both the targets and their associated sentiment polarities. They modelled the latent sentiment scope based on CRF with latent variables, and achieved the best performance among all the existing works. However, they did not explore much on the implicit structural information and their work mostly relied on hand-crafted discrete features. Ma et al. (2018) adopted a multi-layer GRU to learn targets and sentiments jointly by producing the target tag and the sentiment tag at each position. They introduced a constraint forcing the sentiment tag at each position to be consistent with the target tag. However, they did not explore the explicit structural information in the output space as we do in this work.

Model	English		Dutch		Russian	
	target	*sent*	*target*	*sent*	*target*	*sent*
SS (Li and Lu, 2017)	46.3	36.9	44.6	33.4	20.2	14.5

Table 5: F_1 scores of targets (*target*) and their associated sentiment (*sent*) on SemEval 2016 Restaurant Dataset.

6 Conclusion and Future Work

In this work, we argue that properly modeling both *explicit* structures in the output space and the *implicit* structures in the input space are crucial for building a successful targeted sentiment analysis system. Specifically, we propose a new model that captures explicit structures with latent CRF, and uses LSTM and self-attention to capture rich implicit structures in the input space efficiently. Through extensive experiments, we show that our model is able to outperform competitive baseline models significantly, thanks to its ability to properly capture both explicit and implicit structural information.

Future work includes exploring approaches to capture explicit and implicit structural information to other sentiment analysis tasks and other structured prediction problems.

Abstract

Aspect-level sentiment classification is a crucial task for sentiment analysis, which aims to identify the sentiment polarities of specific targets in their context. The main challenge comes from multi-aspect sentences, which express multiple sentiment polarities towards different targets, resulting in overlapped feature representation. However, most existing neural models tend to utilize static pooling operation or attention mechanism to identify sentimental words, which therefore insufficient for dealing with overlapped features. To solve this problem, we propose to utilize capsule network to construct vector-based feature representation and cluster features by an EM routing algorithm. Furthermore, interactive attention mechanism is introduced in the capsule routing procedure to model the semantic relationship between aspect terms and context. The iterative routing also enables encoding sentence from a global perspective. Experimental results on three datasets show that our proposed model achieves state-of-the-art performance.

1 Introduction

Aspect-level sentiment classification is a fine-grained task in the field of sentiment analysis (Pang and Lee, 2008; Liu, 2012), which aims to infer the sentiment polarity (e.g., positive, neutral, negative) of a sentence with respect to the aspect. It demands to differentiate sentiments towards different targets when there are multiple targets in one sentence. For example, given the mentioned aspect term {*food, price, drinks*}, and the sentence is *"The food was definitely good, but when all was said and done, I just could not justify it for the price including 2 drinks, $100/person."* For aspect term *food*, the sentimental polarity is positive, but for aspect term *price*, the polarity is negative while for aspect term *drinks*, the polarity is neutral. Recently, with the development of deep learning techniques, various neural networks are designed for this task and obtain promising results (Wang et al., 2016a; Ma et al., 2017; Fan et al., 2018).

The main challenge in aspect-level sentiment classification is that one sentence expresses multiple sentiment polarities, resulting in overlapped feature representation. Take the same example above, the sentence simultaneously reviews on 'food', 'price', and 'drinks', and expresses three different sentiment polarities. The highly overlapped features will confuse the classifier seriously. However, most existing methods only keep the most active feature by max-pooling operation or utilize attention mechanism to find the sentimental words, which fails to distinguish the overlapped features.

Therefore, we propose a novel capsule network and iterative EM routing method with interactive attention (IACapsNet) to solve this problem. Capsule network (Hinton et al., 2011; Sabour et al., 2017; Hinton et al., 2018) constructs vector-based feature representation. Capsules in adjacent layers are connected by dynamic routing, which shows strengths in distinguishing overlapped features by feature clustering (Sabour et al., 2017; Zhang et al., 2019). In the aspect-level sentimental classification task, the vector-based overlapped sentimental features towards different aspect terms will be clustered by an Expectation-Maximization (EM) routing algorithm, which makes the subsequent classification more clear. Furthermore, we further devise an interactive attention-based routing mechanism in order to highlight the word-level difference and model the semantic relationship between aspect terms and context.

Moreover, our iterative routing mechanism can

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5489–5498,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

be viewed as a top-down attention mechanism, which is more efficient because of the global perspective compared to the standard attention mechanism. Standard attention mechanism in this task only considers a part of the context information in a sentence without considering the overall meaning conveyed by the sentence, which may introduce noise and downgrade the prediction accuracy, especially for complex sentences. For example, in an ironic statement for the aspect term "mac os": "*Maybe the mac os improvement were not the product they want to offer.*", the standard attention mechanism will highlight the sentimental word '*improvement*' and confuse the classifier to make the wrong prediction to be positive. Our routing mechanism can tackle this by adjusting the contribution of each low-level capsule based on the high-level capsules (overall representation), and the iterative update makes the overall representation more accurate compared to other similar top-down attention (Liu et al., 2018; Zhao and Zhang, 2018).

Our proposed model (IACapsNet) is evaluated on three datasets: laptop, restaurant datasets from the SemEval 2014 Task 4 and Twitter collection. The experimental results show that our model outperforms other baseline methods and achieves state-of-the-art performance. Our contributions are summarized as follows:

- We apply capsule network to aspect-level sentiment classification to tackle the overlapped features by feature clustering. To the best of our knowledge, there is no work that investigates the performance of capsule network in this task.
- An interactive attention mechanism is introduced in the capsule routing to help model the semantic relationship between aspect term and context.

2 Related work

2.1 Aspect Level Sentiment Classification

Traditional approaches have designed rich features about content and syntactic structures to capture the sentiment polarity (Jiang et al., 2011; Pérez-Rosas et al., 2012). However, These feature-based methods are labor-intensive and the performance highly depends on the quality of the features. Recently, deep learning methods are becoming popular for aspect-level sentiment classification. Recurrent Neural Networks (RNNs) are the most commonly used technique for this task (Tang et al., 2016a). The attention mechanism is further introduced to model the target-context association (Wang et al., 2016b; Li et al., 2017; Ma et al., 2017). Furthermore, Fan et al. (2018) proposed MGAN to integrate fine-grained attention mechanisms, which is employed to characterize the word-level interactions between aspect and context words. Very recently, CNN-based models have shown the strengths in efficiency to tackle the aspect-level sentiment classification (Xue and Li, 2018; Huang and Carley, 2018; Li et al., 2018). However, all the previous methods utilize static pooling operation or attention mechanism to locate the sentimental words, which fails to handle the overlapped features. We introduces vector-based feature representation and feature clustering to address this.

2.2 Capsule Network

Capsule network was proposed to improve the representational limitations of CNN and RNN by extracting features in the form of vectors. The technique was firstly proposed in (Hinton et al., 2011) and improved in (Sabour et al., 2017; Hinton et al., 2018), which is mainly devised for image processing domain. Introducing capsules allows us to utilize a routing mechanism instead of pooling operation to generate high-level features which is a more efficient way for features encoding. Routing-by-agreement is able to cluster features in an iterative way, which achieved impressive performance recognizing highly overlapped digits.

Several types of capsule networks have been proposed for natural language processing. Yang et al. (2018) investigated capsule networks for text classification. They also found that capsule networks exhibit significant improvement when transferring single-label to multi-label text classification. Similar property has also been observed in the task of relation extraction (Zhang et al., 2019, 2018). However, interactive word-level attention is not considered in these typical capsule routing methods.

3 Model

In this section, we describe the proposed capsule network with interactive attention (IACapsNet) in details. The aim of aspect-level sentiment classification is to predict the sentiment class y of a

sentence over a specific aspect term, where $y \in \{positive, negative, neutral\}$. The overall architecture is shown in Figure 1. It consists of the input embedding layer, bidirectional RNN layer, primary capsule layer, and output layer.

3.1 Input Embedding Layer

The context's input representations of IACapsNet include word embeddings w_n and position embeddings p_n. The aspect term's input representation only consists of word embedding w_n^a.

Word embedding is a distributed representation of a word, where words from the vocabulary are mapped to vectors. Initializing words vectors via pre-trained word vectors can improve the performance due to their ability to capture syntactic and semantic information of words from large scale unlabeled text. In our model, we employ the pre-trained word vector GloVe (Pennington et al., 2014) to obtain the fixed word embedding $w_n, w_n^a \in \mathbb{R}^{d_w}$, where d_w is the word vector dimension.

Considering that the context words with closer distance to an aspect may have higher influence on the sentiment analysis, we introduce position embedding to encode the relative distance r_n from word w_n to the aspect term. We define the position embedding matrix $P \in \mathbb{R}^{d_p \times N}$, which is randomly initialized and updated during the training process. Here, d_p is the position embedding dimension and N denotes the length of the sentence. The corresponding word's position embeddings p_n can be obtained by looking up the position embedding matrix P using r_n.

The input representation for each context word is the concatenation of word embeddings and position embeddings: $x_n = [w_n; p_n] \in \mathbb{R}^{d_w + d_p}$.

3.2 Bidirectional Recurrent Networks Layer

The recurrent neural networks can capture long-distance dependencies within a sentence. A bidirectional recurrent neural network is the first layer of IACapsNet. The forward direction captures the left context h_l for a word and the backward direction captures the right context h_r. We concatenate the left context and the right context as the contextualized word representation h_n^c, $h_n^a \in \mathbb{R}^{2 \times d_l}$, where d_l is the dimension of hidden state, h^a and h^c are the word representations for aspect term and context, respectively.

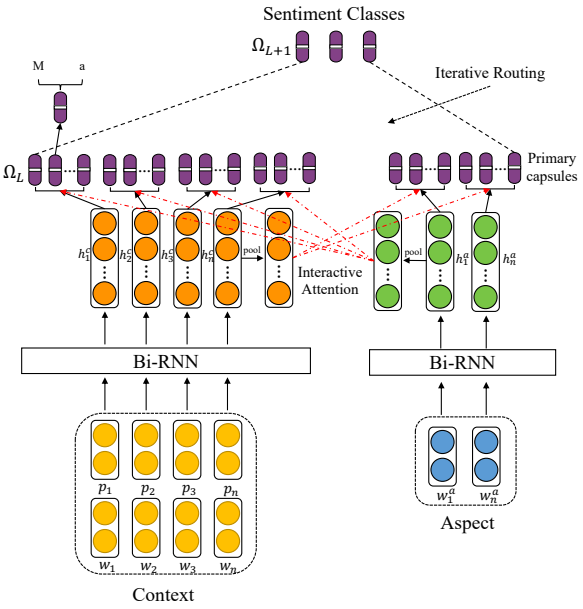

Figure 1: The architecture of IACapsNet

3.3 Primary Capsule Layer

The primary capsule is a group of neurons obtained from the output of the convolutional operation performed on h_n^a and h_n^c. So, the output of capsule is a vector representing different properties of the same objective. In aspect-level sentiment classification task, the properties may contain the sentiment and aspect term features.

EM-based routing method (Hinton et al., 2018) is implemented in our model, and except for the high-dimensional output M, there is one more activation probability $\boldsymbol{a}$ in our capsule, which is like the activity in a standard neural net (shown in Figure 1).

3.4 Interactive Attention EM Routing

We have already decided on the outputs of all the capsules Ω_L in primary capsule layer and we now want to decide which capsules Ω_{L+1} to active in the layer above and how to assign each active low-level capsule to one active higher-level capsule.

The vector-based features get clustered in the high-level capsules by an EM based algorithm where the outputs of high-level capsules play the role of Gaussians and the output vectors of low-level capsules play the role of the datapoints. The means, variances, and activation probabilities of the output capsules, as well as the assignment probabilities R of the input capsules are iteratively updated by alternating between an E-step and an M-step. It can also be viewed as a parallel atten-

tion mechanism in the opposite direction, which can adjust the low-level word's contribution based on the sentence global representation. Moreover, in order to model the semantic relationship between aspect term and context, we further devise an interactive attention-based routing mechanism.

3.4.1 M-step

The M-step holds the assignment probabilities R constant and adjusts each Gaussian (i.e. high-level capsules) to maximize the sum of the weighted log probabilities that the Gaussian would generate the datapoints (i.e. low-level capsules) assigned to it. This procedure aims to obtain the overall representation among the low-level capsules for a given iteration.

Firstly, every primary capsule i is transformed by W_{ij} to cast a vote $V_{ij} = M_i W_{ij}$ for the output of high-level capsule j. And we can get the mean μ_j of the votes from the input capsules and the variance σ_j about that mean for each dimension h:

$$\mu_j^h = \frac{\sum_i R_{ij} V_{ij}^h}{\sum_i R_{ij}}, \tag{1}$$

$$(\sigma_j^h)^2 = \frac{\sum_i R_{ij} (V_{ij}^h - \mu_j^h)^2}{\sum_i R_{ij}}, \tag{2}$$

where μ_j^h is the h^{th} component of the capsule j's vectorized output M_j.

The activation probability of capsule j is calculated by

$$cost_j^h = (\beta_u + log(\sigma_j^h)) \sum_i R_{ij}, \tag{3}$$

$$a_j = \text{sigmoid}(\lambda(\beta_\alpha - \sum_h cost_j^h)), \tag{4}$$

where β_u and β_α are trainable parameters denoting fixed cost per input capsule when not activating it and fixed cost for coding the mean and variance of capsule j when activating it. The variance σ reflects the degree of agreement. An intuitive understanding of this activation probability is that if the votes from low-level capsules are not agreed on one high-level capsule, the activation of the high-level capsule should be low. λ is an inverse temperature parameter set $1e{-}3$ with a fixed schedule.

3.4.2 E-step

The E-step adjusts the assignment probabilities R for each datapoint (i.e. low-level capsule) to the Gaussian (i.e. high-level capsules). This procedure aims to adjust the contribution of each capsule based on the high-level capsule (i.e. overall representation) for a given iteration.

We firstly compute the negative log probability density of the vectorized vote under the j's Gaussian distribution:

$$p_j = \frac{1}{\sqrt{\prod_h^H 2\pi(\sigma_j^h)^2}} \exp(-\sum_h^H \frac{(V_{ij}^h - \mu_j^h)^2}{2(\sigma_j^h)^2}). \tag{5}$$

For capsule i in primary capsule layer, the assignment probability is adjusted by:

$$R_{ij} = \frac{a_j p_j}{\sum_j a_j p_j}. \tag{6}$$

Alternating E-step and M-step will route the output of capsule to a capsule in the layer above that receives a cluster of high-dimensional features.

Algorithm 1 Interactive attention EM routing. Capsule i and j denote a low-level and high-level capsule. Ω_L and Ω_{L+1} denote the low-level and high-level capsules set, respectively.

end procedure

3.4.3 Interactive Attention

The overlapped features in primary capsule layer can be routed and clustered to high-level capsules in an iterative way. However, purely alternating the E-step and M-step will ignore the relationship between the context and aspect term. It has been demonstrated that target and context can determine the representation of each other. And the coordination of targets and their contexts can remarkably enhance the performance of sentiment classification (Ma et al., 2017; Fan et al., 2018). Word-level attention, which has already been demonstrated to be essential is also ignored. So, apart from the assignment probabilities, we further introduce an interactive attention weight α which is learned interactively between the context and the aspect term.

Specifically, we implement scaled dot-product attention which can be described as mapping a query and a set of key-value pairs to a weight on the word-level token. The queries are the averaged representation of the context h^c and the aspect term h^a which are transformed to dimension d_k by trainable parameters:

$$q_c = \frac{\sum_n^N h_n^c}{N} * W_c^q \in \mathbb{R}^{d_k}, \tag{7}$$

$$q_a = \frac{\sum_n^N h_n^a}{N} * W_a^q \in \mathbb{R}^{d_k}, \tag{8}$$

The keys are the corresponding words' representation from aspect term and context which are also transformed to dimension d_k:

$$k_n^c = h_n^c * W_c^k \in \mathbb{R}^{d_k}, \tag{9}$$

$$k_n^a = h_n^a * W_a^k \in \mathbb{R}^{d_k}, \tag{10}$$

where $W_c^q, W_a^q, W_c^k, W_a^k \in \mathbb{R}^{2d_l * d_k}$

The attention weights can be computed as follows:

$$s_n^{a\to c}(q_a, k_n^c) = \frac{k_n^c * q_a^\mathsf{T}}{\sqrt{d_k}}, \tag{11}$$

$$s_n^{c\to a}(q_c, k_n^a) = \frac{k_n^a * q_c^\mathsf{T}}{\sqrt{d_k}}, \tag{12}$$

$$\alpha_n^{a\to c} = \frac{\exp(s_n^{a\to c}(q_a, k_n^c))}{\sum_{n=1}^N \exp(s_n^{a\to c}(q_a, k_n^c))}, \tag{13}$$

$$\alpha_n^{c\to a} = \frac{\exp(s_n^{c\to a}(q_c, k_n^a))}{\sum_{n=1}^N \exp(s_n^{c\to a}(q_c, k_n^a))}. \tag{14}$$

In order to ensure a proper magnitude of s_n avoiding pushing the softmax function into regions where it has extremely small gradients, we introduce the scaling factor $\frac{1}{\sqrt{d_k}}$ following (Vaswani et al., 2017). We can thus get the word-level significance for each token in the context and aspect term in an interactive way, which will be adopted on each primary capsule's activation probability a. We detail the whole routing algorithm in Algorithm 1.

3.5 Training Objective

In IACapsNet, each top-level capsule corresponds to a sentiment category. The activation probability a of each top-level capsule represents the probability that the input sentence belongs to the corresponding category. We use a spread margin loss, L_k for each top-level capsule k to directly maximize the gap between the activation of the target class (a_t) and the activation of the other classes. The total loss L is simply the sum of the losses of all top-level capsules:

$$L = \sum_{k\neq t}(max(0, m - (a_t - a_k))^2, \tag{15}$$

where m is the margin which we set 0.9 with a fixed schedule.

4 Experiments

In this section, we conduct extensive experiments on three datasets to evaluate the proposed IACapsNet.

4.1 Experimental Setup

The experiments are implemented on three datasets. The first two datasets are from the SemEval 2014 Task 4 (Pontiki et al., 2014), which contains reviews about laptops and restaurants, respectively. The third one is a Twitter dataset collected by (Dong et al., 2014). The statistics of these datasets are listed in Table 2. Following (Tang et al., 2016c), conflict category is removed from the SemEval 2014 datasets to avoid datasets getting unbalanced. Sentences are zero-padded to the length of the longest sentence in respective dataset. Results are measured by accuracy and Macro-Averaged F1 score.

In our experiments, the pre-trained GloVe (Pennington et al., 2014) is used to initialize the word embeddings from context and aspect term. The

PBAN (Gu et al., 2018)	74.12	-	81.16	-	-	-
Cabasc (Liu et al., 2018)	75.07	-	80.89	-	71.53	-
IACapsNet	**76.80**	**73.29**	**81.79**	**73.40**	**75.01**	**73.81**

Table 1: Experimental results. The baseline results are retrieved from the original papers and (Li et al., 2018)

out-of-vocabulary words are initialized by sampling from the uniform distribution $U(-0.1, 0.1)$. In the Bi-RNN layer, LSTM is utilized and the dimension of the hidden state is 300. The dimension of the capsule's output is 16. We use Adam optimizer (Kingma and Ba, 2014) as our optimization method with $5e-4$ learning rate. L2 regularization and dropout are adopted to avoid overfitting.

Dataset	Positive		Neural		Negative

Restaurant	2164	728	637	196	807	196
Laptop	994	341	464	169	870	128
Twitter	1561	173	3127	346	1560	173

Table 2: Summary statistics of the datasets.

4.2 Model Comparisons

IACapsNet is compared with the following methods:

ATAE-LSTM(Wang et al., 2016a): An LSTM-based model which learns attention embeddings and combine them with the LSTM hidden states to predict the polarity.

TD-LSTM (Tang et al., 2016b): It employs two LSTMs to estimate the left context and the right context, respectively. The concatenated context representations perform the predictions.

IAN (Ma et al., 2017): An interactive attention is implemented on the representation of context and aspect learned by two LSTMs.

MemNet (Tang et al., 2016c): It applies attention mechanism over the word embeddings multiple times and predicts sentiment based on the topmost sentence representation.

RAM (Chen et al., 2017): Similar to MemNet, RAM is a multi-layer architecture where each layer consists of attention-based aggregation of word features and a GRU cell to learn the sentence representation.

BILSTM-ATT-G: (Zhang and Liu, 2017): It models left and right contexts using two attention-based LSTMs and introduces gates to measure the importance of left context, right context, and the entire sentence for the prediction.

MGAN (Fan et al., 2018): MGAN leverages the fine-grained and coarse-grained attention, which is further employed to characterize the word-level interactions between aspect and context words.

PBAN (Gu et al., 2018): PBAN concentrates on the position information of aspect terms and mutually models the relation between aspect term and sentence by employing bidirectional attention.

TNet (Li et al., 2018): It employs a CNN layer to extract salient features from the transformed word representations originated from a bi-directional RNN layer.

Cabasc (Liu et al., 2018): Cabasc employs sentence-level content attention mechanism to capture the important information about given aspects from a global perspective.

4.3 Main Results

As shown in Table 1, IACapsNet achieves the best performance on all the datasets. From Table 1, we can have the following observations.

ATAE-LSTM performs better than TD-LSTM.

One main reason may be the attention mechanism in TD-LSTM that enables to notice the important parts based on the aspect term. BILSTM-ATT-G adopts a similar architecture with TD-LSTM by modeling left context and right context using attention-based LSTM, which achieves better results than ATAE-LSTM. IAN and MGAN introduce the interactive attention in coarse-grained and multi-grained ways respectively and bring remarkable improvements. PBAN similarly utilize a fine-grained bidirectional attention and performs comparably with MGAN.

MemNet utilizes a more complex structure that contains nine computational layers, which updates the query vector at each hop. RAM also learns multiple attended vectors on the memory, which achieves superior results among the baseline models, especially on Laptop dataset.

Our proposed IACapsNet consistently performs best on all the three datasets. The improvement is mainly attributed to the feature clustering ability to tackle the overlapped features and the iteratively updating on coupling coefficients, which considers the overall meaning of the contexts. Moreover, compared with Cabasc, which also incorporates the overall representation to typical attention mechanism in a static way, our iterative method shows remarkable strengths.

4.4 Ablation Study

To analyze the effect of different components including the routing mechanism and the introduced interactive attention, we report the results of variants of IACapsNet. The results in Table 3 indicate: (1) EM routing based IACapsNet outperforms IACapsNet-Cosine, which routes capsules by cosine similarity (Sabour et al., 2017). One main reason maybe cosine saturates at 1, which is insensitive to the difference between a quite good agreement and a very good agreement. (2) Integrating interactive attention in routing mechanism brings a remarkable improvement on both routing mechanisms, which demonstrates the necessity to consider the relationship between the aspect and contexts during the routing procedure.

Moreover, EM routing also brings a boost on efficiency with fewer trainable parameters and faster speed which is intuitively shown in Table 4 (IAN is listed as baseline). From the table, it is easy to conclude that IACapsNet is much more efficient than IACapsNet-Cosine with about 10% and 36% decrease in the number of trainable parameters and running speed, respectively. Moreover, compared to IAN, IACapsNet achieves a much better accuracy with fewer trainable parameters, meaning that capsule network is more efficient in feature encoding with fewer parameters. However, IACapsNet costs more time compared to IAN, which is the implicit deficiency of capsule network because of the iterative calculation during routing.

4.5 Effects of Routing Iteration Number

As our proposed IACapsNet involves iterative procedure during routing. In this section, we investigate the effects of different routing iteration numbers. Specifically, we conduct experiments on all the three datasets and vary routing iteration numbers r from 1 to 4. The results are illustrated in Figure 3.

The results show that IACapsNet achieves the best performance at routing iteration number 2, 3 and 3 on the dataset RESTAURANT, LAPTOP, and Twitter, respectively. When the number of iteration is 1, our capsule network degrades to a standard network, which obtains comparable results with IAN. While increasing r to 4, the performance gets worse dramatically. Moreover, as the number of iteration increases to 4, it brings many difficulties to train IACapsNet. The model becomes more sensitive, which fluctuates greatly in loss and accuracy during training. Therefore, it is appropriate to limit the routing iteration number r and set it to be 2 or 3 depending on the performance.

Model	Accuracy	Macro-F1
IACapsNet-cosine routing	81.12	72.05
-w/o interactive attention	80.64	71.76
IACapsNet-EM routing	**81.79**	**73.40**
-w/o interactive attention	80.89	71.84

Table 3: Ablation study on Restaurant dataset. Cosine routing denotes routing measured by cosine similarity (Sabour et al., 2017), and w/o means without.

4.6 Case Study

In order to assess the effect of our EM routing with interactive attention mechanism, we visualize the coupling coefficients. Our model is able to adjust the contribution of each part based on the global meaning of a sentence and shows superiority in modeling complicated sentence. In this section, we pick an example from RESTAURANT dataset

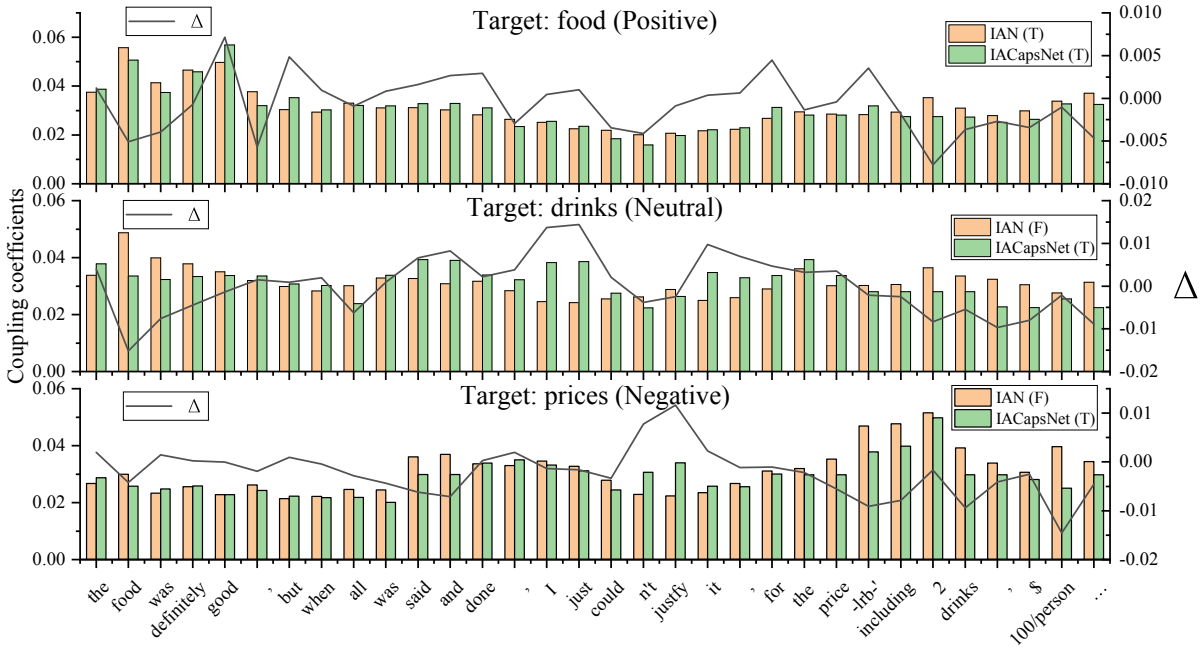

Figure 2: Routing Visualization

Model	Para.	Train	Infer.
IAN (Ma et al., 2017)	5.057	**0.11**	**0.017**
IACapsNet-cosine routing	4.614	0.33	0.044
IACapsNet	**4.189**	0.21	0.024

Table 4: Evaluation of efficiency. "Para." denotes the number of trainable parameters (M). "Train" and "Infer." denotes the training speed and inference speed(second/step). Speed is measured on 1 NVIDIA p100 GPU with batch size 64.

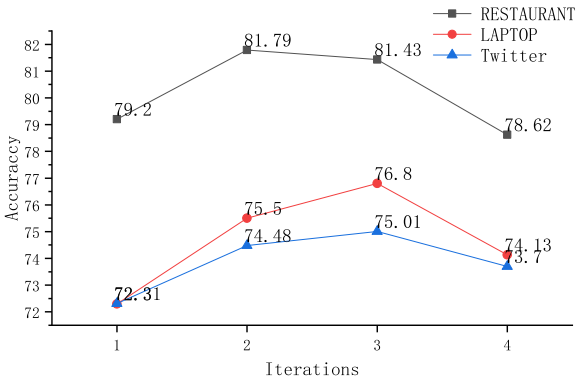

Figure 3: Effects of Routing Iteration Number

consisting of a long and complicated sentence and 3 aspect terms with 3 different sentimental polarities. Figure 2 shows this example and the visualization results of word-level coupling coefficients which are the sum of one word's coupling coefficients to the category. The attention weights from IAN are also shown as a baseline, which is normalized to the same scale with routing coupling coefficients. The line in the chart reflects the difference Δ. 'F' in Figure 2 means false sentiment classification, and 'T' means correct classification.

From the figure, we can observe that our routing methods can adjust the attended words according to different aspect terms, which helps make all the predictions correctly. Moreover, our routing method can locate on the more important words more efficiently. For example, in terms of the aspect 'price', the words "n't" and "justify" is attended, which are the corresponding essential sentimental words. However, they are ignored by the ordinary attention mechanism, which leads a wrong prediction. This shows that our routing mechanism can capture important parts of a sentence more accurately.

4.7 Conclusion and Future Work

We re-examine the deficiencies of existing models with attention mechanism for aspect-level sentiment classification. And we propose to utilize capsule network to handle the overlapped sentiment features by features clustering, and iteratively adjust the attention weights from a global perspective. To the best of our knowledge, capsule network is firstly applied in this task. Moreover, interactive attention is introduced to the dynamic rout-

ing to model the semantic relationship between aspect term and sentence. The experimental results verify that IACapsNet outperforms baseline models. The ablation and case studies show the efficacy of different proposed modules.

In the future, our theory can be generalized to other tasks that highly depends on the attention mechanism. For example, reading comprehension and machine translating.

Abstract

There have been a recent line of works to automatically predict the emotions of posts in social media. Existing approaches consider the posts individually and predict their emotions independently. Different from previous researches, we explore the dependence among relevant posts via the authors' backgrounds, since the authors with similar backgrounds, e.g., *gender*, *location*, tend to express similar emotions. However, such personal attributes are not easy to obtain in most social media websites, and it is hard to capture attributes-aware words to connect similar people. Accordingly, we propose a Neural Personal Discrimination (NPD) approach to address above challenges by determining personal attributes from posts, and connecting relevant posts with similar attributes to jointly learn their emotions. In particular, we employ adversarial discriminators to determine the personal attributes, with attention mechanisms to aggregate attributes-aware words. In this way, social correlationship among different posts can be better addressed. Experimental results show the usefulness of personal attributes, and the effectiveness of our proposed NPD approach in capturing such personal attributes with significant gains over the state-of-the-art models.

1 Introduction

The advent of social media and its prosperity enable the creation of massive online user-generated content including opinions and product reviews. Analyzing such user-generated contents allows to detect the users' emotional states, which are useful for various downstream applications.

In the literature, there are a large number of works on emotion detection (Roberts et al., 2012; Abdul-Mageed and Ungar, 2017; Gupta et al., 2017), both discrete and neural models have been used to predict the emotions of posts in social media. For example, Roberts et al. (2012) used a series of binary SVM classifiers to detect the emotion of a post, while Gupta et al. (2017) used sentiment based semantic embedding and a LSTM model to learn the representation of a post for emotion detection.

Different from previous researches, which consider each post individually, we think that posts in social media are much correlated by the authors' backgrounds. Motivated by the *principle of homophily* (Lazarsfeld et al., 1954), the idea that similarity and connection tend to co-occur, or "birds of a feather flock together", suggests that users, connected by mutual personal backgrounds, may hold similar opinions toward a post (Thelwall, 2010). In the literature, the personal attributes, such as gender, location, age, have been proved useful in personal background construction (Li et al., 2016): people with different attributes tend to express their emotions through different ways. For example, the *happiness* emotion in [E1] is expressed through some femininity sense words, such as "little brother", "handsome", while the *happiness* emotion in [E2] is expressed using a dialectal word "bashi(*comfortable*)", which contains strong characteristic of the Sichuan dialect[1]. Therefore, it is necessary to jointly detect the emotion of posts with the personal attributes.

> **[E1]** 祝贺中国男篮夺冠，新疆小哥哥，真是帅。
> (*Congratulations to Chinese basketball team on becoming the champion, the little brother of Xinjiang is really handsome.*)

* corresponding auther

[1]Sichuan is a southwest province in China, Sichuan dialect(Sichuanese) is quite specific and different from standard Mandarin.

[E2] 这种天气吃这个真是巴适！
(*It is just bashi to eat this in such weather!*)

However, the personal attributes are not easy to obtain in most social media websites. On one hand, most websites may not contain useful personal information. On the other hand, people are normally not willing to attach their personal information in social media. Besides, integrating personal attributes into emotion detection is challenging, since it is hard to capture attributes-aware words, such as "little brother" and "bashi"(*comfortable*), to connect the posts with similar backgrounds. Although there are some related works on either personal attribute extraction (Wang et al., 2014) or emotion detection with personal attributes (Li et al., 2016), none of them address both challenges at the same time.

In this paper, we propose a Neural Personal Discrimination (NPD) model with both adversarial discriminators and attention mechanisms to tackle above challenges. Here, the *Adversarial discriminators* (Goodfellow et al., 2014) are used to determine the personal attributes, e.g., gender or location, of a post, providing the inherent correlationship between emotions and personal backgrounds, while the *Attention mechanisms* (Wang et al., 2016) are utilized to aggregate the representation of informative attributes-aware words into a vector for emotion prediction, providing insights into which words contribute to a personal background. Experimental results show the usefulness of personal attributes in emotion detection, and the effectiveness of our proposed NPD model with both adversarial discriminators and attention mechanisms over the state-of-the-art discrete and neural models.

2 Related Work

Earlier works on emotion detection are based on discrete models. For example, Yang et al. (2007) built a support vector machine (SVM) model and a conditional random field (CRF) model for the emotion detection. Bhowmick et al. (2009) used a multi-label kNN model to classify a new sentence into multiple emotion categories. Quan et al. (2015) proposed a logistic regression model for social emotion detection. Recently, with the development of artificial intelligence, neural network models have been successfully applied to various NLP tasks (Collobert et al., 2011; Goldberg, 2016). However, few works use neural network models for emotion detection. Abdul-Mageed and Ungar (2017) used a gated recurrent neural network model for emotion detection with a large-scale dataset. Zhang et al. (2018) used an auxiliary and attention based LSTM to detect emotion on a cross-lingual dataset.

Lexicon and social information are very important for emotion detection, and there are many researches focus on this topic. For example, Strapparava and Mihalcea (2008) used WordNet-Affect to compute the sentimental score of a post. More recently, In addition, Hovy (2015) used both the age and gender information of the authors to improve the performance of sentiment analysis. Vosoughi et al. (2016) explored the relationship among locations, date time, authors and sentiments.

Different from previous works which consider each post individually, we think that the posts in social media can be connected through the authors' backgrounds and should be better addressed. On the basis, we propose a neural personal discrimination model to determine the personal background attributes from each post through adversarial discriminators, and aggregate the representation of informative attributes-aware words through attention mechanisms.

3 Vanilla Model for Emotion Detection

In this section, we propose a vanilla model. In the next section, we show how to utilize the neural personal discrimination model to improve the vanilla model by capturing personal attributes.

3.1 Document Representation

In general, we denote a post as a document d with n words $\{w_1, w_2, ..., w_n\}$. Given the post, we use a standard Long Short-Term Memory (LSTM) model to learn the shared document representation. Specially, we transform each token w_i into a real-valued vector x_i using the word embedding vector of w_i, obtained by looking up a pre-trained word embedding table D via the skip-gram algorithm to train embeddings (Mikolov et al., 2013). We then employ the LSTM model over d to generate a hidden vector sequence $\{h_1, h_2, ..., h_n\}$. At each step t, the hidden vector h_t of the LSTM model is computed based on the current vector x_t and the previous vector h_{t-1} with $h_t = \text{LSTM}(x_t, h_{t-1})$. The initial state and all stand LSTM parameters are randomly initialized and

tuned during training.

3.2 Multi-label Emotion Detection

Emotion detection aims to predict the emotion labels of posts. We follow (Wang et al., 2016) which adopts five kinds of emotions[2] in the study. Since there may be more than one emotion in a post, emotion detection can be considered as a multi-label classification task: we use K emotion-specific binary perceptions ($K = 5$) to predict if the post has the corresponding emotion or not. The advantage of multi-label classification is that it learns and predicts all the emotion labels jointly.

Formally, giving an input vector H, a hidden layer is first used to induce a set of high-level features for each emotion j:

$$\tilde{H}^j = \sigma(W^j H + b^j), \quad (1)$$

and then, H^j is used as inputs to a softmax output layer:

$$\hat{y}^j = \text{softmax}(\tilde{W}^j \tilde{H}^j + \tilde{b}^j) \quad (2)$$

Here, W^j, b^j, $\tilde{W}^j$, and $\tilde{b}^j$ are model parameters.

3.3 Training

Given the word sequence in a post, our training objective is to minimize the cross-entropy loss over a set of training examples $(x_i, y_i)|_{i=1}^N$, with a ℓ_2-regularization term,

$$J_y(\theta_y) = -\sum_{i=1}^{N}\sum_{j=1}^{K} y_i^j \log \hat{y}_i^j + \frac{\lambda}{2}||\theta_y||^2 \quad (3)$$

where y_i^j represents the label of the j-th emotion for x_i, θ_y is the set of model parameters and λ is the parameter for ℓ_2 regularization.

In this paper, the model parameters are optimized by AdaGrad (Duchi et al., 2011), and Skip-gram algorithm (Mikolov et al., 2013) is used for word embedding.

4 Neural Personal Discrimination Model

The drawback of above vanilla model is that it does not consider the deep personal correlationship among different posts.

[2]The five emotions include *happiness*, *sadness*, *anger*, *fear*, and *surprise*, please refer to "Experiments Section" of the paper for more details.

In this study, we think that the posts in social media can be connected through the authors' backgrounds. Therefore, we propose a Neural Personal Discrimination (NPD) model to connect people and learn their emotions collectively. We use *adversarial discriminators* to determine the personal attributes to construct the personal profiles, and employ *attention mechanisms* to aggregate attributes-aware words. In this way, the social correlationship between different posts can be well addressed.

Figure 1 illustrates our proposed neural personal discrimination model for emotion detection. In particular, we first learn the representation of each post using a LSTM model, same as the vanilla joint model. Then, we use adversarial discriminators to determine the personal attributes of each post. Finally, we employ attention mechanisms to aggregate the representation of informative attributes-aware words into a vector for the emotion prediction. In the following of this section, we illustrate the details of the infrastructure one by one.

4.1 Personal Adversarial Discriminators

A straightforward way to jointly detect personal attributes and the emotion of a post is to treat emotion detection as a multi-label classification. However, such model may not be able to separate the posts from different attributes directly, and thus fail to learn the correlationship between the emotion of a post and the personal backgrounds of the authors. To address this issue, we utilize adversarial discriminators to determine the personal attributes of the authors, and to learn the emotion and the attributes of the authors collectively. Adversarial networks have achieved much success in various studies, especially in image and text generation (Goodfellow et al., 2014; Wang and Wan, 2018; Fedus et al., 2018). In this part, we propose two adversarial discriminators, i.e, a gender discriminator and a location discriminator, to determine the personal attributes of each post.

Gender Discriminator. The gender discriminator is employed to determine the author's gender of each post. Let $g_i \in [0, 1]$ represents the probability of the gender label (female or male) for the gender discriminator, and f is the function parameterized by θ_f which maps an embedding vector to a hidden representation h_i^g from the post x_i. Here, the gender discriminator $G(h_i^g; \theta_g) \rightarrow \hat{g}_i$ param-

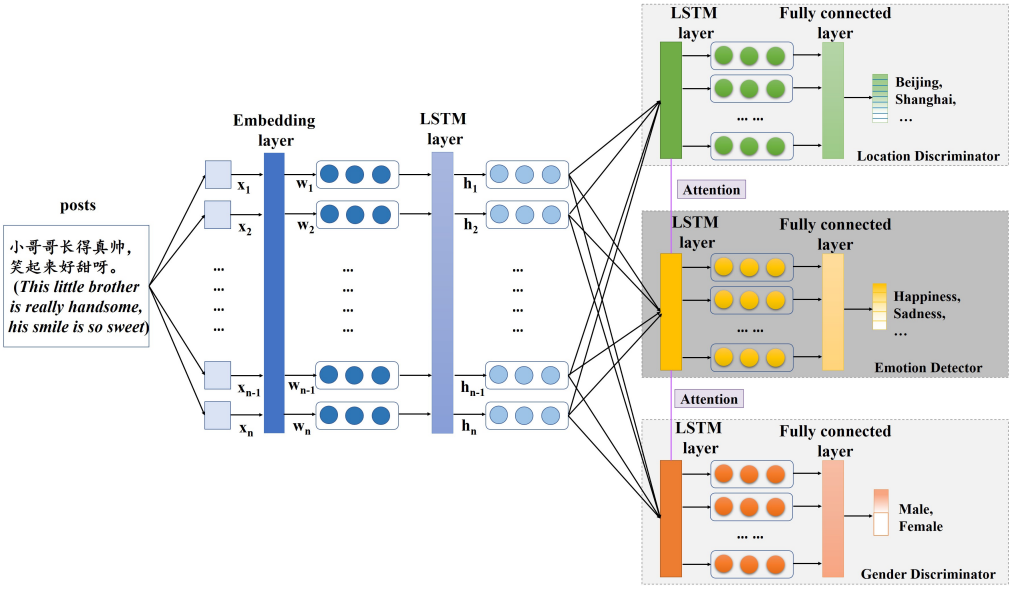

Figure 1: Overview of the neural personal discrimination model.

eterized by θ_g maps a hidden representation vector h_i^g to a predicted gender label $\hat{g}_i$ with the loss function is:

$$J_{gend} = \sum_{i=1}^{N} \{g_i \log \hat{g}_i + (1-g_i) \log(1-\hat{g}_i)\}, \quad (4)$$

where $\hat{g}_i = G(f(x_i))$.

In this study, the gender discriminator is trained towards a saddle point of the loss function through maximizing the loss over θ_g while minimizing the loss over θ_f (Ganin et al., 2017).

Location Discriminator. The location discriminator is employed to determine the authors' location of a post[3]. Let $\ell_i^j \in [0,1]$ represents probability of the j-th location information of the i-th post and $j \in \{1, 2, \ldots, m\}$, where, m is the number of provinces. The loss function is:

$$J_{loc} = \sum_{i=1}^{N} \sum_{j=1}^{m} \ell_i^j \log \hat{\ell}_i^j, \quad (5)$$

where, $\hat{\ell}_i^j = L(f(x_i))$ and $L(h_i^\ell; \theta_\ell)$ are the parameters of the location discriminator, $h_i^\ell = f(x_i)$ is the hidden represent from the post x_i

From the optimization of both discriminators, we can find that both h^g and h^ℓ represent the latent feature representation of posts, which integrate the discrimination of various personal information. With the goal at $G(\theta_g)$ and $L(\theta_\ell)$ try best to determine the gender and location of the authors. The adversarial network makes use of min-max optimization.

[3]In this study, location discriminator is used to detect the author's province of a post.

4.2 Personal Attention Mechanisms

In emotion detection, not all words contribute equally to the representation of emotions and personal attributes. Hence, we employ attention mechanisms to extract the words that are important to the personal backgrounds of posts, and to aggregate the representations of those informative attributes-aware words. With regard to the two adversarial discriminators, we propose attention mechanisms to build two representation (v^g and v^ℓ) from the gender and location discriminators respectively, and then concatenate them together to construct the overall personal representation through the informative attributes-aware words .

Gender Attention. We use an attention function to aggregate the gender-aware representation of the salient words to formulate the gender attention vector v^g. Here, the gender attention model outputs a continuous vector $v^g \in \mathbb{R}^{d \times 1}$ recurrently by feeding the hidden representation vectors $\{h_1^g, h_2^g, \cdots, h_{n_t}^g\}$ as inputs. Specifically, v^g is computed as a weighted sum of h_i^g $(0 \leq i \leq n_t)$, namely

$$v^g = \sum_{i}^{n_t} \alpha_i h_i^g \quad (6)$$

where n_t is the hidden variable size, $\alpha_i \in [0,1]$ is the weight of h_i^g, and $\sum_i \alpha_i = 1$. For each

piece of hidden state h_i^g, the scoring function is calculated as follows:

$$v_i^g = \tanh(W_g h_i^g + b^g) \tag{7}$$

$$\alpha_i = \frac{\exp(v^g)}{\sum_j \exp(v_j^g)} \tag{8}$$

Location Attention. Similar with the gender attention mechanism, the location attention model outputs a continuous vector $v^\ell \in \mathbb{R}^{d\times 1}$ recurrently by feeding the hidden representation vectors $\{h_1^\ell, h_2^\ell, \cdots, h_{n_k}^\ell\}$ as inputs. Specifically, v^ℓ is computed as a weighted sum of h_i^ℓ $(0 \le i \le n_t)$, namely

$$v^\ell = \sum_i^{n_k} \beta_i h_i^\ell \tag{9}$$

$$v_i^\ell = \tanh(W_\ell h_i^\ell + b^\ell) \tag{10}$$

$$\beta_i = \frac{\exp(v^\ell)}{\sum_j \exp(v_j^\ell)} \tag{11}$$

where, n_k is the location hidden variable size, and β_i is the same setting as α_i.

Finally, we concatenate v^g and v^ℓ to capture the overall personal representation through all the personal attributes discriminators.

$$V = v^g \oplus v^\ell \tag{12}$$

4.3 Adversarial Training with Neural Personal Discrimination

The proposed NPD model can be trained in a end-to-end manner once we obtain the loss function of the emotion detector and the attribute discriminators. Our ultimate training goal is to minimize the loss function with parameters $\theta = \{\theta_f, \theta_y, \theta_g, \theta_\ell\}$ as follow:

$$J(\theta) = \lambda_1 J_y + \lambda_2 J_{gend} + \lambda_3 J_{loc} \tag{13}$$

Whereλ_1, λ_2 and λ_3 are the weight parameters to balance the importance of losses between the emotion detection and the two personal attribute discriminators.

Specifically, Eq. 13 is defined by finding a saddle point $\hat{\theta}_y, \hat{\theta}_f, \hat{\theta}_g, \hat{\theta}_\ell$ such that

$$(\hat{\theta}_f, \hat{\theta}_y) = \arg\min_{\theta_f, \theta_y} J(\theta_f, \theta_y, \hat{\theta}_g, \hat{\theta}_\ell) \tag{14}$$

$$\hat{\theta}_g = \arg\max_{\theta_g} J(\hat{\theta}_f, \hat{\theta}_y, \theta_g, \hat{\theta}_\ell) \tag{15}$$

$$\hat{\theta}_\ell = \arg\max_{\theta_\ell} J(\hat{\theta}_f, \hat{\theta}_y, \hat{\theta}_g, \theta_\ell) \tag{16}$$

As suggested previously, a saddle point is defined by Eq. 14−Eq. 16, and can be achieved as a stationary point the gradient updates:

$$\theta_f \leftarrow \theta_f - \mu(\lambda_1 \frac{\partial J_y^i}{\partial \theta_f} - \lambda_2 \frac{\partial J_{gend}^i}{\partial \theta_f} - \lambda_3 \frac{\partial J_{loc}^i}{\partial \theta_f}) \tag{17}$$

$$\theta_y \leftarrow \theta_y - \mu\lambda_1 \frac{\partial J_y^i}{\partial \theta_y} \tag{18}$$

$$\theta_g \leftarrow \theta_g - \mu\lambda_2 \frac{\partial J_{gend}^i}{\partial \theta_g} \tag{19}$$

$$\theta_\ell \leftarrow \theta_\ell - \mu\lambda_3 \frac{\partial J_{loc}^i}{\partial \theta_\ell} \tag{20}$$

where μ is the learning rate.

5 Experimentation

5.1 Experimental Settings

We collect the data from *Weibo.com*, one of the most popular SNS websites in China. We crawl all the posts and corresponding personal profiles from the website. The dataset contains 11,157 microblog posts from 839 users. We employed six graduated students to annotate the corpus with a well-defined annotation guideline. Every two annotators annotate a same part of corpus, if they have disagreement on some posts, we ask another annotator to vote with them. The annotation guideline is based on Lee et al. (2013). Five basic emotions are annotated, namely *happiness*, *sadness*, *fear*, *anger* and *surprise* (Lee et al., 2013; Wang et al., 2017). Table 1 illustrates the statistics of each emotion. From the table, we find that the frequency of *happiness* and *sadness* are similar. Moreover, the frequency of *fear* and *anger* is much less than other three emotions.

We randomly select 70% posts as the training data, and remaining 30% posts as the test data. For evaluation, F1-measure is used to evaluate the performance of proposed model in each emotion. Average F1-measure is used to evaluate the overall performance of all emotions.

The setting of hyper-parameters is: vocabulary size is 2000, batch size is set to 32, dropout ratio is 0.2, learning rate μ is set 0.0001, and $\lambda_1 : \lambda_2 : \lambda_3 = 1 : 1 : 1$

Table 2: Experimental results of different models.

Method	F1.					
	Happiness	Sadness	Anger	Surprise	Fear	Average
SVM	0.628	0.462	0.390	0.117	0.091	0.338
Abdul17	0.656	0.492	0.429	0.103	0.111	0.358
Vaswani17	0.644	0.494	0.392	0.113	0.121	0.353
NPD	**0.657**	**0.510**	**0.459**	**0.135**	**0.127**	**0.378**

Table 1: The statistics of emotion distribution in the dataset

Emtion	Post Number
Happiness	2,915
Sadness	2,454
Fear	359
Anger	153
Surprise	601
None	4,675

5.2 Experimental Results

We compare the proposed Neural Personal Discrimination (NPD) model with several representative baselines models in Table 2, where,1) **SVM** is a widely used baseline to predict the emotion of a post in social media (Yang et al., 2007).2) **Abdul17** is a standard LSTM model which consist of a LSTM layer and a fully connected layer, and it is modified from the model in Abdul-Mageed and Ungar (2017). The LSTM model yields the state-of-the-art performance on emotion detection in recent researches.3)**Vaswani17** is an improved LSTM model with a self-attention mechanism. The self-attention mechanism is used to capture the structural information and has been successfully applied in various natural language processing tasks recently (Cheng et al., 2016; Vaswani et al., 2017)

From Table 2, we find that all of the neural models outperform SVM significantly. This indicates that neural models are much more effective than discrete models in emotion detection. In addition, our proposed NPD model outperforms both the standard LSTM model (Abdul17) and the improved LSTM model with self-attention (Vaswani17) significantly. This shows the effectiveness of our proposed NPD model with both adversarial discriminators and attention mechanisms. This also shows the usefulness of personal attributes for emotion detection. Moreover, we find that the performance of Vaswani17 is even lower than the standard LSTM model. This shows that simply integrating a self-attention mechanism may not be able to well capture informative words for emotion detection in social media.

5.3 Analysis and Discussion

In this subsection, we analyze the influence of different factors in the proposed NPD model, and give some statistics and examples to illustrate the effectiveness of the proposed NPD model with different personal attributes.

5.3.1 Influence of Personal Attributes

We illustrate the influence of personal attributes in the proposed NPD model in Table 3, where, 1)**LSTM-attributes** is a LSTM based multi-label classification model, which predicts both the emotion and the attribute labels of each post collectively.2)**NPD-gender** ablates the location attribute, i.e., only considering the gender attributes in the NPD model.3) **NPD-location** ablates the gender attribute, i.e., only considering the location attributes in the NPD model.

From the table, we can find that the performance of LSTM-attributes is much lower than LSTM model. This indicates that simple multi-label classification setting is not effective for integrating personal attributes. This may be due to the fact that basic multi-label setting fails to learn the correlationship between the emotions of posts and the personal attributes of the authors well. In addition, both the NPD-gender and the NPD-location perform better than the LSTM model respectively. This shows the effectiveness of the proposed NPD model with both adversarial and attention networks, and the usefulness of both gender and location attributes. Finally, the proposed NPD model with all the attributes significantly outperforms all the other models. This suggests that we should integrate all the personal attributes for emotion detection in social media.

Table 3: Comparison of various models with different personal attributes.

Method	Average F1.
LSTM	0.358
LSTM-attributes	0.341
NPD-gender	0.360
NPD-location	0.363
NPD	**0.378**

Table 4: Influence of network structures.

Method	Average F1.
LSTM	0.358
LSTM-attention	0.363
LSTM-adversarial	0.375
NPD	**0.378**

5.3.2 Influence of Network Structures

After analyzing the influence of different attributes, we analyze the influence of network structures in Table 4, where **LSTM-attention** ablates the adversarial discriminators, and only utilizes attention mechanisms with a multi-label classification setting, and **LSTM-adversarial** ablates the attention mechanisms and only utilizes adversarial discriminators for emotion detection.

From Table 4, we can see that both the attention mechanisms (LSTM-attention) and the adversarial discriminators (LSTM-adversarial) are effective in emotion detection. Moreover, the adversarial discriminators are much more effective than the attention mechanisms. This shows that the personal attribute discriminator is more important than learning informative attributes-aware words. Moreover, the NPD model obtains the best results by integrating both adversarial discriminators and attention mechanisms.

5.3.3 Statistics

We give the statistics of gender and location to explore the correlationship between emotion and personal attributes.

Distribution of Gender. Figure 2 illustrates the distribution of emotions between genders. Here, the Y-axis is conditional probability of each emotion given gender. From the figure, we can find that women tend to express the sadness emotion, while men tend to express anger emotion. This may be due to the fact that the different personality has different emotion expressions, i.e., sentimentality of the female and the impulsion of the male.

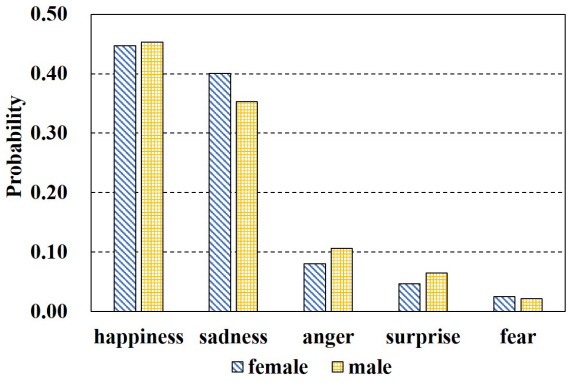

Figure 2: Distribution of gender.

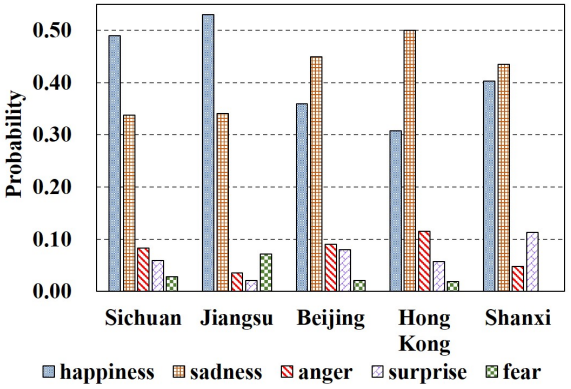

Figure 3: Distribution of location.

Distribution of Location. Figure 3 is an example of the distribution of emotions between locations. As discussed in the above section, we use the province of authors as location attributes. Here, the Y-axis represents the conditional probability of each emotion given location. From the figure, we can find that the authors' location can may influence their emotions in many aspects. For example, people tend to express the positive (i.e., happiness) emotion than the negative emotion in Jiangsu. One of the most comfortable and developed regions in China. Due to air pollution and populations, people tend to express the negative emotion than the positive emotion in Beijing. In addition, people in Hong Kong always feel crowding and tend to express the sadness emotion. Finally, people always feel happy and comfortable in Sichuan, well known as "country of paradise" in China.

From the results of statistics, we can see that the personal attributes, like gender, location, can affect the emotion detection. Also, the experimen-

Table 5: Examples predicted labels of LSTM and NPD

Post	LSTM	NPD
[E3]@嬤嬤俊, 连九份芋圆都会做, 巴适惨了, 冰冰凉Q弹水果甜品. (*@Momo Jun, this guy can even make Taro Balls from Jiufen of Taiwan. It is so bash. This ice fruit dessert is so soft and chewy.*)	Sadness	Happiness
[E4]下期节目, 不容错过, 有我的男神出场. (*Next tv show is not to be missed, because my Mr. Mcdreamy will be coming.*)	None	Happiness
[E5]我这身体不敢恭维啊, 吃了好多的冰, 结果痛经了吧, 赶紧多喝点红糖姜茶. (*I can't compliment my body. Eating too much ice leads to my dysmenorrhea. I must to drink more brown sugar ginger tea*)	None	Sadness

tal results of personal attribute influence shows the same conclusion.

5.3.4 Case Study

We select three examples from the test set to evaluate the effectiveness of the proposed NPD model for better comparison with the LSTM model in Table 5. In [E3], through "bashi(*conformable*)" is a strong cue word of the *happiness* emotion, it is treated as a general word without indicating any location information from the LSTM model. At the same time, the location information (Sichuan Province) determined by the location discriminator and the attention mechanism makes "bashi(*conformable*)" critical in the NPD model, and these enable the NPD model determines the correct *happiness* emotion. In [E4] and [E5], both posts contain implicit gender information. For example, "Mr. Mcdreamy" implies the female's affection for the handsome male, and "dysmenorrhea" is a female physiological disease. Without the background of such gender information, it is impossible to infer any potential emotional information from these two words. This explains why the LSTM model fails to detect any emotion from the examples (*None* of emotion). However, our NPD model successfully determines the gender of these two posts by the gender discriminator, and improves the weight of these two words for emotion detection by the attention mechanisms. In this way, the emotions of the three examples are correctly detected through the proposed NPD model.

6 Conclusion

Most of previous studies consider each post individually in emotion detection, one of the most important tasks in sentiment analysis. However, since the posts in social media are generated by users, it is natural that these posts can be connected through authors' personal background attributes. In this paper, we propose a neural personal discrimination model with both adversarial discriminators and attention mechanisms to connect posts with similar personal attributes. Here, the adversarial discriminators are used to determine the personal attributes, and the attention mechanisms are employed to aggregate attributes-aware words. In this way the social correlations between different posts can be captured. The experimental results show the usefulness of the personal attributes and the effectiveness of our proposed neural personal discrimination model in modeling such personal attributes with significant performance improvement over the state-of-the-art baselines.

Abstract

The task of unsupervised sentiment modification aims to reverse the sentiment polarity of the input text while preserving its semantic content without any parallel data. Most previous work follows a two-step process. They first separate the content from the original sentiment, and then directly generate text with the target sentiment only based on the content produced by the first step. However, the second step bears both the target sentiment addition and content reconstruction, thus resulting in a lack of specific information like proper nouns in the generated text. To remedy this, we propose a specificity-driven cascading approach in this work, which can effectively increase the specificity of the generated text and further improve content preservation. The experiments show that our approach outperforms competitive baselines by a large margin, which achieves 11% and 38% relative improvements of the overall metric on the Yelp and Amazon datasets, respectively.

1 Introduction

The goal of unsupervised sentiment modification is to reverse the sentiment polarity of the input text while preserving its semantic content without any parallel data. It not only has a variety of practical applications, e.g., fighting offensive language on social media (dos Santos et al., 2018), but also serves as an ideal testbed for controllable text generation. However, the input for this task usually contains some specific information like proper nouns. For instance, "*Michael*" in Table 1 is a human name, which belongs to the specific information. This specific information is important because it is often the subject or object of the sentence and the bearer of sentiment. Therefore, it needs to be fully preserved in the process of sentiment modification. We refer this attribute as the specificity of the output.

Input	***Michael** 's work exceeds my expectations.*
Shen et al. (2017)	*Service is terrible.*
Fu et al. (2018)	*I was very disappointed.*
Xu et al. (2018)	*The girls do horrible work.*

Table 1: Examples generated by four different previous methods. "***Michael***" is a proper noun, which belongs to specific information.

Most previous work on unsupervised sentiment modification follows a two-step process. They first separate the content from the original sentiment, either in an implicit (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018; Tsvetkov et al., 2018) or explicit (Xu et al., 2018; Zhang et al., 2018a) way. Then, they directly generate text with the target sentiment only based on the content produced by the first step. In the second step, the decoder does not include the sentiment information in its source input, meaning that the source information is incomplete for generating a sentiment-transferred sentence. This *information gap* at both ends of the decoder causes the decoder needs to bear both the target sentiment addition and content reconstruction. Thus, it is difficult for the decoder to balance sentiment transformation and content preservation simultaneously, resulting in the loss of specific information contained in the source input during decoding. This not only makes the generated text lacks specificity, but also causes poor content preservation. Table 1 intuitively illustrates this problem. All three traditional methods miss proper noun "*Michael*" in the output.

In order to generate text containing more specific information, in this paper, we propose a specificity-driven cascading approach. Our approach consists of three modules: separation module, emotionalization module, and fusion module. The separation module is responsible for explicitly separating sentiment words from content words

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5508–5517,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

via the self-attention mechanism. Then, different from previous work, we divide the process of generating text with the target sentiment based on content words into two steps. First of all, in order to achieve sentiment addition, the emotionalization module generates corresponding target sentiment words based on the content words. Then, the fusion module performs content reconstruction by fusing semantic content and target sentiment words to generate sentiment-transferred sentences. Each step is dedicated to their respective goals, which reduces the burden of the decoder in the fusion module. Besides, with the help of the target sentiment words generated by the emotionalization module, the *information gap* is also eliminated. This allows specific information contained in the input to be well preserved, resulting in more specific output and better content preservation.

The main contributions of this paper are summarized as follows:

- We propose an effective specificity-driven cascading approach for unsupervised sentiment modification, which not only increases the specificity of the generated text, but also further improves content preservation.
- Experimental results show that our approach can outperform the competitive baselines by a large margin. Further analysis demonstrates that the proposed method can achieve better reconcile of sentiment transformation and content preservation.

2 Background

Here we introduce some necessary background knowledge. The core component of our proposed approach is the Seq2Seq model (Sutskever et al., 2014; Bahdanau et al., 2014), which usually consists of an encoder and a decoder with the attention mechanism.

Encoder: Given the input $\boldsymbol{x} = (x_1, \cdots, x_m)$, the encoder implemented as a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) structure reads $\boldsymbol{x}$ from both directions and computes the hidden states for each word,

$$\overrightarrow{h}_i = \overrightarrow{\text{LSTM}}(\overrightarrow{h}_{i-1}, x_i) \quad (1)$$

$$\overleftarrow{h}_i = \overleftarrow{\text{LSTM}}(\overleftarrow{h}_{i+1}, x_i) \quad (2)$$

where $e(x_i)$ denotes the embedding of the word x_i. The final hidden representation of the i-th word is $h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$, which semicolon represents vector concatenation.

Module	Source Input	Target Output	Role
$\textbf{SC}_{\phi}$	$\boldsymbol{x}^+/\boldsymbol{x}^-$	$+/-$	Separate content and sentiment
$\textbf{S2S}_{\theta_{pe}}$	$\boldsymbol{c}^+$	$\boldsymbol{s}^+$	Generate positive sentiment words
$\textbf{S2S}_{\theta_{ne}}$	$\boldsymbol{c}^-$	$\boldsymbol{s}^-$	Generate negative sentiment words
$\textbf{S2S}_{\theta_{pf}}$	$(\boldsymbol{c}^+, \boldsymbol{s}^+)$	$\boldsymbol{x}^+$	Generate positive sentence
$\textbf{S2S}_{\theta_{nf}}$	$(\boldsymbol{c}^-, \boldsymbol{s}^-)$	$\boldsymbol{x}^-$	Generate negative sentence

Table 2: The role of each component of our approach at the training stage. We use "+" and "-" to represent positive and negative sentiment, respectively.

Decoder: Given the hidden representations $(h_1, \cdots, h_m)$, the decoder generates words sequentially. Besides, the attention mechanism is used to automatically select the most informative words at different time steps. In detail, the hidden state s_{t+1} of the decoder at time-step $t+1$ is computed as follows:

$$e_{t,i} = f(s_t, h_i) \quad (3)$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{m} \exp(e_{t,j})} \quad (4)$$

$$c_t = \sum_{i=1}^{m} \alpha_{t,i} h_i \quad (5)$$

$$s_{t+1} = \text{LSTM}(s_t, [e(y_t); c_t]) \quad (6)$$

$$y_t \sim \text{softmax}\left(g(s_t)\right) \quad (7)$$

where $[e(y_t); c_t]$ means the concatenation of vectors $e(y_t)$ and c_t. $e(y_t)$ is the embedding of the word y_t that has the highest probability. $f(s_t, h_i)$ is an aligned model, which measures the dependency between s_t and h_i. g is a function, which is used to transform the hidden state s_t into the probability distribution over the vocabulary space.

The model is trained by maximizing the conditional likelihood of the ground-truth sequence $\boldsymbol{y}^* = (y_1^*, \cdots, y_n^*)$. Specially, the objective is to minimize the cross-entropy loss:

$$\mathcal{L} = -\sum_{t=1}^{n} \log\left(p(y_t^* | \boldsymbol{y}_{<t}^*, \boldsymbol{x})\right) \quad (8)$$

[1]

3 Methodology

3.1 Overview

Here we define some notations and describe the sentiment modification task. We use $\mathcal{D}^+ =$

[1] In this work, $\boldsymbol{y}_{<t}^*$ denotes the sequence $(y_1^*, \cdots, y_{t-1}^*)$.

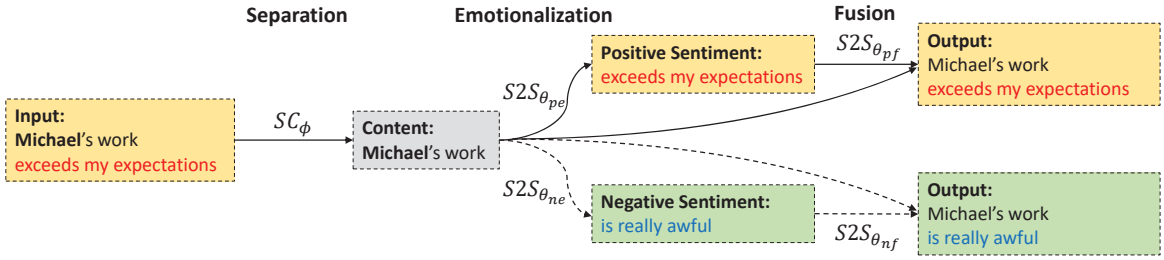

Figure 1: The overview of the proposed cascading approach with a positive input. The process with a negative input is in a similar way. Solid and dashed lines indicate the training process and the testing process, respectively.

$\{\boldsymbol{x}_i^+\}_{i=1}^{n_1}$ and $\mathcal{D}^- = \{\boldsymbol{x}_i^-\}_{i=1}^{n_2}$ to represent the positive corpus and negative corpus, respectively, where $\boldsymbol{x}^+$ ($\boldsymbol{x}^-$) is a positive (negative) sentence. $\mathcal{D} = \mathcal{D}^+ \cup \mathcal{D}^-$ denotes the complete corpus. The sentiment modification task aims to take the sentence $\boldsymbol{x}^+$ ($\boldsymbol{x}^-$) as input and generate a sentiment-transferred sentence $\hat{\boldsymbol{x}}^-$ ($\hat{\boldsymbol{x}}^+$) as output.

The overview of our approach is shown in Figure 1. Our approach consists of three modules: separation module, emotionalization module, and fusion module. The separation module aims to explicitly separate the sentiment words from content words and the emotionalization module receives content words as input to generate the corresponding sentiment words. Finally, the fusion module fuses the content and sentiment words to generate fluent sentences. Table 2 summarizes the source input, target output, and function of each component at the training stage. Besides, the training algorithm and testing algorithm are shown in Algorithm 1 and Algorithm 2, respectively.

3.2 Separation Module

The separation module aims to explicitly separate the sentiment words from content words. Given a sentence $\boldsymbol{x} = (x_1, \cdots, x_m)$, the separation can be accomplished by identifying whether each word x_i is a sentiment word. Here we employ a sentiment classifier with the self-attention mechanism to achieve this goal. The classifier with the self-attention mechanism can select the most informative words automatically by assigning higher attention weights to sentiment words. Therefore, the attention weight α_i of the i-th word can be used to identify whether x_i is a sentiment word.

In detail, we use the bidirectional LSTM model for implementation. The LSTM model reads the input $\boldsymbol{x}$ from both directions and computes the hidden representation $h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i]$ for the i-th word, where semicolon represents vector concatenation. The self-attention mechanism produces final context vector h by aggregating the hidden representations $(h_1, \cdots, h_m)$. Specifically,

$$\alpha_i = \text{softmax}(v^T h_i) \tag{9}$$

$$h = \sum_{i=1}^{m} \alpha_i h_i \tag{10}$$

where v is a parameter vector. At the training stage, we perform classification based on the final context vector h and the loss function is the cross-entropy loss. Then, for the well-trained sentiment classifier, the average attention value of sentence $\boldsymbol{x}$ is calculated as:

$$\bar{\alpha} = \frac{1}{m} \sum_{i=1}^{m} \alpha_i \tag{11}$$

Words with attention weight larger than $\bar{\alpha}$ can be regarded as sentiment words, and the remaining words can be regarded as content words.[2] Therefore, each sentence $\boldsymbol{x}$ can be separated into content words $\boldsymbol{c}$ and sentiment words $\boldsymbol{s}$.[3]

3.3 Emotionalization Module

In previous work, there is an *information gap* at both ends of the decoder, making the decoder to bear both the target sentiment addition and content reconstruction simultaneously. To eliminate the *information gap* and ease the burden of the decoder, we divide the process of generating sentiment sentences based on content into two separate steps: sentiment addition and content reconstruction. Each step is dedicated to their respective goals, which reduces the burden of the

[2]The reason is that there exists an obvious gap between the attention weights of content words and sentiment words, causing the weights of these two types of words to be distributed at both ends of the average. Exploratory experiments show that the separation model can achieve more than 80% F_1 score.

[3]Except for Section 2, we use $\boldsymbol{c}$ and $\boldsymbol{s}$ to represent content words and sentiment words, respectively. This is different from the context vector c and hidden state s in Section 2.

Algorithm 1 The training algorithm.

Require: positive corpus $\mathcal{D}^+ = \{\boldsymbol{x}_i^+\}_{i=1}^{n_1}$; negative corpus $\mathcal{D}^- = \{\boldsymbol{x}_i^-\}_{i=1}^{n_2}$; complete corpus $\mathcal{D} = \mathcal{D}^+ \cup \mathcal{D}^-$

Separation:
  Train the sentiment classifier $\mathbf{SC}_\phi$ on corpus $\mathcal{D}$
  Separate positive sentence $\boldsymbol{x}^+$ in $\mathcal{D}^+$ into $(\boldsymbol{c}^+, \boldsymbol{s}^+)$ using $\mathbf{SC}_\phi$ to construct new positive corpus $\mathcal{N}^+ = \{(\boldsymbol{c}_i^+, \boldsymbol{s}_i^+, \boldsymbol{x}_i^+)\}_{i=1}^{n_1}$
  Separate negative sentence $\boldsymbol{x}^-$ in $\mathcal{D}^-$ into $(\boldsymbol{c}^-, \boldsymbol{s}^-)$ using $\mathbf{SC}_\phi$ to construct new negative corpus $\mathcal{N}^- = \{(\boldsymbol{c}_i^-, \boldsymbol{s}_i^-, \boldsymbol{x}_i^-)\}_{i=1}^{n_2}$
Emotionalization:
  Train $\mathbf{S2S}_{\theta_{pe}}$ using MLE on new positive corpus $\mathcal{N}^+$
  Train $\mathbf{S2S}_{\theta_{ne}}$ using MLE on new negative corpus $\mathcal{N}^-$
Fusion:
  Train $\mathbf{S2S}_{\theta_{pf}}$ using MLE on new positive corpus $\mathcal{N}^+$
  Train $\mathbf{S2S}_{\theta_{nf}}$ using MLE on new negative corpus $\mathcal{N}^-$

decoder. Here the emotionalization module explicitly performs sentiment addition by generating corresponding sentiment words based on content words.

In detail, through the separation module, the sentence $\boldsymbol{x}$ can be separated into $(\boldsymbol{c}, \boldsymbol{s})$, where $\boldsymbol{c}$ and $\boldsymbol{s}$ represent the content words and sentiment words, respectively. Therefore, the new corpus $\mathcal{N}^+ = \{(\boldsymbol{c}_i^+, \boldsymbol{s}_i^+, \boldsymbol{x}_i^+)\}_{i=1}^{n_1}$ can be constructed by explicitly separating the positive sentence $\boldsymbol{x}^+$. Similarly, $\mathcal{N}^- = \{(\boldsymbol{c}_i^-, \boldsymbol{s}_i^-, \boldsymbol{x}_i^-)\}_{i=1}^{n_2}$ can be constructed by separating the negative sentence $\boldsymbol{x}^-$.

The emotionalization module aims to automatically generate corresponding sentiment words according to the content. Since corpus $\mathcal{N}^+$ (or $\mathcal{N}^-$) provides pseudo-parallel data about content words $\boldsymbol{c}^+$ (or $\boldsymbol{c}^-$) and sentiment words $\boldsymbol{s}^+$ (or $\boldsymbol{s}^-$), here we use the Seq2Seq model to accomplish this goal. We train a Seq2Seq model $\mathbf{S2S}_{\theta_{pe}}$ on the new positive corpus $\mathcal{N}^+$, which is responsible for generating positive sentiment words $\boldsymbol{s}^+$ based on the content $\boldsymbol{c}^+$. Another Seq2Seq model $\mathbf{S2S}_{\theta_{ne}}$ is trained on the new negative corpus $\mathcal{N}^-$ to generate negative sentiment words $\boldsymbol{s}^-$ based on content words $\boldsymbol{c}^-$. Therefore, for the well-trained model $\mathbf{S2S}_{\theta_{pe}}$ (or $\mathbf{S2S}_{\theta_{ne}}$), given content words $\boldsymbol{c}$, $\mathbf{S2S}_{\theta_{pe}}$ (or $\mathbf{S2S}_{\theta_{ne}}$) is able to generate corresponding positive (or negative) sentiment words $\boldsymbol{s}^+$ (or $\boldsymbol{s}^-$).

3.4 Fusion Module

The fusion module aims to perform content reconstruction by fusing content words $\boldsymbol{c}$ and sentiment words $\boldsymbol{s}$ to generate fluent emotional sentence $\boldsymbol{x}$. Compared with the previous work, the decoder here has extra sentiment information $\boldsymbol{s}$, thus eliminating the *information gap* at both ends of the decoder. This allows the specific information to be better preserved during the generation process, leading to more specific generation results and better content preservation.

Algorithm 2 The testing algorithm.

Require: positive source input $\boldsymbol{x}^+$

Separate $\boldsymbol{x}^+$ using $\mathbf{SC}_\phi$ to get content words $\boldsymbol{c}^+$
Generate the negative sentiment words $\boldsymbol{s}^-$ using $\mathbf{S2S}_{\theta_{ne}}$ with input $\boldsymbol{c}^+$
Generate the negative sentence $\hat{\boldsymbol{x}}^-$ using $\mathbf{S2S}_{\theta_{nf}}$ with input $(\boldsymbol{c}^+, \boldsymbol{s}^-)$

Similar to the emotionalization module, the fusion module is also composed of two Seq2Seq models, one for generating positive sentences and the other for generating negative sentences. Here each Seq2Seq model consists of two encoders and one decoder. The two encoders are responsible for compressing the semantic content words and emotional words into a dense vector, respectively. The decoder aims to generate fluent emotional sentence based on compressed content vector and sentiment vector. In detail, we train two bi-encoder based Seq2Seq models $\mathbf{S2S}_{\theta_{pf}}$ and $\mathbf{S2S}_{\theta_{nf}}$ on the new positive corpus $\mathcal{N}^+$ and negative corpus $\mathcal{N}^-$, respectively. Each model aims to output $\boldsymbol{x}$ based on the input $(\boldsymbol{c}, \boldsymbol{s})$. Note that the Seq2Seq model here has two encoders, so we need to make modifications to the relevant formulas. Two attention mechanisms similar to Eq. 3 - Eq. 5 aggregate the hidden representations of the content words $\boldsymbol{c}$ and sentiment words $\boldsymbol{s}$ respectively to form the content-side context c_t^c and the sentiment-side context c_t^s. The hidden state s_{t+1} of the decoder at time-step $t+1$ is computed as follows:

$$s_{t+1} = \mathrm{LSTM}(s_t, [e(y_t); c_t^c; c_t^s]) \qquad (12)$$

3.5 Training and Testing

At the training stage, each module is trained by optimizing the cross-entropy loss function. The testing algorithm is shown in Algorithm 2. Without loss of generality, we focus on reversing the positive input to the negative output. The process of reversing negative sentence to positive sentence is in a similar way. Given a positive input $\boldsymbol{x}^+$, the separation module can separate $\boldsymbol{x}^+$ into content words $\boldsymbol{c}^+$ and sentiment words $\boldsymbol{s}^+$. The model $\mathbf{S2S}_{\theta_{ne}}$ in the emotionalization module takes $\boldsymbol{c}^+$ as input to generate corresponding negative sentiment words $\boldsymbol{s}^-$. Finally, $(\boldsymbol{c}^+, \boldsymbol{s}^-)$ is inputted into the model

Dataset	Training	Validation	Test
Yelp	580K	15K	4K
Amazon	230K	10K	2K

$\mathbf{S2S}_{\theta_{nf}}$ in the fusion module to generate a fluent negative sentence $\hat{\boldsymbol{x}}^{-}$.

4 Experiments

In this section, we first introduce the datasets, evaluation metrics, experimental details, and all compared baselines.

4.1 Datasets

We conduct experiments on two datasets, Yelp[4] and Amazon[5] (He and McAuley, 2016). Both datasets are composed of a large number of reviews. Following previous work (Shen et al., 2017), reviews with scores below 3 are labeled as negative, and reviews with scores above 3 are labeled as positive. The reviews which exceed 20 words or less than 5 words are further filtered out. In addition, we train the sentiment classifier (Kim, 2014) to filter samples with the category confidence below 0.8. We divide each dataset into training, validation and test sets. The statistics of the two processed datasets is shown in Table 3.

4.2 Evaluation Metrics

In this paper, we adopt two evaluation methods: automatic evaluation and human evaluation.

4.2.1 Automatic Evaluation

Following previous work (Xu et al., 2018; Shen et al., 2017), we perform automatic evaluation in terms of sentiment transformation and content preservation.

- **ACC:** We pre-train a sentiment classifier, which is implemented as CNN (Kim, 2014) structure, to evaluate whether the sentiment of the generated text matches the target sentiment. The pre-trained sentiment classifier achieves the accuracy of 87% and 89% on Yelp and Amazon datasets, respectively. The higher ACC value indicates better sentiment transformation.

	Yelp		Amazon	
Module	**LSTM Layer**	**Hidden Size**	**LSTM Layer**	**Hidden Size**
$\mathbf{SC}_{\phi}$	2	512	2	256
$\mathbf{S2S}_{\theta_{pe}}$	(2, 3)	(256, 512)	(2, 2)	(256, 512)
$\mathbf{S2S}_{\theta_{ne}}$	(2, 2)	(256, 512)	(1, 2)	(128, 256)
$\mathbf{S2S}_{\theta_{pf}}$	(2, 3)	(256, 512)	(2, 2)	(256, 512)
$\mathbf{S2S}_{\theta_{nf}}$	(2, 2)	(256, 512)	(1, 2)	(128, 256)

Table 4: Main hyper-parameters. For the LSTM layer and hidden size, we use $(\cdot, \cdot)$ to represent the hyper-parameter of the encoder and decoder, respectively.

- **BLEU:** We use the BLEU score (Papineni et al., 2002) between the transferred sentence and the source sentence to evaluate content preservation. The higher BLEU score indicates better content preservation.

- **G-Score:** In order to evaluate the overall performance of different systems, following Xu et al. (2018), we compute the geometric mean (G-score) of ACC value and BLEU score as an overall evaluation metric.

4.2.2 Human Evaluation

In order to evaluate the quality of generated sentences more accurately, we also perform human evaluation. Each item contains the source input, transfer direction, and the transferred sentences generated by different models. Then 200 items are distributed to 3 annotators with the linguistic background. The annotators are required to score the generated sentences from 1 to 5 based on the source input and transfer direction in terms of three criteria: sentiment, content, and overall performance. Sentiment represents whether the generated text matches the target sentiment. Content evaluates the content preservation degree. For each dataset and each metric, the average Pearson correlation coefficient of the scores given by three annotators is greater than 0.65, which indicates that the human scores are highly consistent.

4.3 Baselines

We compare our proposed approach with the following competitive systems:

- **Cross-Aligned Auto-Encoder (CAAE)** is proposed by Shen et al. (2017). They propose to use the refined alignment of latent representations in hidden layers to perform sentiment modification.

Yelp	ACC	BLEU	G-Score
CAAE (Shen et al., 2017)	50.20	1.35	8.23
MDAE (Fu et al., 2018)	81.30	3.27	16.30
SEAE (Fu et al., 2018)	42.25	19.18	28.47
BT (Tsvetkov et al., 2018)	61.45	2.56	12.54
CRL (Xu et al., 2018)	73.70	35.62	51.24
Proposed Method	68.65	47.42	**57.06**
Amazon	**ACC**	**BLEU**	**G-Score**
CAAE (Shen et al., 2017)	51.75	2.17	10.60
MDAE (Fu et al., 2018)	67.85	4.54	17.55
SEAE (Fu et al., 2018)	47.50	28.79	36.98
BT (Tsvetkov et al., 2018)	53.75	3.73	14.16
CRL (Xu et al., 2018)	65.20	22.66	38.44
Proposed Method	56.30	49.83	**52.97**

Table 5: Automatic evaluations of our method and baselines, from which we can see that our approach achieves the best overall performance on both datasets.

Yelp	Sentiment	Content	Overall
CAAE (Shen et al., 2017)	3.48	1.87	2.03
MDAE (Fu et al., 2018)	3.56	2.07	3.11
SEAE (Fu et al., 2018)	2.67	2.71	3.26
BT (Tsvetkov et al., 2018)	1.81	3.14	2.52
CRL (Xu et al., 2018)	3.64	3.03	3.89
Proposed Method	3.31	4.21	**4.09**
Amazon	**Sentiment**	**Content**	**Overall**
CAAE (Shen et al., 2017)	3.37	2.74	2.72
MDAE (Fu et al., 2018)	3.31	2.89	2.58
SEAE (Fu et al., 2018)	2.82	3.05	3.13
BT (Tsvetkov et al., 2018)	2.04	2.58	2.94
CRL (Xu et al., 2018)	3.68	3.21	3.06
Proposed Method	3.42	3.83	**3.71**

Table 6: Human evaluations of different systems, showing that our approach outperforms the baselines by a large margin, especially in content preservation.

- **Multi-Decoder Auto-Encoder (MDAE)** is proposed by Fu et al. (2018). They use a separate decoder for each sentiment to generate transferred sentences based on the extracted content vectors.
- **Style-Embedding Auto-Encoder (SEAE)** is also proposed by Fu et al. (2018). Each sentiment has a unique embedding, which is used to control the sentiment transfer direction of the decoder.
- **Back-Translation (BT)** (Tsvetkov et al., 2018) focuses on learning a latent representation of the input by means of language translation model and further perform generation.
- **Cycled Reinforcement Learning (CRL)** is proposed by Xu et al. (2018). They use a cycled reinforcement learning model to explicitly extract content to further generate transferred sentences.

4.4 Experiment Settings

For both datasets, the vocabulary size is 30,000 and out-of-vocabulary words are replaced with unk. We train *word2vec* (Mikolov et al., 2013) on an English Wikipedia corpus dump to get 300-dimensional word embeddings. The batch size is 64 and the hyper-parameters of each module on two datasets are shown in Table 4. For each module, we use the Adam (Kingma and Ba, 2014) optimizer and the initial learning rate is 0.0003. Besides, we make use of the dropout method (Srivastava et al., 2014) to avoid over-fitting and clip the gradients (Pascanu et al., 2013) to the maximum norm of 10. During training, we train the model for a fixed number of epochs and monitor its performance on the validation set after 100 updates. Once the training is finished, we select the model with the best G-score on the validation set as our final model and evaluate its performance on the test set.

5 Results and Discussion

In this section, we report the experimental results. Besides, further analysis is also provided.

5.1 Experimental Results

The automatic evaluation results on two datasets are shown in Table 5. Results show that our approach achieves the best overall performance. For instance, our model achieves 11% and 38% relative improvement of G-score over the best baseline on the two datasets, respectively. This shows that our approach can further reconcile sentiment transformation and content preservation. We also note that our method achieves particularly high BLEU scores, indicating that the proposed method can enhance the specificity of the generated text, leading to better content preservation.

The human evaluation results are shown in Table 6, from which we can draw similar conclusions. It is obvious that our approach can outperform the baselines by a large margin, especially in terms of content preservation. The reason is that there is no *information gap* at both ends of our decoder when generating sentiment-transferred sen-

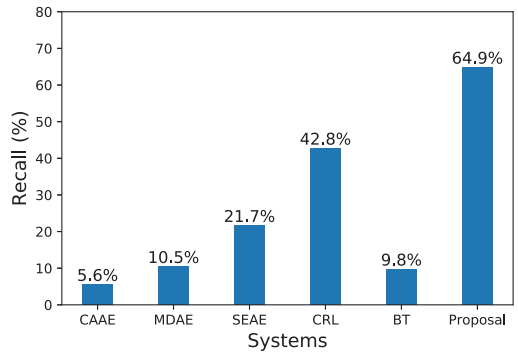

Figure 2: The recall scores of specific information (e.g. proper nouns) on different systems.

tences, which relieves the burden on the decoder. Therefore, more specific information is preserved.

5.2 Effectiveness of Enhancing Specificity

The analysis in Section 5.1 has shown that our approach can achieve excellent content preservation, which shows that the proposed model can generate text containing more specific information to some extent. To further verify this conclusion, we manually select test samples containing specific information (e.g. proper nouns) and then calculate the recall scores of this specific information on different systems. Figure 2 shows the related results, from which we can see that our approach achieves the highest recall score. This further illustrates that our approach can effectively improve the specificity of the generated text.

5.3 Ablation Study

We conduct an ablation study to verify the effectiveness of the emotionalization module. The results are shown in Table 7, illustrating that the removal of the emotionalization module leads to an obvious reduction in model performance. Compared to the ablated version, the full model achieves improvements of 11.14% and 9.87% G-score on two datasets, respectively. Besides, both sentiment transformation and content preservation can be improved with the emotionalization module. The emotionalization module can automatically generate corresponding sentiment words based on the extracted content, which eliminates *information gap* and relieves the burden of the decoder, leading to better model performance.

5.4 Case Study

Table 8 shows several examples of the testing process for our approach, which intuitively reflects

Yelp	**ACC**	**BLEU**	**G-score**
Full model	68.65	47.42	57.06
w/o EM	52.40	40.24	45.92
Amazon	**ACC**	**BLEU**	**G-score**
Full model	56.30	49.83	52.97
w/o EM	44.90	41.37	43.10

Table 7: Ablation study. "EM" denote the emotionalization module.

Input: *The worst and unprofessional company.* **Separation:** *The worst and unprofessional company.* **Emotionalization:** *Exceeded my expectations* **Fusion:** *The company exceeded my expectations.*
Input: *Staff is awesome and always friendly.* **Separation:** *Staff is awesome and always friendly.* **Emotionalization:** *So rude unprofessional* **Fusion:** *So rude and unprofessional staff.*

Table 8: Outputs of different modules of our method. The underlined words are sentiment words recognized by separation module.

the function of each module. Given an input, the separation module can separate sentiment words from content words. For instance, the separation module successfully identifies the sentiment words "*worst and unprofessional*" in the first example. Then, the emotionalization module is able to generate corresponding target sentiment expression "*exceeded my expectations*" based on the given content words "*the company*". Beyond that, the fusion module can fuse content words and target sentiment expression to further generate a fluent sentiment-transferred sentence "*the company exceeded my expectations*".

Table 9 presents several outputs of different systems on the Yelp dataset. The baselines tend to generate outputs lacking specific information, resulting in poor content preservation. For instance, all baselines miss proper noun "*wendys*" in the first example. In contrast, our approach increases the specificity of the output, leading to better content preservation. Our method not only performs sentiment addition and content reconstruction independently, but also eliminates the *information gap*. This eases the burden of the decoder, allowing more specific information to be preserved.

5.5 Error Analysis

Although our approach outperforms the baselines by a large margin, we still observe some failed examples. We conduct a detailed analysis and categorize them into two types demonstrated below.

Input: ***Wendys*** *is my favorite chain, but this location is the worst.* **CAAE:** *Great food and the best food!* **MDAE:** *Best best i ever visit.* **SEAE:** *This place had amazing stars!* **CRL:** *Undoubtedly is my favorite chain.* **Proposal:** ***Wendys*** *is my favorite chain, great location!*
Input: ***Annette*** *in optical was super helpful!* **CAAE:** *I have been to say and i have n't be them.* **MDAE:** *Terrible here is not disappointed , it!* **SEAE:** *Walked in the service was super well.* **CRL:** *Horrible stylist bank was extremely unprofessional.* **Proposal:** ***Annette*** *in optical was rude!*

Table 9: Examples generated by different systems on the Yelp dataset. "***Wendys***" and "***Annette***" belong to the specific information contained in the input.

One type of error is the neutral output without any sentiment polarity, such as "*I went to the bar on Friday*". This is because both datasets contain a large number of neutral reviews, which can be viewed as noises. Since these neutral reviews are also labeled as positive or negative, the separation module may incorrectly identify some content words as sentiment words. Training samples lacking sentiment information make the emotionalization module unable to generate sentiment words, leading to the neutral output.

The other type of error is the output that contains the original sentiment, which can be attributed to the failure of the separation of content and sentiment. Such failure usually occurs when the input contains sentiment words that are unseen in the training data, or the sentiment is implicitly expressed. The separation module may not recognize these unseen or obscure sentiment words, causing that the extracted content still contains original sentiment information. This content is further inputted to the emotionalization module, causing the output to contain original sentiment.

6 Related Work

This paper is mainly related to the following two series of work.

Unsupervised sentiment modification. One line of research for this task focuses on implicitly separating content from original sentiment. To control the sentiment, Hu et al. (2017) combines VAE and attribute discriminator while Shen et al. (2017) strives to align latent representations in hidden layers. Both Fu et al. (2018) and Yang et al. (2018) adopt adversarial training to ensure the success of separation. Tsvetkov et al. (2018) strives to obtain style-independent content representations through additional translation models. However, this implicit separation tends to result in poor content preservation since content and sentiment are entangled in an uninterpretable way. Different from this line of work, we adopt explicit separation of content and sentiment via self-attention, which achieves better content preservation. Another line strives to explicitly separate content and sentiment at the word-level. Li et al. (2018) proposes a retrieval system, which may lead to low-quality outputs. Xu et al. (2018) presents a reinforcement learning (RL) approach to remove sentiment words. However, the training of RL is unstable and sensitive to hyper-parameters. Further, Zhang et al. (2018a) tries to automatically extracts appropriate sentiment information from learned sentiment memories. Different from Zhang et al. (2018a) which extracts entangled sentiment memories from capacity-constrained memory matrices, our work can generate accurate explicit sentiment words flexibly based on specific content, leading to better performance. There also exist some other endeavors which construct pseudo-parallel data by means of back-translation (Sennrich et al., 2015). For instance, Zhang et al. (2018b) and Luo et al. (2019) jointly train two transfer systems via iterative back-translation. Further, Lample et al. (2019) extend this training framework to support multiple attribute control .

Sentiment analysis. Our work is also related to: sentiment analysis (Severyn and Moschitti, 2015; Cambria, 2016; Poria et al., 2017; Lam et al., 2018), sentiment embeddings (Tang et al., 2014; Barnes et al., 2018), and aspect extraction (Poria et al., 2016; He et al., 2017; Pablos et al., 2018).

7 Conclusion

In this paper, we propose a simple but effective specificity-driven cascading approach for unsupervised sentiment modification. The proposed approach performs target sentiment addition and content reconstruction independently, so that more specific information is preserved. Extensive experimental results show that our approach outperforms several competitive systems by a large margin. Further analysis demonstrates that the proposed method not only increases the specificity of the generated text, but also further improves content preservation.

Abstract

Recent work has shown that current sentiment classification models are fragile and sensitive to simple perturbations. In this work, we propose a novel adversarial training approach, LexicalAT, to improve the robustness of current sentiment classification models. The proposed approach consists of a generator and a classifier. The generator learns to generate examples to attack the classifier while the classifier learns to defend these attacks. Considering the diversity of attacks, the generator uses a large-scale lexical knowledge base, WordNet, to generate attacking examples by replacing some words in training examples with their synonyms (e.g., sad and unhappy), neighbor words (e.g., fox and wolf), or super-superior words (e.g., chair and armchair). Due to the discrete generation step in the generator, we use policy gradient, a reinforcement learning approach, to train the two modules. Experiments show LexicalAT outperforms strong baselines and reduces test errors on various neural networks, including CNN, RNN, and BERT.[1]

1 Introduction

Sentiment classification is a fundamental research area in natural language processing (Pang et al., 2002; Glorot et al., 2011; Lai et al., 2015; Kiritchenko and Mohammad, 2018; Liu et al., 2018; Chen et al., 2018). With the development of deep learning, neural networks have obtained state-of-the-art results on many sentiment classification datasets (Kim, 2014; Dong et al., 2014; Tang et al., 2015). However, despite the promising results, recent work has shown that these models easily fail in adversarial examples[2] with little perturbations on real examples. This phenomenon shows that current sentiment classification models have poorly learned the true underlying patterns that determine the correct label. The over-fitting problem still needs to be further explored.

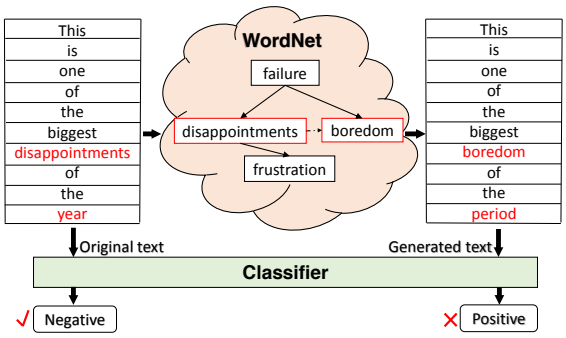

Figure 1: An attacking example for sentiment classification generated by the proposed approach. A pre-trained classifier correctly predicts the label of the original text but fails on the generated text.

Several approaches have been proposed in recent years for the attack problem. These studies can be roughly classified into two categories, data augmentation based approaches and adversarial training based approaches. The key idea of the former approaches is to assist the training of the classifier by augmenting the training data with pre-designed examples (Wang and Yang, 2015; Jia and Liang, 2017; Iyyer et al., 2018). Adversarial training based approaches (Miyato et al., 2017) aim to improve the generalization ability by adding random noises to word embeddings. Although these methods are good pioneering work, they either heavily rely on human knowledge or suffer from low diversity of attacks, which limits the robustness to diverse words and expressions.

In this work, we propose a lexical-based adversarial reinforcement training framework, LexicalAT, for robust sentiment classification. Compar-

*Equal Contribution.

ing to previous studies, our approach can generate diversely attacking examples with self-learned policies. Our framework contains a generator and a classifier. The generator provides examples to attack the classifier while the classifier learns to defend these attacks. To generate diverse examples, we propose to use a large lexical knowledge base, WordNet, to add perturbations on training examples by replacing some words with their synonyms (e.g., sad and unhappy), neighbor words (e.g., fox and wolf), or super-superior words (e.g., chair and armchair)[3], as shown in Figure 1. Specifically, the output of the generator is a sequence of actions deciding which words should be replaced and their replacements. By involving the attacking examples into the training, the classifier will be more robust and powerful.

Since the generator has discrete generation steps, the gradient-based approach cannot be directly used to back-propagate the errors. We consider policy gradient, a reinforcement learning approach, to train the generator. With the feedback from the classifier as the reward, the generator is encouraged to generate tougher examples for the classifier. In return, with the increasing number of hard examples for training, the classifier becomes more robust and powerful. We evaluate the proposed approach on four popular sentiment classification datasets. Experiments show that LexicalAT outperforms strong baselines on various models and various datasets.

- We propose a lexical-based adversarial reinforcement training approach, LexicalAT, to improve the robustness of sentiment classification models.
- To the best of our knowledge, it is the first work of combining a knowledge base and adversarial learning. The knowledge base contributes to diverse example generation and the adversarial learning develops the attacking policy.
- Experiments show that LexicalAT outperforms strong baselines and improves results on various models, including CNN, RNN, and BERT.

[3]These relations are optional. If a relation has a high risk of changing labels in specific datasets, it is feasible to drop it.

2 Related Work

In this work, we focus on single-label sentiment classification where the input is a word sequence and the output is a single label. In many sentiment classification datasets, neural networks have achieved promising results, even comparable or super to humans. However, several studies have noted that these models are vulnerable and the performance is very sensitive to simple perturbations (Szegedy et al., 2014; Huang et al., 2017; Yuan et al., 2017).

Based on these findings, some studies have been proposed to improve the robustness of neural networks. These studies can be roughly classified into two categories, data augmentation based approaches and adversarial training based approaches. The main idea of the data augmentation based approaches is to augment the training data with pre-designed adversarial examples. Iyyer et al. (2018) propose a paraphrase method to generate syntactically adversarial examples for machine translation tasks. To explore semantically adversarial examples, Kobayashi (2018) replaces input words in real examples with the word predicted by a label-conditional language model. In these approaches, the attacking policy is task-specific and elaborately designed by humans. Unlike these approaches, Miyato et al. (2017) propose to use an adversarial training framework to attack the classifier by adding perturbations to the word embedding layer. However, the unchanged input text makes it hard to improve the robustness to diverse words and expressions.

In this work, we propose a new adversarial reinforcement training framework that aims to generate diverse attacks with self-learned policies. We build a generator that acts as a policy learner to automatically learn to attack the classifier. To generate diverse examples, we include WordNet, a large-scale lexical knowledge base, into the generator for word replacement.

3 Approach

3.1 Overview

Figure 2 shows the overall structure of LexicalAT. Given a sentence, the generator first generates a sequence of actions to replace some words with substitutes in WordNet and build a new example. Then, the new example is sent to the classifier to get the action reward. If the generated example

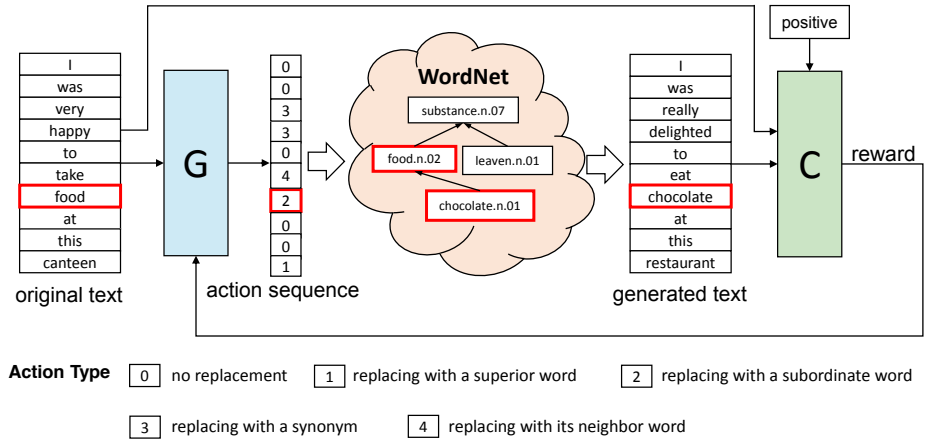

Figure 2: An illustration about the LexicalAT framework. The generator (G) generates an action sequence to replace some words in a training example with new words in WordNet. The classifier (C) calculates the reward of the generated example and returns it to the generator. **G** maximizes the expectation of the reward of generated examples by policy gradient and C minimizes the cross entropy loss between real and generated examples.

successfully confuses the classifier and decreases the probability of the original label, we regard it as a good example and give it a high reward. In this way, the generator is encouraged to generate tough examples for the classifier and the challenging generated examples are used in the training process of the classifier. By alternatively training the generator and the classifier, the classifier is trained to be more robust and powerful.

3.2 Generator

The generator generates attacking examples by adding noises on real examples with WordNet. WordNet is a large English lexical database. Nouns, verbs, adjectives and adverbs are grouped into cognitive synonyms sets (synsets). Each synset represents a distinct concept. As shown in Table 1, WordNet has two basic relations:

- Synonymy. It is the most basic relation, because WordNet uses sets of synonyms (synsets) to represent word senses.
- Hyponymy and hypernymy (super-subordinate). They are transitive relations between synsets. Because there is usually only one hypernym, the semantic relation hierarchically organizes the meanings of nouns.

The generation process is defined as a sequence labeling task for simplification. It takes a text sequence as input and an action sequence as output. Specifically, we define five actions representing the replacement decision, whether a word should be replaced or its replacement type, as shown in Table 2. For example, if a word is labeled with action "2", we choose a word from its subordinate words with the highest frequency as the replacement. Formally, assume that the input is a sequence of words $\boldsymbol{x} = \{x_1, x_2, \cdots, x_n\}$ where n is the length of input text. This module generates a sequence of replacement actions $\boldsymbol{a} = \{a_1, a_2, \cdots, a_n\}$. Then, by querying WordNet based on $\boldsymbol{x}$ and $\boldsymbol{a}$, we can get a new sentence. Since the proposed framework is independent of the structure of the generator, for simplification we use a traditional sequence labeling model, Bi-Directional Long-Short Term Memory Network

Relation	Syntactic Category	Examples
Synonymy (similar)	N, V, Aj, Av	(pipe, tube) (rise, ascend) (sad, unhappy)
Hyponymy and Hypernymy (super-subordinate)	N	(sugar maple, maple) (maple, tree) (tree, plant)
Note: N = Nouns, Aj = Adjectives, V = Verbs, Av = Adverbs		

Table 1: Basic relations in WordNet.

Action	Description	Example
0	No replacement	N/A
1	Replacing with a super word	hamburger vs. sandwich
2	Replacing with a subordinate word	fish vs. salmon
3	Replacing with a synonymy	disappointed vs. frustrated
4	Replacing with a neighbor word	elephant vs.donkey

Table 2: Actions defined in this work. The neighbor word is the word that shares the same super word with the word to be replaced.

(Bi-LSTM) (Hochreiter and Schmidhuber, 1997), as implementation.

3.3 Classifier

In this work, we focus on single-label sentiment classification. The input is a sequence of words and the output is a label from a pre-defined set $Y = \{y_1, y_2, \cdots, y_k\}$, where k is the number of labels. To evaluate the effectiveness of the proposed approach on various settings, we implement two widely-used sentiment classification networks, Recurrent Neural Network (RNN) and Convolutional Neural Network (CNN) (Kim, 2014), and one state-of-the-art pre-trained model, BERT (Devlin et al., 2018).

In the RNN-based classifier, the input word embeddings are fed into a single Long-Short Term Memory Network (LSTM). Then, a feed-forward layer transfers the last hidden vector of LSTM into the probability distribution of labels.

In the CNN-based classifier, we first feed the word embeddings into a convolutional layer with four convolutional filters. Then, the concatenated filter output applies a max-pooling and is fed into a two-layer feed-forward network with ReLU, followed by the softmax function.

In the BERT-based classifier, we use a model pre-trained on a large-scale language modeling dataset for initialization. Following the work (Devlin et al., 2018), we take the final hidden state for the first token in the input as sentence representation for classification. We use the released model and code, BERT-large, as implementation, which is based on 24 transformer layers.[4]

3.4 Adversarial Reinforcement Training

Due to the discrete choice in generation steps, we use policy gradient, a reinforcement learning approach, to adversarially train the two modules. The generator can be viewed as the agent which interacts with the classifier that acts as environment. The generator improves itself by maximizing the reward returned from the environment.

Given a real example $(\boldsymbol{x}, y)$, the generator first samples an action sequence $\hat{\boldsymbol{a}}$ based on the following probability distribution:

$$\hat{\boldsymbol{a}} \sim p_{\mathbf{G}}(\boldsymbol{a}|\boldsymbol{x}, \boldsymbol{\theta}), \tag{1}$$

where $\boldsymbol{\theta}$ represents the parameter of the generator.

[4]The pre-trained model is provided by goo.gl/language/bert

Algorithm 1 Adversarial reinforcement training.

Require: Generator $\mathbf{G}$; classifier $\mathbf{C}$; training corpus $\mathcal{D}$
Initialize $\mathbf{G}$ and $\mathbf{C}$ with random weights

    Build a new example $(\boldsymbol{x'}, y)$ using $\hat{\boldsymbol{a}}$
    Compute reward $r(\hat{\boldsymbol{a}})$ by Eq. (3)
    Update parameters of $\mathbf{G}$ by Eq. (4)
  end for
  for rl-steps **do**
    Sample an action sequence $\hat{\boldsymbol{a}}$ using Eq. (1)
    Build a new example $(\boldsymbol{x'}, y)$ using $\hat{\boldsymbol{a}}$
    Compute reward $r(\hat{\boldsymbol{a}})$ by Eq. (3)
    Update parameters of $\mathbf{G}$ by Eq. (4)
    Update parameters of $\mathbf{C}$ by Eq. (5)
    Update parameters of $\mathbf{C}$ by Eq. (6)
  end for
until convergence

Based on the sampled action sequence $\hat{\boldsymbol{a}}$, we get a new example $(\boldsymbol{x'}, y)$ after word replacement.

Then, we feed the real example $(\boldsymbol{x}, y)$ and the generated example $(\boldsymbol{x'}, y)$ into the classifier to get the replacement reward $r(\hat{\boldsymbol{a}})$. Specifically, we define the reward as the absolute difference of the probability of y between the real example and the generated example:

$$r(\hat{\boldsymbol{a}}) = \log p_{\mathbf{C}}(y|\boldsymbol{x}; \boldsymbol{\phi}) - \log p_{\mathbf{C}}(y|\hat{\boldsymbol{x}}; \boldsymbol{\phi}), \tag{2}$$

where $\boldsymbol{\phi}$ is the parameter of the classifier. If the generated example successfully confuses the classifier and decreases the probability of y, we regard it as a good example and give it a high reward. In practice, we use the following equation to get a new reward to train the generator steadily:

$$r'(\hat{\boldsymbol{a}}) = r(\hat{\boldsymbol{a}}) - \mathbb{E}_{P_G(\boldsymbol{a}|\boldsymbol{x}, \boldsymbol{\theta})}(r(\boldsymbol{a})), \tag{3}$$

where $\mathbb{E}_{P_G(\boldsymbol{a}|\boldsymbol{x}, \boldsymbol{\theta})}(r(\boldsymbol{a}))$ is the expectation of $r(\boldsymbol{a})$.

Then, the reward is fed back to the generator. Formally, the expected gradient of the parameter $\boldsymbol{\theta}$ can be approximated as:

$$\begin{aligned} \nabla_{\boldsymbol{\theta}\mathcal{L}} \approx & - r'(\hat{\boldsymbol{a}}) \nabla_{\boldsymbol{\theta}} \log p_{\mathbf{G}}(\hat{\boldsymbol{a}}|\boldsymbol{x}; \boldsymbol{\theta}) \\ & - \mathbb{E}_{p_{\mathbf{G}}(\hat{\boldsymbol{a}}|\boldsymbol{x}; \boldsymbol{\theta})} r'(\hat{\boldsymbol{a}}), \end{aligned} \tag{4}$$

where $\hat{\boldsymbol{a}}$ is the generated action sequence. The second term $\mathbb{E}_{p_{\mathbf{G}}(\hat{\boldsymbol{a}}|\boldsymbol{x}; \boldsymbol{\theta})} r'(\hat{\boldsymbol{a}})$ means we approximate the expectation with sampling in practice.

The generated example $(\boldsymbol{x'}, y)$ is then used to train the classifier by minimizing the following cross-entropy loss:

$$\mathcal{L} = - \log p_{\mathbf{C}}(y|\boldsymbol{x'}, \boldsymbol{\phi}). \tag{5}$$

Furthermore, to prevent the classifier from forgetting the knowledge of training data, we also use teacher forcing (Goyal et al., 2016) to train the classifier. After each reinforcement training step, we run a teacher forcing step by directly using the real example $(\boldsymbol{x}, y)$ to train the classifier:

$$\mathcal{L} = -\log p_{\mathbf{C}}(y|\boldsymbol{x}, \boldsymbol{\phi}). \quad (6)$$

Considering that reinforcement learning process requires the two modules with the initial learning ability, we pre-train the generator and the classifier before the reinforcement learning stage. The classifier is directly pre-trained on real training data until convergence. Due to the lack of supervisory signals, we build a warm-up stage to pre-train the generator. In the warm-up stage, the feedback of the pre-trained classifier is used to train the generator.

4 Experiments

We evaluate LexicalAT on four sentiment classification datasets. We first introduce datasets, implementation details, and baselines. Then, we show experiment results and provide detailed analysis.

4.1 Datasets

SST-2 & SST-5. The Stanford sentiment treebank (Socher et al., 2013) is a single-sentence classification dataset built on movie reviews. Based on the difference of sentiment granularity, the human annotators design two label sets. Following existing work (Kobayashi, 2018), we run experiments on both label sets. For clarify, we call them SST-2 and SST-5.

RT. The rating inference dataset (Pang and Lee, 2005) is another sentiment classification dataset. The data is from internet movie reviews and has two types of labels.

Yelp. The dataset is built upon reviews from website Yelp.[5] Each review has a rating label varying from 1 to 5. We randomly select 100K for training, 10K for validation, and 10K for testing. It is used to verify whether the proposed approach is applied to tasks with large-scale data.

The dataset statistics are shown in Table 3. For SST-2 and SST-5, we use the standard split in their work. For RT, due to the lack of the standard split, we randomly divide all examples into 90% for the training set and 10% for the test set. To build the development set, we randomly take out 10% from the training set.

[5]https://www.yelp.com/dataset/challenge

Dataset	#Class	Avg. #w	Train	Dev	Test
SST2	2	19	6,920	872	1,821
SST5	5	18	8,544	1,101	2,210
RT	2	21	8,608	964	1,089
Yelp	5	89	100,000	10,000	10,000

Table 3: Dataset statistics. "Class" is the number of pre-defined labels. "Avg. #w" is the average word number in the input text. "Train", "Dev", and "Test" represent the sizes of the training set, the development set, and the test set.

4.2 Baselines

We compare our proposed approach with the following robustness-driven approaches.

SynDA. It is a synonymy based data augmentation approach (Zhang et al., 2015). It uses an English thesaurus, obtained from WordNet, to randomly replace some words in real examples with their synonymys to build new examples.

ConDA. It is a contextual data augmentation approach (Kobayashi, 2018). They build adversarial examples by randomly replacing words in real examples with the words that are predicted by a bidirectional language model at the word positions.

VAT. It is an adversarial training based approach (Miyato et al., 2017) for robust text classification. It adds perturbations to recurrent neural networks to improve the robustness. We use the released code for implementation.

4.3 Experiment settings

Based on the performance on the development sets, we set batch size to 64 except yelp whose batch size is 256. We use the Adam optimizer to train the modules. The details of model-specific hyper-parameter settings are shown in Table 4. In the pre-training stage, we train the classifier until convergence. In the warm-up stage, we train the generator by 3 epoch. In the reinforcement training stage, we set the maximum epcoh to 100 and adopt the early stopping mechanism.

4.4 Results and Discussion

The results of the proposed approach and baselines are shown in Table 5.

	Hyper-Parameter	Setting
Generator	Embedding size	300
	Embedding dropout	0.4
	Hidden size	300
	BiLSTM layer	1
	Learning rate	1e-3

Table 5: Comparisons between LexicalAT and baselines on four datasets.[6] LexicalAT outperforms strong baselines on all datasets, including three small datasets and a large dataset, Yelp.

As expected, LexicalAT, the proposed approach, substantially outperforms the naive baselines (RNN, CNN and BERT). Since RNN and CNN are directly trained on training sets, they tend to suffer from over-fitting. Therefore, it is reasonable that LexicalAT brings improvements to RNN and CNN models. BERT has better generalization ability because it has been pre-trained on a large scale corpus. Even so, LexicalAT still gains accuracy improvements over BERT by 0.43 on SST-2, 0.31 on SST-5, 0.11 on RT, and 0.74 on Yelp, respectively. These results show that the proposed approach is universal and well applied to various models, even the state-of-the-art pre-trained model BERT.

By contrast, SynDA, the synonymy based data augmentation approach, does not bring significant performance improvements over the naive baselines. The main difference between LexicalAT and SynDA is that SynDA uses the random replacement policy to generate new examples, while LexicalAT uses the dynamic replacement policy learned by the proposed adversarial reinforcement training framework. The performance gap between LexicalAT and SynDA shows that the proposed adversarial reinforcement training framework is effective for learning the attacking policy toward the weaknesses of the classifier. Furthermore, the proposed approach beats VAT under various datasets. Since VAT only adds random noises on word embeddings without changing the input text, it does not augment the training data with new words and expressions, and thus limits the robustness improvement. In summary, with adversarial reinforcement training, lexicalAT is capable of learning the attacking policy toward the weaknesses of the classifier. With WordNet, lexicalAT can generate examples with diverse expressions, which improves the classifier robustness. These advantages make the proposed approach perform well and achieve the best performance on various datasets.

To illustrate the training process, we plot the performance on the SST-5 development set in Figure 3. LexicalAT converges to a higher accuracy than the naive baseline RNN. It shows that the adversarial reinforcement training mechanism is robust and can converge to good results.

Furthermore, we compare the performance of lexicalAT and naive baselines on defending attacks, taking RNN and CNN on SST-2, SST-5, and RT as examples. The results are shown in Table 6. "RNN-Attacking Set" and "CNN-Attacking Set" are two sets generated by two different gen-

[6]The results of SynDA and ConDA are from the work of Kobayashi (2018).

CNN-Attacking Set	62.90	61.89	69.88	71.17

Table 6: Comparisons of different classifiers on defending attacks. The classifiers trained in lexicalAT, lexicalAT (RNN) and lexicalAT (CNN), have better defending ability. "Classifier (RNN)" and "Classifier (CNN)" are two different naive baselines trained on real examples. "Lexical (RNN)" and "Lexical (CNN)" are two classifiers trained in the framework of lexicalAT. "Test Set" is the standard test set. "RNN-Attacking Set" and "CNN-Attacking Set" are two attacking sets generated by two generators in the framework of lexicalAT based on real test examples. The two generators are trained based on the interaction with RNN-based and CNN-based classifiers, respectively.

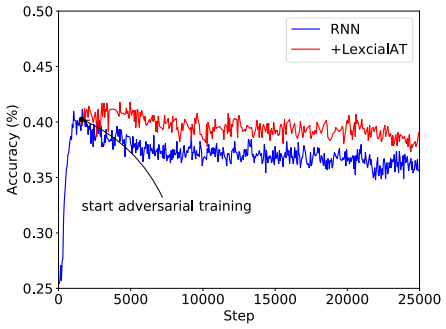

Figure 3: Learning curves of RNN and LexicalAT on the development set of SST-5.

Setting	SST-2	SST-5	RT	Average
all words (RNN)	81.60	41.14	75.76	66.17
-super words	80.72	41.17	75.02	65.64
-subordinate words	80.56	41.67	75.48	65.90
-synonymy words	**80.45**	41.99	76.12	66.19
-neighbor words	80.56	**40.91**	**74.66**	**65.38**
Setting	**SST-2**	**SST-5**	**RT**	**Average**
all words (CNN)	80.18	41.86	74.84	65.63
-super words	79.96	41.67	76.22	65.95
-subordinate words	81.58	41.49	75.39	66.15
-synonymy words	**79.24**	41.67	74.74	**65.22**
-neighbor words	81.33	**40.68**	**74.47**	65.49

Table 7: Effects of different replacement actions. As we can see, neighbor and synonymy words contribute most to the performance.

erators in lexicalAT based on real test examples. The two generators are trained based on the interaction with RNN-based and CNN-based classifiers, respectively. The naive baselines, RNN and CNN, have weak robustness performances and the results drop largely on attacking examples, even a 15% accuracy decrease for "Classifier (CNN)" on SST-2. In comparison, the classifiers trained in lexicalAT, lexicalAT (RNN) and lexicalAT (CNN), have better defending ability.

4.5 Analysis

What is the effect of each action? To show the effect of different actions, we take RNN and CNN on SST-2, SST-5, and RT as examples and conduct experiments by dropping one action at a time. As Table 7 shows, only some actions are useful for the robustness improvement. The average performance becomes better after dropping subordinate words under two different settings. Surprisingly, the neighbor words largely contribute to the performance. Without neighbor words, the average accuracies are dropped from 66.17 to 65.38 for RNN, and from 65.63 to 65.22 for CNN. Neighbor words share the same super word, like "fox" and "wolf". In WordNet, neighbor words usually have similar semantic meanings. By replacing a word with its similar word, the semantic diversity can be largely enhanced. Furthermore, the semantic similarity can reduce the risk of changing the label when modifying the input text. Therefore, it is a good choice to include this relation in models unless the replacement exactly impacts the original label in specific tasks.

Is the learned attacking policy universal or model-specific? To explore this question, we

	Classifier (RNN)	Classifier (CNN)
None	80.81	80.62
Policy-RNN	**81.44**	80.89
Policy-CNN	81.22	**81.27**

Table 8: Results of different classifiers trained with the examples generated by different attacking policies on SST-2 dataset. "Policy-RNN" and "Policy-CNN" are the learned policies from the interaction with RNN-based and CNN-based classifiers in the proposed framework.

conduct the following experiments.

We train two generators based on the feedback of the classifiers with different structures (e.g., RNN and CNN) on SST-2. For clarify, we call the learned attacking policies in the two generators as policy-RNN and policy-CNN, as shown in Table 8. Then, we put the examples generated by policy-RNN and policy-CNN into the training data to train the classifiers with different structures.

For the RNN-based classifier, two attacking policies both outperform the naive RNN baseline, which shows the universality of the learned attacking policy. Furthermore, policy-RNN brings more improvements than policy-CNN does on the RNN-based classifier. It demonstrates that the learned attacking policy has model-specific features. Similar result happens to the CNN-based classifier.

In summary, different classification models share some weaknesses and have their own unique vulnerability. Considering unique weaknesses are difficult to be summarized by human knowledge, our approach is an effective way to automatically learn the attacking policy toward the classifier weaknesses.

4.6 Case Study

Table 9 presents the adversarial examples generated by the generator on SST-5. Even the simple perturbations can confuse the classifier, which shows the weak robustness of the classifier.

4.7 Error Analysis

Although the proposed approach improves the robustness of current classifiers, it is important to note that there still have several problems to be further explored.

First, some generated examples contain low-quality phrases, such as the bottom one in Table 9. This problem is due to the inappropriate word replacement. In the future work, we would like to explore how to generate diverse and high-quality examples by taking sentence context, replaced word features, and replacing word features into consideration.

Original Text	The **movie** is without **intent**.
Generated Text	The **film** is without **spirit**.
Original Text	The **script** is smart not **cloying**.
Generated Text	The **dialogue** is smart not **saccharine**.
Original Text	This is a gorgeous **film** vivid with **color music** and **life**.
Generated Text	This is a gorgeous **movie** vivid with **gloss sound** and **spirit**.
Original Text	Hollywood ending is the most **disappointing** woody allen **movie** ever.
Generated Text	Hollywood ending is the most **fail** woody allen **film** ever.

Table 9: Adversarial examples generated by our approach.

Second, we regard the examples that confuse the classifier as good attacking examples and give them high reward to train the generator. However, not all confusing examples are useful for robustness improvements. To optimize the training time, in the future we will explore an advanced LexicalAT to automatically distinguish between "useful examples" and "useless examples".

5 Conclusion and Future Work

In this work, we propose a new adversarial training approach, LexicalAT, to improve the robustness of current sentiment classification models. The key idea is to use WordNet and adversarial reinforcement training to automatically learn the diversely attacking policy. We evaluate LexicalAT on four representative sentiment classification datasets. Experiments demonstrate that the proposed approach has better generality and reduces test errors on various neural networks, including CNN, RNN, and BERT.

In the future work, we would like to build an advanced version of LexicalAT from the following perspectives. First, to address the problem of low-quality phrases in generated text, we will explore how to keep the syntactic correctness of the generated text. Second, we would like to figure out the detailed effects of the generated examples on the robustness of sentiment classification models. By removing useless examples, we can obtain higher training speed.

Abstract

Opinionated text often involves attributes such as authorship and location that influence the sentiments expressed for different aspects. We posit that structural and semantic correspondence is both prevalent in opinionated text, especially when associated with attributes, and crucial in accurately revealing its latent aspect and sentiment structure. However, it is not recognized by existing approaches.

We propose Trait, an unsupervised probabilistic model that discovers aspects and sentiments from text and associates them with different attributes. To this end, Trait infers and leverages structural and semantic correspondence using a Markov Random Field. We show empirically that by incorporating attributes explicitly Trait significantly outperforms state-of-the-art baselines both by generating attribute profiles that accord with our intuitions, as shown via visualization, and yielding topics of greater semantic cohesion.

1 Introduction

Opinionated text is often associated with different *attributes*—latent variables that serve as reference frames relative to which the underlying aspects and sentiments are expressed. Common attributes in consumer reviews include author type (e.g., business traveler or tourist for hotel reviews; location for reviews of music (McDermott et al., 2016); culture on reviews of food (Bahauddin and Shaarani, 2015)). Whereas current approaches consider attributes in a one-off manner in each application, we posit that attributes can be systematically extracted if we can properly capture the structural and semantic correspondence that is prevalent in opinionated text. We claim that ignoring attributes may lead to biased inference on aspects and sentiments. As evidence, we demonstrate an approach that outperforms the state of the art and yields intuitive and cohesive topics.

We propose Trait, a general model for discovering attribute-oriented aspects and sentiments from text. By incorporating attributes, Trait automatically generates profiles that describe attributes in terms of sentiments and aspects. To leverage structural and semantic correspondence, Trait applies a Markov Random Field as regularization over sentences during inference. We evaluate Trait on four datasets from two domains and consider three attributes. Trait successfully discovers aspects associated with sentiments; the generated word clusters are more cohesive than the state-of-the-art baselines; the generated attribute profiles are well correlated with ground truth.

Motivating Example. Figure 1 presents two hotel reviews from TripAdvisor. We manually assign aspect labels for sentences and calculate pairwise cosine similarity between sentences using sentence embedding from a pretrained sentence encoding model (Cer et al., 2018).

Review A and Review B, which mention aspects *Room*, *Location*, and *Type*, exhibit structural and semantic correspondence. We posit that the correspondence of *Location* and *Type* is a result of the attribute value, Las Vegas, common to the two reviews. *Location* is a crucial aspect for hotels in Las Vegas. On a randomly selected set of 5,000 hotel reviews for Las Vegas, we observe that 4,281 sentences from 2,624 reviews mention the location "Strip." Using a similarity threshold of 0.6, we obtain 1,929 sentences similar to sentence A3 from 1,519 reviews, including sentence B3 in Review B. We obtain 133 sentences similar to sentence B4 from 128 reviews including A4 in Review A. Figure 1 shows some of these sentences. Likewise, using authorship as an attribute, we observe that users stick to their writing styles. For example, in hotel reviews, some users describe the condition of a room and others share travel tips.

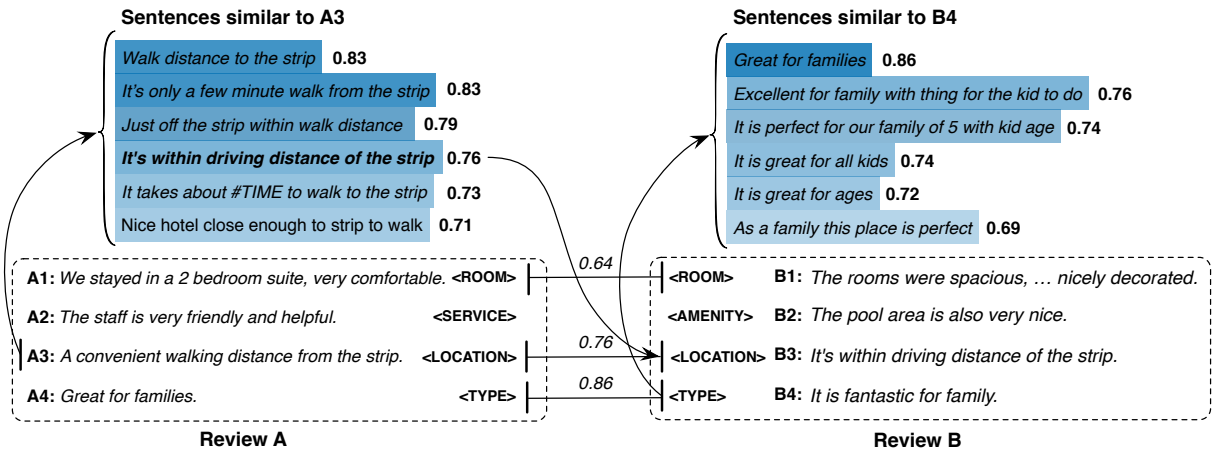

Figure 1: A motivating example.

Contributions and Novelty. Our contributions include: (1) a general model that generates attribute profiles associating aspects and sentiments with attributes in text; (2) empirical results demonstrating the benefit of incorporating attributes on a model's quality; and (3) empirical results demonstrating generalizability using diverse attributes and the quality of the generated attribute profiles.

Trait's novelty lies in its ability to accommodate attributes. First, it is general across attributes as opposed to being limited to predefined attributes. Second, the handling of attributes means that Trait avoids overfitting to the more prevalent attributes in a dataset. That is, Trait can learn a more refined conditional probability distribution that incorporates specific attributes than otherwise possible. Ignoring the observable attribute variables would relax the constraints on the distribution, meaning that the learned approximate distribution would be biased toward the majority attribute.

Summary of Findings. We demonstrate that incorporating attributes into generative models provides a superior, more refined representation of opinionated text. The resulting model generates topics with high semantic cohesion. We show that Markov Random Field can be used for effectively capturing structural and semantic correspondence.

2 Related Work

Generative probabilistic modeling has been widely applied for unsupervised text analysis. Given the observed variables, e.g., tokens in documents, a generative probabilistic model defines a set of dependencies between hidden and observed variables that encodes statistical assumptions underlying the data. Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a well-known topic model, represents a document as a mixture of topics, each topic being a multinomial distribution over words. The learning process approximates the topic and word distributions based on their co-occurrence in documents.

Many efforts guide the topics learned by incorporating additional information. Rosen-Zvi et al.'s (2004) Author Topic model (AT) captures authorship by building a topic distribution for each author. When generating a word in a document, AT conditions the probability of topic assignment on the author of the document. Kim et al.'s (2012) model captures entities mentioned in documents and models the probability of generating a word as conditioned on both entity and topic. Diao and Jiang (2013) jointly model topics, events, and users on Twitter. Trait goes beyond these models by incorporating sentiments and attributes in a flexible way, which eliminates the model's dependency on specific attribute types.

Several probabilistic models tackle opinionated text. Titov and McDonald (2008b) handle global and local topics in documents. JST (Lin et al., 2012) and ASUM (Jo and Oh, 2011) model a review via multinomial distributions of topics and sentiments used to condition the probability of generating words. Kim et al. (2013) extend ASUM's probabilistic model to discover a hierarchical structure of aspect-based sentiments. Wang et al.'s (2016) topic model discovers aspect, sentiment, and both general and aspect-specific opinion words. Whereas these models identify aspects and sentiments, they disregard attribute information.

Titov and McDonald (2008a) discover top-

ics using aspect ratings provided by reviewers. Mukherjee et al.'s (2014) JAST considers authors during aspect and sentiment discovery. Poddar et al.'s (2017) AATS jointly considers author, aspect, sentiment, and the nonrepetitive generation of aspect sequences via a Bernoulli process. Zhang and Singh (2018)'s model jointly captures aspect, sentiment, author, and discourse relations. Trait is novel in that, unlike the above models, it is not tied to a specific attribute.

3 Model and Inference

We now introduce Trait's model and inference mechanism.

3.1 Sentence Embeddings

Measuring semantic similarity between sentences is integral to capturing the structural and semantic correspondence among reviews: high similarity indicates a high degree of correspondence. Cer et al. (2018) propose a pretrained sentence encoding model, Universal Sentence Encoder (USE). USE is based on Vaswani et al.'s (2017) attention-based neural network. Perone et al. (2018) show USE yields the best results among sentence embedding techniques on semantic relatedness and textual similarity tasks. Trait adopts USE to generate sentence embeddings and cosine similarity to measure semantic similarity between sentences.

3.2 Structural and Semantic Correspondence

A Markov Random Field (MRF) defines a joint probability distribution over a set of variables given the dependencies based on an undirected graph. The joint distribution is a factorized product of potential functions.

To capture structural and semantic correspondence, Trait defines an MRF over latent aspects of sentences. Given a set of reviews D_a sharing a common attribute a, for sentence l in D_a, Trait creates its corresponding sentence set L by adding sentence l_i in D_a if the semantic similarity between sentence l_i and l is larger than a preset threshold ρ. For each pair of l and l_i, Trait creates an undirected edge between the aspects associated with the two sentences (t_l, t_{li}). To promote l and sentences in L having a high probability of associating with the same aspect, Trait defines a binary edge potential, $\exp\{\mathcal{I}(t_l, t_{li})\}$, where $\mathcal{I}(\cdot)$ is an indicator function. This binary potential produces a large value if the two sentences have the same aspect and a small value otherwise. Given attribute a, sentiment s, and a document consisting of N sentences, Trait computes the joint probability of aspect assignments of sentences as:

$$p(\boldsymbol{t}|\psi_{s,a}, \lambda) = \prod_{l}^{N} p(t_l|\psi_{s,a}) \exp\left\{\lambda \frac{\sum_{(t_l,t_{l_i})\in\mathcal{E}_l} \mathcal{I}(t_l = t_{l_i})}{|\mathcal{E}_l|}\right\}, \quad (1)$$

where $\psi_{s,a}$ is the aspect distribution given sentiment s and attribute a; parameter λ controls the reinforcing effects of correspondence regularization; and $\mathcal{E}_l$ is the set of undirected edges for l.

3.3 Generative Process

To capture the desired associations, given an attribute type, Trait generates a mixture over sentiments and aspects for each attribute value. Trait assumes that reviews are mixtures of sentiments and considers sentences the basic unit for a sentiment-aspect pair.

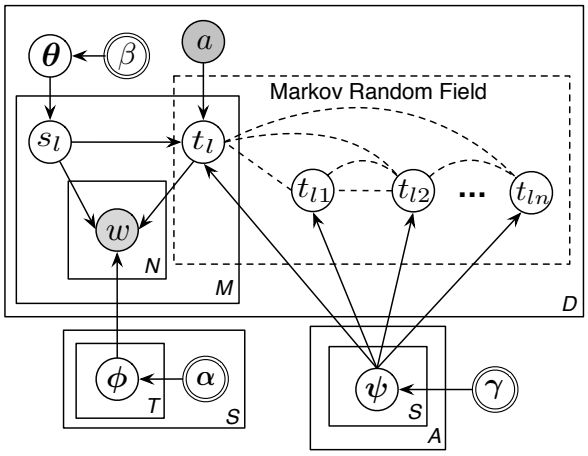

Figure 2: Generative process of Trait.

Figure 2 shows Trait's model. Hyperparameter α is the Dirichlet ($Dir(\cdot)$) prior of the word distribution ϕ; β is the Dirichlet prior of the sentiment distribution θ; and γ is the Dirichlet prior of the aspect distribution ψ. Given a set of reviews D associated with a set of attribute values A over a set of aspects T and a set of sentiments S, each review contains M sentences and each sentence contains N words. Trait's generative process is as follows.

First, for each pair of aspect t and sentiment s, draw a word distribution $\phi_{t,s} \sim Dir(\alpha)$. Second, for each attribute value a and each sentiment

s, draw an aspect distribution $\psi_{s,a} \sim Dir(\gamma)$. Third, given a review d with attribute a, draw a sentiment distribution $\theta_d \sim Dir(\beta)$, and for each sentence in d, (1) choose a sentiment $s \sim Multinomial(\theta_d)$; (2) given s, choose an aspect $t \sim Multinomial(\psi_{s,a})$; (3) given t and s, sample word $w \sim Multinomial(\phi_{t,s})$.

Trait estimates $p(\boldsymbol{s}, \boldsymbol{t}|\boldsymbol{w}, a)$, the posterior distribution of latent variables, sentiments $\boldsymbol{s}$, and aspects $\boldsymbol{t}$, given all words used in reviews involving attribute a. We factor the joint probability of assignments of sentiments, aspects, and words for a:

$$p(\boldsymbol{s}, \boldsymbol{t}, \boldsymbol{w}|a) = p(\boldsymbol{w}|\boldsymbol{s}, \boldsymbol{t})p(\boldsymbol{t}|\boldsymbol{s}, a)p(\boldsymbol{s}). \quad (2)$$

3.4 Inference

We use collapsed Gibbs sampling (Liu, 1994) for posterior inference. By integrating over $\Phi = \{\boldsymbol{\phi_i}\}_{i=1}^{S\times T}$, we obtain Equation 2's first term (Section 4.1 explains α_v).

$$p(\boldsymbol{w}|\boldsymbol{s},\boldsymbol{t},\boldsymbol{\alpha}) = \int p(\boldsymbol{w}|\boldsymbol{s},\boldsymbol{t},\Phi)p(\Phi|\boldsymbol{\alpha})\mathrm{d}\Phi$$
$$= \left(\frac{\Gamma(\sum_{v=1}^{W}\alpha_v)}{\prod_{v=1}^{W}\Gamma(\alpha_v)}\right)^{S\times T} \times \prod_{s=1}^{S}\prod_{t=1}^{T}\frac{\prod_{v=1}^{W}\Gamma(n_{s,t}^{v}+\alpha_v)}{\Gamma\left[\sum_{v=1}^{W}(n_{s,t}^{v}+\alpha_v)\right]}, \quad (3)$$

where W is the vocabulary size; $n_{s,t}^{v}$ is the number of occurrences of word v assigned to sentiment s and aspect t; and $\Gamma(\cdot)$ is the Gamma function.

Next, by integrating over $\Psi_a = \{\boldsymbol{\psi_i}\}_{i=1}^{S}$, we calculate the second term in Equation 2 as (Section 4.1 explains γ_t):

$$p(\boldsymbol{t}|\boldsymbol{s},\boldsymbol{\gamma},a) = \int p(\boldsymbol{t}|\boldsymbol{s},\Psi_a,a)p(\Psi_a|\boldsymbol{\gamma})\mathrm{d}\Psi_a$$
$$= \left(\frac{\Gamma(\sum_{t=1}^{T}\gamma_t)}{\prod_{t=1}^{T}\Gamma(\gamma_t)}\right)^{S} \times \prod_{s=1}^{S}\frac{\prod_{t=1}^{T}\Gamma(n_{s,a}^{t}+\gamma_t)}{\Gamma\left[\sum_{t=1}^{T}(n_{s,a}^{t}+\gamma_t)\right]}$$
$$\times \prod_{m=1}^{M} exp\left\{\lambda\frac{\sum_{t_j\in L_m}\mathcal{I}(t_j=t)}{|L_m|}\right\}, \quad (4)$$

where $n_{s,a}^{t}$ equals the number of sentences in reviews associated with attribute a, sentiment s, and aspect t; M is the number of sentences in reviews; L_m is the set of sentences corresponding to sentence m.

Similarly, for the third term in Equation 2, by integrating over $\Theta = \{\boldsymbol{\theta_i}\}_{i=1}^{D}$, we obtain (Section 4.1 explains β_s):

$$p(\boldsymbol{s}|\boldsymbol{\beta}) = \int p(\boldsymbol{s}|\Theta)p(\Theta|\boldsymbol{\beta})\mathrm{d}\Theta$$
$$= \left(\frac{\Gamma(\sum_{s=1}^{S}\beta_s)}{\prod_{s=1}^{S}\Gamma(\beta_s)}\right)^{D} \times \prod_{d=1}^{D}\frac{\prod_{s=1}^{S}\Gamma(n_d^s+\beta_s)}{\Gamma\left[\sum_{s=1}^{S}(n_d^s+\beta_s)\right]}, \quad (5)$$

where D is the number of reviews; n_d^s is the number of times that a sentence from review d is associated with sentiment s; and n_d is the number of sentences in review d.

For each sweep of a Gibbs iteration, we sample latent aspect t and sentiment s as follows:

$$p(s_i = s, t_i = t|\boldsymbol{s_{-i}}, \boldsymbol{t_{-i}}, \boldsymbol{w}, a)$$
$$\propto \frac{n_{s,a,-i}^{t}+\gamma_t}{\sum_{t=1}^{T}(n_{s,a,-i}^{t}+\gamma_t)} \times \frac{n_{d,-i}^{s}+\beta_s}{\sum_{s=1}^{S}(n_{d,-i}^{s}+\beta_s)}$$
$$\times \frac{\prod_{v\in W_i}\prod_{c=0}^{C_v^i-1}(n_{s,t,-i}^{v}+\alpha_v+c)}{\prod_{c=0}^{C_i-1}(n_{s,t,-i}+\sum_{v=1}^{W}\alpha_v+c)} \quad (6)$$
$$\times exp\left\{\lambda\frac{\sum_{t_j\in L_i}\mathcal{I}(t_j=t)}{|L_i|}\right\},$$

where $n_{s,a}^{t}$ is the number of sentences from reviews associated with attribute a, sentiment s, and aspect t; n_d^s is the number of sentences from review d associated with sentiment s; W_i is the set of words in sentence i. C_v^i is the count of word v in sentence i; C_i is the number of words in sentence i; $n_{s,t}^{v}$ is the number of words v assigned sentiment s and aspect t; $n_{s,t}$ is the number of words assigned sentiment s and aspect t in all reviews; L_i is the set of corresponding sentences of sentence i; and an index of $-i$ indicates excluding sentence i from the count.

Equations 7, 8, and 9, respectively, approximate the probabilities of word w occurring given sentiment s and aspect t; of aspect t of a sentence occurring given sentiment s and attribute a; of sentiment s occurring given document d.

$$\phi_{s,t,w} = \frac{n_{s,t}^{w}+\alpha_w}{\sum_{v=1}^{W}(n_{s,t}^{w}+\alpha_v)}, \quad (7)$$

$$\psi_{s,t,a} = \frac{n_{s,a}^{t}+\gamma_t}{\sum_{t=1}^{T}(n_{s,a}^{t}+\gamma_t)}, \quad (8)$$

$$\theta_{d,s} = \frac{n_d^s+\beta_s}{\sum_{s=1}^{S}(n_d^s+\beta_s)}. \quad (9)$$

The generalized Pólya Urn model (Mahmoud, 2008) has been used for encoding word co-

occurrence information into topic models. Consider an urn containing a mixture of balls, each of which is tagged with a term, for each sampling sweep we draw a ball from the urn. In a standard Pólya Urn model, as used in LDA, we return the ball to the urn with another ball tagged with the same term. This process provides burstiness of the probability of seeing a term but ignores the covariance. The probability increase of one term decreases the probability of the other words. In the generalized Pólya Urn model, when a ball is drawn from the urn, we replace it with two new balls with a set of balls tagged with related terms. Similar to previous models (Mimno et al., 2011; Chen et al., 2013; Fei et al., 2014; Zhang and Singh, 2018), to increase the probability of having semantically related words appear in the same topic, Trait applies a generalized Pólya Urn model in each Gibbs sweep and uses weight ε to promote related words based on the cosine similarity between their Word2Vec (Mikolov et al., 2013) embeddings.

4 Evaluation

To assess Trait's effectiveness, we select the hotel and restaurant domains and prepare four review datasets associated with three attributes: author, trip type, and location. HotelUser, HotelType, and HotelLoc are sets of hotel reviews collected from TripAdvisor. HotelUser contains 28,165 reviews posted by 202 randomly selected reviewers, each of whom contributes at least 100 hotel reviews. HotelType contains reviews associated with five trip types including business, couple, family, friend, and solo. HotelLoc contains a total of 136,446 reviews about seven US cities, split approximately equally. ResUser is a set of restaurant reviews from Yelp Dataset Challenge (2019). It contains 23,874 restaurant reviews posted by 144 users, each of whom contributes at least 100 reviews. Table 1 summarizes our datasets. Datasets and source code are available for research purposes (Trait, 2019).

Table 1: Summary of the evaluation datasets.

Statistic	HotelUser	ResUser	HotelType	HotelLoc
# of reviews	28,165	23,873	22,984	136,446
# of sentences	362,153	276,008	302,920	1,428,722
Sentence/Review	13	12	13	10
Words/Sentence	8	7	7	7

We remove stop words and HTML tags, expand typical abbreviations, and mark special named entities using a rule-based algorithm (e.g., replace a URL by #LINK# and replace a monetary amount by #MONEY#) and the Stanford named entity recognizer (Finkel et al., 2005). We use Porter's (1980) stemming algorithm. To handle negation, for any word pair whose first word is *no*, *not*, or *nothing*, we replace the word pair by a negated term, e.g., producing *not_work* and *not_quiet*. Finally, we split each review into constituent sentences.

4.1 Parameter Settings

Trait includes three manually tuned hyperparameters that have a smoothing effect on the corresponding multinomial distributions. Hyperparameter α is the Dirichlet prior of the word distribution. We use asymmetric priors based on a sentiment lexicon. Table 2 shows Trait's sentiment word list as prior knowledge to set asymmetric priors. This list extends Turney and Littman's (2003) list with additional general sentiment words. For any word in the positive list, we set α to 0 if this word appears in a sentence assigned a negative sentiment, and to 5 if this word appears in a sentence assigned a positive sentiment, and conversely for words in the negative list. For all remaining words, we set α to 0.05. We set hyperparameter β, the Dirichlet prior of the sentiment distribution, to 5 for both sentiments. We set hyperparameter γ, the Dirichlet prior of the aspect distribution, to $50/T$ for all models, where T is the number of aspects. We set the reinforcement weight of structural and semantic correspondence λ to 1.0; sentence semantic similarity ρ to 0.7; and, related word promoting weights to 0.3 for hotel reviews and 0.1 for restaurant reviews.

4.2 Quantitative Evaluation

Whether topics (word clusters) are semantically cohesive is crucial in assessing topic modeling approaches. As in previous studies (Nguyen et al., 2015a,b; Yang et al., 2017), we adopt Normalized Pointwise Mutual Information (NPMI) (Lau et al., 2014) and W2V (O'Callaghan et al., 2015) as our evaluation metrics. Higher NPMI and W2V scores indicate greater semantic cohesion. We compare Trait with four baselines: AT, JST, ASUM, and AATS. We perform our evaluation on HotelUser and ResUser based on the top 20 words in each sentiment-aspect pair. We split data into five folds

Table 2: Lists of sentiment words.

Positive
amazing, attractive, awesome, best, comfortable, correct, enjoy, excellent, fantastic, favorite, fortunate, free, fun, glad, good, great, happy, impressive, love, nice, not_bad, perfect, positive, recommend, satisfied, superior, thank, worth
Negative
annoying, bad, complain, disappointed, hate, inferior, junk, mess, nasty, negative, not_good, not_like, not_recommend, not_worth, poor, problem, regret, slow, small, sorry, terrible, trouble, unacceptable, unfortunate, upset, waste, worst, worthless, wrong

and use training split to train all models. For each number of aspects, we conduct a two-tailed paired t-test for each of the pairwise comparisons. Throughout, $*$, †, and ‡ indicate significance at 0.05, 0.01, and 0.001, respectively.

Table 3 shows average NMPI and W2V scores for different numbers of aspects. AT performs worst, possibly due to missing conditions on sentiments. ASUM and JST are comparable. Trait outperforms all others, with the highest NMPI and W2V scores for each number of aspects. Table 4 shows similar conclusions for restaurant reviews.

For both datasets, Trait's improvements of topic coherence over baseline models are statistically significant for HotelUser ($p < 0.001$) and ResUser ($p = 0.002$). Trait allows reviews written by the same or similar authors to have idiosyncratic preferences over aspects and sentiments. Trait assigns aspects to sentences by sampling attribute-specific aspect distributions. These distributions are regularized by the Markov Random Fields. Sentences with a high degree of correspondence have a high probability to be assigned the same aspects.

4.3 Sentiment Classification

Automatically detecting the sentiment of a document is an important task in sentiment analysis. We compare Trait with JST, ASUM, and AATS for document-level sentiment classification using HotelUser and ResUser. We use integer ratings of reviews to collect ground-truth labels. Reviews with ratings at three and above are labeled as positive and the rest are labeled as negative. Note that our datasets are imbalanced. We conduct five-fold cross-validation with the two-tailed paired t-test. For each user, we use 80% of reviews for training and 20% for testing. For evaluation metrics, we adopt accuracy (Acc) and area under the curve (AUC) of the Receiver Operating Characteristic (ROC) curve. ROC plots the true positive rate against the false positive rate. AUC-ROC is a standard metric for evaluating classifiers' performance on imbalanced data.

Table 3: Topic coherence: Hotel reviews.

NPMI	T=10	T=20	T=30	T=40	T=50	T=60

AATS	0.11	0.14	0.16	0.17	0.18	0.18
JST	0.21	0.21	0.20	0.20	0.20	0.19
ASUM	0.20	0.19	0.18	0.18	0.17	0.17
Trait	**0.25**‡	**0.26**‡	**0.25**‡	**0.24**‡	**0.24**‡	**0.24**‡

Table 5: Accuracy and AUC of sentiment classification on hotel reviews.

	T=20		T=40		T=60	
	Acc	AUC	Acc	AUC	Acc	AUC
AATS	0.79	0.45	0.82	0.48	0.84	0.48
JST	0.61	0.82	0.64	0.83	0.67	0.84
ASUM	0.80	0.83	0.84	0.84	0.87	0.83
Trait	**0.85**†	**0.86***	**0.87***	**0.85***	**0.88**	**0.86**†

Table 5 reports the results of sentiment classification on hotel reviews. AATS achieves better accuracy but worse AUC scores than JST. ASUM yields better accuracy and comparable AUC scores compared with JST. Trait consistently outperforms all baseline models given different aspect numbers with an average gain in accuracy of 3%. Incorporating attributes and structural and semantic cor-

respondence into conditional probability distributions greatly benefit the model in capturing dependencies among attributes, aspects, and sentiments.

Table 6: Accuracy and AUC of sentiment classification on restaurant reviews.

	T=20		T=40		T=60	
	Acc	AUC	Acc	AUC	Acc	AUC
AATS	0.79	0.47	0.80	0.48	0.82	0.50
JST	0.59	0.71	0.61	0.73	0.64	0.73
ASUM	0.80	0.78	0.84	0.78	0.87	0.74
Trait	**0.86**†	**0.79**	**0.87**†	0.78	**0.88**	**0.79***

4.4 Attribute Profile

Given reviews with selected attributes, we expect Trait to generate profiles representing the characteristics associated with those attributes. To evaluate profiles, we run Trait on HotelUser, HotelLoc, and HotelType, associated with three attributes: authors, locations, and trip types, respectively.

4.4.1 Summarization

Trait outputs profiles that summarize attributes in terms of aspects and sentiments in reviews.

Figure 3 shows the profiles of four US cities generated by Trait. We visualize the profiles as aspect-clouds using the top 30 aspects in each sentiment. The size of the aspect label corresponds to its aspect probabilities. Due to space constraints, we place the profiles of Boston, Chicago, and Orlando in Table 7.

These profiles yield salient summaries for each city. For example, *Strip* and *Casino* are the top two positive aspects for Las Vegas, a resort city for gambling. We see from the reviews that most hotels with high ratings are located on the Strip. For Boston, Chicago, and New York, *Location* and *PublicTrans* are the top positive aspects. These cities rank top on the lists of U.S. cities with high transit ridership (Ridership, 2019) and walkability (Walkability, 2019). Hotels' proximity to public transportation, shopping, restaurants, and attractions is appealing to several reviewers. We see *RoomSize* appears in the top five negative aspects. These three cities have among the most expensive hotel room rates (Statista, 2019). Assuming consumers expect more when they pay more, we conjecture that a failed expectation could be caused by room size, especially in New York, where room sizes are smaller than elsewhere in the US (NYC, 2019). For Miami, *Transportation* is attractive, presumably because many cruises depart from Miami.

Table 7: Top five aspects discovered by Trait.

Boston (P)	Boston (N)	Chicago (P)	Chicago (N)
PublicTrans	RoomSize	Location	RoomSize
Location	Service	PublicTrans	Service
Decor	Parking	Decor	Parking
Bar	RoomNoise	Bar	Elevator
Service	StreetNoise	Service	ACHotwater
Orlando (P)	**Orlando (N)**	**Friend (P)**	**Friend (N)**
ThemePark	Pool	Tour	Upgrade
Pool	Transportation	Value	Staff
Food	Supplies	View	BreakfastArea
Amenity	Frontdesk	Breakfast	Bathroom
Overall	Bed	Location	Breakfast
Author A (P)	**Author A(N)**	**Author B (P)**	**Author B (N)**
Helpfulness	NotReturn	Helpfulness	NotReturn
View	Value	View	Value
Value	Charge	Breakfast	Checkin
Breakfast	Checkout	Value	HotelSize
Comfort	Checkin	Transportation	Checkout
Author C (P)	**Author C (N)**	**Author D (P)**	**Author D (N)**
Internet	Elevator	Staff	Value
Comfort	Room	Room	NotReturn
TripType	Food	Recommend	Checkout
View	StreetNoise	Value	Room
Breakfast	Checkout	TripType	Charge

Figure 4 shows the results for HotelType: *Cleanliness*, *Internet*, *TV*, and *Upgrade* are most likely to lead to a negative sentiment for business travelers. For couples, *Atmosphere* and *RestArea* are most preferred positive aspects. *Family*, *Tour*, and *Attraction* are most positive aspects for families. Solo travelers, on business or tourism, express most opinions toward both *Transportation*.

Table 7 (bottom rows) lists the top five aspects for four authors from HotelUser. We can observe strong commonality between Author A and B, They both like to express positive sentiment on *Helpfulness*, *View*, *Value*, and *Breakfast*. They are like to express not returning a hotel and the negative sentiments are mostly toward *Value*, *Checkin*, and *Checkout*. There is little commonality between Authors C and D. For Author C, *Internet* and *Comfort* are most attractive whereas *Staff* and *Room* are most appealing aspects for Author D. In terms of negatives, *Checkout* is the only aspect shared between Authors C and D.

4.4.2 Similarity

Attribute profiles can be used not only for summarization, but also for measuring similarity between attribute values with respect to aspects and sentiments, which can support attribute-based applica-

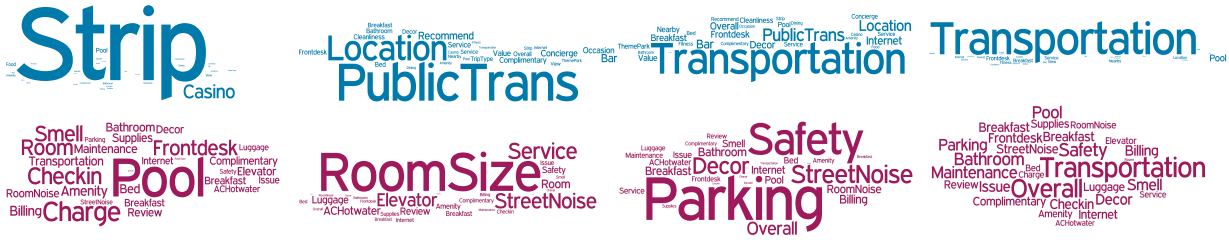

Figure 3: An aspect-cloud visualization of US cities (positive aspects above; negative aspects below).

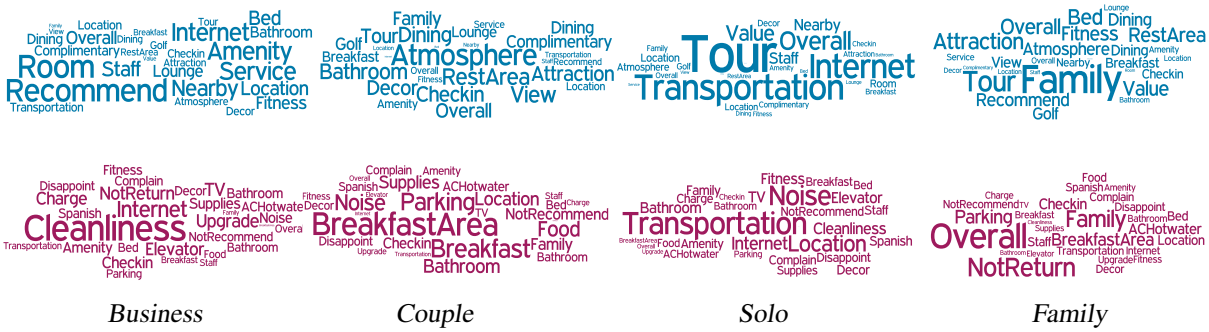

Figure 4: An aspect-cloud visualization of trip types. (positive aspects above; negative aspects below).

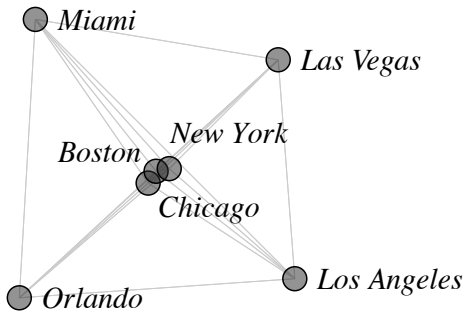
tions such as recommender systems. Our metric of similarity between distinct values of the same attribute is the Jensen-Shannon distance (JSD) (Endres and Schindelin, 2003), the square root of Jensen-Shannon divergence. We compute, D_{JS}, the JSD of attribute profiles P and Q as

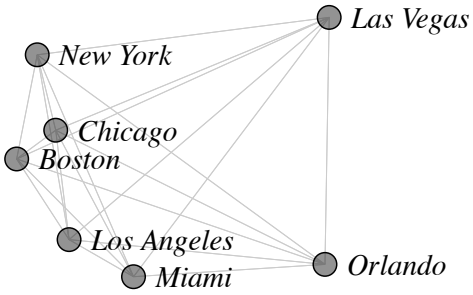
$$D_{\text{JS}} = \sqrt{\frac{1}{2}D_{KL}(P||M) + \frac{1}{2}D_{KL}(Q||M)} \qquad (10)$$
$$M = \frac{1}{2}(P+Q),$$

where $D_{KL}(P||Q)$ is the Kullback-Leibler (KL) divergence of probability distributions $P = \{p_1, \ldots, p_n\}$ and $Q = \{q_1, \ldots, q_n\}$:



$$D_{KL}(P||Q) = \sum_i p_i \log \frac{p_i}{q_i}. \qquad (11)$$

As a baseline, we use a vector space model based on USE sentence embeddings. We calculate mean sentence embeddings for each review. Then, given two sets of reviews, $D = \{d_1, \ldots, d_m\}$ and $R = \{r_1, \ldots, r_n\}$, we compute their similarity as follows (here $sim(d_i, r_j)$ is the cosine similarity between review d_i and r_j):



$$S_{D,R} = \frac{1}{m+n}\sum_{i=1}^{m}\sum_{j=1}^{n} sim(d_i, r_j). \qquad (12)$$

Figure 5a shows the similarities among the profiles of the seven cities generated by the baseline model. We see that Boston is close to New York and Chicago; Las Vegas is far away from Los Angeles and Miami but close to New York, Boston, and Chicago. Figure 5b shows the results generated by Trait. Here, dissimilarity corresponds to distance normalized to $[0, 1]$. Boston, Chicago, and New York are close to each other, as are Los Angeles and Miami; Las Vegas is far from each of the others; and, Orlando is far from all except Miami. Trait's results are arguably more plausible than what the baseline approach produces.

As discussed earlier, hotels in Boston, Chicago, and New York have common characteristics; Las Vegas differs strongly from the others because it is a resort city and its major hotels are combined with casinos; Orlando is a tourism destination but differs from Las Vegas in that it is famous for local attractions, such as theme parks. Orlando's profile exhibits that travelers there tend to be more aware of aspect *Attraction* than elsewhere. An interesting pair is Los Angeles and Miami. We see that *Location* appears as the most important aspect on the positive side for both of them. Such a similarity could be partially explained by the fact that both Los Angeles and Miami serve as locations for taking cruises. Also, the common aspect *Safety*

(a) Baseline.

(b) Trait.

Figure 5: Force fields of similarities: cities.

(negative for both) could increase their similarity.

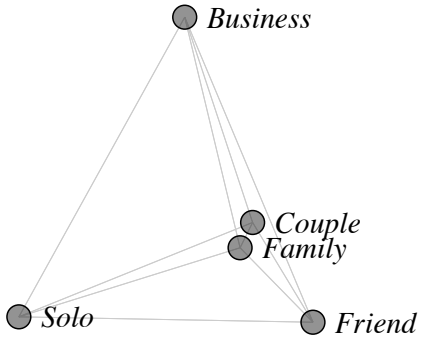


Figure 6a shows similarities among the five trip types generated by the baseline model. Business is closer to Family than Solo and Friend; Solo is closer to Family than Friend. Trait generates more reasonable results, as shown in Figure 6b. Business is far from others but is closer to Friend and Solo than to Couple and Family. Couple, Family, and Friend are relatively close to each other. Business reviewers attend to different aspects from other reviewers. Further, Solo and Friend contain reviews of business trips, although the authors did not select Business as the trip type. However, this situation does not happen for Couple and Family.

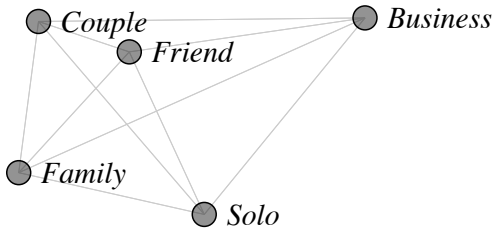
Figure 7 shows similarities among 20 authors, including the four authors mentioned in Section 4.4.1. We see that Authors A and B are close to each other whereas Authors C and D are far away from each other. The results are aligned with their aspect and sentiment profiles.



5 Discussion and Conclusion

Trait not only shows that capturing structural and semantic correspondence leads to improved performance in terms of coherence and naturalness of the aspects discovered but can also be realized in an unsupervised framework. Trait outperforms competing approaches across multiple datasets.

These results open up interesting directions for

(a) Baseline.

(b) Trait.

Figure 6: Force fields of similarities: Purpose.

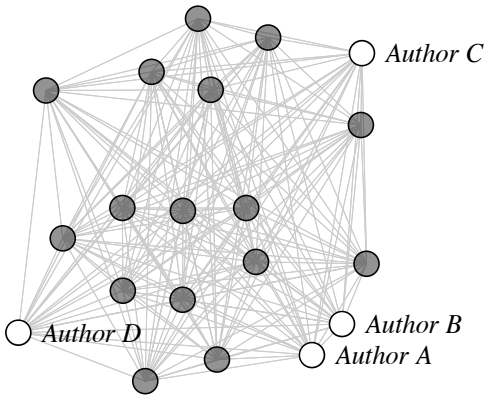


Figure 7: Force field of similarities: 20 authors.

future work. One direction is to learn disentangled latent representations for attributes in neural network's space, such as for disentangling aspects (Jain et al., 2018), text style (John et al., 2019), and syntax and semantics (Chen et al., 2019; Bao et al., 2019). Another direction is to develop a content-based recommender based on Trait, since it provides an effective unsupervised solution for generating profiles based on different attributes.

6 Acknowledgments

We would like to thank the anonymous reviewers for helpful comments and corrections. MPS would like to acknowledge the US Department of Defense for partial support through the NCSU Laboratory for Analytic Sciences.

Abstract

The task of predicting fine grained user opinion based on spontaneous spoken language is a key problem arising in the development of Computational Agents as well as in the development of social network based opinion miners. Unfortunately, gathering reliable data on which a model can be trained is notoriously difficult and existing works rely only on coarsely labeled opinions. In this work we aim at bridging the gap separating fine grained opinion models already developed for written language and coarse grained models developed for spontaneous multimodal opinion mining. We take advantage of the implicit hierarchical structure of opinions to build a joint fine and coarse grained opinion model that exploits different views of the opinion expression. The resulting model shares some properties with attention-based models and is shown to provide competitive results on a recently released multimodal fine grained annotated corpus.

1 Introduction

Recent years have witnessed the increasing popularity of social networks and video streaming platforms. People heavily rely on these channels to express their opinions through video-based discussions or reviews. Whereas such opinionated data has been widely studied in the context of written customer reviews (Liu, 2012) crawled on websites such as Amazon (Hu and Liu, 2004) and IMDB (Maas et al., 2011), only a few studies have been proposed in the case of video-based reviews. Such multimodal data has been shown to provide a mean to disambiguate some hard to understand opinion expressions such as irony and sarcasm (Attardo et al., 2003) and contains crucial information indicating the level of engagement and the persuasiveness of the speaker (Clavel and Callejas, 2016; Ben Youssef et al., 2019; Nojavanasghari et al., 2016). A key problem in this context is the lack of availability of fine grained opinion annotation *i.e.* annotations performed at the token or short span level and highlighting on the components of the structure of opinions. Indeed whereas such resources have been gathered in the case of textual data and can be used to deeply understand the expression of opinions (Wiebe et al., 2005; Pontiki et al., 2016), the different attempts at annotating multimodal reviews have shown that reaching good annotator agreement is nearly impossible at a fine grained level. This results from the disfluent aspect of spontaneous spoken language making it difficult to choose opinions' annotation boundaries (Garcia et al., 2019; Langlet and Clavel, 2015b). Thus the price to pay to gather reliable data is the definition of an annotation scheme focusing on coarse grained information such as long segment categorization as done by Zadeh et al. (2016a) or review level annotation (Park et al., 2014). Building models able to predict fine grained opinion information in a multimodal setting is in fact of high importance in the context of designing human–robot interfaces (Langlet and Clavel, 2016). Indeed the knowledge of opinions decomposed over a set of polarities associated to some targets is a building block of automatic human understanding pipelines (Langlet and Clavel, 2015a). The present work is motivated by the following observations:

- Despite the lack of reliability of fine grained labels collected for multimodal data, the redundancy of the opinion information contained at different granularities can be leveraged to reduce the inherent noise of the labelling process and to build improved opinion predictors. We build a model that takes advantage of this property and joinlty models the different components of an opinion.

- Hierarchical multi-task language models have been recently shown to improve upon the single tasks' models (Sanh et al., 2018). A careful choice of the tasks and the order in which

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5539–5548,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

they are sequentially presented to the model has been proved to be the key to build competitive predictors. It is not clear whether such type of hierarchical model could be adapted to handle multimodal data with the state of the art neural architectures (Zadeh et al., 2018a,b). We discuss in the experimental section the strategies and models that are adapted to the multimodal opinion mining context.

- In the case where no fine grained supervision is available, the attention mechanism (Vaswani et al., 2017) provides a compelling alternative to build models generating interpretable decisions with token-level explanations (Hemamou et al., 2018). In practice such models are notoriously hard to train and require the availability of very large datasets. On the other hand, the injection of fine-grained polarity information has been shown to be a key ingredient to build competitive sentiment predictors by Socher et al. (2013). Our hierarchical approach can be interpreted under the lens of attention-based learning where some supervision is provided at training to counterbalance the difficulty of learning meaningful patterns with spoken language data. We specifically experimentally show that providing this supervision is here necessary to build competitive predictors due to the limited number of data and the difficulty to extract meaningful patterns from it.

2 Background on fine grained opinion mining

The computational models of opinion are grounded in a linguistic framework defining how these objects can be structured over a set of interdependent functional parts. In this work we focus on the model of Martin and White (2013) that defines the expression of opinions as an *evaluation* towards an object. The expression of such evaluations can be summarized by the combination of three components: a *source* (mainly the speaker) expressing a statement on a *target* identifying the entity evaluated and a *polarized expression* making the attitude of the source explicit. In the literature, the task of finding the words indicating these components and categorizing them using a set of predefined possible targets and polarities has been studied under the name of Aspect Based Sentiment Analysis (ABSA) and popularized by the SEMEVAL campaigns (Pontiki et al., 2016). They defined a set of tasks including sentence-level prediction. *Aspect Category Detection* consists in finding the target of an opinion from a set of possible entities; *Opinion Target Expression* is a sequence tagging problem where the goal is to find the word indicating this entity; and *Sentiment Polarity* recognition is a classification task where the predictor has to determine whether the underlying opinion is positive, negative or neutral. Such problems have also been extended at the text level (*text-level ABSA*) where the participants were asked to predict a set of tuples (Entity category, Polarity level) summarizing the opinions contained in a review. In this work we adapt these tasks to a recently released fine-grained multimodal opinion mining corpus and study a category of hierarchical neural architecture able to jointly perform *token*-level, *sentence*-level and review-level predictions. In the next sections, we present the data available and the definition of the different tasks.

3 Data description and model

This work relies on a set of fine and coarse grained opinion annotations gathered for the Persuasive Opinion Multimedia (POM) corpus presented in Garcia et al. (2019). The dataset is composed of 1000 videos carrying a strong opinion content: in each video, a single speaker in frontal view makes a critique of a movie that he/she has watched. The corpus contains 372 unique speakers and 600 unique movie titles. The opinion of each speaker has been annotated at 3 levels of granularity as shown in Figure 1.

At the finest (*Token*) level, the annotators indicated for each token whether it is responsible for the understanding of the polarity of the sentence and whether it describes the target of an opinion. On top of this, a span-level annotation contains a categorization of both the target and the polarity of the underlying opinion in a set of predefined possible target *entities* and polarity *valences*. At the review level (or *text*-level since the annotations are aligned with the tokens of the transcript), an overall score describes the attitude of the reviewer about the movie.

As Garcia et al. (2019) have shown that the boundaries of span-level annotations are unreliable, we relax the corresponding boundaries at the sentence level. This *sentence* granularity is in our data the intermediate level of annotation between the *token* and the *text*. In practice, these

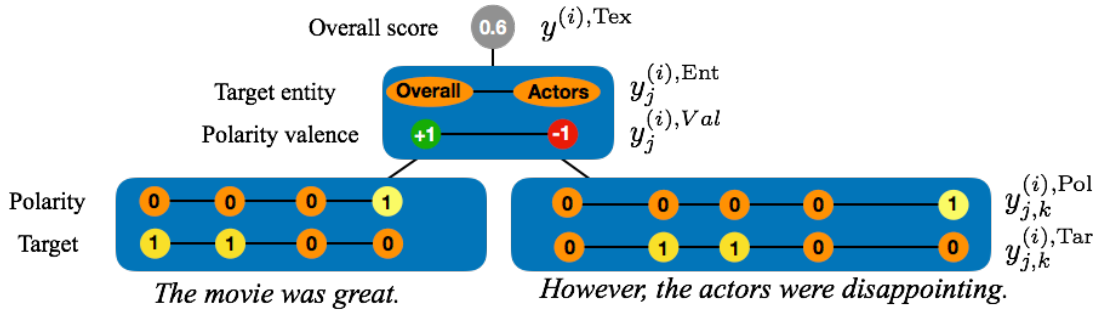

Figure 1: Structure of an annotated opinion

intermediate level labels can be modeled by tuples such as the one provided in the *text-level ABSA* SEMEVAL task which are given for each sentence in the dataset. In what follows, we will refer to the problem of predicting such information as the *sentence level*-prediction problem. Details concerning the determination of the sentence boundaries and the associated pre-processing of the data are given in the supplemental material.

The representation described above can be naturally converted into a mathematical representation: A review $\mathbf{x}^{(i)}$, $i \in \{1, \ldots, N\}$ is made of S_i sentences each containing W_{S_i} words. Thus the canonical feature representation of a review is the following $\mathbf{x}^{(i)} = \{\{x_{1,1}^{(i)}, \ldots, x_{1,W_{S_1}}^{(i)}\}, \ldots, \{x_{S_i,1}^{(i)}, \ldots, x_{S_i,W_{S_i}}^{(i)}\}\}$, where each x is the feature representation of a spoken word corresponding to the concatenation of a textual, audio and video feature representation. It has been shown in (Zadeh et al., 2018a, 2016a,b) that whereas the textual modality carries the most information, taking into account video and audio modalities is mandatory to obtain state of the art results on sentiment analysis problems. Based on this input description, the learning task consists in finding a parameterized function $g_\theta : \mathcal{X} \to \mathcal{Y}$ that predicts various components of an opinion $\mathbf{y} \in \mathcal{Y}$ based on an input review $\mathbf{x} \in \mathcal{X}$. The parameters of such a function are obtained by minimizing an empirical risk:

$$\hat{\theta} = \min_\theta \sum_{i=1}^{N} l(g_\theta(\mathbf{x}^{(i)}), \mathbf{y}^{(i)}), \qquad (1)$$

where l is a non-negative loss function penalizing wrong predictions. In general the loss l is chosen as a surrogate of the evaluation metric whose purpose is to measure the similarity between the predictions and the true labels. In the case of complex objects such as opinions, there is no natural metric for measuring such proximity and we rely instead on distances defined on substructures of the opinion model. To introduce these distances, we first decompose the label-structures following the model previously described:

- *Token-level labels* are represented by a sequence of 2-dimensional binary label vectors $y_{j,k}^{(i),\text{Tok}} = \begin{pmatrix} y_{j,k}^{(i),\text{Pol}} \\ y_{j,k}^{(i),\text{Tar}} \end{pmatrix}$ where $y_{j,k}^{(i),\text{Pol}}$ and $y_{j,k}^{(i),\text{Tar}}$ are some binary variables indicating respectively whether the k^{th} word of the sentence j in review i is a word indicating the polarity of an opinion , and the target of an opinion.

- *Sentence*-level labels carry 2 pieces of information: (1) the categorization of the target *entities* mentioned in an opinion expressed is represented by an E dimensional binary vector $y_j^{(i),\text{Ent}}$ where each component encodes the presence of an entity among E possible values; and (2) the polarity of the opinions contained in the sentence are represented by a 4-dimensional one-hot vector $y_j^{(i),\text{Val}}$ encoding the possible *valences*: *Positive*, *Negative*, *Neutral/Mixed* and *None*. Thus the sentence level label $y_j^{(i),\text{Sent}}$ is the concatenation of the two representations presented above: $y_j^{(i),\text{Sent}} = \begin{pmatrix} y_j^{(i),\text{Ent}} \\ y_j^{(i),\text{Val}} \end{pmatrix}$

- *Text*-level labels are composed of a single continuous score obtained for each review $y^{(i),Tex}$ summarizing the overall rating given by the reviewer to the movie described.

Based on these representations, we define a set of losses, $l^{(\text{Tok})}, l^{(\text{Sent})}, l^{(\text{Tex})}$ dedicated to measuring the similarity of each substructure prediction,

$\hat{\mathbf{y}}^{(\text{Tok})}, \hat{\mathbf{y}}^{(\text{Sent})}, \hat{\mathbf{y}}^{(\text{Tex})}$ with the ground-truth. In the case of binary variables and in the absence of prior preference between targets and polarities, we use the negative log-likelihood for each variable. Each task loss is then defined as the average of the negative log-likelihood computed on the variables that compose it. For continuous variables, we use the mean squared error as the task loss. Consequently the losses to minimize can be expressed as:

$$l^{(Tok)}(\mathbf{y}^{\text{Tok}}, \hat{\mathbf{y}}^{\text{Tok}}) = -\frac{1}{2}\sum_i \big(\big(\mathbf{y}_i^{Pol}\log(\hat{\mathbf{y}}_i^{Pol}) + \mathbf{y}_i^{Tar}\log(\hat{\mathbf{y}}_i{}^{Tar})\big)\big),$$

$$l^{(Sent)}(\mathbf{y}^{Sent}, \hat{\mathbf{y}}^{Sent}) = -\frac{1}{2}\sum_i \big(\mathbf{y}_i^{\text{Ent}}\log(\hat{\mathbf{y}}_i^{\text{Ent}}) + \mathbf{y}_i^{\text{Val}}\log(\hat{\mathbf{y}}_i^{\text{Val}})\big),$$

$$l^{(Tex)}(y^{\text{Tex}}, \hat{y}^{\text{Tex}}) = (y^{\text{Tex}} - \hat{y}^{\text{Tex}})^2,$$

Following previous works on multi-task learning (Argyriou et al., 2007; Ruder, 2017), we argue that optimizing simultaneously the risks derived from these losses should improve the results, compared to the case where they are treated separately, due to the knowledge transferred across tasks. In the multi-task setting, the loss l derived from a set of task losses $l^{(t)}$, is a convex combination of these different task losses. Here the tasks corresponds to each granularity level: $t \in \text{Tasks} = \{\textit{Tok}, \textit{Sent}, \textit{Tex}\}$ weighted according to a set of task weights λ_t :

$$l(\mathbf{y}, \hat{\mathbf{y}}) = \frac{\sum_{t\in\text{Tasks}} \lambda_t l^{(t)}(\mathbf{y}^t, \hat{\mathbf{y}}^t)}{\sum_{t\in\text{Tasks}} \lambda_t}, \ \forall \lambda_t \geq 0. \quad (2)$$

Optimizing this type of objectives in the case of hierarchical deep net predictors requires building some strategy in order to train the different parts of the model: the low level parts as well as the abstract ones. We discuss such an issue in the next section.

4 Learning strategies for multitask objectives

The main concern when optimizing objectives of the form of Equation 2 comes from the variable difficulty in optimizing the different objectives $l^{(t)}$. Previous works (Sanh et al., 2018) have shown that a careful choice of the order in which they are introduced is a key ingredient to correctly train deep hierarchical models. In the case of hierarchical labels, a natural hierarchy in the prediction complexity is given by the problem. In the task at hand, coarse grained labels are predicted by taking advantage of the information coming from predicting fine grained ones. The model processes the text by recursively merging and selecting the information in order to build an abstract representation of the review. In Experiment 1 we show that incorporating these fine grained labels into the learning process is necessary to obtain competitive results from the resulting predictors. In order to gradually guide the model from easy tasks to harder ones, we parameterize each λ_t as a function of the number of epochs of the form $\lambda_t^{(n_{\text{epoch}})} = \lambda_{\max}\frac{\exp\left((n_{\text{epoch}} - Ns_t)/\sigma\right)}{1+\exp\left((n_{\text{epoch}} - Ns_t)/\sigma\right)}$ where Ns_t is a parameter devoted to task t controlling the number of epochs after which the weight switches to $\lambda_{\max}$ and σ is a parameter controlling the slope of the transition. We construct 4 strategies relying on smooth transitions from a low state $\lambda_t^{(0)} = 0$ to a high state $\lambda_t^{(Ns_t)} = \lambda_t^{\max}$ of each task weight varying with the number of epochs. The different strategies described below are illustrated in the supplemental material.

- Strategy 1 (S1) consists in optimizing the different objectives one at a time from the easiest to the hardest. It consists in first moving vector $(\lambda_{\textit{Token}}, \lambda_{\textit{Sentence}}, \lambda_{\textit{Text}})^T$ values from $(1,0,0)^T$ to $(0,1,0)^T$ and then finally to $(0,0,1)^T$. The underlying idea is that the low level labels are only useful as an initialization point for higher level ones.

- Strategy 2 (S2) consists in adding sequentially the different objectives to each other from the easiest to the hardest. It goes from a word only loss $(\lambda_{\textit{Token}}, \lambda_{\textit{Sentence}}, \lambda_{\textit{Text}})^T = (\lambda_{\textit{Token}}^{(N)}, 0, 0)^T$ and then adds the intermediate objectives by setting $\lambda_{\textit{Sentence}}$ to $\lambda_{\textit{Sentence}}^{(N)}$ and then $\lambda_{\textit{Text}}$ to $\lambda_{\textit{Text}}^{(N)}$. This strategy relies on the idea that keeping a supervision on low level labels has a regularizing effect on high level ones. Note that this strategy and the two following require a choice of the stationary weight values $\lambda_{\textit{Token}}^{(N)}, \lambda_{\textit{Sentence}}^{(N)}, \lambda_{\textit{Text}}^{(N)}$.

- Strategy 3 (S3) is similar to (S2) except that the *sentence* and *text* weights are simultaneously increased. This strategy and the following one are introduced to test whether the order in which the tasks are introduced has some importance on the final scores.

- Strategy 4 (S4) is also similar to (S2) except that *text*-level supervision is introduced before the *sentence*-level one. This strategy uses the intermediate level labels as a way to regularize the video level model that would have been learned directly after the *token*-level supervision

These strategies can be implemented in any stochastic gradient training procedure of objectives (Equation 2) since it only requires modifying the values of the weight at the end of each epoch. In the next section, we design a neural architecture that jointly predicts opinions at the three different levels, *i.e.* the *token*, *sentence* and *text* levels, and discuss how to optimize multitask objectives built on top of opinion-based output representations.

5 Architecture

Before digging into the model description, we introduce the set of hidden variables $h^{(i),\text{Tex}}, h_j^{(i),Sent}, h_{j,k}^{(i),\text{Tok}}$ corresponding to the unconstrained scores used to predict the outputs: $\hat{y}^{(i),\text{Tex}} = \sigma^{\text{Tex}}(W^{\text{Tex}} h^{(i),\text{Tex}} + b^{\text{Tex}})$, $\hat{y}_j^{(i),\text{Sent}} = \sigma^{\text{Sent}}(W^{\text{Sent}} h_j^{(i)^{\text{Sent}}} + b^{\text{Sent}})$, $\hat{y}_{j,k}^{(i),\text{Tok}} = \sigma^{\text{Tok}}(W^{\text{Tok}} h_{j,k}^{(i),\text{Tok}} + b^{\text{Tok}})$, where the W and b are some parameters learned from data and the σ are some fixed almost everywhere differentiable functions ensuring that the outputs "match" the inputs of the loss function. In the case of binary variables for example, it is chosen as the sigmoid function $\sigma(x) = \exp(x)/(1+\exp(x))$. From a general perspective, a hierarchical opinion predictor is composed of 3 functions $g^{\text{Tex}}, g^{\text{Sent}}, g^{\text{Tok}}$ encoding the dependency across the levels:

$$
\begin{aligned}
h_{j,k}^{(i),\text{Tok}} &= g_{\theta^{\text{Tok}}}^{\text{Tok}}(x_{j,:}^{(i),\text{Tok}}), \\
h_j^{(i)^{\text{Sent}}} &= g_{\theta^{\text{Sent}}}^{\text{Sent}}(h_{j,:}^{(i)^{\text{Tok}}}), \\
h^{(i)^{\text{Tex}}} &= g_{\theta^{\text{Tex}}}^{\text{Tex}}(h_{:}^{(i)^{\text{Sent}}}).
\end{aligned}
$$

In this setting, low level hidden representations are shared with higher level ones. A large body of work has focused on the design of the g functions in the case of multimodal inputs. In this work we exploit state of the art sequence encoders to build our hidden representations that we detail below. The mathematical expression of the models and a more in depth description are provided in the supplemental material.

- Bidirectional Gated Recurrent Units (GRU) (Cho et al., 2014) especially when coupled with a self attention mechanism have been shown to provide state of the art results on tasks implying the encoding or decoding of a sentence in or from a fixed size representation. Such a problem is encountered in automatic machine translation (Luong et al., 2015), automatic summarization (Nallapati et al., 2017) or image captioning and visual question answering (Anderson et al., 2018). We experiment with both models mixing the 3 concatenated input feature modalities (BiGRU model in Experiment 1) and a model carrying 3 independent BiGRU with a hidden state per modality (Ind BiGRU models).

- The Multi-attention Recurrent Network (MARN) proposed in (Zadeh et al., 2018a) extends the traditional Long Short Term Memory (LSTM) sequential model by both storing a view specific dynamic (similar to the LSTM one) and by taking into account cross-view dynamics computed from the signal of the other modalities. In the original paper, this cross-view dynamic is computed using a multi-attention bloc containing a set of weights for each modality used to mix them in a joint hidden representation. Such a network can model complex dynamics but does not embed a mechanism dedicated to encoding very long-range dependencies.

- Memory Fusion Networks (MFN) are a second family of multi-view sequential models built upon a set of LSTM per modality feeding a joint delta memory. This architecture has been designed to carry some information in the memory even with very long sequences due to the choice of a complex retain / forget mechanism.

The 3 models described previously build a hidden representation of the data contained in each sequence. The transfer from one level of the hierarchy to the next coarser one requires building a fixed length representation summarizing the sequence. Note that in the case of the MARN and the MFN, the model directly creates such a representation. We present the strategies that we deployed to pool these representations in the case of the BiGRU sequential layer.

- Last state representation: Sequential models build their inner state based on observations

from the past. One can thus naturally use the hidden state computed at the last observation of a sequence to represent the entire sequence. In our experiments, this is the representation chosen for the BiGRU and Ind BiGRU models.

- Attention based sequence summarization: Another technique consists in computing a weighted sum of the hidden states of the sequence. The attention weights can be learned from data to focus on the important parts of the sequence only and avoid building too complex inner representations. An example of such a technique successfully applied to the task of text classification based on 3 levels of representation can be found in (Yang et al., 2016). In our experiments, we implemented the attention model for predicting only the *Sentence*-level labels (model Ind BiGRU + att Sent) and the *Sentence* and *Text*-level labels by sharing a common representation (Ind BiGRU + att model).

All the resulting architectures extend the existing hierarchical models by enabling the fusion of multimodal information at different granularity levels while maintaining the ability to introduce some supervision at any level.

6 Experiments

In this section we propose 3 sets of experiments that show the superiority of our model over existing approaches with respect to the difficulties highlighted in the introduction, and explore the question of the best way to train hierarchical models on multimodal opinion data.

All the results presented below have been obtained on the recently released fine grained annotated POM dataset (Garcia et al., 2019). The input features are computed using the CMU-Multimodal SDK: We represented each word by the concatenation of the 3 feature modalities. The textual features are chosen as the 300-dimensional pre-trained Glove embeddings (Pennington et al., 2014) (not updated during training). The acoustic and visual features have been obtained by averaging the descriptors computed following (Park et al., 2014) during the time of pronunciation of each spoken word. These features include MFCC and pitch descriptors for the audio signals. For the video descriptors, posture, head and gaze movement are taken into account. As far as the output representations are concerned, we merely re-scaled the *Text*-level polarity labels in the [0,1] range.

The results are reported in terms of mean average error (MAE) for the continuous labels and micro F1 score $\mu F1$ for binary labels. We used the provided train, val and test set and describe for each experiment the training procedure and displayed values below. More detail concerning the preprocessings and architectures can be found in the supplemental material.

6.1 Experiment 1: Which architecture provides the best results on the task of fine grained opinion polarity prediction?

In this first section, we describe our protocol to select an architecture devoted to performing fine grained multimodal opinion prediction. In order to focus on a restricted set of possible models, we only treat the polarity prediction problem in this section and selected the architectures that provided the best review-level scores (*i.e.* with lowest mean average prediction error). Taking into account the entity categories would only bring an additional level of complexity that is not necessary in this first model selection phase. Building upon previous works (Zadeh et al., 2018b), we use the MFN model as our *sentence*-level sequential model since it has been shown to provide state of the art results on *text*-level prediction problems on the POM dataset. For the *token*-level model, we test different state of the art models able to take advantage of the multimodal information. Our architecture is built upon the *token*-level encoders presented in section 5: the MFN, MARN and independent BiGRUs. Our baseline is computed similarly to Zadeh et al. (2018a): we represent each sentence by taking the average of the feature representation of the Tokens composing it. The best results reported were obtained after a random search on the parameters and presented in Table 1. In the top row, we report results obtained when only using the *text*-level labels to train the entire network. The baseline consisting in representing each sentence by the average of its tokens representation strongly outperforms all the other results. This is due to the moderate size of the training set (600 videos) which is not enough to learn meaningful fine grained representations. In the second part, we introduce some supervision at all levels and found that a choice of $\lambda_{Tok} = 0.05,\ \lambda_{Sent} = 0.5,\ \lambda_{Tex} = 1$ being respec-

	$\lambda_{Tok} = \lambda_{Sent} = 0$: no fine grained supervision						
MAE *Text*	0.35	0.40	0.40	0.38	0.29	0.32	**0.17**
	Supervision at the token, sentence and review levels						
Metric \ Model	BiGRU	Ind BiGRU	Ind BiGRU + att Sent	Ind BiGRU + att	MARN	MFN	Av Emb
$\mu F1$ *Tokens*	0.90	**0.93**	**0.93**	**0.93**	0.90	0.89	X
$\mu F1$ *Sentence*	0.68	0.72	**0.75**	**0.75**	0.52	0.47	X
MAE *Text*	0.16	0.15	0.15	**0.14**	0.35	0.37	X

Table 1: Scores on sentiment label

tively the *token*, *sentence* and *text* weights provides the best *text*-level results. This combination reflects the fact that the main objective (*text*-level) should receive the highest weight but low level ones also add some useful side supervision. Despite the ability of MARN and MFN to learn complex representations, the simpler BiGRU-based Token encoder retrieves the best results at all the levels and provides more than 12% of relative improvement over the Average Embedding based model at the video level. This behavior reveals that the high complexity of MARN and MFN makes them hard to train in the context of hierarchical models with limited data leading to suboptimal performance against simpler ones such as BiGRU. We fix the best architecture obtained in this experiment displayed in Figure 2 and reuse it in the subsequent experiments.

6.2 Experiment 2: What is the best strategy to take into account multiple levels of opinion information?

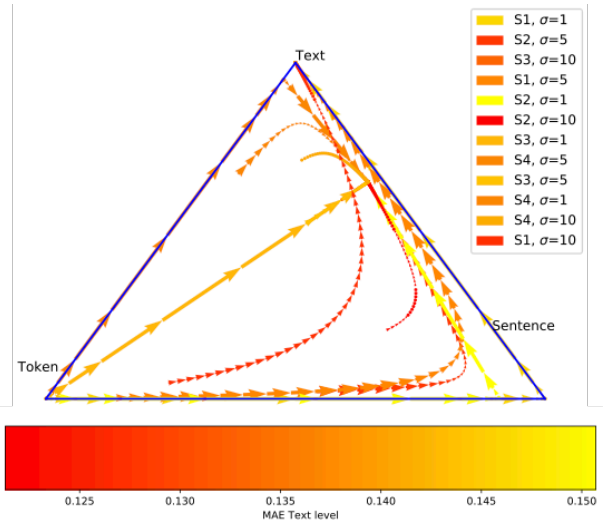

Figure 3: Path of the weight vector in the simplex triangle for the different tested strategies

Motivated by the issues concerning the training of multitask losses raised in Section 4, we implemented the 4 strategies described and chose the final stationary values as the best one obtained in Experiment 1: $(\lambda^{(N)}_{Token}, \lambda^{(N)}_{Sentence}, \lambda^{(N)}_{Text}) = (0.05, 0.5, 1)$ Note that each strategy corresponds to a path of the vector $(\lambda_{Tok}, \lambda_{Sent}, \lambda_{Tex})^T / \sum_t \lambda_t$ in the 3 dimensional simplex. We represent the 3 strategies tested in the Figure 3 corresponding to the projection of the weight vector onto the hyperplane containing the simplex.

The best paths for optimizing the *text*-level objectives are the one that smoothly move from a combination of *sentence* and *token*-level objectives to a *text* oriented one. The path in the simplex seems to be more important than the nature of the strategy since S1 and S2 reach the same *text*-level MAE score while working differently. It also appears than an objective with low σ[1] values corresponding to harder transitions tends to obtain lower scores than smooth transition based strategies. All the strategies are displayed as a function of the number of epochs in the supplemental material. In this last section we deal with the issue of the joint prediction of entities and polarities.

6.3 Experiment 3: Is it better to jointly predict opinions and entities ?

In this section, we introduce the problem of predicting the entities of the movie on which the predictions are expressed, as well as the tokens that mention them. This task is harder than the previously studied polarity prediction task due to (1) the problem of label imbalance appearing in the label distribution reported in the Table 3 and (2) the diversity of the vocabulary incurred when dealing with many entities. However since the presence of a polarity implies the presence of at least one entity, we expect that a joint prediction will perform better than an entitiy-based predictor only. Table 2 contains the results obtained with the architecture described in Figure 2 on the task of joint polarity

[1] described in Section 4

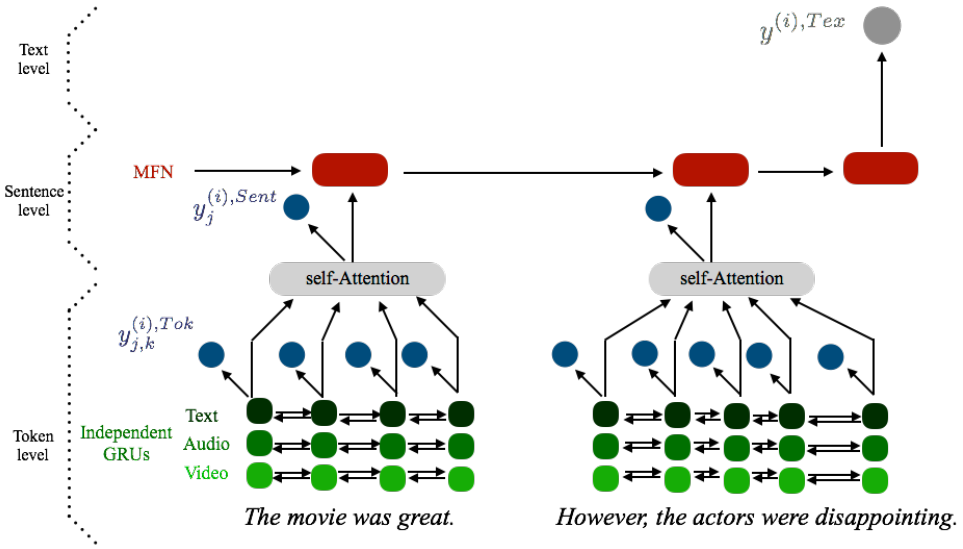

Figure 2: Best architecture selected during the Experiment 1

and entity prediction as well as the results obtained when dealing with these tasks independently.

Using either the joint or the independent models provides the same results on the polarity prediction problems at the *token* and *sentence*-level. The reason is that the polarity prediction problem is easier and relying on the entities prediction would only introduce some noise in the prediction. We

	Polarity labels	Entity labels	Polarity + entities
F1 polarity tokens	0.93	X	0.93
F1 polarity valence	0.75	X	0.75
F1 entities tokens	X	0.97	0.97
F1 entities Entities	X	Table 3	Table 3
MAE score review level	0.14	0.38	0.14

Table 2: Joint and independent prediction of entities and polarities

detail the case of *Entities* in the Table 3 and present the results obtained for the most common entity categories (among 11). As expected, the entity prediction tasks benefits from the polarity information on most of the categories except for the *Vision and special effects*. A 5% of relative improvement can be noted on the two most present *Entities*: *Overall* and *Screenplay*.

	Entity	Entity + Polarity	Value Count
Overall	0.71	**0.73**	1985
Actors	**0.65**	**0.65**	493
Screenplay	0.60	**0.63**	246
Atmosphere and mood	0.62	**0.64**	151
Vision and special effects	**0.62**	0.58	154

Table 3: F1 score per label for the top entity categories annotated at the sentence level (mean score averaged over 7 runs), value counts are provided on the test set.

7 Conclusion

The proposed framework enables the joint prediction of the different components of an opinion based on a hierarchical neural network. The resulting models can be fully or partially supervised and take advantage of the information provided by different views of the opinions. We have experimentally shown that a good learning strategy should first rely on the easy tasks (*i.e.* for which the labels do not require a complex transformation of the inputs) and then move to more abstract tasks by benefiting from the low level knowledge. Future work will explore the use of *structured output learning* methods dedicated to the opinion structure.

Shallow Domain Adaptive Embeddings for Sentiment Analysis

yliang@cs.wisc.edu

Abstract

This paper proposes a way to improve the performance of existing algorithms for text classification in domains with strong language semantics. We propose a domain adaptation layer learns weights to combine a generic and a domain specific (DS) word embedding into a domain adapted (DA) embedding. The DA word embeddings are then used as inputs to a generic encoder + classifier framework to perform a downstream task such as classification. This adaptation layer is particularly suited to datasets that are modest in size, and which are, therefore, not ideal candidates for (re)training a deep neural network architecture. Results on binary and multi-class classification tasks using popular encoder architectures, including current state-of-the-art methods (with and without the shallow adaptation layer) show the effectiveness of the proposed approach.

1 Introduction

Domain Adaptation (DA) algorithms are becoming increasingly relevant in addressing issues related to i) lack of availability of training data in domains of interest and in ii) exploiting domain idiosyncrasies to improve performance of out-of-domain algorithms. While some state of the art DA algorithms focus on improving on a downstream task, such as classification in bilingual or crosslingual framework (Hangya et al., 2018) (Liu et al., 2018), others (Zeng et al., 2018), (Shang et al., 2018) focus on tackling DA at the word level for various downstream applications such as classification, tagging etc.

Particularly, work by (An et al., 2018) and (K Sarma et al., 2018) address the issue of context-based domain adaptation within a single language. The authors of both works argue that word context causes significant changes, especially in document level sentiment associations. The idea is illustrated by providing examples of words such as 'kill,' that has a more positive sentiment in a document describing video games than when used in a news article. Similarly, words used in social media and medical domains tend to be atypical and idiosyncratic as compared to generic language use.

DA algorithms and related transfer learning algorithms are often successfully used to perform sentiment analysis, where given a document, the sentiment label for the document is to be determined. Since adaptation can be viewed as a shift in the position of words within the embeddings spaces across the domains of interest, shifts in the spatial position of the words can be measured to verify that the algorithm is indeed capturing domain knowledge. Once it is established that a given DA method is capturing domain semantics at the word level, the DA word embeddings can then be used as input to an encoder+classification layer to perform sentiment analysis.

This paper applies a generic adaptation framework to tasks that make use of domain semantics. Contributions of this paper are fourfold. i) First, we propose a generic domain adaptation layer that can be interfaced with any neural network block with the aim of improving performance on a downstream sentiment classification task. ii) Second, we measure the significance of the shift in word position when represented in a generic embedding space and when represented in the adapted embedding space. The strategy is to construct DA word embeddings as in (K Sarma et al., 2018) and make use of a seed lexicon as in (Hangya et al., 2018) and (Mikolov et al., 2013a). However, rather than use the seed lexicon to transform words from two different domains into a common space, we use the seed lexicon to verify that the DA word embeddings have indeed captured significant domain semantics. iii) We test

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5549–5558, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

our hypothesis on a recently introduced (Friedland et al., 2017)[1] data set of tweets from Liberal and Conservative Twitter users from the state of Wisconsin. As illustrated in (An et al., 2018), political discourse makes for an interesting setting to study domain adaptation. (iv) Via thorough experimentation we show that using a DA layer helps improve the performance of standard architectures on sentiment analysis tasks by $2-8\%$ on various binary and multi-class balanced and imbalanced data sets. We also, show that our DA architectures outperform sophisticated architectures such as BERT, LR-Bi-LSTM, Self-attention by $1-2\%$.

The rest of this paper is organized as follows, Section 2 discusses related work. Section 3 describes in detail, the proposed algorithm, Section 4 presents the experimental results and Section 5 concludes this work.

2 Related Work

This paper discusses domain adaptation techniques and the applicability of existing algorithms to diverse downstream tasks. Central themes of this paper tie into word level domain semantics, while being related to the overall objective of domain adaptation.

Recent work such as SEMAXIS (An et al., 2018) investigates the use of word level domain semantics for applications beyond sentiment analysis. The authors introduce the concept of a semantic axis based on word antonym pairs to capture semantic differences across corpora. Similarly, work by (Hamilton et al., 2016) captures domain semantics in the form of sentiment lexicons via graph propagation. While both these lexical based approaches are similar to the ideas of this paper, a major difference is that like (K Sarma et al., 2018), we do not make use of any predefined domain specific lexicons to capture domain semantics. Our idea is to use word occurrences and contexts to provide a raw estimate of the domain semantics. Using generic embedding spaces as baselines, adaptation is performed by projecting generic embeddings into a learned 'adaptation' space.

Typical downstream applications such as cross lingual and/or multi-domain sentiment classification, using algorithms proposed by (Hangya et al., 2018), (Liu et al., 2018), make use of DNNs with RNN blocks such as BiLSTMs to learn both generic and domain specific representations. Particularly, work focused on multi-domain sentiment classification as in (Liu et al., 2016), (Nam and Han, 2016), proposes building neural architectures for each domain of interest, in addition to shared representation layers across all domains. While these techniques are effective, they are not ideal in domains with limited data.

On the other hand work such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) propose deeply connected layers to learn sentence embeddings by exploiting bi-directional contexts. While both methods have achieved tremendous success in producing word (ELMo) and sentence (BERT) level encodings that perform well in several disparate NLP tasks such as question-answer solving, paraphrasing, POS tagging, sentiment analysis etc, these models are computationally expensive and require large amounts of training data. Particularly when used in a transfer learning setting, both algorithms assume that a large amount of data is present in the source as well as the target domains. In contrast, our proposed adaptation layer is particularly well suited in applications with limited data in the target domain.

Our proposed algorithms depart from these approaches by capturing domain semantics through shallow layers for use with generic encoder architectures. Since some of the most successful algorithms in text classification (Kim, 2014) and sentence embeddings (Conneau et al., 2017) make use of CNN and BiLSTM building blocks, we suggest a generic adaptation framework that can be interfaced with these standard neural network blocks to improve performance on downstream tasks, particularly on small sized data sets.

3 Shallow Domain Adaptation

This section introduces a 'shallow' adaptation layer[2], to be interfaced with a neural network based sentence encoding layer, followed by a classification layer. Figure 1 describes a generic framework of the proposed model. Brief descriptions of the three layers follow.

Adaptation Layer: Generic word embeddings from GloVe (Pennington et al., 2014) or word2vec (Mikolov et al., 2013b) are combined with an LSA-based (Deerwester et al., 1990) Do-

[1] https://github.com/naacl18sublong/Friedland

[2] Codes for shallow adaptation will be made available upon acceptance of paper for publication.

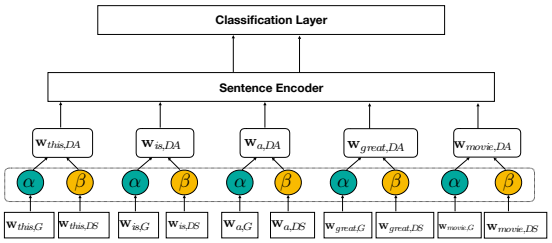

Figure 1: This figure illustrates the three part neural network model. The first part comprises of an adaptation layer, second, a generic sentence encoder and the lastly a classification layer. Inputs to the shallow adaptation layer are the generic and the domain specific (DS) word embeddings. Output of the adaptation layer is the domain adapted (DA) word embedding.

main Specific (DS) word embedding using KCCA as proposed in (K Sarma et al., 2018). Once the KCCA projections $(\bar{\mathbf{w}}_{i,G}, \bar{\mathbf{w}}_{i,DS})$ for the generic and DS word embeddings are obtained for a given word i, weights α and β are learned such that the domain adapted word embedding is $\bar{\mathbf{w}}_{i,DA} = \alpha\bar{\mathbf{w}}_{i,G} + \beta\bar{\mathbf{w}}_{i,DS}$. Weights α and β are learned by a single CNN layer. Since this layer learns only the weights used to obtain the DA embeddings, we call this a 'shallow' adaptation layer.

The output of this layer (i.e., the DA embeddings), is used to initialize a generic sentence encoder. Output from the sentence encoder is sent to a classification layer and the classification error is back propagated to update weights of the adaptation layer. By keeping the sentence encoder fixed, (i.e., the parameters of the encoder are not updated during back propagation), this method can be generalized for use with any pre-trained sentence encoder. This is advantageous, particularly in data sets that are too small to be trained end-to-end. Another advantage is that adaptation is not performed on fully connected layers that need to be trained end-to-end. This considerably reduces the number of parameters that need to be learned.

Figure 2 illustrates the CNN encoder architecture and the Adaptation Layer. Input to the adaptation layer is a word embedding of dimension $2d$, where d is the dimension of the generic and DS embeddings. For a given word, the generic and DS embeddings are concatenated and interleaved. A single layer CNN learns α and β via a 2×1 kernel. The domain adapted word $\mathbf{w}_{i,DA}$ is then passed as input to the CNN encoder as shown in the figure. Note that we also use this framework with a BiLSTM sentence encoder as in (Conneau et al., 2017) and is illustrated in Figure 2. Output of the BiLSTM units is max-pooled to obtain the sentence encoding.

Sentence Encoder: CNN encoder as in (Kim, 2014) and BiLSTM encoder proposed in (Conneau et al., 2017) are used to encode sentences in this work. Since both models have been extensively discussed in literature we shall skip elaborating on the basic model architectures. We reproduced the basic encoder models for the experiments in Section 4 with exception of few hyper-parameters, since the choice of data sets in this work differs from that of (Kim, 2014) and (Conneau et al., 2017).

Classification Layer: This layer learns weights for multi-class classification using a soft-max function.

3.1 Evaluating KCCA for Domain Adaptation

In their work (K Sarma et al., 2018), the authors demonstrate the effectiveness of KCCA based embeddings via classification experiments. However, in order to verify that the word level adaptation performed by the KCCA step can capture relevant domain semantics, we perform the following experiment.

3.2 Experimental Setup

Start with a dataset where language use is polarized. For example, the language used in the tweets of liberals likely differs from the language used in the tweets of conservatives as they express opinions on key political issues such as government, immigration, border control etc. These two vocabularies (Liberal and Conservative) are encoded in DS embeddings which are each paired with a generic embedding, and then again mapped into a common DA space. The words in this common space that are most different are then identified, and compared to a ground truth/gold standard list of keywords which represent ideas or concepts on which the two groups of users are known to have the most polarized opinions. Comparing the gold standard list with the list derived from the DA embedding demonstrates the efficacy of the method. This experiment adopts the list of politically contentious words that appear in (Li et al., 2017).

From the tokenized tweets of the users, construct a vocabulary of words V_{Lib} and V_{Con} that represent the Liberal and Conservative tweets respectively. Domain specific (DS) word embed-

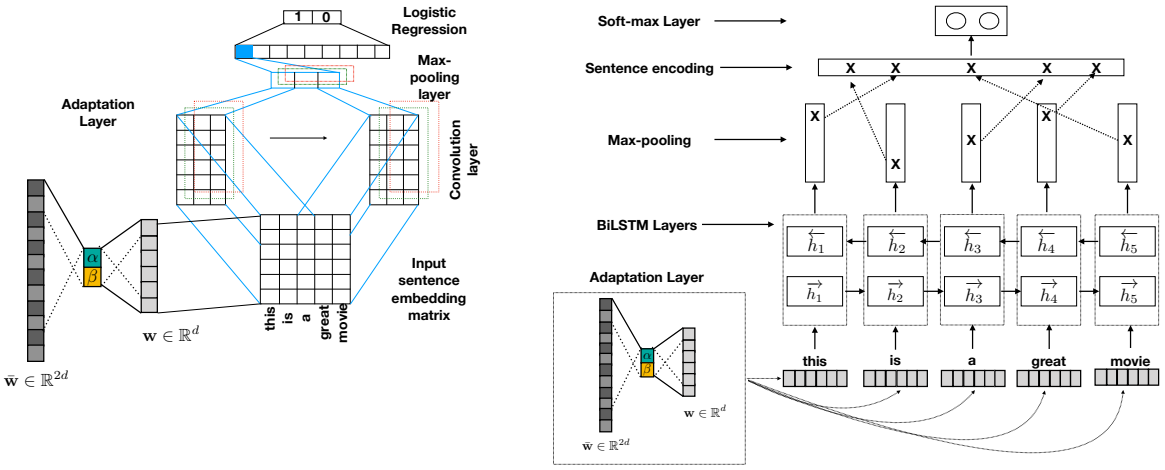

Figure 2: **Left:** This figure illustrates the adaptation layer, that takes as input a $2d$ dimensional word embedding containing the generic and DS KCCA projections and learns a d dimensional DA word embedding. This DA word embedding is then input to the CNN encoder. The network can be optimized to learn only parameters α and β or can be trained end to end to learn sentence embeddings and classifier weights as well. **Right:** This figure illustrates the adaptation layer, out of which, the DA word embedding is then input to the BiLSTM+max-pooling encoder. The entire network can be trained end-to-end to learn parameters α and β in addition to the sentence embedding and classifier, or the network can be optimized to learn only the weights α and β and weights of the classifier.

dings are first constructed from V_{Lib} and V_{Con}. Then, KCCA projections are obtained for generic GloVe embeddings and the DS word embeddings for each user group, in order to construct DA word embeddings for Liberal $\hat{\mathbf{W}}_{DA(Lib)}$ and Conservative $\hat{\mathbf{W}}_{DA(Con)}$ users.

Next consider the set of common words in the two vocabularies, i.e $V_{common} = V_{Lib} \cap V_{Con}$. Perform a second KCCA to bring DA words in V_{common} from both Liberal V_{Lib} and Conservative V_{Con} vocabularies into a common subspace. To measure the 'shift' ψ, calculate the l_2 distance for each word embedding $\hat{\mathbf{W}}_i \in V_{common}$, i.e

$$\psi = ||\hat{\mathbf{W}}_{i,DA(Lib)} - \hat{\mathbf{W}}_{i,DA(Con)}||_2 \quad \forall i \in V_{common} \tag{1}$$

Words with large values of ψ are considered to have shifted the most between the domains of liberal and conservative users. Words are then ordered based on the magnitude of ψ, and cross referenced with words in the gold standard list.

In order to demonstrate that the KCCA can capture domain semantics when learning DA word embeddings, the following section presents an analysis against a random baseline.

3.3 Study of a random baseline

A random baseline is one that picks k words from V_{common}, randomly, and reports these k words as having shifted the most with respect to word use within tweets that correspond to Liberal and Conservative users. This random baseline follows a hypergeometric distribution, which is a discrete probability distribution that calculates the probability of obtaining k successes (of a sample with a specific feature) from n draws, from a finite population of V, without replacement, where exactly K samples contain the specific feature.

For example, suppose $|V_{common}| = V$, and say the number of words in the gold standard list are K. Then the probability of the random baseline picking $k < K$ words out of n words is

$$Pr(X = k) = \frac{\binom{K}{k}\binom{V-K}{n-k}}{\binom{V}{n}}. \tag{2}$$

To calculate these probabilities for the KCCA-DA word embeddings, we shall use the LibCon data set of Section 3.1. A gold standard list of 136 key topics/concepts important to Liberals and Conservatives is obtained from the study by (Li et al., 2017), and additional details about the LibCon data set and the gold standard list can be found in Section 4.1.

From the LibCon data set $|V_{common}| = V = 1573$. Out of these 1573 words, there are 74 words that are present in the gold standard list. Hence $K = 74$. After obtaining the DA word embeddings for words in V_{common} and calculating the shift ψ, we take the top 200 words that shifted

Table 1: This table presents 74 words representing key political concepts common to Liberal and Conservative users on Twitter. Words in bold are the ones that 'shift' the most (by l_2 distance) in use between Liberal and Conservative users on Twitter.

most. From these words, at least 20 are present in the gold standard list.

The number of words-of-interest in a sample of 200 words forms a hypergeometric distribution with mean $\mu = n\frac{K}{V} \approx 9.4$, and standard deviation 2.7984.

Direct calculation shows that the probability of picking exactly 20 words from this subset is $Pr(X = 20) = 0.000346$. Similarly, the probability that 20 or more would have been chosen by chance is,

$$p = \sum_{k=20}^{200} Pr(X = k) \tag{3}$$

which, by numerical calculation, is $p = 0.000524$. Such a result is highly unlikely to occur by chance. Accordingly, the KCCA domain adapted word embeddings are indeed capturing something significant about the language usage in the domain.

Table 1 presents words from the gold standard list with words in bold face indicating words that shift the most across Liberal and Conservative domains.

4 Experimental Results

The discussion in Section 3.1 provides motivation for adopting the KCCA projections as a tool to calculate DA word embeddings. These DA word embeddings can be combined with standard neural network models to obtain sentence embeddings that can be used to improve performance on downstream tasks such as sentiment analysis. To test the effectiveness of our proposed approach, we conduct a series of binary (LibCon, MR and SST) and multi-class (Beauty, Book and Music) classification tasks, using our adaptation layer on top of several standard architectures. The standard architectures used in this paper are architectures that are common in the current State-Of-The-Art (SOTA) for sentence encoders (Conneau et al., 2017) and multi-domain sentiment analysis (Liu et al., 2018). These architectures are a BiLSTM based architecture followed by some sort of pooling and then a soft-max classification layer.

Our main result is that using the proposed domain adaptation layer on top of existing architectures helps improve the performance of the architecture by about $2 - 8\%$. Furthermore, we show that basic architectures enhanced with our DA layer outperform SOTA architectures built specifically for domain adaptation and transfer learning problems. We now give a description of the various datasets that we use and the various baseline algorithm used for our experimental comparisons.

4.1 Data Sets

Motivated by the fact that our DA layer is most useful when the target dataset is of modest size, we present our experimental results on three such datasets. Furthermore, the text used in these datasets often uses the same set of words to express clearly contrastive sentiments, thereby setting up groups or domains of distinct word use within a single data set.

LibCon: The LibCon (**Lib**eral and **Con**servative) data set is obtained from a study that aims towards understanding, analyzing and modeling the changing landscape of political discourse of an entire state over a duration of 10 years (Friedland et al., 2017). A key aspect of this study is the use of Twitter data to analyze the latent network structure among key players of Wisconsin's political-media ecology. To do this, data was drawn from a collection of Twitter data housed at the UW-Madison School of Journalism and Mass Communication. Data is drawn from a 10% sample of Twitter messages worldwide from Twitter's API (Twitter 2012). Note that the period of data collection corresponds to the re-election efforts of Governor Walker (of Wisconsin). Snowball sampling is employed to identify important Twitter handles active in four 28-day periods in the first half of 2012. A hand curated list of Twitter handles corresponding to key players in Wisconsin's political climate is identified. Combined with Twitter handles of nationwide users that interact frequently with users in this list, the final list of Twitter handles of interest is formed.

Twitter handles are confirmed to their corre-

sponding political associations by verifying their party membership. The Twitter handle pool includes a balanced representation from Republican and Democratic accounts. In depth description of data collection methodologies and outcomes can be found in (Friedland et al., 2017) and readers are encouraged to consult this resource for additional information. A subsample of 1000 tweets, each from known Liberal (Democratic party) and Conservative (Republican party) users are considered for experiments here.

Gold standard list of topics key to both Democrat and Republican parties are obtained by analyzing primary debate data over a period of almost 20 years (1999-present) (Li et al., 2017). A combination of modeling techniques involving semantic spaces and neural network architectures is used to arrive at the final list of 136 top/key concepts such as 'Army', 'Border', 'Democracy', 'Justice' etc. Out of these 136 words, 74 occur in the LibCon data set as seen in Table 1.

Movie Review: This is a benchmark dataset (Pang and Lee, 2005) from which we randomly sample 2500 positive and 2500 negative reviews for experiments.

SST: The Stanford Sentiment Tree (SST) bank is yet another standard benchmark data set with reviews binarized to 'positive' or 'negative'. Our experiments use a 5000 sample training data set and a pre-determined test set of 5000 points.

Beauty, Book, Music: These data sets each consist of 6000 beauty product, book and music reviews with a balanced distribution of three class labels. This data set was introduced by (He et al., 2018). Data is obtained by sampling from a larger data set of product reviews obtained from Amazon (McAuley et al., 2015). Labels are 'positive', 'negative' and 'neutral'. An imbalanced setting for each data set is also available, where roughly 80% of the data points are 'positive' and the remaining are 'negative' and 'neutral'. Details about number of data points for each data set can be found in the supplement.

4.2 Baselines

For all test data sets, in addition to contrasting the performance of the proposed adaptation layer added to a CNN and BiLSTM encoder, we also present comparisons against 'Vanilla' CNN and BiLSTM encoders. For popular data sets like the MR and SST data sets we present results against some additional baselines, all of which are variants of the basic vanilla RNN encoders. The baselines that we used in this paper are,

BoW: In this standard baseline each sentence is expressed as a weighted sum of its constituent word embeddings. Weights used are raw word counts. Both generic (GloVe) and DA word embeddings are used in this baseline. Note that the DA embeddings used in this baseline are the same as in (K Sarma et al., 2018), i.e $\alpha = \beta = 0.5$

Vanilla CNN: A CNN based sentence classification framework as introduced by (Kim, 2014) is used as a 'Vanilla' CNN baseline.

Vanilla BiLSTM: A Basic BiLSTM encoder followed by max pooling as proposed by (Conneau et al., 2017) is used as the 'Vanilla' BiLSTM baseline. Note that the vanilla baseline contains no additional features like attention.

BERT: Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) is a generic encoder framework that learns sentence embeddings by jointly conditioning on both left and right context in all layers. The Bert encoder is generic and requires a tuneable output layer to be learned in order to perform a chosen task. In our work, we use the pooled output from the Bert encoder to obtain sentence representations for all our data and then learn weights for a classifier to perform classification on the given data set.

Self-attention: A model that generates interpretable, structured sentence embeddings using Self-attention mechanism (Lin et al., 2017).

LR-Bi-LSTM: A model that imposes linguistic roles to Bi-LSTM architectures (Qian et al., 2017).

DAS: The Domain Adaptive Semi-supervised algorithm (He et al., 2018) is a transfer learning based solution that performs sentiment classification. In their experiments, the authors train on review data from different source domains such as book, music and electronics and test on a target domain such as beauty. In contrast, our method does not train on these three sources; rather, it uses only the Beauty reviews to learn the DS word embeddings (and then combines these with the generic pretrained embedding to learn the DA embedding used for classification. On the balanced data sets, metric reported is Accuracy, the same used by (He et al., 2018). On the imbalanced data sets, in addition to accuracy we report micro f-score.

4.3 Experimental methodology

The LibCon, MR and Beauty, Book and Music data sets do not have dedicated train/dev/test splits, so we created $80/10/10$ splits. For the SST dataset we make use of pre-defined test data set of 2210 data points. When pre-tuned models are available, such as for BERT, we further fine-tune it using our train/dev splits. All the baselines use the same splits of data.

Hyperparameters: All word embeddings-GloVe, DS and KCCA projections used to obtain the DA embeddings are of dimension 300. Both the CNN and BiLSTM encoders learn sentence embeddings of 300 dimensions on all data sets, except on the LibCon data set where the CNN encoders have a filter size of 120. Dropout probability is set to 0.5. The rest of the hyperparameters used are the same as in (He et al., 2018) and are found in the supplement.When using BERT, the 'bert-base-uncased' model is used to obtain sentence embeddings. Pooled output from the BERT encoder is used to represent the input sentence. The classifier learned during tuning on the train data sets is similar to the linear classification layer introduced in the BERT classification framework, with the exception of an additional Tanh activation. The additional Tanh activation function was used in order to obtain comparable results for BERT and other baselines. The size of test data is particularly challenging for a large model like BERT that has several learnable parameters, even when used only for fine-tuning the pre-trained model. The BERT classification framework is reproduced for use in our experiments, reflecting the original tuning scripts to the best of our ability. Additional information about hyperparameters can be found in the supplement.

4.4 Results

Table 2 presents results on the LibCon and the balanced (B) and imbalanced (I) Beauty, Book and Music data sets and Table 3 presents results on the SST and MR data sets. The performance metric reported in both tables is accuracy with with additional micro f-scores reported in Table 2.

From Table 2, it is observed that on the LibCon data set, where we have a considerable difference in language use between the two groups of users, the adapted BiLSTM and adapted CNN perform much better than the vanilla baselines. Furthermore, our proposed adaptation layer improves the performance of the Vanilla BiLSTM to surpass the performance of fine-tuned BERT. Note that the BERT encoder is pre-trained on all of Wikipedia, a much larger training data set than used for training the Adapted BiLSTM encoder. The adapted BiLSTM and CNN encoders also outperform DAS on the multiclass Beauty, Book and Music data sets. Performance of LSTMs for text surpass that of CNNs as seen in current literature. This observation is consistent in our results as well. Since the DAS baseline makes use of a CNN encoder, it is expected that a very basic LSTM such as the Vanilla BiLSTM would perform much better than any CNN framework. Results Table 4 strengthens our hypothesis that the adaptation layer is particularly well suited for small training and test data regimes.

Note that on the MR data set, the performance of fine-tuned BERT is lower than the BiLSTM baselines. While the size of training data used to optimize BERT, makes the encoder an excellent generic sentence encoder, the small size of the tuning data sets poses a considerable challenge. This is because, when the BERT encoder is fine tuned for a particular task, output from the encoder is treated as a fixed feature on top of which it learns a task specific layer. Using pre-trained BERT provides a high quality feature vector that can be used for applications on generic data sets, but this does not assure good performance when tuned on a small data set where words may be used idiosyncratically. On the other hand, on a highly polarized data set like the LibCon data set, while the distinct linguistic features enable the BERT encoder to capture good sentence embeddings, the size of the data set still poses a challenge.

Varying Size of Training Data: To further illustrate the effectiveness of our method on data sets with limited training data, we train the Vanilla and adapted BiLSTM and CNN encoders with even smaller samples of the training data. Our results are consistent on varying size of data sets and performance metrics for the same can be found in the supplement. Table 4 compares accuracy on the MR and SST data sets, of Vanilla and adapted encoders trained with 1000 and 2500 points. Repeating this experiment with BERT resulted in tremendous over-fitting on the test set and so we do not present results from BERT in Table 4.

Qualitative analysis of DA word embeddings: Here we present a small analysis of the DA embed-

Algorithm	Acc on LibCon	Acc on Beauty (B)	Acc on Book (B)	Acc on Music (B)	Beauty (I)		Book (I)		Music (I)

Table 4: This table presents the accuracy obtained by Vanilla and adapted baselines on smaller subsamples of the training data for the MR and SST data sets.

dings obtained from the weights learned via the shallow adaptation layer. The analysis presented here is on the Book review data set consisting of roughly 10000 unique word tokens. Weights learned via the CNN encoder on this data set are $\alpha = 0.7145$ and $\beta = 0.3994$. To compare the DA embeddings against the GloVe common crawl embeddings, we first standardize both sets of embeddings to have an average norm of 1. Then we compute shift via the l_2 distance as described in Section 3.1. Out of 100 most shifted words, Adjectives (21%) and Adverbs (22%) such as 'emotional', 'profound' and 'emotionally' and 'obviously' shift the most. These words are used extensively when writing reviews about books. On the other hand words that shift the least are Nouns (69%) such as 'Higgins', 'Gardner' and 'Schaffer' that correspond to author and character names. This observation is consistent with the domain adaptation hypothesis. A data set of book reviews will use Adjectives and Adverbs differently in-domain as opposed to out-of-domain. On the other hand, Nouns and Noun Phrases such as character and author names remain fixed regardless.

5 Conclusions and Future Work

This paper shows that domain semantics captured in adapted word embeddings can improve the performance of (pre-trained) encoders in downstream tasks such as sentiment classification; particularly on data sets where obtaining data sufficient enough for tuning pre-trained encoders or for end-to-end training is difficult. Experiments show the effectiveness of the method in binary and multiclass classification tasks. The proposed framework outperforms competing transfer learning based algorithms in overcoming limitations posed by the size of training data, while learning fewer parameters than an end-to-end trained network along with obtaining better results on classification tasks. Recent work that focuses on capturing domain semantics in word embeddings, demonstrate the effectiveness of such approaches mostly via performance on a downstream task such as sentiment analysis/classification alone. In Section 3.1 we provide a simple yet effective demonstration of how techniques such as KCCA, that are used to capture domain semantics, can capture relevant semantics in the learned word embeddings. As future work, we will interface the adaptation layer for use recently introduced large scale language models such as BERT. Due to size and memory complexities of available implementation of large scale language models such as BERT, an easy integration with our proposed adaptation framework does not currently exist.

Abstract

Cross-domain sentiment classification has drawn much attention in recent years. Most existing approaches focus on learning domain-invariant representations in both the source and target domains, while few of them pay attention to the domain-specific information. Despite the non-transferability of the domain-specific information, simultaneously learning domain-dependent representations can facilitate the learning of domain-invariant representations. In this paper, we focus on aspect-level cross-domain sentiment classification, and propose to distill the domain-invariant sentiment features with the help of an orthogonal domain-dependent task, i.e. aspect detection, which is built on the aspects varying widely in different domains. We conduct extensive experiments on three public datasets and the experimental results demonstrate the effectiveness of our method.

1 Introduction

Sentiment classification based on deep learning methods has developed rapidly in recent years. While achieving outstanding performance, these methods always need large-scale datasets with sentiment polarity labels to train a robust sentiment classifier. However, in most cases, large-scale labeled datasets are not available in practice and manual annotation costs much. One of the solutions to this problem is *cross-domain sentiment classification*, which aims to exploit the rich labeled data in one domain, i.e. *source domain*, to help the sentiment analysis task in another domain lacking for or even without labeled data, i.e. *target domain*. The rationality of this solution is that the source domain and target domain share some domain-invariant knowledge that can be transferred across domains.

Source Domain: The fried rice is amazing here.
Target Domain: Surprisingly, Britney Spears is amazing.

Figure 1: Example sentences from the source domain (restaurant) and the target domain (twitter) respectively. The sentiment expressions marked by solid lines are domain-invariant, while the aspect terms marked by dashed lines are domain-specific.

Previous works on cross-domain sentiment classification mainly focus on learning the domain-invariant representations in both source and target domains, either based on manual feature selection (Blitzer et al., 2006; Pan et al., 2010) or automatic representation learning (Glorot et al., 2011; Chen et al., 2012; Ganin and Lempitsky, 2015; Li et al., 2017). The sentiment classifier, which makes decisions based on the domain-invariant features and receives the supervisory signals from the source domain, can be also applied to the target domain. We can draw an empirical conclusion: the better domain-invariant features the method obtains, the better performance it gains. However, few studies explore the usage of the domain-specific information, which is also helpful to the cross-domain sentiment classification. Peng et al. (2018) propose to extract the domain-invariant and domain-dependent features of the target domain data and train two classifiers accordingly, but they require a few sentiment polarity labels in the target domain, which limits the practical application of the method.

In this paper, we exploit the domain-specific information by adding an orthogonal domain-dependent task to "distill" the domain-invariant features for cross-domain sentiment classification. The proposed method *domain-invariant feature distillation* (DIFD) does not need any sentiment

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5559–5568, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

polarity labels in the target domain, which is more consistent with the practical settings. Specifically, we focus on the aspect-level cross-domain sentiment classification, and train a shared sentiment classifier and two respective aspect detectors in the source and target domains. We argue that aspect detection is an orthogonal domain-dependent task with respect to the sentiment classification. As shown in Figure 1, given an input sentence, the sentiment classifier predicts its sentiment polarity based on the opinion words shared by different domains, while the aspect detector identifies the aspect terms which vary significantly across domains. The information on which the two tasks depend is mutually exclusive in the sentence, i.e. orthogonal. Therefore, by training these two tasks simultaneously, the aspect detectors will try to strip the domain-specific features from the input sentence and make the domain-invariant features purer, which is helpful to the cross-domain sentiment classification.

Moreover, we design two effective modules to boost the distillation process. One is the word-level context allocation mechanism. It modulates the importance of the words in the input sentence according to the property of different tasks. The other is the domain classifier. It tries to correctly judge which domain the domain-invariant feature comes from, while the other modules in the proposed method try to "fool" it, and the whole framework is trained in an adversarial way.

To summarize, the main contributions of our paper are as follows:

- We distill the domain-invariant sentiment features to improve the cross-domain sentiment classification by simultaneously training an aspect detection task that striping the domain-specific aspect features from the input sentence.
- We boost the separation process of the domain-invariant and domain-specific features by two effective modules which are the context allocation mechanism and domain classifier respectively.
- Experimental results demonstrate the effectiveness of the proposed method, and we further verify the rationality of the context allocation mechanism by visualization.

2 Related Work

Cross-domain sentiment analysis: Many domain adaptation methods have been proposed for sentiment analysis. SCL (Blitzer et al., 2006) learns correspondences among features from different domains. SFA (Pan et al., 2010) aims at reducing the gap between domains by constructing a bipartite graph to model the co-occurrence relationship between domain-specific words and domain-independent words. SDA (Glorot et al., 2011) learns to extract a meaningful representation for each review in an unsupervised fashion. mSDA (Chen et al., 2012) is an efficient method to marginalize noise and learn features. Gradient Reversal Layer (GRL) (Ganin and Lempitsky, 2015; Ganin et al., 2016; Li et al., 2017) is employed to learn domain-invariant representations by fooling the domain classifier. The replacement of gradient reversal with alternating minimization (Shu et al., 2018) stabilizes domain adversarial training, and we employ this method as the adversarial training.

Aspect-level sentiment domain adaptation: To the best of our knowledge, there are two works about aspect-related cross-domain sentiment classification. Li et al. (2019) propose a method to employ abundant aspect-category data to assist the scarce aspect-term level sentiment prediction. Zhang et al. (2019) propose IATN to address that aspects have different effects in different domains. Their method predicts sentiment polarity for the whole sentence rather than a specific aspect.

Our method concentrates on aspect-term level sentiment domain adaptation by separating the domain-specific aspect features. Bousmalis et al. (2016) and Liu et al. (2017) separate features into two subspaces by introducing constraints on the learned features. The difference is that our method is more fine-grained and utilizes the explicit aspect knowledge.

Auxiliary task for sentiment domain adaptation: Auxiliary task has been employed to improve cross-domain sentiment analysis. Yu and Jiang (2016) use two pivot-prediction auxiliary tasks to help induce a sentence embedding, which works well across domains for sentiment classification. Yu and Jiang (2017) propose to jointly learn domain-independent sentence embeddings by auxiliary tasks to predict sentiment scores of domain-independent words. Chen et al. (2018) design auxiliary domain discriminators for better transferring knowledge between do-

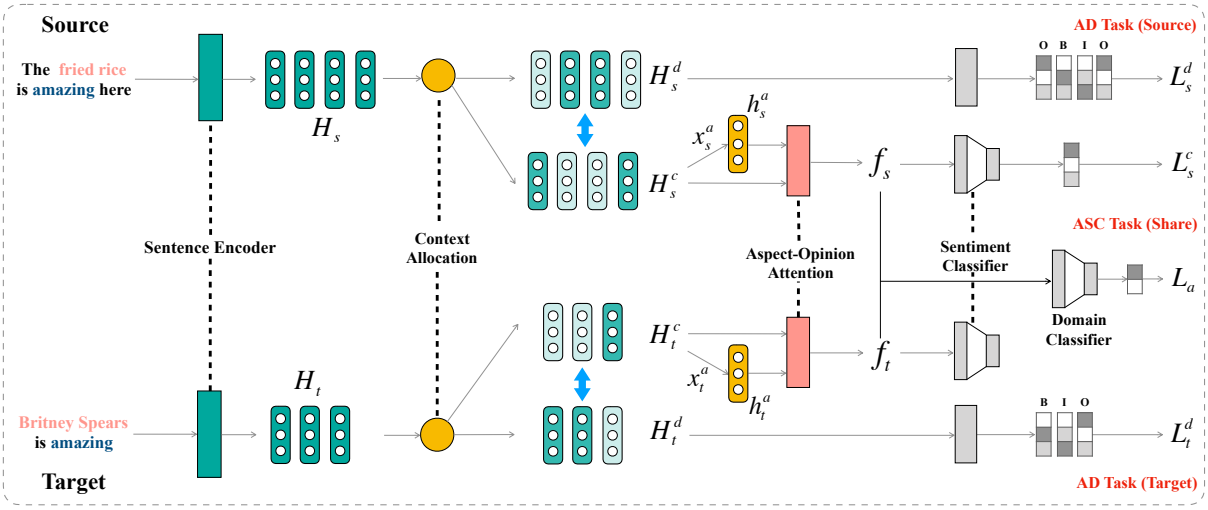

Figure 2: Network Architecture. The dashed line indicates that the parameters are shared by source and target domains. The context from the sentence encoder is divided into task-oriented contexts for ASC and AD tasks.

mains. These auxiliary tasks focus on directly enhancing domain-invariant features, while ours strips domain-specific features to distill domain-invariant features.

3 Methodology

3.1 Formulation and Overview

Suppose the source domain contains labeled data $\mathcal{D}_s = \{(x_s^k, a_s^k), y_s^k\}_{k=1}^{N_s}$, and the target domain contains unlabeled data $\mathcal{D}_t = \{(x_t^k, a_t^k)\}_{k=1}^{N_t}$, where x is a sentence, a is one of the aspects in x, and y is the sentiment polarity label of a. The proposed method handles two kinds of tasks. One is the main task Aspect-level Sentiment Classification (**ASC**). It learns a mapping $\mathcal{F}: \{x\} \rightarrow \{\boldsymbol{f}\} \rightarrow \{y\}$ shared by source and target domains, where $\boldsymbol{f}$ is the domain-invariant feature of x. The other is the orthogonal domain-dependent task Aspect Detection (**AD**). It learns a mapping $\mathcal{G}_s: \{x_s\} \rightarrow \{\boldsymbol{z_s}\} \rightarrow \{a_s\}$ in the source domain, and the other one $\mathcal{G}_t: \{x_t\} \rightarrow \{\boldsymbol{z_t}\} \rightarrow \{a_t\}$ in the target domain, where $\boldsymbol{z}_s$ and $\boldsymbol{z}_t$ are both domain-dependent features of x_s and x_t respectively. The domain-invariant and domain-dependent features are orthogonal, i.e. $\boldsymbol{f} \perp \boldsymbol{z_s}$ and $\boldsymbol{f} \perp \boldsymbol{z_t}$. We facilitate the distillation of $\boldsymbol{f}$ by simultaneously learning $\mathcal{G}_s$ and $\mathcal{G}_t$ which try to strip $\boldsymbol{z_s}$ and $\boldsymbol{z_t}$ from x, and the purer $\boldsymbol{f}$ leads to the better $\mathcal{F}$ for the cross-domain sentiment classification.

Figure 2 illustrates the architecture overview of our method. Given an input sentence either from the source or target domain, we first feed it into the sentence encoder to obtain its distributed representation. Then, the context allocation mechanism divides the distributed representation into two orthogonal parts: domain-invariant and domain-dependent features. Finally, the two orthogonal features are fed into their corresponding downstream tasks. Specifically, we input the domain-invariant feature into the sentiment classifier to predict the sentiment polarity, and input the domain-dependent feature into the aspect detector of the specific domain to identify the aspect terms. In addition, we add a domain classifier to the architecture. It tries to correctly judge which domain the domain-invariant feature comes from. The whole framework is trained in an adversarial way. Next, we will introduce the components of our method in detail.

3.2 Sentence Encoder

Given an input sentence $x = \{w_1, w_2, ..., w_n\}$, we first map it into an embedding sequence $\hat{E} = \{\boldsymbol{e_1}, \boldsymbol{e_2}, ..., \boldsymbol{e_n}\} \in \mathbb{R}^{n \times d_e}$. Then we inject the positional information of each token in x into $\hat{E}$ to obtain the final embedded representation E, following the Position Encoding (PE) method in the work (Vaswani et al., 2017):

$$\begin{aligned} PE(pos, 2i) &= sin(pos/10000^{2i/d_e}) \\ PE(pos, 2i+1) &= cos(pos/10000^{2i/d_e}) \\ E &= \hat{E} + PE \end{aligned} \quad (1)$$

where pos is the word position in the sentence and i is the i-th dimension of d_e. We consider that the injected positional information can facilitate the aspect-level sentiment classification, based on the

observation that sentiment words tend to be close to its related aspect terms (Tang et al., 2016; Chen et al., 2017).

Next we employ a Bi-directional LSTM (BiLSTM) (Graves et al., 2013) to encode E into the contextualized sequence representation $H = [\boldsymbol{h_1}, \boldsymbol{h_2}, ...\boldsymbol{h_n}] \in \mathbb{R}^{n \times 2d_h}$, which preserves the contextual information of each token in the input sentence.

We unify the embedding layer and BiLSTM as the sentence encoder in which different tasks or domains all share the same weights. The advantages of sharing the weights are two-fold: first, different tasks in the same domain can benefit from each other in a multi-task manner; second, distilling the domain-invariant feature from a common transformation is more simple.

3.3 Context Allocation (CA)

In an input sentence, some words have a strong bias towards domain-specific information, such as the aspect terms, e.g. *"pizza"* in Restaurant domain, while others focus on the domain-invariant knowledge, such as the opinion words, e.g. *"amazing"*. Meanwhile, the ASC task and AD task exactly require orthogonal information as discussed before. Therefore, we argue that different words contribute differently according to the property of the downstream task. To facilitate the distillation of the domain invariant features, we propose a Context Allocation (CA) mechanism to allocate different weights on the same word in different downstream tasks. The values of the weights depend on how the information contained in the word matches the need of the specific task. Concretely, at each time step i, the module divides the contextualized representation h_i of word w_i into the sentiment-dominant context h_i^c and aspect-dominant context h_i^d as follows:

$$\boldsymbol{h_i^c} = \beta_i^c \boldsymbol{h_i}, \tag{2}$$

$$\boldsymbol{h_i^d} = \beta_i^d \boldsymbol{h_i}, \tag{3}$$

$$\beta_i^c + \beta_i^d = 1, \quad i \in \{1, 2, ..., n\}. \tag{4}$$

The two-dimensional vector $\beta_i = (\beta_i^c, \beta_i^d)$ is normalized considering that the domain-specific information and domain-invariant knowledge are mutually exclusive. It reflects the importance of w_i on the ASC task and AD task respectively, and is calculated on h_i as follows:

$$\beta_i = \text{softmax}(W_b \text{tanh}(W_a \boldsymbol{h_i}^{\mathrm{T}})), \tag{5}$$

where $W_a \in \mathbb{R}^{2d_h \times 2d_h}$ and $W_b \in \mathbb{R}^{2 \times 2d_h}$. The whole division process at all time steps can be formulated in the following form:

$$\begin{bmatrix} H_c \\ H_d \end{bmatrix} = \boldsymbol{\beta} \cdot \begin{bmatrix} H \\ H \end{bmatrix}, \tag{6}$$

where $\boldsymbol{\beta} = [\beta_1, \beta_2, ..., \beta_n]$. The sentiment-dominant context $H^c \in \mathbb{R}^{n \times 2d_h}$ and aspect-dominant context $H^d \in \mathbb{R}^{n \times 2d_h}$ of the input sentence are then fed into the ASC task and AD task for downstream processing respectively.

3.4 Aspect-level Sentiment Classification (ASC) Task

Aspect-Opinion Attention In the ASC task, we design an attention mechanism to model the relationship between the position of the aspect terms and their corresponding opinion words. For a specific aspect term, the domain-invariant feature based on the aspect-opinion attention contains more information of its corresponding opinion words, which is beneficial to the final aspect-level sentiment classification. Specifically, we first calculate the position representation of a specific aspect term with its position x^a and the sentiment-dominant context H^c:

$$\boldsymbol{h^a} = H^c x^a \tag{7}$$

where $x^a = \{0_1, ..., 1_{i+1}, ..., 1_{i+m}, ...0_n\}$ represents the word positions of an aspect subsequence in the input sentence x with non-zero values and m is the length of the aspect. Then the representation $\boldsymbol{h^a} \in \mathbb{R}^{2d_h}$ is further utilized to calculate the sentiment-dominant feature $\boldsymbol{f}$, which is domain-invariant and should be aligned across source and target domains.

$$\begin{aligned} \gamma_i &= \tanh(\boldsymbol{h_i^c} \cdot W_p \cdot \boldsymbol{h^a} + b_p) \\ \boldsymbol{f} &= \sum_{i=1}^{n} \gamma_i \boldsymbol{h_i^c} \end{aligned} \tag{8}$$

where γ_i reflects how much the word w_i corresponds with the opinion on the aspect term, and $W_p \in \mathbb{R}^{2d_h \times 2d_h}$ and $b_p \in \mathbb{R}^1$ are weight matrix and bias respectively.

Sentiment Classification Loss The sentiment-dominant features $\boldsymbol{f_s}$ and $\boldsymbol{f_t}$ generated from the source and target domains respectively share the same sentiment classifier. Note that the source domain data has sentiment polarity label, while the

target domain is unlabeled. Thus we train the sentiment classifier only with the labeled data in the source domain, while utilizing it for inference in both source and target domains. The training objective of the sentiment classifier is to minimize the following loss on the source domain dataset, which is marked as L_s^c:

$$L_s^c = -\frac{1}{N_s}\sum^{N_s} \log P(y|\boldsymbol{f_s}) \tag{9}$$

where y is the ground-truth sentiment polarity label. For simplicity, we omit the enumerated number of the instance in the loss equation.

Domain Adversarial Loss The domain classifier maps the sentiment-dominant feature $\boldsymbol{f}$ into a two-dimensional normalized value $\boldsymbol{y} = (y_s, y_t)$, which indicates the probability that $\boldsymbol{f}$ comes from the source and target domains respectively. The ground-truth domain label is $\boldsymbol{g_s} = (1, 0)$ for instances in the source domain, and $\boldsymbol{g_t} = (0, 1)$ in the target domain. The training objective of the domain classifier is to minimize the following loss on both source and target domain datasets, which is marked as $L_a^{\theta_D}$:

$$L_a^{\theta_D} = -\frac{1}{N_s}\sum^{N_s} \boldsymbol{g_s}\log\boldsymbol{y} - \frac{1}{N_t}\sum^{N_t} \boldsymbol{g_t}\log\boldsymbol{y}. \tag{10}$$

The part in our architecture which joins the generating process of $\boldsymbol{f}$ (including Sentence Encoder, Context Allocation and Aspect-Opinion Allocation in Figure 2) can be regarded as a domain-invariant feature extractor, which works with the domain classifier in an adversarial way. To further accelerate the distillation process of the domain-invariant features, we also introduce an adversarial loss of the domain classifier for the feature extractor. Specifically, we calculate the loss in Equation 10 with the flipped domain labels inspired by the work (Shu et al., 2018):

$$L_a^{\theta_F} = -\frac{1}{N_s}\sum^{N_s} \boldsymbol{g_t}\log\boldsymbol{y} - \frac{1}{N_t}\sum^{N_t} \boldsymbol{g_s}\log\boldsymbol{y}. \tag{11}$$

3.5 Aspect Detection (AD) Task

We model the AD task as a sequence labeling problem, and each word in the sentence is marked as a tag in $\{\mathrm{B}, \mathrm{I}, \mathrm{O}\}$, which means the word is at the beginning (B) or the inside (I) of an aspect term or other word (O). In this way, we can detect all the aspect terms of an input sentence in one forward pass. Specifically, we first linearly transform the aspect-dominant hidden state $\boldsymbol{h^d}$ into a three-dimensional vector. Then we calculate the aspect detection loss of the source domain as follows:

$$L_s^d = -\frac{1}{N_s}\sum^{N_s}\frac{1}{n}\sum^{n}\lambda_l \log P(y^d|\boldsymbol{h^d}) \tag{12}$$

where y^d is the ground-truth aspect label, n is the sentence length and λ_l is the weight of different labels. The weight λ_l aims to solve the class imbalance problem because the words labeled by O usually make up the majority of one sentence. It is dynamically calculated in the training phase according to the ratio of the words with a specific label in each batch. Henceforth we denote the loss of the AD task in the target domain as L_t^d.

Algorithm 1 Adversarial Training

Input: labeled $\mathcal{D}_s$ and unlabeled $\mathcal{D}_t$

1: **repeat**
2: **Train** All parameters except Domain Classifier with L;
3: **Train** Domain Classifier with $\lambda^a L_a^{\theta_D}$;
4: **until** *performance on the validation set does not improve in 10 epochs.*

3.6 Training

We combine each component loss into an overall object function:

$$L = L_s^c + \lambda^a L_a^{\theta_F} + \lambda^d (L_s^d + L_t^d) \tag{13}$$

where λ^a and λ^d balance the effect of the domain classifier and the auxiliary task (i.e. aspect detection). L and $\lambda^a L_a^{\theta_D}$ are alternatively optimized. The aspect-level sentiment analysis in the unlabeled target domain is predicted by the ASC task.

4 Experiments

4.1 Datasets

To make an extensive evaluation, we employ three different datasets: Restaurants (R) and Laptops (L) from SemEval 2014 task 4 (Pontiki et al., 2014), and Twitters (T) from the work (Dong et al., 2014). The statistics of these three datasets are shown in Table 1. Specifically, we collect the aspect-term level sentences and corresponding labels from these datasets. Comparing aspect terms

Dataset		#Pos	#Neg	#Neu	Total
Restaurants (R)	Train	2164	805	633	3502
	Test	728	196	196	1120
Laptops (L)	Train	987	866	460	2313
	Test	341	128	169	638
Twitters (T)	Train	1561	1560	3127	6248
	Test	173	173	346	692

Table 1: Datasets statistics. #Pos, #Neg, #Neu represent the number of instances with positive, negative and neutral polarities.

in these three datasets, we find more than 98% aspect terms are different between Restaurants and Laptops domains, and there exists no same aspect between Restaurants and Twitters, also only 0.09% same aspects between Laptops and Twitters. This indicates that the aspect terms vary violently in different domains.

4.2 Experimental Settings

To evaluate our proposed method, we construct six aspect-level sentiment transfer tasks: R→L, L→R, R→T, T→R, L→T, T→L. The arrow indicates the transfer direction from the source domain to the target domain. For each transfer pair $\mathcal{D}_s \rightarrow \mathcal{D}_t$, the training set is composed of two parts: one is the labeled training set in $\mathcal{D}_s$, and the other is all unlabeled data which only contain the aspect term information in $\mathcal{D}_t$. The test set in $\mathcal{D}_s$ is employed as the validation set. The reported results are evaluated on all the data of $\mathcal{D}_t$.

The word embeddings are initialized with 100-dimension Glove vectors (Pennington et al., 2014) and fine-tuned during the training. The model hidden size d_h is set to be 64. The model is optimized by the SGD method with the learning rate of 0.01. The batch size is 32. We employ ReLU as the activation function.

We adopt an early stop strategy during training if the performance on the validation set does not improve in 10 epochs, and the best model is chosen for evaluation.

4.3 Compared Methods

We compare with extensive baselines to validate the effectiveness of the proposed method. Some variants of our approach are also compared for analyzing the impacts of individual components.

Transfer Baseline: The aspect-level cross-domain sentiment classification has been rarely explored. We choose the state-of-the-art method IATN (Zhang et al., 2019) which has the most similar settings with our method as the transfer baseline. It proposes to incorporate the information of both sentences and aspect terms in the cross-domain sentiment classification.

Non-Transfer Baselines: The non-transfer baselines are all representative methods in recent years for the aspect-level sentiment classification in a single domain. We train the models on the training set of the source domain, and directly test them in the target domain without domain adaptation.

- **AT-LSTM** (Wang et al., 2016): It utilizes the attention mechanism to generate an aspect-specific sentence representation.
- **ATAE-LSTM** (Wang et al., 2016): It also employs attention. The difference with AT-LSTM is that the aspect embedding is as input to LSTM.
- **MemNet** (Tang et al., 2016): It employs a memory network with multi-hops attentions and predicts the sentiment based on the top-most context representations.
- **IAN** (Ma et al., 2017): It adopts interactive attention mechanism to learn the representations of the context and the aspect respectively.
- **RAM** (Chen et al., 2017): It employs multiple attentions with a GRU cell to non-linearly combine the aggregation of word features in each layer.
- **GACE** (Xue and Li, 2018): It is based on the convolutional neural network with gating mechanisms.

Variants of Our Method:

- **ASC+AT** (ASC with adversarial training): A single task that handles the ASC task with adversarial training.
- **DIFD:** The proposed method in this work.
- **DIFD(S)**: It contains components of the source domain from DIFD and is trained only by the source domain data.
- **DIFD-CA**: DIFD without context allocation.
- **DIFD-AT**: DIFD without adversarial training.
- **DIFD-AT+MMD**: Replace the adversarial training with Maximum Mean Discrepancy (MMD) (Tzeng et al., 2014).
- **DIFD-AT+CORAL**: Replace the adversarial training with CORAL (Sun et al., 2016).

4.4 Experimental Analysis

We report the classification accuracy and macro-f1 of various methods in Table 2 and Table 3, and the best scores on each metric are marked in bold. To validate the effectiveness of our method, we analyze the results from the following perspectives.

Compare with the baselines: We display the comparison results with baselines in Table 2. Comparing with the transfer baseline IATN, we observe that DIFD significantly outperforms IATN on all metrics by +5.51% accuracy and +7.36% macro-f1 on average. This shows that the distillation of domain-invariant features really facilitates the transfer of sentiment information across domains. In addition, for a fair comparison with the non-transfer methods which only exploit the source domain data, we also train our DIFD model without the target domain data and denote this variant as DIFD(S). We observe that DIFD(S) outperforms all the non-transfer baselines on most metrics. It is worth noting that, compared to a strong baseline IAN, DIFD(S) achieves significant improvement by +4.49% accuracy on T→R and +7.05% macro-f1 on R→L. This verifies that the orthogonal task is helpful in striping the domain-specific features from the source domain and effective for accelerating the domain adaptation.

Compare the variants of our method: The results of the variants of our method are reported in Table 3. We first observe that DIFD outperforms ASC+AT on all metrics significantly. This validates that the orthogonality really helps to distill the domain-invariant features and improve the performance of the cross-domain sentiment classification.

Then we can see that DIFD-CA performs much worse than DIFD, which reveals that the context allocation mechanism plays an important role in our method. We further visualize the allocation scores in Figure 3 and the result also indicates that the reasonability of the CA module. The gray tokens and red tokens have a bias towards ASC task and AD task respectively. The allocation scores are consistent with the bias of words: red tokens get larger scores for the aspect detection task, while gray tokens get larger scores for opinion expressions. This shows that our model generates task-oriented contexts successfully.

Finally, DIFD also achieves improvement over DIFD-AT on most metrics. This indicates that

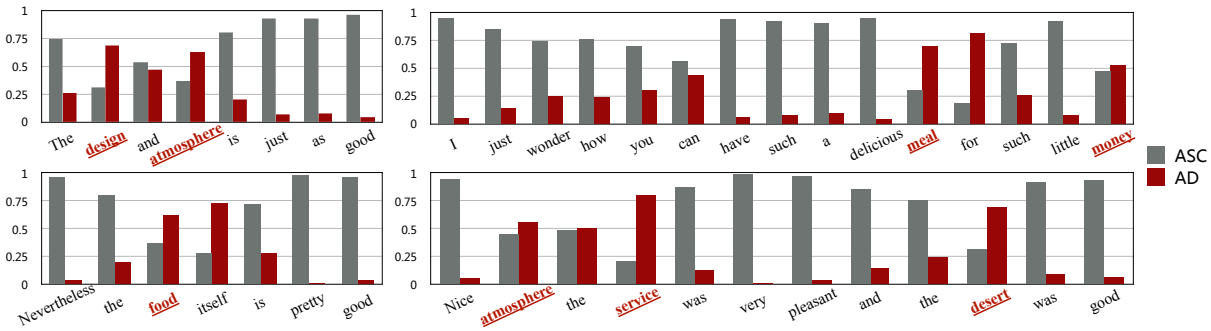

Figure 3: Visualization of context allocation weights of DIFD for different tokens within a sequence.

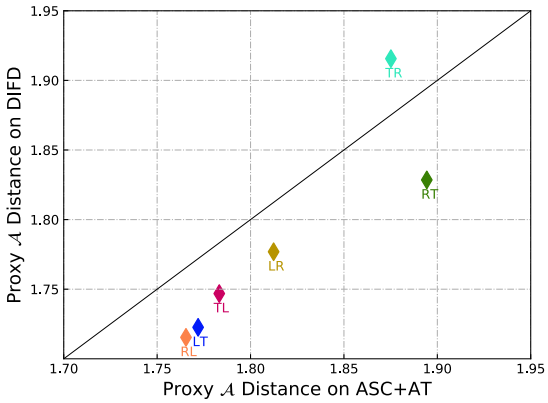

Figure 4: Proxy $\mathcal{A}$ Distance between domain-invariant features for the 6 different pairs.

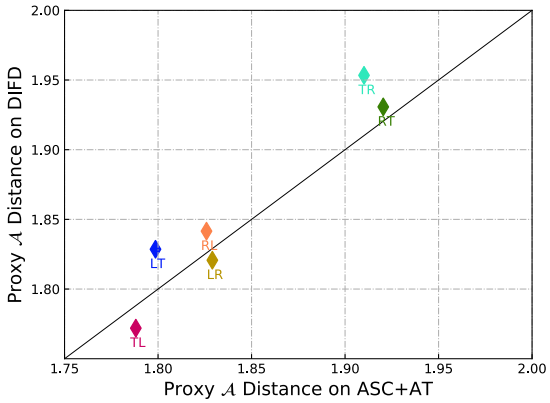

Figure 5: Proxy $\mathcal{A}$ Distance between domain-specific features for the 6 different pairs.

adversarial training with the domain classifier promotes the distillation process of the domain-invariant features. To further validate the effectiveness of adversarial training, we also try to directly minimize the divergence between domain-invariant features from source and target domains based on MMD and CORAL. Comparing with DIFD-AT+MMD and DIFD-AT+CORAL, DIFD is more robust considering that DIFD outperforms the two methods in most experimental settings.

4.5 Transfer Distance Analysis

In this section, we analyze the similarity of features between domains. We exploit the $\mathcal{A}$-distance (Ben-David et al., 2007) to measure the similarity between two probability distributions. The proxy $\mathcal{A}$-distance is 2(1-2ϵ), where ϵ is the generalization error of a classifier (a linear SVM) trained on the binary classification problem to distinguish inputs between the two domains. We focus on the methods ASC+AT and DIFD, and first compare the similarity of domain-invariant features $\boldsymbol{f_s}$ and $\boldsymbol{f_t}$. Figure 4 reports the results for each pair of domains. The proxy $\mathcal{A}$-distance on DIFD is generally smaller than its corresponding value on ASC+AT. This indicates that DIFD can learn purer domain-invariant features than ASC+AT. Secondly, we compare the domain-specific features learned by ASC+AT and DIFD, which are represented by the average hidden state of BiLSTM in ASC+AT and the average aspect-context H^d in DIFD respectively. Figure 5 reports the results for each pair of domains. The proxy $\mathcal{A}$-distance on DIFD is generally larger than its corresponding value on ASC+AT, which demonstrates that DIFD can strip more domain-specific information by the aspect detection task than ASC+AT.

There are exceptions in both Figures, i.e., TR in Figure 4, TL and LR in Figure 5. A possible explanation is that the balance between ASC and AD losses causes some domain-specific information to remain in the domain-invariant space, and vice versa.

5 Conclusion

In this work, we study the problem of aspect-level cross-domain sentiment analysis and propose a domain-invariant feature distillation method that simultaneously learns domain-invariant and

domain-specific features. With the help of the orthogonal domain-dependent task (i.e., aspect detection), the aspect sentiment classification task can learn better domain-invariant features and improve transfer performance. Experimental results clearly verify the effectiveness of our method.

Abstract

Aspect based sentiment analysis (ABSA) aims to identify the sentiment polarity towards the given aspect in a sentence, while previous models typically exploit an aspect-independent (weakly associative) encoder for sentence representation generation. In this paper, we propose a novel **A**spect-**G**uided **D**eep **T**ransition model, named AGDT, which utilizes the given aspect to guide the sentence encoding from scratch with the specially-designed deep transition architecture. Furthermore, an aspect-oriented objective is designed to enforce AGDT to reconstruct the given aspect with the generated sentence representation. In doing so, our AGDT can accurately generate aspect-specific sentence representation, and thus conduct more accurate sentiment predictions. Experimental results on multiple SemEval datasets demonstrate the effectiveness of our proposed approach, which significantly outperforms the best reported results with the same setting.[1]

1 Introduction

Aspect based sentiment analysis (ABSA) is a fine-grained task in sentiment analysis, which can provide important sentiment information for other natural language processing (NLP) tasks. There are two different subtasks in ABSA, namely, aspect-category sentiment analysis and aspect-term sentiment analysis (Pontiki et al., 2014; Xue and Li, 2018). Aspect-category sentiment analysis aims at predicting the sentiment polarity towards the given aspect, which is in predefined several categories and it may not appear in the sentence. For instance, in Table 1, the aspect-category sentiment analysis is going to predict the sentiment polarity towards the aspect "*food*", which is not appeared in the sentence. By contrast, the goal of aspect-term sentiment analysis is to predict the sentiment polarity over the aspect term which is a subsequence of the sentence. For instance, the aspect-term sentiment analysis will predict the sentiment polarity towards the aspect term "*The appetizers*", which is a subsequence of the sentence. Additionally, the number of categories of the aspect term is more than one thousand in the training corpus.

Sentence	The appetizers are ok, but the service is slow.	
Aspect-Category	food	service
Aspect-Term	The appetizers	service
Sentiment Polarity	Neutral	Negative

Table 1: The instance contains different sentiment polarities towards two aspects.

As shown in Table 1, sentiment polarity may be different when different aspects are considered. Thus, the given aspect (term) is crucial to ABSA tasks (Jiang et al., 2011; Ma et al., 2017; Wang et al., 2018; Xing et al., 2019; Liang et al., 2019). Besides, Li et al. (2018a) show that not all words of a sentence are useful for the sentiment prediction towards a given aspect (term). For instance, when the given aspect is the "*service*", the words "*appetizers*" and "*ok*" are irrelevant for the sentiment prediction. Therefore, an aspect-independent (weakly associative) encoder may encode such background words (e.g., "*appetizers*" and "*ok*") into the final representation, which may lead to an incorrect prediction.

Numerous existing models (Tang et al., 2016b; Tay et al., 2017; Fan et al., 2018; Xue and Li, 2018) typically utilize an aspect-independent encoder to generate the sentence representation, and then apply the attention mechanism (Luong et al., 2015) or gating mechanism to conduct feature

selection and extraction, while feature selection and extraction may base on noised representations. In addition, some models (Tang et al., 2016a; Wang et al., 2016; Majumder et al., 2018) simply concatenate the aspect embedding with each word embedding of the sentence, and then leverage conventional Long Short-Term Memories (LSTMs) (Hochreiter and Schmidhuber, 1997) to generate the sentence representation. However, it is insufficient to exploit the given aspect and conduct potentially complex feature selection and extraction.

To address this issue, we investigate a novel architecture to enhance the capability of feature selection and extraction with the guidance of the given aspect from scratch. Based on the deep transition Gated Recurrent Unit (GRU) (Cho et al., 2014; Pascanu et al., 2014; Miceli Barone et al., 2017; Meng and Zhang, 2019), an aspect-guided GRU encoder is thus proposed, which utilizes the given aspect to guide the sentence encoding procedure at the very beginning stage. In particular, we specially design an aspect-gate for the deep transition GRU to control the information flow of each token input, with the aim of guiding feature selection and extraction from scratch, i.e. sentence representation generation. Furthermore, we design an aspect-oriented objective to enforce our model to reconstruct the given aspect, with the sentence representation generated by the aspect-guided encoder. We name this **A**spect-**G**uided **D**eep **T**ransition model as AGDT. With all the above contributions, our AGDT can accurately generate an aspect-specific representation for a sentence, and thus conduct more accurate sentiment predictions towards the given aspect.

We evaluate the AGDT on multiple datasets of two subtasks in ABSA. Experimental results demonstrate the effectiveness of our proposed approach. And the AGDT significantly surpasses existing models with the same setting and achieves state-of-the-art performance among the models without using additional features (e.g., BERT (Devlin et al., 2018)). Moreover, we also provide empirical and visualization analysis to reveal the advantages of our model. Our contributions can be summarized as follows:

- We propose an aspect-guided encoder, which utilizes the given aspect to guide the encoding of a sentence from scratch, in order to conduct the aspect-specific feature selection and extraction at the very beginning stage.
- We propose an aspect-reconstruction approach to further guarantee that the aspect-specific information has been fully embedded into the sentence representation.
- Our AGDT substantially outperforms previous systems with the same setting, and achieves state-of-the-art results on benchmark datasets compared to those models without leveraging additional features (e.g., BERT).

2 Model Description

As shown in Figure 1, the AGDT model mainly consists of three parts: *aspect-guided encoder*, *aspect-reconstruction* and *aspect concatenated embedding*. The aspect-guided encoder is specially designed to guide the encoding of a sentence from scratch for conducting the aspect-specific feature selection and extraction at the very beginning stage. The aspect-reconstruction aims to guarantee that the aspect-specific information has been fully embedded in the sentence representation for more accurate predictions. The aspect concatenated embedding part is used to concatenate the aspect embedding and the generated sentence representation so as to make the final prediction.

2.1 Aspect-Guided Encoder

The aspect-guided encoder is the core module of AGDT, which consists of two key components: Aspect-guided GRU and Transition GRU (Cho et al., 2014).

A-GRU: Aspect-guided GRU (A-GRU) is a specially-designed unit for the ABSA tasks, which is an extension of the L-GRU proposed by Meng and Zhang (2019). In particular, we design an aspect-gate to select aspect-specific representations through controlling the transformation scale of token embeddings at each time step.

At time step t, the hidden state $\mathbf{h}_t$ is computed as follows:

$$\mathbf{h}_t = (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \widetilde{\mathbf{h}}_t \quad (1)$$

where $\odot$ represents element-wise product; $\mathbf{z}_t$ is the update gate (Cho et al., 2014); and $\widetilde{\mathbf{h}}_t$ is the candidate activation, which is computed as:

$$\begin{aligned}\widetilde{\mathbf{h}}_t = \tanh(\mathbf{g}_t \odot (\mathbf{W}_{xh}\mathbf{x}_t) + \mathbf{r}_t \odot (\mathbf{W}_{hh}\mathbf{h}_{t-1})) \\ + \mathbf{l}_t \odot \mathbf{H}_1(\mathbf{x}_t) + \mathbf{g}_t \odot \mathbf{H}_2(\mathbf{x}_t) \quad (2)\end{aligned}$$

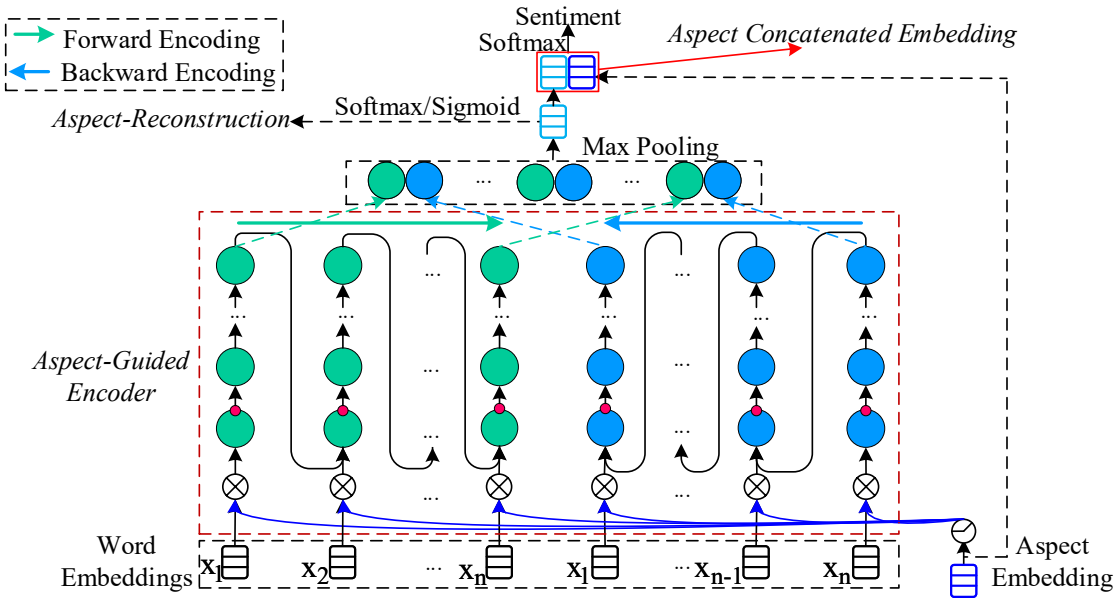

Figure 1: The overview of AGDT. The bottom right dark node (above the aspect embedding) is the aspect gate and other dark nodes (⊗) means element-wise multiply for the input token and the aspect gate. The *aspect-guided encoder* consists of a L-GRU (the circle frames fused with a small circle on above) at the bottom followed by several T-GRUs (the circle frames) from bottom to up.

where $\mathbf{g}_t$ denotes the aspect-gate; $\mathbf{x}_t$ represents the input word embedding at time step t; $\mathbf{r}_t$ is the reset gate (Cho et al., 2014); $\mathbf{H}_1(\mathbf{x}_t)$ and $\mathbf{H}_2(\mathbf{x}_t)$ are the linear transformation of the input $\mathbf{x}_t$, and $\mathbf{l}_t$ is the linear transformation gate for $\mathbf{x}_t$ (Meng and Zhang, 2019). $\mathbf{r}_t$, $\mathbf{z}_t$, $\mathbf{l}_t$, $\mathbf{g}_t$, $\mathbf{H}_1(\mathbf{x}_t)$ and $\mathbf{H}_2(\mathbf{x}_t)$ are computed as:

$$\mathbf{r}_t = \sigma(\mathbf{W}_{xr}\mathbf{x}_t + \mathbf{W}_{hr}\mathbf{h}_{t-1}) \quad (3)$$

$$\mathbf{z}_t = \sigma(\mathbf{W}_{xz}\mathbf{x}_t + \mathbf{W}_{hz}\mathbf{h}_{t-1}) \quad (4)$$

$$\mathbf{l}_t = \sigma(\mathbf{W}_{xl}\mathbf{x}_t + \mathbf{W}_{hl}\mathbf{h}_{t-1}) \quad (5)$$

$$\mathbf{g}_t = \text{relu}(\mathbf{W}_a\mathbf{a} + \mathbf{W}_{hg}\mathbf{h}_{t-1}) \quad (6)$$

$$\mathbf{H_1}(\mathbf{x_t}) = \mathbf{W}_1\mathbf{x}_t \quad (7)$$

$$\mathbf{H_2}(\mathbf{x_t}) = \mathbf{W}_2\mathbf{x}_t \quad (8)$$

where "$\mathbf{a}$" denotes the embedding of the given aspect, which is the same at each time step. The update gate $\mathbf{z}_t$ and reset gate $\mathbf{r}_t$ are the same as them in the conventional GRU.

In Eq. (2) $\sim$ (8), the aspect-gate $\mathbf{g}_t$ controls both nonlinear and linear transformations of the input $\mathbf{x}_t$ under the guidance of the given aspect at each time step. Besides, we also exploit a linear transformation gate $\mathbf{l}_t$ to control the linear transformation of the input, according to the current input $\mathbf{x}_t$ and previous hidden state $\mathbf{h}_{t-1}$, which has been proved powerful in the deep transition architecture (Meng and Zhang, 2019).

As a consequence, A-GRU can control both non-linear transformation and linear transformation for input $\mathbf{x}_t$ at each time step, with the guidance of the given aspect, i.e., A-GRU can guide the encoding of aspect-specific features and block the aspect-irrelevant information at the very beginning stage.

T-GRU: Transition GRU (T-GRU) (Pascanu et al., 2014) is a crucial component of deep transition block, which is a special case of GRU with only "state" as an input, namely its input embedding is zero embedding. As in Figure 1, a deep transition block consists of an A-GRU followed by several T-GRUs at each time step. For the current time step t, the output of one A-GRU/T-GRU is fed into the next T-GRU as the input. The output of the last T-GRU at time step t is fed into A-GRU at the time step $t+1$. For a T-GRU, each hidden state at both time step t and transition depth i is computed as:

$$\mathbf{h}_t^i = (1 - \mathbf{z}_t^i) \odot \mathbf{h}_t^{i-1} + \mathbf{z}_t^i \odot \widetilde{\mathbf{h}}_t^i \quad (9)$$

$$\widetilde{\mathbf{h}}_t^i = \tanh(\mathbf{r}_t^i \odot (\mathbf{W}_h^i \mathbf{h}_t^{i-1})) \quad (10)$$

where the update gate $\mathbf{z}_t^i$ and the reset gate $\mathbf{r}_t^i$ are computed as:

$$\mathbf{z}_t^i = \sigma(\mathbf{W}_z^i \mathbf{h}_t^{i-1}) \quad (11)$$

$$\mathbf{r}_t^i = \sigma(\mathbf{W}_r^i \mathbf{h}_t^{i-1}) \quad (12)$$

The AGDT encoder is based on deep transition cells, where each cell is composed of one A-GRU

at the bottom, followed by several T-GRUs. Such AGDT model can encode the sentence representation with the guidance of aspect information by utilizing the specially designed architecture.

2.2 Aspect-Reconstruction

We propose an aspect-reconstruction approach to guarantee the aspect-specific information has been fully embedded in the sentence representation. Particularly, we devise two objectives for two subtasks in ABSA respectively. In terms of aspect-category sentiment analysis datasets, there are only several predefined aspect categories. While in aspect-term sentiment analysis datasets, the number of categories of term is more than one thousand. In a real-life scenario, the number of term is infinite, while the words that make up terms are limited. Thus we design different loss-functions for these two scenarios.

For the aspect-category sentiment analysis task, we aim to reconstruct the aspect according to the aspect-specific representation. It is a multi-class problem. We take the softmax cross-entropy as the loss function:

$$\mathcal{L}_c = min(-\sum_{i=0}^{C1} y_i^c \log(p_i^c)) \tag{13}$$

where C1 is the number of predefined aspects in the training example; y_i^c is the ground-truth and p_i^c is the estimated probability of a aspect.

For the aspect-term sentiment analysis task, we intend to reconstruct the aspect term (may consist of multiple words) according to the aspect-specific representation. It is a multi-label problem and thus the sigmoid cross-entropy is applied:

$$\begin{aligned}\mathcal{L}_t = min\{-\sum_{i=0}^{C2}[y_i^t \log(p_i^t) \\ + (1-y_i^t)\log(1-p_i^t)]\}\end{aligned} \tag{14}$$

where C2 denotes the number of words that constitute all terms in the training example, y_i^t is the ground-truth and p_i^t represents the predicted value of a word.

Our aspect-oriented objective consists of $\mathcal{L}_c$ and $\mathcal{L}_t$, which guarantee that the aspect-specific information has been fully embedded into the sentence representation.

2.3 Training Objective

The final loss function is as follows:

$$\boldsymbol{J} = min(\underline{-\sum_{i=0}^{C} y_i \log(p_i)} + \boldsymbol{\lambda}\mathcal{L}) \tag{15}$$

where the underlined part denotes the conventional loss function; C is the number of sentiment labels; y_i is the ground-truth and p_i represents the estimated probability of the sentiment label; $\mathcal{L}$ is the aspect-oriented objective, where Eq. 13 is for the aspect-category sentiment analysis task and Eq. 14 is for the aspect-term sentiment analysis task. And $\boldsymbol{\lambda}$ is the weight of $\mathcal{L}$.

As shown in Figure 1, we employ the aspect reconstruction approach to reconstruct the aspect (term), where "softmax" is for the aspect-category sentiment analysis task and "sigmoid" is for the aspect-term sentiment analysis task. Additionally, we concatenate the aspect embedding on the aspect-guided sentence representation to predict the sentiment polarity. Under that loss function (Eq. 15), the AGDT can produce aspect-specific sentence representations.

3 Experiments

3.1 Datasets and Metrics

Data Preparation. We conduct experiments on two datasets of the aspect-category based task and two datasets of the aspect-term based task. For these four datasets, we name the full dataset as "DS". In each "DS", there are some sentences like the example in Table 1, containing different sentiment labels, each of which associates with an aspect (term). For instance, Table 1 shows the customer's different attitude towards two aspects: "*food*" ("*The appetizers*") and "*service*". In order to measure whether a model can detect different sentiment polarities in one sentence towards different aspects, we extract a hard dataset from each "DS", named "HDS", in which each sentence only has different sentiment labels associated with different aspects. When processing the original sentence s that has multiple aspects $a_1, a_2, ..., a_n$ and corresponding sentiment labels $l_1, l_2, ..., l_n$ (n is the number of aspects or terms in a sentence), the sentence will be expanded into (s, a_1, l_1), (s, a_2, l_2), ..., (s, a_n, l_n) in each dataset (Ruder et al., 2016b,a; Xue and Li, 2018), i.e, there will be n duplicated sentences associated with different aspects and labels.

		Positive		Negative		Neutral		Conflict		Total	
		DS	HDS	DS	HDS	DS	HDS	DS	HDS	DS	HDS

Table 3: Statistics of datasets for the aspect-term sentiment analysis task. The '**NC**' indicates No "*Conflict*" label, which is just removed the "*conflict*" label and is prepared for the three-class experiment.

Aspect-Category Sentiment Analysis. For comparison, we follow Xue and Li (2018) and use the restaurant reviews dataset of SemEval 2014 ("restaurant-14") Task 4 (Pontiki et al., 2014) to evaluate our AGDT model. The dataset contains five predefined aspects and four sentiment labels. A large dataset ("restaurant-large") involves restaurant reviews of three years, i.e., 2014 $\sim$ 2016 (Pontiki et al., 2014). There are eight predefined aspects and three labels in that dataset. When creating the "restaurant-large" dataset, we follow the same procedure as in Xue and Li (2018). Statistics of datasets are shown in Table 2.

Aspect-Term Sentiment Analysis. We use the restaurant and laptop review datasets of SemEval 2014 Task 4 (Pontiki et al., 2014) to evaluate our model. Both datasets contain four sentiment labels. Meanwhile, we also conduct a three-class experiment, in order to compare with some work (Wang et al., 2016; Ma et al., 2017; Li et al., 2018a) which removed "conflict" labels. Statistics of both datasets are shown in Table 3.

Metrics. The evaluation metrics are accuracy. All instances are shown in Table 2 and Table 3. Each experiment is repeated five times. The mean and the standard deviation are reported.

3.2 Implementation Details

We use the pre-trained 300d Glove[2] embeddings (Pennington et al., 2014) to initialize word embeddings, which is fixed in all models. For out-of-vocabulary words, we randomly sample their embeddings by the uniform distribution $U(-0.25, 0.25)$. Following Tang et al. (2016b); Chen et al. (2017); Liu and Zhang (2017), we take the averaged word embedding as the aspect representation for multi-word aspect terms. The transition depth of deep transition model is 4 (see Section 3.4). The hidden size is set to 300. We set the dropout rate (Srivastava et al., 2014) to 0.5 for input token embeddings and 0.3 for hidden states. All models are optimized using Adam optimizer (Kingma and Ba, 2014) with gradient clipping equals to 5 (Pascanu et al., 2012). The initial learning rate is set to 0.01 and the batch size is set to 4096 at the token level. The weight of the reconstruction loss $\boldsymbol{\lambda}$ in Eq. 15 is fine-tuned (see Section 3.4) and respectively set to 0.4, 0.4, 0.2 and 0.5 for four datasets. The neural model is implemented in Tensorflow (Abadi et al., 2016) and all computations are done on a NVIDIA Tesla M40 GPU.

3.3 Baselines

To comprehensively evaluate our AGDT, we compare the AGDT with several competitive models.

ATAE-LSTM. It is an attention-based LSTM model. It appends the given aspect embedding with each word embedding, and then the concatenated embedding is taken as the input of LSTM. The output of LSTM is appended aspect embedding again. Furthermore, attention is applied to extract features for final predictions.

[2]Pre-trained Glove embeddings can be obtained from http://nlp.stanford.edu/projects/glove/

CNN. This model focuses on extracting n-gram features to generate sentence representation for the sentiment classification.

TD-LSTM. This model uses two LSTMs to capture the left and right context of the term to generate target-dependent representations for the sentiment prediction.

IAN. This model employs two LSTMs and interactive attention mechanism to learn representations of the sentence and the aspect, and concatenates them for the sentiment prediction.

RAM. This model applies multiple attentions and memory networks to produce the sentence representation.

GCAE. It uses CNNs to extract features and then employs two Gated Tanh-Relu units to selectively output the sentiment information flow towards the aspect for predicting sentiment labels.

3.4 Main Results and Analysis

Aspect-Category Sentiment Analysis Task

We present the overall performance of our model and baseline models in Table 4. Results show that our AGDT outperforms all baseline models on both "restaurant-14" and "restaurant-large" datasets. ATAE-LSTM employs an aspect-weakly associative encoder to generate the aspect-specific sentence representation by simply concatenating the aspect, which is insufficient to exploit the given aspect. Although GCAE incorporates the gating mechanism to control the sentiment information flow according to the given aspect, the information flow is generated by an aspect-independent encoder. Compared with GCAE, our AGDT improves the performance by 2.4% and 1.6% in the "DS" part of the two dataset, respectively. These results demonstrate that our AGDT can sufficiently exploit the given aspect to generate the aspect-guided sentence representation, and thus conduct accurate sentiment prediction. Our model benefits from the following aspects. First, our AGDT utilizes an aspect-guided encoder, which leverages the given aspect to guide the sentence encoding from scratch and generates the aspect-guided representation. Second, the AGDT guarantees that the aspect-specific information has been fully embedded in the sentence representation via reconstructing the given aspect. Third, the given aspect embedding is concatenated on the aspect-guided sentence representation for final predictions.

The "HDS", which is designed to measure whether a model can detect different sentiment polarities in a sentence, consists of replicated sentences with different sentiments towards multiple aspects. Our AGDT surpasses GCAE by a very large margin (**+11.4%** and **+4.9%** respectively) on both datasets. This indicates that the given aspect information is very pivotal to the accurate sentiment prediction, especially when the sentence

has different sentiment labels, which is consistent with existing work (Jiang et al., 2011; Ma et al., 2017; Wang et al., 2018). Those results demonstrate the effectiveness of our model and suggest that our AGDT has better ability to distinguish the different sentiments of multiple aspects compared to GCAE.

Aspect-Term Sentiment Analysis Task

As shown in Table 5, our AGDT consistently outperforms all compared methods on both domains. In this task, TD-LSTM and ATAE-LSTM use a aspect-weakly associative encoder. IAN, RAM and GCAE employ an aspect-independent encoder. In the "DS" part, our AGDT model surpasses all baseline models, which shows that the inclusion of A-GRU (aspect-guided encoder), aspect-reconstruction and aspect concatenated embedding has an overall positive impact on the classification process.

In the "HDS" part, the AGDT model obtains +3.6% higher accuracy than GCAE on the restaurant domain and +4.2% higher accuracy on the laptop domain, which shows that our AGDT has stronger ability for the multi-sentiment problem against GCAE. These results further demonstrate that our model works well across tasks and datasets.

Ablation Study

We conduct ablation experiments to investigate the impacts of each part in AGDT, where the GRU is stacked with 4 layers. Here "AC" represents aspect concatenated embedding , "AG" stands for A-GRU (Eq. (1) $\sim$ (8)) and "AR" denotes the aspect-reconstruction (Eq. (13) $\sim$ (15)).

From Table 6 and Table 7, we can conclude:

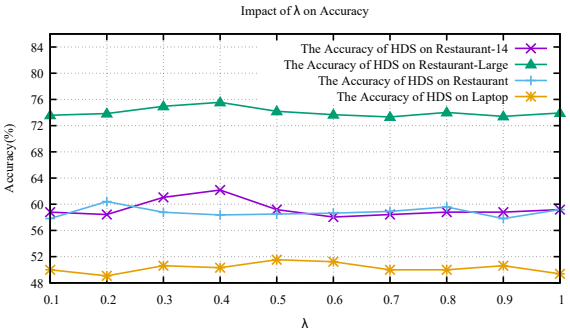

Figure 2: The impact of λ w.r.t. accuracy on "HDS".

1). Deep Transition (DT) achieves superior performances than GRU, which is consistent with previous work (Miceli Barone et al., 2017; Meng and Zhang, 2019) (② vs. ①).

2). Utilizing "AG" to guide encoding aspect-related features from scratch has a significant impact for highly competitive results and particularly in the "HDS" part, which demonstrates that it has the stronger ability to identify different sentiment polarities towards different aspects. (③ vs. ②).

3). Aspect concatenated embedding can promote the accuracy to a degree (④ vs. ③).

4). The aspect-reconstruction approach ("AR") substantially improves the performance, especially in the "HDS" part (⑤ vs. ④).

5). the results in ⑥ show that all modules have an overall positive impact on the sentiment classification.

	AC	AG	AR	Rest-14		Rest-Large		
				DS	HDS	DS	HDS

Impact of Model Depth

We have demonstrated the effectiveness of the AGDT. Here, we investigate the impact of model depth of AGDT, varying the depth from 1 to 6. Table 8 shows the change of accuracy on the test

	Depth	1	2	3	4	5	6
$\mathbb{D}_1$	DS	81.12	81.45	81.52	**81.78**	81.07	80.68
	HDS	55.73	57.08	60.67	**62.02**	59.10	58.65
$\mathbb{D}_2$	DS	87.20	87.47	87.53	**87.55**	87.11	87.21
	HDS	73.93	74.27	**76.07**	75.73	75.56	74.27

	HDS	59.35	58.94	59.43	**60.33**	59.27	57.80
$\mathbb{D}_4$	DS	71.13	71.10	**71.62**	71.50	71.16	70.86
	HDS	49.44	50.00	50.56	**51.30**	49.81	49.63

Table 8: The accuracy of model depth on the four datasets. '$\mathbb{D}_1$': Restaurant-14, '$\mathbb{D}_2$': Restaurant-Large, '$\mathbb{D}_3$': Restaurant, '$\mathbb{D}_4$': Laptop.

	Rest-14	Rest-Large	Rest.	Laptop
DS	99.55	99.80	76.21	70.92

Table 9: The accuracy of aspect reconstruction on the full test set. 'Rest-14': Restaurant-14, 'Rest-Large': Restaurant-Large, 'Rest.': Restaurant.

sets as depth increases. We find that the best results can be obtained when the depth is equal to 4 at most case, and further depth do not provide considerable performance improvement.

Effectiveness of Aspect-reconstruction Approach

Here, we investigate how well the AGDT can reconstruct the aspect information. For the aspect-term reconstruction, we count the construction is correct when all words of the term are reconstructed. Table 9 shows all results on four test datasets, which shows the effectiveness of aspect-reconstruction approach again.

Impact of Loss Weight λ

We randomly sample a temporary development set from the "HDS" part of the training set to choose the lambda for each dataset. And we investigate the impact of λ for aspect-oriented objectives. Specifically, λ is increased from 0.1 to 1.0. Figure 2 illustrates all results on four "HDS" datasets, which show that reconstructing the given aspect can enhance aspect-specific sentiment features and thus obtain better performances.

Comparison on Three-Class for the Aspect-Term Sentiment Analysis Task

We also conduct a three-class experiment to compare our AGDT with previous models, i.e., IARM, TNet, VAE, PBAN, AOA and MGAN, in Table 10.

Models	Rest.	Laptop
IARM(Majumder et al., 2018)*	80.00	73.80
TNet(Li et al., 2018a)*	80.79	**76.54**
VAE(Xu and Tan, 2018)*	81.10	75.34
PBAN(Gu et al., 2018)*	81.16	74.12
AOA(Huang et al., 2018)*	81.20	74.50
MGAN(Fan et al., 2018)*	81.25	75.39
DAuM(Zhu and Qian, 2018)*	82.32	74.45
AGDT	**82.95**	75.86

Table 10: The three-class accuracy of the aspect-term sentiment analysis task on SemEval 2014. '*' refers to citing from the original paper. 'Rest.': Restaurant.

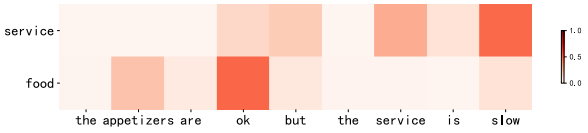

Figure 3: The output of A-GRU.

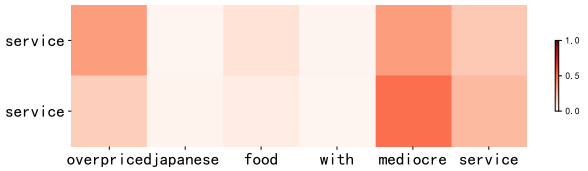

Figure 4: The above is the output of A-GRU. The bottom is the output after reconstructing the given aspect.

These previous models are based on an aspect-independent (weakly associative) encoder to generate sentence representations. Results on all domains suggest that our AGDT substantially outperforms most competitive models, except for the TNet on the laptop dataset. The reason may be TNet incorporates additional features (e.g., position features, local ngrams and word-level features) compared to ours (only word-level features).

4 Analysis and Discussion

Case Study and Visualization. To give an intuitive understanding of how the proposed A-GRU works from scratch with different aspects, we take a review sentence as an example. As the example "*the appetizers are ok, but the service is slow.*" shown in Table 1, it has different sentiment labels towards different aspects. The color depth denotes the semantic relatedness level between the given aspect and each word. More depth means stronger relation to the given aspect.

Figure 3 shows that the A-GRU can effectively guide encoding the aspect-related features with

the given aspect and identify corresponding sentiment. In another case, "*overpriced Japanese food with mediocre service.*", there are two extremely strong sentiment words. As the above of Figure 4 shows, our A-GRU generates almost the same weight to the word "*overpriced*" and "*mediocre*". The bottom of Figure 4 shows that reconstructing the given aspect can effectively enhance aspect-specific sentiment features and produce correct sentiment predictions.

Error Analysis. We further investigate the errors from AGDT, which can be roughly divided into 3 types. **1)** The decision boundary among the sentiment polarity is unclear, even the annotators can not sure what sentiment orientation over the given aspect in the sentence. **2)** The "conflict/neutral" instances are extremely easily misclassified as "positive" or "negative", due to the imbalanced label distribution in training corpus[3]. **3)** The polarity of complex instances is hard to predict, such as the sentence that express subtle emotions, which are hardly effectively captured, or containing negation words (e.g., *never*, *less* and *not*), which easily affect the sentiment polarity.

5 Related Work

Sentiment Analysis. There are kinds of sentiment analysis tasks, such as document-level (Thongtan and Phienthrakul, 2019), sentence-level[4] (Zhang and Zhang, 2019; Zhang et al., 2019), aspect-level (Pontiki et al., 2014; Wang et al., 2019a) and multimodal (Chen et al., 2018; Akhtar et al., 2019) sentiment analysis. For the aspect-level sentiment analysis, previous work typically apply attention mechanism (Luong et al., 2015) combining with memory network (Weston et al., 2014) or gating units to solve this task (Tang et al., 2016b; He et al., 2018a; Huang and Carley, 2018; Xue and Li, 2018; Duan et al., 2018; Tang et al., 2019; Yang et al., 2019; Bao et al., 2019), where an aspect-independent encoder is used to generate the sentence representation. In addition, some work leverage the aspect-weakly associative encoder to generate aspect-specific sentence representation (Tang et al., 2016a; Wang et al., 2016; Majumder et al., 2018). All of these methods make insufficient use of the given aspect information. There are also some work which jointly extract the aspect term (and opinion term) and predict its sentiment polarity (Schmitt et al., 2018; Li et al., 2018b; Ma et al., 2018; Angelidis and Lapata, 2018; He et al., 2019; Luo et al., 2019; Hu et al., 2019; Dai and Song, 2019; Wang et al., 2019b). In this paper, we focus on the latter problem and leave aspect extraction (Shu et al., 2017) to future work. And some work (Sun et al., 2019; Xu et al., 2019; He et al., 2018b; Xu and Tan, 2018; Chen and Qian, 2019; He et al., 2019) employ the well-known BERT (Devlin et al., 2018) or document-level corpora to enhance ABSA tasks, which will be considered in our future work to further improve the performance.

Deep Transition. Deep transition has been proved its superiority in language modeling (Pascanu et al., 2014) and machine translation (Miceli Barone et al., 2017; Meng and Zhang, 2019). We follow the deep transition architecture in Meng and Zhang (2019) and extend it by incorporating a novel A-GRU for ABSA tasks.

6 Conclusions

In this paper, we propose a novel aspect-guided encoder (AGDT) for ABSA tasks, based on a deep transition architecture. Our AGDT can guide the sentence encoding from scratch for the aspect-specific feature selection and extraction. Furthermore, we design an aspect-reconstruction approach to enforce AGDT to reconstruct the given aspect with the generated sentence representation. Empirical studies on four datasets suggest that the AGDT outperforms existing state-of-the-art models substantially on both aspect-category sentiment analysis task and aspect-term sentiment analysis task of ABSA without additional features.

Abstract

Recently, neural networks have shown promising results on Document-level Aspect Sentiment Classification (DASC). However, these approaches often offer little transparency w.r.t. their inner working mechanisms and lack interpretability. In this paper, to simulating the steps of analyzing aspect sentiment in a document by human beings, we propose a new Hierarchical Reinforcement Learning (HRL) approach to DASC. This approach incorporates clause selection and word selection strategies to tackle the data noise problem in the task of DASC. First, a high-level policy is proposed to select aspect-relevant clauses and discard noisy clauses. Then, a low-level policy is proposed to select sentiment-relevant words and discard noisy words inside the selected clauses. Finally, a sentiment rating predictor is designed to provide reward signals to guide both clause and word selection. Experimental results demonstrate the impressive effectiveness of the proposed approach to DASC over the state-of-the-art baselines.

1 Introduction

Document-level Aspect Sentiment Classification (DASC) is a fine-grained sentiment classification task in the field of sentiment analysis (Pang and Lee, 2007; Li et al., 2010). This task aims to predict the sentiment rating for each given aspect mentioned in a document-level review. For instance, Figure 1 shows a review document with four given aspects of a hotel (i.e., *location*, *room*, *value*, *service*). The goal of DASC is to predict the rating score towards each aspect by analyzing the whole document. In the last decade, this task has been drawing more and more interests of researchers in the Natural Language Processing community (Titov and McDonald, 2008; Yin et al., 2017; Li et al., 2018). In previous studies, neural models have shown to be effective for performance improvement on DASC. Despite the advantages, these complex neural network approaches often offer little transparency w.r.t. their inner working mechanisms and suffer from the lack of interpretability. However, clearly understanding where and how such a model makes such a decision is rather important for developing real-world applications (Liu et al., 2018; Marcus, 2018).

Review Document

[This hotel is close to railway station]$_{\text{Clause1}}$ [and very convenient to eat around]$_{\text{Clause2}}$ [but room of Hilton is a little uncomfortable.]$_{\text{Clause3}}$ [I'm often nitpicking for room decoration.]$_{\text{Clause4}}$ [Besides, the price is very expensive]$_{\text{Clause5}}$ [although the staff service is professional.]$_{\text{Clause6}}$

Rating of Each Aspect

- ***location***: ★★★★★ (5)
- ***room***: ★★★☆☆ (3)
- ***value***: ★☆☆☆☆ (1)
- ***service***: ★★★★☆ (4)

Figure 1: An example of a review document, where clauses and words with different colors refer to different aspects.

As human beings, if asked to evaluate the sentiment rating for a specific aspect in a document, we often perform sentiment prediction in two steps. First, we select some **aspect-relevant snippets** (e.g., sentences/clauses) inside the document. Second, we select some **sentiment-relevant words** (e.g., sentiment words) inside these snippets to make a rating decision. For instance, for aspect *location* in Figure 1, we first select the aspect-relevant clauses, i.e., Clause1 and Clause2, and then select sentiment-relevant words, i.e., "*close*" and "*very convenient*" inside the two clauses, for making the rating decision (5 stars).

Inspired by the above cognitive process of human beings, one ideal and interpretable solution for DASC is to select aspect-relevant clauses and sentiment-relevant words, discarding those noisy parts of a document for decision making. In this

solution, two major challenges exist which are illustrated as follows.

The first challenge is how to select aspect-relevant clauses and discard those irrelevant and noisy clauses. For instance, for aspect *location*, Clause5 mentioning another aspect *value* (only 1 star) may induce the noise and should be discarded, because the noise can provide wrong signals to mislead the model into assigning very low sentiment rating to aspect *location*. One possible way to alleviate this noisy problem is to leverage the soft-attention mechanism as proposed in Li et al. (2018) and Wang et al. (2018). However, this soft-attention mechanism has the limitation that the *softmax* function always assigns small but non-zero probabilities to noisy clauses, which will weaken the attention given to the few truly significant clauses for a particular aspect. Therefore, a well-behaved approach should discard noisy clauses for a specific aspect during model training.

The second challenge is how to select sentiment-relevant words and discard those irrelevant and noisy words. For instance, for aspect *location*, words "*this*", "*is*" in Clause1 are noisy words and should be discarded since they make no contribution to implying the sentiment rating. One possible way to alleviate this problem is to also leverage the soft-attention mechanism as proposed in Li et al. (2018). However, this soft-attention mechanism may induce additional noise and lack interpretability because it tends to assign higher weights to some domain-specific words rather than real sentiment-relevant words (Mudinas et al., 2012; Zou et al., 2018). For instance, this soft-attention mechanism tends to regard the name of a hotel "*Hilton*" with a good reputation in Clause3 as a positive word which could mislead the model into assigning a higher rating to aspect *room*. Therefore, a well-behaved approach should highlight sentiment-relevant words and discard noisy words for a specific aspect during model training.

In this paper, we propose a Hierarchical Reinforcement Learning (HRL) approach with a high-level policy and a low-level policy to address the above two challenges in DASC. First, a high-level policy is leveraged to select aspect-relevant clauses and discard noisy clauses during model training. Then, a low-level policy is leveraged to select sentiment-relevant words and discard noisy words inside the above selected clauses. Finally, a sentiment rating predictor is designed to provide reward signals to guide both clause and word selection. The empirical studies show that the proposed approach performs well by incorporating the clause selection and word selection strategies and significantly outperforms several state-of-the-art approaches including those with the soft-attention mechanism.

2 Hierarchical Reinforcement Learning

Figure 2 shows the overall framework of our Hierarchical Reinforcement Learning (HRL) approach which contains three components: a high-level policy for clause selection (Section 2.2); a low-level policy for word selection (Section 2.3); a sentiment rating predictor for providing reward signals to guide both the above clause and word selection (Section 2.4).

As a preprocessing, we adopt RST style discourse segmentation[1] (MANN, 1988) to segment all documents in corpus $\mathcal{C}$ into Elementary Discourse Units (EDUs), and consider thse EDUs as clauses by following Wang et al. (2018).

In summary, we formulate the task of DASC as a semi-Markov Decision process (Sutton et al., 1999b), i.e., hierarchical reinforcement learning with a high-level policy and a low-level policy. In particular, our HRL approach for DASC works as follows. Given a review document with a clause sequence and an aspect, the high-level policy decides whether a clause mentions this aspect. If yes, the high-level policy selects this clause and launches the low-level policy, which scans the words inside this selected clause one by one in order to select sentiment-relevant words. Otherwise, the high-level policy skips current clause and turns to the next clause until all clauses in the review document are scanned. During clause and word selection, a sentiment rating predictor is employed to provide reward signals to guide the above clause and word selection.

2.1 Clause Selection with High-level Policy

Assume that a review document $\mathcal{D}$ with a given aspect x_{aspect} has been segmented into a clause sequence $\{u_1, ..., u_n\}$, high-level policy π^h aims

[1]In preliminary experiments, we tried directly adopting sentence segmentation by following Li et al. (2018) rather than clause splitting and found that adopting clause splitting achieves better performance. Detailed comparison results are presented in ablation study of Section 3.2.

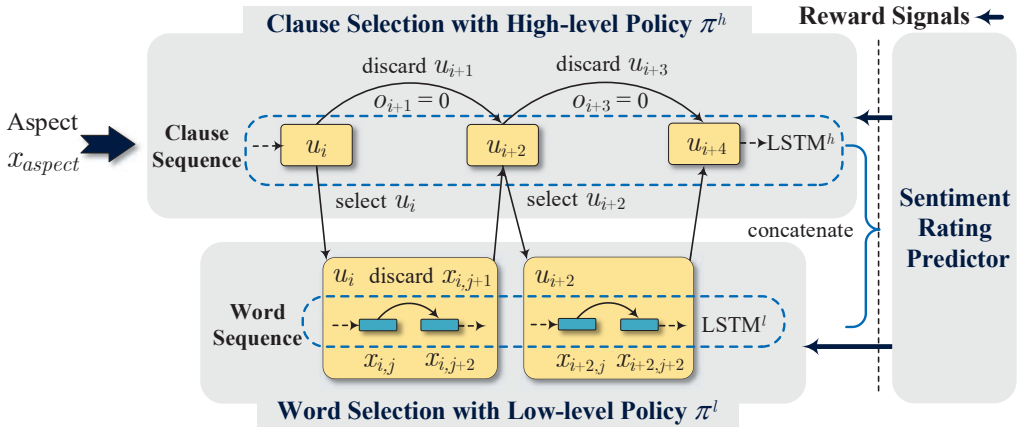

Figure 2: Overall architecture of our Hierarchical Reinforcement Learning (HRL) approach.

to select clause u_i which truly mentions aspect x_{aspect} and discard noisy ones. Here, clause u_i consists of k_i words $\{x_{i,1}, ..., x_{i,k_i}\}$. Once a clause is selected, it is passed to the low-level policy for further word selection.

During clause selection, we adopt a stochastic policy as high-level policy π^h, which can generate a conditional probability distribution $\pi^h(o|\cdot)$ over option (i.e., high-level action) sequence $o = [o_1, ..., o_n]$. Here, $o_i = 1$ indicates u_i is selected; otherwise $o_i = 0$ indicates u_i is discarded. More specifically, we adopt a LSTM model LSTM^h to construct high-level policy π^h for performing clause selection over the clause sequence. In LSTM^h, the hidden state $\hat{v}_i \in \mathbb{R}^d$ of clause u_i and memory cell c_i^h at i-th time-step are given by,

$$\hat{v}_i, c_i^h = \begin{cases} f(\hat{v}_{i-1}, c_{i-1}^h, v_i) & o_i = 1 \\ \hat{v}_{i-1}, c_{i-1}^h & o_i = 0 \end{cases} \quad (1)$$

where v_i is the vector representation of clause u_i and initialized by hidden state $\hat{w}_{i,k_i}$ of the last word $\hat{x}_{i,k_i}$ in clause u_i. Here, $\hat{w}_{i,k_i}$ is obtained from the pre-trained LSTM^l (presented in line 3 of Algorithm 1); f denotes all gate functions and update function of LSTM^h. Note that if $o_i = 0$, LSTM^h will skip (i.e., discard) and not encode clause u_i, memory cell c_i^h and hidden state $\hat{v}_i$ of current time-step i are then directly copied from the previous time-step $i-1$.

In principle, the high-level policy π^h uses a **Reward** to guide clause selection over the clause sequence. It samples an **Option** o_i with the probability $\pi^h(o_i|s_i^h;\theta^h)$ at each **State** s_i^h. More concretely, the state, option and reward of π^h are defined as follows.

• **State.** The state s_i^h at i-th time-step should provide adequate information for deciding to select a clause or not for x_{aspect}. Thus, state $s_i^h \in \mathbb{R}^{4d}$ is composed of four parts, i.e., $\hat{v}_{i-1}$, c_{i-1}^h, v_i and v_a, defined as $s_i^h = \hat{v}_{i-1} \oplus c_{i-1}^h \oplus v_i \oplus v_a$, where $v_a \in \mathbb{R}^d$ is aspect embedding[2] of x_{aspect}.

• **Option.** π^h samples *option* $o_i \in \{0, 1\}$ by the conditional probability $\pi^h(o_i|s_i^h;\theta^h)$ which could be cast as a binary classification problem. Thus, we adopt logistic function to define $\pi^h(o_i|s_i^h;\theta^h)$.

$$\begin{aligned} o_i \sim \pi^h(o_i|s_i^h;\theta^h) &= o_i\sigma(W^h s_i^h + b^h) \\ &+(1-o_i)(1-\sigma(W^h s_i^h + b^h)) \end{aligned} \quad (2)$$

where $\theta^h = \{W^h \in \mathbb{R}^{1\times 4d}, b^h \in \mathbb{R}\}$ is the trainable parameter; $\sim$ denotes sampling operation; σ denotes sigmod function.

• **Reward.** In order to select aspect-relevant clauses inside a clause sequence $\{u_1, ..., u_n\}$, given a sampled *option* trajectory $\tau^h = (s_1^h, o_1, r_1^h, ..., s_n^h, o_n, r_n^h) \sim \pi^h$, we compute the high-level cumulative reward r_i^h at i-th time-step as follows:

$$\begin{aligned} r_i^h &= \lambda_1 \sum_{t=i}^{n} \gamma^{t-i} \log\cos(v_a, \hat{v}_t) \\ &+ \lambda_2 \sum_{t=i}^{n} \gamma^{t-i} r^l(u_t) + \lambda_3 \log p_\theta(y|\hat{v}_n) \end{aligned} \quad (3)$$

where r_i^h consists of three different terms: **1)** The first term $\log\cos(v_a, \hat{v}_t)$ is a cosine intermediate reward computed by *cosine* similarity between aspect embedding $v_a \in \mathbb{R}^d$ and hidden state $\hat{v}_t \in \mathbb{R}^d$ of the t-th clause u_t. This reward provides aspect supervision signals to guide the policy to select aspect-relevant clauses. **2)** The second term

[2]Aspect embedding is initialized by an average of its keywords embeddings. Keywords for aspects (e.g., keywords for aspect *service* are service, smile etc.) are obtained from Yin et al. (2017).

$r^l(u_t) = \sum_{j=1}^{k_t} r^l_{t,j}$ is an intermediate reward from low-level policy after the word selection in the selected clause u_t is finished. Note that if clause u_t is discarded, $r^l(u_t) = 0$. This reward provides a feedback to indicate how well clause selection is. **3)** The third term $\log p_\theta(y|\hat{v}_n)$ is a delay reward from sentiment rating predictor. After LSTM^h finishes all options, we feed the last hidden state $\hat{v}_n$ of LSTM^h to the softmax decoder of sentiment rating predictor and then obtain a rating probability $p_\theta(y|\hat{v}_n)$ for ground-truth rating label y to compute this delay reward. This reward provides additional reward signals to guide policy to select discriminative clauses. Besides, γ is the discount factor; λ_1, λ_2 and λ_3 are weight parameters.

2.2 Word Selection with Low-level Policy

Given a word sequence $\{x_{i,1}, ..., x_{i,k_i}\}$ of clause u_i selected by the high-level policy, low-level policy π^l aims to select the sentiment-relevant word $x_{i,j}$ and discard noisy ones.

During word selection, we still adopt a stochastic policy as low-level policy π^l, which can generate a conditional probability distribution $\pi^l(a|\cdot)$ over action sequence $a = [a_{i,1}, ..., a_{i,k_i}]$, where $a_{i,j} = 1$ indicates j-th word x_{ij} in i-th clause is selected; $a_{i,j} = 0$ indicates $x_{i,j}$ is discarded. Similar to clause selection, we adopt another LSTM model LSTM^l to construct low-level policy π^l for performing word selection over word sequence $\{x_{i,1}, ..., x_{i,k_i}\}$ of each clause (Note that, as shown in Figure 2, LSTM^l is shared by all selected clauses from high-level policy). In LSTM^l, the hidden state $\hat{w}_{i,j} \in \mathbb{R}^d$ of word $x_{i,j}$ and memory cell c^l_j at j-th time-step (Here, we omit the clause index and only use j to denote the j-th time-step in i-th clause u_i) are given by,

$$\hat{w}_{i,j}, c^l_{i,j} = \begin{cases} f(\hat{w}_{i,j-1}, c^l_{i,j-1}, w_{i,j}) & a_{i,j} = 1 \\ \hat{w}_{i,j-1}, c^l_{i,j-1} & a_{i,j} = 0 \end{cases} \tag{4}$$

where $w_{i,j}$ is word embedding of $x_{i,j}$. Similar to LSTM^h, in LSTM^l, if $a_{i,j} = 0$, i.e., word $x_{i,j}$ is discarded, memory cell and hidden state of current time-step are directly copied from the previous time-step. Then, we illustrate state, action and reward of low-level policy as follows.

• **State.** The state $s^l_{i,j}$ at j-th time-step should provide adequate information for deciding to select a word or not. Thus, the state $s^l_{i,j} \in \mathbb{R}^{3d}$ is composed of three parts, i.e., $\hat{w}_{i,i-1}$, $c^l_{i,j-1}$, $w_{i,j}$, defined as $s^l_{i,j} = \hat{w}_{i,j-1} \oplus c^l_{i,j-1} \oplus w_{i,j}$.

• **Action.** π^l samples *action* $a_{i,j} \in \{0, 1\}$ by the conditional probability $\pi^l(a_{i,j}|s^l_{i,j}; \theta^l)$. Thus, similar to high-level policy, we adopt logistic function to define $\pi^l(a_{i,j}|s^l_{i,j}; \theta^l)$.

$$\begin{aligned} a_{i,j} \sim \pi^l(a_{i,j}|s^l_{i,j}; \theta^l) = a_{i,j}\sigma(W^l s^l_{i,j} + b^l) \\ +(1 - a_{i,j})(1 - \sigma(W^l s^l_{i,j} + b^l)) \end{aligned} \tag{5}$$

where $\theta^l = \{W^l \in \mathbb{R}^{1\times 3d}, b^l \in \mathbb{R}\}$ is the trainable parameter.

• **Reward.** Similarly, in order to select sentiment-relevant words inside a word sequence $\{x_{i,1}, ..., x_{i,k_i}\}$, given a sampled *action* trajectory $\tau^l = (s^l_{i,1}, a_{i,1}, r^l_{i,1}, ..., s^l_{i,k_i}, a_{i,k_i}, r^l_{i,k_i}) \sim \pi^l$, we compute the low-level cumulative reward $r^l_{i,j}$ at j-th time-step as:

$$r^l_{i,j} = \lambda'_1 \log p_\theta(y|\hat{w}_{i,k_i}) + \lambda'_2(-N')/N \tag{6}$$

where $r^l_{i,j}$ consists of two terms: **1)** Similar to high-level policy, the first term $\log p_\theta(y|\hat{w}_{i,k_i})$ is a delay reward provided by sentiment rating predictor. After LSTM^l finishes all actions, we feed last hidden state $\hat{w}_{i,k_i}$ in i-th clause to softmax decoder of sentiment rating predictor and then we can obtain this delay reward. This reward provides rating supervision information to guide policy to select discriminative words, i.e., sentiment-relevant words. **2)** The second term $\gamma(-N')/N$ is a penalty delay reward. $N' = \sum_{j=1}^{k_i} a_{i,j}$ denotes the number of selected words. The basic idea of using this penalty reward is to select words as small as possible because sentiment-relevant words is usually a small subset of all words inside the clause. Note that, we could also adopt external sentiment lexicons to achieve this goal, but sentiment lexicons are difficult to obtain in many real-world applications. Besides, λ'_1, λ'_2 are weight parameters.

2.3 Sentiment Rating Predictor

The goal of sentiment rating predictor lies in two-fold. On one hand, during model training, the goal of sentiment rating predictor is to use a softmax decoder to provide rating probabilities as the reward signals (see Eq.(3) and Eq.(6)) to guide both clause and word selection.

On the other hand, when model training is finished, i.e., both high-level and low-level policy finish all their selections, the goal of sentiment rating predictor is to perform DASC. Specifically, we first regard last state $\hat{v}_n$ of LSTM^h as the representation of all selected clauses while last state

$\hat{w}_{n,k_n}$ of LSTM^l as the representation of all selected words. Then, we concatenate $\hat{v}_n$ and $\hat{w}_{n,k_n}$ to compute the final representation z of the review document $\mathcal{D}$ as: $z = \hat{v}_n \oplus \hat{w}_{n,k_n}$, where $\oplus$ denotes concatenation operation. Finally, to perform DASC, we feed z to a softmax decoder as follows:

Softmax Decoder. We first feed z to a softmax classifier $m = Wz + b$, where $m \in \mathbb{R}^C$ is output vector; $\theta = \{W, b\}$ is trainable parameter. Then, the probability of labeling sentence with sentiment rating $\hat{y} \in [1, C]$ is computed by $p_\theta(\hat{y}|z) = \frac{\exp(m_{\hat{y}})}{\sum_{\ell=1}^{C} \exp(m_\ell)}$. Finally, the label with the highest probability stands for the predicted sentiment rating for x_{aspect}.

Note that, for an aspect, if no clauses and words are finally selected from a review document, the model will assign a random rating for this aspect.

2.4 Model Training via Policy Gradient and Back-Propagation

The parameters in HRL are learned according to Algorithm 1. Specifically, these parameters can be divided into two groups: **1)** θ^h and θ^l of high-level policy π^h and low-level policy π^l respectively. **2)** θ of LSTM^h, LSTM^l and softmax decoder.

For θ^h of high-level policy, we optimize it with policy gradient (REINFORCE) (Williams, 1992; Sutton et al., 1999a). The policy gradient w.r.t. θ^h is computed by differentiating the maximized expected reward $J(\theta^h)$ as follows:

$$\nabla_{\theta^h} J(\theta^h) = \mathbb{E}_{\tau^h \sim \pi^h}[\sum_{i=1}^{n} \mathcal{R}^h \nabla_{\theta^h} \log \pi^h(o_i|s_i^h; \theta^h)] \tag{7}$$

where $\mathcal{R}^h = r_i^h - b(\tau^h)$ is the advantage estimate of the high-level reward. Here, $b(\tau^h)$ is the *baseline* (Williams, 1992) which is used to reduce the variance of the high-level reward without altering its expectation theoretically. In practical use, we sample some trajectories $\tau_1^h, \tau_2^h, ..., \tau_m^h$ over the clause sequence with the current high-level policy. The model will assign a reward score to each sequence according to the designed scores function, and then estimates $b(\tau^h)$ as the average of those rewards. Similarly, the policy gradient w.r.t. θ^l of low-level policy is given by,

$$\nabla_{\theta^l} J(\theta^l) = \mathbb{E}_{\tau^l \sim \pi^l}[\sum_{j=1}^{k_i} \mathcal{R}^l \nabla_{\theta^l} \log \pi^l(a_{i,j}|s_{i,j}^l; \theta^l)] \tag{8}$$

Algorithm 1 Hierarchical reinforcement learning

Input: Corpus $\mathcal{C}$; a review document $\mathcal{D}$ with a clause sequence $\{u_1, ..., u_n\}$; a clause u_i with a word sequence $\{x_{i,1}, ..., x_{i,k_i}\}$.
Initialize parameters θ, θ^h and θ^l randomly;
Pre-train LSTM^l by forcing π^l to select all words for classification, and update θ of LSTM^l by Eq.(9);
Pre-train LSTM^h by forcing π^h to select all clauses for classification, and update θ of LSTM^h by Eq.(9);
Fix all parameters θ and update θ^h, θ^l as follows:
for review document $\mathcal{D} \in \mathcal{C}$ **do**
  for clause $u_i \in \{u_1, ..., u_n\}$ **do**
    Sample *option* $o_i \sim \pi^h(o_i|s_i^h; \theta^h)$;
    if option $o_i = 1$ **then**
      for word $x_{i,j} \in \{x_{i,1}, ..., x_{i,k_i}\}$ **do**
        Sample *action* $a_{i,j} \sim \pi^h(a_{i,j}|s_{i,j}^l; \theta^h)$;
      end for
      Compute $r_{i,j}^l$ by Eq.(6);
      Update θ^l by Eq.(8);
    end if
  end for
  Compute r_i^h by Eq.(3);
  Update θ^h by Eq.(7);
end for

Datasets	*#documents*	*#words/doc*	*#Aspect*
TripUser	58632	181.03	7
TripAdvisor	29391	251.7	7
BeerAdvocate	51020	144.5	4

Table 1: Statistics of three datasets. *#words/doc* denotes the number of words (average per document). *#Aspect* denotes the number of aspects in each dataset. The rating scales of TripAdvisor and BeerAdvocate are 1-5 and 1-10 respectively.

where $\mathcal{R}^l = r_{i,j}^l - b(\tau^l)$ is the advantage estimate of the low-level reward. Similarly, $b(\tau^l)$ is used to reduce the variance of the low-level reward.

For θ, we optimize it with back-propagation. The objective of learning θ is to minimize the cross-entropy loss in the classification phase, i.e.,

$$J(\theta) = \mathbb{E}_{(\mathcal{D}, x_{aspect}, y) \sim \mathcal{C}}[-\log p_\theta(y|z)] + \frac{\delta}{2}||\theta||_2^2 \tag{9}$$

where $(\mathcal{D}, x_{aspect}, y)$ denotes a review document $\mathcal{D}$ with a given aspect x_{aspect} from corpus $\mathcal{C}$; y is ground-truth sentiment rating for aspect x_{aspect}. δ is a L_2 regularization.

3 Experimentation

3.1 Experimental Settings

Data. We conduct our experiments on three public datasets on DASC, i.e., TripUser (Li et al., 2018), TripAdvisor (Wang et al., 2010) and BeerAdvocate (McAuley et al., 2012; Lei et al., 2016). In the experiment, we adopt Discourse Segmentation

Table 2: Comparison of our approaches and other baseline approaches to DASC. The results with symbol † are retrieved from Li et al. (2018) and those with ‡ are from Yin et al. (2017)

Tool[3] to segment all reviews in the three datasets into EDUs (i.e., clauses). Moreover, we adopt training/development/testing settings (8:1:1) by following Yin et al. (2017); Li et al. (2018). Table 1 shows the statistics of the three datasets.

Implementation Details. We adopt the pre-trained 200-dimension word embeddings provided by Yin et al. (2017). The dimension of LSTM hidden states is set to be 200. The other hyper-parameters are tuned according to the performance in the development set. Specifically, we adopt Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.012 for cross-entropy training and adopt SGD optimizer with a learning rate of 0.008 for all policy gradients training. For rewards of high-level and low-level policies, γ is 0.8; λ_1, λ_2 and λ_3 are 0.25, 0.25 and 0.5 respectively. λ_1', λ_2' are 0.6 and 0.4. Additionally, the batch size is set to be 64, regularization weight is set to be 10^{-5} and the dropout rate is 0.2.

Evaluation Metrics. The performance is evaluated using Accuracy (Acc.) and MSE as Yin et al. (2017). Moreover, t-test is used to evaluate the significance of the performance difference between two approaches (Yang and Liu, 1999).

Baselines. We compare HRL with the following baselines: **1) SVM** (Yin et al., 2017). This approach only adopts unigram, bigram as features to train an SVM classifier. **2) LSTM** (Tang et al., 2015). This is a neural network approach to document-level sentiment classification which employs gated LSTM to learn text representation. **3) MAMC** (Yin et al., 2017). This approach employs hierarchical iterative attention to learn aspect-specific representation. This is a state-of-the-art approach to DASC. **4) HARN** (Li et al., 2018). This approach adopts hierarchical attention to incorporate overall rating and aspect information so as to learn aspect-specific representation. This is another state-of-the-art approach to DASC. **5) HUARN** (Li et al., 2018). This approach extends HARN by integrating additional user information. This is another state-of-the-art approach to DASC. **6) C-HAN** (Wang et al., 2018). This approach adopts hierarchical attention to incorporate clause and aspect information so as to learn text representation. Although this is a state-of-the-art approach to sentence-level ASC, it could also be directly applied in DASC. **7) HS-LSTM** (Zhang et al., 2018). This is a reinforcement learning approach to text classification, which employs a hierarchically LSTM to learn text representation. **8) RL-Word-Selection.** Our approach which leverages only the word selection strategy by using the low-level policy. **9) RL-Clause-Selection.** Our approach which leverages only the clause selection strategy by using the high-level policy.

3.2 Experimental Results

Table 2 shows the performance comparison of different approaches. From this table, we can see that, all LSTM-based approaches outperform **SVM**, showing that LSTM has potentials in automatically learning text representations and can bring performance improvement for DASC.

Four state-of-the-art ASC approaches including **MAMC**, **HARN**, **HUARN** and **C-HAN** all perform better than **LSTM**. These results confirm the helpfulness of considering aspect information in DASC. Besides, we find the reinforcement learning based approach **HS-LSTM** without consid-

Table 3: Ablation study of HRL on three different datasets.

ering aspect information can achieve comparable performance with **MAMC**, **HARN**, **C-HAN**, and even beat **MAMC** on two datasets **TripUser** and **TripAdvisor**, which demonstrates that using reinforcement learning is a good choice to learn text representation for DASC.

Our approach **RL-Word-Selection** and **RL-Clause-Selection** outperform most above approaches and they only perform slightly worse than **HUARN**. This result encourages to perform clause or word selection in DASC. Among all these approaches, our approach **HRL** performs best and it significantly outperforms (p-value $<$ 0.01) strong baseline **HUARN** which actually considers some other kinds of external information, such as the overall rating and the user information. These results encourage to perform both clause and word selection in DASC.

Ablation Study. Further, we conduct the ablation study of HRL to evaluate the contribution of each component. The results are shown in Table 3. From this table, we can see that **1)** Using *cosine* intermediate reward in Eq.(3) can averagely improve Acc. by 2.87% on three different datasets. **2)** Using penalty delay reward in Eq.(6) can averagely improve Acc. by 1.23%. **3)** To concatenate additional representation of the selected clauses in rating predictor can improve Acc. by 4.38%. **4)** To concatenate additional representation of the selected words in rating predictor can improve Acc. by 2.72%. **5)** Using the clause splitting instead of sentence splitting could improve Acc. by 2.44%. This confirms that it is more appropriate to consider clauses as the segmentation units than sentences. This is because that 90% of clauses contain only one opinion expression as proposed in Bayoudhi et al. (2015). For instance, as shown in Figure 1, if we use the sentences as the segmentation units, Clause1-Clause3 will be assigned into one unit while they talk about two aspects, i.e., *location* and *room*. In this scenario, sentence selection will not be able to discard noisy parts inside the sentence for the aspect *location* or *room*.

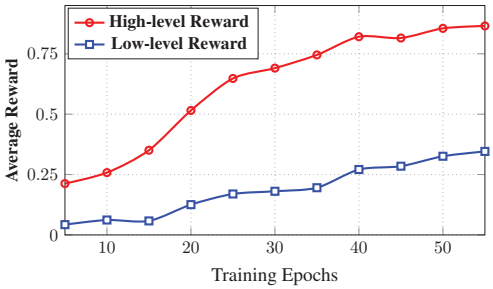

Figure 3: Training reward with different epochs

4 Analysis and Discussion

Analysis of HRL Training. Figure 3 shows two average rewards (each epoch) of high-level and low-level policy on BeerAdvocate respectively. To clearly observe the change of the reward, following Lillicrap et al. (2016), all rewards are normalized to $(0, 1)$. From this figure, we can see that, both the high-level and low-level reward increase as the training algorithm iterates. This result indicates that our HRL approach is capable of stably revising its policies to obtain more discriminative clauses and words for better performing.

Analysis of Clause and Word Selection. Figure 4 shows visualizations of our HRL approach which performs the clause selection and word selection on a review document. From this figure, we can see that HRL is able to precisely select aspect-relevant clauses, i.e., Clause1 and Clause2, for aspect *location* while select Clause3 and Clause4 for *room*. Further, HRL is able to select all sentiment-relevant words, such as "*close*" and "*very convenient*" for aspect *location*, while "*a little uncomfortable*" and "*nitpicking*"for *room*.

Error Type Breakdown. We analyze error cases in the experiments and broadly categorize them into three types: **(1)** The first type of errors are due to negation words. For instance, for the review "*The taste of this beer is not good, don't buy it*", HRL could precisely select the sentiment

(a) For aspect ***location*** (b) For aspect ***room***

Figure 4: Visualizations of clause selection (along with the row ↓) and word selection (along with the column →) for aspect (a) ***location*** and (b) ***room***. Red denotes the clause has been selected, blue denotes the word has been selected and other colors denote the token has been discarded.

"*good*", but fail to select the negation word "*not*". This inspires us to work on optimizing our approach in order to capture negation scope better in our future work. **(2)** The second type of errors are due to comparative opinions. For instance, for the review "*The room of Sheraton is much better than this one.*", HRL incorrectly predicts high rating (5 stars) to aspect *room*. It would be interesting to see if incorporating syntactic information can solve this problem and bring performance improvement. **(3)** Finally, some errors are due to mistakes during clause splitting (i.e., EDU splitting). For instance, for the review "[*This hotel having good location*] [*often needs lots of time to check in.*]", it is assigned into one clause while it talks two aspects, i.e., *location* and *check in/front desk*. This encourages to improve the performance of clause splitting for informal review texts.

5 Related Work

Aspect Sentiment Classification. Traditional studies for DASC mainly focus on feature engineering to explore efficient features for DASC (Titov and McDonald, 2008; Lu et al., 2011; McAuley et al., 2012). Recently, neural networks with the characteristic of automatically mining features have shown promising results on DASC. Lei et al. (2016) focused on extracting rationales for aspects and build a neural text regressor to predict aspect rating; Yin et al. (2017) focused on using hierarchical iterative attention to learn aspect-specific text representation for DASC; Li et al. (2018) employed a hierarchical attention approach to DASC which incorporates both the external user and overall rating information. Besides, neural networks have been widely adopted for performing a closely related task, i.e., Sentence-level Aspect Sentiment Classification (Wang et al., 2016; Tang et al., 2016; Wang and Lu, 2018).

Reinforcement Learning. In recent years, reinforcement learning has been applied successfully to some NLP tasks. Guo (2015) employed deep Q-learning to improve the seq2seq model for the text generation task; Li et al. (2016) showed how to apply deep reinforcement learning to model future reward in the chatbot dialogue task; Takanobu et al. (2018) employed hierarchical reinforcement learning to model the relation extraction task; Zhang et al. (2018) combined LSTM with reinforcement learning to learn structured representations for the text classification task, which is inspirational to our approach.

Unlike all above studies, inspired by the cognitive process of human beings, this paper proposes a new HRL approach to DASC task. To the best of our knowledge, this is the first attempt to address DASC with HRL.

6 Conclusion

In this paper, we propose a hierarchical reinforcement learning approach to DASC. The main idea of the proposed approach is to perform sentiment classification like human beings. Specifically, our approach employs a high-level policy and a low-level policy to perform clause selection and word selection in DASC respectively. Experimentation shows that both the clause and word selection are effective for DASC and the proposed approach significantly outperforms several state-of-the-art baselines for DASC.

In our future work, we would like to solve other challenges in DASC, e.g., negation detection problem, to further improve the performance. Furthermore, we would like to apply our HRL approach to other sentiment analysis tasks, such as aspect and opinion co-extraction, and dialog-level sentiment analysis.

Abstract

In Natural Language Understanding, the task of response generation is usually focused on responses to short texts, such as tweets or a turn in a dialog. Here we present a novel task of producing a critical response to a long argumentative text, and suggest a method based on general rebuttal arguments to address it. We do this in the context of the recently-suggested task of listening comprehension over argumentative content: given a speech on some specified topic, and a list of relevant arguments, the goal is to determine which of the arguments appear in the speech. The general rebuttals we describe here (written in English) overcome the need for topic-specific arguments to be provided, by proving to be applicable for a large set of topics. This allows creating responses beyond the scope of topics for which specific arguments are available. All data collected during this work is freely available for research[1].

1 Introduction

A key element in argumentation is rebuttal: the ability to contest an argument by presenting a counter-argument. It is an important skill, not easily learned, and valued in many fields such as politics and science. It is useful for advancing your own views and beliefs over opposing ones, but perhaps more importantly, it facilitates a critical examination of the views and beliefs that you hold. An automatic rebuttal system could therefore be useful whenever critical analysis of written or spoken content is required – be it an elementary school student writing an essay or a seasoned journalist composing an op-ed.

In the context of Natural Language Understanding, the study of rebuttal and counter-arguments has focused on elucidating such relations between given arguments. Indeed, such "attack" relations are the foundation of *Argumentation Frameworks* (Dung, 1995); such frameworks have been one of the main objects of study in computational argumentation.

A related task, that of generating a response which need not be a rebuttal or even argumentative, has been the subject of much research, especially in the context of dialog systems, chat bots, and question answering. In this line of work the response typically follows a short input text, often only a sentence or two.

Here we suggest the task of producing a rebuttal in response to a long argumentative text. Specifically, we consider spoken speeches around four minutes long. In addition to being longer, and perhaps because they are so, these kinds of texts tend to include very general claims, often implicit in the text. As such, these claims may appear in varied contexts, and it may be feasible to compile a list of such claims independently of the speeches' topics.

For example, a concern that often comes up in debates about policy is that implementing the policy (or failing to do so) disproportionately harms minorities. This claim can be made to oppose school vouchers, to oppose voter registration laws or to support criminal justice reform. Moreover, for some such general claims, it is feasible to phrase a single rebuttal response which can fit many of the contexts in which the claim might be made. In the above example, such a response may talk about separating between the policy at hand, which should be adopted based on its merits, and the need to right historical wrongs, which should be pursued independently.

We envision an automatic rebuttal system based on this observation, which includes a manually curated General-Purpose Rebuttal Knowledge Base (GPR-KB) comprised of claims and matching re-

buttal responses. Given an argumentative text, the system would identify which claims from the GPR-KB are made in the text (explicitly or implicitly), and produce a rebuttal using the available counter-arguments. Clearly, many of the claims made in the text would not appear in the GPR-KB. The objective is therefore not to identify and rebut all arguments, but rather to identify and rebut *some* arguments, and construct a GPR-KB that facilitates that.

Such a system (based on the more elaborate CoPA modeling of Bilu et al., 2019) was indeed implemented as a key element in IBM's Project Debater rebuttal mechanism, and demonstrated during the live debate held between it and debating champion Harish Natarajan[2]. However, a rebuttal system of this nature may be of interest beyond the realm of debating technologies. For example, such a system may be instrumental in making media consumption a more critical process, by automatically challenging the consumer with counter-arguments. Similarly, it can be applicable in the education domain, stimulating critical thinking by prompting students with counter-arguments in response to (or during) essay-composition tasks.

The formation of a GPR-KB that is applicable to the real world poses several challenges. First, phrased claims must be both relevant to a variety of topics, and commonly used. Second, pre-written rebuttals should be effective and persuasive, even though they are created without prior knowledge of the context in which they are to be of use. We address these issues by turning to a domain in which a similar problem is solved by humans: the world of competitive debates. In these contests, successful debaters need to combine specific knowledge about the topic at hand, with general arguments that arise from the underlying principles of the debate. Their ability to use such general arguments for different topics lays the basis for using a GPR-KB as the one described above.

Accordingly, we asked an expert debater to create the initial GPR-KB by suggesting common claims and preparing matching rebuttals. The full process is detailed in §3.2.

To assess the usefulness of the suggested claims and rebuttals in the real world, we performed several steps of labeling on the dataset we constructed in Mirkin et al. (2018), containing spoken argumentative content discussing controversial topics. Details of this process, along with an analysis showing the high coverage obtained by our knowledge base, are described in §4.

Another major challenge is the development of automatic methods for identifying whether knowledge-base claims are mentioned by speakers. We break this problem into a three-stage funnel – identifying whether: (i) a claim is relevant to the topic; (ii) the claim's stance aligns with that of the speaker; (iii) the claim was made by the speaker. We provide simple baseline results for this third step (§5). Interestingly, we observe that simply selecting the claim with the highest acceptance rate in the training data (without looking at the text) provides a challenging baseline.

The main contributions of this work are (i) the introduction of a novel task in NLU: producing rebuttal in response to a long argumentative text (ii) a manually constructed GPR-KB shared across multiple topics (iii) an additional layer of labeling to our dataset from Mirkin et al. (2018) for such claims (iv) a baseline for detecting whether such a claim was mentioned in a speech.

2 Related Work

In Mirkin et al. (2018) we introduced the task of Listening Comprehension over argumentative content. That work analyzes recorded speeches, and tries to identify whether arguments from iDebate[3] are mentioned in the speech. Similarly, in Lavee et al. (2019) we addressed this task by first mining arguments from a large news corpus, and then identifying the arguments which are mentioned in speeches.

This work complements our previous works in two ways. First, the GPR-KB constructed here is of general claims, with wide cross-topic relevance. It facilitates Listening Comprehension for topics not mentioned in iDebate, or topics for which automatic argument mining does not yield satisfactory results. Second, while Mirkin et al. (2018) mention that the iDebate counter points can in principle be used for rebuttal, and Lavee et al. (2019) suggest mining opposing arguments from their corpus to counter arguments mentioned in speeches, pursuing both ideas is left for future work. We pick up the baton (in the context of the GPR-KB suggested here), and annotate the validity of the counter arguments as rebuttal to the ideas

[2]Video of the debate at https://www.youtube.com/watch?v=m3u-1yttrVw

[3]https://idebate.org/debatabase

expressed in a matching speech.

Response generation has been the subject of much research, using a wide variety of methods (e.g. Ritter et al., 2011; Sugiyama et al., 2013; Shin et al., 2015; Yan et al., 2016; Xing et al., 2017). In the context of dialog systems (see recent survey in Chen et al., 2017), there is usually a distinction between task-oriented systems (Wen et al., 2016) and open-domain ones (Mazaré et al., 2018; Weizenbaum, 1966). The task here can be seen as lying in between the two: on the one hand it allows for a response to speeches on a variety of topics; on the other, the response is restricted to be a rebuttal of a claim made in the speech. A major difference from dialog systems is that in this task the analysis is of a complete speech - rather than taking turns, and the goal is to respond to some of the claims - but not necessarily all.

In the context of computational argumentation much attention has been given to mapping rebuttal or disagreement among arguments. Such works include datasets exemplifying these relations (Walker et al., 2012; Peldszus and Stede, 2015a; Musi et al., 2017), modeling them (Sridhar et al., 2015) and explicitly detecting them (Rosenthal and McKeown, 2015; Peldszus and Stede, 2015b; Wachsmuth et al., 2018). The GPR-KB in this work is reminiscent of argument datasets that depict rebuttal relations, but the arguments are of a different type, being manually authored as general and applicable to a wide range of topics.

Most similar to our work is the task of generating an argument from an opposing stance for a given statement (Hua and Wang, 2018; Hua et al., 2019). These works present a neural-based generative approach, and experiment with user-written posts. Our task differs in that the input is longer text, potentially containing multiple arguments.

3 Data

3.1 Motions and Speeches

The speeches analyzed in this work are the 200 speeches provided by Mirkin et al. (2018). Each speech debates one of 50 motions originating from iDebate. In this data, the phrasing of the motions is often simplified to include an explicit *topic* and *action*. For example, the iDebate motion *This House would introduce goal line technology in football* is simplified to *We should introduce goal line technology*, where the topic is *goal line technology* and the action is *introduce*.

Speeches are evenly distributed between motions, each having two speeches supporting it (i.e. the speaker is arguing in favor of the motion) and two contesting it. They were recorded by 14 different speakers. A speech is given in several formats. We use the recorded audios and manually-created transcriptions. Recordings are about 4 minutes long, and the transcript texts contain on average 28.7 sentences and 833.1 tokens.

Lastly, the dataset contains claims taken from iDebate along with annotations identifying specific claims mentioned in particular speeches. Herein we refer to this data as iDebate18.

3.2 Knowledge base construction

An experienced competitive debater was solicited to author claims that tend to come up in debates across varied topics, and to write a rebuttal argument for each such claim (see the Appendix for the guidelines). She was *not* given access to any of the iDebate18 motions, which are analyzed later on. In total, 39 pairs were constructed in this way.

Texts were allowed to incorporate the special tokens *[ACTION]* and *[TOPIC]*, which are replaced by the debate topic and suggested action when applied to a specific motion or speech. For example, in the context of the motion *We should introduce goal line technology*, the claim *[ACTION] [TOPIC] will encourage better choices* is translated to *introducing goal line technology will encourage better choices*.

In a second phase, the claim-rebuttal pairs were edited by the authors, as follows:

(i) Some rebuttal texts were written with the context of a full speech in mind, and included segments that refer to what a debater would include in such a speech. For example, one included the segment "I have proven that this method is effective". Such segments were edited out.

(ii) For some claims, it seemed that an opposite claim could also be made. In these cases the negation of the claim was also added to the knowledge base, along with an appropriate rebuttal. For example, in addition to the claim *"[ACTION] [TOPIC] is the most practical way to solve the problem."*, we also added the claim *"[ACTION] [TOPIC] is not the most practical way to solve the problem."*.

After these modifications, the final knowledge base includes 55 claim-rebuttal pairs. Claims are always one short single sentence, with an average

Claim	Rebuttal
We must limit personal choice in this case	The greater good means nothing if the rights of individuals are being violated. It doesn't make sense to violate rights in order to protect them.
[ACTION] [TOPIC] is good for the economy	While we need to take the economy into account when making decisions, it cannot be the sole consideration or even the top priority in many cases. In this case, the harms outweigh any benefits there may be to the economy.
We need to protect the weakest members of society	A truly fair society is one where different people are afforded similar rights and are also trusted to look after themselves. While weaker segments of society can be more vulnerable, this does not justify paternalistic policies that are not beneficial for society as a whole.

Table 1: Examples of GP-claims and matching rebuttals, created through the process described in §3.2.

length of 8.5 tokens. Rebuttals are longer, on average 1.8 sentences long, and containing on average 32.9 tokens. Three examples from the GPR-KB are given in Table 1; henceforth we refer to the generated claims as *GP-claims*, or simply as *claims* when the context is clear.

4 Annotation Experiments

Four annotation experiments are described next, aimed at assessing the applicability of the generated GPR-KB to the real world. Each of the following subsections describes one experiment and its results. An overview of the whole process is depicted in Figure 1. The full annotation guidelines for each experiment appear in the Appendix.

4.1 Cross-Topic Relevancy

The GP-claims were written based on the experience of a professional debater, but without context of specific topics. The first annotation experiment aims to establish whether these claims indeed attain the desired goal of being applicable to a varied set of topics. For each motion in iDebate18, and for each GP-claim, we asked annotators to decide whether the claim supports the motion, opposes it or is not relevant[4]. Annotation was done by 7 experienced annotators, and 5 answers were collected for each question.

A GP-claim was considered *relevant* to a motion when marked as supporting or opposing it by most annotators. The stance of relevant claims towards the motion was determined by majority. When a relevant claim has an equal number of supporting and opposing answers, its stance is considered undetermined.

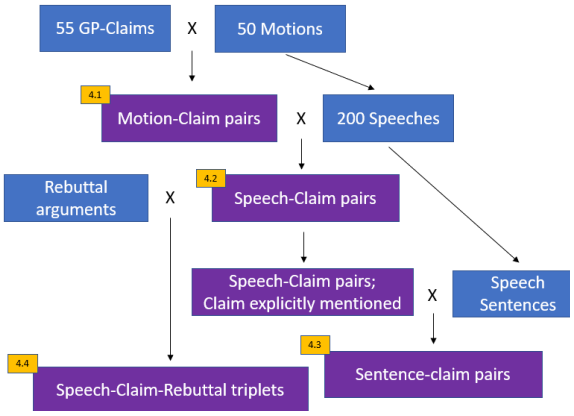

Figure 1: Annotation overview: All motion-claim pairs were annotated for whether the claim is relevant to the motion (see §4.1). For each claim, speeches discussing the relevant motions were annotated for whether the claim was mentioned in the speech (see §4.2), explicitly or implicitly. For explicitly mentioned claims, selected speech sentences were annotated for whether the claim was mentioned in the sentence (see §4.3). In addition, for claims mentioned in the speech, the corresponding Rebuttal Argument was annotated for whether it is a plausible rebuttal in the context of the speech (see §4.4). Blue rectangles indicate textual resources, violet ones indicate annotated resources, yellow ones refer to the relevant subsection.

Results Annotation included 2,750 claim-motion pairs[5], of which 46% are claims annotated as relevant to the motion. 20% are annotated as supporting the motion, 26% as opposing it, and a negligible number have an undetermined stance.

On average, 25.4 claims are annotated as relevant per motion. Inter-annotator agreement (average Cohen's Kappa (Cohen, 1960) over pairs of annotators), is 0.52 for the three-labels task, and 0.45 for the binary label of relevant/irrelevant.

Figure 2 shows the distribution of claims vs. the

[4]The stance is required for the experiment in §4.2.

[5]All pairs of 50 motions and 55 claims.

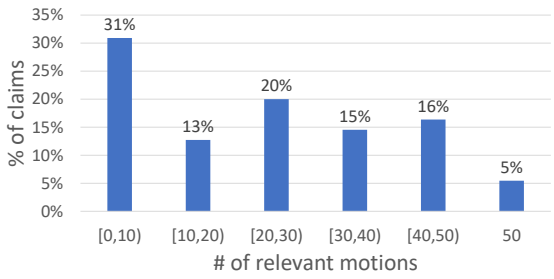

Figure 2: The distribution of GP-claims vs. the number of motions annotated as relevant.

number of motions annotated as relevant. Of note, many claims are relevant to various motions: 56% (sum of the four right-most bars) are relevant to at least 20 (out of 50) motions. However, only 5% are phrased in a manner so general that they may be relevant to all 50 motions. An example of such a general claim is *[ACTION] [TOPIC] will harm others*. At the other extreme, the claim *Animals have rights* is labeled as relevant to only 3 motions discussing various animal-related issues: adopting vegetarianism, banning bullfighting and legalizing ivory trade.

The majority of the claims are therefore general enough to be relevant to a substantial portion of the motions, but not so general as to make them trivially relevant to all motions.

4.2 Usage in Spoken Content

Having established that GP-claims are potentially relevant to many motions, the question still remains of whether or not they are actually commonly made by people debating these motions. This is a crucial point for using them as a basis for generating a rebuttal-response.

To assess this, annotators were shown speeches from iDebate18, alongside a matching list of GP-claims determined to be relevant in the previous stage. Specifically, claims annotated as supporting a motion were shown for speeches in which the speaker is arguing in favor of that motion, and vice versa. To allow for a greater number of potential claims, those which at least 2 annotators considered relevant (rather than 3) were included. Claims with an undetermined stance were excluded.

Speeches were presented in both audio and text formats, and annotators were allowed to choose between listening, reading or both. They then had to determine whether each claim is mentioned in the speech *explicitly*, *implicitly* or not at all. The number of claims presented for each speech was limited to 20; in case a larger number was determined to be relevant, the question was split into chunks of 20 claims.

In total, 3,246 claim-speech pairs required annotation, almost four times more than the corresponding annotation included in iDebate18. Annotation was done using the *Figure-Eight*[6] crowdsourcing platform, with 10 annotators per question. Clearly, this is a challenging task for the crowd, and hence a selected group of 22 annotators was used. Selection was based on their past performance on other tasks done by our team.

To further validate the annotation, the list of claims presented for each speech included claims for which the correct label was known a-priori. These include claims annotated in the previous experiment as irrelevant for the motion, for which it is assumed that the correct label is "not mentioned". In addition, annotation was done in batches. Claim-speech pairs for which unanimous answers were obtained in earlier batches were included in newer ones, with the correct label assumed to be this unanimous answer.

A claim is considered *mentioned* in a speech if a majority labeled it as mentioned (i.e. summing up implicit and explicit answer counts). Otherwise it is considered as *not mentioned*. A mentioned claim is *explicit* in the speech if its explicit answers count strictly exceeds its implicit answers count. Otherwise, it is considered *implicit*.

Results 41% of claim-speech pairs were labeled as mentioned (7% explicit and 34% implicit). On average, each claim is explicit in 4.3 speeches, and implicit in 17.6 speeches.

Pairwise inter-annotator agreement is 0.37 when considering two labels: mentioned or not. The average error rate of all annotators, on questions with a prior known answer, is 7%, suggesting a relatively high-quality annotation.

The *prior* of a claim is defined as the number of speeches in which it was found to be mentioned, divided by the number of speeches in which it was labeled. Figure 3 depicts the percentage of claims vs. their prior, separately for explicit and implicit mentions. Some claims are never mentioned in any speech: 20% are never mentioned explicitly and ∼10% are not mentioned at all, not even implicitly. Note that for the most part, claims

[6] www.figure-eight.com (formerly CrowdFlower).

are mentioned in less than half of the speeches for which they may be relevant.

In conclusion, the results suggest that GP-claims are often used in spoken content discussing various topics, and that this is not due to a small subset of trivial claims. Rather, most claims appear at least once, but usually in no more than half of the speeches for relevant motions.

These properties make automatic detection of these claims in speeches an interesting and challenging task.

Comparison to iDebate18 Table 2 compares the results of this annotation to that of iDebate18, which contains topic-specific claims annotated for the same set of speeches[7].

Surprisingly, topic-specific claims are no more likely to occur in speeches discussing that particular topic. Moreover, the larger number of potential GP-claims leads to a higher absolute number of mentions, to the extent that – in contrast with iDebate18 – all speeches include at least one mention. Hence, the GPR-KB augments the iDebate18 dataset, both by increasing the number of claims that are to be sought in a speech, and by suggesting claims to speeches for which iDebate18 does not contain any.

Speech stat.	GP-claims	iDebate18
Coverage	100%	86.5%
Avg. Mentions	6.7	1.8
Avg. Potential	16.2	4.4

Table 2: A comparison of GP-claims and topic-specific iDebate claims annotation. Coverage is the percentage of speeches with at least one claim annotated as mentioned. Avg. Potential is the average number of possibly relevant claims per speech, and Avg. Mentions is the average number of claims annotated as mentioned.

4.3 Where was it said?

A straightforward approach to determining whether a claim was mentioned in a speech is to go over its sentences, one by one, and decide whether the claim is equivalent to a sentence or implied by it, as indeed is done in Mirkin et al. (2018). This is a challenging task since, as described above, most mentions are implicit. In many cases one can not point to a single sentence

[7]Available answers in iDebate18 are *mentioned* or *not mentioned.*

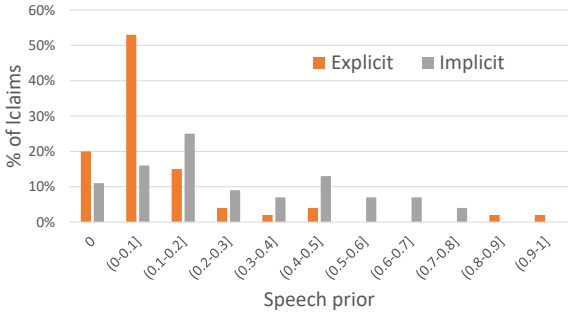

Figure 3: The distribution of GP-claims vs. speech prior (the percentage of labeled speeches in which a claim is mentioned), for explicit or implicit mentions.

mentioning the claim, as the claim is implied by the general stance of the speaker.

Even when a sentence does imply a claim, automatically inferring that may be hard. For example, for the motion *We should end cheerleading*, a relevant opposing claim is *Ending cheerleading limits personal choice*. We identified a sentence implying it, *The only clear moral system we can derive is one in which we value individual preference*, yet it seems hard to deduce this automatically without considering the surrounding context which clarifies that the argument is about personal choice.

An annotation task for identifying *where* a claim was mentioned is considerably more difficult than the aforementioned annotations. Determining ground truth is far from trivial, as annotators may point to different sentences within the same argument as being the location of the claim.

Nonetheless, such information seems a valuable part of a GPR-KB. To provide at least a partial solution, we annotated claim-sentence pairs directly, asking whether the claim is mentioned within the sentence. Algorithms developed on such data can then predict a claim as mentioned in a speech when it is mentioned in one of its sentences. This form of annotation is simple and facilitates easier collection of a large number of labels. To enable research in this direction, such annotations were performed both for GP-claims and, since none are provided in iDebate18, for claims from iDebate.

A careful selection of pairs to annotate is required since there are too many pairs for a comprehensive labeling, and sampling at random would rarely yield a pair such that the claim is mentioned in the sentence. Thus, we limited annotation to claims which were labeled as mentioned explicitly (and assumed all iDebate claims to be

so), and paired them only with sentences which are somewhat similar to them (based on word2vec, Mikolov et al., 2013). Annotation was again done by 10 crowd annotators.

Results Annotation included 4,271 GP-claim and sentence pairs and 2,164 iDebate-claim and sentence pairs, with a similarity of at least 0.5 and 0.7 (resp.) between claim and sentence. The usage of general crowd required some quality control. Annotators not meeting one or more of the following criteria were removed, along with their answers: Answer at least 10 questions; have at least 5 common answers with 3 different peers; have average agreement with peers ≥ 0.2.

The resulting inter-annotator agreement was 0.55 for GP-claims and 0.46 for iDebate claims. Considering only pairs with at least 5 remaining answers, after filtering out annotators as described above, 20% of the GP-claims-sentence pairs were annotated as a match (and 17% of iDebate pairs).

4.4 Validity of Rebuttal Arguments

Recall that rebuttal arguments in the GPR-KB were written without any specific contexts in which they are to be used. Hence, even if the claim they respond to is indeed mentioned in a speech, it is not clear whether the pre-written rebuttal would consist a plausible rebuttal response to the speech.

We assessed the effectiveness of the rebuttal arguments using a two-step procedure. First, as in §4.2, annotators were shown a speech and a claim, and determined whether the claim is mentioned in the speech. Then, if they marked that claim as mentioned, its pre-written rebuttal was shown, and they were asked whether it is a plausible response to the mentioned claim *in the context of the speech*.

This two-step annotation procedure was chosen for three reasons. First, requiring annotators to assess whether a claim is mentioned in a speech motivates them to review its content again and locate the relevant parts in which the claim is expressed. Second, it prevents irrelevant answers from those who do not think that the claim is mentioned in the speech. Finally, asking again about a claim's mention enables result validation, when the answer is known a-priori with high confidence. Specifically, claims for which the annotation is unanimous were used for this purpose.

For each claim, we annotated two randomly sampled speeches mentioning it. This amounted to 103 rebuttal-speech pairs, since not all 55 GP-claims were mentioned in two speeches. We relied on the same group of crowd annotators who took part in the previous experiment, and once again required 10 answers for each question.

Results Measuring agreement using Cohen's Kappa in this scenario is problematic. First, the label distribution is very biased: If rebuttal arguments are always plausible responses, then the correct answer is always yes. Any deviation from that will greatly reduce the score, making it an ill-fitting measure for such data (Jeni et al., 2013). Second, the small number of questions leads to many annotator-pairs whose set of common questions, on which this score is computed, is rather small. This makes the computation unstable, since when averaging over all pairs, such small intersections contribute as much as the large ones.

Instead, looking at the majority annotation for each rebuttal argument, we observed that in 87% of the cases it indicates that the rebuttal is plausible. This suggests that regardless of whether annotators agree with one another, they tend to agree that the rebuttal is usually plausible. Moreover, computing the average kappa between annotators and the majority annotation, and considering only those annotators who answered at least 20 questions, yields 0.47. This value for such biased data, alongside an average error rate of 4% on the questions with known answers, suggests that the annotation is of reasonable quality.

Analysis The results above show most rebuttals are appropriate in the vast majority of contexts. We therefore decided that continuing with this costly annotation is not needed. Furthermore, manual analysis of cases in which the rebuttal was unanimously found inappropriate showed this stemmed from the rebuttal being inappropriate for the topic, rather than a specific speech. For example, when discussing goal-line technology, in response to the claim *"introducing goal-line technology will lead to greater problems in the future"*, the pre-written rebuttal is *"Governments have an obligation to their citizens in the here and now. The better off society is today, the more resources we will have to make the future better when it comes"*. Such a response makes several assumptions which are clearly violated here, such as the involvement of government. Thus, further validation of rebuttals may benefit from first verifying their relevancy to the topic.

4.5 The GPR-KB-55 Dataset

The annotation results show that it is possible to construct a concise set of general claims, such that in most speeches at least one of them will come up. Furthermore, they show that a rebuttal to these claims can be authored independently of the specific motions and speeches, while nonetheless being a plausible response in their context. Table 3 summarizes the statistics for the pair-annotation experiments. The resulting dataset is freely available, and is one of the main contributions of this work[8]. We name the new dataset GPR-KB-55.

Annotation	# pairs	# positives
Motion – GP-claim	2,750	1,265
Speech – GP-claim	3,246	1,491
Sentence – GP-claim	4,271	854
Sentence – iDebate claim	2,164	368

Table 3: Summary of annotation experiment results. Positive pairs are those in which a majority of the annotators indicated that the claim is relevant (motion) or mentioned (speech, sentence).

5 Detecting claims in speeches

Next, we establish baseline results for determining whether a GP-claim is mentioned in a speech, and compare them to results obtained for iDebate claims. For a fair comparison of the two data sources, we assume for both prior knowledge as to which claims are relevant for a motion, as well as their stance towards it. Hence, we take the labeling of GP-claims to motions (described in §4.1) as given. The following algorithms are considered:

word2vec The best performing baseline of Mirkin et al. (2018) utilizes a detailed description of each iDebate claim, comprised of several sentences. It examines the speech sentence by sentence, and for each sentence computes its tf-idf weighted word2vec (*w2v*) similarity to the detailed claim description. A claim is then scored by taking the maximum over all claim-sentence similarity scores. We use this method (*w2v-i18*) as a baseline for the GP-claims as well, yet sentences are scored by their similarity to the GP-claim text, since no detailed topic-specific description exists. The latter is referred to as *w2v-GP-claims*. For comparison, we repeat the experiment using only the iDebate claim texts (*w2v-i18-claims*).

Bert Recently, the Bert architecture (Devlin et al., 2018) has proven successful on similar tasks, and we provide its results as an additional baseline. Specifically, we select at random 80% of the motions as an ad-hoc train set, and the remainder as a test set (*bert-test*). Bert was trained on labeled claim-sentence pairs corresponding to motions from the train set, in two settings, considering: (i) GP-claims (∼3K pairs) – *bert*, and (ii) both GP-claims and iDebate claims (almost 5K pairs) – *bert+*. In inference, given a claim and a speech, sentences semantically similar to the claim (as in §4.3) are scored by the fine-tuned network. Their maximum is the outputted claim-speech score.

Prior One important difference between GP-claims and iDebate claims is that the same GP-claim can (and does) appear across different motions and speeches. Specifically, given a training set, the a-priori probability that a GP-claim will be mentioned in a speech can be computed. Then, test claims are scored with their computed a-priori probability *without considering the text of the speech*. This baseline is referred to as *prior*.

Results Figure 4 plots precision-recall curves comparing claim detection baselines over iDebate claims and GP-claims. As observed by Mirkin et al. (2018), *w2v* works best when given a detailed iDebate claim description. Without it, performance is comparable for the two claim sources, and is rather poor for both. *Prior* results were obtained by using a leave-one-motion-out cross validation: at each fold a single motion is left out and the others are used for training. Its precision-recall curve shows that when considering these statistics, it presents a challenging baseline.

To compare the *bert* baseline to others, the precision-recall curves for both *prior*[9] and *w2v* were computed over speeches from *bert-test*. As shown in Figure 5, while *bert* clearly outperforms *w2v*, it nonetheless does not reach the *prior* baseline. The additional data provided in training to *bert+* does not help.

Note that this comparison is between methods which are derived from different types of data. Here *bert* is trained only on explicitly-mentioned claims, with respect to (ostensibly) semantically

[8] https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml

[9] Here, a-priori probabilities were computed on all motions not in *bert-test*, then applied to motions of *bert-test*.

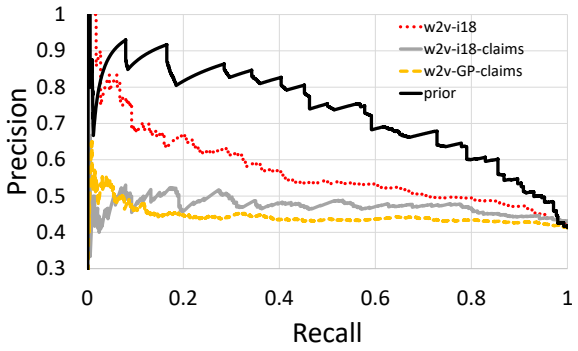

Figure 4: Precision-Recall curves for the matching of GP-claims and iDebate claims to all 200 speeches.

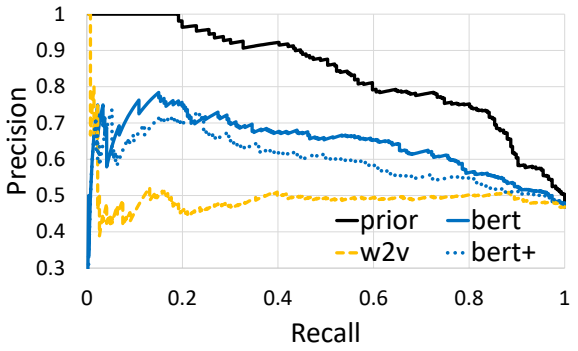

Figure 5: Precision-Recall curves for matching GP-claims to speeches, for *bert-test* (20% of motions).

similar *sentences*. On the other hand, the *prior* baseline is computed based on all claims, and their annotation w.r.t. *the entire speech*. This may be part of the reason why *bert*, which has proven to be successful on many NLP tasks, here achieves lower performance than this simple baseline.

Analysis Although *prior* seems like a strong baseline in terms of precision and recall, it is probably not a desired solution by itself, since it simply produces high probability responses regardless of the rebutted content. For example, among its top-20% predictions, precision is 83% and recall is 40%, yet they include only 22% of available GP-claims. Moreover, 77% of these top-20% are the same 5 claims. This reflects a property of the data: there are a few claims which are relevant to many motions, and are also implicitly mentioned in most speeches. Detection algorithms should be aware of this property, and account for it when evaluating performance. At the same time, a claim's acceptance prior can be useful for inference. For example, it could be combined with other data in a more sophisticated algorithm, or could direct the parameter choice of such an algorithm.

6 Conclusions and Future Work

We presented the problem of producing a rebuttal response to a long argumentative text. This task is especially challenging when the discussed topic is not known in advance, and, accordingly, potential responses are not readily available.

Toward the goal of addressing this problem we constructed a multi-layered dataset: (i) A Knowledge base of GP-claims and corresponding rebuttal arguments, which are shown to be applicable for a wide variety of topics; (ii) A mapping of these claims to motions of iDebate18 in which they might be applicable; (iii) An annotation of the stance of applicable claims; (iv) An annotation for which claims are actually mentioned in relevant speeches, and whether they are mentioned explicitly or implicitly; (v) For explicitly mentioned claims, a (partial) annotation of which sentences imply them and which do not.

In addition, we presented baselines for the related Listening Comprehension task, suggesting that this is a complicated problem. Using state-of-the-art sentence embedding yielded an $F1$-score of 0.64, while trivially taking the claim with the highest prior to be mentioned scored 0.78[10]. This suggests that careful evaluation is required.

While baselines are provided only for detecting GP-claims in spoken content, future work should aim to solve the problem as a whole - either by developing algorithms that determine relevance and stance of GP-claims to given motions, or by forgoing these stages, and successfully deciding whether a claim was mentioned in a speech, without first focusing on relevant claims.

Our results suggest that GP rebuttal arguments usually work well as a response to speeches in which the matching claim was mentioned. However, this is by no means perfect; and in some 13% of the cases they do not. It is interesting to further identify and understand these cases. By doing so, an automatic system could prefer responses that it identifies as more appropriate. Moreover, understanding such cases can lead to improving the rebuttal arguments themselves.

Rethinking Attribute Representation and Injection for Sentiment Classification

Reinald Kim Amplayo

reinald.kim@ed.ac.uk

Abstract

Text attributes, such as user and product information in product reviews, have been used to improve the performance of sentiment classification models. The de facto standard method is to incorporate them as additional biases in the attention mechanism, and more performance gains are achieved by extending the model architecture. In this paper, we show that the above method is the least effective way to represent and inject attributes. To demonstrate this hypothesis, unlike previous models with complicated architectures, we limit our base model to a simple BiLSTM with attention classifier, and instead focus on *how* and *where* the attributes should be incorporated in the model. We propose to represent attributes as chunk-wise importance weight matrices and consider four locations in the model (i.e., embedding, encoding, attention, classifier) to inject attributes. Experiments show that our proposed method achieves significant improvements over the standard approach and that attention mechanism is the worst location to inject attributes, contradicting prior work. We also outperform the state-of-the-art despite our use of a simple base model. Finally, we show that these representations transfer well to other tasks[1].

1 Introduction

The use of categorical attributes (e.g., user, topic, aspects) in the sentiment analysis community (Kim and Hovy, 2004; Pang and Lee, 2007; Liu, 2012) is widespread. Prior to the deep learning era, these information were used as effective categorical features (Li et al., 2011; Tan et al., 2011; Gao et al., 2013; Park et al., 2015) for the machine learning model. Recent work has used them to improve the overall performance (Chen et al., 2016; Dong et al., 2017), interpretability (Amplayo et al., 2018a; Angelidis and Lapata, 2018), and personalization (Ficler and Goldberg, 2017) of neural network models in different tasks such as sentiment classification (Tang et al., 2015), review summarization (Yang et al., 2018a), and text generation (Dong et al., 2017).

In particular, user and product information have been widely incorporated in sentiment classification models, especially since they are important metadata attributes found in review websites. Tang et al. (2015) first showed significant accuracy increase of neural models when these information are used. Currently, the accepted standard method is to use them as additional biases when computing the weights a in the attention mechanism, as introduced by Chen et al. (2016) as:

$$a = \text{softmax}(v^\top e) \quad (1)$$
$$e = \tanh(Wh + W_u u + W_p p + b) \quad (2)$$
$$= \tanh(Wh + b_u + b_p + b) \quad (3)$$
$$= \tanh(Wh + b') \quad (4)$$

where u and p are the user and product embeddings, and h is a word encoding from BiLSTM. Since then, most of the subsequent work attempted to improve the model by extending the model architecture to be able to utilize external features (Zhu and Yang, 2017), handle cold-start entities (Amplayo et al., 2018a), and represent user and product separately (Ma et al., 2017).

Intuitively, however, this method is not the ideal method to represent and inject attributes because of two reasons. First, representing attributes as additional biases cannot model the relationship between the text and attributes. Rather, it only adds a user- and product-specific biases that are independent from the text when calculating the attention weights. Second, injecting the attributes in the attention mechanism means that user and prod-

uct information are only used to customize how the model choose which words to focus on, as also shown empirically in previous work (Chen et al., 2016; Ma et al., 2017). However, we argue that there are more intuitive locations to inject the attributes such as when contextualizing words to modify their sentiment intensity.

We propose to represent user and product information as weight matrices (i.e., W in the equation above). Directly incorporating these attributes into W leads to large increase in parameters and subsequently makes the model difficult to optimize. To mitigate these problems, we introduce chunk-wise importance weight matrices, which (1) uses a weight matrix smaller than W by a chunk size factor, and (2) transforms these matrix into gates such that it corresponds to the relative importance of each neuron in W. We investigate the use of this method when injected to several locations in the base model: word embeddings, BiLSTM encoder, attention mechanism, and logistic classifier.

The results of our experiments can be summarized in three statements. First, our preliminary experiments show that doing bias-based attribute representation and attention-based injection is not an effective method to incorporate user and product information in sentiment classification models. Second, despite using only a simple BiLSTM with attention classifier, we significantly outperform previous state-of-the-art models that use more complicated architectures (e.g., models that use hierarchical models, external memory networks, etc.). Finally, we show that these attribute representations transfer well to other tasks such as product category classification and review headline generation.

2 How and Where to Inject Attributes?

In this section, we explore different ways on how to represent attributes and where in the model can we inject them.

2.1 The Base Model

The majority of this paper uses a base model that accepts a review $\mathbf{x} = x_1, ..., x_n$ as input and returns a sentiment y as output, which we extend to also accept the corresponding user u and product p attributes as additional inputs. Different from previous work where models use complex architectures such as hierarchical LSTMs (Chen et al., 2016; Zhu and Yang, 2017) and external memory networks (Dou, 2017; Long et al., 2018), we aim to achieve improvements by only modifying how we represent and inject attributes. Thus, we use a simple classifier as our base model, which consists of four parts explained briefly as follows.

First, we embed $\mathbf{x}$ using a word embedding matrix that returns word embeddings $x'_1, ..., x'_n$. We subsequently apply a non-linear function to each word:

$$w_t = \tanh(W_{\text{emb}} x'_t + b_{\text{emb}}) \tag{5}$$

Second, we run a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoder to contextualize the words into $h_t = [\overrightarrow{h}_t; \overleftarrow{h}_t]$ based on their forward and backward neighbors. The forward and backward LSTM look similar, thus for brevity we only show the forward LSTM below:

$$\begin{bmatrix} g_t \\ i_t \\ f_t \\ o_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} W_{\text{enc}}[w_t; \overrightarrow{h}_{t-1}] + b_{\text{enc}} \tag{6}$$

$$c_t = f_t * c_{t-1} + i_t * g_t \tag{7}$$

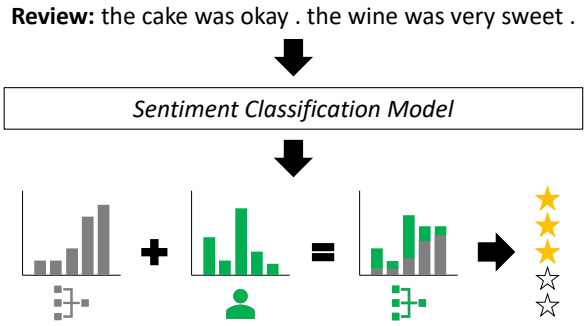
$$\overrightarrow{h}_t = o_t * c_t \tag{8}$$

Third, we pool the encodings h_t into one document encoding d using attention mechanism (Bahdanau et al., 2015), where v is a latent representation of informativeness (Yang et al., 2016):

$$e_t = \tanh(W_{\text{att}} h_t + b_{\text{att}}) \tag{9}$$

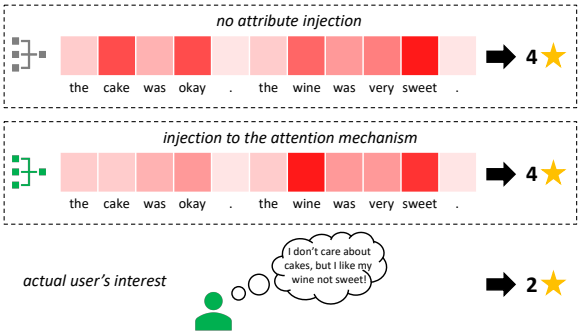
$$a_t = \text{softmax}_t(v^\top e_t) \tag{10}$$

$$d = \sum_t (a_t * h_t) \tag{11}$$



Finally, we classify the document using a logistic classifier to get a predicted y':

$$y' = \text{argmax}(W_{\text{cls}} d + b_{\text{cls}}) \tag{12}$$



Training is done normally by minimizing the cross entropy loss.

2.2 How: Attribute Representation

Note that at each part of the model, we see similar non-linear functions, all using the same form, i.e. $g(f(x)) = g(Wx + b)$, where $f(x)$ is an affine transformation function of x, g is a non-linear activation, W and b are weight matrix and bias parameters, respectively. Without extending the base model architecture, we can represent the attributes either as the weight matrix W or as the bias b to one of these functions by modifying them to accept u and p as inputs, i.e. $f(x, u, p)$.

(a) Logits when representing attributes as biases in the logistic classifier

(b) Attention weights when injecting attributes in the attention mechanism.

Figure 1: Illustrative examples of issues when representing attributes as biases and injecting them in the attention mechanism. The gray process icon indicates the model without incorporating attributes, while the same icon in green indicates the model customized for the green user.

Bias-based The current accepted standard approach to represent the attributes is through the bias parameter b. Most of the previous work (Chen et al., 2016; Zhu and Yang, 2017; Amplayo et al., 2018a; Wu et al., 2018) use Equation 2 in the attention mechanism, which basically updates the original bias b to $b' = W_u u + W_p p + b$. However, we argue that this is not the ideal way to incorporate attributes since it means we only add a user- and product-specific bias towards the goal of the function, *without* looking at the text. Figure 1a shows an intuitive example: When we represent user u as a bias in the logistic classifier, in which it means that u has a biased logits vector b_u of classifying the text as a certain sentiment (e.g., u tends to classify texts as three-star positive), shifting the final probability distribution regardless of what the text content may have been.

Matrix-based A more intuitive way of representing attributes is through the weight matrix W. Specifically, given the attribute embeddings u and p, we linearly transform their concatenation into a vector w' of size $D_1 * D_2$ where D_1 and D_2 are the dimensions of W. We then reshape w' into W' to get the same shape as W and replace W with W':

$$w' = W_c[u; p] + b_c \quad (13)$$

$$W' = \text{reshape}(w', (D_1 \times D_2)) \quad (14)$$

$$f(x, u, p) = W'x + b \quad (15)$$

Theoretically, this should perform better than bias-based representations since direct relationship between text and attributes are modeled. For example, following the example above, $W'x$ is a user-biased logits vector based on the document encoding d (e.g., u tends to classify texts as two-star positive when the text mentions that the dessert was sweet).

However, the model is burdened by a large number of parameters; matrix-based attribute representation increases the number of parameters by $|U| * |P| * D_1 * D_2$, where $|U|$ and $|P|$ correspond to the number of users and products, respectively. This subsequently makes the weights difficult to optimize during training. Thus, directly incorporating attributes into the weight matrix may cause harm in the performance of the model.

CHIM-based We introduce **Ch**unk-wise **I**mportance **M**atrix (CHIM) based representation, which improves over the matrix-based approach by mitigating the optimization problems mentioned above, using the following two tricks. First, instead of using a big weight matrix W' of shape (D_1, D_2), we use a chunked weight matrix C of shape $(D_1/C_1, D_2/C_2)$ where C_1 and C_2 are chunk size factors. Second, we use the chunked weight matrix as importance gates that shrinks the weights close to zero when they are deemed unimportant. We show the CHIM-based representation method in Figure 2.

We start by linearly transforming the concatenated attributes into c. Then we reshape c into C with shape $(D_1/C_1, D_2/C_2)$. These operations are similar to Equations 13 and 14. We then repeat this matrix $C_1 * C_2$ times and concatenate them such that we create a matrix W' of shape (D_1, D_2). Finally, we use the sigmoid function σ to transform the matrix into gates that represent importance:

$$W' = \sigma \begin{bmatrix} C; ...; C \\ ...; ...; ... \\ C; ...; C \end{bmatrix} \in [0, 1]^{D_1 \times D_2} \quad (16)$$

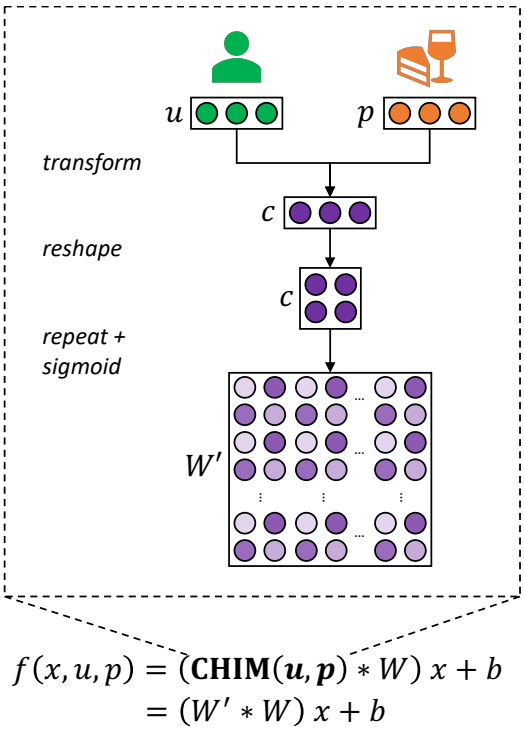


Figure 2: CHIM-based attribute representation and injection to a non-linear funtion in the model.

Finally we broadcast-multiply W' with the original weight matrix W to shrink the weights. The result is a sparse version of W, which can be seen as either a regularization step (Ng, 2004) where most weights are set close to zero, or a correction step (Amplayo et al., 2018b) where the important gates are used to correct the weights. The use of multiple chunks regards CHIM as coarse-grained access control (Shen et al., 2019) where the use of different important gates for every node is unnecessary and expensive. The final function is shown below:

$$f(x, u, p) = (W' * W)x + b \quad (17)$$

To summarize, chunking helps reduce the number of parameters while retaining the model performance, and importance matrix makes optimization easier during training, resulting to a performance improvement. We also tried alternative methods for importance matrix such as residual addition (i.e., $\tanh(W') + W$) introduced in He et al. (2016), and low-rank adaptation methods (Jaech and Ostendorf, 2018; Kim et al., 2019), but these did not improve the model performance.

2.3 Where: Attribute Injection

Using the approaches described above, we can inject attribute representation into four different parts of the model. This section describes what it means to inject attributes to a certain location and why previous work have been injecting them in the worst location (i.e., in the attention mechanism).

In the attention mechanism Injecting attributes to the attention mechanism means that we bias the selection of more informative words during pooling. For example, in Figure 1b, a user may find delicious drinks to be the most important aspect in a restaurant. Injection in the attention mechanism would bias the selection of words such as *wine*, *smooth*, and *sweet* to create the document encoding. This is the standard location in the model to inject the attributes, and several (Chen et al., 2016; Amplayo et al., 2018a) have shown how the injected attention mechanism selects different words when the given user or product is different.

We argue, however, that attention mechanism is not the best location to inject the attributes. This is because we cannot obtain user- or product-biased sentiment information from the representation. In the example above, although we may be able to select, with user bias, the words *wine* and *sweet* in the text, we do not know whether the user has a positive or negative sentiment towards these words (e.g., Does the user like wine? How about *sweet* wines? etc.). In contrast, the three other locations we discuss below use the attributes to modify how the model looks at sentiment at different levels of textual granularity.

In the word embedding Injecting attributes to the word embedding means that we bias the sentiment intensity of a word independent from its neighboring context. For example, if a user normally uses the words *tasty* and *delicious* with a less and more positive intensity, respectively, the corresponding attribute-injected word embeddings would come out less similar, despite both words being synonymous.

In the BiLSTM encoder Injecting attributes to the encoder means that we bias the contextualization of words based on their neighbors in the text. For example, if a user likes their cake sweet but their drink with no sugar, the attribute-injected encoder would give a positive signal to the encoding of *sweet* in the text "*the cake was sweet*" and a negative signal in the text "*the drink was sweet*".

In the logistic classifier Injecting attributes to the classifier means that we bias the probability

Datasets	C	#train	#dev	#test	#users	#products	#docs/user	#docs/product
IMDB	10	67,426	8,381	9,112	1,310	1,635	64.82	51.94
Yelp 2013	5	62,522	7,773	8,671	1,631	1,633	48.42	48.36
Yelp 2014	5	183,019	22,745	25,399	4,818	4,194	47.97	55.11

Table 1: Statistics of the datasets used for the Sentiment Classification task.

distribution of sentiment based on the final document encoding. If a user tends to classify the sentiment of reviews about sweet cakes as highly positive, then the model would give a high probability to highly positive sentiment classes for texts such as "*the cake was sweet*".

3 Experiments

3.1 General Setup

We perform experiments on two tasks. The first task is Sentiment Classification, where we are tasked to classify the sentiment of a review text, given additionally the user and product information as attributes. The second task is Attribute Transfer, where we attempt to transfer the attribute encodings learned from the sentiment classification model to solve two other different tasks: (a) Product Category Classification, where we are tasked to classify the category of the product, and (b) Review Headline Generation, where we are tasked to generate the title of the review, given only both the user and product attribute encodings. Datasets, evaluation metrics, and competing models are different for each task and are described in their corresponding sections.

Unless otherwise stated, our models are implemented with the following settings. We set the dimensions of the word, user, and product vectors to 300. We use pre-trained GloVe embeddings[2] (Pennington et al., 2014) to initialize the word vectors. We also set the dimensions of the hidden state of BiLSTM to 300 (i.e., 150 dimensions for each of the forward/backward hidden state). The chunk size factors C_1 and C_2 are both set to 15. We use dropout (Srivastava et al., 2014) on all non-linear connections with a dropout rate of 0.1. We set the batch size to 32. Training is done via stochastic gradient descent over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012) and with l_2 constraint (Hinton et al., 2012) of 3. We perform early stopping using the development set. Training and experiments are done using an NVIDIA GeForce GTX 1080 Ti graphics card.

3.2 Sentiment Classification

Datasets and Evaluation We use the three widely used sentiment classification datasets with user and product information available: IMDB, Yelp 2013, and Yelp 2014 datasets[3]. These datasets are curated by Tang et al. (2015), where they ensured twenty-core for both users and products (i.e., users have at least twenty products and vice versa), split them into train, dev, and test sets with an 8:1:1 ratio, and tokenized and sentence-split using the Stanford CoreNLP (Manning et al., 2014). Dataset statistics are shown in Table 1. Evaluation is done using two metrics: the accuracy which measures the overall sentiment classification performance, and RMSE which measures the divergence between predicted and ground truth classes.

Comparisons of different attribute representation and injection methods To conduct a fair comparison among the different methods described in Section 2, we compare these methods when applied to our base model using the development set of the datasets. Specifically, we use a smaller version of our base model (with dimensions set to 64) and incorporate the user and product attributes using nine different approaches: (1) **bias-attention**: the bias-based method injected to the attention mechanism, (2-5) the matrix-based method injected to four different locations (**matrix-embedding**, **matrix-encoder**, **matrix-attention**, **matrix-classifier**), and (6-9) the CHIM-based method injected to four different locations (**CHIM-embedding**, **CHIM-encoder**, **CHIM-attention**, **CHIM-classifier**). We then calculate the accuracy of each approach for all datasets.

Results are shown in Figure 3. The figure shows that bias-attention consistently performs poorly compared to other approaches. As expected, matrix-based representations perform the

[3] https://drive.google.com/open?id=1PxAkmPLFMnfom46FMMXkHeqIxDbA16oy

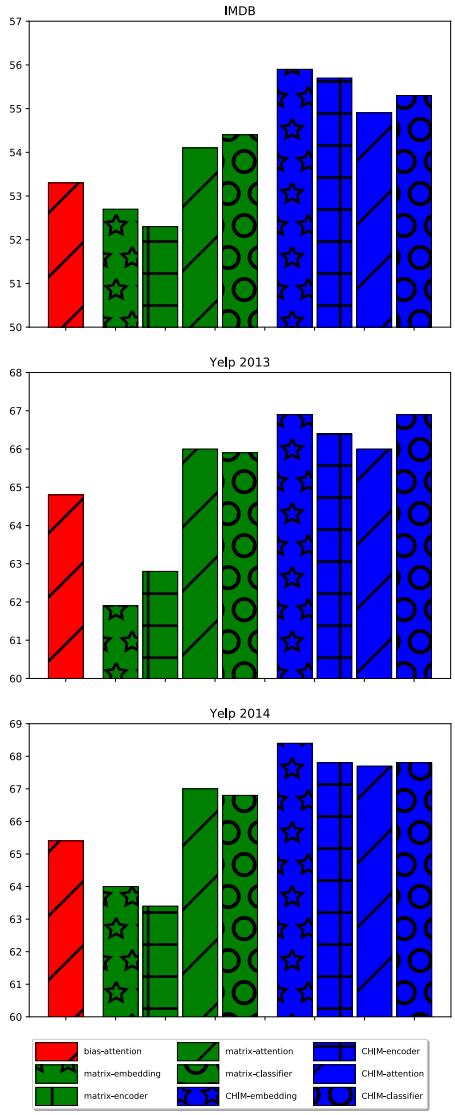

Figure 3: Accuracies (y-axis) of different attribute representation (bias, matrix, CHIM) and injection (emb: embed, enc: encode, att: attend, cls: classify) approaches on the development set of the datasets.

worst when injected to embeddings and encoder, however we can already see improvements over bias-attention when these representations are injected to attention and classifier. This is because the number of parameters used in the the weight matrices of attention and classifier are relatively smaller compared to those of embeddings and encoder, thus they are easier to optimize. The CHIM-based representations perform the best among other approaches, where CHIM-embedding garners the highest accuracy across datasets. Finally, even when using a better representation method, CHIM-attention consistently performs the worst among CHIM-based representations. This shows that attention mechanism is not the optimal location to inject attributes.

Comparisons with models in the literature We also compare with models from previous work, listed below:

1. **UPNN** (Tang et al., 2015) uses a CNN classifier as base model and incorporates attributes as user- and product-specific weight parameters in the word embeddings and logistic classifier.

2. **UPDMN** (Dou, 2017) uses an LSTM classifier as base model and incorporates attributes as a separate deep memory network that uses other related documents as memory.

3. **NSC** (Chen et al., 2016) uses a hierarchical LSTM classifier as base model and incorporates attributes using the bias-attention method on both word- and sentence-level LSTMs.

4. **DUPMN** (Long et al., 2018) also uses a hierarchical LSTM as base model and incorporates attributes as two separate deep memory network, one for each attribute.

5. **PMA** (Zhu and Yang, 2017) is similar to NSC but uses external features such as the ranking preference method of a specific user.

6. **HCSC** (Amplayo et al., 2018a) uses a combination of BiLSTM and CNN as base model, incorporates attributes using the bias-attention method, and also considers the existence of cold start entities.

7. **CMA** (Ma et al., 2017) uses a combination of LSTM and hierarchical attention classifier as base model, incorporates attributes using the bias-attention method, and does this separately for user and product.

Notice that most of these models, especially the later ones, use the bias-attention method to represent and inject attributes, but also employ a more complex model architecture to enjoy a boost in performance.

Results are summarized in Table 2. On all three datasets, our best results outperform all previous models based on accuracy and RMSE. Among our four models, CHIM-embedding performs the best in terms of accuracy, with performance increases of 2.4%, 1.3%, and 1.6% on IMDB, Yelp 2013,

Model			IMDB		Yelp 2013		Yelp 2014	
Name	Base Model	Injection	Acc	RMSE	Acc	RMSE	Acc	RMSE
UPNN	CNN	embedding, classifier	43.5	1.602	59.6	0.748	60.8	0.764
UPDMN	LSTM	memory networks	46.5	1.351	63.9	0.662	61.3	0.720
NSC	HierLSTM	attention	53.3	1.281	65.0	0.692	66.7	0.654
DUPMN	HierLSTM	memory networks	53.9	1.279	66.2	0.667	67.6	0.639
PMA	HierLSTM	attention[1]	54.0	1.301	65.8	0.668	67.5	0.641
HCSC	BiLSTM+CNN	attention[2]	54.2	1.213	65.7	0.660	–	–
CMA	LSTM+HierAtt	attention[3]	54.0	1.191	66.4	0.677	67.6	0.637
	BiLSTM	embedding	**56.4**	**1.161**	**67.8**	0.646	**69.2**	0.629
CHIM	BiLSTM	encoder	55.9	1.234	67.0	0.659	68.4	0.631
(Ours)	BiLSTM	attention	54.4	1.219	66.5	0.664	68.5	0.634
	BiLSTM	classifier	55.5	1.219	67.5	**0.641**	68.9	**0.622**

Table 2: Sentiment classification results of competing models based on accuracy and RMSE metrics on the three datasets. Underlined values correspond to the best values for each block. **Boldfaced** values correspond to the best values across the board. [1]uses additional external features, [2]uses a method that considers cold-start entities, [3]uses separate bias-attention for user and product.

and Yelp 2014, respectively. CHIM-classifier performs the best in terms of RMSE, outperforming all other models on both Yelp 2013 and 2014 datasets. Among our models, CHIM-attention mechanism performs the worst, which shows similar results to our previous experiment (see Figure 3). We emphasize that our models use a simple BiLSTM as base model, and extensions to the base model (e.g., using multiple hierarchical LSTMs as in Wu et al. 2018), as well as to other aspects (e.g., consideration of cold-start entities as in Amplayo et al. 2018a), are orthogonal to our proposed attribute representation and injection method. Thus, we expect a further increase in performance when these extensions are done.

3.3 Attribute Transfer

In this section, we investigate whether it is possible to transfer the attribute encodings, learned from the sentiment classification model, to other tasks: product category classification and review headline generation. The experimental setup is as follows. First, we train a sentiment classification model using an attribute representation and injection method of choice to learn the attribute encodings. Then, we use these fixed encodings as input to the task-specific model.

Dataset We collected a new dataset from Amazon[4], which includes the product category and the review headline, aside from the review text, the sentiment score, and the user and product attributes. Following Tang et al. (2015), we ensured that both users and products are twenty-core, split them into train, dev, and test sets with an 8:1:1 ratio, and tokenized and sentence-split the text using Stanford CoreNLP (Manning et al., 2014). The final dataset contains 77,028 data points, with 1,728 users and 1,890 products. This is used as the sentiment classification dataset.

To create the task-specific datasets, we split the dataset again such that no users and no products are seen in at least two different splits. That is, if user u is found in the train set, then it should not be found in the dev and the test sets. We remove the user-product pairs that do not satistfy this condition. We then append the corresponding product category and review headline for each user-product pair. The final split contains 46,151 training, 711 development, and 840 test instances. It also contains two product categories: Music and Video DVD. The review headline is tokenized using SentencePiece[5] with 10k vocabulary. The datasets are released here for reproducibility: https://github.com/rktamplayo/CHIM.

Evaluation In this experiment, we compare five different attribute representation and injection methods: (1) the bias-attention method, and (2-5) the CHIM-based representation method in-

[5]https://github.com/google/sentencepiece

Method	Accuracy	Perplexity
Majority	60.12	–
Random	60.67 ± 0.27	43.53
Bias - Attention	58.74 ± 0.49	44.00
CHIM - Embedding	62.26 ± 0.22	42.71
CHIM - Encoder	64.62 ± 0.34	42.65
CHIM - Attention	60.95 ± 0.15	42.78
CHIM - Classifier	61.83 ± 0.43	42.69

Table 3: Accuracy (higher is better) and perplexity (lower is better) of competing models on the Amazon dataset for the transfer tasks on product category classification and review headline generation, respectively. Accuracy intervals are calculated by running the model 10 times. Performance worse than the random and majority baselines are colored red.

jected to all four different locations in the model. We use the attribute encodings, which are learned from pre-training on the sentiment classification dataset, as input to the transfer tasks, in which they are fixed and not updated during training. As a baseline, we also show results when using encodings of randomly set weights. Moreover, we additionally show the majority class as additional baseline for product category classification.

For the product category classification task, we use a logistic classifier as the classification model and accuracy as the evaluation metric. For the review headline generation task, we use an LSTM decoder as the generation model and perplexity as the evaluation metric.

Results For the product category classification task, the results are reported in Table 3. The table shows that representations learned from CHIM-based methods perform better than the random baseline. The best model, CHIM-encoder, achieves an increase of at least 3 points in accuracy compared to the baseline. This means that, interestingly, CHIM-based attribute representations have also learned information about the category of the product. In contrast, representations learned from the bias-attention method are not able to transfer well on this task, leading to worse results compared to the random and majority baseline. Moreover, CHIM-attention performs the worst among CHIM-based models, which further shows the ineffectiveness of injecting attributes to the attention mechanism.

Results for the review headline generation task are also shown in Table 3. The table shows less promising results, where the best model, CHIM-encoder, achieves a decrease of 0.88 points in perplexity from the random encodings. Although this still means that some information has been transferred, one may argue that the gain is too small to be considered significant. However, it has been well perceived, that using only the user and product attributes to generate text is unreasonable, since we expect the model to generate coherent texts using only two vectors. This impossibility is also reported by Dong et al. (2017) where they also used sentiment information, and Ni and McAuley (2018) where they additionally used learned aspects and a short version of the text to be able to generate well-formed texts. Nevertheless, the results in this experiment agree to the results above regarding injecting attributes to the attention mechanism; bias-attention performs worse than the random baseline, and CHIM-attention performs the worst among CHIM-based models.

3.4 Where should attributes be injected?

All our experiments unanimously show that (a) the bias-based attribute representation method is not the most optimal method, and (b) injecting attributes in the attention mechanism results to the worst performance among all locations in the model, regardless of the representation method used. The question "where is the best location to inject attributes?" remains unanswered, since different tasks and settings produce different best models. That is, CHIM-embedding achieves the best accuracy while CHIM-classifier achieves the best RMSE on sentiment classification. Moreover, CHIM-encoder produces the most transferable attribute encoding for both product category classification and review headline generation. The suggestion then is to conduct experiments on all locations and check which one is best for the task at hand.

Finally, we also investigate whether injecting in to more than one location would result to better performance. Specifically, we jointly inject in two different locations at once using CHIM, and do this for all possible pairs of locations. We use the smaller version of our base model and calculate the accuracies of different models using the development set of the Yelp 2013 dataset. Figure 4 shows a heatmap of the accuracies of jointly injected models, as well as singly injected models. Overall, the results are mixed and can be summa-

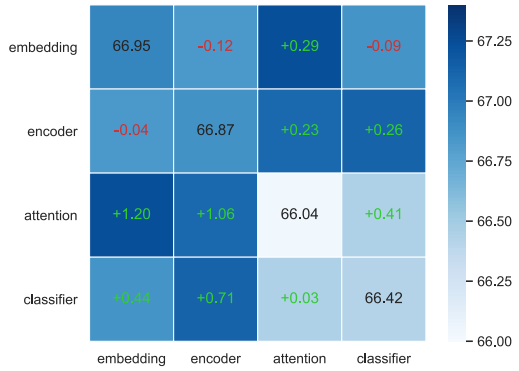

Figure 4: Heatmap of the accuracies of singly and jointly injected CHIM models. Values on each cell represents either the accuracy (for singly injected models) or the difference between the singly and doubly injected models per row.

rized into two statements. Firstly, injecting on the embedding and another location (aside from the attention mechanism) leads to a slight decrease in performance. Secondly and interestingly, injecting on the attention mechanism and another location always leads to the highest increase in performance, where CHIM-attention+embedding performs the best, outperforming CHIM-embedding. This shows that injecting in different locations might capture different information, and we leave this investigation for future work.

4 Related Work

4.1 Attributes for Sentiment Classification

Aside from user and product information, other attributes have been used for sentiment classification. Location-based (Yang et al., 2017) and time-based (Fukuhara et al., 2007) attributes help contextualize the sentiment geographically and temporally. Latent attributes that are learned from another model have also been employed as additional features, such as latent topics from a topic model (Lin and He, 2009), latent aspects from an aspect extraction model (Jo and Oh, 2011), argumentation features (Wachsmuth et al., 2015), among others. Unfortunately, current benchmark datasets do not include these attributes, thus it is practically impossible to compare and use these attributes in our experiments. Nevertheless, the methods in this paper are not limited to only user and product attributes, but also to these other attributes as well, whenever available.

4.2 User/Product Attributes for NLP Tasks

Incorporating user and product attributes to NLP models makes them more personalized and thus user satisfaction can be increased (Baruzzo et al., 2009). Examples of other NLP tasks that use these attributes are text classification (Kim et al., 2019), language modeling (Jaech and Ostendorf, 2018), text generation (Dong et al., 2017; Ni and McAuley, 2018), review summarization (Yang et al., 2018b), machine translation (Michel and Neubig, 2018), and dialogue response generation (Zhang et al., 2017). On these tasks, the usage of the bias-attention method is frequent since it is trivially easy and there have been no attempts to investigate different possible methods for attribute representation and injection. We expect this paper to serve as the first investigatory paper that contradicts to the positive results previous work have seen from the bias-attention method.

5 Conclusions

We showed that the current accepted standard for attribute representation and injection, i.e. bias-attention, which incorporates attributes as additional biases in the attention mechanism, is the least effective method. We proposed to represent attributes as chunk-wise importance weight matrices (CHIM) and showed that this representation method significantly outperforms the bias-attention method. Despite using a simple BiLSTM classifier as base model, CHIM significantly outperforms the current state-of-the-art models, even when those models use a more complex base model architecture. Furthermore, we conducted several experiments that conclude that injection to the attention mechanism, no matter which representation method is used, garners the worst performance. This result contradicts previously reported conclusions regarding attribute injection to the attention mechanism. Finally, we show promising results on transferring the attribute representations from sentiment classification, and use them to two different tasks such as product category classification and review headline generation.

Abstract

Emotion cause analysis, which aims to identify the reasons behind emotions, is a key topic in sentiment analysis. A variety of neural network models have been proposed recently, however, these previous models mostly focus on the learning architecture with local textual information, ignoring the discourse and prior knowledge, which play crucial roles in human text comprehension. In this paper, we propose a new method to extract emotion cause with a hierarchical neural model and knowledge-based regularizations, which aims to incorporate discourse context information and restrain the parameters by sentiment lexicon and common knowledge. The experimental results demonstrate that our proposed method achieves the state-of-the-art performance on two public datasets in different languages (Chinese and English), outperforming a number of competitive baselines by at least 2.08% in F-measure.

1 Introduction

Sentiment analysis has gained increasing popularity in recent years due to many useful applications (Pang and Lee, 2007). The goal of sentiment analysis is to classify the sentiment polarity of a given text as positive, negative, neutral, or more fine-grained classes (Kim, 2014; Li et al., 2015; Yang et al., 2016; Zhou et al., 2016; Chen et al., 2017; Qian et al., 2017; Li et al., 2018b; Yu et al., 2018). Most of these researches have assumed that emotion expressions are already observed and try to identify the emotion categories from text. However, in practice, such as in product comments or political reviews, we may care more about the reason why the customers or critics hold the emotion rather than a simple category label. Because they can improve the quality of the products or services according to the emotion cause provided by users. Emotion cause analysis (ECA) aims to identify the reasons behind a certain emotion expression in an event text, for example:

Ex.1 *When the children saw the gifts I prepared carefully,* (c_{-2})*|they cheered happily and hugged me.* (c_{-1})*| I was full of happiness.* (c_0)

Here, **Ex.1** shows a document with three clauses marked as (c_{-2}), (c_{-1}), and (c_0). The goal of ECA is to determine which clause contains emotion cause (e.g., (c_{-1})) for an emotion word (e.g., *happiness* in (c_0)).

Previous approaches for emotion cause analysis mostly depend on rule-based methods (Lee et al., 2010; Chen et al., 2010) and machine learning algorithms (Ghazi et al., 2015; Gui et al., 2016; Xu et al., 2019). Most of them rely heavily on complicated linguistic rules or feature engineering, which is time-consuming and labor-intensive. Recent studies have focused on solving the task using neural models (Gui et al., 2017; Li et al., 2018a; Chen et al., 2018; Li et al., 2019) with well designed attention mechanism based on local text. Despite the effectiveness of neural models, there are some defects in previous studies. First, they usually consider each clause individually, i.e., ignoring the discourse context information that can impact the semantic expression among different clauses of a document. Second, prior knowledge such as sentiment lexicon and relative position information that can provide crucial emotion cause cues has not been fully exploited in neural models.

To alleviate these limitations, we propose a regularized hierarchical neural network (RHNN) for emotion cause analysis, which combines the discourse context information and knowledge-based regularizations. Our model investigates the following intuitions. Firstly, documents exhibit discourse structure which may carry valuable information about the emotion cause cues. We em-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5614–5624, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ploy a hierarchical learning structure to capture the mutual impacts of semantic expression among the discourse context, to help produce better clause representation. Secondly, in emotion events, emotion causes usually express a certain sentiment polarity by some sentiment words. For example, in the emotion cause of **Ex.1**, the sentiment words *cheered* and *happily* express a positive polarity, also play a crucial role to provoke the emotion *happiness*. Therefore, capturing these sentiment words can enhance the causal connection between learned features and predictions. We approach this issue by designing a regularizer that incorporates linguistic knowledge (e.g., sentiment lexicon) to enlarge the margin of attention weights of sentiment words and non-sentiment words. Besides, it is often the case that humans usually write important points in different sections. For emotion events, emotion causes generally occur on positions very close to the emotion word and occur frequently. **Ex.1** shows an anecdotal example illustrating this behavior that the emotion cause clause c_{-1} adjoins the emotion word *happiness*. To benefit from this phenomenon, we introduce a regularizer biased by relative position information to supervise the representation learning of text and further to revise the **predictive position distribution of emotion causes relative to the emotion word** (in brief, predictive distribution).

To sum up, our contribution includes:

- We propose a novel discourse-aware learning structure with knowledge-based regularizations for emotion cause analysis.
- We empirically evaluate the proposed model on two public datasets in different languages (Chinese and English) and show statistically significant improvements compared to the state-of-the-art methods.
- To make the mechanism of our model clear, we also compare the performance of different combinations by ablation experiments. Extensive analysis on both datasets confirms the feasibility of incorporating discourse information and restraining the parameters by sentiment lexicon and common knowledge.

2 Our Framework

In this section, we first give the task definition. Then, our proposed regularized hierarchical neural network (RHNN), as shown in Fig 1, will be described. The two auxiliary regularizers of RHNN will be introduced in the next section.

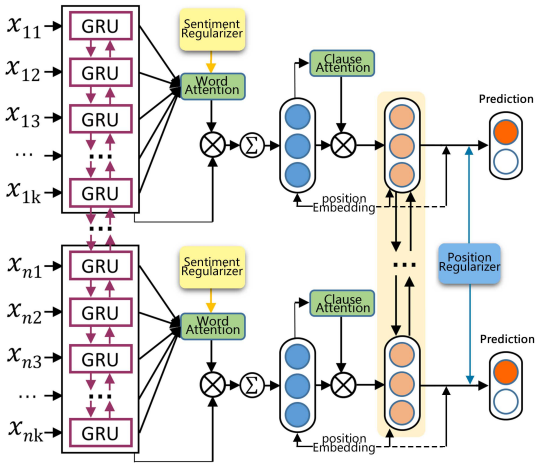

Figure 1: The architecture of our model.

2.1 Task Definition

The formal definition of emotion cause analysis is given in (Gui et al., 2016). Formally, for a document $d = \{c_1, c_2, \ldots, c_n\}$ consisting of n clauses, it contains an emotion word e and at least an emotion cause clause corresponding to this emotion word. Each clause $c_i = \{w_{i1}, w_{i2}, \ldots, w_{ik}\}$ consists of k words and is labeled with emotion cause-oriented labels $\in \{0, 1\}$. We regard ECA as a binary classification task and aim to identify which clause contains emotion cause.

2.2 Hierarchical Attention Network

Documents exhibit discourse structure which can serve as useful information for clause representation generation. One simple but effective approach is to adopt a hierarchical attention network to simulate this structure. Our hierarchical attention network consists of several parts: a word encoder, a word attention layer, a clause attention layer and a clause encoder. The details of each component will be described in the following paragraphs.

Word Encoder Gated Recurrent Unit (GRU) has been widely adopted for text processing (Cho et al., 2014). In this work, we first map each word into a low dimensional embedding space by Word2Vec (Mikolov et al., 2013) and then feed the whole document into a GRU-based word encoder to extract word sequence features. To summarize information from both directions, we use bidirec-

tional GRU to exploit two parallel passes:

$$\overrightarrow{h_{it}} = \overrightarrow{\mathrm{GRU}_w}(x_{it}), t \in [1, k] \quad (1)$$

$$\overleftarrow{h_{it}} = \overleftarrow{\mathrm{GRU}_w}(x_{it}), t \in [k, 1] \quad (2)$$

where x_{it} is embedding vector for the word w_{it} in clause c_i at time step t and k is the length of clause c_i. Then we concatenate hidden states of the two directions $h_{it} = [\overrightarrow{h_{it}}, \overleftarrow{h_{it}}]$ as the representation of each word.

Word Attention We introduce an attention mechanism to extract such words that are important to the meaning of the clause and aggregate the representation of these informative words to construct the clause vector. Specifically,

$$g_{it} = w_m^T(h_{it} \oplus e^E) \quad (3)$$

$$\alpha_{it} = \frac{\exp(g_{it})}{\sum_{t'} \exp(g_{it'})} \quad (4)$$

$$o_{c_i} = \sum_t \alpha_{it} h_{it} \quad (5)$$

where w_m is the parameter for computing attention signals and $\oplus$ is concatenate operation. The embedding of emotion word e is denoted by e^E. α_{it} is the emotion-specific attention signal showing the importance of word w_{it}. o_{c_i} is the weighted sum of word representation based on weights.

Clause Attention Intuitively, different clauses of a document are different informative and should be labeled with different importance. Targeting this problem, we design a clause attention mechanism to indicate the importance of each clause. See it differently, the attention signals can be regarded as some "prior" information to bias the clause encoder toward some content that is more important to extracting the emotion cause.

As for details, we adopt a one-layer MLP to get the attention signals. Apparently, position information plays an important role in capturing the relative distance of the clause to emotion word. Thus, we concatenate the clause vector o_{c_i} and its position embedding as the feature to obtain the attention signal, this yields:

$$\alpha_i = \mathrm{sigmoid}(w_v(o_{c_i} \oplus l_i)) \quad (6)$$

$$o'_{c_i} = o_{c_i} \cdot \alpha_i \quad (7)$$

where w_v is a parameter vector, l_i is the randomly initialized position embedding and keeps unchanged in the training stage, α_i is the weight of clause c_i. Then the clauses with different importance (e.g., o'_{c_i}) are fed into a clause encoder.

Clause Encoder Just as the meaning of a word is determined by its context, the semantic expression of a clause is usually impacted by its discourse context. Based on this observation, we introduce a clause encoder to model the latent semantic relations among different clauses. Analogously, we also append the relative position information to enhance the relations between the clause and its position. Formally,

$$\overrightarrow{h_i} = \overrightarrow{\mathrm{GRU}_c}(o'_{c_i} \oplus l_i), i \in [1, n] \quad (8)$$

$$\overleftarrow{h_i} = \overleftarrow{\mathrm{GRU}_c}(o'_{c_i} \oplus l_i), i \in [n, 1] \quad (9)$$

where n is the number of clauses in a document. Also, the two directional hidden state $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ are concatenated as the final emotion-specific representation $o_i = [\overrightarrow{h_i}, \overleftarrow{h_i}]$.

2.3 Model Training

The emotion-specific representation o_i with its position embedding l_i as the final feature for emotion cause prediction and the model is trained by minimizing the cross entropy:

$$y_i = \mathrm{softmax}(W_m(o_i \oplus l_i)) \quad (10)$$

$$\mathcal{L}_{ce} = -\sum_i \widehat{y}_i \log y_i \quad (11)$$

where W_m is a parameter matrix, $\widehat{y}_i$ and y_i are target class distribution and predictive class distribution respectively.

3 Regularizers Based on Sentiment Lexicon and Relative Position

One crucial emotion cause cue is sentiment words since emotion causes usually express a certain sentiment polarity by sentiment words. However, there is no effective mechanism to guarantee that the above module indeed attends the words with sentiment polarity. Beyond this, a straightforward solution to inject position information is to directly incorporate relative word position embedding, which is a weak representation of the relative distance between the emotion word and each clause. To ease these problems, we introduce two auxiliary regularizers:

- **Sentiment Regularizer (SR.):** If a clause contains several words which exist in a sentiment lexicon, the calculated average weights of these words should be properly larger than other words. We approach this issue with an auxiliary hinge loss function.

- **Position Regularizer (PR.):** Relative position is a critical emotion cause indicator: in general the closer a clause is to the emotion word, the higher emotion cause probability it should be assigned. We approach this issue by introducing a proxy distribution and an auxiliary cross entropy function.

Formally, we disassemble the joint loss of emotion cause detection into an original cross entropy loss, a sentiment regularization loss, and a position regularization loss. The new training objective is revised as:

$$\mathcal{J}(\theta) = \mathcal{L}_{ce} + \lambda_1 * \mathcal{L}_{sr} + \lambda_2 * \mathcal{L}_{pr} \quad (12)$$

where $\mathcal{L}_{ce}$ is the original cross entropy loss (§2.3). λ_1 and λ_2 are hyper-parameters. $\mathcal{L}_{sr}$ and $\mathcal{L}_{pr}$ are two auxiliary regularization losses (§3.1 and §3.2). θ is the parameter set.

3.1 Sentiment Regularizer

The weak causal connection between learned features and predictions is a major issue in emotion cause analysis. Even though sentiment words are key to clause representation generation, most existing models do not focus on sentiment words or place less emphasis on them when producing clause representation. In other words, attention is distracted by irrelevant words with less sentiment polarity. To address this issue and sufficiently benefit from linguistic resources, we explicitly encourage the larger margin of attention weights between sentiment words and non-sentiment words using a sentiment lexicon. For sentiment words, the average attention weight is calculated by:

$$Avg_s = \frac{1}{l_s} \sum_{t=1}^{k} S_{w_{it}} \quad (13)$$

$$S_{w_{it}} = \begin{cases} \alpha_{it} & \text{if} \quad w_{it} \in c_i \cap \mathcal{S} \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

where w_{it} is the t-th word of clause c_i, k is the length of c_i and l_s is the number of sentiment words in c_i. α_{it} is the calculated attention weight in §2.2 and $\mathcal{S}$ is a sentiment lexicon. Correspondingly, for non-sentiment words:

$$Avg_{ns} = \frac{1}{l_{ns}} \sum_{t=1}^{k} NS_{w_{it}} \quad (15)$$

$$NS_{w_{it}} = \begin{cases} \alpha_{it} & \text{if} \quad w_{it} \in c_i - \mathcal{S} \\ 0 & \text{otherwise} \end{cases} \quad (16)$$

Our training objective is to lead the model to pay more attention to sentiment words. Thus, the regularization term is formally expressed as:

$$\mathcal{L}_{sr} = \sum_i \max(0, m - (Avg_s - Avg_{ns})) \quad (17)$$

where m is a hyper-parameter for margin.

3.2 Position Regularizer

Empirically, emotion causes usually occur at the positions which are very close to the emotion word. However, another main issue is that the predictive distribution may locates the clauses that are distant from and irrelevant to the emotion word. The goal of this regularizer is to narrow the difference between the predictive distribution and the **true position distribution of emotion causes relative to the emotion word** (in brief, true distribution). Obviously we can not obtain the true distribution. Hence, we assume that it should satisfy the following conditions: (1) It should be a normed function within $[0, 1]$; (2) It should be a symmetric function of a certain value. Based on these conditions, we employ a function defined as follows:

$$q_i = \begin{cases} 1 - \frac{|r_i|}{n} & \text{if} - b \leq r_i \leq b \\ 0 & \text{otherwise} \end{cases} \quad (18)$$

where r_i is the relative distance of clause c_i to emotion word, n is the number of clauses in a document, and b is the left and right boundary which limits the scope of emotion cause. Then we apply $q = (q_1, q_2, \ldots, q_n)$ as the proxy distribution to simulate the true distribution.

Simultaneously, from section 2.3, we get the predictive class distribution y_i of clause c_i. Then, the probability for the emotion cause at position i can be calculated as:

$$p_i = y_i(label = 1) \quad (19)$$

Similarity, we can obtain the predictive distribution of emotion causes relative to the emotion word by:

$$p = (p_1, p_2, \ldots, p_n) \quad (20)$$

The goal is to enforce the model to constrain the difference between the p and q, thus, we use cross entropy to measure the difference:

$$\mathcal{L}_{pr} = -\sum_i q_i \log(p_i) \quad (21)$$

Note that the two introduced regularizers work like L_1 and L_2 terms, which **do not introduce**

any new parameters and only influence the training of the standard model parameters. The hyper-parameters λ_1 and λ_2 guide the model to achieve the best trade-off among three types of losses.

4 Datasets and Implementation Details

4.1 Datasets

We select two public datasets from different languages to evaluate the proposed model: Chinese Dataset (Gui et al., 2016) collected from SINA city news[1] and English Dataset (Gao et al., 2017) collected from English novels. Each document of both datasets has only one emotion word and one or more emotion causes. It has been ensured that the emotion and the causes are relevant. The documents are segmented into several clauses manually for emotion cause analysis. The details about the two datasets are summarized in Table 1.

4.2 Implementation Details

For the Chinese dataset, there is no training/test split, we randomly divide the documents into a training/development/test set in a ratio of 8:1:1 and partition the clauses by Jieba[2]. For the English dataset, we randomly select 10% from the original training set as the development set and lowercase, lemmatize all the tokens by NLTK[3]. We evaluate our method 25 times with different splits and then perform one sample t-test on the experimental results by following (Gui et al., 2017). The precision (P), recall (R) and F-measure (F) are employed to measure the performance in this task.

The sentiment lexicon adopted for the Chinese dataset consists of two parts. The first part is selected from HowNet (Dong et al., 2006) sentiment analysis lexicon set[4] and the second part comes from NTUSD (Ku et al., 2006). The combination of the two parts serves as the Chinese sentiment lexicon of this research. The English sentiment lexicon comes from MPQA (Wilson et al., 2005) and we only select the words with high sentiment polarity, because they are less sensitive to contextual information and usually express consistence sentiment polarities from their prior polarity. For both sentiment lexica, we filter out the words that are not in the datasets. Ultimately, 2022 and 1348 sentiment words are selected for the Chinese and English dataset respectively.

Online learning is performed with the Adam optimizer (Kingma and Ba, 2015) and initial learning rate 0.001 is adopted. The number of layers in Bi-GRU is set to 2 and dropout rate 0.5 is used to avoid overfitting. The word vectors are pre-trained by word2vec (Mikolov et al., 2013) and keep unchanged during training stage. We perform grid search over the hyper-parameters m ($\{0.10, 0.15, 0.20\}$), the boundary b ($\{2, 3, 4\}$), the dimensionality of the Bi-GRU ($\{64, 128\}$), λ_1 and λ_2 (both $\{0.25, 0.5, 0.75\}$). For each corpus, the highest F-measure combination of these hyper-parameters is selected using development set.

5 Experiments

In this section, we will compare our RHNN model with the following groups of methods:

- Rule-based and commonsense-based methods: Rule-based method (**RB**) is a traditional rule-based method proposed by Lee et al. (2010). Commonsense-based methods (**CB**) is a knowledge-based method proposed by Russo et al. (2011). It uses Chinese Emotion Cognition Lexicon (Xu et al., 2013) as commonsense knowledge.

- Machine learning method: **SVM** is a SVM classifier trained on unigrams, bigrams and trigrams features (Li and Xu, 2014). **Word2vec** is a SVM classifier trained on word representations pre-trained by Word2vec (Mikolov et al., 2013). **Multi-kernel** represents a document by a syntactic structure and utilizes a modified convolution kernel method to determine which clause contains the emotion cause (Gui et al., 2016).

LambdaMART extracts emotion causes using learning to rank methods which based on the emotion-independent and emotion-dependent features (Xu et al., 2019).

- Deep learning method: **CNN** is a convolutional neural network for sentence classification (Kim, 2014). **ConvMS-Memnet** considers emotion cause analysis as a reading comprehension task and designs a multiple-slot deep memory network to model context information (Gui et al., 2017). **CANN** uses a co-attention neural network to identify emotion causes (Li et al., 2018a). **HCS** is proposed by Yu et al. (2019) using a multiple-level hierarchical network to detect the emotion causes. **MANN** is the current state-of-the-art method employing a multi-attention-based model for emotion cause extraction (Li et al., 2019). **RHNN** is our proposed model.

5.1 Main Results

The experimental results on both datasets are shown in Table 2 and Table 3, respectively. RB yields high precision but with low recall. CB has an opposite scenario from RB. A possible reason is that these linguistic-based methods depend on some cue words to identify the emotion cause, different rules or common sense may contain different cue words.

For the machine learning methods, SVM and Word2vec have similar performance on the Chinese dataset, but SVM outperforms Word2vec on the English dataset. The main reason is that the polysemantic phenomenon is more obvious in English expressions. Multi-kernel has better performance by capturing context information through a syntactic tree. LambdaMART, which is based on ranking strategy and global emotion features, performs best among feature-based methods. However, both Multi-kernel and LambdaMART rely on expensive human-based features and lack of expandability on different dataset.

Compared with CNN, ConvMS-Memnet models the context of each word and obtains better performance on both datasets. The co-attention based CANN captures the mutual relations between the emotion clause and each candidate clause, which has a comparable result with hierarchical-based HCS. MANN considers the interaction between the emotion clause and candidate clauses by designing a multi-attention mechanism and achieves the best performance among baselines.

The proposed RHNN model further improves the performance on both datasets as shown in the tables. The improvement is significant with p-value less than 0.001 in one sample t-test. Specifically, RHNN manages to boost the performance by 3.06% in F-measure compared to LambdaMART, which exhibits that by restraining the parameters with knowledge-based regularizations, RHNN is better to identify the emotion cause cues than feature engineering. RHNN also outperforms the current best-performing method MANN by 2.08% on the Chinese dataset and 6.47% on the English dataset in F-measure respectively. Furthermore, for the English dataset, our proposed model has balance performance in precision and recall. The reason for this phenomenon is that RHNN can capture more emotion cue (e.g., sen-

timent words) information to optimize the model extracting emotion causes more exactly.

5.2 Detailed Analysis

Ablations of RHNN Model The proposed RHNN model consists of three components, including hierarchical structure (H.), sentiment regularizer (SR.) and position regularizer (PR.). We conduct ablation experiments to reveal the effect of each component. As illustrated in Table 4, all models with the proposed component consistently improve upon the Base model, verifying the effectiveness of the proposed approach. Compare with H. and PR. model, the SR. improve the performance most. The main reason is that there are 55.24% and 66.49% of emotion causes which contain sentiment words on the Chinese dataset and English dataset respectively, enforcing the model to pay more attention to sentiment words can enhance the causal connection between learned features and predictions.

On the Chinese dataset, the RHNN achieves the best performance with a 7.62% improvement on

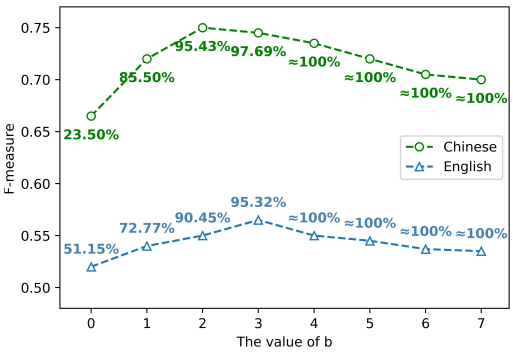

Figure 2: The F-measure of different limited scopes of emotion cause on two datasets.

the F score compared with the baseline. However, on the English dataset, the HSR model performs better than the RHNN model. It may be caused by the overlapping between components. Besides, the performance on the English dataset always lower about 20% in F-measure than that on the Chinese dataset, one possible explanation for this phenomenon is that there are more clause structures in English expressions which is difficult for the model to capture this information without discourse tree.

Effect of Sentiment Regularizer To gain more insights into our proposed model, we conduct further experiments to examine the effectiveness of sentiment regularizer on the subset of two datasets. The experiment results in Table 5 show that: 1) RHNN and HSR model achieve the best performance on the subset of two datasets respectively, similar observations can be found regarding on whole dataset; 2) With sentiment regularizer, the performance is boosted on both subsets compared to that on the whole dataset. This is consistent with our intuition because sentiment regularizer contributes much to pick up the words with sentiment polarity and these words are important causal indicators in clauses. Meanwhile, each clause contains sentiment words in the subsets, resulting in a better performance on the subsets. 3) The performance improvement on the English subset is remarkably higher than that on the Chinese subset, one possibility is that there are more explicit emotion terms in English expression than in Chinese.

Effect of Position Regularizer From Eq.(18), we see that the value of b limits the scope of emotion cause. In this section, we further investigate the effect of different limited scopes. For simplicity and efficiency, here we only apply the PR

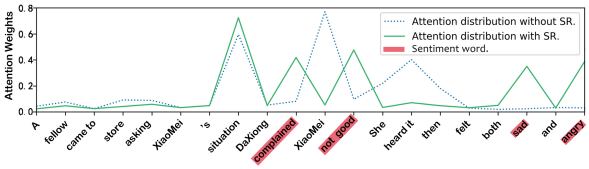

Figure 3: Comparison of attention distribution with or without sentiment regularizer.

model on this experiment. The results are shown in Fig 2, the percentages denote the coverage of emotion cause in datasets. For instance, 72.77% represents that there are 72.77% emotion causes adjoining the emotion word in English dataset. From Fig 2, we can see that the performance trends for the two datasets are similar, and the performance improves with the expanding limited scope of emotion cause. However, when the limited scope of emotion cause is larger than a certain value (2 or 3), the performance decreases. This may be due to the reason that the larger of limited scope, the higher coverage of emotion cause in datasets. Nevertheless, when the limited scope is too large, the model is forced to allocate higher probability to these clauses which are distant from and irrelevant to the emotion word, and then leads to the performance degradation.

5.3 Case Study

Essentially, sentiment regularizer (SR.) aims to enlarge the margin between sentiment words and non-sentiment words. The question is, will the model focus on the words with sentiment polarity? We randomly choose one example (**Ex.2**) from the Chinese dataset to visualize its attention distribution and compare the difference between plusing sentiment regularizer or not.

Ex.2 一个老乡来到店里问起小美的情况, (c_{-2})|大熊抱怨小美不好. (c_{-1})|她听到后感到既伤心又生气. (c_0)

Ex.2 *A fellow came to store asking XiaoMei's situation,* (c_{-2})*|DaXiong complained XiaoMei not good.* (c_{-1})*| She heard it then felt both sad and angry.* (c_0)

In this example, the cause of emotion word *sad* is in (c_0). The visualization results are shown in Fig 3, we can observe that the model without sentiment regularizer most focus on non-sentiment words such as *XiaoMei*, *she* and *heard it* which are inessential to provoke the emotion. However, when we plus the SR. into model, we can see an obvious weights shift on attention distribution.

Emotion cause events	RHNN results
1 ***I was immediately *ashamed* of myself for my vanity, for having assumed that he wanted me to stay with him forever.*** *I'm sorry, that was a little arrogant*	for having assumed that he wanted me to stay with him forever
2 ***He hopes of being *admitted* to a sight of the young ladies,*** *of whose beauty he had heard much. But he saw only the father.*	of whose beauty he had heard much
3 ***I didn't know where in the hell you was,*** *said Ennis, four years, I about *give up* on you.*	**Null**

Table 6: The error instances of RHNN model for emotion cause analysis.

More clearly, the model captures the sentiment words *complained* and *not good* which are crucial to identify the emotion cause. This shows that our model with sentiment regularizer is more effective in extracting the most important keywords relating to the emotion cause. Also, better results are obtained using sentiment regularizer, this is consistent with what we observed in Table 4.

Finally, we perform error analysis to understand what types of errors are introduced with the proposed model, focusing on three cases from the English dataset. The results are listed in Table 6, where the first column depicts the content of the emotion cause events and the second column depicts the emotion causes identified by RHNN. As shown in Table 6, the emotion causes appear in bold and emotion word is labeled between *.

From Table 6, we can find that there are two clauses contain the emotion cause in event 1. However, our model only detects one emotion cause clause. In event 2, our model has an error prediction. One possible reason is that our model is prone to treating clauses which contain sentiment words as emotion cause. RHNN extracts nothing from event 3, it may be due to the reason that the far distance between the emotion word and emotion cause clause, resulting in a difficult understanding of causal relations. Our proposed model is capable of getting rich emotion cause

cues with knowledge-based regularizations. However, it also introduces some noisy into emotion cause analysis.

6 Related Work

Emotion classification is an important fundamental aspect of sentiment analysis. Going one step further, emotion cause analysis (ECA) which aims to discover the reason behind emotions, can be constructive to guide the direction of future work, i.e., improving the quality of products or services according to the emotion causes of comments provided by users. In this section, we describe the related work on emotion cause analysis.

Lee et al. (2010) first gave the formal definition of emotion cause analysis and manually constructed a dataset from the Academia Sinica Balanced Chinese Corpus. Based on this corpus, Chen et al. (2010) designed two sets of features built on six groups of linguistic cues to detect emotion cause. Support vector machines (SVMs) and conditional random fields (CRFs) were investigated to detect cause or non-cause text with extended rule-based features in existing methods (Gui et al., 2014; Ghazi et al., 2015). Other than rule-based methods, Russo et al. (2011) proposed a crowdsourcing method to construct a commonsense knowledge base for emotion cause extraction in Italian newspaper articles. But it is challenging to extend the common-sense knowledge base automatically. Recently, Gui et al. (2016) proposed a multi-kernel based method to identify the emotion cause from a manually annotated emotion cause corpus. Xu et al. (2019) proposed a method based on learning to re-rank candidate emotion cause clauses with extracting a number of emotion-dependent and emotion-independent features. However, these methods are heavily dependent on the expensive human-based features and are too difficult in a real-world application.

Inspired by the success of neural network methods, deep neural models and attention mechanisms have been widely used in emotion cause analysis. Gui et al. (2017) proposed a novel deep neural network which regarded emotion cause analysis as a question-answering task. In this study, a convolution-based memory network was introduced to store the context information. Li et al. (2018a) considered the context around the emotion word as a query instead of only emotion word to model the mutual impacts between each candidate clause and the emotion clause. Cheng et al. (2017) constructed a corpus based on Chinese microblog and proposed to detect emotion cause using multiple-user structures. Besides, Yu et al. (2019) proposed a multiple-level hierarchical network-based clause selection strategy. Li et al. (2019) proposed a multi-attention-based neural model to capture the mutual influences between the emotion clause and each candidate clause, and then generate the representations for the above two clauses separately. This method achieves the current best performance. However, the existing approaches usually focus on the local textural information, ignoring the discourse structure (Zubiaga et al., 2018), and prior knowledge such as sentiment lexicon (Qian et al., 2017) and relative position information, which can provide important emotion cues for emotion cause analysis task.

7 Conclusion and Future Work

In this paper, we provide a regularized hierarchical neural network (RHNN) for emotion cause analysis. The proposed model aggregates discourse context information through a hierarchical learning structure and restrains the parameters with knowledge-based regularizations. We evaluate the proposed model on two public datasets in different languages. The experimental results demonstrate that our proposed method achieves the state-of-the-art performance on both datasets and extensive analysis confirms the feasibility of incorporating the discourse context and knowledge-based regularizations.

To preserve the simplicity of the proposed model, we do not consider document as a tree structure. In the future, we will exploit how to incorporate discourse parse tree or discourse relations into emotion cause analysis task to further improve the performance.

IBM Research

Abstract

We explore the task of automatic assessment of argument quality. To that end, we actively collected $6.3k$ arguments, more than a factor of five compared to previously examined data. Each argument was explicitly and carefully annotated for its quality. In addition, $14k$ pairs of arguments were annotated independently, identifying the higher quality argument in each pair. In spite of the inherent subjective nature of the task, both annotation schemes led to surprisingly consistent results. We release the labeled datasets to the community. Furthermore, we suggest neural methods based on a recently released language model, for argument ranking as well as for argument-pair classification. In the former task, our results are comparable to state-of-the-art; in the latter task our results significantly outperform earlier methods.

1 Introduction

Computational argumentation has been receiving growing interest in the NLP community in recent years (Reed, 2016). With this field rapidly expanding, various methods have been developed for subtasks such as argument detection (Lippi and Torroni, 2016; Levy et al., 2014; Rinott et al., 2015), stance detection (Bar-Haim et al., 2017) and argument clustering (Reimers et al., 2019).

Recently, IBM introduced *Project Debater*, the first AI system able to debate humans on complex topics. The system participated in a live debate against a world champion debater, and was able to mine arguments, use them for composing a speech supporting its side of the debate, and also rebut its human competitor.[1] The underlying technology is intended to enhance decision-making.

More recently, IBM also introduced *Speech by Crowd*, a service which supports the collection of free-text arguments from large audiences on debatable topics to generate meaningful narratives. A real-world use-case of Speech by Crowd is in the field of civic engagement, where the aim is to exploit the wisdom of the crowd to enhance decision making on various topics. There are already several public organizations and commercial companies in this domain, e.g., Decide Madrid[2] and Zencity.[3] As part of the development of Speech by Crowd, $6.3k$ arguments were collected from contributors of various levels, and are released as part of this work.

An important sub-task of such a service is the automatic assessment of argument quality, which has already shown its importance for prospective applications such as automated decision making (Bench-Capon et al., 2009), argument search (Wachsmuth et al., 2017b), and writing support (Stab and Gurevych, 2014). Identifying argument quality in the context of Speech by Crowd allows for the top-quality arguments to surface out of many contributions.

Assessing argument quality has driven practitioners in a plethora of fields for centuries from philosophers (Aristotle et al., 1991), through academic debaters, to argumentation scholars (Walton et al., 2008). An inherent difficulty in this domain is the presumably subjective nature of the task. Wachsmuth et al. (2017a) proposed a taxonomy of quantifiable dimensions of argument quality, comprised of high-level dimensions such as *cogency* and *effectiveness*, and sub-dimensions such as *relevance* and *clarity*, that together enable the assignment of a holistic quality score to an argument.

Habernal and Gurevych (2016b) and Simpson

*These authors equally contributed to this work.

and Gurevych (2018) take a relative approach and treat the problem as relation classification. They focus on *convincingness* – a primary dimension of quality – and determine it by comparing pairs of arguments with similar stance. In this view, the convincingness of an individual argument is a derivative of its relative convincingness: arguments that are judged as more convincing when compared to others are attributed higher scores. These works explore the labeling and automatic assessment of argument convincingness using two datasets introduced by Habernal and Gurevych (2016b): *UKPConvArgRank* (henceforth, *UKPRank*) and *UKPConvArgAll*, which contain $1k$ and $16k$ arguments and argument-pairs, respectively.

Gleize et al. (2019) also take a relative approach to argument quality, focusing on ranking convincingness of *evidence*. Their solution is based on a Siamese neural network, which outperforms the results achieved in Simpson and Gurevych (2018) on the *UKP* datasets, as well as several baselines on their own dataset, *IBM-ConvEnv*.[4]

Here, we extend earlier work in several ways: (1) introducing a large dataset of actively collected arguments, carefully annotated for quality; (2) suggesting a method for argument-pair classification, which outperforms state-of-the-art accuracy on available datasets; (3) suggesting a method for individual argument ranking, which achieves results comparable to the state of the art.

Our data was collected actively, via a dedicated user interface. This is in contrast to previous datasets, which were sampled from online debate portals. We believe that our approach to data collection is more controlled and reduces noise in the data, thus making it easier to utilize it in the context of learning algorithms (see Section 7).

Moreover, we applied various cleansing methods to ensure the high quality of the contributed data and the annotations, as detailed in Section 3.

We packaged our data in the following datasets, which are released to the research community[5]:

- *IBM-ArgQ-6.3kArgs* - the full dataset, comprised of all $6.3k$ arguments that were collected and annotated with an individual quality score in the range $[0, 1]$.
- *IBM-ArgQ-14kPairs* - $14k$ argument pairs annotated with a relative quality label, indicating which argument is of higher quality.
- *IBM-ArgQ-5.3kArgs* - the subset of $5.3k$ arguments from *IBM-ArgQ-6.3kArgs* that passed our cleansing process. This set is used in the argument ranking experiments in Section 9.2, henceforth: *IBMRank*.
- *IBM-ArgQ-9.1kPairs* - the subset of $9.1k$ argument pairs from *IBM-ArgQ-14kPairs* that passed our cleansing process, used in the argument-pair classification experiments in Section 9.1. Henceforth: *IBMPairs*.

The dataset *IBMRank* differs from *UKPRank* in a number of ways. Firstly, *IBMRank* includes $5.3k$ arguments, which make it more than 5 times larger than *UKPRank*. Secondly, the arguments in *IBMRank* were collected actively from contributors. Thirdly, *IBMRank* includes *explicit* quality-labeling of all individual arguments, which is absent from earlier data, enabling us to explore the potential of training quality-prediction methods on top of such labels, presumably easier to collect.

Finally, with the abundance of technologies such as automated personal assistants, we envision automated argument quality assessment expanding to applications that include oral communication. Such use-cases pose new challenges, overlooked by prior work, that mainly focused on written arguments. As an initial attempt to address these issues, in the newly contributed data we guided annotators to assess the quality of an argument within the context of using the argument as-is to generate a persuasive *speech* on the topic. Correspondingly, we expect these data to reflect additional quality dimensions – e.g., a quality premium on efficiently phrased arguments, and low tolerance to blunt mistakes such as typos that may lead to poorly stated arguments.

2 Argument Collection

As part of the development of Speech by Crowd, online and on-site experiments have been conducted, enabling to test the ability of the service to generate a narrative based on collected arguments. Arguments were collected from two main sources: (1) debate club members, including all levels, from novices to experts; and (2) a broad audience of people attending the experiments.

[4] As this work is relatively recent and was published after our submission, we were not able to compare to it.

[5] https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml#ArgumentQuality

For the purpose of collecting arguments, we first selected 11 well known controversial concepts, common in the debate world, such as *Social Media*, *Doping in Sports* and *Flu vaccination*. Using debate jargon, each concept is used to phrase two "motions", by proposing two specific and opposing policies or views towards that concept. For example, for the concept *Autonomous Cars*, we suggested the motions *We should promote Autonomous Cars* and *We should limit Autonomous Cars*.[6] The full list of motions appears in Table 1 with the number of arguments collected for each.[7]

Guidelines Contributors were invited to a dedicated user interface in which they were guided to contribute arguments per concept, using the following concise instructions:

> You can submit as many arguments as you like, both pro and con, using original language and no personal information (i.e. information about an identifiable person).

In addition, to exemplify the type of arguments that we expect to receive, contributors were shown an example of one argument related to the motion, provided by a professional debater. The arguments collected had to have $8 - 36$ words, aimed at obtaining efficiently phrased arguments (longer/shorter arguments were rejected by the UI). In total, we collected $6,257$ arguments.

Motion	#Args
Flu vaccination should be mandatory	204
Flu vaccination should not be mandatory	174
Gambling should be banned	342

3 Argument Quality Labeling

We explored two approaches to labeling argument quality: (a) labeling individual arguments (absolute approach): each individual argument is directly labeled for its quality; and (b) labeling argument pairs (relative approach): each argument pair is labeled for which of the two arguments is of higher quality. In this section we describe the pros and cons of each approach as well as the associated labeling process.

Approaches to Argument Quality Labeling

The effort in labeling individual arguments scales linearly with the number of arguments, compared to the quadratic scaling of labeling pairs (within the same motion); thus, it is clearly more feasible when considering a large number of arguments. However, the task of determining the quality of arguments in isolation is presumably more challenging; it requires to evaluate the quality of an argument without a clear reference point (except for the motion text). This is where the relative approach has its strength, as it frames the labeling task in a specific context of two competing arguments, and is expected to yield higher inter-annotator agreement. Indeed, a comparative approach is widely used in many NLP applications, e.g. in Chen et al. (2013) for assessing reading difficulty of documents and in Aranberri et al. (2017) for machine translation. In light of these considerations, here we decided to investigate and compare both approaches. We used the Figure Eight platform[8], with a relatively large number of $15 - 17$ annotators per instance, to improve the reliability of the collected annotations.

3.1 Labeling Individual Arguments

The goal of this task is to assign a quality score for each individual argument. Annotators were presented with the following binary question per argument:

> Disregarding your own opinion on the topic, would you recommend a friend preparing a speech supporting/contesting the topic to use this argument *as is* in the speech? (yes/no)

All arguments that were collected as described in

[6] Habernal and Gurevych (2016b) uses the term *topic* for what we refer to as *motion*.

[7] In Table 1, *vvg* stands for *violent video games*.

[8] http://figure-eight.com/

Section 2 were labeled in this task. We model the quality of each individual argument as a real value in the range of $[0, 1]$, by calculating the fraction of 'yes' answers. To ensure the annotators will carefully read each argument, the labeling of each argument started with a test question about the stance of the argument towards the concept (*pro* or *con*). The annotators' performance on these test questions was used in the quality control process described in Section 4, and also in determining which pairs of arguments to label.

3.2 Labeling Argument Pairs

In this task, annotators were presented with a pair of arguments, having the same stance towards the concept (to reduce bias due to the annotator's opinion), and were asked the following:

> Which of the two arguments would have been preferred by most people to support/contest the topic?

Table 2 presents an example of such an argument pair in which the annotators unanimously preferred the first argument.

Argument 1	Argument 2
Children emulate the media they consume and so will be more violent if you don't ban them from violent video games	These are less fun and more harmful games but specifically violent games are played in groups and exclude softer souls

Table 2: An example of an argument pair for the motion *We should ban the sale of violent video games to minors*. The first argument was unanimously preferred by all annotators.

As mentioned, annotating all pairs in a large collection of arguments is often not feasible. Thus, we focused our attention on pairs that are presumably most valuable to train a learning algorithm. Specifically, we annotated $14k$ randomly selected pairs, that satisfy the following criteria:

1. At least 80% of the annotators agreed on the stance of each argument, aiming to focus on clearly stated arguments.

2. Individual quality scores in each pair differ by at least 0.2, aiming for pairs with a relatively high chance of a clear winner.

3. The length of both arguments, as measured by number of tokens, differs by $\leq 20\%$, aiming to focus the task on dimensions beyond argument length.

4 Quality Control

To monitor and ensure the quality of collected annotations, we employed the following analyses:

Kappa Analysis –

1. Pairwise Cohen's kappa (κ) (Cohen, 1960) is calculated for each pair of annotators that share *at least* 50 common argument/argument pairs judgments, and based only on those common judgments.

2. *Annotator-*κ is obtained by averaging all pairwise κ for this annotator as calculated in Step 1, and if and only if this annotator had ≥ 5 pairwise κ values estimated. This is used to ignore annotators as described later.

3. Averaging all *Annotator-*κ, calculated in Step 2, results in *Task-Average-*κ.[9]

Test Questions Analysis – Hidden embedded test questions, based on ground truth, are often valuable for monitoring crowd work. In our setup, at least one fifth of the judgments provided by each annotator are on test questions. When annotators fail a test question, they are alerted. Thus, beyond monitoring annotator's quality, test questions also provide annotators feedback on task expectations. In addition, an annotator that fails more than a prespecified fraction (e.g., 20%) of the test questions is removed from the task, and his judgments are ignored.

High Prior Analysis – An annotator that always answers 'yes' to a particular question should obviously be ignored; more generally, we discarded the judgments contributed by annotators with a relatively high prior to answer positively on the presented questions.

Note, if an annotator is discarded due to failure in any of the above analyses, he is further discarded from the estimation of *Annotator-*κ and *Task-Average-*κ.

[9] It is noted that some annotators remain without valid *Annotator-*κ and cannot be filtered out based on their κ. Similarly, those annotators do not contribute to the *Task-Average-*κ. However, in both annotation tasks, those annotators contributed only $0.01 - 0.03$ of the judgments collected.

5 Data Cleansing

5.1 Cleansing of Individual Arguments Judgments

To enhance the quality of the collected data, we discard judgments by annotators who (1) failed $\geq 20\%$ of the test-questions[10]; and/or (2) obtained *Annotator-*$\kappa \leq 0.35$ in the stance judgment task; and/or (3) answered 'yes' for $\geq 80\%$ of the quality judgment questions. Finally, we discarded arguments that were left with less than 7 valid judgments. This process left us with $5.3k$ arguments, each with 11.4 valid annotations on average. The *Task-Average-*κ was 0.69 on the stance question and 0.1 on the quality question. We refer to the full, unfiltered, set as *IBM-ArgQ-6.3kArgs*, and to the filtered set as *IBM-ArgQ-5.3kArgs* (*IBMRank*).

For completeness, we also attempted to utilize an alternative data cleansing tool, MACE (Hovy et al., 2013). We ran MACE with a threshold k, keeping the top k percent of arguments according to their entropy. We then re-calculated *Task-Average-*κ on the resulting dataset. We ran MACE with k=0.95, as used in Habernal and Gurevych (2016b), and with k=0.85, as this results in a dataset similar in size to *IBMRank*. The resulting *Task-Average-*κ is 0.08 and 0.09, respectively, lower than our reported 0.1. We thus maintain our approach to data cleansing as described above.

The low average κ of 0.1 for quality judgments is expected due to the subjective nature of the task, but nonetheless requires further attention. Based on the following observations, we argue that the labels inferred from these annotations are still meaningful and valuable: (1) the high *Task-Average-*κ on the stance task conveys the annotators carefully read the arguments before providing their judgments; (2) we report high agreement of the individual quality labels with the argument-pair annotations, to which much better κ values were obtained (see Section 6.1); (3) we demonstrate that the collected labels can be successfully used by a neural network to predict argument ranking (see section 9.2), suggesting these labels carry a real signal related to arguments' properties.

5.2 Cleansing of Argument Pair Labeling

To enhance the quality of the collected pairwise data, we discard judgments by annotators who (1) failed $\geq 30\%$ of the test-questions; and/or (2) obtained *Annotator-*$\kappa \leq 0.15$ in this task. Here, the test questions were directly addressing the (relative) quality judgment of pairs, and not the stance of the arguments. In initial annotation rounds the test questions were created based on the previously collected individual arguments labels - considering pairs in which the difference in individual quality scores was ≥ 0.6.[11] In following annotation rounds, the test questions were defined based on pairs for which $\geq 90\%$ of the annotators agreed on the winning pair. Following this process we were left with an average of 15.9 valid annotations for each pair, and with *Task-Average-*κ of 0.42 on the quality judgments – a relatively high value for such a subjective task. As an additional cleansing, for training the learning algorithms, we considered only pairs for which $\geq 70\%$ of the annotators agreed on the winner, leaving us with a total of $9.1k$ pairs for training and evaluation. We refer to the full, unfiltered, set as *IBM-ArgQ-14kPairs*, and to the filtered set as *IBM-ArgQ-9.1kPairs*.

6 Data Consistency

6.1 Consistency of Labeling Tasks

Provided with both individual and pairwise quality labeling, we estimated the consistency of these two approaches. For each pair of arguments, we define the *expected winning argument* as the one with the higher *individual* argument score, and compare that to the *actual winning argument*, namely the argument preferred by most annotators when considering the pair directly. Overall, in 75% of the pairs the actual winner was the expected one. Moreover, when focusing on pairs in which the individual argument scores differ by > 0.5, this agreement reaches 84.3% of pairs.

6.2 Reproducibility Evaluation

An important property of a valid annotation is its reproducibility. For this purpose, a random sample of 500 argument pairs from the *IBMPairs* dataset was relabeled by the crowd. This relabeling took place a few months after the main annotation tasks, with the exact task and data cleansing methods that were employed originally. For measuring correlation, the following A_score was defined: the fraction of valid annotations selecting

[10] Since quality judgments are relatively subjective, we focused the test questions on the stance question.

[11] Note, that annotators have the option of contesting problematic test questions, and thus unfitting ones were disabled during the task by our team.

"argument A" in an argument pair (A, B) as having higher quality, out of the total number of valid annotations. Pearson's correlation coefficient between A_score in initial and secondary annotation of the defined sample was 0.81.

A similar process was followed with the individual arguments quality labeling. Instead of relabeling, we split existing annotations to two even groups. We chose only individual arguments in which at least 14 valid annotations remained after data cleansing ($1,154$ such arguments). This resulted in two sets of labels for the same data, each based on at least 7 annotations. Pearson's correlation coefficient between quality scores of the two sets was 0.53. We then divided the quality score, which ranges between 0 to 1, to 10 equal bins. The bin frequency counts between the two sets are displayed in the heatmap in Figure 1.

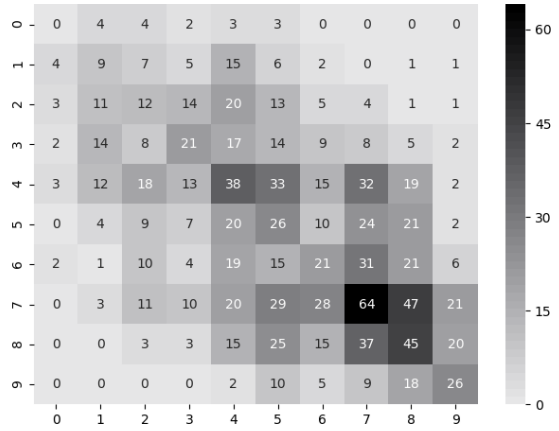

Figure 1: Counts of quality score bins between two equally sized sets of annotators.

6.3 Transitivity Evaluation

Following Habernal and Gurevych (2016b), we further examined to what extent our labeled pairs satisfy *transitivity*. Specifically, a triplet of arguments (A, B, C) in which A is preferred over B, and B is preferred over C, is considered transitive if and only if A is also preferred over C. We examined all 892 argument triplets for which all pair-wise combinations were labeled, and found that transitivity holds in 96.2% of the triplets, further strengthening the validity of our data.

7 Comparison of *IBMRank* and *UKPRank*

A distinctive feature of our *IBMRank* dataset is that it was collected actively, via a dedicated user interface with clear instructions and enforced length limitations. Correspondingly, we end up with cleaner texts, that are also more homogeneous in terms of length, compared to the *UKPRank* that relies on arguments collected from debate portals.

Text Cleanliness

We counted tokens representing a malformed span of text in *IBMRank* and *UKPRank*. These are HTML markup tags, links, excessive punctuation[12], and tokens not found in GloVE vocabulary (Pennington et al., 2014). Our findings show that 94.78% of *IBMRank* arguments contain no malformed text, 4.38% include one such token, and 0.71% include two such tokens. In the case of *UKPRank*, only 62.36% of the arguments are free of malformed text, 17.59% include one such token, and 20.05% include two or more tokens of malformed text.

Text Length

As depicted in Figure 2, the arguments in *IBMRank* are substantially more homogeneous in their length compared to *UKPRank*. A potential drawback of the length limitation is that it possibly prevents any learning system from being able to model long arguments correctly. However, by imposing this restriction we expect our quality labeling to be less biased due to argument length, holding greater potential to reveal other properties that contribute to argument quality. We confirmed this intuition with respect to the argument pair labeling as described in Section 9.1.

Data Size and Individual Argument Labeling

Finally, *IBMRank* covers $5,298$ arguments, compared to $1,052$ in *UKPRank*. In addition, in *UKPRank* no individual labeling is provided, and individual quality scores are inferred from pairs labeling. In contrast, for *IBMRank* each argument is individually labeled for quality, and we explicitly demonstrate the consistency of these individual labeling with the provided pairwise labeling.

8 Methods

In this section we describe neural methods for predicting the individual score and the pair-wise

[12] Sequences of three or more punctuation characters, e.g. *"?!?!?!"*

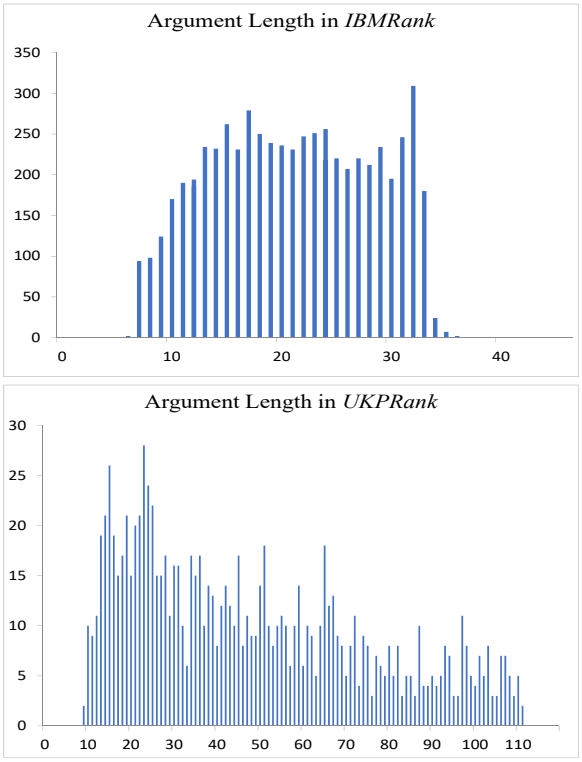

Figure 2: Histograms of argument length in *IBMRank* and *UKPRank*. X-axis: length (token count). Y-axis: the number of arguments at that length.

classification of arguments. We devise two methods corresponding to the two newly introduced datasets. Our methods are based upon a powerful language representational model named Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) which achieves state-of-the-art results on a wide range of tasks in NLP (Wang et al. (2018), Rajpurkar et al. (2016, 2018)). BERT has been extensively trained over large corpora to perform two tasks: (1) *Masked Language Model* - randomly replace words with a predefined token, `[MASK]`, and predict the missing word. (2) *Next Sentence Prediction* - given a pair of sentences `A` and `B`, predict whether sentence `B` follows sentence `A`. Due to its bidirectional nature, BERT achieves remarkable results when fine-tuned to different tasks without the need for specific modifications per task. For further details refer to Devlin et al. (2018).

8.1 Argument-Pair Classification

We fine-tune BERT's Base Uncased English pre-trained model for a binary classification task.[13] The fine-tuning process is initialized with weights from the general purpose pre-trained model and a task specific weight matrix $W_{out} \in R^{768\times 2}$ is added to the 12-layer base network. Following standard practice with BERT, given a pair of arguments `A` and `B`, we feed the network with the following sequence '`[CLS]A[SEP]B`'. The `[SEP]` token indicates to the network that the input is to be treated as a pair and `[CLS]` is a token which is used to obtain contextual embedding for the entire sequence. The network is trained for 3 epochs with a learning rate of 2^{-5}. We refer to this model as *Arg-Classifier*.

8.2 Argument Ranking

For training a model to output a score between $[0, 1]$ we obtain contextual embeddings from the Arg-Classifier fine-tuned model. We concatenate the last 4 layers of the model output to obtain an embedding vector of size $4 \times 768 = 3072$. The embedding vectors are used as input to a neural network with a single output and one hidden layer with 300 neurons. In order for the network to output values in $[0, 1]$, we use a sigmoid activation, $\sigma_{sigmoid}(x) = \frac{1}{1+e^{-x}}$. Denote the weight matrices $W_1 \in R^{3072\times 300}$ and $W_2 \in R^{300\times 1}$, the regressor model, f_R, is a 2-layered neural network with $\sigma_{relu}(x) = \max\{0, x\}$ activation. f_R can be written as:[14]

$$f_R(x) = \sigma_{sigmoid}\left(W_2^T \sigma_{relu}(W_1^T x)\right)$$

where $x \in R^{3072}$ is the embedding vector representing an argument. We refer to this regression model as *Arg-Ranker*.

9 Experiments

9.1 Argument-Pair Classification

In this section we evaluate the methods described in Section 8. First, we evaluate the accuracy of *Arg-Classifier* on our *IBMPairs* dataset and on *UKPConvArgStrict* (henceforth, *UKPStrict*), the filtered argument pairs dataset of Habernal and Gurevych (2016b), in k-fold cross-validation.[15] We calculate accuracy and ROC area under curve (AUC) for each fold, and report the weighted averages over all folds. We also evaluate Simpson and Gurevych (2018)'s *GPPL* median heuristic method with *GloVe + ling* features in cross-

[13] Initial experiments with BERT's Large model showed only minor improvements, so for the purpose of the experiments detailed in Section 9 we used the Base model.

[14] We omit bias terms for readability.

[15] 22 and 32 folds respectively.

validation on our *IBMPairs* dataset. For completeness, we quote Simpson and Gurevych (2018)'s figures of *GPPL opt.* and *GPC* on *UKPStrict*.[16] We add a simple baseline classifying arguments based on their token count (*Arg-Length*).

	IBMPairs		
	Arg-Length	Arg-Classifier	GPPL
Acc.	.55	**.80**	.71
AUC	.59	**.86**	.78

	UKPStrict				
	Arg-Length	Arg-Classifier	GPPL	GPPL opt.	GPC
Acc.	.76	**.83**	.79	.80	.81
AUC	.78	**.89**	.87	.87	**.89**

Table 3: Accuracy and AUC on *IBMPairs* and *UKPStrict*.

As can be seen in Tables 3, *Arg-Classifier* improves on the *GPPL* method on both datasets ($p \ll .01$ using two-tailed Wilcoxon signed-rank test).[17] We note that *Arg-Classifier*'s accuracy on the *UKPStrict* set is higher than all methods tested on this dataset in Habernal and Gurevych (2016b); Simpson and Gurevych (2018). Interestingly, all methods reach higher accuracy on *UKPStrict* compared to *IBMPairs*, presumably indicating that the data in *IBMPairs* is more challenging to classify. With regards to *Arg-Length*, we can see that it is inaccurate on *IBMPairs* but achieves a respectable result on *UKPStrict*. This is in agreement with Habernal and Gurevych (2016a) who analyzed the reasons that annotators provided for their labeling. In most cases the reason indicated preference for arguments with more information – which is what longer arguments tend to be better at. This further strengthens the value of creating *IBMPairs* and *IBMRank* as much more homogeneous datasets in terms of argument length.

9.2 Argument Ranking

We proceed to evaluate the *Arg-Ranker* on the *IBMRank* and *UKPRank* datasets in k-fold cross-validation, and report weighted correlation measures. We also evaluate the *Arg-Ranker* by feeding it vanilla BERT embeddings, instead of the fine-tuned embeddings generated by the *Arg-Classifier* model. We refer to this version as *Arg-Ranker-base*. In both *Arg-Ranker* and *Arg-Ranker-base* evaluations we report the mean of 3 runs.[18]

	IBMRank		UKPRank		
	Arg-Ranker-base	Arg-Ranker	Arg-Ranker-base	Arg-Ranker	GPPL
r	.41	**.42**	.44	**.49**	.45
ρ	.38	**.41**	.57	.59	**.65**

Table 4: Pearson's (r) and Spearman's (ρ) correlation of *Arg-Ranker-base*, *Arg-Ranker* and *GPPL* on the *IBMRank* and *UKPRank* datasets.

As can be seen in Table 4, on the *UKPRank* dataset, *Arg-Ranker* is slightly better than *GPPL* for Pearson's correlation, but slightly worse for Spearman's correlation. Additionally, using direct BERT embeddings provides worse correlation[19] than using the *Arg-Classifier* embeddings for both datasets, justifying its use. Finally, similarly to the findings in the argument-pair classification task, the *IBMRank* dataset is harder to predict.[20]

10 Error Analysis

We present a qualitative analysis of examples that the *Arg-Classifier* and *Arg-Ranker* models did not predict correctly. For each of the argument-pair and ranking tasks, we analyzed $50 - 100$ arguments from three motions on which the performance of the respective model was poor. For each motion we selected the arguments in which the model was most confident in the wrong direction.

A prominent insight from this analysis, common to both models, is that the model tends to fail when the argument persuasiveness outweighs its delivery quality (such as bad phrasing or typos). An example of this is shown in row 1 of Table 5. In this case, Argument2 is labeled as having a higher quality, even though it contains multiple typos, and thus is typical to arguments that the model was trained to avoid selecting.

Another phenomenon that both our models fail to address is arguments that are off-topic, too provocative or not grounded. An example of this, from the argument-pair task, is shown in row 2 - Argument2 is presumably considered harsh by annotators, even though it is fine in terms of gram-

[16] We were unable to reproduce the results reported in Simpson and Gurevych (2018) by running the *GPPL opt.* and *GPC* algorithms on the *UKPStrict* dataset. We have approached the authors and reported the issue, which was not solved by the time this paper was published, and hence we only quote the figures as reported there.

[17] The results per fold in both tasks are included in the supplementary material.

[18] The *GPPL* regressor of Simpson and Gurevych (2018) relies on pair-wise (relative) labeling of arguments and as a result it cannot be used for predicting the individual (absolute) labeling of arguments, as in *IBMRank*.

[19] Significantly for the *IBMRank* data on both measures, and for the *UKPRank* on Pearson's correlation, $p \ll .05$.

[20] For the experiments on *IBMRank*, we included by mistake a small fraction of arguments which actually should have been filtered. The effect on the results is minimal.

Motion	Type	Argument1	Argument2
We should ban fossil fuels	Impact over delivery	*the only way to provide any space for energy alternatives to enter the market is by artificially decreasing the power of fossil fuels through a ban.*	**fossil fuels are bad for the environment, they have so2 in them that is the thing that maks acid rain and it is today harming the environment and will only be wors.**
Flu vaccination should not be mandatory	Provocative or not grounded	**the only responsible persons for kids are their parents. if they dont think that their kids should get the vaccine its their own decision.**	*the body has an automatic vaccination due to evolution, those who got sick and died are the weakest link and we are better off without them*
We should abandon vegetarianism	Consistent annotator preference	**it's harder to get all the things you need for a balanced diet while being vegetarian.**	*animals deserve less rights than humans, and it is legitimate for humans to prioritize their enjoyment over the suffering of animals.*

Table 5: Examples of argument pairs for which there is a high difference between the argument selected by the annotators, marked in bold, and the argument predicted to be of higher quality by the model, marked in italics.

matical structure and impact on the topic. These types of arguments are becoming more important to recognize, especially in the "fake-news" era. We leave dealing with them for future work.

Finally, we also notice certain arguments were consistently preferred by annotators, regardless of the quality of the opposing argument. This is a pattern relevant only to the *Arg-Classifier* model, shown in row 3.

11 Conclusions and Future Work

A significant barrier in developing automatic methods for estimating argument quality is the lack of suitable data. An important contribution of this work is a newly introduced data composed of $6.3k$ carefully annotated arguments, compared to $1k$ arguments in previously considered data. Another barrier is the inherent subjectivity of the *manual* task for determining argument quality. To overcome this issue, we employed a relatively large set of crowd annotators to consider each instance, associated with various measures to ensure the quality of the annotations associated with the released data. In addition, while previous work focused on arguments collected from web debate portals, here we collected arguments via a dedicated interface, enforcing length limitations, and providing contributors with clear guidance. Moreover, previous work relied solely on annotating pairs of arguments, and used these annotations to *infer* the individual ranking of arguments; in contrast, here, we annotated all individual arguments for their quality, and further annotated $14k$ pairs. This two–fold approach allowed us, for the first time, to explicitly examine the relation between relative (pairwise) annotation and explicit (individual) annotation of argument quality. Our analysis suggests that these two schemes provide relatively consistent results. In addition, these annotation efforts may complement each other. As pairs of arguments with a high difference in individual quality scores appear to agree with argument-pair annotations, one may deduce the latter from the former. Thus, it may be beneficial to dedicate the more expensive pair-wise annotation efforts to pairs in which the difference in individual quality scores is small, reminiscent of active learning (Settles, 2009). In future work we intend to further investigate this approach, as well as explore in more detail the low fraction of cases where these two schemes led to clearly different results.

The second contribution of this work is suggesting neural methods, based on Devlin et al. (2018), for argument ranking as well as for argument-pair classification. In the former task, our results are comparable to state-of-the-art; in the latter task they significantly outperform earlier methods (Habernal and Gurevych, 2016b).

Finally, to the best of our knowledge, current approaches do not deal with argument pairs of relatively *similar* quality. A natural extension is to develop a ternary-class classification model that will be trained and evaluated on such pairs, as we intend to explore in future work.

Abstract

Propaganda aims at influencing people's mindset with the purpose of advancing a specific agenda. Previous work has addressed propaganda detection at the document level, typically labelling *all* articles from a propagandistic news outlet as propaganda. Such noisy gold labels inevitably affect the quality of any learning system trained on them. A further issue with most existing systems is the lack of explainability. To overcome these limitations, we propose a novel task: performing fine-grained analysis of texts by detecting all fragments that contain propaganda techniques as well as their type. In particular, we create a corpus of news articles manually annotated at the fragment level with eighteen propaganda techniques and we propose a suitable evaluation measure. We further design a novel multi-granularity neural network, and we show that it outperforms several strong BERT-based baselines.

1 Introduction

Research on detecting propaganda has focused primarily on articles (Barrón-Cedeno et al., 2019; Rashkin et al., 2017). In many cases, there are no labeled data for individual articles, but there are such labels for entire news outlets. Thus, often all articles from the same news outlet get labeled the way that this outlet is labeled. Yet, it has been observed that propagandistic sources could post objective non-propagandistic articles periodically to increase their credibility (Horne et al., 2018). Similarly, media generally recognized as objective might occasionally post articles that promote a particular editorial agenda and are thus propagandistic. Thus, it is clear that transferring the label of the news outlet to each of its articles, could introduce noise. Such labels can still be useful for training robust systems, but they cannot be used to get a fair assessment of a system at testing time.

One option to deal with the lack of labels for articles is to crowdsource the annotation. However, in preliminary experiments we observed that the average annotator cannot detach her personal mindset from the judgment of propaganda and bias, i.e., if a clearly propagandistic text expresses ideas aligned with the annotator's beliefs, it is unlikely that she would judge it as such.

We argue that in order to study propaganda in a sound and reliable way, we need to rely on high-quality trusted professional annotations and it is best to do so at the fragment level, targeting specific techniques rather than using a label for an entire document or an entire news outlet.

Ours is the first work that goes at a fine-grained level: identifying specific instances of propaganda techniques used within an article. In particular, we create a corresponding corpus. For this purpose, we asked six experts to annotate articles from news outlets recognized as propagandistic and non-propagandistic, marking specific text spans with eighteen propaganda techniques. We also designed appropriate evaluation measures. Taken together, the annotated corpus and the evaluation measures represent the first manually-curated evaluation framework for the analysis of fine-grained propaganda. We release the corpus (350K tokens) as well as our code in order to enable future research.[1] Our contributions are as follows:

- We formulate a new problem: detect the use of specific propaganda techniques in text.
- We build a new large corpus for this problem.
- We propose a suitable evaluation measure.
- We design a novel multi-granularity neural network, and we show that it outperforms several strong BERT-based baselines.

[1]The corpus, the evaluation measures, and the models are available at http://propaganda.qcri.org/

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5636–5646,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Our corpus could enable research in propagandistic and non-objective news, including the development of explainable AI systems. A system that can detect instances of use of specific propagandistic techniques would be able to make it explicit to the users why a given article was predicted to be propagandistic. It could also help train the users to spot the use of such techniques in the news.

The remainder of this paper is organized as follows: Section 2 presents the propagandistic techniques we focus on. Section 3 describes our corpus. Section 4 discusses an evaluation measures for comparing labeled fragments. Section 5 presents the formulation of the task and our proposed models. Section 6 describes our experiments and the evaluation results. Section 7 presents some relevant related work. Finally, Section 8 concludes and discusses future work.

2 Propaganda and its Techniques

Propaganda comes in many forms, but it can be recognized by its persuasive function, sizable target audience, the representation of a specific group's agenda, and the use of faulty reasoning and/or emotional appeals (Miller, 1939). Since propaganda is conveyed through the use of a number of techniques, their detection allows for a deeper analysis at the paragraph and the sentence level that goes beyond a single document-level judgment on whether a text is propagandistic.

Whereas the definition of propaganda is widely accepted in the literature, the set of propaganda techniques differs between scholars (Torok, 2015). For instance, Miller (1939) considers seven techniques, whereas Weston (2018) lists at least 24, and Wikipedia discusses 69.[2] The differences are mainly due to some authors ignoring some techniques, or using definitions that subsume the definition used by other authors. Below, we describe the propaganda techniques we consider: a curated list of eighteen items derived from the aforementioned studies. The list only includes techniques that can be found in journalistic articles and can be judged intrinsically, without the need to retrieve supporting information from external resources. For example, we do not include techniques such as *card stacking* (Jowett and O'Donnell, 2012, page 237), since it would require comparing against external sources of information.

[2] http://en.wikipedia.org/wiki/Propaganda_techniques; last visit May 2019.

The eighteen techniques we consider are as follows (cf. Table 1 for examples):

1. Loaded language. Using words/phrases with strong emotional implications (positive or negative) to influence an audience (Weston, 2018, p. 6). *Ex.:* "[. . .] a lone lawmaker's childish shouting."

2. Name calling or labeling. Labeling the object of the propaganda campaign as either something the target audience fears, hates, finds undesirable or otherwise loves or praises (Miller, 1939). *Ex.:* "Republican congressweasels", "Bush the Lesser."

3. Repetition. Repeating the same message over and over again, so that the audience will eventually accept it (Torok, 2015; Miller, 1939).

4. Exaggeration or minimization. Either representing something in an excessive manner: making things larger, better, worse (e.g., "the best of the best", "quality guaranteed") or making something seem less important or smaller than it actually is (Jowett and O'Donnell, 2012, p. 303), e.g., saying that an insult was just a joke. *Ex.:* "Democrats bolted as soon as Trump's speech ended in an apparent effort to signal they can't even stomach being in the same room as the president"; "I was not fighting with her; we were just playing."

5. Doubt. Questioning the credibility of someone or something. *Ex.:* A candidate says about his opponent: "Is he ready to be the Mayor?"

6. Appeal to fear/prejudice. Seeking to build support for an idea by instilling anxiety and/or panic in the population towards an alternative, possibly based on preconceived judgments. *Ex.:* "stop those refugees; they are terrorists."

7. Flag-waving. Playing on strong national feeling (or with respect to a group, e.g., race, gender, political preference) to justify or promote an action or idea (Hobbs and Mcgee, 2008). *Ex.:* "entering this war will make us have a better future in our country."

8. Causal oversimplification. Assuming one cause when there are multiple causes behind an issue. We include *scapegoating* as well: the transfer of the blame to one person or group of people without investigating the complexities of an issue. *Ex.:* "If France had not declared war on Germany, World War II would have never happened."

Doc ID	Technique • Snippet
783702663	`loaded language` • until forced to act by **a worldwide storm of outrage**.
732708002	`name calling, labeling` • dismissing the protesters as "**lefties**" and hugging Barros publicly
701225819	`repetition` • Farrakhan repeatedly refers to Jews as "**Satan**." He states to his audience [. . .] call them by their real name, '**Satan**.'
782086447	`exaggeration, minimization` • heal the situation of **extremely grave** immoral behavior
761969038	`doubt` • **Can the same be said for the Obama Administration**?
696694316	`appeal to fear/prejudice` • **A dark, impenetrable and "irreversible" winter of persecution of the faithful by their own shepherds will fall**.
776368676	`flag-waving` • conflicted, and **his 17 Angry Democrats that are doing his dirty work are a disgrace to USA**! —Donald J. Trump
776368676	`flag-waving` • attempt (Mueller) **to stop the will of We the People**!!! It's time to jail Mueller
735815173	`causal oversimplification` • he said **The people who talk about the "Jewish question" are generally anti-Semites**. Somehow I don't think
781768042	`causal oversimplification` • will not be reversed, **which leaves no alternative as to why God judges and is judging America today**
111111113	`slogans` • **BUILD THE WALL!"** Trump tweeted.
783702663	`appeal to authority` • **Monsignor Jean-François Lantheaume, who served as first Counsellor of the Nunciature in Washington, confirmed that "Viganò said the truth. That's all"**
783702663	`black-and-white fallacy` • Francis said these words: "**Everyone is guilty for the good he could have done and did not do . . . If we do not oppose evil, we tacitly feed it**.
729410793	`thought-terminating cliches` • **I do not really see any problems there.** Marx is the President
770156173	`whataboutism` • President Trump —**who himself avoided national military service** in the 1960's— keeps beating the war drums over North Korea
778139122	`reductio ad hitlerum` • "Vichy journalism," a term which now fits so much of the mainstream media. **It collaborates in the same way that the Vichy government in France collaborated with the Nazis.**
778139122	`red herring` • It describes the tsunami of vindictive personal abuse that has been heaped upon Julian from well-known journalists, many claiming liberal credentials. The Guardian, **which used to consider itself the most enlightened newspaper in the country**, has probably been the worst.
698018235	`bandwagon` • He tweeted, "**EU no longer considers #Hamas a terrorist group. Time for US to do same."**
729410793	obfusc., int. vagueness, confusion • **The cardinal's office maintains that rather than saying "yes," there is a possibility of liturgical "blessing" of gay unions, he answered the question in a more subtle way without giving an explicit "yes."**
783702663	`straw man` • "Take it seriously, but with a large grain of salt." **Which is just Allen's more nuanced way of saying: "Don't believe it**."

Table 1: Instances of the different propaganda techniques from our corpus. We show the document ID, the technique, and the text snippet, in bold. When necessary, some context is provided to better understand the example.

9. Slogans. A brief and striking phrase that may include labeling and stereotyping. Slogans tend to act as emotional appeals (Dan, 2015). *Ex.:* "Make America great again!"

10. Appeal to authority. Stating that a claim is true simply because a valid authority/expert on the issue supports it, without any other supporting evidence (Goodwin, 2011). We include the special case where the reference is not an authority/expert, although it is referred to as *testimonial* in the literature (Jowett and O'Donnell, 2012, p. 237).

11. Black-and-white fallacy, dictatorship. Presenting two alternative options as the only possibilities, when in fact more possibilities exist (Torok, 2015). As an extreme case, telling the audience exactly what actions to take, eliminating any other possible choice (*dictatorship*). *Ex.:* "You must be a Republican or Democrat; you are not a Democrat. Therefore, you must be a Republican"; "There is no alternative to war."

12. Thought-terminating *cliché*. Words or phrases that discourage critical thought and meaningful discussion about a given topic. They are typically short, generic sentences that offer seemingly simple answers to complex questions or that distract attention away from other lines of thought (Hunter, 2015, p. 78). *Ex.:* "it is what it is"; "you cannot judge it without experiencing it"; "it's common sense", "nothing is permanent except change", "better late than never"; "mind your own business"; "nobody's perfect"; "it doesn't matter"; "you can't change human nature."

13. Whataboutism. Discredit an opponent's position by charging them with hypocrisy without directly disproving their argument (Richter, 2017). For example, mentioning an event that discredits the opponent: "What about . . . ?" (Richter, 2017). *Ex.:* Russia Today had a proclivity for whataboutism in its coverage of the 2015 Baltimore and Ferguson protests in the US, which re-

vealed a consistent refrain: "the oppression of blacks in the US has become so unbearable that the eruption of violence was inevitable", and that the US therefore lacks "the moral high ground to discuss human rights issues in countries like Russia and China."

14. Reductio ad Hitlerum. Persuading an audience to disapprove an action or idea by suggesting that the idea is popular with groups hated in contempt by the target audience. It can refer to any person or concept with a negative connotation (Teninbaum, 2009). *Ex.:* "Only one kind of person can think this way: a communist."

15. Red herring. Introducing irrelevant material to the issue being discussed, so that everyone's attention is diverted away from the points made (Weston, 2018, p. 78). Those subjected to a red herring argument are led away from the issue that had been the focus of the discussion and urged to follow an observation or claim that may be associated with the original claim, but is not highly relevant to the issue in dispute (Teninbaum, 2009). Ex.: "You may claim that the death penalty is an ineffective deterrent against crime – but what about the victims of crime? How do you think surviving family members feel when they see the man who murdered their son kept in prison at their expense? Is it right that they should pay for their son's murderer to be fed and housed?"

16. Bandwagon. Attempting to persuade the target audience to join in and take the course of action because "everyone else is taking the same action" (Hobbs and Mcgee, 2008). Ex.: "Would you vote for Clinton as president? 57% say yes."

17. Obfuscation, intentional vagueness, confusion. Using deliberately unclear words, so that the audience may have its own interpretation (Suprabandari, 2007; Weston, 2018, p. 8). For instance, when an unclear phrase with multiple possible meanings is used within the argument, and, therefore, it does not really support the conclusion. Ex.: "It is a good idea to listen to victims of theft. Therefore, if the victims say to have the thief shot, then you should do it."

18. Straw man. When an opponent's proposition is substituted with a similar one which is then refuted in place of the original (Walton, 1996). Weston (2018, p. 78) specifies the characteristics of the substituted proposition: "caricaturing an opposing view so that it is easy to refute."

	Prop	**Non-prop**	**All**
articles	372	79	451
avg length (lines)	49.8	34.4	47.1
avg length (words)	973.2	635.4	914.0
avg length (chars)	5,942	3,916	5,587

Table 3: Number of articles retrieved from news outlets deemed propagandistic by Media Bias/Fact Check.

We provided the above definitions, together with some examples and an annotation schema, to our professional annotators, so that they can manually annotate news articles. The details are provided in the next section.

3 Data Creation

We retrieved 451 news articles from 48 news outlets, both propagandistic and non-propagandistic, which we annotated as described below.

3.1 Article Retrieval

First, we selected 13 propagandistic and 36 non-propagandistic news media outlets, as labeled by Media Bias/Fact Check.[3] Then, we retrieved articles from these sources, as shown in Table 2. Note that 82.5% of the articles are from propagandistic sources, and these articles tend to be longer.

Table 3 shows the number of articles retrieved from each propagandistic outlet. Overall, we have 350k word tokens, which is comparable to standard datasets for other fine-grained text analysis tasks, such as named entity recognition, e.g., CoNLL'02 and CoNLL'03 covered 381K, 333K, 310K, and 301K tokens for Spanish, Dutch, German, and English, respectively (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003).

[3] http://mediabiasfactcheck.com/

3.2 Manual Annotation

We aim at obtaining text fragments annotated with any of the 18 techniques described in Section 2 (see Figure 1 for an example). Since the time required to understand and memorize all the propaganda techniques is significant, this annotation task is not well-suited for crowdsourcing. We partnered instead with a company that performs professional annotations, A Data Pro.[4] Appendix A shows details about the instructions and the tools provided to the annotators.

We computed the γ inter-annotator agreement (Mathet et al., 2015). We chose γ because (*i*) it is designed for tasks where both the span and its label are to be found and (*ii*) it can deal with overlaps in the annotations by the same annotator[5] (e.g., instances of *doubt* often use *name calling* or *loaded language* to reinforce their message). We computed γ_s, where we only consider the identified spans, regardless of the technique, and γ_{sl}, where we consider both the spans and their labels.

Let a be an annotator. In a preliminary exercise, four annotators $a_{[1,..,4]}$ annotated six articles independently, and the agreement was $\gamma_s = 0.34$ and $\gamma_{sl} = 0.31$. Even taking into account that γ is a pessimistic measure (Mathet et al., 2015), these values are low. Thus, we designed an annotation schema composed of two stages and involving two annotator teams, each of which covered about 220 documents. In stage 1, both a_1 and a_2 annotated the same documents independently. In stage 2, they gathered with a consolidator c_1 to discuss all instances and to come up with a final annotation. Annotators a_3 and a_4 and consolidator c_2 followed the same procedure. Annotating the full corpus took 395 man hours.

Table 4 shows the γ agreements on the full corpus. As in the preliminary annotation, the agreements for both teams are relatively low: 0.30 and 0.34 for span selection, and slightly lower when labeling is considered as well. After the annotators discussed with the consolidator on the disagreed cases, the γ values got much higher: up to 0.74 and 0.76 for each team. We further analyzed the annotations to determine the main cause for the disagreement by computing the percentage of instances spotted by one annotator only in the first stage that are retained as gold annotations.

[4] http://www.aiidatapro.com

[5] See (Meyer et al., 2014; Mathet et al., 2015) for other alternatives, which lack some properties; (*ii*) in particular.

Annotations		spans (γ_s)	+labels (γ_{sl})
a_1	a_2	0.30	0.24
a_3	a_4	0.34	0.28
a_1	c_1	0.58	0.54
a_2	c_1	0.74	0.72
a_3	c_2	0.76	0.74
a_4	c_2	0.42	0.39

Table 4: γ inter-annotator agreement between annotators spotting spans alone (**spans**) and spotting spans+labeling (**+labels**). The top-2 rows refer to the first stage: agreement between annotators. The bottom 4 rows refer to the consolidation stage: agreement between each annotator and the final gold annotation.

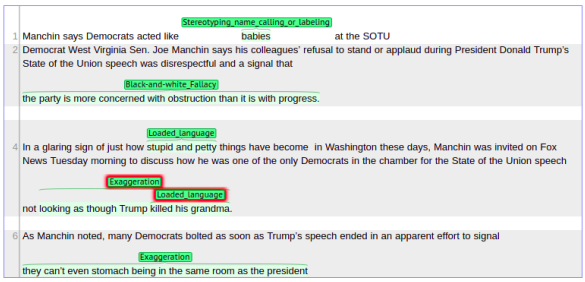

Figure 1: Example given to the annotators.

Overall the percentage is 53% (5,921 out of 11,122), and for each annotator is $a_1 = 70\%$, $a_2 = 48\%$, $a_3 = 57\%$, $a_4 = 31\%$. Observing such percentages together with the relatively low differences in Table 4 between γ_s and γ_{sl} for the same pairs (a_i, a_j) and (a_i, c_j), we can conclude that disagreements are in general not due to the two annotators assigning different labels to the same or mostly overlapping spans, but rather because one has missed an instance in the first stage.

3.3 Statistics about the Dataset

The total number of technique instances found in the articles, after the consolidation phase, is 7,485, with respect to a total number of 21,230 sentences (35.2%). Table 5 reports some statistics about the annotations. The average propagandistic fragment has a length of 47 characters and the average length of a sentence is 112.5 characters.

On average, the propagandistic techniques are half a sentence long. The most common ones are *loaded language* and *name calling, labeling* with 2,547 and 1,294 occurrences, respectively. They appear 6.7 and 4.7 times per article, while no other technique appears more than twice. Note that repetition are inflated as we asked the annotators to mark both the original and the repeated instances.

Propaganda Technique	inst	avg. length
loaded language	2,547	23.70 ± 25.30
name calling, labeling	1,294	26.10 ± 19.88
repetition	767	16.90 ± 18.92
exaggeration, minimization	571	45.36 ± 35.55
doubt	562	123.21 ± 97.65
appeal to fear/prejudice	367	93.56 ± 74.59
flag-waving	330	61.88 ± 68.61
causal oversimplification	233	121.03 ± 71.66
slogans	172	25.30 ± 13.49
appeal to authority	169	131.23 ± 123.2
black-and-white fallacy	134	98.42 ± 73.66
thought-terminating cliches	95	34.85 ± 29.28
whataboutism	76	120.93 ± 69.62
reductio ad hitlerum	66	94.58 ± 64.16
red herring	48	63.79 ± 61.63
bandwagon	17	100.29 ± 97.05
obfusc., int. vagueness, confusion	17	107.88 ± 86.74
straw man	15	79.13 ± 50.72
all	7,485	46.99 ± 61.45

Table 5: Corpus statistics including **inst**ances per technique and their **avg. length** in terms of characters.

4 Evaluation Measures

Our task is a sequence labeling one, with the following key characteristics: (*i*) a large number of techniques whose spans might overlap in the text, and (*ii*) large lengths of these spans. This requires an evaluation measure that gives credit for partial overlaps.[6] We derive an *ad hoc* measure following related work on named entity recognition (NER) (Nadeau and Sekine, 2007) and (intrinsic) plagiarism detection (PD) (Potthast et al., 2010).

While in NER, the relevant fragments tend to be short multi-word strings, in PD —and in our propaganda technique identification task— the length varies widely (cf. Table 5), and instances span from single tokens to full sentences or even longer pieces of text. Thus, in our precision and recall versions, we give partial credit to imperfect matches at the character level, as in PD.

Let document $\boldsymbol{d}$ be represented as a sequence of characters. A propagandistic text fragment is then represented as $t = [t_i, \ldots, t_j] \subseteq \boldsymbol{d}$. A document includes a set of (possibly overlapping) fragments T. Similarly, a learning algorithm produces a set S with fragments $s = [s_m, \ldots, s_n]$, predicted on $\boldsymbol{d}$. A labeling function $l(x) \in \{1, \ldots, 18\}$ associates $s \in S$ to one of the eighteen techniques. Figure 2 gives examples of gold and predicted fragments.

[6]The evaluation measures for the CoNLL'02 and CoNLL'03 NER tasks, where an instance is considered properly identified if and only if both the boundaries and the label are correct (Tsai et al., 2006), are not suitable in our context.

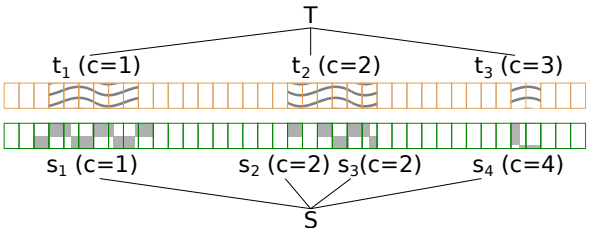

Figure 2: Example of gold annotation (top) and the predictions of a supervised model (bottom) in a document represented as a sequence of characters. The class of each fragment is shown in parentheses. s_1 goes beyond t_1's proper boundaries; s_2 and s_3 partially spot t_2, but fail to identify it entirely; s_4 spots the exact boundaries of t_3, but fails to assign it the right label.

We define the following function to handle partial overlaps between fragments with same labels:

$$C(s, t, h) = \frac{|(s \cap t)|}{h} \delta\left(l(s), l(t)\right), \qquad (1)$$

where h is a normalizing factor and $\delta(a, b) = 1$ if $a = b$, and 0 otherwise. In the future, δ could be refined to account for custom distance functions between classes, e.g., we might consider mistaking *loaded language* for *name calling or labeling* less problematic than confusing it with *Reduction ad Hitlerum*. Given Eq. (1), we now define variants of precision and recall able to account for the imbalance in the corpus:

$$P(S, T) = \frac{1}{|S|} \sum_{\substack{s \in S, \\ t \in T}} C(s, t, |s|), \qquad (2)$$

$$R(S, T) = \frac{1}{|T|} \sum_{\substack{s \in S, \\ t \in T}} C(s, t, |t|), \qquad (3)$$

We define Eq. (2) to be zero if $|S| = 0$ and Eq. (3) to be zero if $|T| = 0$. Following Potthast et al. (2010), in Eqs. (2) and (3) we penalize systems predicting too many or too few instances by dividing by $|S|$ and $|T|$, respectively, e.g., in Figure 2 $P(\{s_2, s_3\}, T) < P(\{s_3\}, T)$. Finally, we combine Eqs. (2) and (3) into an F_1-measure, the harmonic mean of precision and recall.

Having a separate function C to be responsible for comparing two annotations gives us some additional flexibility that is missing in standard NER measures that operate at the token/character level. For example, in Eq. (1) we could easily change the factor that gives credit for partial overlaps by being more forgiving when only few characters are wrong.

5 Tasks and Proposed Models

We define two tasks based on the corpus described in Section 3: (*i*) **SLC (Sentence-level Classification)**, which asks to predict whether a sentence contains at least one propaganda technique, and (*ii*) **FLC (Fragment-level classification)**, which asks to identify both the spans and the type of propaganda technique. Note that these two tasks are of different granularities, g_1 and g_2, i.e., tokens for FLC and sentences for SLC. We split the corpus into training, development and test, each containing 293, 57, 101 articles and 14,857, 2,108, 4,265 sentences.

5.1 Baselines

We depart from BERT (Devlin et al., 2019), as it has achieved state-of-the-art performance on multiple NLP benchmarks, and we design three baselines based on it.

BERT. We add a linear layer on top of BERT and we fine-tune it, as suggested in (Devlin et al., 2019). For the FLC task, we feed the final hidden representation for each token to a layer L_{g_2} that makes a 19-way classification: does this token belong to one of the eighteen propaganda techniques or to none of them (cf. Figure 3-a). For the SLC task, we feed the final hidden representation for the special `[CLS]` token, which BERT uses to represent the full sentence, to a two-dimensional layer L_{g_1} to make a binary classification.

BERT-Joint. We use the layers for both tasks in the BERT baseline, L_{g_1} and L_{g_2}, and we train for both FLC and SLC jointly (cf. Figure 3-b).

BERT-Granularity. We modify BERT-Joint to transfer information from SLC directly to FLC. Instead of using only the L_{g_2} layer for FLC, we concatenate L_{g_1} and L_{g_2}, and we add an extra 19-dimensional classification layer $L_{g_{1,2}}$ on top of that concatenation to perform the prediction for FLC (cf. Figure 3-c).

5.2 Multi-Granularity Network

We propose a model that can drive the higher-granularity task (FLC) on the basis of the lower-granularity information (SLC), rather than simply using low-granularity information directly. Figure 3-d shows the architecture of this model. More generally, suppose there are k tasks of increasing granularity, e.g., document-level, paragraph-level, sentence-level, word-level, subword-level, character-level.

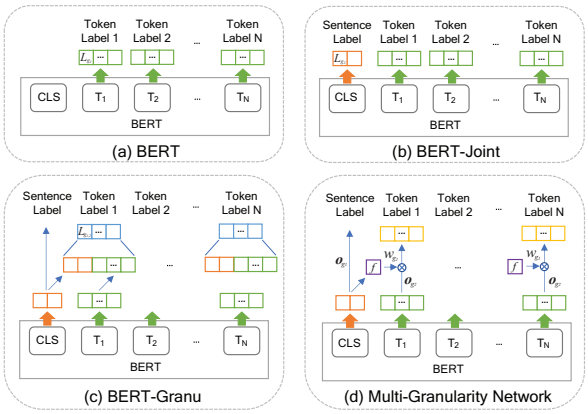

Figure 3: The architecture of the baseline models (a-c), and of our proposed multi-granularity network (d).

Each task has a separated classification layer L_{g_k} that receives the feature representation of the specific level of granularity g_k and outputs $\boldsymbol{o}_{g_k}$. The dimension of the representation depends on the embedding layer, while the dimension of the output depends on the number of classes in the task. The output $\boldsymbol{o}_{g_k}$ generates a weight for the next granularity task g_{k+1} through a trainable gate f:

$$w_{g_k} = f(\boldsymbol{o}_{g_k}) \tag{4}$$

The gate f consists of a projection layer to one dimension and an activation function. The resulting weight is multiplied by each element of the output of layer $L_{g_{k+1}}$ to produce the output for task g_{k+1}:

$$\boldsymbol{o}_{g_{k+1}} = w_{g_k} * \boldsymbol{o}_{g_{k+1}} \tag{5}$$

If $w_{g_k} = 0$ for a given example, the output of the next granularity task $\boldsymbol{o}_{g_{k+1}}$ would be 0 as well. In our setting this means that, if the sentence-level classifier is confident the sentence does not contain propaganda, i.e., $w_{g_k} = 0$, then $\boldsymbol{o}_{g_{k+1}} = 0$ and there would be no propagandistic technique predicted for any span within that sentence. Similarly, when back-propagating the error, if $w_{g_k} = 0$ for a given example, the final entropy loss would become zero; i.e. the model would not get any information from that example. As a result, only examples strongly classified as negative in a lower-granularity task would be ignored in the high-granularity task. Having the lower-granularity as the main task means that higher-granularity information can be selectively used as additional information to improve the performance, but only if the example is not considered as highly negative. We show this in Section 6.3.

For the loss function, we use a cross-entropy loss with sigmoid activation for every layer, except for the highest-granularity layer L_{g_K}, which uses a cross-entropy loss with softmax activation. Unlike softmax, which normalizes over all dimensions, the sigmoid allows each output component of layer L_{g_k} to be independent from the rest. Thus, the output of the sigmoid for the positive class increases the degree of freedom by not affecting the negative class, and vice versa. As we have two tasks, we use sigmoid activation for L_{g_1} and softmax activation for L_{g_2}. Moreover, we use a weighted sum of losses with a hyper-parameter α:

$$\mathcal{L}_{\mathcal{J}} = \mathcal{L}_{g_1} * \alpha + \mathcal{L}_{g_2} * (1 - \alpha) \quad (6)$$

Again, we use BERT (Devlin et al., 2019) for the contextualized embedding layer and we place the multi-granularity network on top of it.

6 Experiments and Evaluation

6.1 Experimental Setup

We used the PyTorch framework and the pre-trained BERT model, which we fine-tuned for our tasks. We trained all models using the following hyper-parameters: batch size of 16, sequence length of 210, weight decay of 0.01, and early stopping on validation F_1 with patience of 7. For optimization, we used Adam with a learning rate of 3e-5 and a warmup proportion of 0.1. To deal with class imbalance, we give weight to the binary cross-entropy according to the proportion of positive samples. For the α in the joint loss function, we use 0.9 for sentence classification, and 0.1 for word-level classification. In order to reduce the effect of random fluctuations for BERT, all the reported numbers are the average of three experimental runs with different random seeds. As it is standard, we tune our models on the dev partition and we report results on the test partition.

6.2 Fragment-Level Propaganda Detection

Table 6 shows the performance for the three baselines and for our multi-granularity network on the FLC task. For the latter, we vary the degree to which the gate function is applied: using ReLU is more aggressive compared to using the Sigmoid, as the ReLU outputs zero for a negative input. Note that, even though we train the model to predict both the spans and the labels, we also evaluated it with respect to the spans only.

Model	Spans			Full Task		
	P	R	F_1	P	R	F_1
BERT	39.57	36.42	37.90	21.48	**21.39**	21.39
Joint	39.26	35.48	37.25	20.11	19.74	19.92
Granu	43.08	33.98	37.93	23.85	20.14	21.80
Multi-Granularity						
ReLU	43.29	34.74	38.28	23.98	20.33	21.82
Sigmoid	**44.12**	**35.01**	**38.98**	**24.42**	21.05	**22.58**

Table 6: Fragment-level experiments (FLC task). Shown are two evaluations: (*i*) **Spans** checks only whether the model has identified the fragment spans correctly, while (*ii*) **Full task** is evaluation wrt the actual task of identifying the spans and also assigning the correct propaganda technique for each span.

Table 6 shows that joint learning (BERT-Joint) hurts the performance compared to single-task BERT. However, using additional information from the sentence-level for the token-level classification (BERT-Granularity) yields small improvements. The multi-granularity models outperform all baselines thanks to their higher precision. This shows the effect of the model excluding sentences that it determined to be non-propagandistic from being considered for token-level classification. Nevertheless, the performance of sentence-level classification is far from perfect, achieving an F_1 of up to 60.98 (cf. Table 7). The information it contributes to the final classification is noisy and the more conservative removal of instances performed by the Sigmoid function yields better performance than the more aggressive ReLU.

6.3 Sentence-Level Propaganda Detection

Table 7 shows the results for the SLC task. We apply our multi-granularity network model to the sentence-level classification task to see its effect on low granularity when we train the model with a high granularity task. Interestingly, it yields huge performance improvements on the sentence-level classification result. Compared to the BERT baseline, it increases the recall by 8.42%, resulting in a 3.24% increase of the F_1 score. In this case, the result of token-level classification is used as additional information for the sentence-level task, and it helps to find more positive samples. This shows the opposite effect of our model compared to the FLC task. Note also that using ReLU is more effective than using the Sigmoid, unlike in token-level classification.

Model	Precision	Recall	F1
All-Propaganda	23.92	100.00	38.61
BERT	**63.20**	53.16	57.74
BERT-Granu	62.80	55.24	58.76
BERT-Joint	62.84	55.46	58.91
MGN Sigmoid	62.27	59.56	60.71
MGN ReLU	60.41	**61.58**	**60.98**

Table 7: Sentence-level (SLC) results. *All-propaganda* is a baseline which always output the propaganda class.

Thus, since the performance range of the token-level classification is low, we think it is more effective to get additional information after aggressively removing negative samples by using ReLU as a gate in the model.

7 Related Work

Propaganda identification has been tackled mostly at the article level. Rashkin et al. (2017) created a corpus of news articles labelled as belonging to four categories: propaganda, trusted, hoax, or satire. They included articles from eight sources, two of which are propagandistic. Barrón-Cedeño et al. (2019) experimented with a binarized version of the corpus from (Rashkin et al., 2017): propaganda vs. the other three categories. The corpus labels were obtained with distant supervision, assuming that all articles from a given news outlet share the label of that outlet, which inevitably introduces noise (Horne et al., 2018).

A related field is that of computational argumentation which, among others, deals with some logical fallacies related to propaganda. Habernal et al. (2018b) presented a corpus of Web forum discussions with cases of *ad hominem* fallacy identified. Habernal et al. (2017, 2018a) introduced *Argotario*, a game to educate people to recognize and create fallacies. A byproduct of Argotario is a corpus with $1.3k$ arguments annotated with five fallacies, including *ad hominem*, *red herring* and *irrelevant authority*, which directly relate to propaganda techniques (cf. Section 2). Differently from (Habernal et al., 2017, 2018a,b), our corpus has 18 techniques annotated on the same set of news articles. Moreover, our annotations aim at identifying the minimal fragments related to a technique instead of flagging entire arguments.

8 Conclusion and Future Work

We have argued for a new way to study propaganda in news media: by focusing on identifying the instances of use of specific propaganda techniques. Going at this fine-grained level can yield more reliable systems and it also makes it possible to explain to the user why an article was judged as propagandistic by an automatic system.

In particular, we designed an annotation schema of 18 propaganda techniques, and we annotated a sizable dataset of documents with instances of these techniques in use. We further designed an evaluation measure specifically tailored for this task. We made the schema and the dataset publicly available, thus facilitating further research. We hope that the corpus would raise interest outside of the community of researchers studying propaganda: the techniques related to fallacies and the ones relying on emotions might provide a novel setting for the researchers interested in Argumentation and Sentiment Analysis.

We experimented with a number of BERT-based models and devised a novel architecture which outperforms standard BERT-based baselines. Our fine-grained task can complement document-level judgments, both to come out with an aggregated decision and to explain why a document —or an entire news outlet— has been flagged as potentially propagandistic by an automatic system.

We are collaborating with A Data Pro to expand the corpus. In the mid-term, we plan to build an online platform where professors in relevant fields (e.g., journalism, mass communication) can train their students to recognize and annotate propaganda techniques. The hope is to be able to accumulate annotations as a by-product of using the platform for training purposes.

Acknowledgments

This research is part of the Tanbih project,[7] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL) and the Qatar Computing Research Institute (QCRI), HBKU.

Abstract

In recent times, multi-modal analysis has been an emerging and highly sought-after field at the intersection of natural language processing, computer vision, and speech processing. The prime objective of such studies is to leverage the diversified information, (e.g., textual, acoustic and visual), for learning a model. The effective interaction among these modalities often leads to a better system in terms of performance. In this paper, we introduce a recurrent neural network based approach for the multi-modal sentiment and emotion analysis. The proposed model learns the inter-modal interaction among the participating modalities through an auto-encoder mechanism. We employ a context-aware attention module to exploit the correspondence among the neighboring utterances. We evaluate our proposed approach for five standard multi-modal affect analysis datasets. Experimental results suggest the efficacy of the proposed model for both sentiment and emotion analysis over various existing state-of-the-art systems.

1 Introduction

In recent past, the world has witnessed tremendous growth of various social media platforms, e.g., YouTube, Instagram, Twitter, Facebook, etc. People treat these platforms as a communication medium and freely express themselves with the help of a diverse set of input sources, e.g. *videos*, *images*, *audio*, *text* etc. The amount of information produced daily through these mediums are enormous, and hence, the research on multi-modal information processing has attracted attention to the researchers and developers. A video is a multi-modal input which provides visual, acoustic, and textual information.

The motivation of multi-modal sentiment and emotion analysis lies in fact to leverage the varieties of (often distinct) information from multiple sources for building more efficient systems. For some cases, text can provide a better clue for the prediction, whereas for the others, acoustic or visual sources can be more informative. Similarly, in some situations, a combination of two or more information sources together ensures better and unambiguous classification decision. For example, only text *"shut up"* can not decide the mood of a person but *acoustic (tone of a person)* and *visual (expression of a person)* can reveal the exact mood. Similarly, for some instances visual features such as *gesture*, *postures*, *facial expression* etc. have important roles to play in determining the correctness of the system. However, effectively combining this information is a non-trivial task that researchers often have to face (Poria et al., 2016; Ranganathan et al., 2016; Lee et al., 2018).

Traditionally, '*text*' has been the key factor in any Natural Language Processing (NLP) tasks, including sentiment and emotion analysis. However, with the recent emergence of social media platforms, an interdisciplinary study involving *text*, *visual* and *acoustic* features have drawn a great interest among the research community. Expressing the feelings and emotions through a video is much convenient than the text for a user, and it is the best source to extract all multi-modal information. Not only the *visual*, it also provides other information such as *acoustic* and *textual* representation of *spoken language*. Additionally, a single video can have multiple utterances based on a speaker's pause (speech bounded by breaths) with different sentiments and emotions. The sentiments and emotions of an utterance often have inter-dependence on the other contextual utterances. Independently classifying such an utterance poses several challenges to the underlying problem. In contrast, multi-modal sentiment and emotion analysis take inputs from more than one sources e.g.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5647–5657,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

text, *visual*, *acoustic* for the analysis. Effectively fusing this diverse information is non-trivial and poses several challenges to the underlying problem.

In our current work, we propose an end-to-end Context-aware Interactive Attention (CIA) based recurrent neural network for sentiment and emotion analysis. We aim to leverage the interaction between the modalities to increase the confidence of individual task in prediction. The main contributions of our current research are as follows: **(1)** *We propose an Inter-modal Interactive Module (IIM) that aims to learn the interaction among the diverse and distinct features of the input modalities, i.e., text, acoustic and visual*; **(2)** *We employ a Context-aware Attention Module (CAM) that identifies and assigns the weights to the neighboring utterances based on their contributing features. It exploits the interactive representations of pairwise modalities to learn the attention weights*, and **(3)** *We present new state-of-the-arts for five benchmark datasets for both sentiment and emotion predictions*.

2 Related Work

Different reviews in (Arevalo et al., 2017; Poria et al., 2016, 2017b; Ghosal et al., 2018; Morency et al., 2011a; Zadeh et al., 2018a; Mihalcea, 2012; Lee et al., 2018; Tsai et al., 2018) suggest that multi-modal sentiment and emotion analysis are relatively new areas as compared to uni-modal analysis. Feature selection (fusion) is a challenging and important task for any multi-modal analysis. Poria et al. (2016) proposed a multi-kernel learning based feature selection method for multimodal sentiment and emotion recognition. A convolutional deep belief network (CDBN) is proposed in (Ranganathan et al., 2016) to learn salient multi-modal features of low-intensity expressions of emotions, whereas Lee et al. (2018) introduced a convolutional attention network to learn multimodal feature representation between speech and text data for multi-modal emotion recognition.

A feature level fusion vector was built, and then a Support Vector Machine (SVM) classifier was used to detect the emotional duality and mixed emotional experience in (Patwardhan, 2017). Similar work on feature-level fusion based on self- attention mechanism is reported in (Hazarika et al., 2018). Fu et al. (2017) introduced an enhanced sparse local discriminative canonical correlation analysis approach (En-SLDCCA) to learn the multi-modal shared feature representation. Tzirakis et al. (2017) introduced a Long Short Term Memory (LSTM) based end-to-end multi-modal emotion recognition system in which convolutional neural network (CNN) and a deep residual network are used to capture the emotional content for various styles of speaking, robust features.

Poria et al. (2017a) presented a literature survey on various affect dimensions e.g., sentiment analysis, emotion analysis, etc., for the multi-modal analysis. A multi-modal fusion-based approach is proposed in (Blanchard et al., 2018) for sentiment classification. The author used exclusively high-level fusion of visual and acoustic features to classify the sentiment. Zadeh et al. (2016) presented the multi-modal dictionary-based technique to capture the interaction between spoken words and facial expression better when expressing the sentiment. In another work, Zadeh et al. (2017) proposed a Tensor Fusion Network (TFN) to capture the inter-modality and intra-modality dynamics between the multi-modalities (i.e., text, visual, and acoustic).

These works did not take contextual information into account. Poria et al. (2017b) introduced an Long Short Term Memory (LSTM) based framework for sentiment classification which uses contextual information to capture interrelationships between the utterances. In another work, Poria et al. (2017c) proposed a user opinion based framework to combine all the multi-modal inputs (i.e., visual, acoustic, and textual) by applying a multi-kernel learning-based approach. Contextual inter-modal attention mechanism was not explored in much details until recently. Zadeh et al. (2018a) introduced a multi-attention blocks based model for multi-modal sentiment classification but did not account for contextual information, whereas Ghosal et al. (2018) proposed a contextual inter-modal attention based framework for multi-modal sentiment classification. Recently, Zadeh et al. (2018c) introduced the largest multimodal dataset namely *CMU-MOSEI* for sentiment and emotion analysis. Author effectively fused the multi-modality inputs *i.e., text, visual, and acoustic* through a dynamic fusion graph and reported competitive performance *w.r.t.* various state-of-the-art systems for both sentiment and emotion analysis. Very recently, Akhtar et al. (2019) in-

troduced an attention based multi-task learning framework for sentiment and emotion classification on the *CMU-MOSEI* dataset.

In comparison to the existing systems, our proposed approach aims to exploits the interaction between the input modalities through an auto-encoder based *inter-modal interactive module*. The interactive module learns the joint representation for the participating modalities, which are further utilized to capture the contributing contextual utterances in a *context-aware attention module*.

3 Context-aware Interactive Attention (CIA) Affect Analysis

In this section, we describe our proposed approach for the effective fusion of multi-modal input sources. We propose an end-to-end Context-aware Interactive Attention (CIA) based recurrent neural network for sentiment and emotion analysis. As discussed earlier, one of the main challenges for multi-modal information analysis is to exploit the interaction among the input modalities. Therefore, we introduce an Inter-modal Interactive Module (IIM) that aims to learn the interaction between any two modalities through an auto-encoder like structure. For the *text-acoustic* pair of modalities, we aim to decode the *acoustic* representation through the encoded *textual* representation. After training of IIM, we extract the encoded representation for further processing. We argue that the encoded representation learns the interaction between the *text* and *acoustic* modalities. Similarly, we compute the interaction among all the other pairs (i.e., *acoustic-text*, *text-visual*, *visual-text*, *acoustic-visual*, and *visual-acoustic*). Next, we extract the sequential pattern of the utterances through a Bi-directional Gated Recurrent Unit (Bi-GRU) (Cho et al., 2014)). For each pair of modalities, the two representations denoting the interactions between them are combined through a mean operation. For an instance, we compute the mean of the *text-acoustic* and *acoustic-text* representations for text and acoustic modalities. The mean operation ensures that the network utilizes the two distinct representations by keeping the minimal dimension.

In our network, we, additionally, learn the interaction among the modalities through a feed-forward network. At first, all the three modalities are passed through a separate Bi-GRU. Then, pair-wise concatenation is performed over the output of Bi-GRU and passed through a fully-connected layer to extract the bi-modal interaction (BI). Further, we employ a Context-aware Attention Module (CAM) to exploit the correspondence among the neighboring utterances. The inputs to the CAM are the two representations for each pair of modalities, e.g., mean representation M_{TA} and bi-modal interaction BI_{TA} for the text-acoustic

Algorithm 1 Inter-modal Interactive Module for Multi-modal Sentiment and Emotion Recognition (IIM-MMSE)

  $A \leftarrow O \odot M$ ▷ Multiplicative gating.
  return A

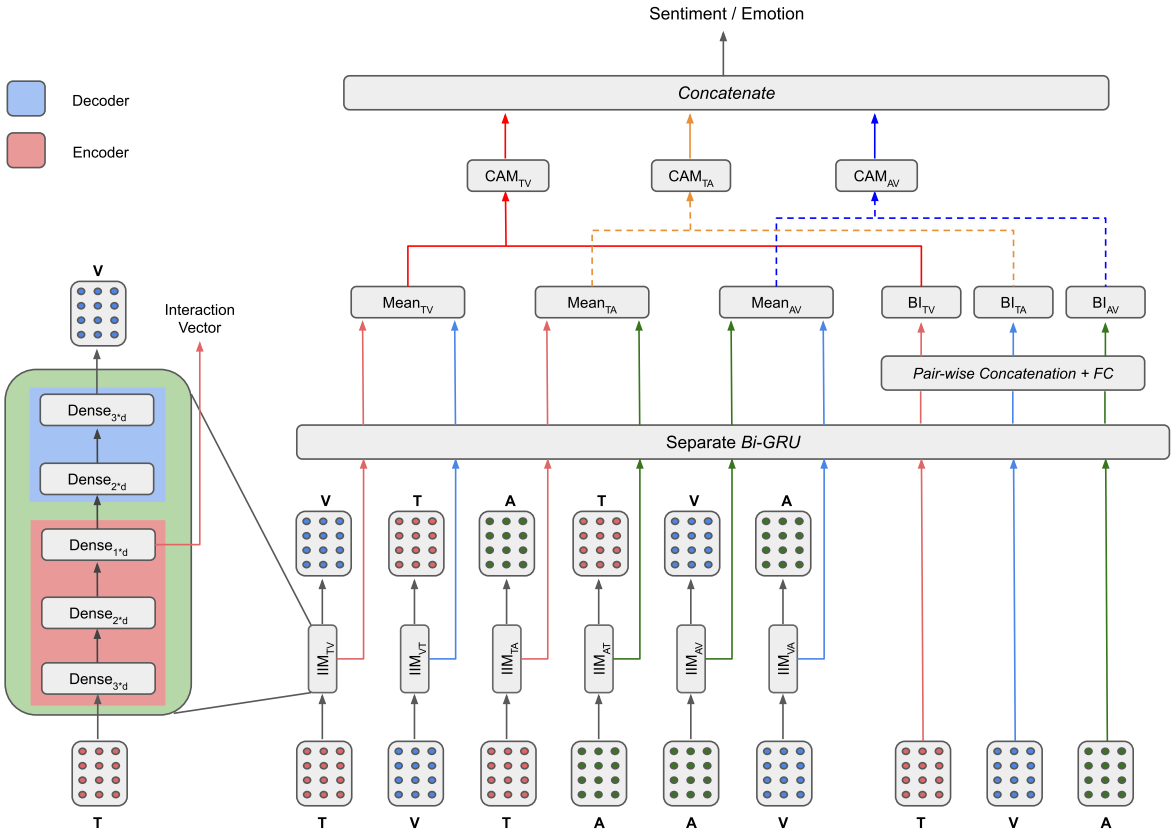

Figure 1: Overall architecture of the proposed Context-aware Interactive Attention framework.

pair. The attention module assists the network in attending the contributing features by putting weights to the current and the neighboring utterances in a video. In the end, the pair-wise (i.e., *text-acoustic*, *text-visual*, and *acoustic-visual*) attended representations are concatenated and fed to an output layer for the prediction.

We depict and summarize the proposed approach in Figure 1 and Algorithm 1, 2, and 3. The source code is available at `http://www.iitp.ac.in/~ai-nlp-ml/resources.html`.

3.1 Context-aware Attention Module (CAM)

Since the utterances in a video are the split units of the break/pause of the speech, their emotions (or sentiments) often have relations with their neighboring utterances. Therefore, knowledge of the emotions (or, sentiments) of the neighboring utterances is an important piece of information and has the capability to derive the prediction of an utterance, if the available inputs are insufficient for the correct prediction.

Our proposed context-aware attention module leverages the contextual information. For each utterance in a video, we compute the attention weights of all the neighboring utterances based on their contributions in predicting the current utterance. It ensures that the network properly utilizes the local contextual information of an utterance as well as the global contextual information of a video together. The aim is to compute the interactive attention weights utilizing a *softmax* activation for each utterance in the video. Next, we apply a multiplicative gating mechanism following the work of Dhingra et al. (2016). The attentive representation is, then, forwarded to the upper layers for further processing. We summarize the process of *CAM* in Algorithm3.

3.2 Inter-modal Interactive Module (IIM)

One of the key objectives of the multi-modal analysis is to fuse the available input modalities effectively. In general, different modalities represent distinct features despite serving a common goal. For example, in multi-modal sentiment analysis all the three modalities, i.e., *text*, *acoustic*, and *visual*, aim to predict the expressed polarity of an utterance. The distinctive features in isolation

might create an ambiguous scenario for a network to learn effectively. Therefore, we introduce an auto-encoder based inter-modal interactive module whose objective is to learn the interaction between two distinct modalities to serve a common goal. The IIM encodes the feature representation of one modality (say, text), and aims to decode it into the feature representation of another modality (say, acoustic). Similar to an auto-encoder where the input and output are conceptually the same (or closely related), in our case the input and output feature representations of two modalities also intuitively serve a common goal. After training of IIM, the encoded vector signifies a joint representation of the two modalities, which can be further utilized in the network.

As the proposed architecture in Figure 1 depicts, our proposed model is an *end-to-end* system, which takes multi-modal raw features for each utterance in a video and predicts an output. We also train our proposed IIM in the combined framework. For any pair of modalities, e.g., *text-visual*, the encoded vector in IIM receives two gradients of errors, i.e., one error from the IIM output (visual) l_1 and another from the task-specific label l_2. We aggregate the errors ($l_1 + l_2$) at the encoded vector and backpropagate it to the input (text). Thus, the weights in the encoder part will adjust according to the desired task-specific label as well. However, in contrast, the decoder part does not have such information. Therefore, we employ another IIM to capture the interaction between the *visual-text*. This time, the *visual* features are aware of the desired label during the interaction with *textual* features. A conceptual diagram, depicting the gradient flow in IIM for the text and visual modalities, is shown in Figure 2.

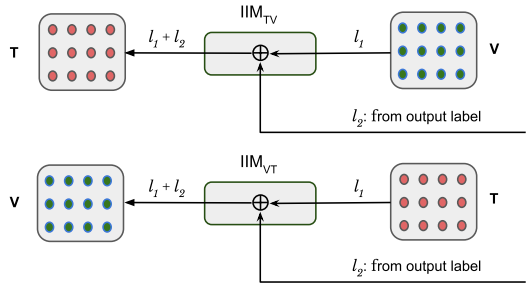

Figure 2: Difference between the interaction modules of *text-visual* and *visual-text* pairs. l_1 & l_2 are the losses from the IIM and output labels, respectively.

4 Datasets, Experiments and Analysis

In this section, we present our experimental results along with necessary analysis. We also compare our obtained results with several state-of-the-art systems.

4.1 Datasets

For the evaluation of our proposed approach, we employ five multi-modal benchmark datasets[1] covering two affect analysis tasks, i.e., sentiment and emotion.

1. **YouTube** (Morency et al., 2011b): The YouTube opinion dataset contains 269 product reviews utterances across 47 videos. There are 169, 41, and 59 utterances in training, validation, and test set, respectively.

2. **MOUD** (Pérez-Rosas et al., 2013): The dataset consists of 79 product review videos in Spanish. Each video consists of multiple utterances labeled with either positive, negative, or neutral sentiment. There are 243, 37, 106 utterances in training, validation, and test set, respectively.

3. **ICT-MMMO** (Wöllmer et al., 2013): It is an extension of YouTube opinion dataset that extends the number of videos from 47 to 340. Each online social review video is annotated for the sentiment. There are 220, 40, and 80 videos in training, validation, and test set, respectively.

4. **CMU-MOSI** (Zadeh et al., 2016): It is a collection of 2199 opinion utterances annotated with the sentiment class. There are 1284 utterances in the training set, 229 utterances in the validation set, and 686 utterances in the test set.

5. **CMU-MOSEI** (Zadeh et al., 2018c): CMU-MOSEI is the largest dataset among all the above. It has 3,229 videos which comprise of approximately 23,000 utterances. Each utterance is associated with one sentiment value and six emotions (i.e., *anger* (4903 utterances), *disgust* (4028 utterance), *fear* (1850 utterance), *happy* (12135 utterance),

[1]These datasets can be accessed through https://github.com/A2Zadeh/CMU-MultimodalSDK.

	MOSEI								MOSI					ICT-MMMO		YouTube		MOUD

sad (5856 utterance), and *surprise* (2262 utterance). The emotion class *happy* is approximately 52% of the total utterances, while emotions *fear* and *surprise* are approximately 8-9% in the dataset. Further, many utterances have more than one emotions representing the case of multi-label classification problem. The utterances for which all the emotions are absent, we classify them into a *no-emotion* class. We depict the statistics of multi-label emotions in Table 2. The training, validation and test set distributions are approximately 16K, 2K, and 4.6K, respectively.

4.2 Setups

The above datasets offer different dimension of sentiment analysis. We define the following setups for our experiments.

- **Two-class** (*pos* and *neg*) classification: MOSEI, MOSI, ICT-MMMO, and MOUD.
- **Three-class** (*pos*, *neu*, and *neg*) classification: YouTube.
- **Five-class** (*strong pos*, *weak pos*, *neu*, *weak neg*, and *strong neg*) classification: MOSEI.
- **Seven-class** (*strong pos*, *moderate pos*, *weak pos*, *neu*, *weak neg*, *moderate neg*, and *strong neg*) classification: MOSEI and MOSI.
- **Intensity prediction:** MOSEI and MOSI.

4.3 Experiments

We implement our proposed model on the Python-based Keras deep learning library. As the evaluation metric, we employ accuracy (weighted accuracy (Tong et al., 2017)) and F1-score for the classification problems, while for the intensity prediction task, we compute Pearson correlation scores and mean-absolute-error (MAE).

We evaluate our proposed *CIA* model on five benchmark datasets *i.e., MOUD, MOSI, YouTube, ICT-MMMO, and MOSEI*. For all the datasets, we perform *grid search* to find the optimal hyper-parameters (c.f. Table 4). Though we push for a generic hyper-parameter configuration for all datasets, in some cases, a different choice of the parameter has a significant effect. Therefore, we choose different parameters for different datasets for our experiments. Details of hyper-parameters for different datasets are depicted in Table 4.

We use different activation functions for the various modules in our model. We use *tanh* as the activation function for the inter-modal interactive module (IIM), while we employ *ReLu* for the context-aware attention module. For each dataset, we use *Adam* as optimizer.

In this paper, we address three multi-modal affective analysis problems, namely *i.e., sentiment classification (S_C), sentiment intensity (S_I) and emotion classification (E_C)*. We use *softmax* as a classifier for sentiment classification, while optimizing the *categorical cross-entropy* as a loss function. In comparison, we use *sigmoid* for prediction and *binary cross-entropy* as the loss function for the emotion classification. As the emotions in the dataset are multi-labeled, we apply a threshold over the predicted *sigmoid* outputs for each emotion and consider all the emotions as present whose respective values are above the threshold. We cross-validate and optimize both

Table 4: Hyper-parameters for our experiments where *N, D*, S_C, S_I and E_C stands for #neurons, dropout, sentiment classification, sentiment intensity and emotion classification respectively.

We evaluate our proposed approach for all the possible input combinations *i.e., uni-modal (T, A, V), bi-modal (T+V, T+A, A+V) and tri-modal (T+V+A)*. We depict our obtained results in Table 1. For MOSEI dataset, with tri-modal inputs, our proposed system reports 79.02% F1-score and 62.97% weighted-accuracy for emotion classification. For sentiment classification, we obtain 78.23%, 80.37%, 49.15% and 50.14% as F1-score for two-class, five-class and seven-class, respectively. For sentiment intensity prediction task, our proposed system yields MAE and Pearson score of 0.683 and 0.594, respectively. We also observe that the proposed approach yields better performance for the tri-modal inputs than the bi-modal and uni-modal input combinations. This improvement implies that our proposed CIA architecture utilizes the interaction among the input modalities very effectively. Furthermore, for the other datasets, i.e., MOSI, ICT-MMMO, YouTube, and MOUD, we also observe a similar phenomenon as well (c.f. Table 1).

To show that our proposed IIM module, indeed, learns the interaction among the distinct modalities, we also perform an ablation study of the proposed CIA architecture. Consequently, we omit the IIM module from our architecture and compute the self-attention on the pair-wise fully-connected representations for the prediction. We observe that, for all the datasets, the performance of this modified architecture (i.e., CIA - IIM) is constantly inferior (with 1% to 7% F-score points) to the proposed CIA architecture. This performance degradation suggests that the IIM module is, indeed, an important component of our proposed architecture. In Table 3, we depict the evaluation results for both- with and without IIM.

4.4 Comparative Analysis

In this section, we present our comparative studies against several existing and recent state-of-the-art systems. For each dataset, we report three best systems for the comparisons[2]. In particular, we compare with the following systems: **Bag of Feature - Multimodal Sentiment Analysis (BoF-MSA)** (Blanchard et al., 2018), **Memory Fusion Network (MFN)** (Zadeh et al., 2018b), **Deep Fusion - Deep Neural Network (DF-DNN)** (Nojavanasghari et al., 2016), **Multi View - LSTM (MV-LSTM)** (Rajagopalan et al., 2016), **Early Fusion - LSTM (EF-LSTM)** (Zadeh et al., 2018c), **Tensor Fusion Network (TFN)** (Zadeh et al., 2017), **Random Forest (RF)** (Breiman, 2001), **Support Vector Machine** (Zadeh et al., 2016), **Multi-Attention Recurrent Network (MARN)** (Zadeh et al., 2018a), **Dynamic Fusion Graph (DFG)** (Zadeh et al., 2018c), **Multi Modal Multi Utterance-Bimodal Attention (MMMU-BA)** (Ghosal et al., 2018), **Bi-directional Contextual LSTM (BC-LSTM)** (Poria et al., 2017b) and **Multimodal Factorization Model (MFM)** (Tsai et al., 2018).

We show the comparative results in Table 5a and Table 5b for emotion and sentiment analysis, respectively. We observe that the proposed CIA framework yields better performance against the state-of-the-art for all the cases. For emotion classification, our proposed approach achieves approximately 3 and 0.6 percentage higher F1-

(b) Sentiment Analysis

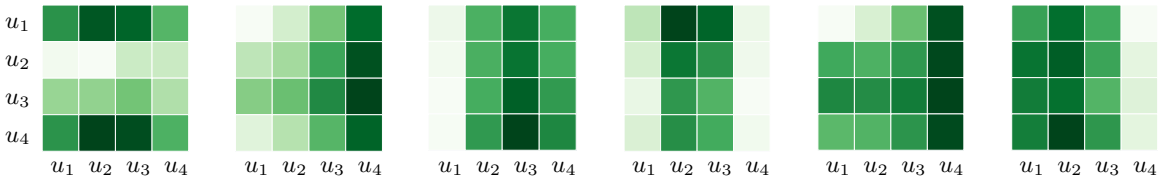
Table 5: **Comparative results.** ⋆Values are taken from (Zadeh et al., 2018c). †Values are taken from (Tsai et al., 2018). Significance *T*-test (< 0.05) signifies that the obtained results are statistically significant over the existing systems with 95% confidence score.

score and weighted accuracy, respectively, than the state-of-the-art DFG (Zadeh et al., 2018c) system. Furthermore, we also see improvements for most of the individual emotion classes as well.

In sentiment analysis (c.f. Table 5b), for all the five datasets and different experimental setups, the proposed CIA framework obtains the improved accuracies for the classification tasks. For intensity prediction, our proposed framework yields lesser mean-absolute-error with high Pearson correlation scores. On average, we observe 1 to 5% improvement in accuracy values in comparison to the next best systems. Similarly, for the intensity prediction task, we report approximately 0.03 and 0.04 points improvement in mean-absolute-error and Pearson score, respectively.

We perform statistical significance test (*paired T-test*) on the obtained results and observe that performance improvement in the proposed model over the state-of-the-art is significant with 95% confidence (i.e., p-value< 0.05).

4.5 Error Analysis



We analyze our proposed *CIA* model to understand the importance of the baseline framework *CIA-IIM*. We study the predictions of both the models and observe that the proposed *CIA* framework improves the predictions of the baseline *CIA–IIM* model. It indicates that the CIA framework, indeed, learns the interaction among the input modalities, and the model effectively exploits this interaction for better judgment. In Table 6, we list the utterances of a CMU-MOSEI video along with their correct and predicted labels for both the proposed and baseline systems.

The video in Table 6 has 4 utterances, out of which the correct sentiments of three utterances (i.e., u_1, u_3, and u_4) are *positive*, while one utterance (i.e., u_2) is *negative*. We observe that our proposed *CIA* model predicts all the 4 utterances correctly, while the *CIA-IIM* mis-classify the sentiments of the utterances, u_2 and u_3.

We also analyze the *context-aware attention module (CAM)* with the help of heatmaps of the attention weights. The heatmaps, as depicted in Figure 3, represent the contributing utterances in the neighbourhood for the classification of each utterance. Figures 3a, 3b and 3c show the heatmaps of the pair-wise modality interaction of the proposed model *CIA*. In Figure 3a, each cell(*i,j*) of

	Utterances	Sentiment			Emotion		
		Actual	CIA−IIM	CIA	Actual	CIA−IIM	CIA
1	*these critics argue that the welfare state breeds dependence and incompetence among those who receive it they*	Pos	Pos	Pos	Happy, Sad	Happy	Happy, Sad
2	*argue that it creates social pathologies such as single parent families excess fertility and laziness*	Neg	Pos	Neg	Sad	Happy	Sad
3	*some argue that people who receive welfare benefits cannot spend their benefits rationally and*	Pos	Neg	Pos	Fear, Sad	Sad	Fear, Sad
4	*and then lastly some people on the moral side argue that nothing should be given to a person without requiring a reciprocal obligation from that person so*	Pos	Pos	Pos	Sad	Happy, Sad	Sad

Table 6: **Comparison between proposed *CIA* and *CIA−IIM* frameworks in MOSEI dataset.** Few cases where *CIA* framework performs better than the *CIA−IIM* framework. Red text signifies error in classification.

(a) $Sentiment_{TV}$ (b) $Sentiment_{TA}$ (c) $Sentiment_{AV}$ (d) $Emotion_{TV}$ (e) $Emotion_{TA}$ (f) $Emotion_{AV}$

Figure 3: **Heatmap analysis of MOSEI dataset** where **(a), (b) & (c)** represents the *Contextual Attention weights* for *TV, TA and AV* for sentiment and **(d), (e) & (f)** are *contextual attention weights* for *TV, TA and AV* for emotion.

the heatmap signifies the weights of utterance '*j*' for the classification of utterance '*i*'. For the utterance u_4, the model puts more attention weights on the u_2 and u_3 of the *text-visual* interactions, while for the *text-acoustic* interaction the model assigns higher weights to the u_4 utterance itself. Similarly, the model assigns the least weight to the u_1 utterance, whereas the utterance u_3 gets the highest weights. We argue that the proposed CAM module captures the diversity in the input modalities of the contextual utterances for the correct prediction.

For emotion prediction, the *CIA* model captures all the emotions correctly, while the *CIA-IIM* framework fails to predict the correct emotions of the utterances, u_2 and u_3. For the same video, we also show the attention heatmaps for emotion in Figure 3. For the utterance u_2, our proposed model (CIA) captures the emotion class '*sad*' as the CAM module assigns higher attention weights on the utterances u_2 and u_3 in Figure 3d, u_4 in Figure 3e, and u_2 in Figure 3f. Since the system finds the contributing neighbours as utterances u_2, u_3 and u_4 for various combinations, we argue that it utilizes the information of these utterances - which all express the '*sad*' emotion - for the correct prediction of utterance u_2 as '*sad*'.

5 Conclusion

In this paper, we have proposed a Context-aware Interactive Attention framework that aims to capture the interaction between the input modalities for the multi-modal sentiment and emotion prediction. We employed a contextual attention module to learn the contributing utterances in the neighborhood by exploiting the interaction among the input modalities. We evaluate our proposed approach on five standard multi-modal datasets. Experiments suggest the effectiveness of the proposed model over various existing systems, for both sentiment and emotion analysis, as we obtained new state-of-the-art for all five datasets.

In current work, we undertook the problem of sentiment and emotion analysis for a single-party utterances. In future, we would like to extend our work towards the multi-party dialogue.

Abstract

Text classification has been one of the major problems in natural language processing. With the advent of deep learning, convolutional neural network (CNN) has been a popular solution to this task. However, CNNs which were first proposed for images, face many crucial challenges in the context of text processing, namely in their elementary blocks: convolution filters and max pooling. These challenges have largely been overlooked by the most existing CNN models proposed for text classification. In this paper, we present an experimental study on the fundamental blocks of CNNs in text categorization. Based on this critique, we propose Sequential Convolutional Attentive Recurrent Network (SCARN). The proposed SCARN model utilizes both the advantages of recurrent and convolutional structures efficiently in comparison to previously proposed recurrent convolutional models. We test our model on different text classification datasets across tasks like sentiment analysis and question classification. Extensive experiments establish that SCARN outperforms other recurrent convolutional architectures with significantly less parameters. Furthermore, SCARN achieves better performance compared to equally large various deep CNN and LSTM architectures.

1 Introduction

Text classification is one of the major applications of Natural Language Processing (NLP). Text classification involves classifying a text segment into different predefined categories. Sentiment analysis of product reviews, language detection, topic classification of various news articles are some of the problem statements of text classification. Prior to the success of deep learning, text classification was dealt using lexicon based features. These primarily involve parts-of-speech (POS) tagging where verbs and adjectives are given more importance compared to other POS. Frequency based feature selection techniques like Bag-of-Words (BoW), Term frequency-Inverse document frequency (TF-IDF) have been used and the features are trained using machine learning classifiers like Logistic Regression (LR) or Naive Bayes (NB). These approaches provided strong baselines for text classification (Wang and Manning, 2012). However, sequential patterns and semantic structure between words play a crucial role in deciding the category of a text. Traditional lexicon approaches fail to capture such complexities. Since the success of deep learning, neural network architectures have outperformed traditional methods like BoW and count based feature selection techniques. Neural network architectures especially Convolutional Neural Networks (CNN) and Long Short Term Memory (Hochreiter and Schmidhuber, 1997) (LSTM) have achieved state-of-the-art results in text classification. Shallow CNN architectures (Kim, 2014; Madasu and Rao, 2019a,b) achieved admirable results on text classification as well. Very deep CNN architectures were proposed based on character level features (Zhang et al., 2015) and word level features (Conneau et al., 2016) which significantly improved the performance in text classification. In image classification and object detection, previously proposed deep CNN architectures (Szegedy et al., 2016) achieved state-of-the-art results. The effectiveness of deep CNNs can be very well explained where primary convolutional layers detect the edges of an object. As we go deeper, more complex features of an image are learnt. But in case of text, there hasn't been much understanding behind their success. Popular CNN architectures use convolution with a fixed window size over the words in a sentence. However, a question arises whether sequential information is preserved using convolu-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5658–5667,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tion across words. *What will be the effect if word sequences are randomly shuffled and convolution is applied on them?* In case of LSTM, random shuffling results in least performance as LSTMs rely on sequential learning and random ordering harms any such learning. Whereas, in case of a fixed window convolution applied across words, there is no strong evidence that it preserves sequential information. Previously proposed CNN architectures use max pooling operation across convolution outputs to capture most important features (Kim, 2014). This leads to another question, if the feature selected by max pooling will always be the most important feature of the input or otherwise.

To answer the above questions, we conduct a study of experiments about the effects of using fixed window convolution across words as discussed in Section 3.1. And the effects of using max pooling operation on convolution outputs are discussed in Section 3.2. Based on their critique, we propose a Sequential Convolutional Attentive Recurrent Network (SCARN) model for effective text classification. The proposed model relies on recurrent structures for preserving sequential information and convolution layers to learn task specific representations. In summary, the contributions of the paper are:

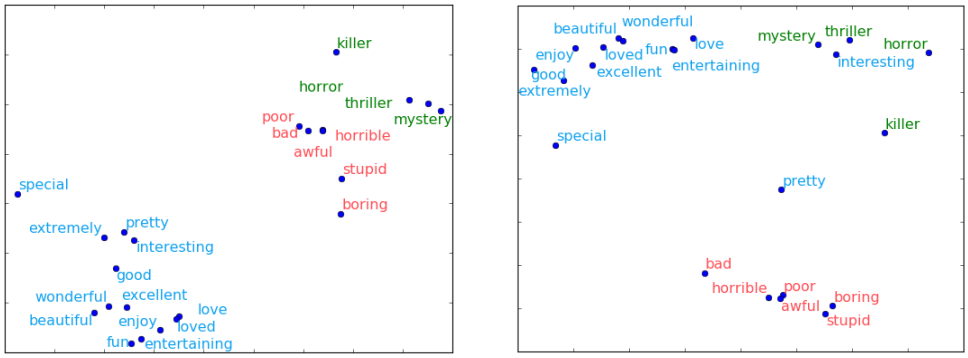
- We propose a new recurrent convolutional model for text classification by discussing the shortcomings of max pooling operation and also the strength and weakness of convolution operation.
- We evaluate the proposed model's performance on seven benchmark text classification datasets. The results show that the proposed model achieves better results with lesser number of parameters than other recurrent convolutional architectures.

2 Related Work

2.1 Recurrent Convolutional Networks

Previous architectures proposed for text classification were entirely convolution or recurrent based. There have been limited but popular works on combining recurrent structures with convolutional structures. (Lai et al., 2015) proposed a neural network (RCNN) model which combined recurrent and convolutional architectures. In their model each word is represented by a triplet of the word itself, its left and right context words, which are then trained sequentially using LSTM. Max pooling is then applied to capture the most important features of a sentence. Another attempt to combine recurrent and convolutional structures was made by Lee and Dernoncourt (2016) for sequential short-text classification. Their model uses LSTM to train short-texts and max pooling is applied on the outputs of all timesteps of LSTM to create a vector representation for each short-text. These architectures first use LSTM to train sequences and then max pooling operation is applied on its output. Zhou et al. (2015) proposed a recurrent convolutional network (C-LSTM) where convolution is applied over windows of multiple pretrained word vectors (fixed window size) to obtain higher level representations. These features serve as input to an LSTM for learning sequential information.

2.2 Attention Mechanism



Attention significantly improves the focusing on most meaningful information in the sentence. CNN and RNN architectures that were proposed with attention mechanism achieved superior performance to non-attention architectures. Attention originally proposed for machine translation (Bahdanau et al., 2014) was applied for document classification (Yang et al., 2016) as well. Several variants of attention mechanism have been proposed like global and local attention (Luong et al., 2015) and self attention (Lin et al., 2017). Attention has been applied to CNN blocks like pooling layers (Santos et al., 2016) for discriminative model training. Recently, attention based architectures achieved state-of-art results in question answering (Devlin et al., 2018).

3 Understanding Convolution and Max pooling

In this section we explore the working of CNNs in the context of natural language to better explain the intuition behind proposing SCARN. The key components of CNNs, namely convolution and max pooling strengths and weaknesses are discussed in this section.

3.1 Convolution operation

The convolution operation in the context of its application on word embeddings is discussed as follows.

(a) Original Embeddings (b) Convolution Transformation

Figure 1: t-SNE projection of original embeddings and after convolution transformation

What it doesn't learn

Convolution operation can be explained as a weighted sum across timesteps. This may result in loss of sequential information. To illustrate our hypothesis, we conduct an experiment on the Rotten Tomatoes dataset (Pang and Lee, 2005). In this experiment we train a CNN with convolution being applied on words with the fixed window size varying from one to maximum sentence length. We repeat this experiment with randomly shuffling all the words in an input sentence (Random ordering), and with shuffling every two consecutive words as shown in this example "read book forget movie" to "book read movie forget" (Alternate shuffle). The results of this experiment are illustrated in Figure 2[1]. Our observations in this experiment are the following:

- CNNs fail to fully incorporate sequential information as performance on random ordering and correct ordering are marginally near each other. As evident in the figure, the performance with correct ordering on window size 7 is comparable to performance with random ordering on window size 1.
- As window size increases, the difference between correct and incorrect orderings diminishes and finally converges when window size is complete sentence length. This indicates that the ability to capture sequential information by CNNs, decline with increasing window size.

Furthermore, we also note that while performance on random ordering is marginally less than correct ordering, it is still higher than other context blind algorithms like bag-of-words as shown in Table 1. This implies that while not fully exploiting sequential information, convolution filters still learn something valuable which we explore in next section.

What it learns

To understand what convolution filters do, we train a CNN with single window size on the SST2 dataset (Socher et al., 2013) for sentiment classification. As the convolution acts over a single word, it has no ability to capture sequential information. Hence, irrespective of input sentence word order, words will always have same respective convolution output. Essentially, convolution layer here acts like an embedding transformation, where input embedding space is transformed into another space. To understand this new space we project the respective embeddings using t-SNE (Maaten and Hinton, 2008) and illustrate them in Figure 1. Here we make a distinction between the semantic knowledge of a word and the task specific knowledge of a word. As this experiment is done on dataset SST2, we refer to task specific knowledge as the sentiment knowledge of a word. Word embeddings[2] are generally trained on huge domain generic data because of which they capture the general semantic information of the word. Figure 1a shows these word embeddings as they are in the original space. As we can see, semantically similar words cluster together. Figure 1b shows words after their convolutional transformation. Blue coloured words represent words with positive sentiment. Red with negative sentiment

[1]Experiment on more datasets could be found in the Appendix B

[2]In this experiment GloVE word embeddings were used.

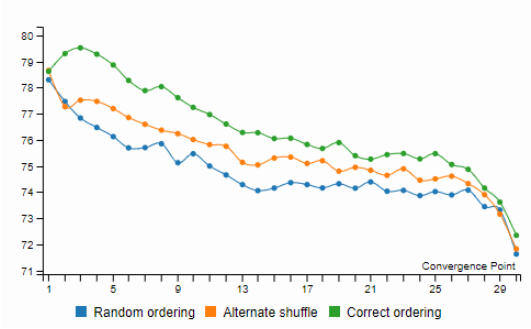


Figure 2: Accuracy (y-axis) percentage on Rotten Tomatoes dataset with varying window size.

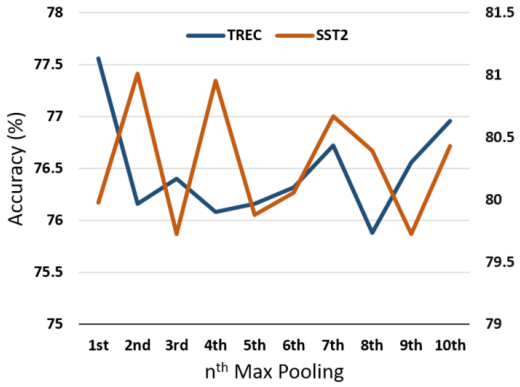

Figure 3: Accuracy (y-axis) percentage on TREC and SST2 datasets with varying n for the n^{th} Max pooling.

and green words are those which are semantically close to negative sentiment words. However, in the context of movie reviews, their sentiment value is close to positive sentiment words. From this experiment we observe:

- The transformation of the green words between original and convoluted outputs, shows that the convolution layer is able to tune their input embeddings such that they are more closer to the positive sentiment cluster than to their original semantic cluster. For example, a word like "killer" in the original embedding space is very close to negative sentiment words like, "bad" and "awful", especially if the word embeddings were produced on huge fact based datasets like Wikipedia or news datasets. However in the SST2 dataset, "killer" is often used to describe a movie very positively. Hence sequential learning on such transformed embeddings will be more effective than the original semantic embeddings.

- Some words like "pretty" might be semantically closer to the positive sentiment words. However in the dataset, we find common occurrences of phrases like "pretty good" or "pretty bad". The layer has hence transformed its position nearly equidistant to both the negative and positive clusters. In other words, convolution layer is able to robustly create a transformation which can handle any task specific noise.

The above observations show the effectiveness of the convolution operation. This is because a single convolution filter output value captures a weighted summation over all the features of the original word embedding. This enables the network to learn more task appropriate features as many as the number of filters.

With the above points in mind, we observe that convolution operation does not fully exploit sequential information, especially on larger window sizes. However we do see their effectiveness in conforming the input embeddings to a representation specifically meaningful to the task. Hence, for sequential learning instead of relying on convolution, we use recurrent architectures in our proposed SCARN model.

3.2 Max pooling operation: More doesn't mean better

Max pooling operation in images identify the discriminative features from convolution outputs. However this does not relate the same way of selecting most relevant features from convoluted features in texts. To illustrate this, we perform an experiment using a CNN architecture based on architecture by Kim (2014) popularly used in text classification. We define n^{th} Max pooling as choosing n^{th} highest value of all filters as opposed to first (n=1). By analyzing the performance distinctions on varying values of n, we make an attempt to assess whether maximum necessarily means task meaningful. The results are illustrated in Figure 3[3]. The results show that when n is increased the performance varies arbitrarily on all datasets. This shows that there is no apparent corelation between magnitude of the values to importance for the task. Hence, this relationship does not stand strong for text based inputs.

[3]Experiment on more datasets could be found in the Appendix B

4 Model

4.1 Overview

The proposed SCARN model architecture is shown in the Figure 4. Let V be the vocabulary size considered and X $\in \mathbb{R}^{V \times d}$ represent embedding matrix where X_i is a d dimensional word vector. Vocabulary words contained in the pretrained embeddings are initialized to their respective embedding vectors and words that are not present are assigned 0's. For each input text, a maximum length N is considered. Zero padding is applied if the length of input text is less than N. Hence, each sentence or paragraph is converted to I $\in \mathbb{R}^{N \times d}$ dimensional vector which is the input to SCARN model.

The model consists of two subnetworks: Convolution Recurrent subnetwork and Recurrent Attentive subnetwork. In the first subnetwork, convolution with single window size is applied on the input I. Convolution filters learn the higher level representations from the input text. The output from convolution is trained sequentially using LSTM network. In the second subnetwork, the input I is trained using LSTM. To better focus on most relevant words, attention mechanism is applied to the outputs of LSTM from every time step. Attention creates an alternate context vector for the input I by choosing the most suitable words necessary for classification. The outputs from the first subnetwork and second subnetwork are concatenated and connected to the output layer through a dense connection.

4.2 Convolution Recurrent subnetwork

Let I be represented as sequence of words $I = w_1 w_2 w_3 ... w_N$ where w_i represent the i^{th} word in the input. A total of K convolution filters are applied on each word w_i of input. Let $L \in \mathbb{R}^{K \times d}$ be the weight matrices of all filters. For each filter $l \in \mathbb{R}^{1 \times d}$ when applied on w_i, outputs a new feature C_{il}. Therefore, a new feature vector C_i is obtained for each word w_i after convolving with K filters.

$$C_i = C_{i1} C_{i2} C_{i3} ..... C_{iK} \quad (1)$$

Similarly, the above procedure is repeated for all the words in the input to produce a feature vector $C \in \mathbb{R}^{N \times d \times K}$.

$$C = f(I \circledast L) \quad (2)$$

where $\circledast$ represents convolution operation and f is the non-linear activation (ReLU). Applying convolution to individual words preserve the sequential information. Convolution learns the higher level representations for the input words. Each word will be transformed to a new representation pertinent to the task. The new feature representations are trained sequentially using LSTM.

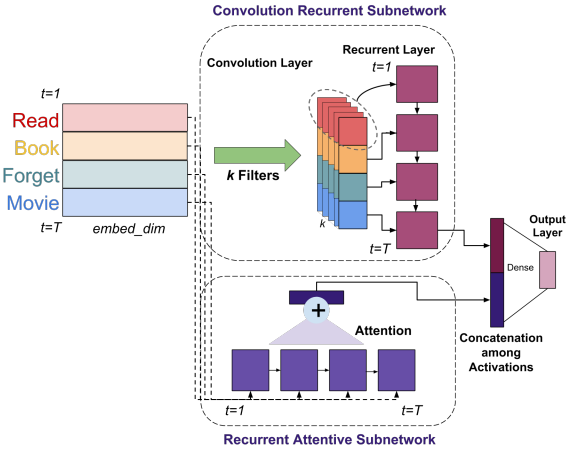

Figure 4: SCARN Architecture

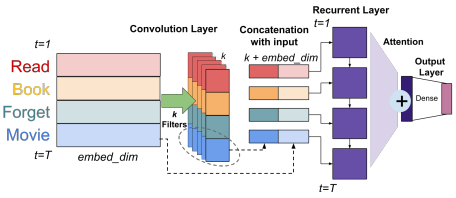

Figure 5: concat-SCARN architecture

4.3 Recurrent Attentive subnetwork

In this subnetwork, the input word embeddings are trained using LSTM. All words in the input sentence are not equally important in predicting final output. Although, LSTM learns sequential information, selecting significant information is a key issue for text classification. For this purpose, we employ an attention layer on the top of LSTM outputs. Attention mechanism focuses on specific significant words and tries to construct alternate context vector by aggregating the word representations.

5 Experiments

5.1 Datasets

We tested our model on standard benchmark datasets: Rotten-Tomatoes (RT) (Pang and Lee, 2005), Polarity V2.0 (Pol) (Pang and Lee, 2004), SST-2 (Socher et al., 2013), Home and Kitchen reviews (AR) (He and McAuley, 2016), TREC (Li and Roth, 2002), IMDB (Maas et al., 2011)

and Subjectivity Objectivity (SO) (Pang and Lee, 2004). The statistics for the datasets are shown in Table 3

5.2 Baselines

We compared our model to various text classification approaches[4].

BoW and TF-IDF + LR

Bag-of-words(BoW) and TF-IDF are strong baselines for text classification. BoW and TF-IDF features are extracted and softmax is applied on the top for classification.

Average Word Vectors + MLP

This baseline uses the average of word embeddings as features for the input text which are then trained using Multilayer perceptron (MLP).

Paragraph2Vec + MLP

Each input sentence is converted to a feature vector using Paragraph2vec(Le and Mikolov, 2014) which are then trained using Multilayer perceptron (MLP).

Deep CNN

This baseline is based on deep CNN architecture (Conneau et al., 2016) with approximately matching number of parameters as our model.

Char CNN

For our comparison, we employed the Char CNN architecture (Zhou et al., 2015) with less parameters compared to the original model, as the datasets used by them were considerably huge than ours.

LSTM and Bi-LSTM

We also offer a comparison with LSTM and Bi-LSTM architectures with a single hidden layer and approximately matching number of parameters as our model.

LSTM + Attention

In this baseline, attention mechanism is applied on the top of LSTM outputs across different time steps.

concat-SCARN

In this model, we concatenate the outputs from convolution layer as in SCARN, with input word embeddings at each time step. The concatenated outputs are trained using LSTM. Attention is applied on the top of this layer. Figure 5 shows the architecture of concat-SCARN model.

RCNN

We compared our model to the RCNN model (Lai et al., 2015) which uses max pooling for selecting the most appropriate features of a sentence.

C-LSTM

We compared our model to C-LSTM model (Zhou et al., 2015) which uses convolution over fixed window of words to learn higher level representations.

5.3 Implementation

Input and Training Details

We used google pretrained word vectors for C-LSTM[5], as it was used in the original work. For all the other experiments which require embeddings, we use GloVe pretrained word vectors[6]. The size of a word embedding in this model is 300. For each dataset, a maximum sentence length is considered which is 30 for TREC, SO, RT, Pol, SST-2 datasets, 400 for IMDB and 100 for AR dataset.

We apply a dropout layer (Srivastava et al., 2014) with a probability of 0.5 on the pretrained embeddings. We also apply dropout with a probability 0.5 on the dense layer that connects to output. We use Adam as the optimizer with a batch-size of 16 for small SCARN model and 50 for Large SCARN model. The initial learning rate is set to 0.0003. Training is done for 30 epochs.

Architecture

We employ two different architectures of SCARN model since the datasets vary in size. For datasets TREC, SO, RT, Pol, SST-2 the number of convolution filters are 50. Number of LSTM cells considered for these datasets are 32. We call this architecture **Small SCARN model**. For datasets AR and IMDB, number of convolution filters are 100 and number of LSTM cells are 64. We call this architecture **Large SCARN model**. The comparison of number of parameters for each model is shown in Table 2. ReLU is used as the activation function in convolution layers. In the output layer, softmax is used for multi-class classification and sigmoid for binary.

[4]For lack of code, results are from our implementations

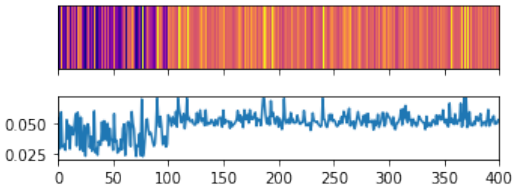
6 Results and Discussion

Results of the experiments are tabulated in Table 1. We observe that, the proposed SCARN model outperforms linear and word vector based models, because of their inability to incorporate sequential information. We also compare our model to recurrent models like LSTM, Bidirectional-LSTM and find that SCARN outperforms them as these recurrent architectures even though learn sequential information, lack SCARN's learning of task specific representations through convolution. Meanwhile, SCARN outperforms deep CNN and char CNN models, for their lack of learning sequential information the same way recurrent architectures can. When SCARN is compared to other recurrent convolutional architectures RCNN and C-LSTM, SCARN achieves significantly much better performance with lesser parameters as shown in Table 2. RCNN uses max pooling to capture the most important feature. However our discussions in Section 3.2 show max pooling's choice of maximum may not necessitate importance. C-LSTM used fixed window convolution across words. But as seen in Section 3.1 fixed window convolution do not capture sequential information adequately. In SCARN model, we apply convolution across single word to learn task specific information, on which LSTM architecture is trained to capture contextual information.



We observe that SCARN significantly outperforms concat-SCARN on all the datasets. We believe this is because in concat-SCARN, concatenation between input embeddings and convolution activations is done. However they belong to a very different distribution. In Figure 7, we show the

Dataset	Dataset size	Train	Dev	Test	Max Vocab size	Classes
IMDB	50000	20000	5000	25000	30000	2
TREC	5952	4906	546	500	5000	6

Table 3: Summary Statistics of all datasets

(a) Mean

(b) Standard Deviation

Figure 7: Statistics of each feature in concatenation layer outputs on the IMDB dataset's training set.

average and standard deviation of outputs at the concatenation layer of concat-SCARN on IMDB dataset's training set. As evident from the figure, we can make a stark distinction between the two concatenated sections as shown in the architecture of concat-SCARN in Figure 5. Because of the irregular distributions, the learning may become biased towards one of the segments. Furthermore, attempts to address this issue by using batch normalization layers may not be a good idea, as normalizing word embedding inputs may spoil the semantic concepts underlying them. Hence, in our SCARN model, subnetworks are trained differently, and final activations are concatenated as illustrated in SCARN's architecture in Figure 4. As long as both subnetworks' outputs come from similar activation function, they will have similar distributions as well and hence they won't suffer from the same problem as concat-SCARN.

Effectiveness of attention has also been illustrated in Figure 6, where attention weights have been shown in a heat map, with darker colors corresponding to a higher weightage. We observe that SCARN is able to effectively utilize attention weights to focus on most contributing input words.

7 Conclusion

In this paper we present a critical study and viewpoint of CNNs, which even though are popularly used in text classification, details of it are often overlooked. We find that convolutional filters learn particularly in the context of sequential information. But at the same time, they are good at learning higher level task-relevant features. On the other hand, we find max pooling to be very arbitrary in selection of crucial features and hence contributing minimal to the overall task. We also find that the problems with input concatenation, as it imbalances the representations because of difference in nature of distributions. Based on our study we proposed SCARN, for effectively utilizing convolution and recurrent features for text classification. Our model beats other popular ways of combining recurrent and convolutional architectures with quite less number of parameters on various benchmark datasets. Our model also outperforms CNN and RNN architectures with equally deep or same number of parameters.

Figure 8: n^{th} Max pooling experiments on RT, IMDB and SO Datasets

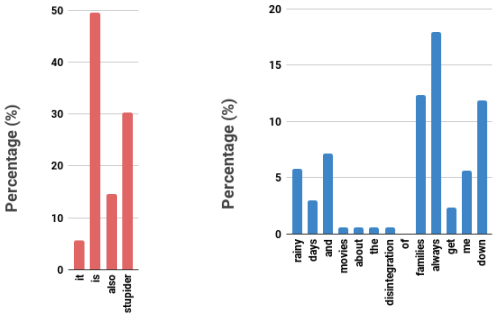

Figure 9: Percentage distribution of max pooling outputs for misclassified samples from SST2 dataset

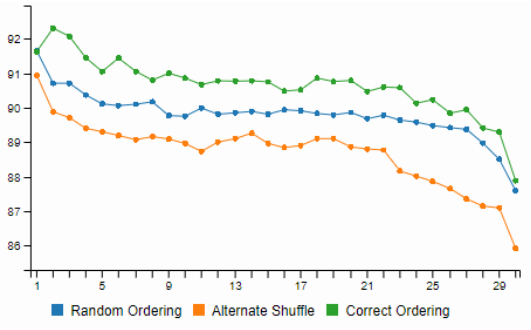

Figure 10: Accuracy (y-axis) percentage on SO dataset with varying window size.

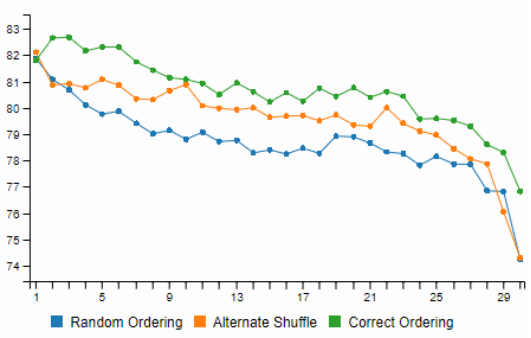

Figure 11: Accuracy (y-axis) percentage on SST2 dataset with varying window size.

A Max Pooling: missclassified examples

For this experiment, after convolution over single word, we perform max pooling across filter outputs and attempt to discern the max pooling outputs. We identify which input words' convolution outputs were chosen by the max pooling operation. These distributions illustrated in Figure 9 are presented on some misclassified examples from the SST2 dataset. We see that often words that should have been contributing most to the overall sentiment value, have very less or minimal share. For example in the sentence, "it is also stupider", we see "is" having the near majority share, even though it tells nothing about the sentiment of the sentence. At the same time in "rainy days and movies about the disintegration of families always get me down", "disintegration" has almost no share despite being an important word for evaluating sentiment.

B Experiments on more datasets

Figure 8 shows the n^{th} Max pooling experiment explained in Section 3.2 on other datasets, namely RT, IMDB and SO. We still find that there is no co-relation between importance for task and magnitude of the values. Figure 10 and Figure 11 show the Ordering experiment from Section 3.1 on SO and SST2 datasets respectively. As evident from the figures, the proposed hypotheses stay sound on other datasets as well.

The Role of Pragmatic and Discourse Context in Determining Argument Impact

Abstract

Research in the social sciences and psychology has shown that the persuasiveness of an argument depends not only the language employed, but also on attributes of the source/communicator, the audience, and the appropriateness and strength of the argument's claims given the pragmatic and discourse context of the argument. Among these characteristics of persuasive arguments, prior work in NLP does not explicitly investigate the effect of the pragmatic and discourse context when determining argument quality. This paper presents a new dataset to initiate the study of this aspect of argumentation: it consists of a diverse collection of arguments covering 741 controversial topics and comprising over 47,000 claims. We further propose predictive models that incorporate the pragmatic and discourse context of argumentative claims and show that they outperform models that rely only on claim-specific linguistic features for predicting the perceived impact of individual claims within a particular line of argument.

1 Introduction

Previous work in the social sciences and psychology has shown that the impact and persuasive power of an argument depends not only on the language employed, but also on the credibility and character of the communicator (i.e. ethos) (Miller et al., 1976; Chaiken, 1979, 1980); the traits and prior beliefs of the audience (G. Lord et al., 1979; Davies, 1998; Correll et al., 2004; Hullett, 2005); and the pragmatic context in which the argument is presented (i.e. kairos) (Haugtvedt and Wegener, 1994; Joyce and Harwood, 2014).

Research in Natural Language Processing (NLP) has only partially corroborated these findings. One very influential line of work, for example, develops computational methods to automatically determine the linguistic characteristics of persuasive arguments (Habernal and Gurevych, 2016; Tan et al., 2016; Zhang et al., 2016), but it does so without controlling for the audience, the communicator or the pragmatic context.

Very recent work, on the other hand, shows that attributes of both the audience and the communicator constitute important cues for determining argument strength (Lukin et al., 2017; Durmus and Cardie, 2018). They further show that audience and communicator attributes can influence the relative importance of linguistic features for predicting the persuasiveness of an argument. These results confirm previous findings in the social sciences that show a person's perception of an argument can be influenced by his background and personality traits.

To the best of our knowledge, however, no NLP studies explicitly investigate the role of *kairos* — a component of pragmatic context that refers to the context-dependent "timeliness" and "appropriateness" of an argument and its claims within an argumentative discourse — in argument quality prediction. Among the many social science studies of attitude change, the order in which argumentative claims are shared with the audience has been studied extensively: Haugtvedt and Wegener (1994), for example, summarize studies showing that the argument-related claims a person is exposed to beforehand can affect his perception of an alternative argument in complex ways. Joyce and Harwood (2014) similarly find that changes in an argument's context can have a big impact on the audience's perception of the argument.

Some recent studies in NLP have investigated the effect of interactions on the overall persuasive power of posts in social media (Tan et al., 2016; Hidey and McKeown, 2018). However, in social media not all posts have to express arguments or stay on topic (Rakshit et al., 2017), and qualitative evaluation of the posts can be influenced by many

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5668–5678, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

other factors such as interactions between the individuals (Durmus and Cardie, 2019). Therefore, it is difficult to measure the effect of argumentative pragmatic context alone in argument quality prediction without the effect of these confounding factors using the datasets and models currently available in this line of research.

In this paper, we study the role of kairos on argument quality prediction by examining the individual claims of an argument for their timeliness and appropriateness in the context of a particular line of argument. We define kairos as the sequence of **argumentative** text (e.g. claims) along a particular line of argumentative reasoning.

To start, we present a dataset extracted from *kialo.com* of over 47,000 claims that are part of a diverse collection of arguments on 741 controversial topics. The structure of the website dictates that each argument must present a supporting or opposing claim for its parent claim, and stay within the topic of the main thesis. Rather than being posts on a social media platform, these are community-curated claims. Furthermore, for each presented claim, the audience votes on its impact within the given line of reasoning. Critically then, the dataset includes the argument context for each claim, allowing us to investigate the characteristics associated with impactful arguments.

With the dataset in hand, we propose the task of studying the characteristics of impactful claims by (1) taking the argument context into account, (2) studying the extent to which this context is important, and (3) determining the representation of context that is more effective. To the best of our knowledge, ours is the first dataset that includes claims with both impact votes and the corresponding context of the argument.

2 Related Work

Recent studies in computational argumentation have mainly focused on the tasks of identifying the structure of the arguments such as argument structure parsing (Peldszus and Stede, 2015; Park and Cardie, 2014), and argument component classification (Habernal and Gurevych, 2017; Mochales and Moens, 2011). More recently, there is an increased research interest to develop computational methods that can automatically evaluate qualitative characteristic of arguments, such as their impact and persuasive power (Habernal and Gurevych, 2016; Tan et al., 2016; Kelman, 1961; Burgoon et al., 1975; Chaiken, 1987; Tykocinskl et al., 1994; Dillard and Pfau, 2002; Cialdini, 2007; Durik et al., 2008; Marquart and Naderer, 2016). Consistent with findings in the social sciences and psychology, some of the work in NLP has shown that the impact and persuasive power of the arguments are not simply related to the linguistic characteristics of the language, but also on characteristics the source (ethos) (Durmus and Cardie, 2019) and the audience (Lukin et al., 2017; Durmus and Cardie, 2018). These studies suggest that perception of the arguments can be influenced by the credibility of the source, and the background of the audience.

It has also been shown, in social science studies, that *kairos*, which refers to the "timeliness" and "appropropriateness" of arguments and claims, is important to consider in studies of argument impact and persuasiveness (Haugtvedt and Wegener, 1994; Joyce and Harwood, 2014). One recent study in NLP has investigated the role of argument sequencing in argument persuasion looking at (Hidey and McKeown, 2018) Change My View[1], which is a social media platform where users post their views, and challenge other users to present arguments in an attempt to change their them. However, as stated in (Rakshit et al., 2017) many posts on social media platforms either do not express an argument, or diverge from the main topic of conversation. Therefore, it is difficult to measure the effect of pragmatic context in argument impact and persuasion, without confounding factors from using noisy social media data. In contrast, we provide a dataset of claims along with their structured argument path, which only consists of claims and corresponds to a particular line of reasoning for the given controversial topic. This structure enables us to study the characteristics of impactful claims, accounting for the effect of the pragmatic context.

Consistent with previous findings in the social sciences, we find that incorporating pragmatic and discourse context is important in computational studies of persuasion, as predictive models that with the context representation outperform models that only incorporate claim-specific linguistic features, in predicting the impact of a claim. Such a system that can predict the impact of a claim given an argumentative discourse, for example, could potentially be employed by argument retrieval and

[1]https://www.reddit.com/r/changemyview/.

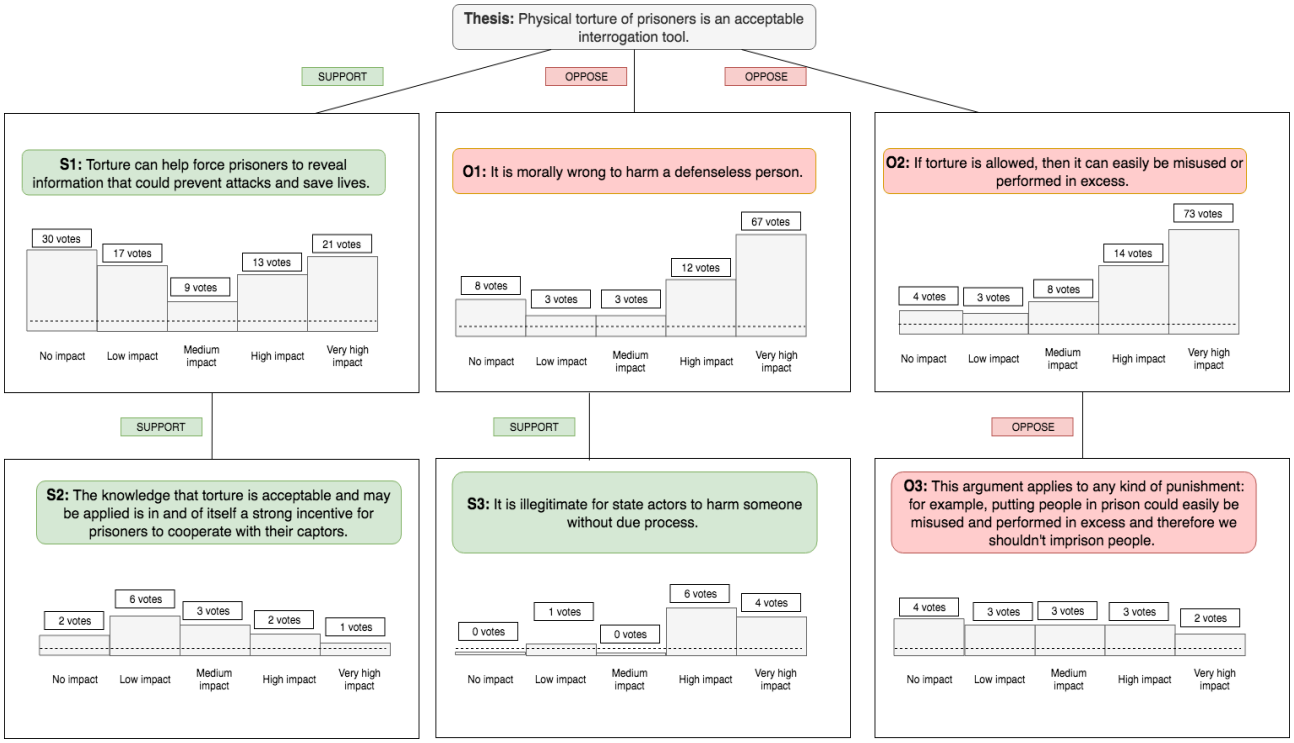

Figure 1: Example partial argument tree with claims and corresponding impact votes for the thesis "PHYSICAL TORTURE OF PRISONERS IS AN ACCEPTABLE INTERROGATION TOOL.".

generation models which aims to pick or generate the most appropriate possible claim given the discourse.

3 Dataset

Claims and impact votes. We collected 47,219 claims from *kialo.com*[2][3] for 741 controversial topics and their corresponding impact votes. Impact votes are provided by the users of the platform to evaluate how impactful a particular claim is. Users can pick one of 5 possible impact labels for a particular claim: NO IMPACT, LOW IMPACT, MEDIUM IMPACT, HIGH IMPACT and VERY HIGH IMPACT. While evaluating the impact of a claim, users have access to the full argument context and therefore, they can assess how impactful a claim is in the given context of an argument. An interesting observation is that, in this dataset, the same claim can have different impact labels depending on the context in which it is presented.

Figure 1 shows a partial **argument tree** for the argument **thesis** "PHYSICAL TORTURE OF PRISONERS IS AN ACCEPTABLE INTERROGATION TOOL.". Each node in the argument tree corresponds to a claim, and these argument trees are constructed and edited collaboratively by the users of the platform.

Except the thesis, every claim in the argument tree either opposes or supports its parent claim. Each path from the root to leaf nodes corresponds to an **argument path** which represents a particular line of reasoning on the given controversial topic.

Moreover, each claim has **impact votes** assigned by the users of the platform. The impact votes evaluate how impactful a claim is within its context, which consists of its predecessor claims from the thesis of the tree. For example, claim **O1** "IT IS MORALLY WRONG TO HARM A DEFENSELESS PERSON" is an opposing claim for the thesis and it is an IMPACTFUL CLAIM since most of its impact votes belong to the category of VERY HIGH IMPACT. However, claim **S3** "IT IS ILLEGITIMATE FOR STATE ACTORS TO HARM SOMEONE WITHOUT THE PROCESS" is a supporting claim for its parent **O1** and it is a less impactful claim since most of the impact votes belong to the NO IMPACT and LOW IMPACT categories.

Distribution of impact votes. The distribution of claims with the given range of number of im-

[2]The data is collected from this website in accordance with the terms and conditions.

[3]There is prior work by Durmus et al. (2019) which created a dataset of argument trees from *kialo.com*. That dataset, however, does not include any impact labels.

# impact votes	# claims
$[3, 5)$	4,495
$[5, 10)$	5,405
$[10, 15)$	5,338
$[15, 20)$	2,093
$[20, 25)$	934
$[25, 50)$	992
$[50, 333)$	255

Table 1: Number of claims for the given range of number of votes. There are 19,512 claims in the dataset with 3 or more votes. Out of the claims with 3 or more votes, majority of them have 5 or more votes.

pact votes are shown in Table 1. There are 19,512 claims in total with 3 or more votes. Out of the claims with 3 or more votes, majority of them have 5 or more votes. We limit our study to the claims with at least 5 votes to have a more reliable assignment for the accumulated impact label for each claim.

Impact label statistics. Table 3 shows the distribution of the number of votes for each of the impact categories. The claims have $241,884$ total votes. The majority of the impact votes belong to MEDIUM IMPACT category. We observe that users assign more HIGH IMPACT and VERY HIGH IMPACT votes than LOW IMPACT and NO IMPACT votes respectively. When we restrict the claims to the ones with at least 5 impact votes, we have $213,277$ votes in total[4].

Agreement for the impact votes. To determine the agreement in assigning the impact label for a particular claim, for each claim, we compute the percentage of the votes that are the same as the majority impact vote for that claim. Let c_i denote the count of the claims with the class labels C=[NO IMPACT, LOW IMPACT, MEDIUM IMPACT, HIGH IMPACT, VERY HIGH IMPACT] for the impact label l at index i.

$$\text{Agreement} = 100 * \frac{\max_{0 \leq i \leq 4} c_i}{\sum_{i=0}^{4} c_i}\% \quad (1)$$

For example, for claim S1 in Figure 1, the agreement score is $100 * \frac{30}{90}\% = 33.33\%$ since the majority class (NO IMPACT) has 30 votes and there are 90 impact votes in total for this particular claim. We compute the agreement score for the cases where (1) we treat each impact label separately (5-class case) and (2) we combine the classes HIGH IMPACT and VERY HIGH IMPACT into a one class: IMPACTFUL and NO IMPACT and LOW IMPACT into a one class: NOT IMPACTFUL (3-class case).

Table 2 shows the number of claims with the given agreement score thresholds when we include the claims with at least 5 votes. We see that when we combine the low impact and high impact classes, there are more claims with high agreement score. This may imply that distinguishing between no impact-low impact and high impact-very high impact classes is difficult. To decrease the sparsity issue, in our experiments, we use 3-class representation for the impact labels. Moreover, to have a more reliable assignment of impact labels, we consider only the claims with have more than 60% agreement.

Context. In an argument tree, the claims from the thesis node (root) to each leaf node, form an argument path. This argument path represents a particular line of reasoning for the given thesis. Similarly, for each claim, all the claims along the path from the thesis to the claim, represent the **context** for the claim. For example, in Figure 1, the context for **O1** consists of only the thesis, whereas the context for **S3** consists of both the thesis and **O1** since **S3** is provided to support the claim **O1** which is an opposing claim for the thesis.

The claims are not constructed independently from their context since they are written in consideration with the line of reasoning so far. In most cases, each claim elaborates on the point made by its parent and presents cases to support or oppose the parent claim's points. Similarly, when users evaluate the impact of a claim, they consider if the claim is timely and appropriate given its context. There are cases in the dataset where the same claim has different impact labels, when presented within a different context. Therefore, we claim that it is not sufficient to only study the linguistic characteristic of a claim to determine its impact, but it is also necessary to consider its context in determining the impact.

Context length (C_l) for a particular claim *C* is defined by number of claims included in the argument path starting from the thesis until the claim *C*. For example, in Figure 1, the context length for **O1** and **S3** are 1 and 2 respectively. Table 4 shows number of claims with the given range of con-

[4]26,998 of them NO IMPACT, 33,789 of them LOW IMPACT, 55,616 of them MEDIUM IMPACT, 47,494 of them HIGH IMPACT and 49,380 of them VERY HIGH IMPACT.

	3-class case	5-class case
Agreement score	Number of claims	Number of claims
$> 50\%$	10,848	7,304
$> 60\%$	7,386	4,329
$> 70\%$	4,412	2,195
$> 80\%$	2,068	840

Table 2: Number of claims, with at least 5 votes, above the given threshold of agreement percentage for 3-class and 5-class cases. When we combine the low impact and high impact classes, there are more claims with high agreement score.

Impact label	# votes- all claims
No impact	32,681
Low impact	37,457
Medium impact	60,136
High impact	52,764
Very high impact	58,846
Total # votes	241,884

Table 3: Number of votes for the given impact label. There are $241,884$ total votes and majority of them belongs to the category MEDIUM IMPACT.

Context length	# claims
1	1,524
2	1,977
3	1,181
$[4, 5]$	1,436
$(5, 10]$	1,115
> 10	153

Table 4: Number of claims for the given range of context length, for claims with more than 5 votes and an agreement score greater than 60%.

text length for the claims with more than 5 votes and 60% agreement score. We observe that more than half of these claims have 3 or higher context length.

4 Methodology

4.1 Hypothesis and Task Description

Similar to prior work, our aim is to understand the characteristics of impactful claims in argumentation. However, we **hypothesize** that the qualitative characteristics of arguments is not independent of the context in which they are presented. To understand the relationship between argument context and the impact of a claim, we aim to incorporate the context along with the claim itself in our predictive models.

Prediction task. Given a claim, we want to predict the impact label that is assigned to it by the users: NOT IMPACTFUL, MEDIUM IMPACT, or IMPACTFUL.

Preprocessing. We restrict our study to claims with at least 5 or more votes and greater than 60% agreement, to have a reliable impact label assignment. We have $7,386$ claims in the dataset satisfying these constraints[5]. We see that the impact class IMPACFUL is the majority class since around 58% of the claims belong to this category.

For our experiments, we split our data to train (70%), validation (15%) and test (15%) sets.

4.2 Baseline Models

4.2.1 Majority

The majority baseline assigns the most common label of the training examples (HIGH IMPACT) to every test example.

4.2.2 SVM with RBF kernel

Similar to (Habernal and Gurevych, 2016), we experiment with SVM with RBF kernel, with features that represent (1) the simple characteristics of the argument tree and (2) the linguistic characteristics of the claim.

The features that represent the simple characteristics of the claim's argument tree include the distance and similarity of the claim to the thesis, the similarity of a claim with its parent, and the impact votes of the claim's parent claim. We encode the similarity of a claim to its parent and the thesis claim with the cosine similarity of their tf-idf vectors. The distance and similarity metrics aim to model whether claims which are more similar (i.e. potentially more topically relevant) to their parent claim or the thesis claim, are more impactful.

[5]We have 1,633 NOT IMPACTFUL, 1,445 MEDIUM IMPACT and 4,308 IMPACFUL claims.

We encode the quality of the parent claim as the number of votes for each impact class, and incorporate it as a feature to understand if it is more likely for a claim to impactful given an impactful parent claim.

Linguistic features. To represent each claim, we extracted the linguistic features proposed by (Habernal and Gurevych, 2016) such as tf-idf scores for unigrams and bigrams, ratio of quotation marks, exclamation marks, modal verbs, stop words, type-token ratio, hedging (Hyland, 1998), named entity types, POS n-grams, sentiment (Hutto and Gilbert, 2014) and subjectivity scores (Wilson et al., 2005), spell-checking, readibility features such as *Coleman-Liau* (Coleman and Liau, 1975), *Flesch* (Flesch, 1948), argument lexicon features (Somasundaran et al., 2007) and surface features such as word lengths, sentence lengths, word types, and number of complex words[6].

4.2.3 FastText

Joulin et al. (2017) introduced a simple, yet effective baseline for text classification, which they show to be competitive with deep learning classifiers in terms of accuracy. Their method represents a sequence of text as a bag of n-grams, and each n-gram is passed through a look-up table to get its dense vector representation. The overall sequence representation is simply an average over the dense representations of the bag of n-grams, and is fed into a linear classifier to predict the label. We use the code released by Joulin et al. (2017) to train a classifier for argument impact prediction, based on the claim text[7].

4.2.4 BiLSTM with Attention

Another effective baseline (Zhou et al., 2016; Yang et al., 2016) for text classification consists of encoding the text sequence using a bidirectional Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), to get the token representations in context, and then attending (Luong et al., 2015) over the tokens to get the sequence representation. For the query vector for attention, we use a learned context vector, similar to Yang et al. (2016). We picked our hyperparameters based on performance on the validation set, and report our results for the best set of hyperparameters[8]. We initialized our word embeddings with glove vectors (Pennington et al., 2014) pre-trained on Wikipedia + Gigaword, and used the Adam optimizer (Kingma and Ba, 2015) with its default settings.

4.3 Fine-tuned BERT model

Devlin et al. (2018) fine-tuned a pre-trained deep bi-directional transformer language model (which they call BERT), by adding a simple classification layer on top, and achieved state of the art results across a variety of NLP tasks. We employ their pre-trained language models for our task and compare it to our baseline models. For all the architectures described below, we finetune for 10 epochs, with a learning rate of 2e-5. We employ an early stopping procedure based on the model performance on a validation set.

4.3.1 Claim with no context

In this setting, we attempt to classify the impact of the claim, based on the text of the claim only. We follow the fine-tuning procedure for sequence classification detailed in (Devlin et al., 2018), and input the claim text as a sequence of tokens preceded by the special [CLS] token and followed by the special [SEP] token. We add a classification layer on top of the BERT encoder, to which we pass the representation of the [CLS] token, and fine-tune this for argument impact prediction.

4.3.2 Claim with parent representation

In this setting, we use the parent claim's text, in addition to the target claim text, in order to classify the impact of the target claim. We treat this as a sequence pair classification task, and combine both the target claim and parent claim as a single sequence of tokens, separated by the special separator [SEP]. We then follow the same procedure above, for fine-tuning.

4.3.3 Incorporating larger context

In this setting, we consider incorporating a larger context from the discourse, in order to assess the impact of a claim. In particular, we consider up

[6] We pick the parameters for SVM model according to the performance validation split, and report the results on the test split.

[7] We used maxNgram legnth of 2, learning rate of 0.8, num epochs of 15, vector dim of 300. We also used the pre-trained 300-dim wiki-news vectors made available on the fastText website.

[8] Our final hyperparams were: 100-dim word embedding, 100-dim context vector, 1 layer BiLSTM with 64 units, trained for 40 epochs with early stopping based on validation performance.

	Precision	Recall	F1

Table 5: Results for the baselines and the BERT models with and without the context. Best performing model is BERT with the representation of previous 3 claims in the path along with the claim representation itself. We run the models 5 times and we report the mean and standard deviation.

to four previous claims in the discourse (for a total context length of 5). We attempt to incorporate larger context into the BERT model in three different ways.

Flat representation of the path. The first, simple approach is to represent the entire path (claim + context) as a single sequence, where each of the claims is separated by the [SEP] token. BERT was trained on sequence pairs, and therefore the pre-trained encoders only have two segment embeddings (Devlin et al., 2018). So to fit multiple sequences into this framework, we indicate all tokens of the target claim as belonging to segment A and the tokens for all the claims in the discourse context as belonging to segment B. This way of representing the input, requires no additional changes to the architecture or retraining, and we can just finetune in a similar manner as above. We refer to this representation of the context as a flat representation, and denote the model as Context$_f(i)$, where i indicates the length of the context that is incorporated into the model.

Attention over context. Recent work in incorporating argument sequence in predicting persuasiveness (Hidey and McKeown, 2018) has shown that hierarchical representations are effective in representing context. Similarly, we consider hierarchical representations for representing the discourse. We first encode each claim using the pre-trained BERT model as the claim encoder, and use the representation of the [CLS] token as claim representation. We then employ dot-product attention (Luong et al., 2015), to get a weighted representation for the context. We use a learned context vector as the query, for computing attention scores, similar to Yang et al. (2016). The attention score α_c is computed as shown below:

$$\alpha_c = \frac{exp(V_c^T V_l)}{\sum_{c \in D} exp(V_c^T V_l)} \quad (2)$$

Where V_c is the claim representation that was computed with the BERT encoder as described above, V_l is the learned context vector that is used for computing attention scores, and D is the set of claims in the discourse. After computing the attention scores, the final context representation v_d is computed as follows:

$$V_d = \sum_{c \in D} \alpha_c V_c \quad (3)$$

We then concatenate the context representation with the target claim representation $[V_d, V_r]$ and pass it to the classification layer to predict the quality. We denote this model as Context$_a(i)$.

GRU to encode context Similar to the approach above, we consider a hierarchical representation for representing the context. We compute the claim representations, as detailed above, and we then feed the discourse claims' representations (in sequence) into a bidirectional Gated Recurrent

	$C_l = 1$	$C_l = 2$	$C_l = 3$	$C_l = 4$
BERT models				
Claim only	$48.61_{\pm 3.16}$	$53.15_{\pm 1.95}$	$54.51_{\pm 1.91}$	$50.89_{\pm 2.95}$
Claim + Parent	$51.49_{\pm 2.63}$	$54.78_{\pm 2.95}$	$54.94_{\pm 2.72}$	$51.94_{\pm 2.59}$
Claim + Context$_f(2)$	$52.84_{\pm 2.55}$	$53.77_{\pm 1.00}$	$55.24_{\pm 2.52}$	$57.04_{\pm 1.19}$
Claim + Context$_f(3)$	$\mathbf{54.88_{\pm 2.49}}$	$54.71_{\pm 1.74}$	$52.93_{\pm 2.07}$	$\mathbf{58.17_{\pm 1.89}}$
Claim + Context$_f(4)$	$54.47_{\pm 2.95}$	$\mathbf{54.88_{\pm 1.53}}$	$\mathbf{57.11_{\pm 3.38}}$	$57.02_{\pm 2.22}$

Table 6: F1 scores of each model for the claims with various context length values.

Unit (GRU) (Cho et al., 2014), to compute the context representation. We concatenate this with the target claim representation and use this to predict the claim impact. We denote this model as Context$_{gru}(i)$.

5 Results and Analysis

Table 5 shows the macro precision, recall and F1 scores for the baselines as well as the BERT models with and without context representations[9].

We see that *parent quality* is a simple yet effective feature and SVM model with this feature can achieve significantly higher ($p < 0.001$)[10] F1 score (46.61%) than *distance from the thesis* and *linguistic features*. Claims with higher impact parents are more likely to be have higher impact. *Similarity with the parent and thesis* is not significantly better than the *majority* baseline. Although the BiLSTM model with attention and FastText baselines performs better than the SVM with *distance from the thesis* and *linguistic features*, it has similar performance to the *parent quality* baseline.

We find that the BERT model with *claim only* representation performs significantly better ($p < 0.001$) than the baseline models. Incorporating the *parent representation* only along with the *claim representation* does not give significant improvement over representing the claim only. However, *incorporating the flat representation of the larger context* along with the claim representation consistently achieves significantly better ($p < 0.001$) performance than the claim representation alone. Similarly, *attention representation* over the context with the learned query vector achieves significantly better performance then the *claim representation* only ($p < 0.05$).

We find that the *flat representation* of the context achieves the highest F1 score. It may be more difficult for the models with a larger number of parameters to perform better than the *flat representation* since the dataset is small. We also observe that modeling 3 claims on the argument path before the target claim achieves the best F1 score (55.98%).

To understand for what kinds of claims the best performing contextual model is more effective, we evaluate the BERT model with *flat context representation* for claims with context length values 1, 2, 3 and 4 separately. Table 6 shows the F1 score of the BERT model without context and with *flat context representation* with different lengths of context. For the claims with context length 1, adding Context$_f(3)$ and Context$_f(4)$ representation along with the claim achieves significantly better ($p < 0.05$) F1 score than modeling the *claim only*. Similarly for the claims with context length 3 and 4, Context$_f(4)$ and Context$_f(3)$ perform significantly better than BERT with *claim only* (($p < 0.05$) and ($p < 0.01$) respectively). We see that models with larger context are helpful even for claims which have limited context (e.g. $C_l = 1$). This may suggest that when we train the models with larger context, they learn how to represent the claims and their context better.

6 Conclusion

In this paper, we present a dataset of claims with their corresponding impact votes, and investigate the role of argumentative discourse context in argument impact classification. We experiment with various models to represent the claims and their context and find that incorporating the context information gives significant improvement in predicting argument impact. In our study, we find that *flat representation* of the context gives the best improvement in the performance and our analysis indicates that the contextual models perform better even for the claims with limited context.

[9]For the models that result in different scores with different random seed, we run them 5 times and report the mean and standard deviation.

[10]We perform two-sided t test for significance analysis.

Abstract

We propose a method based on neural networks to identify the sentiment polarity of opinion words expressed on a specific aspect of a sentence. Although a large majority of works typically focus on leveraging the expressive power of neural networks in handling this task, we explore the possibility of integrating dependency trees with neural networks for representation learning. To this end, we present a convolution over a dependency tree (CDT) model which exploits a Bi-directional Long Short Term Memory (Bi-LSTM) to learn representations for features of a sentence, and further enhance the embeddings with a graph convolutional network (GCN) which operates directly on the dependency tree of the sentence. Our approach propagates both contextual and dependency information from opinion words to aspect words, offering discriminative properties for supervision. Experimental results ranks our approach as the new state-of-the-art in aspect-based sentiment classification.

1 Introduction

The current explosion in digital technology in recent years has led to a vast amount of opinionated materials on the internet. In particular, individuals have expressed opinions on several aspects of products, services, blogs, and comments which are deemed to be influential, especially when making purchase decisions based on product reviews (Schouten and Frasincar, 2015). However, due to the voluminous amount of content online, sifting through reviews to learn knowledge of opinions expressed on specific aspects of a review is cumbersome. This fact has led to an increase in research in aspect-based sentiment analysis (ABSA), which aims to find scalable solutions to address the problem automatically. More specifically, ABSA involves two tasks: (1) to identify aspects of a sentence, and (2) to determine the sentiment polarity (e.g. positive, negative, neutral) expressed on a specific aspect. In this paper, we focus on the second task: aspect-based sentiment classification.

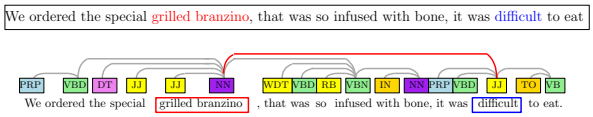

Figure 1: An example of a dependency tree where an opinion word (blue) and the specific aspect expression (red) are connected with other word tokens based on their syntactic dependencies.

With the aim to address the classification task, several methods have been developed. Majority of recent works such as (Dong et al., 2014; Tang et al., 2015; Wang et al., 2016; Chen et al., 2017; Cheng et al., 2017) have exploited neural networks due to its ability to model representations for sentences automatically. Even so, some recent methods have integrated both lexical resources with neural networks to achieve state-of-the-art performance in ABSA (Wang et al., 2018; Ouyang and Su, 2018).

Generally, we find that a dependency tree shortens the distance between the aspects and opinion words of a sentence, captures the syntactic relations between words, and offers discriminative syntactic paths on arbitrary sentences for information propagation across the tree. For instance, consider the dependency tree as depicted in Figure 1, the distance between the aspect expression *'grilled branzino'* and the opinion word *'difficult'* is shortened by a single path based on their syntactic dependencies. These properties allow neural network models to capture long-term syntactic dependencies effortlessly. Besides, dependency

trees have graph-like structures bringing to play the recent class of neural networks, namely, graph convolutional networks (GCN) (Kipf and Welling, 2016). The GCN has been successful in learning representations for nodes, capturing the local position of nodes in the graph. Several AI applications such as link prediction (Schlichtkrull et al., 2018; Zitnik et al., 2018; Kong et al., 2019), semantic role labeling (Marcheggiani and Titov, 2017), and relation extraction (Zhang et al., 2018) have successfully exploited GCNs to improve representation learning.

These observations motivate us to develop a neural model which can operate on the dependency tree of a sentence, with the aim to make accurate sentiment predictions with respect to specific aspects. Specifically, we propose a convolution over a dependency tree (CDT) model which exploits a GCN to model the structure of a sentence through its dependency tree, where node (word) embeddings of the tree are initialized by means of a Bi-directional Long Short Term Memory (Bi-LSTM) network. Motivated by the recent work of (Zhang et al., 2018) in a relation extraction task, we find that the architecture of CDT allows the Bi-LSTM account for contextual information between successive words, while the GCN enhances the embeddings by modeling the dependencies along the syntactic paths of the dependency tree. Such operations allow information to be transferred from opinion words to aspect words, implying that the encoding for aspect words is sufficient for supervision in the classification task. Experimental results, including visualizations show the effectiveness of our proposed model.

2 Related Work

The performance bottleneck in the classification task of ABSA comes from modeling representations which efficiently encode the relationship between a specific aspect and the opinion words of a sentence. Most recent methods have focused on leveraging neural networks (Chen et al., 2017; Gu et al., 2018; Majumder et al., 2018; Fan et al., 2018a; Xue and Li, 2018; Huang and Carley, 2018; Zheng and Xia, 2018) which model representations automatically. Besides, in contrast to rule-based methods (Hu and Liu, 2004; Popescu and Etzioni, 2005; Ding et al., 2008; Popescu and Etzioni, 2005), neural networks are more capable of dealing with situations where opinion words are found in more complicated contexts.

Among neural network methods, some model the sentence representation using RNN variants such as LSTM and gated recurrent units (GRU). (Chen et al., 2017) handles the encoding of reviews using BiLSTM and attention networks. (Gu et al., 2018) improves the performance by considering the position of the aspect words. Similarly, (Zheng and Xia, 2018) use LSTMs to learn embeddings for the left context, right context and target phrase of sentences while considering the interactions between targets and contexts. (Majumder et al., 2018) on the other hand models the sentence representations using GRU and attention mechanisms. However convenient, these neural network based methods neglect informative resources such as dependency trees which is capable of shortening the distance between aspect and opinion words, enabling dependency information to be preserved effectively in lengthy sentences.

The state-of-the-art methods for representation learning have integrated dependency trees with neural networks. (Tai et al., 2015) proposed a tree-structured LSTM: a generalized class of LSTMs which enables the learning of dependency information between words and phrases. (Mou et al., 2015) exploit the short paths of dependency trees to learn representations of sentences using convolutional neural networks, while preserving dependency information. Motivated by such works, (Gu et al., 2018) proposed a position encoding convolutional neural network which takes into account the relative position of words and entities of a dependency tree for relation classification. Given that dependency trees can be considered as a graph, (Marcheggiani and Titov, 2017) introduced a variant of a GCN to model representations for dependency graphs in semantic role labeling tasks.

In a recent relation extraction task, (Zhang et al., 2018) extract entity-based representations via a GCN which operates on a dependecy tree. (Zhang et al., 2018) observed that stacking a GCN layer over an LSTM improves performance immensely. We follow a similar approach and propose CDT: a method which performs convolutions over a dependency tree to extract rich representations for aspect-based sentiment classification. CDT extracts a final representation for the ABSA classification task by aggregating only the aspect vec-

tors. We believe this is sufficient because the GCN componet can be interpreted as a messaging passing network which propagates information along edges. Thus, successive GCN operations allow information to be propagated across the network, and hence aspect vectors are encoded with information from opinion words which should be sufficient for supervision.

3 Convolution over Dependency Tree Model

In this section, we describe the CDT model which takes as input a dependency tree of a sentence. Node embeddings of the dependency tree are initially modeled by means of a BiLSTM, and the embeddings are further enhanced via a GCN. Finally, an aggregator is applied over the enhanced aspect embeddings to distill a dense vector embedding for the classification task. In particular, we aim to extract embeddings which encode both contextual and dependency information between a specific aspect expression and opinion words, providing supervisory signals for the aspect-based classification task.

We briefly describe the BiLSTM model, which takes as input the sentence s with n ordered word embeddings. The BiLSTM integrates context information in the word embeddings by keeping track of dependencies along the chain of words. Given an aspect-sentence pair (a, s), where $a = \{a_1, a_2, \ldots, a_l\}$ is a sub-sequence of the sentence $s = \{w_1, w_2, \ldots, w_n\}$. The sentence s has corresponding word embeddings $x = \{x_1, x_2, \ldots x_n\}$. The LSTM learns hidden state representations $\{\overrightarrow{h_1^0}, \overrightarrow{h_2^0}, \ldots \overrightarrow{h_n^0}\}$ in the forward direction on the word embeddings in x. This allows contextual information to be captured in a forward direction. In a similar fashion, a backward LSTM will learn representations $\{\overleftarrow{h_1^0}, \overleftarrow{h_2^0}, \ldots \overleftarrow{h_n^0}\}$ on x. Finally, we can concatenate the corresponding parallel representations modeled by both forward and backward LSTMs into higher dimensional representations $\{h_1^0, h_2^0, \ldots, h_n^0\}$, which contains the subsequence $\{h_{a_1}^0, h_{a_2}^0, \ldots, h_{a_l}^0\}$ corresponding to the aspect expression a. In doing so, we capture contextual information between opinion words and aspects. Besides, we integrate dependency information in the contextualized embeddings using a GCN which operates directly on the dependency tree of the sentence.

3.1 Graph Convolutional Network

The dependency tree can be interpreted as a graph G with n nodes, where nodes represent words in the sentence and edges represent syntactic dependency paths between words in the graph. The nodes of the dependency tree are given by real-valued vectors modeled by BiLSTM as described above. This structure allows a GCN to operate directly on the graph to model dependencies that exist between words. To allow the GCN to model node embeddings efficiently, we allow G to have self-loops. The GCN approach ensures that the sentence structure represented by the dependency tree is encoded efficiently, whereby the representations for nodes encode the local position of opinion words and the target words in the dependency tree.

The dependency tree G for any arbitrary sentence can be represented as an $n \times n$ adjacency matrix A, with entries A_{ij} signaling if node i is connected to node j by a single dependency path in G. Specifically, $A_{ij} = 1$ if node i is connected to node j, and $A_{ij} = 0$ otherwise. Together with node embeddings modeled by BiLSTMs, we can exploit a GCN capable of operating directly on graphs. The GCN makes efficient use of dependency paths to transform and propagate information across the paths, and update node embeddings by aggregating the propagated information. In such an operation, the GCN only considers the first-order neighborhood of a node when modeling its embeddings. However, k successive GCN operations result in the propagation of information across the k-th order neighborhood. A single node embedding update takes the form

$$h_i^{(k+1)} = \phi\left(\sum_{j=1}^{n} c^i A_{ij}\left(W^{(k)} h_j^{(k)} + b^{(k)}\right)\right), \tag{1}$$

where $h_j^{(k)}$ is the hidden state representation for node j at the k^{th} layer of the GCN, $b^{(k)}$ is a bias term, $W^{(k)}$ is a parameter matrix, c^i is a normalization constant, which we choose as $c^i = 1/d_i$. d_i denotes the degree of node i in the graph calculated as $d_i = \sum_{j=1}^{n} A_{ij}$. $\phi(\cdot)$ is a relu elementwise non-linear activation function. Note that h_i^0 represent the initial embeddings modeled by a BiLSTM, and $h_i^{(k+1)}$ is the final output for node i at layer k.

In extracting a final embedding for the classifi-

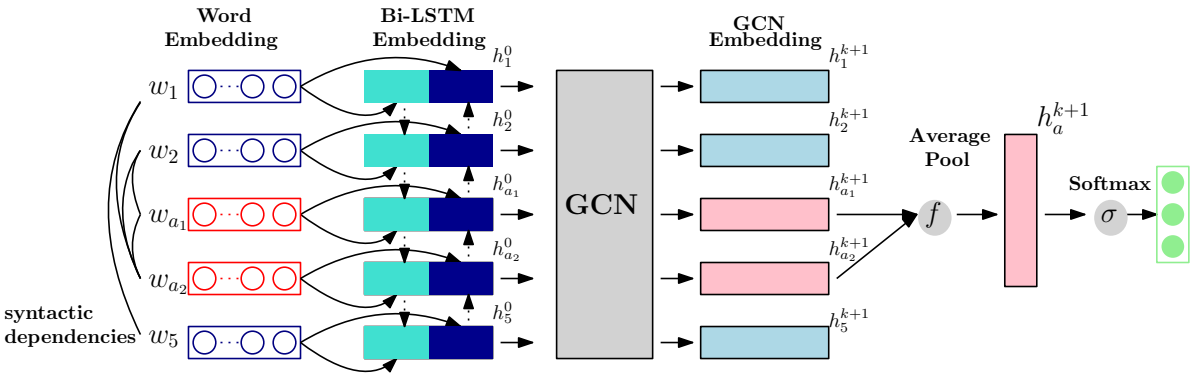

Figure 2: Overview of the CDT model based on the sentence $s = [w_1, w_2, w_{a_1}, w_{a_2}, w_5]$, where $[w_{a_1}, w_{a_2}]$ is the specific aspect expression in s, and k is the number of GCN layers.

cation task, we exploit a simple aggregator. For our framework, we choose an average pool which aggregates information over the aspect vectors. We choose to aggregate only the aspect vectors because we believe that these vectors encode contextual and dependency information owing to the BiLSTM and the GCN respectively. The BiLSTM and the GCN can be interpreted as message passing networks. Specifically, the BiLSTM allow aspect words of an arbitrary sentence to be contextualize, while the GCN finds the local position of aspect words in the syntactic dependency tree. The local position within the dependency tree encodes dependency information of a word with respect to its neighbors. As a result, the BiLSTM and the GCN allow embeddings for aspect words to have discriminative features, providing supervisory signals for the classification task. Moreover, we perform an average pool to retain most of the information in the aspect vectors. The pool operation over the aspect vectors takes the form of

$$h_a^{(k+1)} = f\left(\{h_{a_1}^{k+1}, h_{a_2}^{k+1}, \ldots, h_{a_l}^{k+1}\}\right), \quad (2)$$

where $f(\cdot)$ is an average pool function applied over the enhanced aspect vectors. We present an overview of the model architecture in Figure 2 based on an example sentence input.

4 Model Training

The aspect-based representation $h_a^{(k+1)}$ is passed to a fully connected softmax layer σ whose output is a probability distribution over the different sentiment polarities. The model is trained end-to-end through a backpropagation, where the objective function to be minimized is the cross entropy error defined as

$$J(\theta_1, \theta_2) = -\sum_{(a,s)\in D}\sum_{c\in C} y_c((a,s)) \log \hat{y}_c((a,s)), \quad (3)$$

where D is a collection of aspect-sentence pairs, C is the collection of distinct sentiment classes, $y_c((a,s))$ is the ground truth for (a,s) which takes the value of either 1 or 0. Besides, (a,s) can belong to only one sentiment class. Hence $y_c((a,s)) = 1$ indicates that the ground truth sentiment class for (a,s) is c. $\hat{y}_c((a,s))$ is the model's prediction for (a,s). θ_1, θ_2 are trainable parameters for the BiLSTM and GCN respectively.

5 Experiment

In this section, we conduct experiments to validate our model which we denote as CDT on benchmark datasets. We also present restricted versions of our model denoted as ASP-BiLSTM and ASP-GCN. Unlike our main model, ASP-BiLSTM only exploits BiLSTM to model contextual information with respect to a specific aspect expression, while ASP-GCN exploits a GCN to model dependencies between words. Both models extract a final embedding on the aspect vectors. We propose these two models to observe the performance of GCN and BiLSTM, as well as the performance when we stack a GCN on a BiLSTM which forms the CDT model. To distinguish CDT as the new state-of-the-art in aspect-based sentiment classification, we compare CDT with several well established models, showing that CDT outperforms the very recent models in the classification task. In particular, we perform case studies with visualizations to verify our approach of aggregating only aspect vectors for the final embedding. We further present visualizations on case examples showing how GCN

improves on a simple BiLSTM model.

5.1 Datasets

We evaluate the performance of our model on SemEval 2014 (Pontiki et al., 2014), which consists of restaurant reviews (Rest14) and laptop reviews (Laptop14). We also evaluate our model on SemEval 2016 [1] containing restaurant reviews (Rest16). Experiments are also performed on a collection of tweets from Twitter provided in the works of (Dong et al., 2014). We summarize the statistics of the datasets in Table 1.

Dataset	Positive		Neutral		Negative	
	train	test	train	test	train	test
Rest14	2164	727	637	196	807	196
Laptop14	976	337	455	167	851	128
Rest16	1657	611	101	44	748	204
Twitter	1507	172	3016	336	1528	169

Table 1: Distribution of samples by class labels on benchmark datasets

5.2 Implementation and parameter settings

For fairness in model comparation, we use similar parameters in compared models. Specifically, we exploit 300-dimensional Glove vectors (Pennington et al., 2014) for the word embeddings, as well as a 30-dimensional part-of-speech (POS) embeddings, 30-dimensional position embeddings, which is used to identify the relative position of each word with respect to the aspect in the sentence. We concatenate both word, POS and position embeddings, and learn a 50-dimensional BiLSTM embeddings for each word. The GCN operates on the dependency tree of the sentence to enhance the BiLSTM embeddings. All sentences are parsed by the Stanford parser. [2] To encourage the GCN to model dependencies between words, we randomly dropout 10% of neurons per layer, and about 0.7 at the input layer. The GCN model is trained for 100 epochs with batch size 32. We use the adam optimizer with learning rate 0.01 for all datasets. The code for our model is found on the Github page [3].

5.3 Compared Prior Art

As a baseline, we include CNN and LSTM models, which learn representations from both word embeddings and position embeddings. We denote these models as CNN+Position and LSTM+Position. We also include a CNN baseline method which exploits an attention mechanism to model the relation between aspect words and context words. We denote this model as CNN+ATT. These models extract a final embedding by aggregating all learned embeddings using an average pool. In particular, we compare our proposed model with very recent models on the benchmark datasets. The models we consider include,

- TNet (Li et al., 2018a): In this work, BiLSTM embeddings are transformed into target-specific embeddings, and a CNN model is used to extract a final embedding.
- PRET+MULT (He et al., 2018b): A multi-task framework based on LSTMs is proposed to transfer knowledge from a document-level model task to an aspect-level model task.
- SA-LSTM-P (Wang and Lu, 2018): This work first learn embeddings using BiLSTM and model structural dependencies between words by means of a segmentation attention mechanism.
- LSTM+SynATT+TarRep (He et al., 2018a): This method models target representation as a weighted sum of aspect embeddings, and models the syntactic structure of the sentence using an attention mechanism.
- MGAN (Fan et al., 2018b): A BiLSTM is exploited to capture contextual information in the sentence, while a multi-grained attention mechanism is proposed to extract an embedding which effectively captures the interaction between the aspect and the context.
- MGAN (Li et al., 2018b): This work integrates an alignment mechanism in a multi-task model comprising of an aspect-term task and an aspect-category task to effectively extract aspect-specific representations.
- HSCN (Lei et al., 2019): A model is proposed to capture interactions between the context and target, select target words and extract target-specific contextual representation, while measuring the deviation between target-specific contextual representation and target representations.

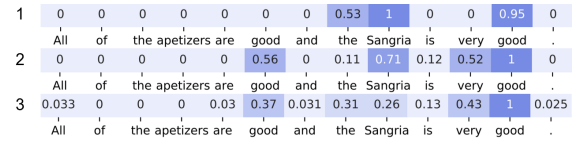
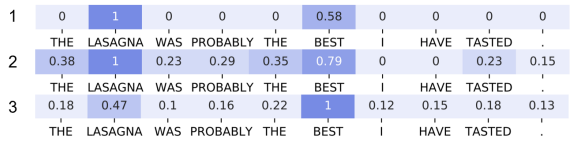
5.4 Performance Comparison

In this section, we compare model performance of recent methods with CDT, ASP-BiLSTM and ASP-GCN. We implement and report results for the baseline methods CNN+Position, LSTM+Position and CNN+ATT, and report the results in the original paper for the recent models under comparison. The classification results are shown in Table 2.



From the table, we find that CDT generally ouperforms all models for the different datasets, while having a slight accuracy performance degradation of 0.31 on the twitter dataset for the TNet model. The difference between TNet and CDT is not really significant. Hence it is fair to conclude that both models are competitive on the Twitter dataset. Even with simple architectures, we find that ASP-BiLSTM and ASP-GCN have competitive performance with the recent models on benchmark datasets. Particularly, ASP-GCN outperforms the models on the Rest14 dataset.

ASP-BiLSTM, ASP-GCN and CDT extract final representations from only the aspect vectors. Based on the performance, it seems as a sufficient technique for the classification task. We believe that the aspect vector is encoded with context and dependency information from the context and structure of the sentence by means of the BiLSTM and the GCN. The BiLSTM and GCN can be regarded as message passing networks, propagating information along a chain of sequence of words(BiLSTM) or along syntactic dependency path(GCN). Due to the fact that relevant information is passed to the aspect words, a simple average pool is all we need to retain information relevant to the classification task. Note that the information propagated in the network is learned therefore only weighed information is encoded within the aspect words.



5.5 GCN Performance

We conduct an experiment to demonstrate that the performance of our proposed models, namely CDT and ASP-GCN, depend on the number of layers of the GCN. We perform this experiment on the Rest14 dataset and present the result in Figure 4.

In our experimentation, we find that as we increase the number of layers the accuracy performance increase to an extent. In particular, ASP-GCN increase in model performance over 6 layers of the GCN. The performance becomes unstable after the 6-th layer. Since GCN passes information in the local neighborhood of any node, successive operations on the dependency tree allows ASP-GCN to pass information to the furthest node. The problem of overfitting takes effect when the layers rises beyond a threshold, explaining the accuracy curve after the 6-th layer in the figure. Another important observation is the convergence of accuracy performance of the ASP-BiLSTM and ASP-GCN at the 6-th layer. Note that ASP-BiLSTM only captures contextual information while ASP-GCN captures dependency information. However, both models converge in performance at the 6-th layer. Taking advantage of the GCN and the BiLSTM we expect to improve performance, capturing both context and dependencies with respect to the aspect expression. As seen in the accuracy curve of CDT, the GCN integrates dependency informa-

Figure 3: Word relevance scores with respect to the final embedding of ASP-GCN. Number of layers for ASP-GCN is 1, 2, 3 for row 1, row 2, and row 3 respectively in both examples.

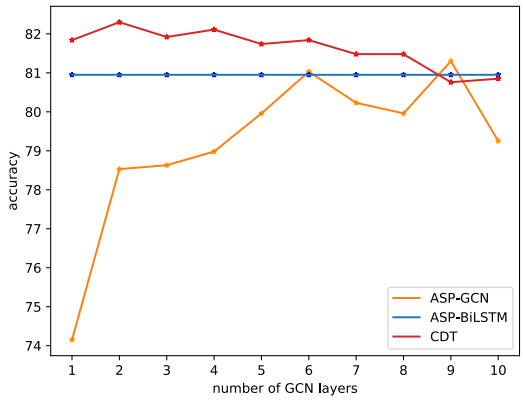

Figure 4: Accuracy curves for ASP-GCN, ASP-BiLSTM and CDT on the Rest14 dataset

tion in the contextualized embeddings to improve accuracy performance over just 2 layers, reducing the number of GCN layers needed.

5.6 Mask Experiment

Our primary assumption was that the aspect embeddings learned by our GCN model contains sufficient information necessary for the classification task. Based on this assumption we aggregate only the aspect embeddings using a max pool with the aim to retain most of the information. To verify this assumption, we trace from the input embeddings to the final embedding. We propose a mask method designed to estimate the relevance of a word with respect to the final embedding, and perform mask experiments using ASP-GCN.

The mask method works as follows. First, we follow through the conventional procedure to extract a final embedding h_s for a given sentence s using ASP-GCN. We perform a subsequent run of ASP-GCN on the same sentence s to extract a final embedding, but in this instance we conceal a specific input word w. We conceal w by mapping it to the zero vector before applying ASP-GCN on s. As a result a final embedding $h_{(s\backslash w)}$ is generated for s. If $h_s = h_{(s\backslash w)}$, the word w has no impact on the representation h_s. In other words, h_s does not capture w or no information flows from w to h_s. To this end, we can define a score function to estimate the relevance of w on h_s. We define the score function for w as

$$\gamma(w, s) = m \sum_{i=1}^{d} |h_s^i - h_{(s\backslash w)}^i| \quad (4)$$

where d is the dimension of the final embedding distilled by ASP-GCN, m is a normalization constant which we choose as $m = \max_{w \in s} \gamma(w, s)$. Generally, the final embedding should capture information on opinion words with respect to the target aspect. Hence, we expect to score high values for opinion words. Consider the scores for words shown in Figure 3, we find that γ scores high values for opinion words as we increase the number of layers of ASP-GCN, while reducing scores on irrelevant words. Implying that the final embedding captures information from opinions. The results as seen in these case examples convinces us that the final embedding distilled by our model captures relevant information necessary for the classification task.

5.7 Case Study

In this section we study the behaviour of ASP-BiLSTM, TNet and CDT on case examples. To this end we present visualizations showing the attention these models place on words. For a good model, we expect the model to attend to words which influence the sentiment inferred on a specific aspect.

From Table 2 and Figure 4, it is clear that GCN complements the BiLSTM to improve model performance. This means that the BiLSTM can identify opinion words within the context with respect to a specific aspect. However, in some complicated contexts, it might perform poorly. But the GCN can build upon BiLSTM to attend to the correct opinion words by leveraging the dependencies among words. Consider the case example shown

Figure 5: Attention visualization for ASP-BiLSTM (1st row), TNet(2nd row) and CDT (3rd row) for the aspect word 'Sangria'

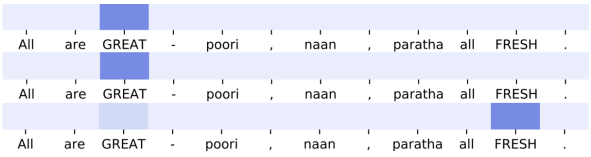

Figure 6: Attention visualization for ASP-BiLSTM (1st row), TNet (2nd row) and CDT (3rd row) for the aspect word 'paratha'

in Figure 5, ASP-BiLSTM was clever to know that the word 'good' is an opinion word with respect to the aspect 'Sangria'. But ASP-BiLSTM failed to identify whether 'good' on the far left is associated to the 'Sangria' or 'good' on the far right is associated to 'Sangria'. Interestingly, we find that the GCN could analyze this further through the dependencies between words to identify that it is the 'good' on the far right. TNet on the other hand measures the association between 'Sangria' and 'good' in both directions to identify the correct 'good'.

In Figure 6, even though the BiLSTM is able to identify the opinion word 'GREAT' which expresses an opinion on the aspect 'parathra', CDT is able to capture the opinion word 'FRESH' which directly expresses the sentiment towards the aspect. However, from the visualization is easily observed that CDT still attends to 'GREAT'. This suggest that the GCN is able to model the importance of the words with respect to the aspect, placing larger weights to words directly expressing the opinion on the aspect. At the same time, TNet misses the opinion word 'FRESH' and places attention to the word 'GREAT' just like ASP-BiLSTM.

In the case example shown in Figure 7, we find that ASP-BiLSTM places small attention on the opinion word 'BEST' which expresses the sentiment on the aspect word 'LASAGNA', while focusing its attention on 'WAS PROBABLY' which is not meaningful alone. Interestingly, CDT builds upon this little information and rely on the dependencies between the words through the dependency tree to learn that 'BEST' is the correct word to attend to. Similar to ASP-BiLSTM, TNet misses the important word 'BEST' and places attention to 'WAS PROBABLY'. This result suggest that TNet heavily depends on the representations modeled by its BiLSTM layer, while CDT considers other information such as the dependencies among words to accurately identify words which expresses opinions on specific aspects.

Figure 7: Attention visualization for ASP-BiLSTM (1st row), TNet (2nd row) and CDT (3rd row) for the aspect word 'LASAGNA'

6 Conclusion

Modeling representations for aspect-based sentiment classification generally require capturing informative words which express the sentiment inferred on the target aspect. Leveraging neural networks are highly desirable for representation learning. BiLSTM-based models have been successful to capture contextual information in prior works.

In this paper, we integrate a GCN with a simple BiLSTM model, with the aim to capture structural and contextual information of sentences. We have shown that the GCN successfully performs convolutions on the dependency tree to refine BiLSTM embeddings. Experimental results with visualizations support our argument on the extraction of a final embedding based on only the aspect vectors. In fact, the model we propose is simple and outperforms more complex and recent models tackling the same problem.

Abstract

Many Data Augmentation (DA) methods have been proposed for neural machine translation. Existing works measure the superiority of DA methods in terms of their performance on a specific test set, but we find that some DA methods do not exhibit consistent improvements across translation tasks. Based on the observation, this paper makes an initial attempt to answer a fundamental question: what benefits, which are consistent across different methods and tasks, does DA in general obtain? Inspired by recent theoretic advances in deep learning, the paper understands DA from two perspectives towards the generalization ability of a model: input sensitivity and prediction margin, which are defined independent of specific test set thereby may lead to findings with relatively low variance. Extensive experiments show that relatively consistent benefits across five DA methods and four translation tasks are achieved regarding both perspectives.

1 Introduction

Data Augmentation (DA) is a training paradigm that has been proved to be very effective in many modalities (Park et al., 2019; Perez and Wang, 2017; Sennrich et al., 2016a), especially for classification (Perez and Wang, 2017). In structured domain, Neural Machine Translation (NMT) is the frontier of DA research (Sennrich et al., 2016a; Norouzi et al., 2016; Zhang and Zong, 2016; Fadaee et al., 2017; Wang et al., 2018; Zhang et al., 2019; Edunov et al., 2018; Fadaee and Monz, 2018). However, by investigating a variety of DA methods, we find that their test performance across different translation tasks does not exhibit consistent improvement, and this phenomenon can be initially observed in (Wang et al., 2018) as well. The reason might be the evaluation metric on a specific test set when compared to the whole data population, which generates all possible data, has large variance so that leads to the inconsistency. This evaluation dilemma is also recognized and explored by Recht et al. (2018, 2019); Werpachowski et al. (2019), and is especially notorious for language generation tasks (Chaganty et al., 2018; Hashimoto et al., 2019) where the evaluation metrics, e.g. BLEU (Papineni et al., 2001), are extrinsic and heavily relies on the reference provided. Therefore, we ask a fundamental question: what benefits, which are more consistent across different DA methods and translation tasks, can DA in general obtain?

A direct answer to the above question is to use generalization gap (Kawaguchi et al., 2018) defined by the difference between population risk and empirical risk. This measure does not rely on any specific test set, accurately depicts generalization but is intractable to compute. So recently, many theorists have proposed either non-vacuous generalization bound (Dziugaite and Roy, 2017; Zhou et al., 2019) or novel generalization measures (Novak et al., 2018; Bartlett et al., 2017; Neyshabur et al., 2017; Jiang et al., 2019) to roughly reflect the gap. Inspired by them, we propose to understand the benefits of DA from two perspectives: input sensitivity and prediction margin. The proposed underlying two measures are well adapted from Novak et al. (2018) and Bartlett et al. (2017) and can be computed only on the train samples to unveil the consistent benefits of DA. Under a carefully designed fair setting over four different translation tasks, we examine five methods from two main categories of DA and compare them with a model trained without DA. The empirical experiments demonstrate the following findings: a). DA methods exhibit more consistent effects across different translation tasks in terms of both measures. b). DA methods can either allevi-

ate input sensitivity or promote prediction margin.

By and large, our main contributions are:

- We make an initial attempt to understand the essence of DA in NMT by investigating its benefits which are relatively consistent across five DA methods and four translation tasks.
- We highlight two perspectives towards generalization to measure the benefits of DA in NMT and study them with carefully designed fair experiments.

2 DA Methods in NMT

2.1 Training Objective Decomposition

Given the train set $\mathcal{T}$ the baseline NMT model $p_\theta(\mathrm{y}|\mathrm{x})$ without using DA is trained under the empirical data distribution $\hat{p}(X, Y|\mathcal{T})$ through maximum likelihood estimation:

$$J_{\mathrm{MLE}} = \mathbb{E}_{\mathrm{x,y}\sim\hat{p}(X,Y|\mathcal{T})}[\log p_\theta(\mathrm{y}|\mathrm{x})], \quad (1)$$

where $\hat{p}$ is a mixture of Dirac distribution concentrated around each training instance with uniform mixture coefficients $(1/|\mathcal{T}|)$. Then we define the augmentation (AUG) model as a conditional distribution over the train set, $q(X, Y|\mathcal{T})$. [1] Under the AUG model, the training objective becomes:

$$J_{\mathrm{AUG}} = \mathbb{E}_{\mathrm{x,y}\sim q(X,Y|\mathcal{T})}[\log p_\theta(\mathrm{y}|\mathrm{x})]. \quad (2)$$

More realistically, for any DA method in any training run, we can collect the augmented instances to form a set $\mathcal{A}$ distinguishing $\mathcal{T}$, when considering the curriculum of mixing $\mathcal{A}$ with the original train $\mathcal{T}$. Since we would like to derive a conceptual framework that reflects this form of importance weighting, we further decompose AUG model into a linear interpolation (α) of $\hat{p}(X, Y|\mathcal{T})$ and an augmentation distribution $q_{\mathrm{AUG}}(X, Y|\mathcal{T})$:

$$\alpha \cdot \hat{p}(X, Y|\mathcal{T}) + (1 - \alpha) \cdot q_{\mathrm{AUG}}(X, Y|\mathcal{T}), \quad (3)$$

where α controls the mixture ratio within a batch during SGD training. The ratio has been founded as an important factor influencing final performance (Sennrich et al., 2016a; Fadaee et al., 2017; Edunov et al., 2018; Fadaee and Monz, 2018).

[1] In the paper, we do not consider using monolingual data for DA thus conditioning only on bilingual data since this will further bring monolingual data selection discussed in Fadaee and Monz (2018) as a factor to influence the performance of different DA methods; we leave this factor for future study.

Table 1: Main BLEU results (CTC=0.62).

Key factors Through Eq. 3, we can identify two key factors for conducting fair experiments: a) the number of SGD updates on every original training instance means how much the model learns from $\mathcal{T}$; b) the mixture ratio means how much the model learns from $\mathcal{A}$ online, with which together balance the learning of the translation knowledge.

2.2 Settings and Main Performance

Settings By carefully controlling the above two factors, we conduct fair and extensive experiments with Transformer (Vaswani et al., 2017) on four translation tasks for five DA methods. Fairseq (Ott et al., 2019) is used as our codebase. We use standard benchmarks IWSLT17 En-Fr, WMT19 Zh-En, WMT19 En-De, where we train both translation directions on the IWSLT corpus. The five DA methods are briefly summarized as follows:

- RAML: reward-augmented maximum likelihood training, which augment the target-side with a sampling distribution $P(Y|Y^*)$ concentrated around Y^* (Norouzi et al., 2016).
- Switchout (SO): similar to RAML, but also adds the some kind of augmentation to the source-side (Wang et al., 2018).
- Self-training (ST): fix the source-side, uses an forward NMT model to generate the target-side (Zhang and Zong, 2016).
- Target-agree (TA): similar to ST, but uses a forward NMT model with right-to-left decoder (Zhang et al., 2019).
- Back-translation (BT): fix the target-side, uses an backward NMT model to generate the source-side (Sennrich et al., 2016a).

The implementation of RAML and SO are borrowed from the Appx. of Wang et al. (2018). [2]

[2] We categorize and analyze how we choose or train DA methods with a generative formulation in Appx. A and B.

Table 2: Sensitivity measure (CTC=0.72).

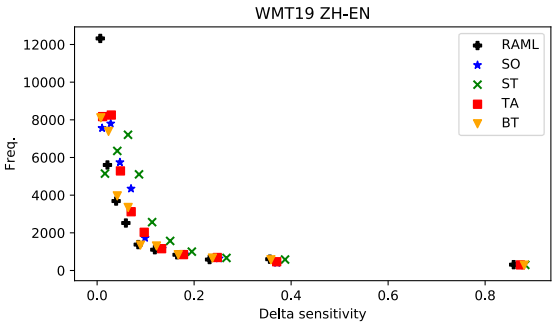

Figure 1: Δ sensitivity binned avg. token freq. statistics. Each point represents a bin from which we compute the token level average Δ sensitivity between that DA method and the baseline and the token level average frequency as its x and y coordinate value.

CTC Table 1 shows the main BLEU results of different methods on the test set. However, we cannot identify the best DA method because their rankings across the four translation tasks vary a bit. To measure the degree of consistency, we use a correlation measure called Kendall's coefficient of concordance (Kendall and Smith, 1939; Mazurek, 2011) to evaluate the correlation of the rankings produced on the four translation tasks (appx. C). The value shows strong consistency (correlation) of different rankings when it is close to 1. We call the correlation value Cross-Task Consistency measure or CTC. The CTC for the BLEU measure is 0.62, which is of weak consistency. This phenomenon might be a result of the intrinsic nature of using a single specific test as a substitute of the whole data population for evaluation. In the next section, we introduce two measures that are more consistent (with close-to-1 CTC value). They in some extent reflect the model generalization and are easy-to-compute as well.

3 Two Measures Towards Generalization

We attempt to understand the benefits that DA can obtain through the quantification of input sensitivity and prediction margin. The two measures are adapted from Novak et al. (2018) and Bartlett et al. (2017); Neyshabur et al. (2017); Jiang et al. (2019). They have been proved through massive experiments to be correlated with model generalization. Our main purpose here is to utilize them to unveil the consistency property (measured by CTC) of DA across different methods and translation tasks. The next two subsections define the two measures and report their statistics on subsamples of the train set respectively.

3.1 Input Sensitivity

Input sensitivity is the sensitivity of the loss computed from the model towards a minor change of input representation. Given a point of interest x, the original form in Novak et al. (2018) is defined as the expected Jacobian norm of the loss vector $\log p_\theta(\cdot|\mathrm{x})$ and p_θ is a softmax classifier:

$$\mathbb{E}_{\mathrm{x}}||J(\mathrm{x})||_F, \tag{4}$$

where $J(\mathrm{x}) = \partial \log p_\theta(\cdot|\mathrm{x})/\partial \mathrm{x}^T$, and $||\cdot||_F$ the Frobenius or L2 norm of the matrix. The paper also suggests a more predictive quantity of the generalization ability. That is to take advantage of the label y of x and only compute the L2 norm of a slice of the Jacobian matrix indexed by the label. We adopt the later measure which is the gradient norm of the loss scalar indexed by y to x:

$$\mathbb{E}_{\mathrm{x}}||J(\mathrm{x})_y||_F. \tag{5}$$

If $\mathrm{x} \in \mathbb{R}^d$ lies in a space with differential structure, we can apply Eq. 5 directly. But in NMT the naive representation of an instance (x, y) is the token index given by the vocabulary, so we cannot compute the gradient of the loss with respect to x. We follow Sundararajan et al. (2017) and use the result of x after embedding lookup as its learned representation, denoted as $\mathrm{Emb}(\mathrm{x}) \in \mathbb{R}^{L_\mathrm{x} \times d}$ where L_x is the length of the input and d the size of the embedding. By regarding the translation model $p_\theta(\mathrm{y}|\mathrm{x})$ as a function that decomposes at each step of y given $\mathrm{Emb}(\mathrm{x})$ as input to get a scalar average log likelihood, denoted as $\mathcal{L}_{\mathrm{x,y}} = \frac{1}{L_\mathrm{y}} \sum_t \log p_\theta(\mathrm{y}_t|\mathrm{y}_{<t}, \mathrm{x})$. Moreover, initial experiments on just using the single original x_i to evaluate the gradient will still result in inconsistency, due to the non-equivalence of the localness concept compared with the continuous setting, i.e. for language input, the localness is between discrete inputs in the neighbor of x_i. So we

evaluate the sensitivity of x_i by averaging gradient norms over its k nearest neighbor $\mathrm{x}_{i(j)} \in \mathrm{kNN}[\mathrm{x}_i]$ through cosine similarity between word embeddings. We set k to 5 in our experiment to guarantee words in the k nearest neighbor has similar semantic meaning. Formally, we define the input sensitivity of an NMT model as:

$$\mathbb{E}_{(\mathrm{x},\mathrm{y})} \frac{1}{L_\mathrm{x}} \sum_i \frac{1}{k} \sum_{\mathrm{x}_{i(j)} \in \mathrm{kNN}[\mathrm{x}_i]} \left|\left| \frac{\partial \mathcal{L}_{\mathrm{x},\mathrm{y}}}{\partial \mathrm{Emb}(\mathrm{x})_{i(j)}} \right|\right|_F, \tag{6}$$

where the $\mathrm{Emb}(\mathrm{x})_i$ is the embedding lookup of the i^{th} token index, so we compute the average token-wise gradient of each instance.

We use subsamples of the train set to approximately compute the expectation in Eq. 6 and the overall statistics are shown in Table 2. Similar to Table 1, the DA methods are shown in their Δ value respect to the baseline. A first thing to notice is that the ranking is more steady across tasks (CTC=0.72). It also shows that for input x, DA in general can reduce the gradient norm of the prediction loss on $\mathrm{Emb}(\mathrm{x})_i$, which shows that DA can obtain more stable model towards data corruption.

To further understand what effect DA in general has on each input token type, we compute the Δ sensitivity between the baseline and one DA method on the same token type and sort them according to the Δ with positive value (which means DA reduces the sensitivity of that token type). We then divide the sorted types into ten bins and compute the average token type frequency of that bin. As shown in Figure 1, DA in general, improves the sensitivity of token types with relatively low frequency more than those with high frequency, thus may somehow improve the translation quality of low frequency token types.

3.2 Prediction Margin

Margin is a classic concept in support vector machine (Vapnik, 2013), which is defined as the geometric distance between the support vectors and the decision boundary. Larger margin implies better generalization. In nonlinear case, it reflects the distance of a correctly classified input representation with class i to move towards the decision boundary between i and any other class j (Jiang et al., 2019). However, since the decision boundary does not have analytical form due to nonlinearity, computing the geometric distance is intractable. In our setting we regard NMT model as doing step-wise classification with $\mathrm{z} = (\mathrm{x}, \mathrm{y}_{<t})$ as input feature and y_t as the label. In Bartlett et al. (2017), the original definition of the margin of correctly predicted input is:

Method	Fr⇒En	En⇒Fr	Zh⇒En	En⇒De
Baseline	0.797 (4)	0.592 (4)	0.756 (4)	0.679 (4)
RAML	*-0.028* (6)	*-0.063* (6)	*-0.024* (6)	*-0.006* (5)
SO	*-0.027* (5)	*-0.060* (5)	*-0.022* (5)	*-0.009* (6)
ST	*+0.046* (1)	*+0.036* (1)	*+0.035* (1)	*+0.044* (1)
TA	*+0.037* (2)	*+0.019* (2)	*+0.025* (2)	*+0.043* (2)
BT	*+0.017* (3)	*+0.015* (3)	*+0.004* (3)	*+0.016* (3)

Table 3: Margin measure (CTC=0.98).

$$\frac{p_\theta(\mathrm{y}_t|\mathrm{z}) - max_{v' \neq \mathrm{y}_t} p_\theta(v'|\mathrm{z})}{\mathcal{R} \cdot ||\mathrm{x}||_2 / N}, \tag{7}$$

where y_t is the ground-truth label, v' another class type, $\mathcal{R}$ the spectral complexity of the model and N the number of training instance in the train subsamples for computing their margins. We simplify Eq. 7 to only consider the numerator. The reasons are: a) under the same model architecture, $\mathcal{R}$s are very close across different DA methods; b) we can omit $||x||_2/N$ since it remains unchanged as well. In this way, we can map every z, y_t to a margin with label type $\mathrm{y}_t = v$, where $v \in \mathcal{V}_{tgt}$:

$$m^v_{\mathrm{z},\mathrm{y}_t} := p_\theta(\mathrm{y}_t|\mathrm{z}) - max_{v' \neq \mathrm{y}_t} p_\theta(v'|\mathrm{z}). \tag{8}$$

So for every target token type v we can collect a set of margins $\{m^v_{\mathrm{z},\mathrm{y}_t}\}$, and the margin sets of all token types are combined as the total margin set $\cup_v \{m^v_{\mathrm{z},\mathrm{y}_t}\}$. Following Neyshabur et al. (2017), we do not compute the minimum margin of the total set which can be highly sensitive to outliers. Instead, if the total set has cardinality N', we obtain the $\epsilon N'$-th smallest margin from the set as the overall prediction margin, with a tolerant coefficient $\epsilon \in [0, 0.1]$ (ϵ is set to 0.001). [3] We can also obtain token-wise prediction margin from $\{m^v_{\mathrm{z},\mathrm{y}_t}\}$, which is the prediction margin of a specific token type v.

The overall prediction margins are listed in Table 3. The relative rank is highly consistent across the four translation tasks (CTC=0.98). Although RAML and SO seem to be inferior to the baseline, other DA methods improve the margin in general. We give a possible explanation for this in the next subsection. Similar to the previous subsection, we

[3] Note that, we have tried different tolerant coefficents and find they do not effect the final rankings of DA methods.

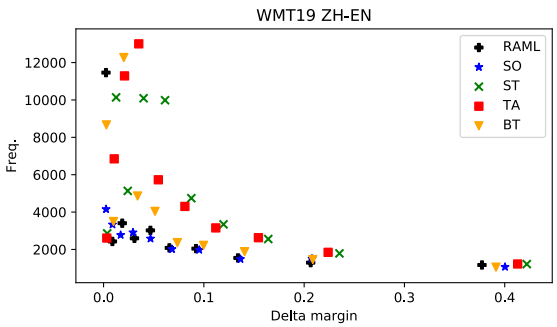

Figure 2: Δ margin binned avg. token freq. statistics.

also report the average token type frequency of each margin binned token groups in Figure 2 and find that DA, in general, brings larger margin improvement over low frequency tokens.

3.3 Discussion

Why use these two measures? We have conducted a relatively complete survey of the recent measures towards measuring generalization ability proposed by the deep learning community, such as model complexity (Zhang et al., 2016; Neyshabur et al., 2017), flatness (Dinh et al., 2017), stiffness (Fort et al., 2019) and second order Hessian of the input or the number of linear regions in hiddens (Novak et al., 2018; Montufar et al., 2014). Some of those measures have complex definition such as linear regions, others are very expensive to compute for models as large as Transformer such as Hessian and stiffness. However, we compute weight norm with different forms proposed in Neyshabur et al. (2017) and find no regularity which suggests that the complexity measure through norms for networks architectures like Transformer or convolutional/recurrent neural networks might be very different from simple feed-forward ones which might be still an open problem in theoretic deep learning community. As a matter of fact, due to computational easiness and large-scale empirical evidence, we choose sensitivity and margin the measures.

Why no absolute consistency between the two measures? In Section 3.1 and 3.2, the two measures do not show well consistency between them: under the margin based measure, RAML and SO do not exhibit superiority over the baseline like they do under the sensitivity measure. One reason might be: despite the measures are empirically proved to reflect generalization, they are only one view towards generalization respectively. Specifically, in recent generalization theory (Novak et al., 2018; Bartlett et al., 2017), the measures are evaluated between models with extremely evident difference in generalization ability (measured by test performance difference), for example, between models trained with random labels and true labels. Instead, our comparison is among models with similar capacity and are well-trained, which rises challenge for us to get very consistent statistics through a single view. This may inspire us to combine multiple views of model training to design better measures with stronger correlation.

4 Conclusion and Future Work

This paper aims at delivering relatively consistent benefit measures of DA due to the phenomenon of inconsistant BLEU improvement across translation tasks. To our expect, the proposed two measures exhibit relative consistency (especially prediction margin) on five DA methods across four translation tasks, which demonstrate that DA can benefit model with improved sensitivity or prediction margin especially for low frequency words.

However, the problem of intrinsic evaluation or better understanding of the unreasonable effective of DA should just be a start. DA is a trade-off between noise vs. knowledge injection, so it could be a nice theoretic direction to think about DA under statistical query model (Kearns, 1998) with translation between formal languages (ws-, 2019). This could inspire another essential question: what is the intrinsic properties of the augmented data (Branchaud-Charron et al., 2019) that matter in discrete domain. Applications like active data selection (Coleman et al., 2019) guided with margin or sensitivity can be derived. In general, understanding NMT model's behavior (not only with DAs) beyond BLEU (Neubig et al., 2019) should be taken seriously, e.g. to design a bevavior suite like Osband et al. (2019) is most valuable.

Acknowledgements

The authors are grateful to all the anonymous reviewers for pointing out the topic of intrinsic evaluation of DA methods to summarize our work as well as proposing several critical issues regarding limitations of the proposed measures. We thank Xintong, Zhirui for valuable discussions; Xintong, Chaoqun, Yong Jiang for proof-reading. Tiejun Zhao is supported by National Key R&D Program of China (Project No. 2017YFB1002102).

Simple and Effective Noisy Channel Modeling for Neural Machine Translation

Kyra Yee[△] **Yann N. Dauphin**[▽†] **Michael Auli**[△]

Abstract

Previous work on neural noisy channel modeling relied on latent variable models that incrementally process the source and target sentence. This makes decoding decisions based on partial source prefixes even though the full source is available. We pursue an alternative approach based on standard sequence to sequence models which utilize the entire source. These models perform remarkably well as channel models, even though they have neither been trained on, nor designed to factor over incomplete target sentences. Experiments with neural language models trained on billions of words show that noisy channel models can outperform a direct model by up to 3.2 BLEU on WMT'17 German-English translation. We evaluate on four language-pairs and our channel models consistently outperform strong alternatives such right-to-left reranking models and ensembles of direct models.[1]

1 Introduction

Sequence to sequence models directly estimate the posterior probability of a target sequence y given a source sequence x (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) and can be trained with pairs of source and target sequences. Unpaired sequences can be leveraged by data augmentation schemes such as back-translation, but direct models cannot naturally take advantage of unpaired data (Sennrich et al., 2016a; Edunov et al., 2018a).

The noisy channel approach is an alternative which is used in statistical machine translation (Brown et al., 1993; Koehn et al., 2003). It entails a channel model probability $p(x|y)$ that operates in the reverse direction as well as a language model probability $p(y)$. The language model can be estimated on unpaired data and can take a separate form to the channel model. Noisy channel modeling mitigates explaining away effects that result in the source being ignored for highly likely output prefixes (Klein and Manning, 2001).

Previous work on neural noisy channel modeling relied on a complex latent variable model that incrementally processes source and target prefixes (Yu et al., 2017). This trades efficiency for accuracy because their model performs significantly less well than a vanilla sequence to sequence model. For languages with similar word order, it can be sufficient to predict the first target token based on a short source prefix, but for languages where word order differs significantly, we may need to take the entire source sentence into account to make a decision.

In this paper, we show that a standard sequence to sequence model is an effective parameterization of the channel probability. We train the model on full sentences and apply it to score the source given an incomplete target sentence. This bases decoding decisions on scoring the entire source sequence and it is very simple and effective (§2). We analyze this approach for various target prefix sizes and find that it is most accurate for large target context sizes. Our simple noisy channel approach consistently outperforms strong baselines such as online ensembles and left-to-right reranking setups (§3).

2 Approach

The noisy channel approach applies Bayes' rule to model $p(y|x) = p(x|y)p(y)/p(x)$, that is, the channel model $p(x|y)$ operating from the target to the source and a language model $p(y)$. We do not model $p(x)$ since it is constant for all y. We com-

† Work done while at Facebook AI Research.

[1]We release code and pre-trained models at https://github.com/pytorch/fairseq

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5696–5701, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

pute the channel model probabilities as follows:

$$p(x|y) = \sum_{j}^{|x|} \log p(x_j|x_0, x_1, ...x_{j-1}, y)$$

We refer to $p(y|x)$ as the direct model. A critical choice in our approach is to model $p(x|y)$ with a standard Transformer architecture (Vaswani et al., 2017) as opposed to a model which factors over target prefixes (Yu et al., 2017). This setup presents a clear train/test mismatch: we train $p(x|y)$ on complete sentence-pairs and perform inference with incomplete target prefixes of varying size k, i.e., $p(x|y_1, \ldots, y_k)$. However, we find standard sequence to sequence models to be very robust to this mismatch (§3).

Decoding. To generate y given x with the channel model, we wish to compute $\arg\max_y \log p(x|y) + \log p(y)$. However, naïve decoding in this way is computationally expensive because the channel model $p(x|y)$ is conditional on each candidate target prefix. For the direct model, it is sufficient to perform a single forward pass over the network parameterizing $p(y|x)$ to obtain output word probabilities for the entire vocabulary. However, the channel model requires separate forward passes for each vocabulary word.

Approximation. To mitigate this issue, we perform a two-step beam search where the direct model pre-prunes the vocabulary (Yu et al., 2017). For beam size k_1, and for each beam, we collect k_2 possible next word extensions according to the direct model. Next, we score the resulting $k_1 \times k_2$ partial candidates with the channel model and then prune this set to size k_1. Other approaches to pre-pruning may be equally beneficial but we adopt this approach for simplicity.[2] A downside of online decoding with the channel model approach is the high computational overhead: we need to invoke the channel model $k_1 \times k_2$ times compared to just k_1 times for the direct model.

Complexity. The model of Yu et al. (2017) factorizes over source and target prefixes. During decoding, their model alternates between incrementally reading the target prefix and scoring a source prefix, resulting in a runtime of $O(n + m)$, where n and m are the source and target lengths, respectively. In comparison, our approach repeatedly scores the entire source for each target prefix, resulting in $O(mn)$ runtime. Although our approach has greater time complexity, the practical difference of scoring the tokens of a single source sentence instead of just one token is likely to be negligible on modern GPUs since all source tokens can be scored in parallel. Inference is mostly slowed down by the autoregressive nature of decoding. Scoring the entire source enables capturing more dependencies between the source and target, since the beginning of the target must explain the entire source, not just the beginning. This is especially important when the word order between the source and target language varies considerably, and likely accounts for the lower performance of the direct model of Yu et al. (2017) in comparison to a standard seq2seq model.

Model combinaton. Since the direct model needs to be evaluated for pre-pruning, we also include these probabilities in making decoding decisions. We use the following linear combination of the channel model, the language model and the direct model for decoding:

$$\frac{1}{t} \log p(y|x) + \frac{\lambda_1}{s} \Big(\log p(x|y) + \log p(y) \Big) \quad (1)$$

where t is the length of the target prefix y, s is the source sentence length and λ is a tunable weight. Initially, we used separate weights for $p(x|y)$ and $p(y)$ but we found that a single weight resulted in the same accuracy and was easier to tune. Scaling by t and s makes the scores of the direct and channel model comparable to each other throughout decoding. In n-best re-ranking, we have complete target sentences which are of roughly equal length and therefore do not use per word scores.[3]

3 Experiments

Datasets. For English-German (En-De) we train on WMT'17 data, validate on news2016 and test on news2017. For reranking, we train models with a 40K joint byte pair encoding vocabulary (BPE; Sennrich et al. 2016b). To be able to use the language model during online decoding, we use the vocabulary of the langauge model on the target side. For the source vocabulary, we learn a 40K

[2] Vocabulary selection can prune the vocabulary to a few hundred types with no loss in accuracy (L'Hostis et al., 2016).

[3] Reranking experiments are also based on separate tunable weights for the LM and the channel model. However, results are comparable to a single weight.

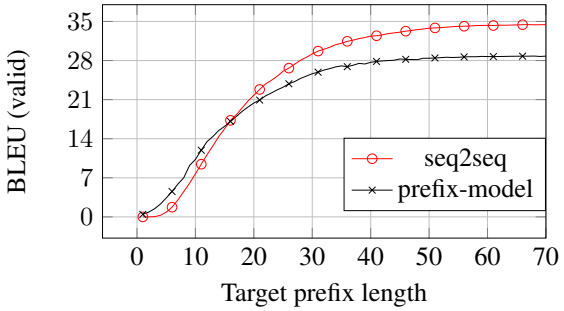

Figure 1: Comparison of two channel models: a standard seq2seq model trained on full sentence-pairs and a model trained on all possible target prefixes with the full source (prefix-model). We measure accuracy of predicting the full source with increasing target prefixes for both models. Results are on news2016.

byte pair encoding on the source portion of the bitext; we find using LM and bitext vocabularies give similar accuracy. For Chinese-English (Zh-En), we pre-process WMT'17 data following Hassan et al. (2018), we develop on dev2017 and test on news2017. For IWSLT'14 De-En we follow the setup of Edunov et al. (2018b) and measure case-sensitive tokenized BLEU. For WMT De-En, En-De and Zh-En we measure detokenized BLEU (Post, 2018).

Language Models. We train two big Transformer language models with 12 blocks (Baevski and Auli, 2018): one on the German newscrawl data distributed by WMT'18 comprising 260M sentences and another one on the English newscrawl data comprising 193M sentences. Both use a BPE vocabulary of 32K types. We train on 32 Nvidia V100 GPUs with 16-bit floating point operations (Ott et al., 2018) and training took four days.

Sequence to Sequence Model training. For En-De, De-En, Zh-En we use big Transformers and for IWSLT De-En a base Transformer (Vaswani et al., 2017) as implemented in fairseq (Ott et al., 2019). For online decoding experiments, we do not share encoder and decoder embeddings since the source and target vocabularies were learned separately. We report average accuracy of three random initializations of a each configuration. We generally use $k_1 = 5$ and $k_2 = 10$. We tune λ_1, and a length penalty on the validation set.

3.1 Simple Channel Model

We first motivate a standard sequence to sequence model to parameterize $p(x|y)$ as opposed to a model that is trained to operate over prefixes. We train Transformer models to translate from the target to the source (En-De) and compare two variants: i) a standard sequence to sequence model trained to predict full source sentences based on full targets (seq2seq). ii) a model trained to predict the full source based on a prefix of the target; we train on all possible prefixes of a target sentence, each paired with the full source (prefix-model).

Figure 1 shows that the prefix-model performs slightly better for short target prefixes but this advantage disappears after 15 tokens. On full target sentences seq2seq outperforms the prefix model by 5.7 BLEU. This is likely because the prefix-model needs to learn how to process both long and short prefixes which results in lower accuracy. The lower performance on long prefixes is even more problematic considering our subsequent finding that channel models perform over-proportionally well on long target prefixes (§3.4). The seq2seq model has not been trained to process incomplete targets but empirically it provides a simple and effective parameterization of $p(x|y)$.

3.2 Effect of Scoring the Entire Source Given Partial Target Prefixes

The model of (Yu et al., 2017) uses a latent variable to incrementally score the source for prefixes of the target. Although this results in a faster run time, the model makes decoding decisions based on source prefixes even though the full source is available. In order to quantify the benefit of scoring the entire source instead of a learned prefix length, we simulate different fractions of the source and target in an n-best list reranking setup.

The n-best list is generated by the direct model and we re-rank the list in setups where we only have a fraction of the candidate hypothesis and the source sentence. We report BLEU of the selected full candidate hypothesis.

Figure 2 shows that for any given fraction of the target, scoring the entire source (src 1) has better or comparable performance than all other source prefix lengths. It is therefore beneficial to have a channel model that scores the entire source sentence.

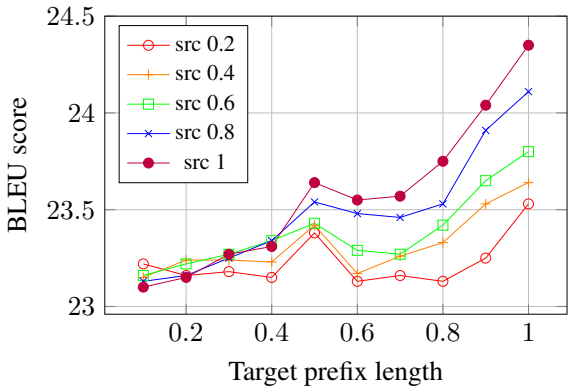

Figure 2: For any given target prefix fraction, scoring the entire source has the best or comparable performance compared to other source prefixes. We show detokenized BLEU on the dev set of WMT17 Zh-En with beam 50.

DIR+LM	39.8	35.2
CH+DIR+LM	41.0	36.2
- per word scores	40.0	35.1

Table 1: Online decoding accuracy for a direct model (DIR), ensembling two direct models (DIR ENS) and the channel approach (CH+DIR+LM). We ablate the impact of using per word scores. Results are on WMT De-En. Table 4 in the appendix shows standard deviations.

3.3 Online Decoding

Next, we evaluate online decoding with a noisy channel setup compared to just a direct model (DIR) as well as an ensemble of two direct models (DIR ENS). Table 1 shows that adding a language model to DIR (DIR+LM) gives a good improvement (Gulcehre et al., 2015) over a single direct model but ensembling two direct models is slightly more effective (DIR ENS). The noisy channel approach (CH+DIR+LM) improves by 1.9 BLEU over DIR on news2017 and by 0.9 BLEU over the ensemble. Without per word scores, accuracy drops because the direct model and the channel model are not balanced and their weight shifts throughout decoding. Our simple approach outperforms strong online ensembles which illustrates the advantage over incremental architectures (Yu et al., 2017) that do not match vanilla seq2seq models by themselves.

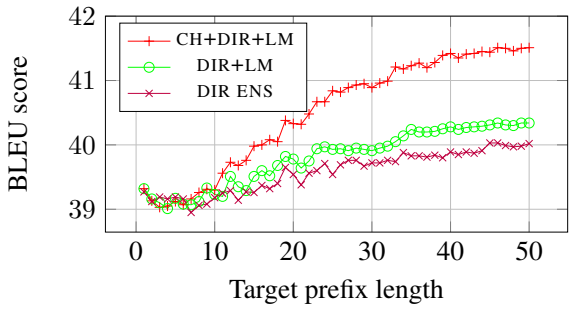

Figure 3: Impact of target prefix length for the channel model (CH+DIR+LM), direct model + LM (DIR+LM) and a direct ensemble (DIR ENS). We show detokenized BLEU on WMT De-En news2016 with beam 10.

3.4 Analysis

Using the channel model in online decoding enables searching a much larger space compared to n-best list re-ranking. However, online decoding is also challenging because the channel model needs to score the entire source sequence given a partial target which can be hard. To measure this, we simulate different target prefix lengths in an n-best list re-ranking setup. The n-best list is generated by the direct model and we re-rank it for different target prefixes of the candidate hypothesis. As in 3.2, we measure BLEU of the selected full candidate hypothesis. Figure 3 shows that the channel model enjoys much larger benefits from more target context than re-ranking with just the direct model and an LM (DIR+LM) or re-ranking with a direct ensemble (DIR ENS). This experiment shows the importance of large context sizes for the channel approach to work well. It indicates that the channel approach may not be able to effectively exploit the large search space in online decoding due to the limited conditioning context provided by partial target prefixes.

3.5 Re-ranking

Next, we switch to n-best re-ranking where we have the full target sentence available compared to online decoding. Noisy channel model re-ranking has been used by the top ranked entries of the WMT 2019 news translation shared task for English-German, German-English, Englsh-Russian and Russian-English (Ng et al., 2019). We compare to various baselines including right-to-left sequence to sequence models which are a popular choice for re-ranking and regularly feature in successful WMT submissions (Deng et al., 2018;

	5	10	50	100

DIR+LM	40.0	40.2	40.6	40.7
DIR+RL	39.7	40.1	40.8	40.8
DIR+RL+LM	40.4	40.9	41.6	41.8
CH+DIR	39.7	40.0	40.5	40.5
CH+DIR+LM	40.8	41.5	42.8	43.2

Table 2: Re-ranking BLEU with different n-best list sizes on news2016 of WMT De-En. We compare to decoding with a direct model only (DIR) and decoding with an ensemble of direct models (DIR ENS). Table 5 in the appendix shows standard deviations.

	WMT De-En	WMT En-De	WMT Zh-En	IWSLT De-En
DIR	34.5	28.4	24.4	33.3
DIR ENS	35.5	29.0	25.2	34.5
DIR+LM	36.0	29.4	24.9	34.2
DIR+RL	35.7	29.3	25.3	34.4
DIR+RL+LM	36.8	30.0	25.4	34.9
CH+DIR	35.1	28.3	24.8	34.0
CH+DIR+LM	37.7	30.5	25.6	35.5

Table 3: Re-ranking accuracy with $k_1 = 50$ on four language directions on the respective test sets. See Table 6 in the appendix for standard deviations.

Koehn et al., 2018; Junczys-Dowmunt, 2018).

Table 2 shows that the noisy channel model outperforms the baseline (DIR) by up to 4.0 BLEU for very large beams, the ensemble by up to 2.9 BLEU (DIR ENS) and the best right-to-left configuration by 1.4 BLEU (DIR+RL+LM). The channel approach improves more than other methods with larger n-best lists by adding 2.4 BLEU from $k_1 = 5$ to $k_1 = 100$. Other methods improve a lot less with larger beams, e.g., DIR+RL+LM has the next largest improvement of 1.4 BLEU when increasing the beam size but this is still significantly lower than for the noisy channel approach. Adding a language model benefits all settings (DIR+LM, DIR+RL+LM, CH+DIR+LM) but the channel approach benefits most (CH+DIR vs CH+DIR+LM). The direct model with a language model (DIR+LM) performs better than for online decoding, likely because the constrained reranking setup mitigates explaining away effects (cf. Table 1).

Interestingly, both CH+DIR or DIR+LM give only modest improvements compared to CH+DIR+LM. Although previous work demonstrated that reranking with CH+DIR can improve over DIR, we show that the channel model is important to properly leverage the language model without suffering from explaining away effects (Xu and Carpuat, 2018; Wang et al., 2017). Test results on all language directions confirm that CH+DIR+LM performs best (Table 3).

4 Conclusion

Previous work relied on incremental channel models which do not make use of the entire source even though it is available and, as we demonstrate, beneficial. Standard sequence to sequence models are a simple parameterization for the channel probability that naturally exploits the entire source. This parameterization outperforms strong baselines such as ensembles of direct models and right-to-left models. Channel models are particularly effective with large context sizes and an interesting future direction is to iteratively refine the output while conditioning on previous contexts.

Abstract

Pretrained language models are promising particularly for low-resource languages as they only require unlabelled data. However, training existing models requires huge amounts of compute, while pretrained cross-lingual models often underperform on low-resource languages. We propose Multi-lingual language model Fine-Tuning (MultiFiT) to enable practitioners to train and fine-tune language models efficiently in their own language. In addition, we propose a zero-shot method using an existing pretrained cross-lingual model. We evaluate our methods on two widely used cross-lingual classification datasets where they outperform models pretrained on orders of magnitude more data and compute. We release all models and code[1].

1 Introduction

Pretrained language models (LMs) have shown striking improvements on a range of natural language processing (NLP) tasks (Peters et al., 2018a; Howard and Ruder, 2018; Devlin et al., 2018). These models only require unlabelled data for training and are thus particularly useful in scenarios where labelled data is scarce. As much of NLP research has focused on the English language, the larger promise of these models is to bridge the digital language divide[2] and enable the application of NLP methods to many of the world's other 6,000 languages where labelled data is less plentiful.

Recently, cross-lingual extensions of these LMs have been proposed that train on multiple languages jointly (Artetxe and Schwenk, 2018; Lample and Conneau, 2019). These models are able to perform zero-shot learning, only requiring labelled data in the source language. However, source data in another language may often not be available, whereas obtaining a small number of labels is typically straightforward.

Furthermore such models have several downsides: a) some variants rely on large amounts of parallel data, which may not be available for truly low-resource languages; b) they require a huge amount of compute for training[3]; and c) cross-lingual models underperform on low-resource languages—precisely the setting where they would be most useful. We are aware of two possible reasons for this: 1) Languages that are less frequently seen during training are underrepresented in the embedding space.[4] 2) Infrequent scripts are over-segmented in the shared word piece vocabulary (Wang et al., 2019).

In this work, we show that small monolingual LMs are able to outperform expensive cross-lingual models both in the zero-shot and the supervised setting. We propose Multi-lingual language model Fine-tuning (MultiFit) to enable practitioners to train and fine-tune language models efficiently.[5] Our model combines universal language model fine-tuning (ULMFiT; Howard and Ruder, 2018) with the quasi-recurrent neural network (QRNN; Bradbury et al., 2017) and subword tokenization (Kudo, 2018) and can be pretrained on a single Tesla V100 GPU in a few hours. In addition, we propose to use a pretrained cross-lingual model's predictions as pseudo labels to adapt the

[3] The training cost is amortized over time as pretraining only needs to be performed once and fine-tuning is much cheaper. However, if a model needs to be applied to a new language or a domain not covered by the model, a new model needs to be trained from scratch.

[4] This is similar to how word embeddings are known to underperform on low-frequency tokens (Gong et al., 2018).

[5] We use 'multilingual' as referring to training *independent* models in multiple languages. We use 'cross-lingual' to refer to training a *joint* model across multiple languages.

monolingual language model to the zero-shot setting. We evaluate our models on two widely used cross-lingual classification datasets, MLDoc (Schwenk and Li, 2018) and CLS (Prettenhofer and Stein, 2010) where we outperform the state-of-the-art zero-shot model LASER (Artetxe and Schwenk, 2018) and multi-lingual BERT (Devlin et al., 2018) in the supervised setting—even without any pretraining. In the zero-shot setting, we outperform both models using pseudo labels—and report significantly higher performance with as little as 100 examples. We finally show that information from monolingual and cross-lingual language models is complementary and that pretraining makes models robust to noise.

2 Related work

Pretrained language models Pretrained language models based on an LSTM (Peters et al., 2018a; Howard and Ruder, 2018) and a Transformer (Radford et al., 2018; Devlin et al., 2018) have been proposed. Recent work (Peters et al., 2018b) suggests that—all else being equal—an LSTM outperforms the Transformer in terms of downstream performance. For this reason, we use a variant of the LSTM as our language model.

Cross-lingual pretrained language models The multi-lingual BERT model is pretrained on the Wikipedias of 104 languages using a shared word piece vocabulary. LASER (Artetxe and Schwenk, 2018) is trained on parallel data of 93 languages with a shared BPE vocabulary. XLM (Lample and Conneau, 2019) additionally pretrains BERT with parallel data. These models enable zero-shot transfer, but achieve lower results than monolingual models. In contrast, we focus on making the training of monolingual language models more efficient in a multi-lingual context. Concurrent work (Mulcaire et al., 2019) pretrains on English and another language, but shows that cross-lingual pretraining only helps sometimes.

Multi-lingual language modeling Training language models in non-English languages has only recently received some attention. Kawakami et al. (2017) evaluate on seven languages. Cotterell et al. (2018) study 21 languages. Gerz et al. (2018) create datasets for 50 languages. All of these studies, however, only create small datasets, which are inadequate for pretraining language models. In contrast, we are among the first to report the performance of monolingual language models on downstream tasks in multiple languages.

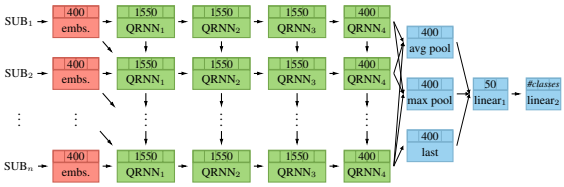

Figure 1: The MultiFiT language model with classifier consisting of a subword embedding layer, four QRNN layers, an aggregation layer, and two linear layers.

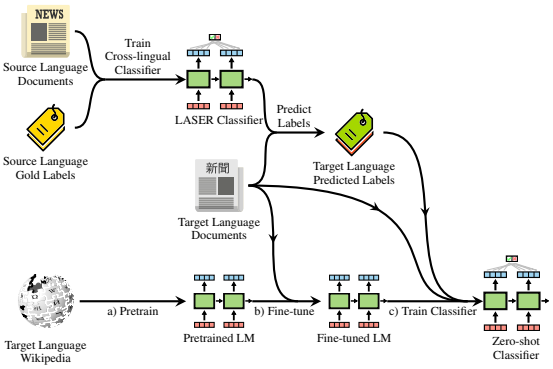

Figure 2: The steps of our cross-lingual bootstrapping method for zero-shot cross-lingual transfer. a) A monolingual language model (LM) is pretrained on target language data; b) the LM is fine-tuned on target language documents; and c) the LM is fine-tuned as a classifier using the zero-shot predictions from a linear classification layer fine-tuned on top of cross-lingual representations from LASER.

3 Our method

3.1 Multi-lingual Fine-Tuning

We propose Multi-lingual Fine-tuning (MultiFit). Our method uses the ULMFiT model (Howard and Ruder, 2018) with discriminative fine-tuning as foundation. ULMFiT is based on a 3-layer AWD-LSTM (Mer, 2017) language model. The AWD-LSTM is a regular LSTM (Hochreiter and Schmidhuber, 1997) with tuned dropout hyperparameters. To enable faster training and fine-tuning of the model, we replace it with a QRNN (Bradbury et al., 2017). The QRNN alternates convolutional layers, which are parallel across timesteps, and a recurrent pooling function, which is parallel across channels. It has been shown to outperform LSTMs, while being up to 16× faster at train and test time. ULMFiT in addition is restricted to words as input. To make our model

more robust across languages, we use subword tokenization based on a unigram language model (Kudo, 2018), which is more flexible compared to byte-pair encoding (Sennrich et al., 2016). We additionally employ label smoothing (Szegedy et al., 2016) and a novel cosine variant of the one-cycle policy (Smith, 2018)[6], which we found to outperform ULMFiT's slanted triangular learning rate schedule and gradual unfreezing. The full model can be seen in Figure 1.

3.2 Cross-lingual Bootstrapping

Prior methods have employed cross-lingual training strategies relying on parallel data and a shared BPE vocabulary. These can be combined with our language model, but increase its training complexity. For the case where an existing pretrained cross-lingual model and source language data are available, we propose a bootstrapping method (Ruder and Plank, 2018) that uses the pretrained model's zero-shot predictions as pseudo labels to fine-tune the monolingual model on target language data.

The steps of the method can be seen in Figure 2. Specifically, we first fine-tune a linear classification layer on top of pretrained cross-lingual representations on source language training data. We then apply this cross-lingual classifier to the target language data and store its predicted label for every example. We now fine-tune our pretrained LM on the target language data and these pseudo labels[7]. Importantly, this method enables our monolingual LM to significantly outperform its cross-lingual teacher in the zero-shot setting (§5).

4 Experimental setup

This section provides an overview of our experimental setup; see the appendix for full details.

Data We evaluate our models on the Multilingual Document Classification Corpus (MLDoc; Schwenk and Li, 2018)[8]—a new subset of Reuters Corpus Volume 2 (Lewis et al., 2004) with balanced class priors for eight languages—and on the Cross-Lingual Sentiment dataset (CLS; Prettenhofer and Stein, 2010)[9] consisting of Amazon product reviews in four languages. We provide an overview of the datasets in Table 1.

	Domain	Languages	Train	Dev	Test
MLDoc	News	EN, DE, ES, FR, IT, JA, RU, ZH	1k / 2k / 5k / 10k	2k	10k
CLS	Product reviews	EN, DE, FR, JA	2k	-	2k

Table 2: Comparison of zero-shot and supervised methods on MLDoc.

Pretraining We pretrain our models on 100M tokens extracted from the Wikipedia of the corresponding language for 10 epochs. As fewer tokens might be available for some languages, we also compare against a version (no wiki) that uses no pretraining. For all models, we fine-tune the LMs on the target data of the same language for 20 epochs. We perform subword tokenization with the unigram language model (Kudo, 2018).

Evaluation settings We compare two settings based on the availability of source and target language data: supervised and zero-shot. In the supervised setting, every model is fine-tuned and evaluated on examples from the target language. In the zero-shot setting, every model is fine-tuned on source language examples and evaluated on target language examples. In all cases, we use English as the source language.

Baselines We compare against the state-of-the-art cross-lingual embedding models LASER (Artetxe and Schwenk, 2018), which uses a large parallel corpus, multilingual BERT (MultiB-

5 Results

MLDoc We show results for MLDoc in Table 2. In the zero-shot setting, MultiBERT underperforms the comparison methods as the shared embedding space between many languages is overly restrictive. Our monolingual LMs outperform their cross-lingual teacher LASER in almost every setting. When fine-tuned with only 100 target language examples, they are able to outperform all zero-shot approaches except MultiFiT on DE and FR. This calls into question the need for zero-shot approaches, as fine-tuning with even a small number of target examples is able to yield superior performance. When fine-tuning with 1,000 target examples, MultiFiT—even without pretraining—outperforms all comparison methods, including monolingual BERT.

CLS We show results for CLS in Table 3. MultiFiT is able to outperform its zero-shot teacher LASER across all domains. Importantly, the bootstrapped monolingual model also outperforms more sophisticated models that are trained on translations across almost all domains. In the supervised setting, MultiFiT similarly outperforms multilingual BERT. For both datasets, our methods that have been pretrained on 100 million tokens outperform both multilingual BERT and LASER, models that have been trained with orders of magnitude more data and compute.

6 Analysis

Speed We compare the LSTM and QRNN cell in MultiFiT based on the speed for processing a single batch for pretraining and fine-tuning in Table 4. MultiFiT with a QRNN pretrains and fine-tunes about 2× and 3× faster respectively.

MultiFiT vs. ULMFiT We compare MultiFiT pretrained on 100M Wikipedia tokens against

[10] https://github.com/google-research/bert/blob/master/multilingual.md

[11] Models are available for English, Chinese, and German (https://deepset.ai/german-bert).

ULMFiT pretrained on the same data using a 3-layer LSTM and spaCy tokenization[12] as well as MultiFiT pretrained on 2M Wikipedia tokens, and MultiFiT with no pretraining in Table 5. Pretraining on more data generally helps. MultiFiT outperforms ULMFiT significantly; the performance improvement is particularly pronounced in Chinese where ULMFiT's word-based tokenization underperformed.

Table 7: Comparison of different tokenization strategies for different languages on MLDoc.

Robustness to noise We suspect that MultiFiT is able to outperform its teacher as the information from pretraining makes it robust to label noise. To test this hypothesis, we train MultiFiT and a randomly initialized model with the same architecture on 1k and 10k examples of the Spanish MLDoc. We randomly perturb labels with a probability ranging from 0-0.75 and show results in Figure 3. The pretrained MultiFiT is able to partially ignore the noise, up to 65% of noisy training examples. Without pretraining, the model does not exceed the theoretical baseline (the percentage of correct examples). In addition, we compare MultiFiT with and without pretraining in Table 6. Pretraining enables MultiFiT to achieve much better performance compared to a randomly initialised model. Both results together suggest a) that pretraining increases robustness to noise and b) that information from monolingual and cross-lingual language models is complementary.

Tokenization Subword tokenization has been found useful for language modeling with morphologically rich languages (Czapla et al., 2018; Mielke and Eisner, 2019) and has been used in recent pretrained LMs (Devlin et al., 2018), but its concrete impact on downstream performance has not been observed. We train models with the best performing vocabulary sizes for subword (15k) and regular word-based tokenization (60k) with the Moses tokenizer (Koehn et al., 2007) on German and Russian MLDoc and show results in Table 7. Subword tokenization outperforms word-based tokenization on most languages, while being faster to train due to the smaller vocabulary size.

7 Conclusion

We have proposed novel methods for multilingual fine-tuning of languages that outperform models trained with far more data and compute on two widely studied cross-lingual text classification datasets on eight languages in both the zero-shot and supervised setting.

Abstract

Due to the unparallelizable nature of the autoregressive factorization, AutoRegressive Translation (ART) models have to generate tokens sequentially during decoding and thus suffer from high inference latency. Non-AutoRegressive Translation (NART) models were proposed to reduce the inference time, but could only achieve inferior translation accuracy. In this paper, we proposed a novel approach to leveraging the hints from hidden states and word alignments to help the training of NART models. The results achieve significant improvement over previous NART models for the WMT14 En-De and De-En datasets and are even comparable to a strong LSTM-based ART baseline but one order of magnitude faster in inference.

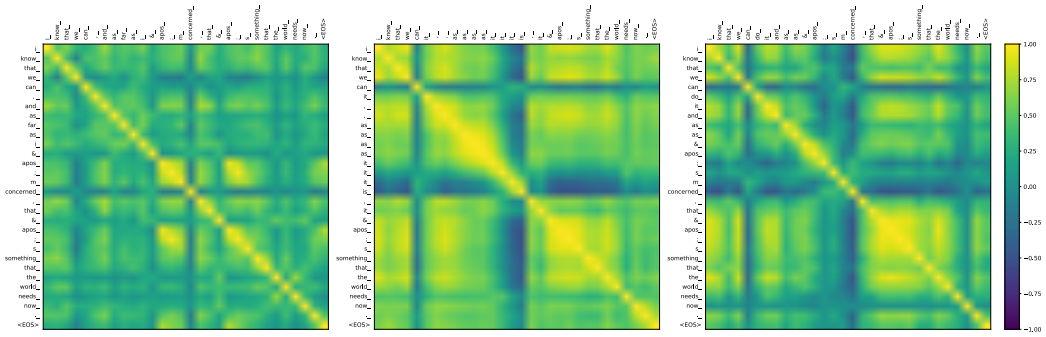
1 Introduction

Neural machine translation has attracted much attention in recent years (Bahdanau et al., 2014, 2016; Kalchbrenner et al., 2016; Gehring et al., 2016). Given a sentence $x = (x_1, \ldots, x_{T_x})$ from the source language, the straight-forward way for translation is to generate the target words $y = (y_1, \ldots, y_{T_y})$ one by one from left to right. This is also known as the *AutoRegressive* Translation (ART) models, in which the joint probability is decomposed into a chain of conditional probabilities:

$$P(y|x) = \Pi_{t=1}^{T_y} P(y_t|y_{<t}, x), \tag{1}$$

While the ART models have achieved great success in terms of translation quality, the time consumption during inference is still far away from satisfactory. During training, the predictions at different positions can be estimated in parallel since the ground truth pair (x, y) is exposed to the model. However, during inference, the model has to generate tokens sequentially as $y_{<t}$ must be inferred on the fly. Such autoregressive behavior becomes the bottleneck of the computational time (Wu et al., 2016).

In order to speed up the inference process, a line of works begin to develop non-autoregressive translation models. These models break the autoregressive dependency by decomposing the joint probability with



$$P(y|x) = P(T_y|x)\Pi_{t=1}^{T_y} P(y_t|x). \tag{2}$$

The lost of autoregressive dependency largely hurt the consistency of the output sentences, increase the difficulty in the learning process and thus lead to a low quality translation. Previous works mainly focus on adding different components into the NART model to improve the expressiveness of the network structure to overcome the loss of autoregressive dependency (Gu et al., 2017; Lee et al., 2018; Kaiser et al., 2018). However, the computational overhead of new components will hurt the inference speed, contradicting with the goal of the NART models: to parallelize and speed up neural machine translation models.

To tackle this, we proposed a novel hint-based method for NART model training. We first investigate the causes of the poor performance of the NART model. Comparing with the ART model, we find that: (1) the positions where the NART model outputs incoherent tokens will have very high hidden states similarity; (2) the attention distributions of the NART model are more ambiguous than those of ART model. Therefore, we design two kinds of hints from the hidden states and attention distributions of the ART model to help the training of the NART model. The experimental results show that our model achieves significant improvement over the NART baseline models and is even comparable to a strong ART baseline in Wu et al. (2016).

The work was performed at Microsoft Research Asia.

(a) ART Teacher (b) NART without Hints (c) NART with Hints

Figure 1: Case study: the above three figures visualize the hidden state cosine similarities of different models. The axes correspond to the generated target tokens. Each pixel shows the cosine similarities $\cos_{ij}$ between the last layer hidden states of the i-th and j-th generated tokens, where the diagonal pixel will always be 1.0.

2 Approach

In this section, we first describe the observations on the ART and NART models, and then discuss what kinds of information can be used as hints to help the training of the NART model. We follow the network structure in Vaswani et al. (2017), use a copy of the source sentence as decoder input, remove the attention masks in decoder self-attention layers and add a positional attention layer as suggested in Gu et al. (2017). We provide a visualization of ART and NART models we used in Figure 3 and a detailed description of the model structure in Appendix.

2.1 Observation: Illed States and Attentions

According to the case study in Gu et al. (2017), the translations of the NART models contain incoherent phrases (e.g. repetitive words) and miss meaningful tokens on the source side, while these patterns do not commonly appear in ART models. After some empirical study, we find two non-obvious facts that lead to this phenomenon.

First, we visualize the cosine similarities between decoder hidden states of a certain layer in both ART and NART models for sampled cases. Mathematically, for a set of hidden states $r_1, \ldots, r_T$, the pairwise cosine similarity can be derived by $\cos_{ij} = \langle r_i, r_j \rangle / (\|r_i\| \cdot \|r_j\|)$. We then plot the heatmap of the resulting matrix cos. A typical example is shown in Figure 1, where the cosine similarities in the NART model are larger than those of the ART model, indicating that the hidden states across positions in the NART model are "similar". Positions with highly-correlated hidden states tend to generate the same word and make the NART model output repetitive tokens, e.g., the yellow area on the top-left of Figure 1(b), while this does not happen in the ART model (Figure 1(a)). According to our statistics, 70% of the cosine similarities between hidden states in the ART model are less than 0.25, and 95% are less than 0.5.

Second, we visualize the encoder-decoder attentions for sampled cases, shown in Figure 2. Good attentions between the source and target sentences are usually considered to lead to accurate translation while poor ones may cause wrong output tokens (Bahdanau et al., 2014). In Figure 2(b), the attentions of the ART model almost covers all source tokens, while the attentions of the NART model do not cover "farm" but with two "morning". This directly makes the translation result worse in the NART model. These phenomena inspire us to use the intermediate hidden information in the ART model to guide the learning process of the NART model.

2.2 Hints from the ART teacher Model

Our study motivates us to leverage the intermediate hidden information from an ART model to improve the NART model. We focus on how to define hints from a well-trained ART *teacher* model and use it to guide the training process of a NART *student* model. We study layer-to-layer hints and assume both the teacher and student models have an M-layer encoder and an N-layer decoder, despite the difference in stacked components.

Without the loss of generality, we discuss our method on a given paired sentence (x, y). In real experiments, losses are averaged over all training data. For the teacher model, we use $a^{tr}_{t,l,h}$ as the encoder-to-decoder attention distribution of h-th head in the l-th decoder layer at position t, and

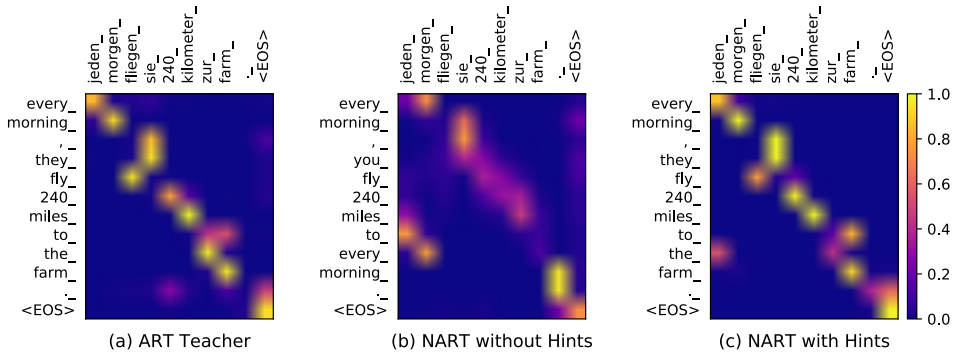

Figure 2: Case study: the above three figures visualize the encoder-decoder attention weights of different models. The x-axis and y-axis correspond to the source and generated target tokens respectively. The attention distribution is from a single head of the third layer encoder-decoder attention, which is the most informative one according to our observation. Each pixel shows attention weights α_{ij} between the i-th source token and j-th target token.

use $r^{tr}_{t,l}$ as the output of the l-th decoder layer after feed forward network at position t. Correspondingly, $a^{st}_{t,l,h}$ and $r^{st}_{t,l}$ are used for the student model. We propose a hint-based training framework that contains two kinds of hints:

Hints from hidden states The discrepancy of hidden states motivates us to use hidden states of the ART model as a hint for the learning process of the NART model. One straight-forward method is to regularize the L_1 or L_2 distance between each pair of hidden states in ART and NART models. However, since the network components are quite different in ART and NART models, applying the straight-forward regression on hidden states hurts the learning process and fails. Therefore, we design a more implicit loss to help the student refrain from the incoherent translation results by acting towards the teacher in the hidden-state level:

$$\mathcal{L}_{hid} = \frac{2}{(T_y-1)T_yN}\sum_{s=1}^{T_y-1}\sum_{t=s+1}^{T_y}\sum_{l=1}^{N}\phi(d_{st}, d_{tr}),$$

where $d_{st} = \cos(r^{st}_{s,l}, r^{st}_{t,l})$, $d_{tr} = \cos(r^{tr}_{s,l}, r^{tr}_{t,l})$, and ϕ is a penalty function. In particular, we let

$$\phi(d_{st}, d_{tr}) = \begin{cases} -\log(1-d_{st}), & \text{if } d_{st} \geq \gamma_{st} \\ & \text{and } d_{tr} \leq \gamma_{tr}; \\ 0, & \text{else,} \end{cases}$$

where $-1 \leq \gamma_{st}, \gamma_{tr} \leq 1$ are two thresholds controlling whether to penalize or not. We design this loss since we only want to penalize hidden states that are highly similar in the NART model, but not similar in the ART model. We have tested several choices of $-\log(1-d_{st})$, e.g., $\exp(d_{st})$, from which we find similar experimental results.

Hints from word alignments We observe that meaningful words in the source sentence are sometimes untranslated by the NART model, and the corresponding positions often suffer from ambiguous attention distributions. Therefore, we use the word alignment information from the ART model to help the training of the NART model.

In particular, we minimize KL-divergence between the per-head encoder-to-decoder attention distributions of the teacher and the student to encourage the student to have similar word alignments to the teacher model, i.e.

$$\mathcal{L}_{align} = \frac{1}{T_yNH}\sum_{t=1}^{T_y}\sum_{l=1}^{N}\sum_{h=1}^{H} D_{\mathrm{KL}}(a^{tr}_{t,l,h} \| a^{st}_{t,l,h}).$$

Our final training loss $\mathcal{L}$ is a weighted sum of two parts stated above and the negative log-likelihood loss $\mathcal{L}_{nll}$ defined on bilingual sentence pair (x, y), i.e.

$$\mathcal{L} = \mathcal{L}_{nll} + \lambda\mathcal{L}_{hid} + \mu\mathcal{L}_{align}, \quad (3)$$

where λ and μ are hyperparameters controlling the weight of different loss terms.

3 Experiments

3.1 Experimental Settings

The evaluation is on two widely used public machine translation datasets: IWSLT14 German-to-English (De-En) (Huang et al., 2017; Bahdanau et al., 2016) and WMT14 English-to-German (En-De) dataset (Wu et al., 2016; Gehring et al., 2017). To compare with previous works, we also reverse WMT14 English-to-German dataset and obtain WMT14 German-to-English dataset.

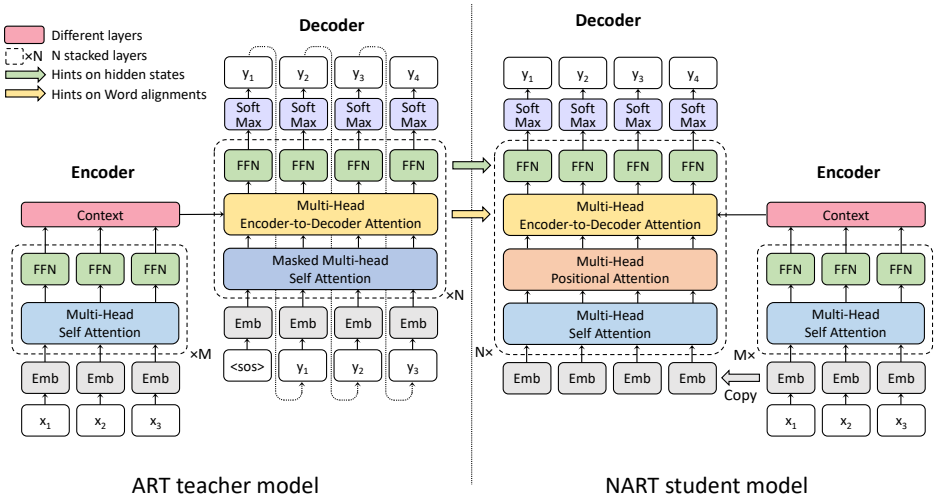

Figure 3: Hint-based training from ART model to NART model.

We pretrain Transformer (Vaswani et al., 2017) as the teacher model on each dataset, which achieves 33.26/27.30/31.29 in terms of BLEU (Papineni et al., 2002) in IWSLT14 De-En, WMT14 En-De and De-En test sets. The student model shares the same number of layers in encoder/decoder, size of hidden states/embeddings and number of heads as the teacher models (Figure 3). Following Gu et al. (2017); Kim and Rush (2016), we replace the target sentences by the decoded output of the teacher models.

Hyperparameters $(\gamma_{st}, \gamma_{tr}, \lambda, \mu)$ for hint-based learning are determined to make the scales of three loss components similar after initialization. We also employ label smoothing of value $\epsilon_{ls} = 0.1$ (Szegedy et al., 2016) in all experiments. We use Adam optimizer and follow the setting in Vaswani et al. (2017). Models for WMT14/IWSLT14 tasks are trained on 8/1 NVIDIA M40 GPUs respectively. The model is based on the open-sourced `tensor2tensor` (Vaswani et al., 2018).[1] More settings can be found in Appendix.

3.2 Inference

During training, T_y does not need to be predicted as the target sentence is given. During testing, we have to predict the length of the target sentence for each source sentence. In many languages, the length of the target sentence can be roughly estimated from the length of the source sentence. We choose a simple method to avoid the computational overhead, which uses input length to determine target sentence length: $T_y = T_x + C$, where C is a constant bias determined by the average length differences between the source and target training sentences. We can also predict the target length ranging from $[(T_x+C)-B, (T_x+C)+B]$, where B is the halfwidth. By doing this, we can obtain multiple translation results with different lengths. Note that we choose this method only to show the effectiveness of our proposed method and a more advanced length estimation method can be used to further improve the performance.

Once we have multiple translation results, we additionally use our ART teacher model to evaluate each result and select the one that achieves the highest probability. As the evaluation is fully parallelizable (since it is identical to the parallel training of the ART model), this rescoring operation will not hurt the non-autoregressive property of the NART model.

3.3 Experimental Results

We compare our model with several baselines, including three ART models, the fertility based (FT) NART model (Gu et al., 2017), the deterministic iterative refinement based (IR) NART model (Lee et al., 2018), and the Latent Transformer (LT; Kaiser et al., 2018) which is not fully non-autoregressive by incorporating an autoregressive sub-module in the NART model architecture.

The results are shown in the Table 1.[2] Across

[1] Open-source code can be found at `https://github.com/zhuohan123/hint-nart`

[2] ‡ and † indicate that the latency is measured on our own platform or by previous works, respectively. Note that the latencies may be affected by hardware settings and such absolute values are not fair for direct comparison, so we also list the speedup of the works compared to their ART baselines.

Models	WMT14 En-De	WMT14 De-En	IWSLT14 De-En	Latency	Speedup
Autoregressive models					
LSTM-based S2S (Wu et al., 2016; Bahdanau et al., 2016)	24.60	/	28.53	/	/
ConvS2S (Gehring et al., 2017; Edunov et al., 2017)	26.43	/	32.84	/	/
Transformer (Vaswani et al., 2017)	27.30	31.29	33.26	784 ms‡	1.00×
Non-autoregressive models					
FT (Gu et al., 2017)	17.69	20.62	/	39 ms†	15.6×
FT (rescoring 10 candidates)	18.66	22.41	/	79 ms†	7.68×
FT (rescoring 100 candidates)	19.17	23.20	/	257 ms†	2.36×
IR (Lee et al., 2018, adaptive refinement steps)	21.54	25.43	/	/	2.39×
LT (Kaiser et al., 2018)	19.8	/	/	105 ms†	5.78×
LT (rescoring 10 candidates)	21.0	/	/	/	/
LT (rescoring 100 candidates)	22.5	/	/	/	/
NART w/ hints	**21.11**	**25.24**	**25.55**	**26 ms**‡	**30.2×**
NART w/ hints ($B = 4$, 9 candidates)	**25.20**	**29.52**	**28.80**	**44 ms**‡	**17.8×**

Table 1: Performance on WMT14 En-De, De-En and IWSLT14 De-En tasks. "/" means non-reportable.

different datasets, our method achieves significant improvements over previous non-autoregressive models. Specifically, our method outperforms fertility based NART model with 6.54/7.11 BLEU score improvements on WMT En-De and De-En tasks in similar settings and achieves comparable results with state-of-the-art LSTM-based model on WMT En-De task. Furthermore, our model achieves a speedup of 30.2 (output a single sentence) or 17.8 (teacher rescoring) times over the ART counterparts. Note that our speedups significantly outperform all previous works, because of our lighter design of the NART model: without any computationally expensive module trying to improve the expressiveness.

We also visualize the hidden state cosine similarities and attention distributions for the NART model with hint-based training, as shown in Figure 1(c) and 2(c). With hints from hidden states, the hidden states similarities of the NART model decrease in general, and especially for the positions where the original NART model outputs incoherent phrases. The attention distribution of the NART model after hint-based training is more similar to the ART teacher model and less ambiguous comparing to the NART model without hints.

According to our empirical analysis, the percentage of repetitive words drops from 8.3% to 6.5% by our proposed methods on the IWSLT14 De-En test set, which is a 20%+ reduction. This shows that our proposed method effectively improve the quality of the translation outputs. We also provide several case studies in Appendix.

Finally, we conduct an ablation study on IWSLT14 De-En task. As shown in Table 2, the hints from word alignments provide an improvement of about 1.6 BLEU points, and the hints from hidden states improve the results by about 0.8 BLEU points. We also test these models on a subsampled set whose source sentence lengths are at least 40. Our model outperforms the baseline model by more than 3 BLEU points (20.63 v.s. 17.48).

Model	$\mathcal{L}_{nll}$	$\mathcal{L}_{nll} + \mathcal{L}_{align}$	$\mathcal{L}_{nll} + \mathcal{L}_{align} + \mathcal{L}_{hid}$
BLEU	23.08	24.76	**25.55**
Long-sentence BLEU	17.48	19.24	**20.63**

Table 2: Ablation studies on IWSLT14 De-En. Results are BLEU scores without teacher rescoring.

4 Conclusion

In this paper, we proposed to use hints from a well-trained ART model to enhance the training of NART models. Our results on WMT14 En-De and De-En significantly outperform previous NART baselines, with one order of magnitude faster in inference than ART models. In the future, we will focus on designing new architectures and training methods for NART models to achieve comparable accuracy as ART models.

Working Hard or Hardly Working: Challenges of Integrating Typology into Neural Dependency Parsers

Abstract

This paper explores the task of leveraging typology in the context of cross-lingual dependency parsing. While this linguistic information has shown great promise in pre-neural parsing, results for neural architectures have been mixed. The aim of our investigation is to better understand this state-of-the-art. Our main findings are as follows: 1) The benefit of typological information is derived from coarsely grouping languages into syntactically-homogeneous clusters rather than from learning to leverage variations along individual typological dimensions in a compositional manner; 2) Typology consistent with the actual corpus statistics yields better transfer performance; 3) Typological similarity is only a rough proxy of cross-lingual transferability with respect to parsing.[1]

1 Introduction

Over the last decade, dependency parsers for resource-rich languages have steadily continued to improve. In parallel, significant research efforts have been dedicated towards advancing cross-lingual parsing. This direction seeks to capitalize on existing annotations in resource-rich languages by transferring them to the rest of the world's over 7,000 languages (Bender, 2011). The NLP community has devoted substantial resources towards this goal, such as the creation of universal annotation schemas, and the expansion of existing treebanks to diverse language families. Nevertheless, cross-lingual transfer gains remain modest when put in perspective: the performance of transfer models can often be exceeded using only a handful of annotated sentences in the target language (Section 5). The considerable divergence of language structures proves challenging for current models.

One promising direction for handling these divergences is linguistic typology. Linguistic typology classifies languages according to their structural and functional features. By explicitly highlighting specific similarities and differences in languages' syntactic structures, typology holds great potential for facilitating cross-lingual transfer (O'Horan et al., 2016). Indeed, non-neural parsing approaches have already demonstrated empirical benefits of typology-aware models (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015) While adding discrete typological attributes is straightforward for traditional feature-based approaches, for modern neural parsers finding an effective implementation choice is more of an open question. Not surprisingly, the reported results have been mixed. For instance, Ammar et al. (2016) found no benefit to using typology for parsing when using a neural-based model, while Wang and Eisner (2018) and Scholivet et al. (2019) did in several cases.

There are many possible hypotheses that can attempt to explain the state-of-the-art. Might neural models already implicitly learn typological information on their own? Is the hand-specified typology information sufficiently accurate — or provided in the right granularity — to always be useful? How do cross-lingual parsers use, or ignore, typology when making predictions? Without understanding answers to these questions, it is difficult to develop a principled way for robustly incorporating linguistic knowledge as an inductive bias for cross-lingual transfer.

In this paper, we explore these questions in the context of two predominantly-used typology-based neural architectures for delexicalized dependency parsing.[2] The first method implements a variant of selective sharing (Naseem et al., 2012);

*The first two authors contributed equally.
[1]Code: github.com/ajfisch/TypologyParser
[2]We focus on delexicalized parsing in order to isolate the effects of syntax by removing lexical influences.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5714–5720, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the second adds typological information as an additional feature of the input sentence. Both models are built on top of the popular Biaffine Parser (Dozat and Manning, 2017). We study model performance across multiple forms of typological representation and resolution.

Our key findings are as follows:

- **Typology as Quantization** Cross-lingual parsers use typology to coarsely group languages into syntactically-homogeneous clusters, yet fail to significantly capture finer distinctions or typological feature compositions. Our results indicate that they primarily take advantage of the simple geometry of the typological space (e.g. language distances), rather than specific variations in individual typological dimensions (e.g. `SV` vs. `VS`).
- **Typology Quality** Typology that is consistent with the actual corpus statistics results in better transfer performance, most likely by capturing a better reflection of the typological variations within that sample. Typology granularity also matters. Finer-grained, high-dimensional representations prove harder to use robustly.
- **Typology vs. Parser Transferability** Typological similarity only partially explains cross-lingual transferability with respect to parsing. The geometry of the typological space does not fully mirror that of the "parsing" space, and therefore requires task-specific refinement.

2 Typology Representations

Linguistic Typology, $\mathbf{T}_L$: The standard representation of typology is sets of annotations by linguists for a variety of language-level properties. These properties can be found in online databases such as The World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013). We consider the same subset of features related to word order as used by Naseem et al. (2012), represented as a k-hot vector $T \in \{0,1\}^{\sum_f |V_f|}$, where V_f is the set of values feature f may take.

Liu Directionalities, $\mathbf{T}_D$: Liu (2010) proposed using a real-valued vector $T \in [0,1]^r$ of the average *directionalities* of each of a corpus' r dependency relations as a typological descriptor. These serve as a more fine-grained alternative to linguistic typology. Compared to WALS, there are rarely missing values, and the *degree* of dominance of each dependency ordering is directly encoded — potentially allowing for better modeling of local variance within a language. It is important to note, however, that true directionalities require a parsed corpus to be derived; thus, they are not a realistic option for cross-lingual parsing in practice.[3] Nevertheless, we include them for completeness.

Surface Statistics, $\mathbf{T}_S$: It is possible to derive a proxy measure of typology from part-of-speech tag sequences alone. Wang and Eisner (2017) found surface statistics to be highly predictive of language typology, while Wang and Eisner (2018) replaced typological features entirely with surface statistics in their augmented dependency parser. Surface statistics have the advantage of being readily available and are not restricted to narrow linguistic definitions, but are less informed by the true underlying structure. We compute the set of hand-engineered features used in (Wang and Eisner, 2018), yielding a real-valued vector $T \in [0,1]^{2380}$.

3 Parsing Architecture

We use the graph-based Deep Biaffine Attention neural parser of (Dozat and Manning, 2017) as our baseline model. Given a delexicalized sentence s consisting of n part-of-speech tags, the Biaffine Parser embeds each tag $\boldsymbol{p}_i$, and encodes the sequence with a bi-directional LSTM to produce tag-level contextual representations $\boldsymbol{h}_i$. Each $\boldsymbol{h}_i$ is then mapped into head- and child-specific representations for arc and relation prediction, $\boldsymbol{h}_i^{\text{arc-dep}}$, $\boldsymbol{h}_i^{\text{arc-head}}$, $\boldsymbol{h}_i^{\text{rel-dep}}$, and $\boldsymbol{h}_i^{\text{rel-head}}$, using four separate multi-layer perceptrons.

For decoding, arc scores are computed as:

$$s_{ij}^{\text{arc}} = \left(\boldsymbol{h}_i^{\text{arc-head}}\right)^T \left(U^{\text{arc}} \boldsymbol{h}_j^{\text{arc-dep}} + \boldsymbol{b}^{\text{arc}}\right) \quad (1)$$

while the score for dependency label r for edge (i,j) is computed in a similar fashion:

$$\begin{aligned} s_{(i,j),r}^{\text{rel}} = &\left(\boldsymbol{h}_i^{\text{rel-head}}\right)^T U_r^{\text{rel}} \boldsymbol{h}_j^{\text{rel-dep}} + \\ &\left(\boldsymbol{u}_r^{\text{rel-head}}\right)^T \boldsymbol{h}_i^{\text{rel-head}} + \\ &\left(\boldsymbol{u}_r^{\text{rel-dep}}\right)^T \boldsymbol{h}_j^{\text{rel-dep}} + b_r \end{aligned} \quad (2)$$

Both s_{ij}^{arc} and $s_{(i,j),r}^{\text{rel}}$ are trained greedily using cross-entropy loss with the correct head or label. At test time the final tree is composed using the Chu-Liu-Edmonds (CLE) maximum spanning tree algorithm (Chu and Liu, 1965; Edmonds, 1967).

[3] Though Wang and Eisner (2017) indicate that they can be predicted from unparsed corpora with reasonable accuracy.

Table 1: A comparison of all methods on held-out test languages. UAS results are reported over the *train* splits of the held-out languages, following (Wang and Eisner, 2018). B* and +$\mathbf{T}^*_S$ are the baseline and surface statistics model results, respectively, of (Wang and Eisner, 2018).[4] *Fine-tune* is the result of adapting our baseline model using only 10 sentences from the target language. All of our reported numbers are the average of three runs with different random seeds. Results with differences that are statistically *insignificant* compared to the baseline are marked with † (arc-level paired permutation test with $p \geq 0.05$).

4 Typology Augmented Parsing

Selective Sharing: Naseem et al. (2012) introduced the idea of *selective sharing* in a generative parser, where the features provided to a parser were controlled by its typology. The idea was extended to discriminative models by Täckström et al. (2013). For neural parsers which do not rely on manually-defined feature templates, however, there isn't an explicit way of using selective sharing. Here we choose to directly incorporate selective sharing as a bias term for arc-scoring:

$$s_{ij}^{\text{arc-aug}} = s_{ij}^{\text{arc}} + \boldsymbol{v}^\top \boldsymbol{f}_{ij} \tag{3}$$

where $\boldsymbol{v}$ is a learned weight vector and $\boldsymbol{f}_{ij}$ is a feature vector engineered using Täckström et al.'s head-modifier feature templates (Appendix B).

Input Features: We follow Wang and Eisner (2018) and encode the typology for language l with an MLP, and concatenate it with each input:

$$\Phi = W_2 \cdot \tanh\left(W_1 \cdot \mathbf{T}^{(l)} + \boldsymbol{b}\right) \tag{4}$$

$$\boldsymbol{h} = \texttt{BiLSTM}\left(\{\boldsymbol{p}_1 \oplus \Phi, \ldots, \boldsymbol{p}_n \oplus \Phi\}\right) \tag{5}$$

This approach assumes the parser is able to learn to use information in $\mathbf{T}^{(l)} \in \{\mathbf{T}_L^{(l)}, \mathbf{T}_D^{(l)}, \mathbf{T}_S^{(l)}\}$ to induce some distinctive change in encoding $\boldsymbol{h}$.

5 Experiments

Data: We conduct our analysis on the Universal Dependencies v1.2 dataset (Nivre et al., 2015) and follow the same train-test partitioning of languages as Wang and Eisner (2018). We train on 20 treebanks and evaluate cross-lingual performance on the other 15; test languages are shown in Table 1.[5] We perform hyper-parameter tuning via 5-fold cross-validation on the training languages.

Results: Table 1 presents our cross-lingual transfer results. Our baseline model improves over the benchmark in (Wang and Eisner, 2018) by more than 6%. As expected, using typology yields mixed results. Selective sharing provides little to no benefit over the baseline. Incorporating the typology vector as an input feature is more effective, with the Liu Directionalities ($\mathbf{T}_D$) driving the most measurable improvements — achieving statistically significant gains on 13/15 languages. The Linguistic Typology ($\mathbf{T}_L$) gives statistically significant gains on 10/15 languages. Nevertheless, the results are still modest. Fine-tuning on only 10 sentences yields a **2.3× larger** average UAS increase, a noteworthy point of reference.

[4] Wang and Eisner (2018)'s final $\mathbf{T}^*_S$ also contains additional neural features that we omitted, as we found it to underperform using only hand-engineered features.

[5] Two treebanks are excluded from evaluation, following the setting of Wang and Eisner (2018).

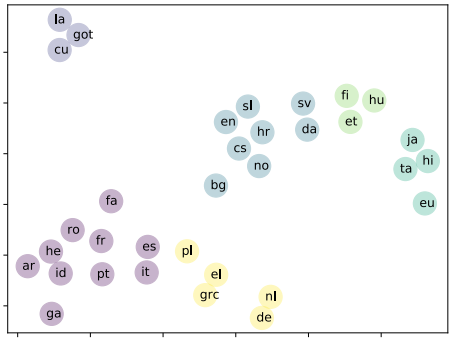

Figure 1: t-SNE projection of WALS vectors with clustering. Persian (fa) is an example of a poorly performing language that is also far from its cluster center.

6 Analysis

Typology as Quantization: Adding simple, discrete language identifiers to the input has been shown to be useful in multi-task multi-lingual settings (Ammar et al., 2016; Johnson et al., 2017). We hypothesize that the model utilizes typological information for a similar purpose by clustering languages by their parsing behavior. Testing this to the extreme, we encode languages using one-hot representations of their cluster membership. The clusters are computed by applying K-Means[6] to WALS feature vectors (see Figure 1 for an illustration). In this sparse form, compositional aspects of cross-lingual sharing are erased. Performance using this impoverished representation, however, only suffers slightly compared to the original — dropping by just 0.56% UAS overall and achieving statistically significant parity or better with $\mathbf{T}_L$ on $7/15$ languages. A gap does still partially remain; future work may investigate this further.

This phenomenon is also reflected in the performance when the original WALS features are used. Test languages that do belong to compact clusters have higher performance on average than that of those who are isolates (e.g., Persian, Basque). Indeed from Table 1 and Fig. 1 we observe that the worst performing languages are isolated from their cluster centers. Even though their typology vectors can be viewed as compositions of training languages, the model appears to have limited generalization ability. This suggests that the model does not effectively use individual typological features.

This can likely be attributed to the training routine, which poses two inherent difficulties: 1) the parser has few examples (entire languages) to generalize from, making it hard from a learning perspective and 2) a naïve encoder can already implicitly capture important typological features within its hidden state, using only the surface forms of the input. This renders the additional typology features redundant. Table 2 presents the results of probing the final max-pooled output of the `BiLSTM` encoder for typological features on a *sentence level*. We find they are nearly linearly separable — logistic regression achieves greater than 90% accuracy on average.

WALS ID	82A	83A	85A	86A	87A	88A
Logreg	87	85	97	92	94	92
Majority	61	56	87	75	51	82

Table 2: Performance of typology prediction using hidden states of the parser's encoder, compared to a majority baseline which predicts the most frequent category.

Average	–	67.11	68.45	69.23	68.36	67.12

Table 3: Average UAS results when training with Galactic Dependencies. The Linguistic Typology ($\mathbf{T}^\ddagger_L$) here is computed directly from the corpora using the rules in Appendix E. All of our reported numbers are the average of three runs.

Wang and Eisner (2018) attempt to address the learning problem by using the synthetic Galactic Dependencies (GD) dataset (Wang and Eisner, 2016) as a form of data augmentation. GD constructs "new" treebanks with novel typological qualities by systematically permuting the behaviors of real languages. Following their work, we add $8,820$ GD treebanks synthesized from the 20 UD training languages, giving $8,840$ training treebanks in total. Table 3 presents the results of training on this setting. While GD helps the weaker $\mathbf{T}^*_S$ substantially, the same gains are not realized for models built on top of our stronger baseline — in fact, the baseline only narrows the gap even further by increasing by 0.92% UAS overall.[7]

Typology Quality: The notion of typology is predicated on the idea that some language features are consistent across different language samples, yet in practice this is not always the case. For instance, *Arabic* is listed in WALS as `SV` (82A, `Subject`$\curvearrowright$`Verb`), yet follows a large number of `Verb`$\curvearrowright$`Subject` patterns in UD v1.2. Fig. 2 fur-

[6] We use Euclidean distance as our metric, another extreme simplification. There is no guarantee that all dimensions should be given equal weight, as indicated in Table 4.

[7] Sourcing a greater number of real languages may still be helpful. The synthetic GD setting is not entirely natural, and might be sensitive to hyper-parameters.

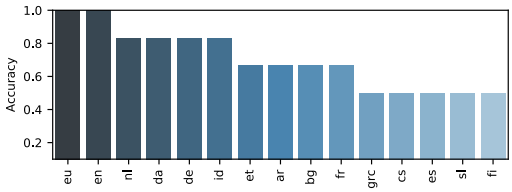

Figure 2: Averaged matching accuracy of the linguistically-defined WALS features on 15 randomly sampled languages compared to their corpus-specific values derived from UD v1.2. Rules for deriving the features from corpus are described in Appendix E.

ther demonstrates that for some languages these divergences are significant (see Appendix F for concrete examples). Given this finding, we are interested in measuring the impact this noise has on typology utilization. Empirically, $\mathbf{T}_D$, which is consistent with the corpus, performs best. Furthermore, updating our typology features for $\mathbf{T}_L$ to match the dominant ordering of the corpus yields a slight improvement of 0.21% UAS overall, with statistically significant gains on $7/15$ languages.

In addition to the quality of the representation, we can also analyze the impact of its resolution. In theory, a richer, high-dimensional representation of typology may capture subtle variations. In practice, however, we observe an opposite effect, where the Linguistic Typology ($\mathbf{T}_L$) and the Liu Directionalities ($\mathbf{T}_D$) outperform the surface statistics ($\mathbf{T}_S$), with $|\mathbf{T}_L| \approx |\mathbf{T}_D| \ll |\mathbf{T}_S|$. This is likely due to the limited number of languages used for training (though training on GD exhibits the same trend). This suggests that future work may consider using targeted dimensionality reduction mechanisms, optimized for performance.

Typology vs. Parser Transferability: The implicit assumption of all the typology based methods is that the typological similarity of two languages is a good indicator of their parsing transferability. As a measure of parser transferability, for each language we select the oracle source language which results in the best transfer performance. We then compute precision@k for the nearest k neighbors in the typological space, i.e. whether the best source appears in the k nearest neighbors. As shown in Table 4, we observe that while there is some correlation between the two, they are far from perfectly aligned. $\mathbf{T}_D$ has the best alignment, which is consistent with its corresponding best parsing performance. Overall, this divergence motivates the development of approaches that better match the two distributions.

	P@1	P@3	P@5	P@10
$\mathbf{T}_L$	13	33	60	80
$\mathbf{T}_D$	27	67	67	93
$\mathbf{T}_S$	13	27	27	73

Table 4: Precision@k for identifying the best *parsing* transfer language, for the k typological neighbors.

7 Related Work

Other recent progress in cross-lingual parsing has focused on lexical alignment (Guo et al., 2015, 2016; Schuster et al., 2019). Data augmentation (Wang and Eisner, 2017) is another promising direction, but at the cost of greater training demands. Both directions do not directly address structure. Ahmad et al. (2019) showed structural-sensitivity is important for modern parsers; insensitive parsers suffer. Data transfer is an alternative solution to alleviate the typological divergences, such as annotation projection (Tiedemann, 2014) and source treebank reordering (Rasooli and Collins, 2019). These approaches are typically limited by parallel data and imperfect alignments. Our work aims to understand cross-lingual parsing in the context of model transfer, with typology serving as language descriptors, with the goal of eventually addressing the issue of structure.

8 Conclusion

Realizing the potential for typology may require rethinking current approaches. We can further drive performance by refining typology-based similarities into a metric more representative of actual transfer quality. Ultimately, we would like to design models that can directly leverage typological compositionality for distant languages.

Abstract

This paper investigates the problem of learning cross-lingual representations in a contextual space. We propose **C**ross-**L**ingual **B**ERT **T**ransformation (CLBT), a simple and efficient approach to generate cross-lingual contextualized word embeddings based on publicly available pre-trained BERT models (Devlin et al., 2018). In this approach, a linear transformation is learned from contextual word alignments to align the contextualized embeddings independently trained in different languages. We demonstrate the effectiveness of this approach on zero-shot cross-lingual transfer parsing. Experiments show that our embeddings substantially outperform the previous state-of-the-art that uses static embeddings. We further compare our approach with XLM (Lample and Conneau, 2019), a recently proposed cross-lingual language model trained with massive parallel data, and achieve highly competitive results. [1]

1 Introduction

One of the most promising directions for cross-lingual dependency parsing, which also remains a challenge, is to bridge the gap of lexical features. Prior works (Xiao and Guo, 2014; Guo et al., 2015) have shown that cross-lingual word embeddings are able to significantly improve the transfer performance compared to delexicalized models (McDonald et al., 2011, 2013). These cross-lingual word embeddings are *static* in the sense that they do not change with the context.[2]

Recently, contextualized word embeddings derived from large-scale pre-trained language models (McCann et al., 2017; Peters et al., 2017, 2018; Devlin et al., 2018) have demonstrated dramatic superiority over traditional static word embeddings, establishing new state-of-the-arts in various monolingual NLP tasks (Ilić et al., 2018; Schuster et al., 2018). The success has also been recognized in dependency parsing (Che et al., 2018). The great potential of these contextualized embeddings has inspired us to extend its power to cross-lingual scenarios.

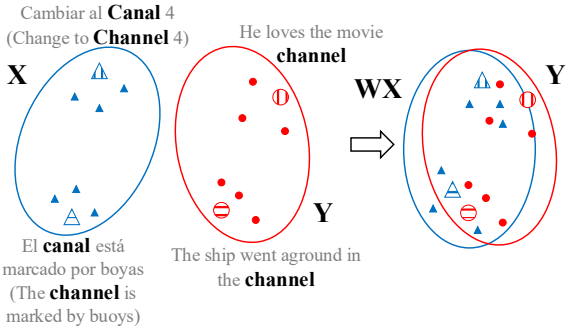

Figure 1: A toy illustration of the method, where contextualized embeddings of the word *canal* from Spanish is transformed to the semantic space of English.

Several recent works have been proposed to learn contextualized cross-lingual embeddings by training cross-lingual language models from scratch with parallel data as supervision, and has been demonstrated effective in several downstream tasks (Schuster et al., 2018; Mulcaire et al., 2019; Lample and Conneau, 2019). These methods are typically resource-demanding and time-consuming.[3] In this paper, we propose **C**ross-**L**ingual **B**ERT **T**ransformation (CLBT), a simple and efficient off-line approach that learns a linear transformation from contextual word alignments. With CLBT, contextualized embeddings

[1]Our code is released at https://github.com/WangYuxuan93/CLBT

[2]In this paper, we refer to these embeddings as *static* as opposed to *contextualized* ones.

[3]For instance, XLM was trained on 64 Volta GPUs (Lample and Conneau, 2019). While the time of training is not described in the paper, we may take the statistics from BERT as a reference, e.g., $\text{BERT}_{\text{BASE}}$ was trained on 4 Cloud TPUs for 4 days (Devlin et al., 2018).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5721–5727,

from pre-trained BERT models in different languages are projected into a shared semantic space. The learned transformation is then used on top of the BERT encodings for each sentence, which are further fed as input to a parser.

Our approach utilizes the semantic equivalence in word alignments, and thus is supposed to be *word sense-preserving*. Figure 1 illustrates our approach, where contextualized embeddings of the Spanish word "canal" are transformed to the corresponding semantic space in English.

Experiments on the Universal Dependencies (UD) treebanks (v2.2) (Nivre et al., 2018) show that our approach substantially outperforms previous models that use static cross-lingual embeddings, with an absolute gain of 2.91% in averaged LAS. We further compare to XLM (Lample and Conneau, 2019), a recently proposed large-scale cross-lingual language model. Results demonstrate that our approach requires significantly fewer training data, computing resources and less training time than XLM, yet achieving highly competitive results.

2 Related Work

Static cross-lingual embedding learning methods can be roughly categorized as *on-line* and *off-line* methods. Typically, on-line approaches integrate monolingual and cross-lingual objectives to learn cross-lingual word embeddings in a joint manner (Klementiev et al., 2012; Kočiský et al., 2014; Guo et al., 2016), while off-line approaches take pre-trained monolingual word embeddings of different languages as input and retrofit them into a shared semantic space (Xing et al., 2015; Lample et al., 2018; Chen and Cardie, 2018).

Several approaches have been proposed recently to connect the rich expressiveness of contextualized word embeddings with cross-lingual transfer. Mulcaire et al. (2019) based their model on ELMo (Peters et al., 2018) and proposed a polyglot contextual representation model by capturing character-level information from multilingual data. Lample and Conneau (2019) adapted the objectives of BERT (Devlin et al., 2018) to incorporate cross-lingual supervision from parallel data to learn cross-lingual language models (XLMs), which have obtained state-of-the-art results on several cross-lingual tasks. Similar to our approach, Schuster et al. (2019) also aligned pre-trained contextualized word embeddings through linear transformation in an off-line fashion. They used the averaged contextualized embeddings as an *anchor* for each word type, and learn a transformation in the anchor space. Our approach, however, learns this transformation directly in the contextual space, and hence is explicitly designed to be *word sense-preserving*.

3 Cross-Lingual BERT Transformation

This section describes our proposed approach, namely CLBT, to transform pre-trained monolingual contextualized embeddings to a shared semantic space.

3.1 Contextual Word Alignment

Traditional methods of learning static cross-lingual word embeddings have been relying on various sources of supervision such as bilingual dictionaries (Lazaridou et al., 2015; Smith et al., 2017), parallel corpus (Guo et al., 2015) or on-line Google Translate (Mikolov et al., 2013; Xing et al., 2015). To learn contextualized cross-lingual word embeddings, however, we require supervision at word token-level (or context-level) rather than type-level (i.e. dictionaries). Therefore, we assume a parallel corpus as our supervision, analogous to on-line methods such as XLM (Lample and Conneau, 2019).

In our approach, unsupervised bidirectional word alignment is first applied to the parallel corpus to obtain a set of aligned word pairs with their contexts, or *contextual word pairs* for short. For one-to-many and many-to-one alignments, we use the left-most aligned word,[4] such that all the resulting word pairs are one-to-one. In practice, since WordPiece embeddings (Wu et al., 2016) are used in BERT, all the parallel sentences are tokenized using BERT's wordpiece vocabulary before being aligned.

3.2 Off-Line Transformation

Given a set of contextual word pairs, their BERT representations $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{n}$ can be easily obtained from pre-trained BERT models,[5] where $\mathbf{x}_i \in \mathbb{R}^{d_1}$ is the contextualized embedding of token i in the

[4] Preliminary experiments indicate that this way works better than keeping all the alignments.

[5] In this work, we use the English BERT (enBERT) for the source language (English) and the multilingual BERT (mBERT), which is trained on 102 languages without cross-lingual supervision, for all the target languages.

target language, and $\mathbf{y}_i \in \mathbb{R}^{d_2}$ is the representation of its alignment in the source language.

In our experiments, a parser is trained on source language data and applied directly to all the target languages. Therefore, we propose to project the embeddings of target languages to the space of the source language, instead of the opposite direction. Specifically, we aim at finding an appropriate linear transformation $\mathbf{W}$, such that $\mathbf{W}\mathbf{x}_i$ approximates $\mathbf{y}_i$.[6] This can be achieved by solving the following optimization problem:

$$\min_{\mathbf{W}} \sum_{i=1}^{n} ||\mathbf{W}\mathbf{x}_i - \mathbf{y}_i||^2,$$

where $\mathbf{W} \in \mathbb{R}^{d_1 \times d_2}$ is a parameter matrix.

Previous works on static cross-lingual embeddings have shown that an orthogonal $\mathbf{W}$ (i.e. $\mathbf{W}^\top\mathbf{W} = \mathbf{I}$) is helpful for the word translation task (Xing et al., 2015). In this case, an analytical solution can be found through singular value decomposition (SVD) of $\mathbf{Y}^\top\mathbf{X}$:

$$\mathbf{W} = \mathbf{V}\mathbf{U}^\top, \text{where } \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top = \text{SVD}(\mathbf{Y}^\top\mathbf{X}).$$

Here $\mathbf{X} \in \mathbb{R}^{n \times d}$ and $\mathbf{Y} \in \mathbb{R}^{n \times d}$ are the contextualized embedding matrices, where n is the number of aligned contextual word pairs, d is the dimension of monolingual contextualized embeddings. Each pair of rows $(\mathbf{x}_i, \mathbf{y}_i)$ indicates an aligned contextual word pair.

Although this can be computed in CPUs within several minutes, more memories will be required with the growth of the amount of training data. Therefore, we present an approximate solution, where $\mathbf{W}$ is optimized with gradient decent (GD) and is not constrained to be orthogonal.[7] This GD-based approach can be trained on a single GPU and typically converges in several hours.

To validate the effectiveness of our approach in cross-lingual dependency parsing, we first obtain the CLBT embeddings with the proposed approach, and then use them as input to a modern graph-based neural parser (described in next section), in replacement of the pre-trained static embeddings. Note that BERT produces embeddings in wordpiece-level, so we only use the left-most wordpiece embedding of each word.[8]

[6] We also investigated non-linear transformation in our experiments, but didn't observe any improvements.

[7] We found the orthogonal constraint doesn't help for GD.

[8] We tried alternative strategies such as averaging, using the middle or right-most wordpiece, but observed no significant difference.

4 Experiments

4.1 Data and Settings

In our experiments, the contextual word pairs are obtained from the Europarl corpora (Koehn, 2005) using the *fast_align* toolkit (Dyer et al., 2010). Only 10,000 sentence pairs are used for each target language. For the parsing datasets, we use the Universal Dependencies(UD) Treebanks (v2.2) (Nivre et al., 2018),[9] following the settings of the previous state-of-the-art system (Ahmad et al., 2018). From the 31 languages they have analyzed, we select 18 whose Europarl data is publicly available.[10] Statistics of the selected languages and treebanks can be found in the Appendix. We employ the Biaffine Graph-based Parser of Dozat and Manning (2017) and adopt their hyper-parameters for all of our models.

In all the experiments, English is used as the source language, and the other 17 languages as targets. The model is trained on the English treebank and applied directly to target languages with the transformed contextualized embeddings. We train our models using the Adam optimizer (Kingma and Ba, 2015), and most of the them converge within a few thousand epochs in several hours. More implementation details are reported in the Appendix.

4.2 Baseline Systems

We compare our method with the following three baseline models:

- **mBERT** (contextualized). Embeddings generated by the mBERT model are directly used in the training and testing procedures.
- **FT-SVD** (Ahmad et al., 2018, off-line, static). SVD-based transformation (Smith et al., 2017) is applied on 300-dimensional FastText embeddings (Bojanowski et al., 2017) to obtain cross-lingual static embeddings, which represents the previous state-of-the-art. We report results from their paper of the RNNGraph model which used the same architecture as ours.
- **XLM** (Lample and Conneau, 2019, on-line, contextualized). A strong method which learns contextualized cross-lingual embeddings from scratch with cross-lingual data.

[9] hdl.handle.net/11234/1-2837

[10] For languages with multiple treebanks, we use the same combinations as they did.

Table 1: Results (LAS%) on test sets. Languages are split by language families with dashed lines. AVG. means the average of results from all target languages. Statistically significant differences between our methods and the mBERT model are marked with *, with p-value < 0.05 under McNemar's test.

For the **XLM** model, we employ the XNLI-15 model[11] they released to generate embeddings and apply them to cross-lingual dependency parsing in the same way as we do with our own model. We compare with them in the 4 overlapped languages both works have researched on.

4.3 Comparison with Off-Line Methods

Results on the test sets are shown in Table 1.[12] Languages are grouped by language families. Overall, our approach with either SVD or GD outperforms both FT-SVD and mBERT by a substantial margin (+2.91% in averaged LAS), among which GD turns out to be slightly better than SVD in most of the languages. When combined with FT-SVD, the performances can be further improved by 0.33% in LAS for the GD method and 0.51% for SVD (see the Appendix for more details). Interestingly, the mBERT model which is trained without any cross-lingual supervision but using a shared multilingual wordpiece vocabulary works surprisingly well in some languages, especially in those linguistically close to English. Similar observations have also been identified in other works (Pires et al., 2019; Wu and Dredze, 2019).

[11] github.com/facebookresearch/XLM

[12] UAS results are listed in the Appendix due to space limit. Note that since we have no access to the parsed files of the FT-SVD model, we only report statistical significant tests between our methods and the mBERT model, which is highly comparable to the FT-SVD model on average.

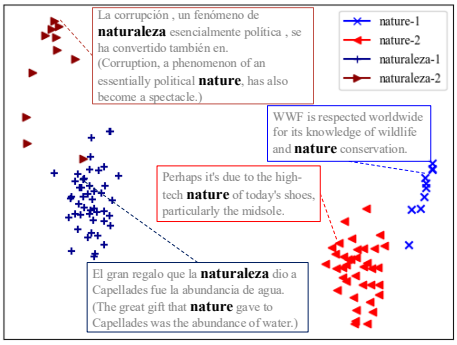
Table 2: Results (UAS%/LAS%) on test sets. The last row shows the training data used in each language by sentence. AVG. means the average of results from 4 target languages. Statistically significant differences between our methods and the XLM are marked with an asterisk, with p-value < 0.05 under McNemar's test.

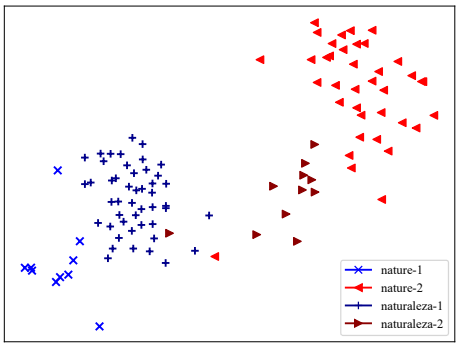
4.4 Comparison with On-Line Methods

Comparison of our approach and a cross-lingual language model pre-training (XLM) method (Lample and Conneau, 2019) in the 4 overlapped languages is shown in Table 2. CLBT outperforms XLM in 3 out of the 4 languages but lower in German (de). The amount of training data used in each method is also shown in the bottom: the number of parallel sentences used by XLM ranges from 0.2 million (10 million tokens) for Bulgarian to 13.1 million (682 million tokens) for French. In comparison, only 10,000 parallel sentences (0.4 million tokens) are used for each language in CLBT, demonstrating the data-efficiency of our approach. Moreover, given the efficiency in both data and training, CLBT can be readily scaled to new language pairs in hours.



4.5 Analysis

4.5.1 Transformation of Cross-lingual BERT Embedding



In order to investigate the properties of contextualized representations before and after the linear transformation, we employ the SENSEVAL2 data (Edmonds and Cotton, 2001),[13] where words from different languages are tagged by their word senses in different contexts.

We took contextualized representations of the English word *nature* and its Spanish transla-

(b)

Figure 2: t-SNE visualization of the English word *nature* and its Spanish translation *naturaleza* in different contexts by the contextualized representations before (a) and after (b) the linear transformation. Points are colored by word senses. Example contexts are given in (a). Translations of Spanish sentences are in brackets.

tion *naturaleza* in different contexts from pre-trained English and multilingual BERT respectively and visualize their distributions in Figure 2(a), where we can observe obvious clustering of word senses. Specifically, words with sense *nature-1* and *naturaleza-1* mean *the physical world*, whereas *nature-2* and *naturaleza-2* mean *inherent features*. We then apply our GD-based method to embeddings of *naturaleza* and depict the resulting cross-lingual embeddings in Figure 2(b). The distance between embeddings from English and Spanish is effectively reduced after the transformation. And it is apparent that embeddings of Spanish words are closer to those with similar meanings from English, which indicates the effectiveness of our approach.

4.5.2 Effect of Training Data Size

We select several languages from each language family, and investigate the effect of the amount of training data on the performances of zero-shot cross-lingual dependency parsing. Specifically,

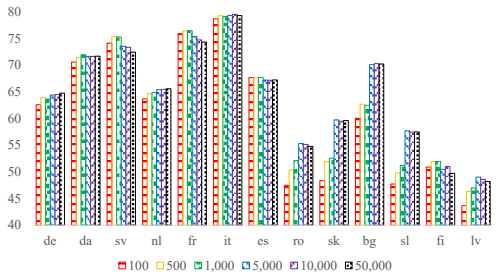

Figure 3: Effects of the amount of training data on different languages. (y-axis represents the LAS.)

we take the SVD-based approach, since it is faster than the GD-based one, and trained different transformation models with different amount of parallel sentences from Europarl dataset on each of the 13 selected languages.

As shown in Figure 3, for most of the languages, the best performance is achieved with only 5000 parallel sentences. It is also worth noting that for most of Germanic (e.g. German, Danish, Swedish and Dutch) and Romance (e.g. French, Italian, Spanish and Romanian) languages, which are typologically closer to English, a rather small training set of merely 100 sentences is capable of achieving comparative results.

5 Conclusion

We propose the Cross-Lingual BERT Transformation (CLBT) approach for contextualized cross-lingual embedding learning, which substantially outperforms the previous state-of-the-art in zero-shot cross-lingual dependency parsing. By exploiting publicly available pre-trained BERT models, our approach provides a fast and data-efficient solution to learning cross-lingual contextualized embeddings. Compared to the XLM, our method requires much fewer parallel data and less training time, yet achieving comparable performance.

For future work, we are interested in unsupervised cross-lingual alignment, inspired by prior success on static embeddings (Lample et al., 2018; Alvarez-Melis and Jaakkola, 2018), which demands a deeper understanding to the geometry of the multilingual contextualized embedding space.

Abstract

The key to multilingual grammar induction is to couple grammar parameters of different languages together by exploiting the similarity between languages. Previous work relies on linguistic phylogenetic knowledge to specify similarity between languages. In this work, we propose a novel universal grammar induction approach that represents language identities with continuous vectors and employs a neural network to predict grammar parameters based on the representation. Without any prior linguistic phylogenetic knowledge, we automatically capture similarity between languages with the vector representations and softly tie the grammar parameters of different languages. In our experiments, we apply our approach to 15 languages across 8 language families and subfamilies in the Universal Dependency Treebank dataset, and we observe substantial performance gain on average over monolingual and multilingual baselines.

1 Introduction

Human languages bear striking resemblance at the syntactic level in spite of their diversity on the surface, as many studies have revealed (Greenberg, 1963; Hawkins, 2014). This fact provides the basis for multilingual grammar induction which tries to simultaneously induce grammars of multiple languages. Intuitively, one can couple grammar parameters of different languages with similar typology and learn them simultaneously. However, the lacking of measures of language similarity prevents this idea from being further exploited in practice.

Previous work in multilingual grammar induction either does not consider language similarity measures (Iwata et al., 2010) or models language similarity based on linguistic phylogeny (Berg-Kirkpatrick and Klein, 2010). The phylogenetic knowledge, however, could be misleading in measuring language similarity. For example, English and German are both Germanic languages, but English exhibits dominant Subject-Verb-Object (SVO) word order while German does not.

In this paper, we propose a novel approach to multilingual grammar induction. Our induction model represents language identities as continuous vectors (i.e., language embeddings) and employs a neural network to predict the grammar parameters of each language based on its embedding. The neural network parameters are universally shared across languages, which softly tie the grammar parameters of different languages. The language embeddings and the neural network parameters are trained with a standard grammar induction objective without any guidance from prior linguistic phylogenetic knowledge. We also introduce an auxiliary language identification task in which we predict the language identities of input sentences using the language embeddings.

We evaluate our approach on corpora of 15 languages across 8 language families and subfamilies. We observe that our approach achieves substantial performance gain on average over monolingual and multilingual baselines.

2 Dependency Model with Valence and Other Related Works

Dependency Model with Valence (DMV) (Klein and Manning, 2004) is the best known generative model for dependency grammar induction. The DMV generates a sentence and its dependency tree following three types of grammar rules (ATTACH, DECISION and ROOT). It firstly samples a token c from the ROOT distribution $\mathrm{P}_{\mathrm{ROOT}}(c)$

*The first and second authors contributed equally. The third author contributed to this work when at ShanghaiTech University. The fourth author is the corresponding author.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 5728–5733,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

and then recursively decides whether to generate a new child token and what child token to generate by sampling from the DECISION and ATTACH distributions $\mathrm{P}_{\text{DECISION}}(dec|h, dir, val)$ and $\mathrm{P}_{\text{ATTACH}}(c|h, dir)$, where dir is a binary variable representing the direction of generation (left or right), val is a binary variable representing whether the current head token already has a child in the direction dir or not, dec is a binary variable deciding whether to continue generation in the current direction, c is the child token and h is the head token.

Almost all previous methods of multilingual grammar induction are based on DMV. Their focus is on designing various priors to couple DMV parameters across languages: Cohen and Smith (2009) propose a logistic normal prior while Berg-Kirkpatrick and Klein (2010) design a hierarchical Gaussian prior according to linguistic phylogeny.

The usage of continuous language embeddings has been explored in other tasks. For example, Ammar et al. (2016) and de Lhoneux et al. (2018) apply language embeddings in supervised multilingual dependency parsing.

3 Approach

We perform unlexicalized grammar induction in which a sentence is represented as a sequence of part-of-speech (POS) tags. We assume that all the languages share the same set of POS tags.

3.1 Multilingual Grammar Model

Our multilingual grammar model adopts the NDMV (Jiang et al., 2016), a monolingual model, as the basic component. NDMV predicts grammar rule probabilities using neural networks. In our model, we add a continuous vector representation of the language identity l (i.e., a language embedding) as an additional input to the neural networks in NDMV. Specifically, to predict an ATTACH rule probability $\mathrm{P}_{\text{ATTACH}}(c|h, dir, val, l)$, we use a multilayer neural network that takes the embeddings of the head token h, valence val and language identity l as input, uses a weight matrix W_{dir} specific to the direction dir in the first layer, and uses a weight matrix W_c consisting of all the child POS tag vectors in the softmax output layer. The neural network structure is shown in the left part of Figure 1. We predict the DECISION rule probabilities in a similar way. We record the number of ROOT rule probabilities instead of predicting them

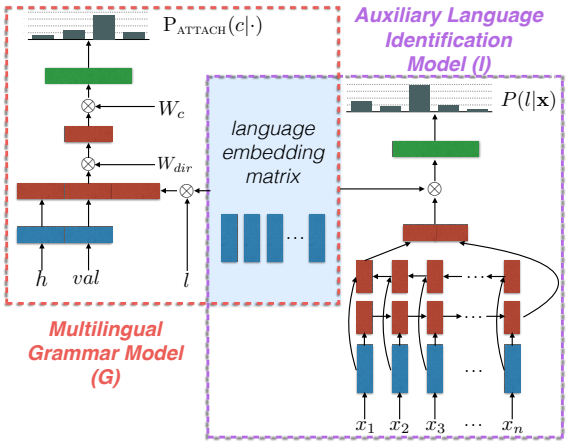

Figure 1: Model Architecture. The language embedding matrix contains the embeddings of all the languages. l is a one-hot vector and $\otimes$ means matrix multiplication. Blue bars represent the embeddings of input symbols; brown bars represent the hidden states of the neural networks; green bars represent the logits which are the inputs to the Softmax layers.

since there are only a small number of such rules. The language embeddings are part of the model parameters and are trained simultaneously with all the other parameters. We hope that after training, similar languages would have similar embeddings and therefore similar grammar rule probabilities.

3.2 Auxiliary Task

To improve the learning of the language embeddings, we introduce an auxiliary language identification task: given an input sentence represented by a sequence of POS tags $\{x_1, x_2, \ldots, x_n\}$, predict its language. We use a standard Bidirectional Long Short-Term Memory (Bi-LSTM) to encode the input sentence, and then a multilayer perceptron to classify the sentence into one of the languages. The weight matrix of the output layer of the multilayer perceptron contains the embeddings of all the languages. The model structure is shown in the right part of Figure 1.

3.3 Training

Denote the set of model parameters as $\mathbf{\Theta}$, the set of languages as $\mathbf{L}$, the set of grammars of different languages as $\mathbf{G} = \{\mathbf{G}_l, l \in \mathbf{L}\}$, and the training data as $\mathcal{D} = \{\mathbf{x}^{(i)}, l^{(i)}\}_{i=1}^{N}$ where $\mathbf{x}^{(i)}$ is the i-th training sentence and $l^{(i)}$ is its language identity. Our training objective function $\mathcal{L}(\mathbf{\Theta})$ combines two conditional probabilities for each training sentence $\mathbf{x}^{(i)}$: $P(\mathbf{x}^{(i)}|\mathbf{G}_{l^{(i)}})$, the probability of the training sentence $\mathbf{x}^{(i)}$ being generated from the corresponding grammar $\mathbf{G}_{l^{(i)}}$; and $P(l^{(i)}|\mathbf{x}^{(i)})$,

the probability of correct language identification of $\mathbf{x}^{(i)}$.

$$\mathcal{L}(\mathbf{\Theta}) = \sum_{(\mathbf{x},l)\in\mathcal{D}} \Big(\log P_{\mathbf{\Theta}}(\mathbf{x}|\mathbf{G}_l) + \lambda \log P_{\mathbf{\Theta}}(l|\mathbf{x}) \Big)$$

where λ is a hyper-parameter and is set to 1 by default. We follow the approach in NDMV to optimize the first term and use Adam (Kingma and Ba, 2014) to optimize the second term.

Note that the language identification model is only used during training to improve the learning of language embeddings. During testing, we run the multilingual grammar model to predict grammar rule probabilities without the need to invoke the language identification model.

4 Experiment

4.1 Setup

We selected 15 languages across 8 language families and subfamilies to ensure diversity. To enable comparisons with previous state-of-the-art approaches (Jiang et al., 2017; Li et al., 2019), we conducted our experiments on UD Treebank 1.4. For each language, we show its language family and the training corpus size in Table 1. We trained our method on the training sentences with length $\leq$ 15 and tested our method on the testing sentences with length $\leq$ 40 after removing all punctuations. Since we are doing unsupervised learning, gold dependency trees were not used during training. We use the directed dependency accuracy (DDA, the percentage of words in the testing dataset which are assigned the correct head, same to the unlabeled attachment score normally used in supervised parsing) as the evaluation metric and report the average DDA of 5 runs for each experiment. All the parameters of neural networks including language embeddings were randomly initialized and trained with learning rate 0.001, mini-batch size 1000 and epoch 50. The dimension of the head token embedding and the child token embedding is set to 10. The shape of the weight matrix W_{dir} is 20×10. The dimension of the valence embedding and language identity embedding is set to 5. For the auxiliary language identification task, we use a Bi-LSTM with hidden vector dimension of 10.[1]

4.2 Results

We first compare our method with two baseline methods, DMV and NDMV, which are similar to our method[2]. The baseline methods are experimented in both monolingual and multilingual settings. For the monolingual setting we trained the baseline models on each language independently. For the multilingual setting we trained them on the combined training data of all the 15 languages and tested on one of the languages. Table 2 shows the experimental results. It can be seen that our multilingual grammar model (G) performs better on average than all the baselines. The improvement be-

[2]We re-implemented the DMV and the NDMV. We set the ATTACH valence and DECISION valence to 2 and used root constraints, similar to previous work (Gimpel and Smith, 2012; Bisk and Hockenmaier, 2013; Noji et al., 2016).

comes more significant when our model is jointly trained with the auxiliary language identification task (G+I). Note that our approach performs worse than the monolingual baseline on some languages, and we speculate that it is partly caused by data imbalance. In particular, the worst-performing Hindi language has only 4997 training sentences, much smaller than the average 7532. It would be interesting to make training more balanced by assigning weights to training samples of different languages, which we leave for future work.

To measure the statistical significance of the advantage of our method, we performed the nonparametric Friedman's test to support/reject the claim (null hypothesis): there is no difference between the G+I model and the NDMV model in a multilingual setting. Based on the above sample data, the P-value 7.8911×10^{-4} would result in rejection of the claim at the 0.05 significance level, thus showing the significance in our performance gain.

In Table 3 we compare our method with recent state-of-the-art approaches on the UD Treebank dataset: Convex-MST (Grave and Elhadad, 2015), LC-DMV (Noji et al., 2016) and D-J (Jiang et al., 2017). For the three approaches we use the results reported by Jiang et al. (2017). Our G+I model performs better than Convex-MST and LC-DMV on average, even though additional priors and delicate biases are integrated into the two methods (e.g, the universal linguistic prior for Convex-MST and the limited center-embedding for LC-DMV). Our method also slightly outperforms D-J on average, even though D-J combines Convex-MST and LC-DMV and therefore utilizes even more linguistic prior knowledge.

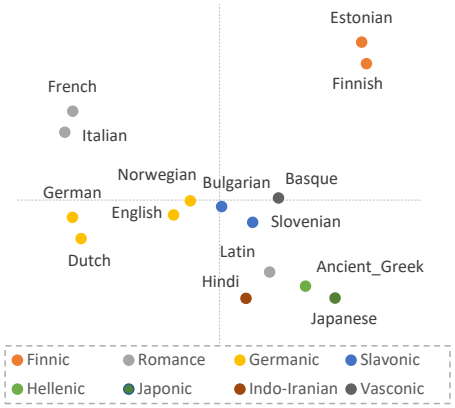

Figure 2: Visualization of the language embeddings.

5 Analysis

5.1 Visualization of Language Embeddings

One of our main expectations is that our approach can automatically learn language embeddings that capture similarities in typology between different languages. In order to verify our expectation, we collected the learned language embeddings and visualized them on a 2D plane using the t-SNE algorithm (Van der Maaten and Hinton, 2008).

Figure 2 shows the visualization result. It can be seen that in most cases languages in the same language family are close to each other. For example, Finnish is close to Estonian (Finnic languages) and Slovenian is close to Bulgarian (Slavonic languages). It is also interesting to note that some languages, such as English and Norwegian in the Germanic family and Latin in the Romance family, are closer to languages outside of their families than to their family siblings. We attribute this phenomenon to the difference in typology among some in-family languages: the flexible word order in German and Dutch is not shared by English and Norwegian; Latin, on the other hand, seems to share more common typological features with its classical counterpart, ancient Greek, than with its modern phylogenetic relatives in the Romance family. Such differences cannot be inferred from linguistic phylogeny, but our language embeddings have undoubtedly captured them.

5.2 In-family vs. Cross-family
